To the many talented and dedicated laboratory and translational investigators and clinical researchers who have been committed to the breast cancer problem and have contributed to the substantial progress made in recent decades in fighting this disease.

In memory of Jonathan Pine, our highly esteemed editor, who left all of us much too soon.

CONTRIBUTORS

Albert J. Aboulafia, MD, FACS, MBA
Director, Sarcoma Services
Alvin and Lois Lapidos Cancer Center
Department of Orthopaedic Surgery
Sinai Hospital
Assistant Clinical Professor
University of Maryland
Baltimore, Maryland

David H. Abramson, MD, FACS
Professor of Ophthalmology
Weill Cornell Medical Center
Chief, Ophthalmic Oncology Service
Department of Ophthalmic Oncology
Memorial Sloan-Kettering Cancer Center
New York, New York

Brian M. Alexander, MD, MPH
Assistant Professor of Radiation Oncology
Harvard Medical School
Disease Center Leader, Radiation Oncology
Center for Neuro-Oncology
Department of Radiation Oncology
Dana-Farber/Brigham and Women's Cancer Center
Boston, Massachusetts

Kimberly H. Allison, MD
Associate Professor of Pathology
Department of Pathology
Stanford University Medical Center
Stanford, California

Benjamin O. Anderson, MD, FACS
Director
Breast Health Clinic
Seattle Cancer Care Alliance (SCCA)
Professor of Surgery and Global Health Medicine
University of Washington
Seattle, Washington

Carlos L. Arteaga, MD
Professor of Medicine and Cancer Biology
Associate Director for Clinical Research
Director Breast Cancer Program
Department of Medicine (Oncology)
Vanderbilt-Ingram Cancer Center
Vanderbilt University
Nashville, Tennessee

Nils D. Arvold, MD
Assistant Professor
Department of Radiation Oncology
Harvard Medical School
Attending Physician
Department of Radiation Oncology
Dana-Farber/Brigham and Women's Cancer Center
Boston, Massachusetts

Alan Ashworth, FRS, FMedSci
Chief Executive
The Institute of Cancer Research
London, United Kingdom

Aditya Bardia, MBBS, MPH
Attending Physician
Massachusetts General Hospital Cancer Center
Harvard Medical School
Boston, Massachusetts

Christopher A. Barker, MD
Assistant Member
Department of Radiation Oncology
Memorial Sloan-Kettering Cancer Center
Assistant Attending Radiation Oncologist
Department of Radiation Oncology
Memorial Hospital for Cancer and Allied Diseases
New York, New York

José Baselga, MD, PhD
Physician-in-Chief
Memorial Sloan-Kettering Cancer Center
New York, New York

J. Sybil Biermann, MD
Professor
Department of Orthopaedic Surgery
Director, Musculoskeletal Oncology
Department of Orthopaedic Surgery
University of Michigan
University of Michigan Hospital
Ann Arbor, Michigan

Richard J. Bleicher, MD, FACS
Associate Professor and Co-Leader
Breast Service Line
Director, Breast Fellowship Program
Department of Surgical Oncology
Fox Chase Cancer Center
Philadelphia, Pennsylvania

Susan K. Boolbol, MD, FACS
Associate Professor of Clinical Surgery
Albert Einstein College of Medicine
Chief
Appel-Venet Comprehensive Breast Service
Beth Israel Medical Center
New York, New York

Ron Bose, MD, PhD
Assistant Professor of Medicine
Department of Internal Medicine
Division of Oncology
Washington University School of Medicine
Attending Physician
Division of Oncology
Department of Medicine
Barnes Jewish Hospital
St. Louis, Missouri

Glenn D. Braunstein, MD
Professor of Medicine
Department of Medicine
Vice President for Clinical Innovation
Cedars-Sinai Health System
Los Angeles, California

Edi Brogi, MD, PhD
Associate Professor of Clinical Pathology and Laboratory Medicine
Weill Cornell Medical College
Attending Pathologist—Director of Breast Pathology
Department of Pathology
Memorial Sloan-Kettering Cancer Center
New York, New York

Powel H. Brown, MD, PhD
Professor and Chairman
Department of Clinical Cancer Prevention
Professor and Chairman
Breast Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Thomas A. Buchholz, MD, FACR
Frank T. McGraw Memorial Chair in the Study of Cancer
Division Head, Department of Radiation Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Nigel J. Bundred, MD, FRCS
Professor of Surgical Oncology
Academic Surgery
University of Manchester
Consultant Oncoplastic Breast Surgeon
Surgical Oncology
University of South Manchester
Manchester, United Kingdom

Burcu Cakar, MD
Oncologist
Tulay Aktas Oncology Hospital
Ege University School of Medicine
Izmir, Turkey

Kristine E. Calhoun, MD
Associate Professor
Department of Surgery
Division of Surgical Oncology
University of Washington School of Medicine
Seattle, Washington

Rena D. Callahan, MD
Assistant Clinical Professor of Medicine
Clinical Instructor
Department of Medicine
Division of Hematology Oncology
University of California at Los Angeles
Los Angeles, California

Lisa A. Carey, MD
Preyer Distinguished Professor in Breast Cancer Research
Chief
Division of Hematology / Oncology
Department of Medicine
University of North Carolina at Chapel Hill
Physician-in-Charge
North Carolina Cancer Hospital
Medical Director
UNC Breast Center
UNC Healthcare
Chapel Hill, North Carolina

Robert W. Carlson, MD
Professor of Medicine, Emeritus
Division of Medical Oncology
Stanford University Medical Center
Stanford, California
Adjunct Professor of Medical Oncology
Department of Medical Oncology
Fox Chase Cancer Center
Philadelphia, Pennsylvania

Anees B. Chagpar, MD, MSc, MA, MPH, FACS, FRCS(C)
Associate Professor
Department of Surgery
Yale University School of Medicine
Director
The Breast Center
Smilow Cancer Hospital at Yale New Haven
New Haven, Connecticut

Maggie Chon U Cheang, PhD
Research Associate
Department of Genetics
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

M. Jennifer Cheng, MD
Postdoctoral Research Fellow
Department of Palliative Medicine
Johns Hopkins School of Medicine
Baltimore, Maryland

Nathan I. Cherny, MBBS, FRACP, FRCP (Lon.)
Associate Professor of Medicine
Ben Gurion University
Beer Sheba, Israel
Norman Levan Chair of Humanistic Medicine
Director Cancer Pain and Palliative Medicine
Department of Oncology
Shaare Zedek Medical Center
Jerusalem, Israel

Andrea L. Cheville, MD, MSCE
Associate Professor and Research Chair of Physical Medicine and Rehabilitation
Mayo Clinic
Rochester, Minnesota

Rowan T. Chlebowski, MD, PhD
Professor of Medicine
Department of Medicine
David Geffen School of Medicine at the University of California–Los Angeles
Los Angeles, California
Chief
Division of Medical Oncology and Hematology
Department of Medicine
Harbor-University of California Medical Center
Torrance, California

Alice P. Chung, MD, FACS
Assistant Professor
Department of Surgery
Division of Surgical Oncology
Cedars-Sinai Medical Center
Los Angeles, California
Staff Physician
Department of Surgery
Saul and Joyce Brandman Breast Center
Los Angeles, California

Hiram S. Cody III, MD
Professor of Clinical Surgery
Weill Cornell Medical College
Attending Surgeon
Breast Service
Department of Surgery
Memorial Sloan-Kettering Cancer Center
New York, New York

Graham A. Colditz, MD, DrPH
Niess-Gain Professor
Department of Surgery
Washington University in St. Louis School of Medicine
St. Louis, Missouri

Robert E. Coleman, MBBS, MD, FRCP, FRCPE
Director
Cancer Research UK/YCR Sheffield Cancer Research Center
University of Sheffield
Hon. Consultant Medical Oncologist
Weston Park Hospital
Sheffield, United Kingdom

Laura C. Collins, MD
Associate Professor of Pathology
Department of Pathology
Beth Israel Deconess Medical Center and Harvard Medical School
Associate Director
Division of Anatomic Pathology
Department of Pathology
Beth Israel Deconess Medical Center
Boston, Massachusetts

Steven Come, MD
Associate Professor of Medicine
Department of Medicine
Harvard Medical School
Director
Breast Medical Oncology Program
Department of Medicine
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Christopher E. Comstock, MD
Attending Radiologist
Director of Breast Imaging Postgraduate Training and Education
Department of Radiology
Memorial Sloan-Kettering Cancer Center
New York, New York

Adriana D. Corben, MD
Assistant Attending
Department of Pathology
Memorial Sloan-Kettering Cancer Center
New York, New York

Chau Dang, MD
Associate Professor of Medicine
Weill Cornell Medical College
Associate Attending Physician
Department of Medicine Memorial Sloan-Kettering Cancer Center
New York, New York

Andrew J. Dannenberg, MD
Professor of Medicine
Weill Cornell Medical College
New York, New York

Nancy E. Davidson, MD
Director
University of Pittsburgh Cancer Institute and UPMC Cancer Center
Distinguished Professor of Medicine and Pharmacology and Chemical Biology
University of Pittsburgh
Pittsburgh, Pennsylvania

Lisa M. DeAngelis, MD
Professor of Neurology
Department of Neurology
Weill Cornell Medical College
Chairman
Department of Neurology
Memorial Sloan-Kettering Cancer Center
New York, New York

Eli L. Diamond, MD, MPhil
Instructor
Department of Neurology
Weill Cornell Medical College
Assistant Attending
Department of Neurology
Memorial Sloan-Kettering Cancer Center
New York, New York

Deborah Dillon, MD
Assistant Professor
Department of Pathology
Harvard Medical School
Staff Pathologist
Department of Pathology
Brigham and Women's Hospital
Boston, Massachusetts

J. Michael Dixon, BSC, MBChB, MD, FRCS, FRCS (Ed), FRCP (Hon)
Professor of Surgery
Edinburgh Breast Unit
University of Edinburgh
Consultant Surgeon
Edinburgh Breast Unit
Western General Hospital
Edinburgh, United Kingdom

Susan M. Domchek, MD
Basser Professor in Oncology
Director
Basser Research Center
University of Pennsylvania
Philadelphia, Pennsylvania

Mitchell Dowsett, PhD, BSc
Professor of Biochemical Endocrinology
Department of Biochemistry
Institute of Cancer Research
Head of Biochemistry and Centre for Molecular Pathology
Royal Marsden Hospital
London, United Kingdom

Ian F. Dunn, MD
Assistant Professor of Neurosurgery
Department of Neurosurgery
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

A. Heather Eliassen, ScD
Assistant Professor
Department of Medicine
Harvard Medical School
Associate Epidemiologist
Department of Medicine
Channing Division of Network Medicine
Brigham and Women's Hospital
Boston, Massachusetts

Matthew J. Ellis, MB, Bchir, PhD, FRCP
Professor
Department of Medical Oncology
Washington University School of Medicine
Director of Breast Cancer Program
Department of Medical Oncology
Barnes Jewish Hospital and Siteman Cancer Center
St. Louis, Missouri

Joann G. Elmore, MD, MPH
Professor
Department of Medicine
School of Medicine
Adjunct Professor of Epidemiology
School of Public Health
University of Washington School of Medicine
Attending Physician
Department of Medicine
Harborview Medical Center
Seattle, Washington

Francisco J. Esteva, MD, PhD
Professor of Medicine
New York University Cancer Institute
New York University
Director
Breast Medical Oncology Program
Division of Hematology/Oncology
New York University Langone Medical Center
New York, New York

Alain Fourquet, MD
Chairman
Department of Radiation Oncology
Institut Curie
Paris, France

Patricia A. Ganz, MD
Distinguished University Professor
Department of Medicine and Health Policy and Management
David Geffen School of Medicine and Fielding School of Public Health at UCLA
Los Angeles, California

Richard D. Gelber, PhD
Professor
Department of Biostatistics
Harvard School of Public Health
Senior Biostatistician
Department of Biostatistics and Computational Biology
Dana-Farber Cancer Institute
Boston, Massachusetts

Shari Gelber, MS, MSW
Biostatistician
Adult Oncology
Dana-Farber Cancer Institute
Boston, Massachusetts

Elizabeth S. Ginsburg, MD
Assistant Professor of Obstetrics, Gynecology and Reproductive Biology
Department of Obstetrics and Gynecology
Harvard Medical School
Medical Director, In Vitro Fertilization
Department of Obstetrics and Gynecology
Brigham and Women's Hospital
Boston, Massachusetts

Armando E. Giuliano, MD, FACS, FRCSEd
Clinical Professor
Department of Surgery
University of California
Executive Vice Chair
Department of Surgery
Cedars-Sinai Medical Center
Los Angeles, California

Aron Goldhirsch, MD
Professor of Medical Oncology
University of Bern
Bern, Switzerland
Director
Department of Medicine
European Institute of Oncology
Milan, Italy

Mehra Golshan, MD
Associate Professor of Surgery
Department of Surgery
Harvard Medical School
Director of Breast Surgical Services
Dana-Farber/Brigham and Women's Cancer Center
Dr. Abdul Mohsen and Sultana Al-Tuwaijri Distinguished Chair in Surgical Oncology
Department of Surgery
Brigham and Women's Hospital
Boston, Massachusetts

Rodrigo Goncalves, MD
Research Associate
Department of Medical Oncology
Washington University
St. Louis, Missouri

William J. Gradishar, MD, FASCO, FACP
Betsy Bramsen Professor of Breast Oncology
Director
Maggie Daley Center for Women's Cancer Center
Robert H. Lurie Comprehensive Cancer Center
Feinberg School of Medicine
Northwestern University
Attending Physician
Department of Hematology/Oncology
Northwestern Memorial Hospital
Chicago, Illinois

Michael W. Groff, MD
Director of Spinal Neurosurgery
Department of Neurosurgery
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts

Ayca Gucalp, MD
Assistant Member
Department of Medicine
Memorial Sloan-Kettering Cancer Center
Instructor
Department of Medicine
Weill Cornell Medical College
Assistant Attending Physician
Breast Cancer Medicine Service
Division of Solid Tumor
Department of Medicine
Memorial Sloan-Kettering Cancer Center
New York, New York

Anthony J. Guidi, MD
Assistant Clinical Professor
Department of Pathology
Tufts University School of Medicine
Boston, Massachusetts
Chair
Department of Pathology
Newton-Wellesley Hospital
Newton, Massachusetts

Carolina Gutiérrez, MD
Associate Professor
Department of Pathology and Lester and Sue Smith Breast Center
Director of Breast Pathology
Baylor College of Medicine
Houston, Texas

Bruce G. Haffty, MD, FACR, FASTRO
Professor and Chair
Department of Radiation Oncology
Rutgers Cancer Institute of New Jersey
Rutgers, The State University of New Jersey
Chair
Robert Wood Johnson University Hospital
New Brunswick, New Jersey

Susan E. Hankinson, ScD
Professor of Epidemiology
Department of Public Health
University of Massachusetts, Boston
Epidemiologist
Department of Medicine
Brigham and Women's Hospital
Boston, Massachusetts

Nora M. Hansen, MD
Associate Professor of Surgery
Department of Surgery
Feinberg School of Medicine
Northwestern University
Director
Lynn Sage Comprehensive Breast Cancer
Chief, Division of Breast Surgery
Department of Surgery
Prentice Women's Hospital of Northwestern Memorial Hospital
Chicago, Illinois

Douglas W. Hanto, MD, PhD
Lewis Thomas Professor of Surgery Emeritus
Harvard Medical School
Boston, Massachusetts
Associate Dean for Continuing Medical Education
Professor of Surgery
Washington University School of Medicine
Chief
General Surgery Service
Department of Surgery
St. Louis Veteran's Administration Medical Center
St. Louis, Missouri

Jay R. Harris, MD
Professor
Department of Radiation Oncology
Harvard Medical School
Chair
Department of Radiation Oncology
Dana-Farber Cancer Institute and Brigham and Women's Hospital
Boston, Massachusetts

Daniel F. Hayes, MD, FASCO
Professor
Department of Internal Medicine
University of Michigan School of Medicine
Clinical Director
Breast Oncology Program
Department of Internal Medicine
University of Michigan Health System
Ann Arbor, Michigan

James A. Hayman, MD, MBA
Professor
Department of Radiation Oncology
University of Michigan Health System
Ann Arbor, Michigan

Aditi Hazra, PhD, MPH
Assistant Professor of Medicine
Department of Medicine
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

Mark A. Helvie, MD
Professor
Director of Breast Imaging
Department of Radiology
University of Michigan Health System
Ann Arbor, Michigan

Dawn Hershman, MD
Associate Professor of Medicine and Epidemiology
Department of Medicine
Columbia University
New York, New York

Bruce E. Hillner, MD
Professor of Medicine and Eminent University Scholar
Department of Internal Medicine
School of Medicine
Virginia Commonwealth University
Attending Physician
Department of Internal Medicine
Virginia Commonwealth University Medical Center
Richmond, Virginia

Alice Y. Ho, MD, MBA
Assistant Attending
Assistant Member
Department of Radiation Oncology
Memorial Sloan-Kettering Cancer Center
New York, New York

Gabriel N. Hortobagyi, MD, FACP, FASCO
Professor
Co-Director of the Breast Cancer Research Program
Department of Breast Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Clifford A. Hudis, MD
Member
Department of Medicine
Memorial Sloan-Kettering Cancer Center
Professor of Medicine
Department of Medicine
Weill Cornell Medical College
Attending Physician and Chief
Breast Cancer Medicine Service
Division of Solid Tumor
Department of Medicine
Memorial Sloan-Kettering Cancer Center
New York, New York

Kevin S. Hughes, MD, FACS
Associate Professor of Surgery
Department of Surgery
Harvard Medical School
Co-Director
Avon Comprehensive Breast Evaluation Center
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

Kelly K. Hunt, MD
Professor
Department of Surgical Oncology
Chief
Breast Surgical Oncolgy
The University of Texas MD Anderson Cancer Center
Houston, Texas

Claudine Isaacs, MD, FRCPC
Professor of Medicine
Department of Medicine and Oncology
Co-Director Fisher Center for Familial Cancer Research
Lombardi Comprehensive Cancer Center
Georgetown University
Washington, DC

Sarika Jain, MD
Assistant Professor of Medicine
Department of Medicine
Northwestern University and Robert H. Lurie Comprehensive Cancer Center
Attending Physician
Department of Medicine
Northwestern Memorial Hospital
Chicago, Illinois

Maxine S. Jochelson, MD
Associate Professor of Clinical Radiology
Department of Radiology
Weill Cornell Medical College
Associate Clinical Member
Department of Radiology
Memorial Sloan Kettering Cancer Center
New York, New York

Stephen R.D. Johnston, MA, PhD, FRCP
Professor of Breast Cancer Medicine
Department of Medical Oncology
Consultant Medical Oncologist
The Breast Unit, The Royal Marsden NHS Foundation Trust
Royal Marsden Hospital
London, United Kingdom

Atif Khan, MD
Associate Professor of Radiation Oncology and Medical Director
Proton Therapy
Robert Wood Johnson Medical School
Rutgers Cancer Institute of New Jersey
Radiation Oncologist
Department of Radiation Oncology
Robert Wood Johnson Hospital
New Brunswick, New Jersey

Seema A. Khan, MD, PhD
Professor of Surgery
Department of Surgery
Northwestern University
Surgeon
Department of Surgery
Robert H. Lurie Comprehensive Cancer Center
Northwestern Memorial Hospital
Chicago, Illinois

Janice N. Kim, MD
Associate Professor
Department of Radiation Oncology
University of Washington Medical Center
Seattle, Washington

Gretchen Kimmick, MD, MS
Associate Professor of Medicine
Department of Breast Medical Oncology
Duke University Medical Center
Durham, North Carolina

Tari A. King, MD, FACS
Associate Attending Surgeon
Jeanne A. Petrek Junior Faculty | Chair
Breast Service
Memorial Sloan-Kettering Cancer Center
Associate Professor of Surgery
Weill Cornell Medical Collegef
New York, New York

Youlia M. Kirova, MD
Senior Radiation Oncologist
Department of Radiation Oncology
Institut Curie
Paris, France

Ian E. Krop, MD, PhD
Assistant Professor of Medicine
Department of Medicine
Harvard Medical School
Senior Physician and Director of Clinical Research
Breast Oncology Center
Department of Medical Oncology
Dana-Farber Cancer Institute
Boston, Massachusetts

Christoph I. Lee, MD, MSHS
Assistant Professor
Department of Radiology
University of Washington School of Medicine
Seattle, Washington

Susan Carole Lester, MD, PhD
Assistant Professor
Department of Pathology
Harvard Medical School
Chief
Breast Pathology Services
Department of Pathology
Brigham and Women's Hospital
Boston, Massachusetts

Jennifer A. Ligibel, MD
Assistant Professor
Department of Medicine
Harvard Medical School
Senior Physician
Adult Oncology
Dana-Farber Cancer Institute
Boston, Massachusetts

Nancy U. Lin, MD
Assistant Professor
Department of Medicine
Harvard Medical School
Clinical Director
Breast Oncology Center
Department of Medical Oncology
Dana-Farber Cancer Institute
Boston, Massachusetts

Marc E. Lippman, MD, MACP
Kathleen & Stanley Glaser Professor
University of Miami Miller School of Medicine
Miami, Florida

Jennifer K. Litton, MD
Associate Professor
Breast Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Suling Liu, PhD
School of Life Sciences
University of Science and Technology of China
Hefei, Anhui, China

Stephen V. Liu, MD
Assistant Professor
Department of Medicine
Lombardi Comprehensive Cancer Center
Georgetown University
Washington, DC

Charles L. Loprinzi, MD
Regis Professor of Breast Cancer Research
Department of Oncology
Mayo Clinic
Rochester, Minnesota

Cynthia X. Ma, MA, MD, PhD
Associate Professor of Medicine
Department of Internal Medicine
Division of Oncology
Washington University School of Medicine
Barnes Jewish Hospital
St. Louis, Missouri

Yanling Ma, MD
Associate Professor of Clinical Pathology
Department of Pathology and Laboratory Medicine
University of Southern California
Keck School of Medicine
Physician Specialist
Department of Pathology and Laboratory Medicine
Norris Comprehensive Cancer Center
University Hospital
Los Angeles, California

Robert E. Mansel, MS, FRCS (Eng), FRCS (Edin)
Professor of Surgery
Department of Surgery
Cardiff University
Honorary Consultant
Department of Surgery
University Hospital of Wales
Cardiff, Wales, United Kingdom

Holly S. Mason, MD, FACS
Assistant Professor of Surgery
Department of Surgery
Tufts University School of Medicine
Director of Breast Surgical Services
Department of Surgery
Baystate Medical Center
Springfield, Massachusetts

Mary Jane Massie, MD
Attending Physician
Department of Psychiatry and Behavioral Sciences
Memorial Sloan-Kettering Cancer Center
New York, New York

Erica L. Mayer, MD, MPH
Assistant Professor of Medicine
Harvard Medical School
Senior Physician
Susan F. Smith Center for Women's Cancers
Dana-Farber Cancer Institute
Boston, Massachusetts

Ingrid A. Mayer, MD, MSCI
Assistant Professor of Medicine
Department of Medicine (Oncology)
Vanderbilt-Ingram Cancer Center
Vanderbilt University
Nashville, Tennessee

Beryl McCormick, MD, FACR
Attending Radiation Oncologist
Department of Radiation Oncology
Memorial Sloan-Kettering Cancer Center
New York, New York

Sarah A. McLaughlin, MD
Assistant Professor of Surgery
Department of Surgery
Mayo Clinic
Jacksonville, Florida

Babak J. Mehrara, MD
Associate Professor
Associate Attending
Plastic and Reconstructive Surgery
Memorial Sloan-Kettering Cancer Center
New York, New York

Karen Meneses, PhD, RN, FAAN
Professor and Associate Dean for Research
School of Nursing
University of Alabama at Birmingham
Birmingham, Alabama

Funda Meric-Bernstam, MD
Chair
Department of Investigational Cancer Therapeutics
Medical Director
Institute for Personalized Cancer Therapy
Professor
Department of Surgical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Rebecca Miksad, MD, MPH
Assistant Professor
Department of Medicine
Harvard Medical School
Attending Physician
Gastrointestinal Malignancies
Division of Hematology and Oncology
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Kimberley L. Miller, MD, FRCPC
Assistant Professor
Department of Psychiatry
University of Toronto
Attending Psychiatrist
Department of Psychosocial Oncology and Palliative Care
Princess Margaret Cancer Center
Toronto, Ontario, Canada

William Miller, BSc, PhD, DSc
Professor (Emeritus)
University of Edinburgh
Edinburgh, Scotland

Frederick L. Moffat, Jr., MD
Professor of Surgery
DeWitt Daughtry Family Department of Surgery
Division of Surgical Oncology
University of Miami Miller School of Medicine
Attending Surgeon
Jackson Memorial Hospital
Sylvester Comprehensive Cancer Center
Department of Surgery
University of Miami Hospital
Miami Florida

Meena S. Moran, MD
Associate Professor
Department of Therapeutic Radiology
Yale University School of Medicine
New Haven, Connecticut
Medical Director
Backus Breast Center
William W. Backus Hospital
Norwich, Connecticut

Patrick G. Morris, MD, MSc
Research Consultant
Breast Cancer Medicine
Memorial Sloan-Kettering Cancer Center
New York, New York
Consultant Medical Oncologist
Clinical Trials Office
Beaumont Hospital
Dublin, Ireland

Monica Morrow, MD
Anne Burnett Windfohr Chair of Clinical Oncology
Chief
Breast Surgery Service
Member
Memorial Sloan-Kettering Cancer Center
Professor of Surgery
Weill Cornell Medical College
New York, New York

Hyman B. Muss, MD
Professor of Medicine
Department of Medicine
Lineberger Comprehensive Cancer Center
University of North Carolina
Chapel Hill, North Carolina

Larissa Nekhlyudov, MD, MPH
Associate Professor
Department of Population Medicine
Harvard Medical School
Internist
Department of Medicine
Harvard Vanguard Medical Associates
Boston, Massachusetts

Polly Niravath, MD
Assistant Professor
Lester and Sue Smith Breast Center
Baylor College of Medicine
Houston, Texas

Susan Orel Roth, MD
Professor of Radiology
Department of Radiology
University of Pennsylvania
Philadelphia, Pennsylvania

Michael P. Osborne, MD, Msurg, FRCS, FACS
Attending Surgeon
Appel-Venet Comprehensive Breast Center
Department of Surgery
Beth Israel Medical Center
New York, New York

C. Kent Osborne, MD
The Tina and Dudley Sharp Chair of Oncology
Professor of Medicine and Molecular and Cellular Biology
Director, Dan L. Duncan Cancer Center
Director, Lester and Sue Smith Breast Center
Baylor College of Medicine
Houston, Texas

Maria Ouzounova, PhD
Research Fellow
University of Michigan Comprehensive Cancer Center
Ann Arbor, Michigan

Beth Overmoyer, MD
Assistant Professor
Department of Medicine
Harvard Medical School
Director
Inflammatory Breast Cancer Program
Breast Oncology Center
Dana-Farber Cancer Institute
Boston, Massachusetts

Sumanta Kumar Pal, MD
Assistant Professor
Medical Oncology and Experimental Therapeutics
City of Hope Comprehensive Cancer Center
Genitourinary Malignancies
Department of Medical Oncology
City of Hope
Duarte, California

Costanza Paoletti, MD
Research Investigator
Department of Internal Medicine
Division of Hematology Oncology
University of Michigan Medical School
University of Michigan
Ann Arbor, Michigan

Ann H. Partridge, MD, MPH
Associate Professor of Medicine
Harvard Medical School
Director Adult Survivorship Program
Dana-Farber Cancer Institute
Boston, Massachusetts

Stephanie K. Patterson, MD
Clinical Associate Professor
Department of Radiology
University of Michigan
Ann Arbor, Michigan

Mark D. Pegram, MD
Susy Yuan-Huey Hung Professor of Medical Oncology
Director
Stanford Breast Oncology Program
Stanford University School of Medicine
Co-Director
Molecular Therapeutics Program
Stanford Cancer Institute
Stanford, California

Charles M. Perou, PhD
The May Goldman Shaw Distinguished Professor of Molecular Oncology
Departments of Genetics and Pathology and Laboratory Medicine
Lineberger Comprehensive Cancer Center
The University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Beth N. Peshkin, MS, CGC
Professor of Oncology
Senior Genetic Counselor
Department of Oncology
Fisher Center for Familial Cancer Research
Georgetown University
Washington, DC

Lori J. Pierce, MD
Professor
Department of Radiation Oncology
University of Michigan School of Medicine
Ann Arbor, Michigan

George Plitas, MD
Assistant Professor
Department of Surgery
Weill Cornell Medical College
Assistant Attending Physician
Breast Service
Department of Surgery
Memorial Sloan-Kettering Cancer Center
New York, New York

Michael F. Press, MD, PhD
Harold E. Lee Chair in Cancer Research
Department of Pathology
University of Southern California
Attending
Department of Pathology
USC Norris Comprehensive Cancer Center Keck School of Medicine
Los Angeles County and University of Southern California County Hospital
Los Angeles, California

James M. Rae, PhD
Associate Professor
Department of Internal Medicine and Pharmacology
University of Michigan
Ann Arbor, Michigan

Habib Rahbar, MD
Acting Assistant Professor
Department of Radiology
University of Washington
Seattle, Washington

Katherine E. Reeder-Hayes, MD, MBA
Assistant Professor
Division of Hematology/Oncology
University of North Carolina at Chapel Hill
Chaptel Hill, North Carolina

Jorge S. Reis-Filho, MD, PhD, FRCPath
Attending and Member
Department of Pathology
Memorial Sloan-Kettering Cancer Center
New York, New York

Mothaffar F. Rimawi, MD
Associate Professor
Department of Medicine and the Breast Center
Baylor College of Medicine
Houston, Texas

Julia H. Rowland, PhD
Director
Office of Cancer Survivorship
Division of Cancer Control and Population Sciences
National Cancer Institute
Bethesda, Maryland

Kathryn J. Ruddy, MD, MPH
Assistant Professor of Oncology
Department of Oncology
Senior Associate Consultant
Department of Oncology
Mayo Clinic
Rochester, Minnesota

Christy A. Russell, MD
Associate Professor of Medicine
Department of Medicine
University of Southern California
Norris Comprehensive Cancer Center
Los Angeles, California

Sunati Sahoo, MD
Associate Professor
Department of Pathology and Laboratory Medicine
University of Texas Southwestern Medical Center
Dallas, Texas

Michelle I. Savage, BS
Program Manager
Clinical Cancer Prevention
The University of Texas MD Anderson Cancer Center
Houston, Texas

Gaia Schiavon, MD, PhD
Clinical Fellow
Molecular Oncology Laboratory
Institute of Cancer Research
Clinical Fellow in Medical Oncology
Breast Unit
The Royal Marsden Hospital Foundation Trust
London, United Kingdom

Stuart J. Schnitt, MD
Professor
Department of Pathology
Harvard Medical School
Director
Division of Anatomic Pathology
Department of Pathology
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Marc D. Schwartz, PhD
Professor of Oncology
Co-Director
Cancer Prevention and Control
Co-Director Jess and Mildred Fisher Center for Familial Cancer Research
Lombardi Comprehensive Cancer Center
Georgetown University
Washington, DC

Emily L. Sedgwick, MD
Assistant Professor
Department of Radiology
Baylor College of Medicine
Houston, Texas

Soma Sengupta, MD, PhD
Neuro-Oncology Fellow
Department of Neurology
Harvard University
Massachusetts General Hospital
Dana-Farber Cancer Institute and Brigham and Women's Hospital
Boston, Massachusetts

Shruti Sheth, MD, MSc
Clinical Educator
Breast Oncology
Medical Oncology
Department of Medicine
Stanford University
Stanford Hospital and Clinics
Stanford, California

Jeffrey B. Smerage, MD, PhD
Associate Professor
University of Michigan Medical School
Department of Internal Medicine
Division of Hematology Oncology
University of Michigan Comprehensive Cancer Center
Medical Oncologist
Breast Oncology Program
Director
Medical Information Technology
Ann Arbor, Michigan

Ian E. Smith, MD, FRCP, FRCPE

PREFACE TO THE FIFTH EDITION

The previous four editions of *Diseases of the Breast* were intended as up-to-date, single-source multidisciplinary compilations of important knowledge on breast diseases, with a focus on breast cancer, presented in a form accessible to practicing clinicians. We have been gratified by the success of this effort and, for the fifth edition, we have similarly invited a diverse and distinguished group of experts to summarize the current knowledge about breast diseases, including its biology and epidemiology, clinical features, and management. The underlying premise for this book has been that multidisciplinary care of the breast cancer patient is critical to obtaining best outcomes and that effective communication between pathologists, breast imagers, medical geneticists, experts in nursing, psychosocial support, and rehabilitation as well as surgical, medical and radiation oncologists is essential.

This fifth edition comes at a time when considerable progress has been made in the treatment of breast cancer. In the United States and in Western Europe, there has been a substantial decrease in the death rate from the disease, attributable to early detection with screening mammography and increasingly effective systemic treatment. Also, it is now established that effective local treatment is essential to decreasing breast cancer mortality. A key contributor to this decrease in breast cancer mortality has been the willingness of many thousands of women with breast cancer who have participated in clinical trials. Of importance as well to this progress are the many talented and dedicated laboratory and translational investigators and clinical researchers who have been committed to the breast cancer problem. This edition is dedicated to them.

Efforts have also been made to understand and improve the quality of life of breast cancer patients. The widespread use of sentinel node biopsy as an alternative to axillary lymph node dissection is a prominent example. Systemic therapy is increasingly targeted and less toxic and advances in the molecular characterization of breast cancers have begun to explain the heterogeneity of the disease and allow for individualization of treatments. Radiation treatment has advanced by better incorporation of imaging modalities and more sophisticated irradiation techniques also allowing for more targeted, less toxic, and, in many cases, abbreviated courses of treatments. While there has been progress in the treatment of breast cancer, we are very aware that there are still many patients who die of the disease and that much more progress is needed.

We hope that the fifth edition of *Diseases of the Breast* will be a useful resource for both clinicians and translational investigators and will foster the understanding and communication necessary to provide optimal patient care and to help foster advances in managing diseases of the breast, especially breast cancer.

PREFACE TO THE FIRST EDITION

Interest in, and knowledge about, breast diseases, especially breast cancer, have increased greatly in recent years. A number of factors have contributed to this, the foremost of which are the high occurrence of breast cancer in westernized countries and the dramatic upswing in this incidence during the past few decades. Clinical investigators have also helped define various benign diseases of the breast and have described their management and relation to subsequent breast cancer development. Moreover, clinical trials performed throughout the world have contributed considerable information about the early detection and management of breast cancer using surgery, radiation therapy, and systemic therapies, including chemotherapy and hormonal interventions. Finally, rapid advances in the understanding of the molecular biology and genetics of both normal tissues and cancers have raised optimism that new, more specific methods can be developed to identify a woman's risk for breast cancer, to prevent, or at least detect, the disease at an earlier stage, and, failing this, to cure it with minimal toxicity. Ultimately a source of hope, these factors have nevertheless caused considerable anxiety in the population, as well as provided a proliferation of information important for clinicians dealing with diseases that strike the breast.

Diseases of the Breast is intended as a single-source compilation of the new knowledge on breast diseases presented in a form accessible to practicing clinicians. Although it is widely recognized that multidisciplinary interaction and information sharing are essential to effective clinical management of diseases of the breast, new developments are rapidly demonstrating that clinicians also need to be knowledgeable about advances in basic science. A prominent example of how advances in basic science can rapidly enter the clinical arena is the discovery of the first genetic mutations at specific loci shown to be associated with a high risk of breast cancer. Clinicians are now faced with patient questions about the nature and meaning of such testing as well as its risks and benefits. We believe that other advances in basic science will quickly be reflected in clinical practice.

For *Diseases of the Breast,* we invited a large, diverse, and distinguished group of experts to summarize the current knowledge about breast diseases, including clinical features, management, and underlying biologic and epidemiologic factors. In assembling these contributions, we have tried to make the book comprehensive and timely, as well as accessible to practicing clinicians. We believe that this book will also be an aid to basic and translational scientists concerned about a breast cancer problem by providing clinical information that can help focus their energies and talents. We hope that *Diseases of the Breast* will be a useful resource for both clinicians and scientists and will foster the understanding and communication necessary to provide optimal patient care and to rapidly achieve advances in managing diseases of the breast, especially breast cancer.

CONTENTS

SECTION I

Breast Anatomy and Development

CHAPTER 1

Breast Anatomy and Development

Michael P. Osborne and Susan K. Boolbol

CHAPTER CONTENTS

Mammary glands are a distinguishing feature of mammals. Nursing of the young in the animal kingdom has many physiologic advantages for the mother, such as aiding postpartum uterine involution, and for the neonate, in terms of the transfer of immunity and bonding. It has become increasingly apparent that the advantages of nursing are substantial for both mother and child.

An understanding of the morphology and physiology of the breast, and the many endocrine interrelationships of both, is essential to the study of the pathophysiology of the breast and the management of benign, preneoplastic, and neoplastic disorders.

EMBRYOLOGY

During the fifth week of human fetal development, the ectodermal primitive milk streak, or "galactic band," develops from axilla to groin on the embryonic trunk (1). The ectoderm over the thorax invaginates into the surrounding mesenchyme, with subsequent epithelial budding and branching (2). In the region of the thorax, the band develops to form a mammary ridge, whereas the remaining galactic band regresses. Incomplete regression or dispersion of the primitive galactic band leads to accessory mammary tissues, found in 2% to 6% of women in the form of accessory nipples or axillary breast tissue.

At 7 to 8 weeks' gestation, a thickening occurs in the mammary anlage (milk hill stage), followed by invagination into the chest wall mesenchyme (disc stage) and tridimensional growth (globular stage). Further invasion of the chest wall mesenchyme results in a flattening of the ridge (cone stage) at 10 to 14 weeks' gestation. Between 12 and 16 weeks' gestation, mesenchymal cells differentiate into the smooth muscle of the nipple and areola. Epithelial buds develop (budding stage) and then branch to form 15 to 25 strips of epithelium (branching stage) at 16 weeks' gestation; these strips represent the future secretory alveoli (3). The secondary mammary anlage then develops, with differentiation of the hair follicle, sebaceous gland, and sweat gland elements, but only the sweat glands develop fully at this time. Phylogenetically, the breast parenchyma is believed to develop from sweat gland tissue. In addition, apocrine glands develop to form the Montgomery glands around the nipple. The developments described thus far are independent of hormonal influences.

During the third trimester of pregnancy, placental sex hormones enter the fetal circulation and induce canalization of the branched epithelial tissues (canalization stage) (4). This process continues from the 20th to the 32nd week of gestation. At term, 15 to 25 mammary ducts have been formed, with coalescence of approximately 10 major ducts and sebaceous glands near the epidermis (5). Parenchymal differentiation occurs at 32 to 40 weeks with the development of lobuloalveolar structures that contain colostrum (end-vesicle stage). A fourfold increase in mammary gland mass occurs at this time, and the nipple–areolar complex develops and becomes pigmented. Externally the nipple is small and flattened, although rudimentary sebaceous glands and Montgomery tubercles are present. The circular smooth muscle fibers that lead to the erectile function of the nipple are developed by this stage.

In the neonate, the stimulated mammary tissue secretes colostral milk (sometimes called *witch's milk*), which can be expressed from the nipple for 4 to 7 days postpartum in most neonates of either sex. At birth, the withdrawal of maternal steroids results in the secretion of neonatal prolactin. It is this hormone that stimulates newborn breast secretion. In the newborn, colostral secretion declines over a 3- to 4-week period owing to involution of the breast after

withdrawal of placental hormones. During early childhood, the end vesicles become further canalized and develop into ductal structures by additional growth and branching.

After birth, the male breast undergoes minimal additional development and remains rudimentary. In the female, the breasts undergo extensive further development, which is regulated by hormones that influence reproduction. The breast has reached its major development by 20 years of age and will usually begin to undergo atrophic changes in the fifth decade of life.

DEVELOPMENTAL ABNORMALITIES

The developmental abnormalities may be unilateral or bilateral and involve both the nipple and the breast or both. These abnormalities are usually isolated to the breast, but there are reports of being associated with a variety of other abnormalities. The most common association is with upper limb and urinary tract abnormalities.

Congenital Abnormalities

Polythelia and Polymastia

The most frequently observed abnormality seen in both sexes is an accessory nipple (polythelia). Ectopic nipple tissue may be mistaken for a pigmented nevus, and it may occur at any point along the milk streak from the axilla to the groin. The reported incidence of polythelia varies greatly in the literature. In a prospective study, Mimoumi et al. (6) found the incidence of polythelia to be 2.5%. Urbani and Betti (7) evaluated the association between polythelia and kidney and urinary tract malformations. These data indicate a significantly higher frequency of kidney and urinary tract malformations in patients with polythelia. This is a controversial issue, and many studies in the literature do not find any connection between polythelia and renal anomalies (8,9).

Rarely, accessory true mammary glands develop; these are most often located in the axilla (polymastia). During pregnancy and lactation, an accessory breast may enlarge; occasionally, if it has an associated nipple, the accessory breast may function.

Hypoplasia and Amastia

Hypoplasia is the underdevelopment of the breast; congenital absence of a breast is termed *amastia*. When breast tissue is lacking but a nipple is present, the condition is termed *amazia*. A wide range of breast abnormalities have been described and can be classified as follows (10,11):

Unilateral hypoplasia, contralateral normal
Bilateral hypoplasia with asymmetry
Unilateral hyperplasia, contralateral normal
Bilateral hyperplasia with asymmetry
Unilateral hypoplasia, contralateral hyperplasia
Unilateral hypoplasia of breast, thorax, and pectoral muscles (Poland's syndrome)

Most of these abnormalities are not severe. The most severe deformity, amastia or marked breast hypoplasia, is associated with hypoplasia of the pectoral muscle in 90% of cases (12), but the reverse does not apply. Of women with pectoral muscle abnormalities, 92% have a normal breast (13). Congenital abnormalities of the pectoral muscle are usually manifested by the lack of the lower third of the muscle and an associated deformity of the ipsilateral rib cage. The association among absence of the pectoral muscle, chest wall deformity, and breast abnormalities was first recognized by Poland in 1841. The original description, however, did not note the concomitant abnormalities of the hand (symbrachydactyly, with hypoplasia of the middle phalanges and central skin webbing) (14), and considerable controversy has evolved concerning the validity of the eponym for this congenital syndrome (15,16).

Athelia

The congenital absence of the nipple areolar complex is a rare entity and is usually associated with absence of the breast. This condition is typically associated with other anomalies.

Acquired Abnormalities

The most common—and avoidable—cause of amastia is iatrogenic. Injudicious biopsy of a precociously developing breast results in excision of most of the breast bud and subsequent marked deformity during puberty. The use of radiation therapy in prepubertal girls to treat either hemangioma of the breast or intrathoracic disease can also result in amastia. Traumatic injury of the developing breast, such as that caused by a severe cutaneous burn, with subsequent contracture, can also result in deformity.

NORMAL BREAST DEVELOPMENT DURING PUBERTY

Puberty in girls begins at the age of 10 to 12 years as a result of the influence of hypothalamic gonadotropin-releasing hormones secreted into the hypothalamic–pituitary portal venous system. The basophilic cells of the anterior pituitary release follicle-stimulating hormone and luteinizing hormone. Follicle-stimulating hormone causes the primordial ovarian follicles to mature into Graafian follicles, which secrete estrogens, primarily in the form of 17-estradiol. These hormones induce the growth and maturation of the breasts and genital organs (17). During the first 1 to 2 years after menarche, hypothalamic–adenohypophyseal function is unbalanced because the maturation of the primordial ovarian follicles does not result in ovulation or a luteal phase. Therefore, ovarian estrogen synthesis predominates over luteal progesterone synthesis. The physiologic effect of estrogens on the maturing breast is to stimulate longitudinal growth of ductal epithelium. Terminal ductules also form buds that precede formation of breast lobules. Simultaneously, periductal connective tissues increase in volume and elasticity, with enhanced vascularity and fat deposition. These initial changes are induced by estrogens synthesized in immature ovarian follicles, which are anovulatory; subsequently, mature follicles ovulate, and the corpus luteum releases progesterone. The relative role of these hormones is not clear. In experimental studies, estrogens alone induce a pronounced ductular increase, whereas progesterone alone does not. The two hormones together produce full ductular–lobular–alveolar development of mammary tissues (17). The marked individual variation in development of the breast makes it impossible to categorize histologic changes on the basis of age (4). Breast development by age has been described by external morphologic changes. The evolution of the breast from childhood to maturity has been divided into five phases by Tanner (18), as shown in Table 1-1.

MORPHOLOGY

Adult Breast

The adult breast lies between the second and sixth ribs in the vertical axis and between the sternal edge and the midaxillary line in the horizontal axis (Fig. 1-1). The average breast

TABLE 1-1

Phases of Breast Development

Phase I	
Age: puberty	Preadolescent elevation of the nipple with no palpable glandular tissue or areolar pigmentation.
Phase II	
Age: 11.1 ± 1.1 yr	Presence of glandular tissue in the subareolar region. The nipple and breast project as a single mound from the chest wall.
Phase III	
Age: 12.2 ± 1.09 yr	Increase in the amount of readily palpable glandular tissue with enlargement of the breast and increased diameter and pigmentation of the areola. The contour of the breast and nipple remains in a single plane.
Phase IV	
Age: 13.1 ± 1.15 yr	Enlargement of the areola and increased areolar pigmentation. The nipple and areola form a secondary mound above the level of the breast.
Phase V	
Age: 15.3 ± 1.7 yr	Final adolescent development of a smooth contour with no projection of the areola and nipple.

From Tanner JM. *Wachstun und Reifung des Menschen*. Stuttgart: Georg Thieme Verlag, 1962, with permission.

measures 10 to 12 cm in diameter, and its average thickness centrally is 5 to 7 cm. Breast tissue also projects into the axilla as the axillary tail of Spence. The contour of the breast varies but is usually dome-like, with a conical configuration in the nulliparous woman and a pendulous contour in the parous woman. The breast is comprised of three major structures: skin, subcutaneous tissue, and breast tissue, with the last comprising both parenchyma and stroma. The parenchyma is divided into 15 to 20 segments that converge at the nipple in a radial arrangement. The collecting ducts that drain each segment are 2 mm in diameter, with subareolar lactiferous sinuses of 5 to 8 mm in diameter. Approximately 10 major collecting milk ducts open at the nipple (5).

The nomenclature of the duct system is varied. The branching system can be named in a logical fashion, starting with the collecting ducts in the nipple and extending to the ducts that drain each alveolus, as shown in Table 1-2. Each duct drains a lobe made up of 20 to 40 lobules. Each lobule consists of 10 to 100 alveoli or tubulosaccular secretory units (5,19). The stroma and subcutaneous tissues of the breast contain fat, connective tissue, blood vessels, nerves, and lymphatics.

The skin of the breast is thin and contains hair follicles, sebaceous glands, and eccrine sweat glands. The nipple, which is located over the fourth intercostal space in the nonpendulous breast, contains abundant sensory nerve endings, including Ruffini-like bodies and end bulbs of Krause. Moreover, sebaceous and apocrine sweat glands are present, but not hair follicles. The areola is circular and pigmented, measuring 15 to 60 mm in diameter. The Morgagni tubercles, located near the periphery of the areola, are elevations formed by openings of the ducts of the Montgomery glands. The Montgomery glands are large sebaceous glands capable of secreting milk; they represent an intermediate stage between sweat and mammary glands. Fascial tissues envelop the breast; the superficial pectoral fascia envelops the breast and is continuous with the superficial abdominal fascia of Camper. The undersurface of the breast lies on the deep pectoral fascia, covering the pectoralis major and anterior serratus muscles. Connecting these two fascial layers are fibrous bands (Cooper suspensory ligaments) that represent the "natural" means of support of the breast.

Vascular Anatomy of the Breast

The principal blood supply to the breast is derived from the internal mammary and lateral thoracic arteries. Approximately 60% of the breast, mainly the medial and central parts, is supplied by the anterior perforating branches of the internal mammary artery. Approximately 30% of the breast, mainly the upper, outer quadrant, is supplied by the lateral thoracic artery. The pectoral branch of the thoracoacromial artery; the lateral branches of the third, fourth, and fifth intercostal arteries; and the subscapular and thoracodorsal arteries all make minor contributions to the blood supply.

The principal veins involved in the venous drainage of the thoracic wall and the breast are the perforating branches of the internal thoracic vein, tributaries of the axillary vein, and perforating branches of posterior intercostal veins.

Lymphatic Drainage of the Breast

Lymph Vessels

The lymphatic drainage of the breast is of great importance in the spread of malignant disease of the breast. The subepithelial or papillary plexus of the lymphatics of the breast is confluent with the subepithelial lymphatics over the surface of the body. These valveless lymphatic vessels communicate with subdermal lymphatic vessels and merge with the Sappey subareolar plexus. The subareolar plexus receives lymphatic vessels from the nipple and areola and communicates by way of vertical lymphatic vessels equivalent to those that connect the subepithelial and subdermal plexus elsewhere (20). Lymph flows unidirectionally from the superficial to deep plexus and from the subareolar plexus through the lymphatic vessels of the lactiferous ducts to the perilobular and deep subcutaneous plexus. The periductal lymphatic vessels lie just outside the myoepithelial layer of the duct wall (21). Flow from the deep subcutaneous and intramammary lymphatic vessels moves centrifugally toward the axillary and internal mammary lymph nodes. Injection studies with radiolabeled colloid (22) have demonstrated the physiology of lymph flow and have countered the old hypothesis of centripetal flow toward the Sappey subareolar plexus (23). Approximately 3% of the lymph from the breast is estimated to flow to the internal mammary chain, whereas 97% flows to the axillary nodes (24).

New insight into lymphatic anatomy and the physiology of lymph flow has been gained from sentinel lymph node studies. It has been observed that the dermal and parenchymal lymphatics drain to the same axillary lymph nodes that are the main basin for lymph draining from the breast (25–30). This might be expected considering the embryology of the breast described earlier in this chapter.

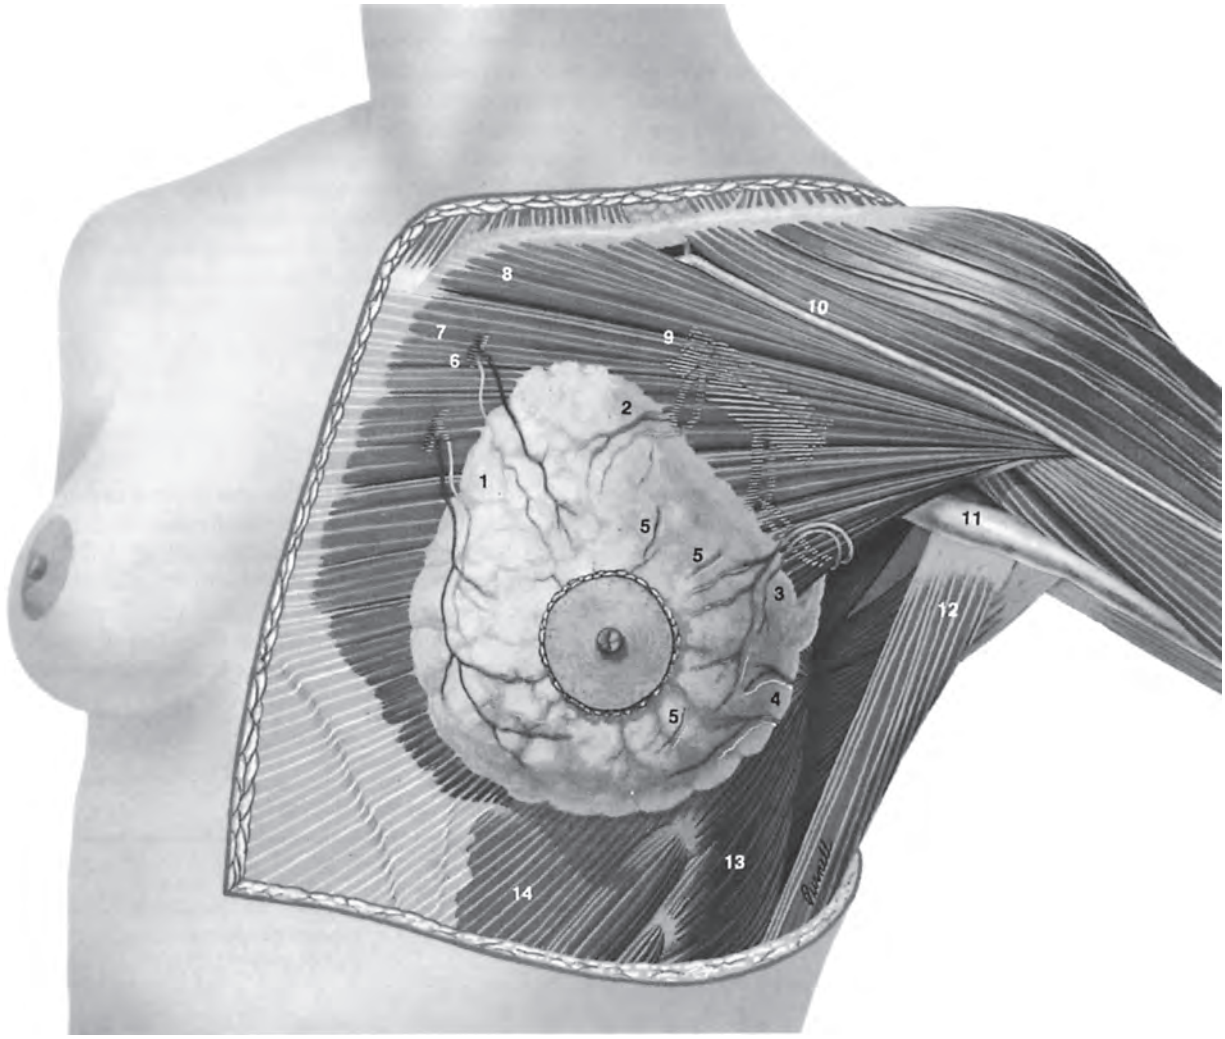

FIGURE 1-1 **Normal anatomy of the breast and pectoralis major muscle.** 1. Perforating branches from internal mammary artery and vein; 2. Pectoral branches from thoracoacromial artery and vein; 3. External mammary branch from lateral thoracic artery and vein; 4. Branches from subscapular and thoracodorsal arteries and veins; 5. Lateral branches of third, fourth, and fifth intercostal arteries and veins; 6. Internal mammary artery and veins; 7. Sternocostal head of pectoralis major muscle; 8. Clavicular head of pectoralis major muscle; 9. Axillary artery and vein; 10. Cephalic vein; 11. Axillary sheath; 12. Latissimus dorsi muscle; 13. Serratus anterior muscle; 14. External abdominal oblique muscle.

Lymphoscintigraphic studies have also shown that deeper parenchymal or retromammary lymphatics preferentially drain to the internal mammary lymph nodes when compared to intradermal or subdermal injection (31–35). There has been controversy over the direction of parenchymal lymph flow in relation to the subareolar plexus. Isotope injection of technetium-99m–labeled sulfur colloid into the subareolar region results in localization of isotope in the axillary sentinel lymph node (36–38). A detailed isotope study of subareolar injection and the lymphatic channels leading to the sentinel lymph node showed that in 90% of cases a single channel exited the areolar margin superiorly or laterally and terminated in an axillary sentinel lymph node (39). Secondary lymphatic channels exited the areola in 75% of cases. None entered the internal mammary lymph node chain.

Suami et al. (40) studied 24 breasts in 14 fresh human cadavers to examine the lymphatic drainage. Lymph collecting vessels were found evenly spaced at the periphery of the anterior upper torso draining radially into the axillary nodes. As identified in cross-section analysis, as these collecting vessels reached the breast some passed over and some through the breast parenchyma. Perforating lymph vessels that coursed beside the branches of the internal mammary vessels and drained into the ipsilateral internal mammary

Segmental ducts	Lobules
Subsegmental ducts	Alveoli
Terminal duct–lobular unit	

lymphatics were also found. Some of these findings are discordant with current knowledge and may explain some of the false-negative rates of sentinel lymph node biopsy.

Axillary Lymph Nodes

The topographic anatomy of the axillary lymph nodes has been studied as the major route of regional spread in primary mammary carcinoma. The anatomic arrangement of the axillary lymph nodes has been subject to many different classifications. The most detailed studies are those of Pickren (41), which show the pathologic anatomy of tumor spread. Axillary lymph nodes can be grouped as the apical or subclavicular nodes, lying medial to the pectoralis minor muscle, and the axillary vein lymph nodes, grouped along the axillary vein from the pectoralis minor muscle to the lateral limit of the axilla; the interpectoral (Rotter) nodes, lying between the pectoralis major and minor muscles along the lateral pectoral nerve (42,43); the scapular group, comprising the nodes lying along the subscapular vessels; and the central nodes, lying beneath the lateral border of the pectoralis major muscle and below the pectoralis minor muscle (Fig. 1-2). Other groups can be identified, such as the external mammary nodes lying over the axillary tail, intramammary lymph nodes, which are found in 28% of breasts (44), and the paramammary nodes located in the subcutaneous fat over the upper, outer quadrant of the breast.

An alternative method of delineating metastatic spread, for the purposes of determining pathologic anatomy and metastatic progression, is to divide the axillary lymph nodes into arbitrary levels (45). Level I lymph nodes lie lateral to the lateral border of the pectoralis minor muscle, level II nodes lie behind the pectoralis minor muscle, and level III nodes are located medial to the medial border of the pectoralis minor muscle (Fig. 1-3). These levels can be determined accurately only by marking them with tags at the time of surgery.

Internal Mammary Lymph Nodes

The internal mammary nodes lie in the intercostal spaces in the parasternal region. The nodes lie close to the internal mammary vessels in extrapleural fat and are distributed in the intercostal spaces, as shown in Figure 1-3. From the second intercostal space downward, the internal mammary nodes are separated from the pleura by a thin layer of fascia in the same plane as the transverse thoracic muscle. The number of lymph nodes described in the internal mammary chain varies. The nodes lie medial to the internal mammary vessels in the first and second intercostal spaces in 88% and 76% of cases, respectively, whereas they lie lateral to the vessels in the third intercostal space in 79% of cases. The prevalence of nodes in each intercostal space is as follows: first space, 97%; second space, 98%; third space, 82%; fourth space, 9%; fifth space, 12%; and sixth space, 62% (46). The pathologic anatomy of this route of lymphatic drainage in the spread of breast disease has been described by Handley and Thackray (47) and Urban and Marjani (48).

In the presence of nodal metastases, obstruction of the physiologic routes of lymphatic flow may occur, and alternative pathways may then become important. The alternative routes that have been described are deep, substernal, cross-drainage to the contralateral internal mammary chain (49,50); superficial presternal crossover, lateral intercostal, and mediastinal drainage (51); and spread through the rectus abdominis muscle sheath to the subdiaphragmatic and subperitoneal plexus (the Gerota pathway). This last route allows the direct spread of tumor to the liver and retroperitoneal lymph nodes. Substernal crossover is demonstrable by isotope imaging of the lymph nodes and may be of significance in early breast cancer (52).

Muscular and Neural Anatomy

The important muscles in the region of the breast are the pectoralis major and minor, serratus anterior, and latissimus dorsi muscles, as well as the aponeurosis of the external oblique and rectus abdominis muscles (Fig. 1-2).

The pectoralis minor muscle arises from the outer aspect of the third, fourth, and fifth ribs and is inserted into the medial border of the upper surface of the coracoid process of the scapula. The muscle is usually prefixed, rather than postfixed, and is innervated by the medial pectoral nerve, which arises mainly from the medial cord of the brachial plexus (cervical vertebra number, or C8, T1 segmental origin) and descends posteriorly to the muscle crossing the axillary vein anteriorly. The nerve enters the interpectoral space, passing through the muscle itself in 62% of cases and around the lateral border as a single branch in 38% of cases (53). Varying numbers of branches passing through the muscle provide motor supply to the lateral part of the pectoralis major muscle. The terms *medial* and *lateral* pectoral nerves are confusing: The standard terminology refers to their brachial plexus origin rather than their anatomic positions. Changes in terminology have been proposed but have not yet been generally accepted. The arrangement of these nerves is of particular importance in performing an axillary dissection.

The serratus anterior muscle stabilizes the scapula on the chest wall. The muscle arises by a series of digitations from the upper eight ribs laterally; its origin from the first rib is in the posterior triangle of the neck. At its origin from the fifth, sixth, seventh, and eighth ribs, the serratus anterior muscle interdigitates with the origin of the external oblique muscle. The muscle inserts into the vertebral border of the scapula on its costal surface and is supplied by the long thoracic nerve of Bell (the nerve to the serratus anterior muscle). The origin of this important nerve is the posterior aspect of the C5, C6, and C7 roots of the brachial plexus. It passes posteriorly to the axillary vessels, emerging on the chest wall high in the medial part of the subscapular fossa. The nerve lies superficial to the deep fascia overlying the anterior serratus muscle and marks the posterior limit of dissection of the deep fascia. Preservation of the nerve to the serratus anterior muscle as it passes downward is essential to avoid "winging" of the scapula and loss of shoulder power.

The latissimus dorsi muscle, the largest muscle in the body, is characterized by a wide origin from the spinous processes and supraspinous ligaments of the seventh thoracic vertebra downward, including all the lumbar and sacral vertebrae. The muscle inserts, by a narrow tendon forming the posterior axillary fold, into a 2.5-cm insertion in the bicipital groove of the humerus. As the muscle spirals around the teres major muscle, the surfaces of the muscle become reversed to the point of insertion. The muscle is supplied by the thoracodorsal nerve (the nerve to the latissimus dorsi muscle), which arises from the posterior cord of the brachial plexus, with segmental origin from C6, C7, and C8. The nerve passes behind the axillary vessels, approaches the subscapular vessels from the medial side, and then crosses anterior to these vessels to enter the medial surface of the muscle. As the nerve passes through the axilla it is intimately involved in the scapular group of lymph nodes. Resection of the nerve does not result in any important cosmetic or functional defect; nevertheless, it should be preserved when possible.

An important landmark in the apex of the axilla is the origin of the subclavius muscle, which arises from the costochondral junction of the first rib. At the tendinous part of the lower border of this muscle, two layers of the clavipectoral fascia fuse together to form a well-developed

band, the costocoracoid ligament, which stretches from the coracoid process to the first costochondral junction (the Halsted ligament). At this point, the axillary vessels (the vein being anterior and inferior to the artery) enter the thorax, passing over the first rib and beneath the clavicle. Many unnamed small branches enter the axillary vein at its lower border. Near the apex, a small artery, the highest thoracic artery, arises from the axillary artery and lies on the first and second ribs.

Muscular Abnormalities

Congenital absence of the sternocostal head of the pectoralis major muscle and its associated abnormalities (Poland's syndrome) have been described earlier in this chapter. In 5% of cadavers, a sternalis muscle can be found lying longitudinally between the sternal insertion of the sternocleidomastoid muscle and the rectus abdominis muscle. The pectoralis minor muscle is inserted into the head of the humerus as well as the coracoid process of the scapula in 15% of cases. Part of the tendon then passes between the two parts of the coracoacromial ligament to insert into the coracohumeral ligament. Rarely, the axillopectoral muscle arises as a separate part of the latissimus dorsi muscle and inferolaterally crosses the base of the axilla superficially, passing deep to the pectoralis major muscle to join its insertion or to continue to the coracoid process (the axillohumeral arch of Langer). This anatomic arrangement can cause compression of the axillary vessels (54) and difficulty in orientation during axillary dissection.

Microanatomy of Breast Development

The developing breast at puberty has been described in detail by Russo and Russo (55) as growing and dividing ducts that form club-shaped terminal end buds. Growing terminal end buds form new branches, twigs, and small ductules termed *alveolar buds* (Fig. 1-4). Alveolar buds subsequently differentiate into the terminal structure of the resting breast, named the *acines* by German pathologists or the *ductule* by Dawson (4). The term *alveolus* is best applied to the resting secretory unit, and *acines* to the fully developed secretory unit of pregnancy and lactation (55).

Lobules develop during the first few years after menarche. The alveolar buds cluster around a terminal duct and form type I (virginal) lobules, comprising approximately 11 alveolar buds lined by two layers of epithelium. Full differentiation of the mammary gland proceeds through puberty, takes many years, and may not be fully completed if interrupted by pregnancies.

Detailed microanatomic studies of the breast have shown the presence of three distinct types of lobules (55). Type I lobules, previously described, are the first generation of lobules that develop just after the menarche. The transition to type II and type III gradually results from continued sprouting of new alveolar buds. The characteristics of the four lobular types are described in Tables 1-3 and 1-4.

Russo et al. (56) recently determined that the breast tissue of women with invasive cancer and those with a familial pattern of breast cancer have an architectural pattern different from the control group of normal tissue. They also found that the *BRCA1* or related genes may have a functional role in the branching pattern of the breast during lobular development. This is seen mainly in the epithelial stroma interaction.

Microscopic Anatomy of the Adult Breast

In the immature breast, the ducts and alveoli are lined by a two-layer epithelium that consists of a basal cuboidal layer and a flattened surface layer. In the presence of estrogens at puberty and subsequently, this epithelium proliferates, becoming multilayered in the adult breast (Figs. 1-5 and 1-6). Three alveolar cell types have been observed: superficial (luminal) A cells, basal B cells (chief cells), and myoepithelial cells.

Superficial, or luminal, A cells are dark, basophilic-staining cells that are rich in ribosomes. Superficial cells undergo intercellular dehiscence, with swelling of the mitochondria, and become grouped, forming buds within the lumen. Basal B cells, or chief cells, are the major cell type in mammary epithelium. They are clear, with an ovoid nucleus without nucleoli. Where the basal cells are in contact with the lumen, microvilli occur on the cell membrane. Intracytoplasmic filaments are similar to those in myoepithelial cells, suggesting their differentiation toward that cell type. Myoepithelial cells are located around alveoli and small excretory milk ducts between the inner aspect of the basement membrane and the tunica propria. Myoepithelial cells are arranged in a branching, star-like fashion. The sarcoplasm contains filaments that are 50 to 80 nm in diameter; these myofilaments are inserted by hemidesmosomes into the basal membrane. These cells are not innervated but are stimulated by the steroid hormones prolactin and oxytocin.

Anatomy of the Nipple and Breast Ducts

Recent advances exploring ductal lavage (57) and direct visualization of the ducts with breast endoscopy (58) have made the anatomy of the nipple clinically relevant. Utilizing six different approaches to examine the ductal anatomy, Love and Barsky (59) found that more than 90% of all nipples examined contained five to nine ductal orifices, generally arranged as a central group and a peripheral group. The central ducts did not extend in a radial fashion from the nipple as previously thought but traveled back from the nipple toward the chest wall. They also found that each nipple orifice communicated with a

separate, nonanastomosing ductal system, which extended to the terminal duct lobular unit. Rusby et al. (60) prospectively examined nipples from mastectomy specimens. The median number of ducts was 23, but they found far fewer ductal orifices on the nipple surface. This study demonstrates that many ducts share a few common openings on the nipple surface and explains the discrepancy between the number of ductal openings on the nipple and the number of actual ducts.

There is evidence to suggest that both ductal and lobular carcinoma arises in the terminal duct lobular unit. Stolier and Wang (61) examined 32 nipples of mastectomy specimens. In 29 of the specimens, there were no terminal duct lobular units identified. Three of the 32 specimens were found to have terminal duct lobular units. All terminal duct lobular units were found at the base of the nipple as opposed to near the tip. As interest in intraductal approaches and treatment increases, so too will knowledge of ductal and nipple anatomy.

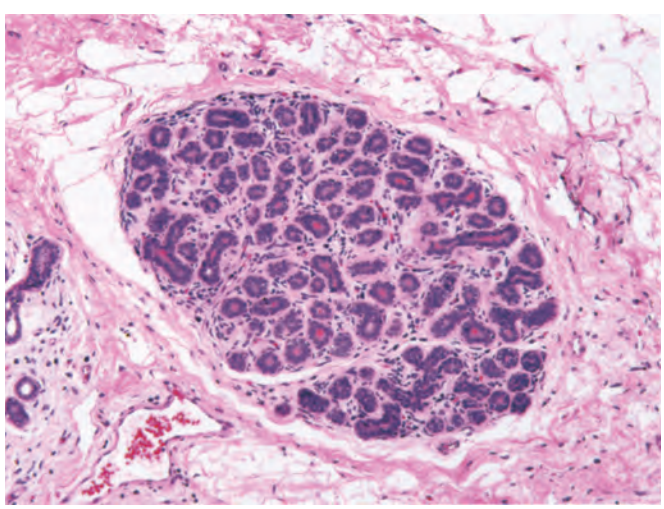

FIGURE 1-5 **Normal lobule in adult female breast.** The lobule is the functional unit of the breast. It is lined by two cell layers: inner epithelial layer and outer myoepithelial layer. The latter are inconspicuous on routine hematoxylin and eosin (H&E) stain such as this. (Photomicrograph courtesy of Dr. Syed Hoda.)

PHYSIOLOGY

Microscopy, Morphology, and the Menstrual Cycle

Histologic changes in the normal breast have been identified in relation to the endocrine variations of the menstrual cycle (62). Normal menstrual cycle–dependent histologic changes in both stroma and epithelium have been observed.

Cyclic changes in the sex steroid hormone levels during the menstrual cycle profoundly influence breast morphology. Under the influence of follicle-stimulating hormone and luteinizing hormone during the follicular phase of the menstrual cycle, increasing levels of estrogen secreted by the ovarian graafian follicles stimulate breast epithelial proliferation. During this proliferative phase, the epithelium exhibits sprouting, with increased cellular mitoses, RNA synthesis, increased nuclear density, enlargement of the nucleolus, and changes in other intercellular organelles. In particular, the Golgi apparatus, ribosomes, and mitochondria increase in size or number. During the follicular phase, at the time of maximal estrogen synthesis and secretion in midcycle, ovulation occurs. A second peak occurs in the midluteal phase, when luteal progesterone synthesis is maximal. Similarly, progestogens induce changes in the mammary epithelium during the luteal phase of the ovulatory cycles. Mammary ducts dilate, and the alveolar epithelial cells differentiate into secretory cells, with a partly monolayer arrangement. The combination of these sex steroid hormones and other hormones results in the formation of lipid droplets in the alveolar cells and some intraluminal secretion.

The changes in breast epithelium in response to hormones are mediated through either intracellular steroid receptors or membrane-bound peptide receptors. The presence of steroid receptors for estrogen and progestogens in the cytosol of normal mammary epithelium has been demonstrated (63). Through the binding of these hormones to specific receptors, the molecular changes, with their observed morphologic effects, are induced as physiologic changes. Similarly, membrane receptors are present to mediate the actions of prolactin. Increases in endogenous estrogen can also exert a histamine-like effect on the mammary microcirculation (64), resulting in an increased blood flow 3 to 4 days

before menstruation, with an average increase in breast volume of 15 to 30 cm^3. Premenstrual breast fullness is attributable to increasing interlobular edema and enhanced ductular–acinar proliferation under the influence of estrogens and progestogens. With the onset of menstruation, after a rapid decline in the circulating levels of sex steroid hormones, secretory activity of the epithelium regresses.

Postmenstrually, tissue edema is reduced, and regression of the epithelium ceases as a new cycle begins, with concomitant rises in estrogen levels. Minimum breast volume is observed 5 to 7 days after menstruation. The cyclic changes in breast cellular growth rates are related to hormonal variations in the follicular and luteal phases of the menstrual cycle. Measurement of these changes can be made by observation and measurement of a variety of cellular and nuclear parameters:

- Histologic pattern
- Cellular morphology
- Nuclear morphology
- Mitoses
- Tritiated thymidine uptake
- Image cytometry
  - Nuclear area
  - Circumference
  - Boundary fluctuation
  - Chromatin granularity
  - Stain intensity
- Proliferation markers
  - Ki-67
  - Proliferating cell nuclear antigen
  - MIB1

Most observations have been made from surgical specimens, which are usually from women with breast abnormalities, or from autopsy specimens, which may have resulted in inconsistent and contradictory results.

Most studies have shown that breast epithelial cell proliferation increases in the second half (luteal phase) of the menstrual cycle (65–71).

A study of nuclear tritiated thymidine uptake in surgically excised breast tissue showed that peak uptake was during the luteal phase on days 22 to 24, coinciding with an increase in circulatory progesterone levels and a second peak of estrogen. The role of estrogen was considered unimportant because the preovulatory peak of estrogen was not associated with an increase in tritiated thymidine uptake (67). The possibility of a synergistic action between estrogen and progesterone would therefore be unlikely.

The role of estrogen and progesterone was subsequently studied in explants of human breast tissue implanted subcutaneously in nude mice (72). An increase in epithelial cell growth was observed 7 days after exposure to estrogen; progesterone had no effect, and a combination of estrogen and progesterone neither enhanced nor diminished the proliferative effect of estrogen. These observations may explain why proliferation increases during the luteal phase subsequent to the preovulatory estrogen peak.

Breast Changes during Pregnancy

During pregnancy, marked ductular, lobular, and alveolar growth occurs as a result of the influence of luteal and placental sex steroids, placental lactogen, prolactin, and chorionic gonadotropin (Fig. 1-4B). In experimental studies, these effects are observed when estrogen and progesterone cause a release of prolactin by reducing the hypothalamic release of prolactin-inhibiting factor (PIF) (69). Prolactin in humans is also released progressively during pregnancy and probably stimulates epithelial growth and secretion (70,71). Prolactin increases slowly during the first half of pregnancy; during the second and third trimesters, blood levels of prolactin are three to five times higher than normal, and mammary epithelium initiates protein synthesis.

In the first 3 to 4 weeks of pregnancy, marked ductular sprouting occurs with some branching, and lobular formation occurs under estrogenic influence. At 5 to 8 weeks, breast enlargement is significant, with dilatation of the superficial veins, heaviness, and increasing pigmentation of the nipple–areolar complex. In the second trimester, lobular formation exceeds ductular sprouting under progestogenic influence. The alveoli contain colostrum but no fat, which is secreted under the influence of prolactin. From the second half of pregnancy onward, increasing breast size results not from mammary epithelial proliferation but from increasing dilatation of the alveoli with colostrum, as well as from hypertrophy of myoepithelial cells, connective tissue, and fat. If these processes are interrupted by early delivery, lactation may be adequate from 16 weeks of pregnancy onward.

At the beginning of the second trimester, the mammary alveoli, but not the milk ducts, lose the superficial layer of A cells. Before this, as in the nonpregnant woman, the two-layer structure is maintained. In the second and third trimesters, this monolayer differentiates into a colostrum–cell layer and accumulates eosinophilic cells, plasma cells, and leukocytes around the alveoli. As pregnancy continues, colostrum, composed of desquamated epithelial cells, accumulates. Aggregations of lymphocytes, round cells, and desquamated phagocytic alveolar cells (foam cells) may be found in colostrum; these are termed the *Donné corpuscles*.

Lactation

After parturition, an immediate withdrawal of placental lactogen and sex steroid hormones occurs. During pregnancy, these hormones antagonize the effect of prolactin on mammary epithelium. Concomitant to the abrupt removal of the placental hormones, luteal production of the sex steroid hormones also ceases. A nadir is reached on the fourth to fifth day postpartum; at this time, the secretion of PIF from the hypothalamus into the hypothalamoadenohypophyseal portal system decreases. This reduction in PIF secretion allows the transmembrane secretion of prolactin by pituitary lactotrophs. Sex steroid hormones are not necessary for successful lactation, and physiologic increases, such as may occur with postpartum ovulatory cycles, do not inhibit it.

Prolactin, in the presence of growth hormone, insulin, and cortisol, converts the mammary epithelial cells from a presecretory to a secretory state. During the first 4 or 5 days after giving birth, the breasts enlarge as a result of the accumulation of secretions in the alveoli and ducts (Fig. 1-7). The initial secretion is of colostrum, a thin, serous fluid that is, at first, sticky and yellow. Colostrum contains lactoglobulin, which is identical to blood immunoglobulins. The importance of these immunoglobulins is unknown; many maternal antibodies cross the placenta, transferring passive immunity to the fetus *in utero*. Fatty acids such as decadienoic acid, phospholipids, fat-soluble vitamins, and lactalbumin in colostrum have considerable nutritional value. After colostrum secretion, transitional milk and then mature milk are elaborated.

Mechanisms of Milk Synthesis and Secretion

The effects of prolactin are mediated through membrane receptors in the mammary epithelial cells. The release of prolactin is maintained and stimulated by suckling, as is the release of corticotrophin (adrenocorticotropic hormone). The mammary cells are cuboidal, depending on the degree of intracellular accumulation of secretions. The DNA and RNA of the nuclei increase, and abundant mitochondria,

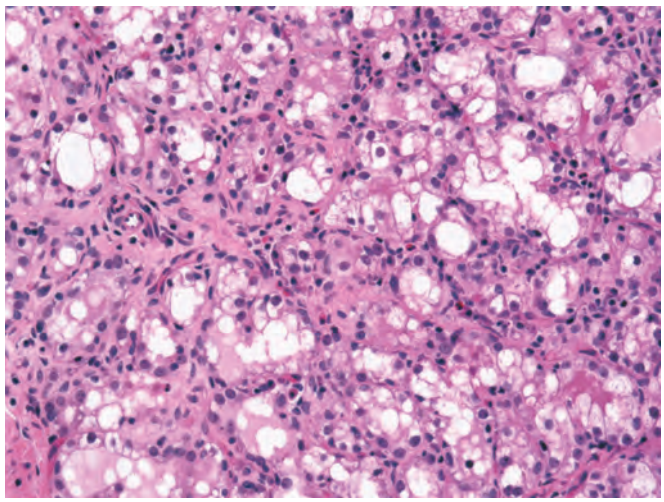

FIGURE 1-7 **Lactating breast tissue.** The glands within the lobules are enlarged and dilated. The stroma within the lobule is diminished. Secretory vacuoles are present within the individual lobular epithelial cells. Hematoxylin and eosin (H&E) stain. (Photomicrograph courtesy of Dr. Syed Hoda.)

ribosomes, and rough endoplasmic reticulum, with a prominent Golgi apparatus, are apparent in the epithelial cells. Complex protein, mild fat, and lactose synthetic pathways are activated, as are water–ion transport mechanisms. These processes are initiated by the activation of hormone-specific membrane receptors. Changes in cyclic adenosine monophosphate stimulate milk synthesis through the induction of messenger and transfer RNA. Prolactin stimulates cyclic adenosine monophosphate–induced protein kinase activity, resulting in the phosphorylation of milk proteins. Polymerase activity and cellular transcription are enhanced (17).

Large fat vacuoles develop and move toward the apex of the cell. At the same time, the nucleus also moves toward the apex. As the water intake of the cell increases, longitudinal cellular striations may be observed. Ultimately, the vacuoles pass from the cell along with part of the cell membrane and cytoplasm; the apical cell membrane reconstitutes as secretion takes place.

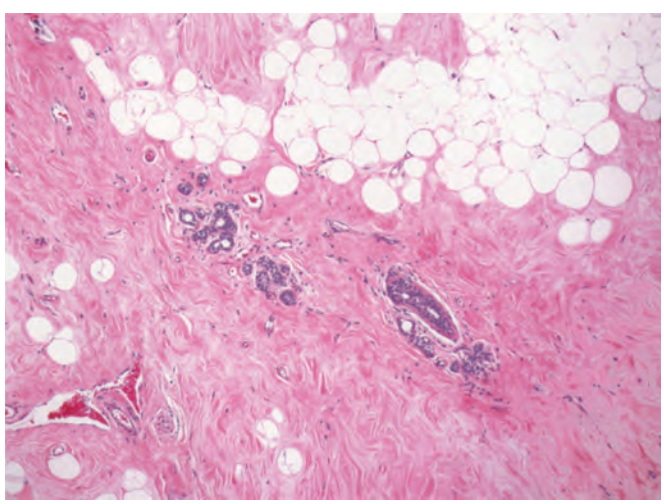

FIGURE 1-8 **Atrophic breast tissue in a postmenopausal woman.** Only a few atrophic ducts and lobules are present amid dense fibrous and fatty tissue. Hematoxylin and eosin (H&E) stain. (Photomicrograph courtesy of Dr. Syed Hoda.)

Enhanced activity occurs during suckling. Fat is secreted chiefly through an apocrine mechanism, lactose is secreted through a merocrine mechanism, and the secretion of proteins occurs as a result of a combination of mechanisms. Ions enter the milk by diffusion and active transport. Relatively little holocrine secretion is thought to take place. The end result of secretion and subsequent intraductal dilution of extracellular fluid is milk, comprising a suspension of proteins—casein, β-lactalbumin, and β-lactoglobulin—and fat in a lactose–mineral solution. The white appearance of milk is due to emulsified lipids and calcium caseinate, whereas the yellow color of butterfat is due to the presence of carotenoids.

Mechanisms of Milk Ejection

The removal of milk by suckling is aided by active ejection. Sensory nerve endings in the nipple–areolar complex are activated by tactile stimuli. Impulses pass by way of sensory nerves through the dorsal roots to the spinal cord. In the spinal cord, impulses are relayed through the dorsal, lateral, and ventral spinothalamic tracts to the mesencephalon and lateral hypothalamus. Inhibition of PIF secretion permits the unimpeded secretion of prolactin from the anterior pituitary. Simultaneously, through a different pathway in the paraventricular nucleus, the synthesis of oxytocin occurs. Oxytocin is released from the posterior pituitary neurovesicles by impulses traveling along the neurosecretory fibers of the hypothalamoneurohypophyseal tract. Oxytocin released into the systemic circulation acts on the myoepithelial cells, which contract and eject milk from the alveoli into the lactiferous ducts and sinuses. This phenomenon is specific to oxytocin, and changes in intramammary ductal pressures of 20 to 25 mm Hg may be observed in relation to peak blood levels. Oxytocin also acts on the uterus and cervix to promote involution. This effect may be stimulated by cervical dilatation and by vaginal stretching through the ascending afferent neural pathways (Ferguson reflex).

Complex neuroendocrine interactions determine normal lactation. An appreciation of these mechanisms is essential to the understanding of abnormalities and to the treatment of problems of lactation (17).

Menopause

Menopause is the result of the atresia of more than 400,000 follicles that are present in the ovaries of a female fetus at 5 months' gestation. Declining ovarian function in late premenopause through the menopause leads to regression of epithelial structures and stroma. Menopausal involution of the breast results in reduction of both the number of ducts and lobules. Stromal changes dominate and fat deposition increases while the regression of connective tissue continues. The duct system remains, but the lobules shrink and collapse (Fig. 1-8). Lymphatic channels are also reduced in number in the postmenopausal breast (36). The last structures to appear with sexual maturity are the first ones to regress (17).

CHAPTER 2

Stem Cells in Breast Development and Carcinogenesis: Concepts and Clinical Perspectives

Maria Ouzounova, Suling Liu, and Max S. Wicha

CHAPTER CONTENTS

There has been accumulating evidence for the existence of a subcomponent of cancer cells that have stem cell properties and have been termed "cancer stem cells." Although the concept that cancer originates from the transformation of "germ cells" or "stem cells" was first proposed over 150 years ago, it is only recently that advances in stem cell biology have allowed for a more direct testing of the cancer stem cell hypothesis. Stem cells are defined by their ability to undergo self-renewal, as well as multi-lineage differentiation. This self-renewal can be either asymmetric or symmetric. Self-renewal is distinguished from other proliferative processes in that at least one of the progeny of self-renewal is identical to the initial stem cell. In all other replicative processes, the progeny of division undergo a series of differentiation events (1). In asymmetric stem cell self-renewal, one of the two progeny is identical to the initial stem cell, whereas the other cell is a committed progenitor cell, which undergoes cellular differentiation. Because the product of an asymmetric self-renewal division is one stem cell and one differentiated cell, this process maintains stem cell numbers. In contrast, symmetric self-renewal results in the production of two stem cells; by its very nature this results in stem cell expansion. Although stem cells themselves are slowly dividing, progenitor cells derived from them are highly proliferative (2). This expanding progenitor cell also has the ability to differentiate into the lineages comprising the adult tissue. Embryonic stem cells are pluripotent, able to differentiate into all derivatives of the three primary germ layers (ectoderm, endoderm, and mesoderm), whereas adult stem cells are multipotent, able to form all of the cell types that are found in the mature tissue of an organ. In the mammary gland, these differentiating cells generate three lineages: ductal epithelial cells, which line ducts; alveolar epithelial cells, which are the milk-producing cells; and myoepithelial cells, which are contractile cells lining ducts and alveoli.

Based on this definition, cancer stem cells retain key stem cell properties. These properties include self-renewal, which initiates and drives tumorigenesis, and differentiation, albeit aberrant, which contributes to cellular heterogeneity (3)

In breast cancer, the discovery of tumor cells that display stem cell properties provides a possible explanation as to why cancer may be so difficult to eradicate, as well as suggesting strategies for the targeting of this cell population. This chapter will examine the implications of the cancer stem cell hypothesis and enable an understanding of carcinogenesis, as well as its implications for developing new strategies for prevention and therapy of breast cancer.

IDENTIFICATION OF NORMAL BREAST STEM CELLS

The existence of adult mammary stem cells was established nearly 50 years ago when DeOme et al. (4) observed that tissue fragments of epithelium isolated from several different regions of the mammary gland were able to reconstitute the entire mammary ductal tree upon transplantation. Later, serial transplantation experiments by Charles Daniel and colleagues (5) demonstrated that stem cells exist throughout the life span of the mouse. Further studies by Smith and Medina (6) suggested that mammary stem cells were present in all portions of the ductal mammary tree at all developmental stages. In 2006, two complementary studies demonstrated that a single cell from either the $CD24^{lo}$ (heat-stable antigen)/ $CD29^{hi}$ (α1-integrin) (7) or $CD24^{lo}/CD49f^{hi}$ (α6-integrin) (8) epithelial population isolated from an adult virgin mouse could generate a functional mammary gland when transplanted into the cleared fat pad of recipient mice.

Further analysis of the $CD24^{lo}CD29^{hi}$ cells revealed that this was a basal population of cells that was ERα-negative (9). Limiting dilution transplantation experiments by Smalley and co-workers (10) illustrated that $CD24^{lo}$ ERα-negative basal cells displayed the highest stem cell activity (as defined by mammary repopulating units), whereas ERα-positive luminal cells exhibited very little stem cell activity. Conversely, Booth and Smith (11) suggested that long-lived, slow-dividing, label-retaining ERα-positive cells comprise a progenitor cell population that can directly respond to hormones. The relationship of these cells characterized *in situ* to the $CD24^{lo}$ cells identified by fluorescence activated cell sorting remains to be established. A well-established *in vitro* system for assays of stem cell behavior—the mammospheres culture system—is a nonadherent assay in which mammary stem cells are cultured as floating cell colonies, without inducing cell differentiation. It was shown that human breast epithelial cells formed mammospheres after 7 to 10 days of culture, which maintained a primitive phenotype and therefore did not express markers associated with terminal differentiation (12,13). In culture conditions which favored cell differentiation, cells isolated from dissociated mammospheres were shown to have the capacity for multi-lineage differentiation in two dimensional culture (as assessed by expression of cell-type specific markers) and in three-dimensional culture gave rise to lobular-alveolar structures (12).

Ginestier et al. (14) have described the expression of aldehyde dehydrogenase 1 (ALDH1) as a stem cell marker that can be utilized to isolate human mammary stem cells. ALDH1 is a detoxifying enzyme responsible for the oxidation of intracellular aldehydes. This enzyme may play a role in early differentiation of stem cells through its role in oxidizing retinol to retinoic acid (15). It is expressed in hematopoietic and neuronal stem and progenitor cells and can be detected utilizing an enzymatic assay (ALDEFLUOR; Aldagen, Durham, North Carolina) (16). Human mammary epithelial cells with a high enzymatic activity for ALDH (ALDEFLUOR positive), isolated from reduction mammoplasties, were able to reconstitute human mammary gland structures when implanted in the humanized fat pad of NOD/SCID mice. Using ALDH1 antibody to immunostain paraffin-embedded sections of human normal breast epithelium researchers identified a relatively rare population of ALDH1-positive cells located in the terminal ductal lobular units (TDLUs). ALDH1-positive cells appeared to form a bridge in the lumen that was located at the bifurcation point of side branches in the TDLUs (14). This is consistent with recently published data demonstrating that human stem/progenitor cells are localized in the ductal part of the TDLU structures (17).

The identification of mammary stem cell markers and the development of *in vitro* and murine models utilizing these cells should facilitate the study of adult breast stem cells to elucidate their role in mammary development. Furthermore, defining the pathways that regulate mammary stem cell self-renewal and differentiation should shed light on events involved in breast carcinogenesis.

BREAST CARCINOGENESIS

Traditionally, cancer has been considered as a multistep process defined by the sequential mutation of key genes driving the uncontrolled clonal expansion of a cell. However, important recent progress in basic research has challenged these concepts at different levels. First, the role of the tumor microenvironment is now well recognized, including the interaction with the extracellular matrix (ECM) and the immune system (18,19). Indeed, epithelial cells are dependent on interactions with specific components of the ECM for survival, proliferation, and differentiation. In addition, the initial steps in tumor establishment are associated with a deficiency in the mechanisms of immunosurveillance. Second, the role of epigenetic deregulation, as opposed to genetic aberrations, in most human tumors is becoming increasingly evident. Epigenetic mechanisms appear to play a fundamental role in cancer establishment and progression, and their deregulation has been reported at multiple levels, including DNA methylation, histone modifications, and microRNA expression (20–24). Third, a "cancer stem cell" model of tumorigenesis has gained experimental support. This model suggests that tumors are sustained in their pathological growth by a small subpopulation of tumor cells with "stem-like" properties, in a way analogous to normal organogenesis. *Cancer stem cell* (CSC) is an operational term to functionally define this distinct subpopulation of tumor cells with deregulated potential for self-renewal, excessive proliferation, and aberrant differentiation into heterogeneous progeny, generating intratumor heterogeneity (25,26) Indeed, classical models of carcinogenesis can be described as "stochastic" or "random," in which any cell in an organ, such as the breast, can be transformed by the right combination of mutations (27). As a result, all or most of the cells in a fully developed cancer are equally malignant (Fig. 2-1). It follows that strategies designed to treat and ultimately cure these cancers require the killing of all these malignant cells. Conversely, the cancer stem cell hypothesis is a fundamentally different model composed of two separate, but interrelated components. The first is that tumors originate in tissue stem and/or progenitor cells through the deregulation of the normally tightly regulated process of self-renewal (28). As a consequence, it is believed that tumors contain a cellular component that retains key stem cell properties including self-renewal, which initiates and drives carcinogenesis and differentiation, albeit aberrant, that contributes to tumor cellular heterogeneity (Fig. 2-1B) (29). However, it is important to emphasize that the CSC and stochastic model of carcinogenesis are not mutually exclusive and probably both mechanisms contribute to tumor heterogeneity. As a result tumors may be constituted by multiple CSC clones which evolve during tumor development and treatment.

ISOLATION AND CHARACTERIZATION OF BREAST CANCER STEM CELLS

Even though important progress has been made, the isolation and characterization of cancer stem cells remains a challenge. In order to validate the method selected as an appropriate technique to isolate cancer stem cells, it is crucial to use assays that can assess the stem cell properties of self-renewal and differentiation. Presently, the gold standard for identifying breast cancer stem cell activity is the xenograft model based on the orthotopic injection of human breast cancer cells into the humanized clear mammary fat pad of immunodeficient mice. The cancer stem cell population is characterized by enhanced tumorigenicity and is able to regenerate the tumor upon serial passage, whereas the tumor cell population depleted of cancer stem cells cannot sustain tumor growth upon serial transformation (Fig. 2-2). In addition to self-renewal, cancer stem cells retain the ability to differentiate, albeit abnormally, generating non–self-renewing cell populations that constitute the bulk of a tumor. Development

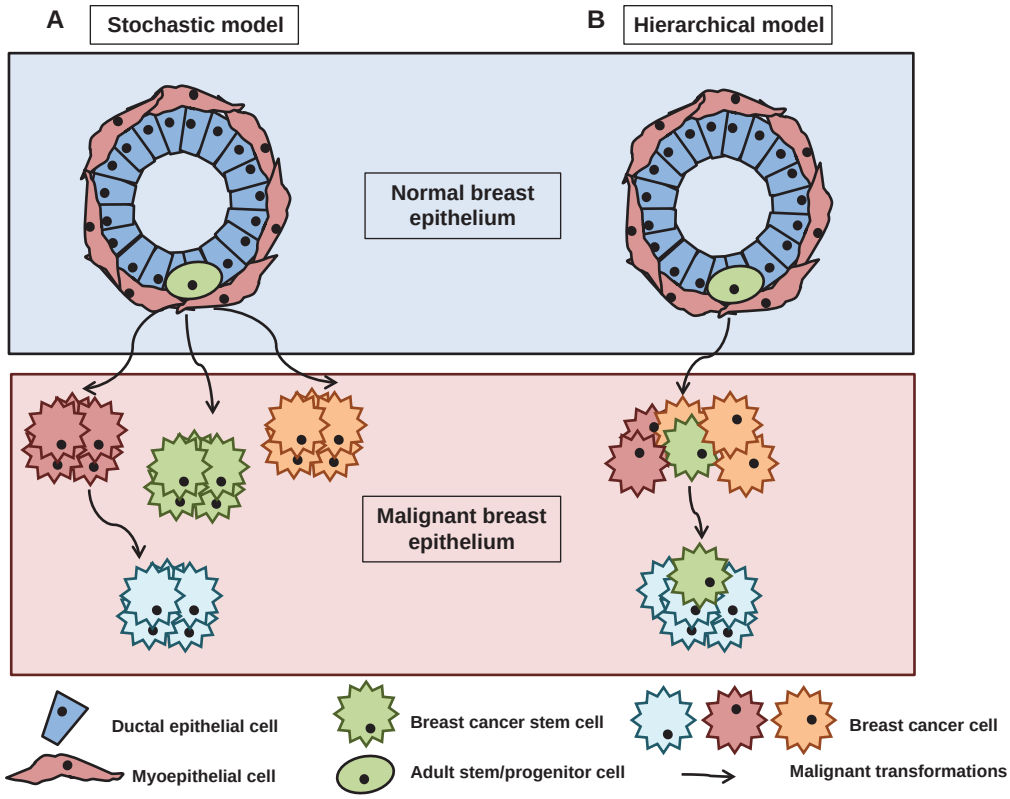

FIGURE 2-1 Two Models of Breast Carcinogenesis. **A:** According to the stochastic model any mammary epithelial cell can be transformed by the right combination of mutations and resultant cancer cells of different phenotypes have extensive proliferation potential. **B:** According to the stem cell hierarchical model, cancers originate from the malignant transformation of a normal breast stem/progenitor cell. Most cancer cells have only limited proliferative potential, but cancer stem cells that have self-renewal capacity drive tumorigenesis.

of *in vitro* assays such as the mammosphere assay has been also used for enrichment of cancer stem cell population. This method is a nonadherent colony forming assay developed by Dontu et al. (30) where only cells with self-renewal capacity are able to survive and grow in anchorage-independent conditions while differentiated cells will undergo anoikis.

In summary, several different techniques have been utilized to enrich for and identify breast cancer stem cells. The *in vitro* cancer stem cell assays provide an important tool for mechanistic studies as well as for screening of specific drugs targeting this population. However, at this time, self-renewal can only be confirmed by serial passage in xenograft models. A potential limitation of these systems relates to the microenvironmental difference found in humans compared to NOD/SCID mice (31). Another important characteristic of both *in vivo* and *in vitro* assays to be taken into account is that these techniques may only detect proliferating stem cells but not dormant cancer stem cells.

BCSC MARKERS

The first evidence for the existence of cancer stem cells in human solid tumors came from the study of Al-Hajj et al. (32) where they utilized techniques based on seminal studies identifying leukemic stem cells by Bonnet and Dick (33). Utilizing cell surface markers and flow cytometry, these authors isolated a tumorigenic population of cells in human breast cancer that displayed cancer stem cell properties. This population was defined by the expression of cell surface markers ($CD44^+/CD24^{-/low}/lin^-$). When injected in the mammary fat pad of NOD/SCID mice as few as 200 of these cells were able to form tumors, whereas 20,000 cells that did not display this phenotype failed to generate tumors. Tumors that formed in mice recapitulated the phenotypic heterogeneity of the initial tumor. The ability to serially transplant the tumors from an enriched stem cell population provides strong support for the existence of stem cells in breast cancers. CD44 appears to be also expressed in cancer stem cells in other tumor types including colon, pancreas, prostate, and head and neck (34–37).

Recently it has been suggested that expression of the cell surface markers EpCAM and CD49f can be used to define functional populations of normal mouse and human mammary cells. Based on *in vitro* and mouse fat pad re-implantation studies it has been suggested that $EpCAM^-$ $CD49f^+$ cells represent mammary stem cells, $EpCAM^+CD49^+$ (double-positive cells): luminal progenitors; $EpCAM^+CD49f^-$: differentiated luminal cells; and $EpCAM^-CD49f^-$: stromal cells. However, double positive ($EpCAM^+CD49f^+$) so-called luminal progenitor cells, have been found to give rise to basal as well as luminal cells when cultured *in vitro*. These results suggest that in addition to luminal progenitors, the $EpCAM^+CD49f^+$ population may also contain a sub-population with stem cell characteristics. A recent study in triple negative breast cancer demonstrated the existence of two different subpopulations based on CD49f expression: $CD49f^-$ quiescent cells and $CD49f^+$ cells. $CD49f^-$ quiescent cells present high tumor-initiating potential as compared to $CD49f^+$ cells. Gene expression analysis reveals that $CD49f^-$ quiescent cells overexpress epithelial-to-mesenchymal transition-driving genes, reminiscent of tumor-initiating cells and claudin-low breast cancer (38). Emerging studies suggest that while $CD49f^+/EpCAM^-$ and $CD44^+/CD24^-$ cells may represent the EMT-like CSC phenotype, $ALDH^+$ cells may represent the MET-like CSC phenotype. These two CSC states may be interconvertible. EMT-like CSCs

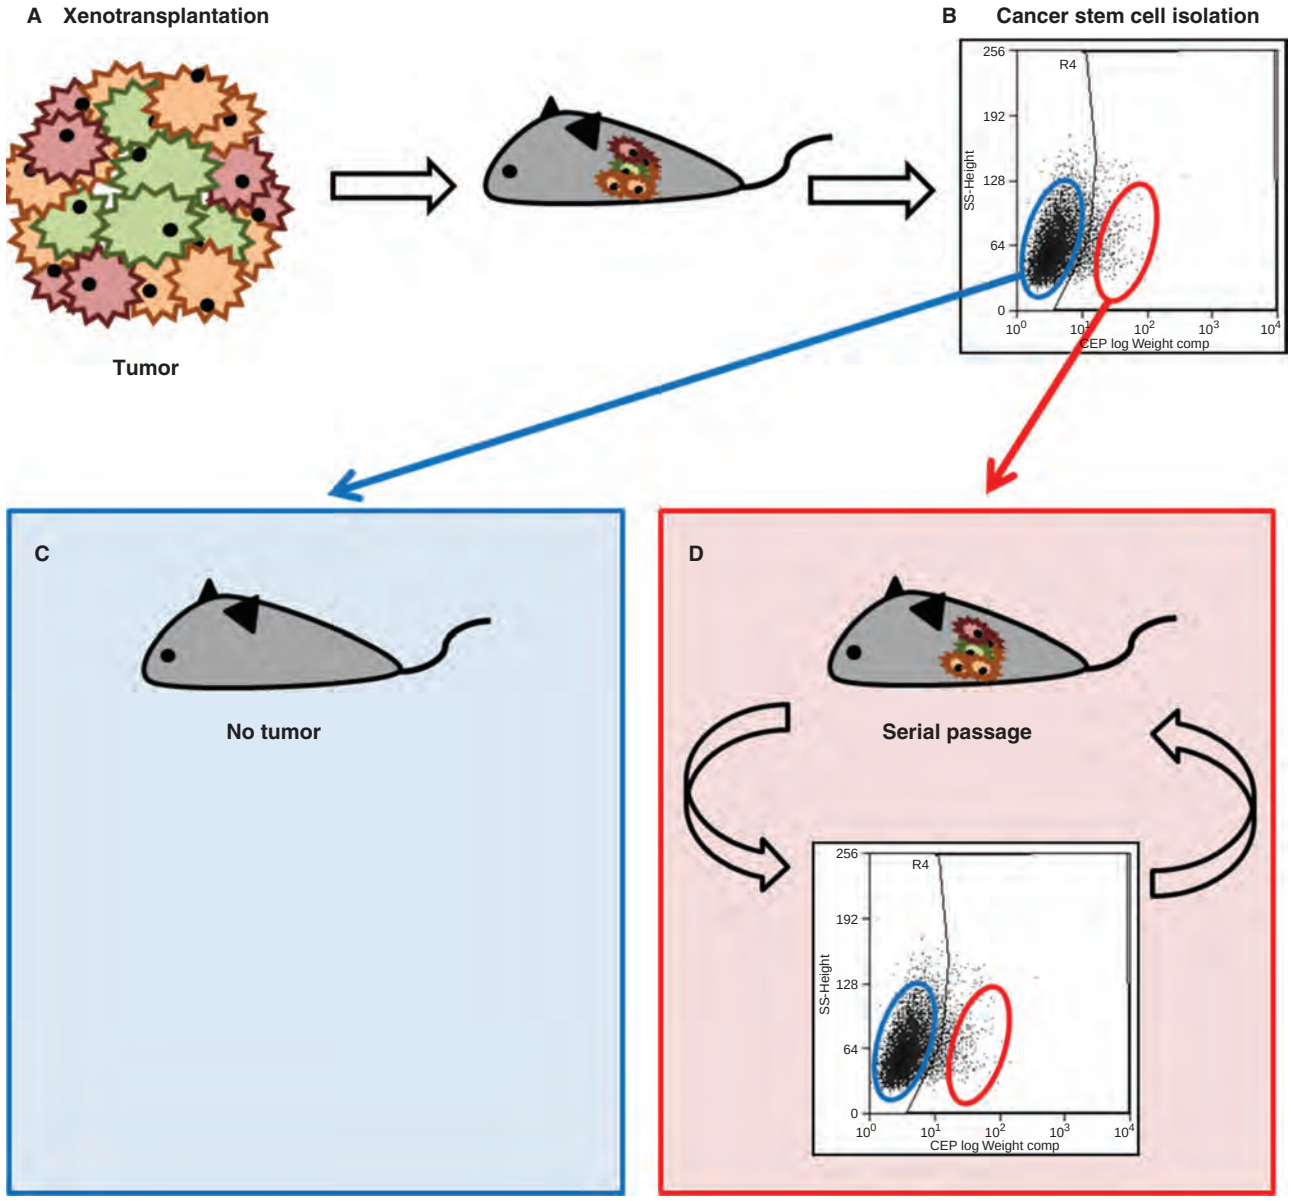

FIGURE 2-2 **Isolation and characterization of breast cancer stem cells. A:** The xenograft model involves introduction of tumor cells into the cleared fat pad of not otherwise specified/severe combined immunodeficiency (NOD/SCID) mice that have been humanized by the introduction of human mammary fibroblasts. **B:** When the xenograft is established, breast cancer stem cells can be separated from the rest of the tumor cells utilizing different techniques such as the ALDEFLUOR (Aldagen, Durham, North Carolina) assay. **C:** When transplanted, the cancer stem cell population initiates and maintains tumor growth upon serial passage, whereas the tumor cell population depleted of the cancer stem cell population fails to generate tumors **D**.

have a mesenchymal morphology, are largely quiescent, invasive, and characterized by expression of the CSC markers $CD24^{-}CD44^{+}$ and are $EpCAM^{-}CD49f^{+}$. In contrast, the MET (mesenchymal epithelial transition) state of CSCs is characterized by active self-renewal and expression of the CSC markers ALDH and $EpCAM^{+}CD49f^{+}$. A subpopulation of cells expressing both $CD24^{-}CD44^{+}$ and ALDH may represent cells in transition between these states. This transition is regulated by signals originating in the microenvironment that could be a potential therapeutic target.

ALDEHYDE DEHYDROGENASE 1

ALDH enzymatic activity has been recently used to isolate normal human breast stem and progenitors cells (14). The authors demonstrated that ALDEFLUOR-positive cells isolated from human breast cancer display properties of cancer stem cells shown by the ability of these cells, but not ALDEFLUOR-negative cells, to generate tumors in NOD/SCID mice. Serial passages of the ALDEFLUOR-positive cells generate tumors that recapitulated the phenotypic heterogeneity

of the initial tumor. Interestingly, the ALDEFLUOR-positive cell population detected in breast tumors has a small overlap with the previously described cancer stem cell, $CD44^+/CD24^-/lin^-$ phenotype (32). In the tumors investigated, the overlap represented approximately 1% or less of the total cancer cell population. The ALDEFLUOR-positive $CD44^+/CD24^-/lin^-$ cells appeared to be highly enriched in tumorigenic capability, being able to generate tumors from as few as 20 cells. ALDH1 immunostaining of paraffin-embedded specimens was utilized to identify breast cancer stem cells *in situ*. Analysis of ALDH1 expression in 577 human breast carcinomas showed that this stem or progenitor cell marker is a powerful predictor of poor clinical outcome and correlates with tumor histological grade, ER and PR negativity, proliferation index as assessed by Ki-67 expression, and *ERBB2* overexpression.

LINEAGE TRACING

Recent studies utilizing mouse models of glioblastoma, skin and intestinal tumors provide important validation of the cancer stem cell model (39–41). These studies provide the first evidence that CSC arise de novo during tumor development in intact organs. Lineage tracing methods take advantage of fluorescent marking of stem cells and their progeny allowing for the visualization and monitoring of cancer stem cells. Chen et al. and Driessens et al., together with Schepers et al., traced individual cells in intact tumors and demonstrated that cancer cells are organized hierarchically. Using lineage tracing Driessens et al. observed that the cells present an important variability in proliferation potential with only 20% able to generate daughter cells capable of tumor regeneration. Moreover, the studies of Chen et al. suggested that targeting both CSC and their progeny improved therapeutic outcome *in vivo*. These studies raise the issue of a possible evolutionary competition between non-stem cells and stem cells within the tumor, with the non-stem cells presence representing a brake for the tumor development. In accordance with this idea Driessens et al. observed enrichment of the CSC population and a concomitant decrease in the non-stem cell population during cancer progression. Together these results suggest that prevention of the increase in the stem-like compartment would retard tumor progression.

THERAPEUTIC IMPLICATIONS OF BREAST CANCER STEM CELLS

Although advances have been made in the treatment of localized breast cancer, there has been less progress in the treatment of advanced metastatic disease. Some of this lack of progress may be due to the failure of current therapies to target cancer stem cells (Fig. 2-3). The cancer stem cell hypothesis has important implications for the development of cancer therapeutics. Recent evidence indicates that breast CSC (42) as well as CSC from other tumor types, are relatively resistant to both radiation and chemotherapy (43). There are several postulated mechanisms for this resistance. Stem cells proliferate slowly; they are largely in the G0 phase of the cell cycle for extended periods of time, making them resistant to cell-cycle–dependent chemotherapeutic agents. In addition, CSC expressed increased adenosine triphosphate–binding cassette proteins known to efflux chemotherapeutic drugs. Indeed, ABCG2, or breast cancer–resistance protein, was initially identified in breast cancers. This molecule is overexpressed in stem cells and has been utilized to purify breast and other stem cells by exclusion of Hoechst dye, generating the so-called side population detected by flow cytometry (44). In addition, enzymes such as ALDH that are highly expressed in stem cells are able to metabolize chemotherapeutic agents such as cyclophosphamide (45).

CSC may also express increased levels of antiapoptotic molecules such as survivin and BCL2-family proteins (46). Current clinical trial designs have largely been based on

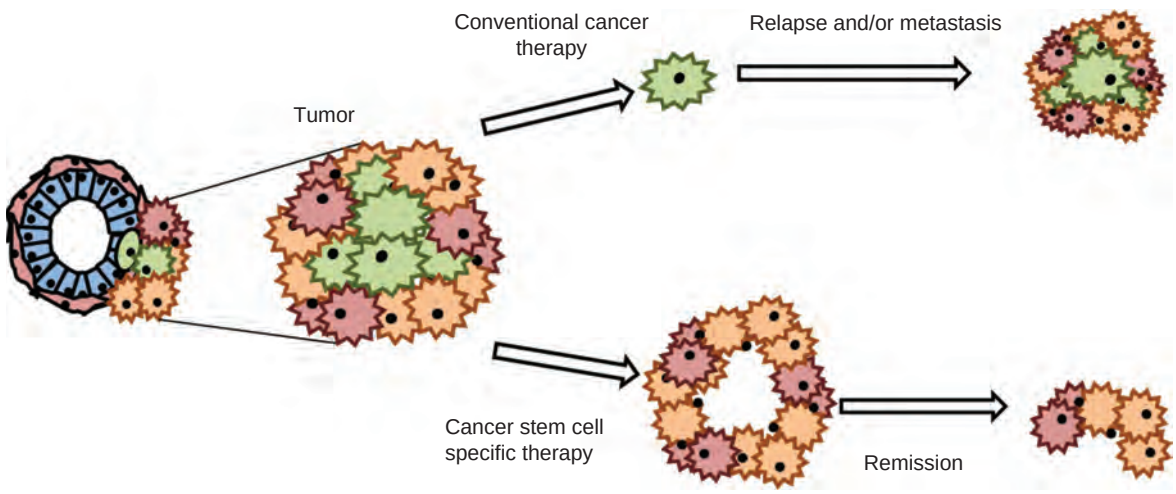

FIGURE 2-3 **Therapeutic implications of breast cancer stem cells.** Current therapies may shrink tumors by killing cells forming the tumor bulk. Because cancer stem cells are less sensitive to these therapies, they remain viable after therapy and re-establish the tumor. In contrast, therapies that target the cancer stem cell population limit tumor growth. Thus, even if cancer stem cell–directed therapies do not shrink tumors initially, they may eventually lead to cures. Furthermore, there is increasing evidence that cancer stem cells may play an important role in mediating tumor metastasis. The development of therapies targeting the cancer stem cell population may provide new opportunities to target metastatic disease.

strategies aimed at producing tumor regression. Indeed, the Response Evaluation Criteria in Solid Tumors (RECIST) criteria measuring tumor response have been utilized to assess the efficacy of new therapeutic agents (47).

However, in breast cancer, as is the case with other malignancies, tumor regression does not correlate well with patient survival (48). In the neoadjuvant setting, only a complete pathologic response correlates with recurrence and survival, whereas partial response does not (49). Together with studies demonstrating resistance of breast CSC to chemotherapy and radiation therapy, these studies suggest that the limitations of present therapies may relate to their inability to target the cancer stem cell component. Recent neoadjuvant studies demonstrating an increase in the proportion of $CD44^+/CD24^-$ breast CSC after chemotherapy suggest that this is the case (50,51). Furthermore, Korkaya et al. (52) have recently found that *ERBB2* overexpression in normal human mammary epithelial cells as well as mammary carcinomas increases the proportion of stem cells as indicated by ALDH1 expression. The clinical relevance of this was demonstrated in a recent neoadjuvant breast cancer trial. Tumor regression induced by neoadjuvant chemotherapy was associated with an increase in $CD44^+/CD24^-$ cancer stem cells in residual tumors. In contrast, breast cancers with *ERBB2* amplification had an increased proportion of $CD44^+/CD24^-$ cells before treatment that was reduced by administration of the *ERBB2* inhibitor lapatinib (53). Moreover Magnifico and colleagues used several HER2-overexpressing breast cancer cell lines to show an important role for HER2 in maintaining the cancer stem cell population. They show that within each cell line, cells displaying stem cell properties such as sphere formation or increased aldehyde dehydrogenase expression also have increased HER2 expression compared with the bulk cell population. Furthermore, they show that the HER2 inhibitor trastuzumab or the combined HER2 and epidermal growth factor inhibitor lapatinib are able to specifically target this HER2-overexpressing cancer stem cell population (54). Using breast cancer cell lines, mouse xenograft models, and matched human primary and metastatic tissues, Ithimakin et al. (55) show that HER2 is selectively expressed in, and regulates self-renewal of, the cancer stem cell population in estrogen receptor-positive (ER^+), $HER2^-$ luminal breast cancers. Although trastuzumab had no effects on the growth of established luminal breast cancer mouse xenografts, administration after tumor inoculation blocked subsequent tumor growth. HER2 expression is increased in luminal tumors grown in mouse bone xenografts, as well as in bone metastases from patients with breast cancer as compared with matched primary tumors. Furthermore, this increase in HER2 protein expression was not due to gene amplification but rather was mediated by receptor activator of NF-κB (RANK)-ligand in the bone microenvironment. These studies suggest that the clinical efficacy of adjuvant trastuzumab may relate to the ability of this agent to target the CSC population in a process that does not require HER2 gene amplification.

The clinical efficiency of *ERBB2* inhibitors provides evidence for the effectiveness of agents capable of targeting breast cancer stem cells. In addition, elucidation of other pathways that regulate breast cancer stem cells, such as Notch and Hedgehog may provide new targets for therapeutic development.

NOTCH PATHWAY

In mammals, there are four Notch receptors (Notch1 to Notch4), which interact with surface bound or secreted ligands (Delta-like 1, Delta-like 3, Delta-like 4, Jagged 1 and Jagged 2). Upon ligand binding, Notch receptors are activated by serial cleavage events involving members of the ADAM protease family followed by intramembranous cleavage regulated by γ-secretase (presenilin). Following proteolytic cleavage, the intracellular domain of Notch translocates to the nucleus to act on downstream targets such as the Hes and Hey transcription factors. Evidence for the role of Notch signaling in mammary development has been provided by transgenic models. The Notch pathway has been shown to play an important role in mammary carcinogenesis. Stimulation of Notch signaling resulted in a 10-fold increase in the number of secondary mammospheres obtained after dissociation of the primary spheres and Notch activation acts as a regulator of asymmetric cell fate decisions by promoting mammary self-renewal (56). Since γ-secretase is necessary for Notch processing γ-secretase inhibitors are able to inhibit Notch signaling. These results suggest that Notch is required for CSC expansion. Another study demonstrated different targeted subpopulations for Notch1 and Notch4 (57). Notch4 inhibition in $EpCAM^+/CD44^+/CD24^{lo}$ subpopulation decreased sphere formation efficiency *in vitro* and abrogated tumor formation *in vivo*, while down regulation of Notch1 resulted in decreased tumor growth and rate. These data suggest a role of Notch4 in CSC maintenance and initiation, and a role of Notch1 in tumor proliferation. A relationship between Notch and HER2 signaling has been suggested by the demonstration that the HER2 promoter contains Notch-binding sequences. In addition, tumor cells derived from HER2 transgenic mice cultured *in vitro* in the presence of a γ-secretase inhibitor form spheres at lower efficiency compared to untreated cells (58). These studies show important interactions between the Notch and HER2 pathways, both of which are involved in the regulation of cancer stem cells. As in the previously discussed studies, it was shown that lapatinib was able to reduce the cancer stem cell population following neoadjuvant chemotherapy. In metastatic disease, the clinical end points of tumor regression or time to tumor progression may reflect changes in bulk cell populations. The efficacy of trastuzumab or lapatinib in this setting may reflect the overexpression of HER2 in both cancer stem cells and bulk cell populations. In contrast, in the adjuvant setting, tumor recurrence may be driven by the cancer stem cell compartment. This compartment in turn may be driven by pathways such as Notch that do not depend on HER2 amplification. This could explain the benefit of HER2 inhibition in the adjuvant setting in patients whose tumors do not display HER2 amplification suggested by retrospective analysis of trastuzumab adjuvant clinical trials. It would be interesting to determine whether these tumors display Notch activation, which has been reported to occur in as many as 40% of human breast cancers (59). In these patients, inhibition of Notch signaling in addition to HER2 blockade represents a rational therapeutic strategy. These concepts may be tested in future trials as γ-secretase inhibitors that inhibit Notch signaling are currently in clinical development (60).

HEDGEHOG PATHWAY

The Hedgehog pathway is critical for many developmental processes. In the absence of Hedgehog, a cell-surface transmembrane protein Patched (PTCH) acts to prevent high expression and activity of a seven membrane spanning receptor Smoothened (SMO). When extracellular Hedgehog is present, it binds to, and inhibits, PTCH, allowing SMO to accumulate and inhibit the proteolytic cleavage of the Ci protein with subsequent activation of nuclear transcription factors including Gli1 and Gli2. In the mammary gland, the

Breast cancer	CXCR1	Reparixin	A. Schott, University of Michigan

Hedgehog pathway is required for normal development. Alterations in Hedgehog signaling result in defects in both embryonic and postnatal mammary gland development. Utilizing *in vitro* culture systems and NOD/SCID mice, Liu et al. (61) demonstrated that hedgehog signaling mediated by the polycomb gene *BMI1* regulates the self-renewal of both normal and malignant human mammary stem cells. This process is blocked by specific inhibitors such as cyclopamine (11-deoxojervine). This compound has been shown to inhibit tumor growth in several mouse models. In order to reduce cyclopamine toxicity several cyclopamine derivatives such as IPI-96 have been developed, which are currently in Phase I clinical trials.

OTHER PATHWAYS

Other pathways that regulate the self-renewal and fate of cancer stem cells are being elucidated. In addition to pathways such as Wnt, Notch, and Hedgehog, known to regulate self-renewal of normal stem cells, tumor suppressor genes such as PTEN (phosphatase and tensin homolog on chromosome 10) and p53 have also been implicated in the regulation of normal and malignant breast stem cell self-renewal. It is believed that these pathways are deregulated in cancer stem cells, leading to uncontrolled self-renewal of these cells, which may generate tumors that are resistant to conventional therapies. Reduced PTEN expression is found in approximately 40% of $HER2^-$ amplified breast cancers, an alteration associated with trastuzumab resistance (62). PTEN downregulation increases the breast CSC population via Akt activation of the Wnt signaling pathway (63). The Akt inhibitor perifosine was able to partially block this pathway, reducing the CSC population. In a recent study Korkaya et al demonstrate that PTEN deletion in HER2-overexpressing breast cancer cells activates an IL6 mediated inflammatory feedback loop (64). This results in an expanded CSC population displaying an EMT phenotype, a process mediated by both autocrine and paracrine mechanisms, which in turn confer trastuzumab resistance. In addition, the authors demonstrate that interfering with this feedback loop utilizing an IL6 receptor (IL6R) antibody reduces the CSC population and inhibits tumor growth and metastasis.

Studies by Singh and colleagues (65) further our understanding of these pathways by showing interactions between the IL-8/CXCR1/2 axis and HER2 signaling in the regulation of BCSCs. These studies confirm previous work showing independent roles for these pathways in regulating the self-renewal of BCSCs. CXCR1 is a receptor for the cytokine interleukin-8 (IL-8), and it has been shown that recombinant IL-8 increased BCSC self-renewal as determined by the ability of these cells to form tumor spheres as well as by increased ALDH expression (66). Singh and colleagues show the clinical importance of IL-8 by directly measuring IL-8 levels in plural effusions and ascites from 10 patients with metastatic breast cancer. Of interest, they show a clear association between metastatic fluid IL-8 levels and ability of cells isolated from these effusions to generate primary and secondary tumor spheres. Reparixin, a small-molecule inhibitor of CXCR1/2, inhibits BCSC in mouse xenografts (66). On the basis of this, a phase I clinical trial combining reparixin with chemotherapy in women with advanced breast cancers has been initiated. Moreover, the studies of Singh and colleagues suggest that $HER2^-$ blocking agents may synergize with CXCR1/2 inhibitors in targeting the BCSC population. The simultaneous targeting of interacting extrinsic and intrinsic CSC regulatory pathways may result in more efficient elimination of BCSC populations improving patient outcome.

In summary, the cancer stem cell model suggests that it may be necessary to target and eliminate cancer stem cells in order to eradicate cancers. Drugs that interfere with stem cell self-renewal or survival may prove effective in targeting these cell populations. Because normal and tumoral stem cells share many common regulatory pathways, it will be critical to identify agents that have a therapeutic index between normal and cancer stem cells. A number of agents targeting breast cancer stem cell self-renewal pathways are now entering early phase clinical trials (Table 2-1). These trials will provide a direct test of the cancer stem cell hypothesis.

SECTION II

Diagnosis and Management of Benign Breast Disease

CHAPTER 3

Physical Examination of the Breast

Monica Morrow

CHAPTER CONTENT

Obtaining a careful history is the initial step in a breast examination. Regardless of the presenting complaint, baseline information regarding menstrual status and breast cancer risk factors should be obtained. The basic elements of a breast history are listed in Table 3-1. In premenopausal women, knowing the date of the last menstrual period and the regularity of the cycle is useful in evaluating breast nodularity, pain, and cysts. Postmenopausal women should be questioned about use of hormone replacement therapy, given that many benign breast problems are uncommon after menopause in the absence of exogenous hormones. Specific information about the patient's presenting complaint is then elicited. A breast lump is most often the clinical breast problem that causes women to seek treatment, and remains the most common presentation of breast carcinoma. Haagensen (1) observed that 65% of 2,198 breast cancer cases identified before the use of screening mammography presented as breast masses. Breast pain, a change in the size and shape of the breast, nipple discharge, and changes in the appearance of the skin are infrequent symptoms of carcinoma. The evaluation and management of these conditions are described in Chapters 5, 6, and 7. In general, the duration of symptoms, their persistence over time, and their fluctuation with the menstrual cycle should be assessed.

TECHNIQUE OF BREAST EXAMINATION

A woman must be disrobed from the waist up for a complete breast examination. Although attention to modesty is appropriate, and a gown or drape should be provided, inspection is an important part of the examination, and subtle abnormalities are best appreciated by comparing the appearance of both breasts. Breast examination should be done with the patient in both the sitting and supine positions, and care should be taken at all times to be gentle. The steps of a breast examination are illustrated in Figure 3-1.

The breasts should initially be inspected while the patient is in the sitting position with the arms relaxed (Fig. 3-1A). A comparison of breast size and shape should be made. If a size discrepancy is noted, its chronicity should be determined. Many women's breasts are not identical in size, and the finding of small size discrepancies is rarely a sign of malignancy. Differences in breast size that are of recent onset or progressive in nature, however, may be owing to both benign and malignant tumors, and require further evaluation (Fig. 3-2). Alterations in breast shape, in the absence of previous surgery, are of more concern. Superficially located tumors can cause bulges in the breast contour or retraction of the overlying skin. The skin retraction seen with superficial tumors may be caused by direct extension of tumor or fibrosis. Tumors deep within the substance of the breast that involve the fibrous septa (Cooper's ligaments) can also cause retraction. Retraction is not itself a prognostic factor except when caused by the direct extension of tumor into the skin and, for this reason, it is not a part of the clinical staging of breast cancer (2). Although retraction is often a sign of malignancy, benign lesions of the breast, such as granular cell tumors (3) and fat necrosis (4), also cause retraction. Other benign causes of retraction include surgical biopsy and thrombophlebitis of the thoracoepigastric vein (Mondor's disease) (5) (Fig. 3-3).

The skin of the breasts and the nipples should also be carefully inspected. Edema of the skin of the breast (*peau d'orange*), when present, is usually extensive and readily apparent. Localized edema is frequently most prominent in the lower half of the breast and periareolar region, and is most noticeable when the patient's arms are raised. Although breast edema usually occurs as a result of obstruction of the dermal lymphatics with tumor cells, it can also be caused by extensive axillary lymph node involvement related to metastatic tumor, primary diseases of the axillary nodes, or axillary dissection. Some degree of breast edema is very common after irradiation of the breast and should not be considered abnormal in this circumstance. Erythema is another sign of a pathologic process that is evident on inspection (Fig. 3-4). It may be caused by cellulitis or abscess in the breast, but a diagnosis of inflammatory carcinoma should always be considered. The erythema of inflammatory carcinoma usually involves the entire breast; it is distinguished from the inflammation caused by infection by the absence of breast tenderness and fever. A small percentage of large-breasted women have mild, dependent erythema of the most pendulous portion of the breast, a condition that resolves when they lie down, and that is of no concern.

Examination of the nipples should include inspection for symmetry, retraction, and changes in the character of the skin. The new onset of nipple retraction should be regarded with a high index of suspicion, except when it occurs immediately after cessation of breast-feeding. Ulceration and eczematous changes of the nipple may be the first signs of Paget's disease.

TABLE 3-1

Components of the Medical History of a Breast Problem

All Women
- Age at menarche
- Number of pregnancies
- Number of live births
- Age at first birth
- Family history of breast cancer, including affected relative, age of onset, and presence of bilateral disease
- History of breast biopsies (and histologic diagnosis, if available)

Premenopausal Women
- Date of last menstrual period
- Length and regularity of cycles
- Use of oral contraceptives

Postmenopausal Women
- Date of menopause
- Use of hormone replacement therapy

The initial nipple abnormality may be limited in extent, but, if untreated, it progresses to involve the entire nipple.

After inspection with the arms relaxed, the patient should be asked to raise her arms to allow a more complete inspection of the lower half of the breasts (Fig. 3-5). Inspection is completed with the patient contracting the pectoral muscles by pressing her hands against her hips. This maneuver often highlights subtle areas of retraction that are not readily apparent with the arms relaxed.

The next step in the examination is palpation of the regional nodes. Examination of the axillary and supraclavicular nodes is done optimally with the patient upright. The right axilla is examined with the physician's left hand while the patient's flexed right arm is supported (Fig. 3-1B). This position allows relaxation of the pectoral muscle and access to the axillary space, and is reversed to examine the left axilla. If lymph nodes are palpable, their size and character (soft, firm, tender) should be noted, as well as whether they are single, multiple, or matted together. An assessment of whether the nodes are mobile or fixed should also be made. Based on this information, the physician can assess whether the nodes are clinically suspect. Many women have palpable axillary nodes secondary to hangnails, minor abrasions of the arm, or folliculitis of the axilla, and nodes that are small (<1 cm), soft, and mobile (especially if bilateral) should

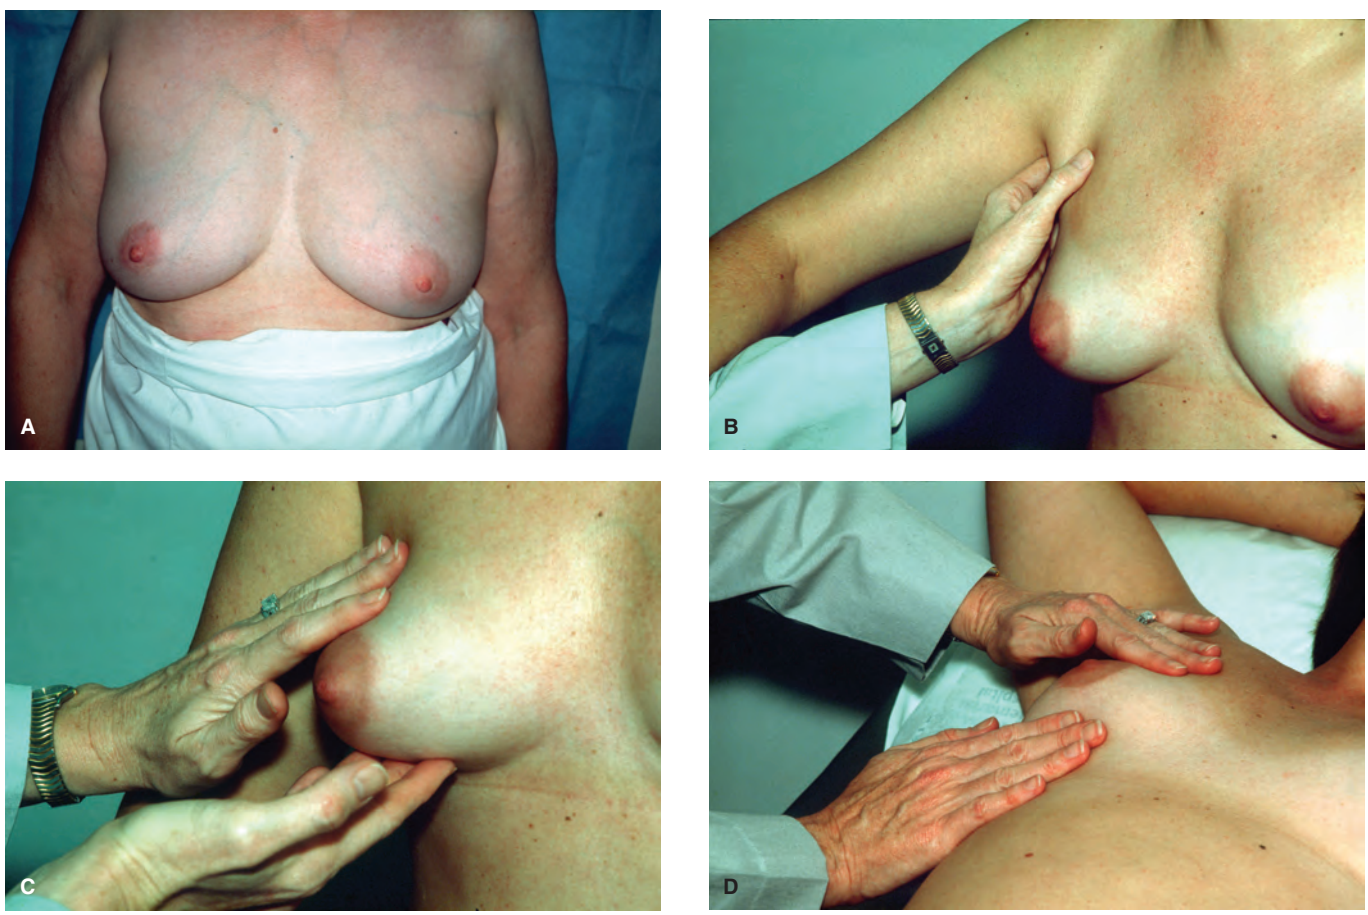

FIGURE 3-1 **Inspection of the patient in the upright position with arms relaxed (A).** Palpation of the axillary nodes **(B)**. The patient's ipsilateral arm is supported to relax the pectoral muscle. Palpation of the breast in the upright position **(C)**. Palpation of the breast in the supine position **(D)**. The breast is stabilized with one hand.

FIGURE 3-2 Marked breast asymmetry owing to a benign breast tumor.

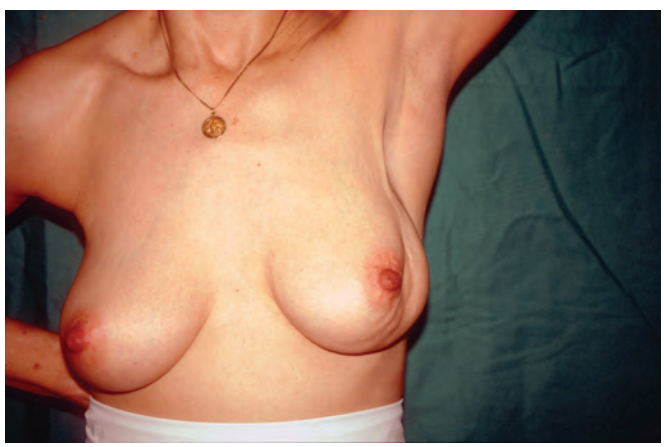

FIGURE 3-3 **Breast retraction caused by thrombophlebitis of the thoracoepigastric vein (Mondor's disease).** Seen is the characteristic pattern of lateral retraction superior to the nipple and crossing to the midline below the nipple.

FIGURE 3-4 Signs of locally advanced breast cancer that are apparent on inspection: breast asymmetry, erythema, and eczema owing to dermal involvement with tumor.

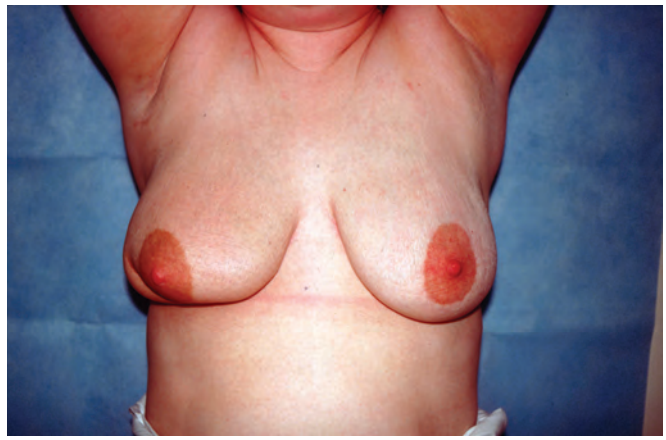

FIGURE 3-5 Retraction in the inferior right breast that is apparent only when the patient's arms are raised.

not be regarded with a high level of suspicion. In contrast, palpable supraclavicular adenopathy is uncommon and is an indication for further evaluation.

After the nodal evaluation is completed, palpation of the breasts should be done with the patient erect. Examination of the breast tissue in this position allows detection of lesions that might be obscured with the patient supine, such as those in the tail of the breast. The breast should be gently supported with one hand while examination is done with the flat portions of the fingers (Fig. 3-1C). Pinching breast tissue between two fingers always results in the perception of a mass and is a common error of inexperienced examiners and women attempting self-examination.

The breast examination is completed with the patient in the supine position and the ipsilateral arm raised above the head (Fig. 3-1D). In patients with extremely large breasts, it may be necessary to place a folded towel or a small pillow beneath the ipsilateral shoulder to elevate the breast, but this is not routinely necessary. The breast tissue is then systematically examined. Whether the examination is done using a radial search pattern or concentric circular pattern is unimportant, provided that the entire breast is examined. The examination should extend superiorly to the clavicle, inferiorly to the lower rib cage, medially to the sternal border, and laterally to the midaxillary line. Examination is done with one hand while the other hand stabilizes the breast. The degree of pressure needed to examine the breast tissue varies, but should not cause the patient discomfort.

One of the most difficult aspects of breast examination results from the nodular, irregular texture of normal breasts in premenopausal women. Normal breasts tend to be most nodular in the upper outer quadrants where the glandular tissue is concentrated, in the inframammary ridge area, and in the subareolar region. The characteristics that distinguish a dominant breast mass include the absence of other abnormalities of a similar character, density that differs from the surrounding breast tissue, and three dimensions. Generalized lumpiness is not a pathologic finding. Comparing the breasts is often helpful in determining whether a questionable area requires further evaluation. If the patient notices a mass that is not evident to the examiner, she should be asked to indicate the area of concern. The location of the perceived abnormality and the character of the breast tissue in the region should be described in the

medical record. If uncertainty remains regarding the significance of an area of nodular breast tissue in a premenopausal woman, a repeat examination at a different time during the menstrual cycle may clarify the issue. If a dominant mass is identified, it should be measured, and its location, mobility, and character should be described in the medical record. The identification of a dominant mass is an indication for further evaluation. The steps in the evaluation of a palpable mass are described in Chapter 5.

CHAPTER 4

Management of the Palpable Breast Mass

Richard J. Bleicher

CHAPTER CONTENTS

The breast mass is the most common symptom of women presenting to breast centers, accounting for more than half of the complaints. Although most are benign, the presence of a mass can cause considerable anxiety because of the concern for cancer. The most important task of the physician evaluating a breast mass is to exclude the presence of malignancy, and provide an accurate diagnosis.

The presence of a mass should never be dismissed because of young age, male gender, or a lack of risk factors such as a family history of cancer. Diagnostic delays of breast cancer are a common cause for litigation, and such claims are most frequently seen for non-Hispanic white women in their 40s who are premenopausal, married, have a history of fibrocystic change, and who are enrolled in an HMO. Although delays in the diagnosis of a breast cancer may need to be 8 months or longer to be detrimental, no factor should override an expeditious and thorough evaluation, which must provide an explanation that is concordant with the patient's history, physical examination, imaging, and pathologic findings.

HISTORY

A thorough history is the first step in the proper evaluation of any breast mass. Historical elements must, at bare minimum, include a proper breast history which includes current and prior symptoms, risk factors for cancer, and the patient's gynecologic and menstrual history. The etiology of previous masses should be detailed, and specifics about any current and prior breast problems must include the character, frequency, severity, and duration of the issue.

Breast evaluation nearly always includes diagnostic imaging. The complete history must therefore include details about mammograms, ultrasounds, and magnetic resonance imaging (MRI), including the dates, findings, and follow-up for abnormalities on these studies. Although annual mammographic screening is currently recommended for average-risk women aged 40 years and older, many patients are either not aware of this recommendation or choose not to follow it. MRI is also recommended as a screening modality only in women whose lifetime risk is ≥20% to 25% (1), but MRIs are still being used outside this setting.

Other symptoms such as palpable lymph nodes, breast pain, skin changes, nipple inversion, and the character of any discharge (including color, bilaterality, number of ducts involved, and spontaneity) should also be assessed, as these complete the history and may narrow the differential diagnosis. While a complete review of systems is often performed solely to satisfy reimbursement criteria, discussion of other organ systems may contribute substantially to understanding the current illness and to determine a patient's candidacy for certain treatments, especially if a mass is found to be malignant (Table 4-1).

Past medical history may also shed light on current findings, either clarifying an ongoing process, or suggesting something that can recur over a woman's lifetime. Mass-forming lesions are listed in Table 4-2. Certain

TABLE 4-1

Examples of Potential Contributions by the Review of Systems

System	*Contribution*
General	Fever suggests an inflammatory process.
Neurologic	Deficits suggest metastatic disease.
Pulmonary	Cough or compromise clarify operative candidacy.
Cardiac	Compromise may contraindicate operation or anthracycline chemotherapy.
	Inability to lie flat contraindicates whole-breast radiotherapy.
Integument	Nipple changes suggest Paget's disease.
	Breast erythema and edema suggest mastitis, or breast cancer that is locally advanced or inflammatory.
	Symptoms of active collagen vascular disease contraindicate radiotherapy.
Musculoskeletal	Back or bone pain suggest metastatic disease.
	Inability to abduct the arm over the head may contraindicate whole-breast radiotherapy.
Gynecologic	Active menses contraindicate aromatase inhibitor administration.
Hematologic	Frequent ecchymosis and bleeding suggest a need for preoperative evaluation.
	Deep venous thrombosis may contraindicate tamoxifen therapy.

benign entities may present as a recurring mass, such as pseudoangiomatous stromal hyperplasia, fibroadenomas, duct ectasia, mastitis, or abscess formation.

A discussion of past surgical history, including breast surgeries and needle biopsies, often reminds patients to mention prior benign conditions such as fibrocystic change, simple cysts, fibroadenomata, and fat necrosis. Knowledge of a patient's prior breast pathology is important for overall assessment and to help determine their risk of cancer. Often, patients are unfamiliar with specifics of their pathology and simply told that their prior biopsies are "benign," but this lay description may encompass atypical hyperplasia (a lesion requiring further evaluation if recently diagnosed), lobular carcinoma *in situ* (LCIS, a high-risk marker), or other entities that confer elevated risk. Pathology reports and/or slides may be of assistance to complete the evaluation if details are uncertain.

In men, the history should include additional questions about hepatic dysfunction, sexual dysfunction, and current medications to rule out potential causes of gynecomastia which can present as a central breast mass. Clearance of testosterone can be impaired by hepatic dysfunction, resulting in increased peripheral conversion of testosterone to estradiol and estrone, resulting in stimulation and hypertrophy of the breast tissue. Sexual dysfunction may indicate abnormal testosterone levels. Several medications such as H_2 blockers and phenytoin, and drugs such as marijuana have also been associated with gynecomastia. Acute hypertrophy may also be painful, and associated symptoms should therefore be elicited.

TABLE 4-2

Breast Lesions That May Present as a Palpable Abnormality

Abscesses	Idiopathic granulomatous mastitis
Adenopathy	Invasive carcinoma
Amyloidosis	Lactating adenomas
Duct ectasia	Lipomas
Ductal carcinoma *in situ*	Lymphadenopathy
Epidermal inclusion cysts	Mucoceles
Fat necrosis	Pseudoangiomatous stromal hyperplasia
Fibroadenomata	Sarcomas, including phyllodes tumors
Fibrocystic change	Sarcoidosis
Focal fibrosis	Seromas
Galactoceles	Simple and complex cysts
Gynecomastia	
Hamartomas	
Hematomas	

PHYSICAL EXAMINATION

A presenting symptom that is designated as a new breast "mass" can span everything from a barely perceptible thickened region of the breast to a large fungating cancer or severe adenopathy. Physical examination is important prior to any diagnostic imaging so that the study can be chosen and targeted appropriately, and so that the radiologist can best assist in evaluating what has been seen on examination. Normal breast tissue can demonstrate nodularity which is difficult to distinguish from an abnormal process, causing difficulty for patients as well as physicians. One study of 542 patients under 30 years of age referred for a breast mass found that among the 80% of masses detected by self-breast examination, only 53% were true masses, underscoring the difficulties seen in younger women (2). A second study by Morrow and colleagues evaluating 605 patients under 40 years of age also found that only 27% had an identifiable etiology other than fibrocystic change (3). Among masses felt to be true abnormalities on examination by the surgeon, 28% were false positives.

In some cases, the physician will not detect any abnormality on the clinical breast examination even after focusing on the area of concern. In this situation, the patient should be reassured about the absence of worrisome findings and the physician should recheck to ensure that a screening mammogram has been performed within the past year for the average-risk patient who is 40 years of age and older.
In other women, a subtle abnormality that remains ill-defined is detected. Such a lesion, sometimes referred to as a breast "thickening," is one whose extent cannot be clearly defined in three dimensions. These poorly defined areas of prominence may represent a true parenchymal abnormality, or in many cases may reflect the prominence of an underlying rib that elevates the normally nodular breast tissue superficial to it. If there is uncertainty about whether a finding represents a true mass, the clinician should compare it to the mirror-image location in the opposite breast, and if applicable, palpate that region of breast tissue again once it has been moved off the underlying bony prominence. If any level of concern remains, further imaging evaluation is required, and for those physicians whose experience evaluating breast

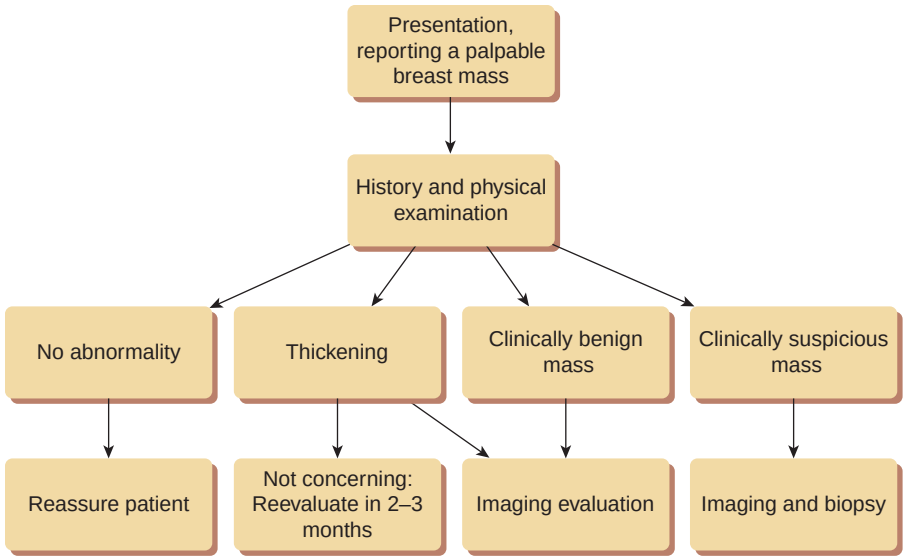

FIGURE 4-1 General schema for initial evaluation of a mass on examination based on its palpable characteristics. On presentation with the complaint of a mass, four findings can occur: (i) No abnormality noted, (ii) a thickening that may be either uncertain or equivocal, (iii) a clinically benign mass, or (iv) a clinically suspicious mass. These characteristics determine the next appropriate step in evaluation. When the characteristics of a thickening are equivocal or uncertain, imaging is indicated.

masses is limited, a follow-up examination in 2 to 3 months after the initial visit is appropriate.

When the examination is complete, the patient can be characterized as having four possible findings: (i) no abnormality present, (ii) a thickening without the characteristics of a dominant mass, (iii) a dominant mass with benign characteristics on palpation, or (iv) a dominant mass with malignant characteristics (Fig. 4-1).

Documentation

The documentation of any findings present on physical examination should be performed consistently and include a description of the superficial appearance of the breasts, including the skin, nipples, and areolae, as well as whether a mass or retractions can be detected by observation alone, or with movement. Exanthems, nipple inversion, and the character of any discharge should be noted.

When documenting the characteristics of a mass, detail is of the utmost importance as it assists in the formulation of a differential diagnosis. Many women have diffusely nodular breasts and therefore the size of the mass and its location should be detailed. At minimum, the mass should be described by indicating the breast in question and the quadrant of the mass, although it is helpful to specify more detail whenever possible by utilizing tangents emanating from the nipple as numbers on the clock when facing the patient. The mass is also described by its distance from the nipple along that tangent, such as "a 2-cm left breast mass at the 4:00 position, 6 cm from the nipple." Other characteristics that should be specified include whether its borders are smooth or irregular, details about its consistency (such as being soft, firm, or scirrhous), and whether it is discrete or an indistinct thickening. Characteristics associated with malignancy should also be noted. These include fixation to the chest wall or skin, skin satellite nodules, or edema of the skin (including *peau d'orange*) and ulceration. These characteristics are indicative of cancer and assist in its evaluation and staging.

The Axilla

The location of some masses may be difficult to distinguish between being present in the tail of the breast or the low axilla. Although normal lymph nodes are usually not palpable, small nonsuspicious lymph nodes may be detectable especially in thin individuals, often described as "shotty" nodes (the term originating from and referring to shot or pellets of lead and not "shoddy," as in poor quality). Lymph nodes may vary in size from several millimeters to several centimeters when abnormally enlarged, and tend to be discrete oblong nodules that have greater freedom of movement than breast parenchymal masses unless the nodes are fixed to one another or to the chest wall. These should also be described in detail, paying particular attention to the number of palpable nodes, fixation, laterality, and size.

The Male Breast

In men, there is usually less breast tissue, except in those with gynecomastia. Most of the breast tissue is located behind and concentric to the nipple–areola complex, and gynecomastia is typically described as disc-like or plate-like. Eccentricity in relation to the nipple and areola should be noted as such lesions are more likely to be malignant. Despite the smaller amount of breast tissue, the examination and documentation for the male breast remains similar to the female examination.

RADIOLOGIC EXAMINATION

Mammography

Mammogram remains the standard of care for the evaluation of breast abnormalities, and is necessary even when a mass very clearly seems malignant. When a palpable abnormality is found, a diagnostic mammogram is performed that consists of at least one view in addition to those taken in a screening study. A skin marker is placed over the palpable area of interest, and additional views are taken if deemed appropriate by the radiologist. Mammographic imaging may be sufficient if a suspicious mass is found, corresponding to the area in question. If nothing is seen on mammogram or if the mass appears to be benign, characterization by ultrasound is indicated, as mammograms typically miss approximately 10% to 25% of cancers detectable by physical examination regardless of tumor size (4), and they cannot differentiate solid from cystic abnormalities.

When possible, mammograms should be obtained prior to a biopsy of any mass because of the consequent mammographic changes that may occur. The two exceptions to this are in evaluating the pregnant and very young patient

(covered below). Hann et al. reviewed mammographic results immediately after stereotactic biopsy, and demonstrated that among 113 cases, 76% demonstrated changes due to the core biopsy, with 58 (51%) having a core biopsy–induced hematoma (5). There were 31 (27%) lesions where the visualized lesion size changed, and three cases (3%) where hematoma obscured the ability to see calcifications at the site.

Prior mammograms from outside facilities should be obtained for comparison prior to any intervention. Review of all imaging by all treating physicians is critical for correlation to the palpable abnormality. If a breast cancer is diagnosed histologically without the use of bilateral imaging, the clinician should ensure that a bilateral mammogram has been obtained within the past 6 months to rule out evident multicentric or contralateral disease requiring simultaneous intervention, even if no other palpable findings are present on examination.

The inability to see a palpable mass on mammogram should prompt an ultrasound, but the inability to see the lesion on either set of imaging does not mean that the lesion should be disregarded. If the lesion is discrete, biopsy should be performed. MRI is sometimes performed as an additional step to evaluate a mass that is mammographically occult, although MRI adds little because it is a poor substitute for the required pathologic diagnosis due to its lack of specificity. A palpable mass not seen on mammogram or ultrasound should undergo needle biopsy as the next step.

Mammography in Men

Although mammography in men may confirm that a mass is of low clinical suspicion or assist in cases where body habitus makes a patient's physical examination more difficult, it generally adds little to the workup of the palpable breast mass. The physical examination in males is particularly important, largely because of the smaller amount of breast tissue that allows a prominence of male breast cancers on examination and the low prevalence of benign breast masses other than gynecomastia. In a Mayo Clinic study evaluating mammograms performed on men, 196 were performed for breast masses and other symptomatic complaints. Among these, 1 benign-appearing mammogram among 203 missed a cancer (0.5%), but all three cancers in this series presented with a discrete palpable mass, 2 associated with overlying retractions and 1 with interval enlargement and lymphadenopathy (6). In a series of 104 male patients with cancer, Borgen et al. also reported that most patients presented with more than one symptom, including masses in 77, nipple retraction in 18, bloody discharge in 16, skin ulceration in 10, and others with Paget's disease, clinical inflammatory carcinoma, and fixed tumors (7). These series suggest that male cancers usually present with at least one suspicious physical examination finding, and while bilateral mammography may be considered in men once a cancer is suspected or diagnosed to rule out bilaterality, its role and benefit in the routine evaluation of the male breast mass has yet to be defined.

Ultrasound

Ultrasound enables directed characterization of an abnormality, but is not a screening study. Ultrasound is most commonly used to determine whether a breast mass is cystic or solid, and to characterize its appearance. Solid masses may appear benign or malignant, and cystic masses are characterized as simple or complex.

Cyst Evaluation

Cysts are most frequently seen between the ages of 40 and 49 years (8) but account for only 10% of masses in women younger than 40, and 25% of masses in women overall (3). More than half of all women who have cysts develop more one than during their lifetime, which may present synchronously or metachronously. Ultrasound can characterize them as simple, containing a smooth, thin wall that is well circumscribed with few internal echoes, or complex, which is defined as any cyst that doesn't meet these criteria, specifically having a significant solid component, internal echoes or a fluid-debris level, scalloped or irregular borders, and the presence of septations. Ultrasound is 98% to 100% accurate for characterization of benign cysts when strict criteria are utilized (9). Complex cysts have an overall rate of malignancy as low as 0.3%, but complex cystic lesions containing a significant solid component may be malignant in up to 23% of cases and so complex cysts are generally aspirated.

Cysts that appear simple on ultrasound have a negligible risk of cancer, and do not require aspiration unless the patient is symptomatic. In such cases, aspiration is performed to relieve the distension and discomfort and not for fluid evaluation. Complex cysts require aspiration to rule out bloody fluid which is suggestive of malignancy. Benign cyst fluid is typically green, yellow, or brown, and should not be sent for cytology because dead epithelial cells present in that fluid may appear atypical despite the low likelihood of malignancy. One study evaluating 6,747 cysts in 4,105 women with nonbloody aspiration found no cancers (8).

Ultrasound is often the only imaging study required for a clinically benign breast mass found in women younger than 35 years, because of the substantially lower risk of malignancy, and because breast density often precludes mammographic visualization in this age group. Despite this difficulty in younger women, bilateral mammograms remain standard and should still be obtained when breast cancer is diagnosed because of its potential to assess the presence of multicentric or bilateral disease. Digital mammography has demonstrated some benefit over analogue studies in younger women and those with dense breasts (10), but in those who are the most difficult to assess, MRI may be of assistance because it is not affected by breast density.

In the young woman, masses that are benign to palpation may undergo an attempt at aspiration prior to ultrasonographic imaging. Those with nonbloody benign cyst aspirate in whom the aspiration resolves the palpable abnormality may undergo observation. When planning to perform an aspiration, one must be cognizant that a traumatic aspiration can cause a bloody aspirate or potentially a hematoma, leading to further unnecessary workup and making ultrasound assessment more difficult. It is therefore important to attempt blind aspiration only in cases where the lesion is easily accessible by minimal manipulation and few needle passes.

For those in whom the cyst recurs, repeat aspiration is acceptable, although with multiple recurrences, a mammogram (because of the small increase in risk of malignancy) and ultrasound (to further evaluate the cyst) should be considered, and excision is an option primarily reserved for a suspicious lesion or when repeat aspirations are no longer desired by the patient.

Solid Mass Evaluation

The physical examination is important in combination with imaging to assess solid lesions. One of the more common solid abnormalities seen in young women are fibroadenomas (11), but these have also been found in women in their 40s and 50s (12). These masses are typically round or multilobulated, firm or "rubbery," nontender, and freely mobile within the breast parenchyma. The physical examination for diagnosis of the fibroadenoma is helpful, but not definitive, as demonstrated by one study evaluating women

under 35 years of age in whom a clinical diagnosis of a fibroadenoma was made. Although imaging and histologic evaluation in this subset was not specified, in the 77 women where the mass persisted, only 56 (72%) were confirmed histologically to be fibroadenomas by FNA (13).

Combining imaging and physical examination for evaluation of the palpable mass improves cancer detection over imaging alone. van Dam and colleagues found that in their series of 201 patients, ultrasound and mammogram each had respective sensitivities for cancer detection of 78% and 94% and specificities of 94% and 55% (14). When combining ultrasound, mammogram, and physical examination together, sensitivity increased to 97% for cancer detection, but with a decrease in specificity to only 49%. In the Sydney Breast Imaging Accuracy Study in which 240 women with, and 240 age-matched women without cancer were evaluated, ultrasound had a 76% sensitivity for cancer and an 88% specificity. Most notable was the significant sensitivity advantage that ultrasound had over mammography in women aged 45 and younger (85% vs. 72%), suggesting that ultrasound is a critical addition to mammography in the evaluation of breast lesions in young women (15).

Unfortunately, the common and benign fibroadenoma can be difficult to distinguish by imaging from the uncommon and malignant phyllodes tumors. Bode et al. reviewed ultrasonography and core biopsy with subsequent excision performed on 57 fibroadenomas and 12 phyllodes tumors, finding that 42% of the phyllodes tumors were initially felt to be benign on ultrasound, while 46% of the fibroadenomas were indeterminate or suspicious (16). This underscores the need for the triple test (see below), which is standard even when imaging suggests a benign solid mass (Fig. 4-2).

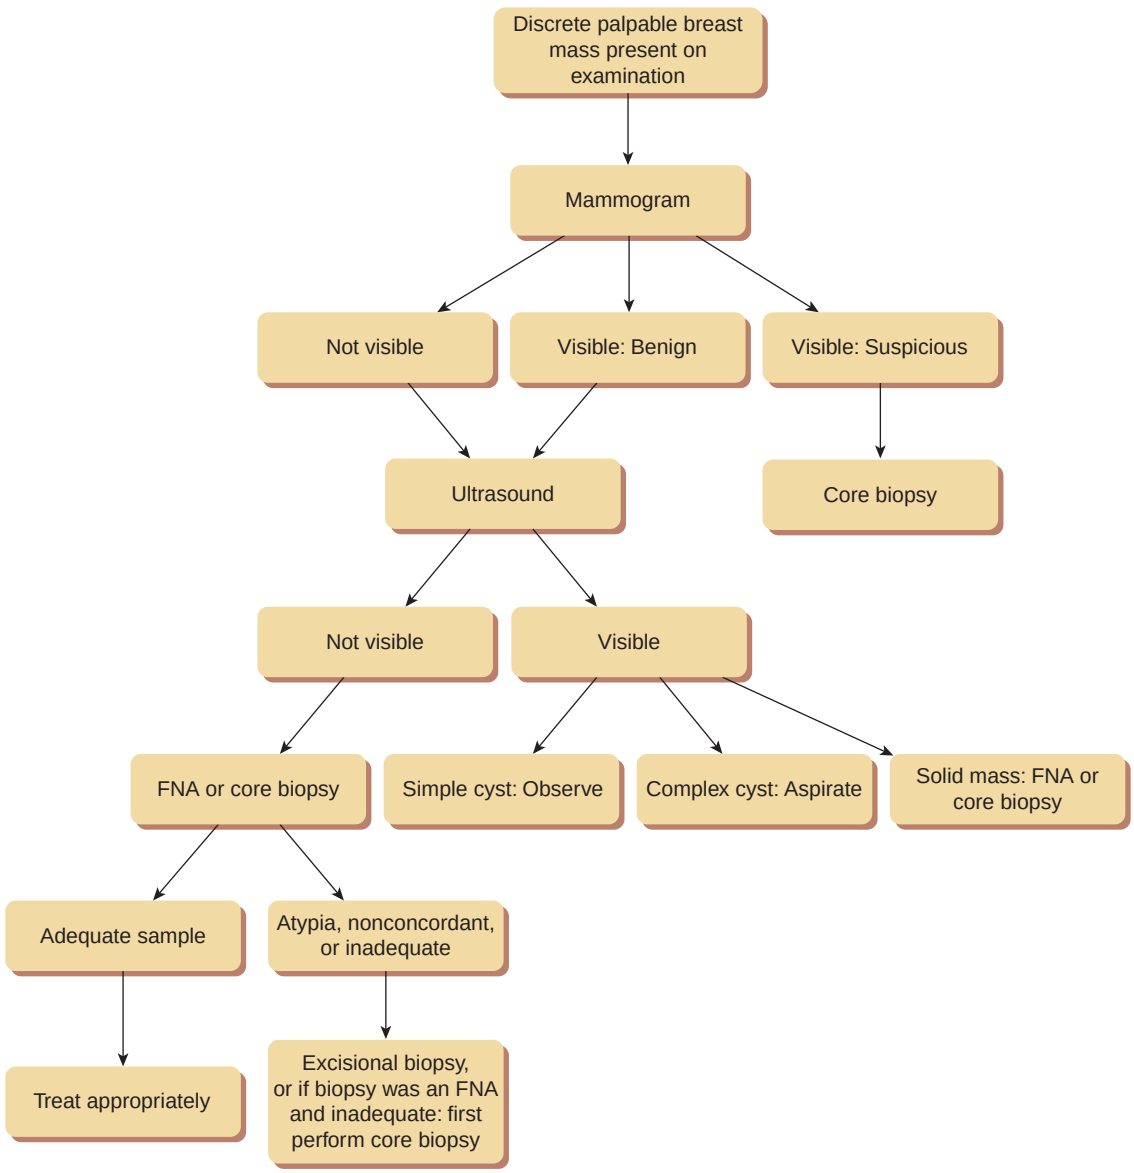

FIGURE 4-2 **Specific schema for evaluation of a discrete mass on examination.** Evaluation workflow, including imaging and tissue diagnosis, based on the presence of a discrete mass on examination. If a mass is found to be clinically suspicious on examination, imaging should still be performed, but in such as case a tissue diagnosis is indicated, regardless of the imaging findings.

Magnetic Resonance Imaging

There are few indications for MRI in the workup of breast masses. MRI is best suited for settings where standard imaging techniques are insufficient, or where a patient's elevated breast cancer risk outweighs the false-positives, costs, and disadvantages of the modality. The absence of a lesion noted on MRI does not negate the presence of a concerning mass on physical examination. MRI has an 85% negative predictive value for cancer in palpable masses containing calcifications, which drops to less than 80% when no calcifications are present. MRI is highly sensitive, but also nonspecific. One study of 1,909 women with a significant familial risk of cancer demonstrated a threefold increase in the number of unnecessary biopsies because of the MRIs performed (17).

PATHOLOGIC EXAMINATION

Triple-Test Evaluation

Masses that are found to be solid on imaging require triple-test evaluation which refers to physical examination, radiologic examination, and needle biopsy performed by core or fine-needle aspiration (FNA). The triple test requires concordance between the three aspects of evaluation and is not confirmatory if a mammogram does not visualize the lesion or if an FNA contains insufficient cells for diagnosis. The latter case mandates core needle biopsy for completion of the triple-test evaluation without surgery.

The triple test is performed even in cases where masses are considered benign on imaging because some malignant lesions can have a benign appearance. In one series of 191 patients, Steinberg et al. found the sensitivity and specificity of triple test to be 95.5% and 100%, respectively (18). In a smaller series of 46 lesions in 43 patients, concordance between the three modalities provided a positive predictive value and specificity of 100%, while nonconcordance dropped the positive predictive value to 64% (19). The triple test also saved an average of $1,412 per case in comparison with open biopsy, demonstrating that it provides accurate diagnostic results and is cost-effective, despite the use of both imaging and pathologic evaluation. In one of the largest series evaluating the combination, benign triple tests in 2,184 patients demonstrated only 7 (0.32%) with carcinoma on follow-up (20).

Postbiopsy Follow-Up

Although the accuracy of the triple test is high, benign concordant results do not obviate further surveillance of a palpable mass. Serial examinations and imaging at 6-month intervals for 1 to 2 years are often recommended to ensure stability, and growth should prompt surgical excision, especially in older women where benign masses are less frequently seen. Even fibroadenomas undergoing needle biopsy should be followed as those that are monoclonal have been reported on very rare occasions to transform into or recur as phyllodes tumors. There is no consensus regarding a threshold for excision when growth of a lesion occurs, although one series noted that 20% growth on ultrasound over 6 months was the 95th percentile in women under 50 and the 90th percentile in those 50 and older (21). They found that all masses excised with slower growth were benign, and recommended that a 6-month growth rate of 20% become the threshold above which excision should be performed. This threshold has not been universally adopted, however, and smaller growth rates may prompt excision as there are no data relating outcome to growth rates of masses initially diagnosed as benign.

The triple test has been found to be the most accurate combination of modalities, but anxiety over a palpable mass remains an indication for surgical excision once the relevant literature and data have been disclosed to the patient. Prior to performing a core biopsy to complete the triple test there should be a discussion with the patient. The triple test implies observation if the biopsy is concordant and benign, and the consent process should clarify that the patient is comfortable with leaving the mass *in situ*.

Fine-Needle Aspiration

FNA involves the use of a handheld syringe and needle to percutaneously aspirate a tumor mass in order to obtain cytology for evaluation. This was first described in detail by Martin and Ellis in 1930, and is most commonly employed for palpable breast lesions that do not require imaging in order to target the lesion. FNA has been established as a variably accurate method of diagnosis and clinicians should consequently perform validation of their own results. In a large meta-analysis of 29 studies comprising 31,340 aspirations, the sensitivity of FNA varied from 65% to 98% and specificity ranged between 34% and 100% (22).

FNA has the advantages of being easily performed with readily available equipment, requiring only a syringe and an appropriately sized needle. Its biggest limitations are that insufficient material may make proper diagnosis difficult, and FNA usually cannot rule out the presence of an invasive component for the uncommon mass that is pure DCIS (ductal carcinoma *in situ;* see below). It also does not capture histologic architecture making subtyping difficult and it is inaccurate for some masses such as hamartomas.

Core Needle Biopsy

Core needle biopsy is associated with slightly greater discomfort and higher cost, but provides more tissue than FNA and provides histologic architecture to better classify pathologic subtype. It is less morbid than excisional biopsy, and even in early series comparing core needle to excisional biopsy, the results were identical in 90% of lesions. In the case of malignancy, the presence of invasion can be more easily assessed with core biopsy than FNA. Westenend and colleagues (23) performed both FNA and core needle biopsy in 286 breast lesions, of which 232 were palpable masses. FNA and core biopsy demonstrated no statistical differences in either sensitivity (92% and 88%, respectively), overall positive predictive value (100% and 99%, respectively), or the number of inadequate specimens (7% for both). The diagnostic differences were present in their specificity, which was higher at 90% for core biopsy (as vs. 82% for FNA), and for the positive predictive value of suspicious lesions (100% vs. 78%), and atypia (80% vs. 18%). In a multi-institutional study by Parker et al., among 1,363 lesions undergoing core and excisional biopsy under image guidance, only 15 (1.1%) false-negative core biopsies occurred, of which 12 were performed using stereotaxis, and 3 using ultrasound guidance (24). Although this study was performed for lesions detected by imaging, it underscores the value of utilizing imaging with core biopsy for those areas of thickening that are equivocal on examination. Core biopsy remains the current standard of care for evaluation of masses of the breast.

Incisional Biopsy

Incisional biopsy is very rarely performed. This method of tissue sampling refers to the intentional surgical excision of only a portion of a mass. Palpable lesions requiring biopsy are typically removed by excising the entire lesion (see below). When a mass cannot be excised *in toto*

(such as a large fungating cancer), a core biopsy or FNA is nearly always the preferred method of diagnosis, thereby avoiding the associated morbidities, including operative and anesthesia risks. Markers such as estrogen and progesterone receptors as well as HER2/neu overexpression can be obtained from core biopsy, also eliminating any need for incisional or excisional biopsy.

Excisional Biopsy

The surgical excision of a lesion in the breast with the intent to remove it entirely is referred to as an excisional biopsy. In 2013, excisional biopsy is no longer the standard of care for the initial diagnosis of palpable breast masses, except where needle biopsy is not feasible for technical reasons, is nonconcordant with imaging or exam, is nondiagnostic, or demonstrates a high-risk lesion such as atypia.

Unfortunately, excisional biopsies are all too often performed without specimen orientation for the pathologist. For those excisional biopsies that demonstrate a malignancy, lack of orientation may necessitate complete reexcision of the entire cavity for even a single positive margin. This results in needless resection of tissue, especially as orientation of excisional biopsy specimens is simple to perform. It is also inadvisable to perform intraoperative frozen section of an excisional biopsy because of the concerns about the accuracy of the analysis (25). Intraoperative assessment of an excised mass has few advantages other than to satisfy immediate physician and patient curiosity, and no change in definitive surgery (such as conversion from breast conservation to mastectomy) should ever be performed based on an initial result and without an in-depth discussion about treatment options. The specific schema for imaging and treatment of a discrete mass is shown in Figure 4-2.

SPECIFIC CLINICAL SETTINGS

The Young Patient

Assessment of the young female patient with a breast mass poses a challenge because of the difficulties in imaging dense breast tissue, because of the greater nodularity seen in those 30 and under whose breasts contain a lower proportion of fat, and because cosmetic and sexuality concerns about treatment tend to be greater in women of younger age. Malignancy is rare in women under 30, but complete evaluation of all masses is still required, including a tissue diagnosis for those masses found to be solid. In a large series of 542 women under 30 who presented with the complaint of a breast mass (2), only 2% of cases were demonstrated to be malignant on biopsy, and among the benign lesions, the most common diagnosis was fibroadenoma, accounting for 72% of cases, with fibrocystic change next in frequency at 8%.

The evaluation and treatment of young women should proceed similarly to older women, although with their increased breast density ultrasound is the primary modality used to characterize a mass. If ultrasound demonstrates that the lesion is solid, core biopsy or FNA is indicated, and if malignancy is found, bilateral mammographic evaluation should then be performed. Likewise, if a lesion that is discrete is not seen on ultrasound, mammographic evaluation may characterize the lesion, but needle biopsy (or excision if not possible) should be performed as with any other age group. In the younger woman in whom a nonsuspicious lesion is less well defined, reexamination within 2 to 3 months at a different point during the menstrual cycle may demonstrate resolution of the lesion, implying fibrocystic change. If any question remains, needle biopsy should be performed, but if the results are felt to be non concordant, excision may be considered.

Care must be taken when excising lesions in younger adolescents. In addition to considering the cosmetic outcome of the scar that will be lifelong for the patient, the central subareolar breast bud can be mistaken for a new breast mass. This subareolar tissue should be spared because this is the origin of the ducts and deposition of fat that becomes the mature breast in the adult. Surgical damage of the breast bud has been reported to cause breast hypoplasia and significant disfigurement.

Young male patients referred for breast masses will predominantly be adolescents found to have gynecomastia. Welch et al. reviewed all male breast patients at a large tertiary pediatric hospital that were referred for ultrasound. The patients were between 1 month and 18 years, and 72% of the 25 patients, between 7 and 18 years of age, were found to have gynecomastia, 13 of which were unilateral and three bilateral but asymmetric (26). In most cases, adolescent male gynecomastia can be observed as it will resolve in adulthood.

The Pregnant Patient

The pregnant patient poses a dilemma when presenting with a breast mass. During pregnancy, the proliferative effect of circulating hormones causes the breasts to become increasingly nodular and engorged, making the physical examination extremely difficult. A nodule found prior to pregnancy or early in its course should be evaluated promptly and not observed. This is because the increasing proliferation of glandular elements and consequent nodularity during pregnancy and lactation can obscure an initial finding. Ultrasound is the imaging modality of choice, as this will determine whether a mass represents a simple cyst, a galactocele, an abscess, or a benign lymph node. The sensitivity of mammography and ultrasound for pregnancy associated breast cancer are 78% and 100%, respectively.

Even with shielding, mammography is incorrectly thought by many to be contraindicated during pregnancy, even by physicians, despite its delivery of only 0.5 mGy to the fetus in comparison to the 1.0 mGy of normal background radiation that the fetus receives over the 9 months of pregnancy. Although MRI is safe, the gadolinium used as the contrast agent is contraindicated, leaving MRI without contrast as an option that is less optimal than ultrasound.

If the mass is solid, needle biopsy should be attempted prior to mammogram since mammography will not provide a definitive diagnosis of a solid mass. Core biopsy in the pregnant patient prior to mammography will also reduce unnecessary fetal irradiation, even though the consequent risk is low. If malignancy is diagnosed, bilateral mammography with fetal shielding is then appropriate.

Core biopsy is the best option for tissue sampling in the pregnant patient. Fine-needle aspiration is more difficult to perform and is associated with a higher risk of false-positives during pregnancy due to the proliferative changes that occur within the breast. Although core biopsy during pregnancy has the added risk of milk fistula, this should not deter or raise the threshold for its use in the evaluation of a palpable mass. In theory, core biopsy should have a lower risk of milk fistula than excisional biopsy, but this has not been proven. Excisional biopsy is not appropriate during pregnancy when core biopsy is an option because of its unnecessary morbidity and cost.

Ductal Carcinoma *In Situ*

As with any malignancy, ductal carcinoma *in situ* (DCIS) can be found in association with a mass, although it most commonly now presents as calcifications on mammogram without abnormal examination findings. Comedo DCIS is generally high grade and more likely to contain invasion which is why it is the only subtype likely to present with a mass, and why it accounted for the majority of DCIS cases detected before mammography was routinely used.

Core needle biopsy is the current standard of care for the diagnosis of breast masses; however, 10% to 20% of lesions diagnosed as DCIS by core needle biopsy are found to be understaged on final excision, demonstrating invasion. Meijnen et al. evaluated 172 DCIS lesions diagnosed by core biopsy, and found that a mass on examination or a mass on imaging were the two most significant independent risk factors for the presence of invasion (27). It remains unclear whether DCIS that presents as a mass in men also has a higher risk of invasion because the series have been too small and too few to make generalizations.

The Patient with a Personal History of Cancer

The patient who has a history of breast cancer has undergone either breast-conserving therapy or mastectomy. In those women who have had BCT, surgical scarring and radiation-induced changes may make evaluation more difficult. Mammography after BCT is less sensitive overall and specifically in the quadrant of the prior surgery, which may explain why 45% of recurrences after BCT can be detected only by palpation. In the patient who has had a mastectomy without reconstruction, abnormal nodularity on examination is most commonly found in the scar or skin and should immediately undergo biopsy, as imaging is likely to add little to the evaluation. In those having had a mastectomy and reconstruction, ultrasound or MRI may assist in characterizing recurrences. Imaging may be of benefit in this setting so that adequate surgical planning can help minimize any risk to the reconstruction.

OTHER MASS-FORMING LESIONS

Hematoma

Hematomas of the breast are most commonly reported as a result of iatrogenic intervention, either in evaluation of a breast lesion or subsequent to its treatment, although spontaneous hematomas have been reported. They have also been rarely reported to identically mimic carcinoma on presentation. Physicians most likely encounter breast hematomas on examination after core biopsy, where it may be difficult to determine whether a lesion is truly palpable or whether a thickening in that location is due to a small amount of bleeding. Core needle biopsy can result in hematoma, and although significant bleeding is uncommon, a malignancy may be obscured in extreme examples (5). Postbiopsy hematoma rates range widely from less than 1% (24) to 51% (5). When any question about a lesion's palpability exists, needle localization should be planned in case the thickened area is solely due to hematoma and resolves by the date of surgery, leaving a nonconcordant mass.

The appropriate management of a hematoma varies with its presentation. A palpable mass may be present with or without ecchymosis, which can sometimes extend laterally to the chest wall, below the inframammary fold and over to the opposite breast. In most cases, observation with use of supportive garments and non-NSAID analgesics is sufficient, although hematomas in the postoperative period require a low threshold for reexploration. Expanding hematomas should be explored and evacuated with the intent to achieve hemostasis.

Seroma

Seromas are localized regions of serous fluid that usually occur after iatrogenic intervention. In some cases, ultrasound may be required to differentiate a seroma from a solid nodule, depending on the degree of distension of the surrounding tissue. The breast contains an extensive lymphatic network, and any operative site may develop a seroma. While these are advantageous at local breast excision sites by maintaining breast contour, large seromas may create a palpable mass. When present after mastectomy, they may impede flap healing by interfering with skin adherence to the chest wall. Finally, a postreconstruction seroma can create a palpable mass that is most easily evaluated with ultrasound.

There are few data on what predisposes women undergoing BCT to develop significant breast seromas. Most investigations have focused on those that develop after axillary dissection, but factors that are known to contribute to seroma formation generally include the use of cautery, the extent of the dissection and amount of disease present, primary tumor size, patient weight, the use of chemotherapy, and the type of surgery performed. Seromas are usually of little consequence and confer few symptoms, but when they become bothersome to the patient they may be ameliorated with a small number of repeated aspirations.

Fat Necrosis

Fat necrosis is a phenomenon that is occasionally seen in the breast due to its high fat content, and is significantly correlated with trauma or surgical intervention. Fat necrosis results from lipase-induced aseptic saponification of adipose tissue that can create mass lesions that are tough to distinguish from carcinoma. Oil or lipid cysts are one manifestation of fat necrosis that can be seen on imaging and are composed of a confined pool of neutral lipid surrounded by a membrane. This pathognomonic finding is not present in all cases, but when evident demonstrates a characteristic lucent center with a water-density rim that may calcify with time. Such a lesion does not require further evaluation, especially with a history of trauma. Unfortunately, many cases of fat necrosis do not present in this fashion and may contain calcifications or fibrosis, which can appear as a spiculated mass and have a scirrhous feel on examination. Such a presentation makes the diagnosis uncertain and necessitates core or excisional biopsy for diagnosis. On diagnosis, no treatment is required.

Hamartomas

Hamartomas, previously known as fibroadenolipomas or lipofibroadenomas because of their components, are benign lesions that are often palpable as a mass and can grow to extremely large sizes, pushing the breast tissue outward as they grow rather than replacing it. Although they have been reported in men, they are most commonly seen in women, and traditionally appear mammographically as a fibrofatty mass, but may have a variable mammographic appearance. Ultrasound appearance is usually solid, but cystic regions may be present in 24% of cases. While most hamartomas have a benign radiographic appearance, biopsy is recommended as with other solid masses to confirm the diagnosis.

Neither FNA nor core biopsy can accurately make the diagnosis of a hamartoma without correlation to imaging findings because of the variety of elements required to make a diagnosis. FNA results, at best, in a diagnosis of a nonspecified benign lesion (28) because the cytologic features overlap with other benign disease. Core biopsy also often yields an insufficient variety of tissue types for a diagnosis, and surgical excision may be required when imaging correlation is not performed in order to reach a definitive diagnosis. Hamartomas have on occasion been seen in association with atypia, as well as *in situ* and invasive malignancies, but correlation to these more concerning pathologic entities has not been found consistently enough to universally recommend surgical excision.

If the diagnosis of hamartoma is entertained on evaluation of a breast mass, mammograms should be obtained and core biopsy attempted, while providing the pathologist with the imaging and clinical findings. Surgical excision may be required for definitive diagnosis, and clear margins should be sought because of the possibility of recurrence. As with any large solid mass, discomfort or anxiety regarding the lesion is an indication for excision, as is enlargement on subsequent follow-up.

CHAPTER 5

Management of Disorders of the Ductal System and Infections

J. Michael Dixon and Nigel J. Bundred

CHAPTER CONTENTS

Disorders of the ductal system can present as nipple discharge, nipple inversion, a breast mass, or periareolar infection.

NIPPLE DISCHARGE

Nipple discharge accounts for approximately 5% of referrals to breast clinics. It is a frightening symptom because of the fear of breast cancer. Approximately 95% of women presenting to the hospital with nipple discharge have a benign cause for the discharge. Discharge associated with a significant underlying pathologic process is spontaneous and more likely to be unilateral, arise from a single duct, be persistent (defined as more than twice per week), be troublesome, and be bloodstained or contain blood on testing. One study of 416 women with discharge identified bloody nipple discharge (odds ratio 3.7) and spontaneous discharge (odds ratio 3.2) as significant factors associated with a causative lesion (1).

For this reason, the physician must establish whether the discharge is spontaneous or induced, whether it arises from a single or from multiple ducts, and whether it is from one or both breasts. The characteristics of the discharge also need to be defined: whether it is serous, serosanguineous, bloody, clear, milky, green, or blue-black. The frequency of discharge and the amount of fluid also need to be assessed; this assessment is important for milky discharge, as galactorrhea should be diagnosed only if the milky discharge is spontaneous, copious in amount, and arises from multiple ducts of both breasts.

Investigations

Assessment should include the performance of a complete physical examination (Chapter 4) to identify the presence or absence of a breast mass. During the examination, firm pressure should be applied around the areola as pressure over a dilated duct will often produce the discharge; this is helpful in defining where an incision should be made for any subsequent surgery. The nipple is squeezed with firm digital pressure and, if fluid is expressed, the site and character of the discharge are recorded. Testing the discharge for hemoglobin determines whether blood is present. Bloody discharge increases the risks of cancer being the cause for the discharge with an odds ratio (OR) 2.27, 95% confidence intervals (CI) 1.32–3.89, $p < .001$. In a recent meta-analysis, up to 20% of patients who had a bloodstained discharge or who had a discharge containing moderate or large amounts of blood had an underlying malignancy (2). The absence of blood in nipple discharge is not an absolute indication that the discharge is not related to an underlying malignancy; in one series of 108 patients the sensitivity of hemoccult testing was only 50% (3). If the discharge is serous or colored but spontaneous and persistent, then malignancy still needs to be excluded. Age is said to be an important predictor of malignancy; in one series, 3% of patients younger than 40 years of age, 10% of patients between ages 40 and 60 years, and 32% of patients older than 60 years who presented with nipple discharge as their only symptom were found to have cancer. Cytology of nipple discharge is of little value in determining whether duct excision should be performed. In a recent study of 618 patients who had nipple discharge cytology, the sensitivity and specificity of cytology were 16.7% and 66.1%, respectively. In comparison, the sensitivity for macroscopically bloodstained discharge was 60.6% with a specificity at 53.6% (4). Although some studies have reported better results with cytology, the variability of reported results is such that it cannot be relied on in the routine assessment of nipple discharge.

Two related techniques have emerged: ductal lavage, in which fluid-yielding nipple ducts are cannulated at their

orifices and lavaged with saline while the breast is intermittently massaged (Chapter 20); and ductoscopy, in which discharging or fluid-yielding duct orifices are dilated and intubated with a microendoscope, and the lumen directly visualized. Both techniques have significant potential in terms of allowing repeated sampling of ductal epithelium over time and diagnosing the cause of nipple discharge (5). To learn ductoscopy takes longer than 6 months to overcome technical problems. Fiberoptic ductoscopy applied to 415 patients with nipple discharge was successful in identifying a lesion in 166 patients (40%) (6). Of these 166, 11 were subsequently shown to have ductal carcinoma *in situ* (DCIS); ductoscopy was suspicious in 8, a sensitivity of 73%, with a specificity of 99% and a positive predictive value of 80% (6). DCIS in this series tended to affect more peripheral ducts compared with papillomas. Numerous other small series have evaluated ductoscopy in nipple discharge (7,8). The sensitivity for malignancy in these other series varies from 81% to 100% (8). Ductoscopy appears of particular value for directing duct excision (7) and for detecting deeper lesions that can be missed by blind central duct excision (8). Surgical resection of lesions visualized on ductoscopy is facilitated by transillumination of the skin overlying the lesion. Lesions visualized by ductoscopy can be sampled; in one report, 38 of 46 women with biopsy-proved papillomas were observed for 2 years with no case of missed cancer becoming evident (8). Newer biopsy devices using vacuum assistance are now available for diagnostic assessment and can be ductoscope or sonograph guided.

Ductal lavage increases cell yield approximately 100 times compared with analysis of discharge alone, averaging 5,000 cells per washed duct in one series (6). The sensitivity for cytology obtained by ductal lavage in this series was 64%, with a 100% positive predictive value. Other studies have reported lower sensitivities in the range of 50%, but a high specificity and a high overall accuracy rate (5). Both ductoscopy and ductal lavage remain investigative techniques, and the evidence that they are valuable in the detection of significant breast disease is limited.

Imaging of the ductal tree by ductography or galactography can identify intraductal lesions. Although this investigation has only a 60% sensitivity for malignancy, a filling defect or duct cutoff has a high positive predictive value for the presence of either a papilloma or a carcinoma (9). In one report, ductography-directed excisions were significantly more likely than central duct excisions to identify a specific underlying lesion (10). Ductography in one large study was, however, a poor predictor of underlying pathology and could not exclude malignancy (11). The value of ductography is that like ductoscopy, it can allow identification of the site of any lesion in younger women, allowing localization and excision of the causative lesion while retaining the ability to lactate.

Mammography has a high overall sensitivity for breast cancer, but not all malignant lesions that cause nipple discharge are visible mammographically and most patients with nipple discharge have negative mammograms (Chapter 12). In one series, the sensitivity of mammography for malignancy in patients with nipple discharge was only 57% with a positive predictive value of 16.7% and a negative predictive value of 91.4% (3). Nonetheless, mammography should be performed in women of appropriate age, because if a lesion is visualized it may help establish the cause of the discharge. Ultrasound has a low sensitivity for malignancy in patients with nipple discharge but is a valuable method for localizing intraductal abnormalities, especially papillomatous lesions, in patients with no other clinical or radiologic findings (12). Any lesion visualized can be biopsied by core biopsy or excised using a vacuum-assisted large core biopsy device. (10,13) Patients with a visible lesion on ultrasonography appear significantly more likely to have malignancy than those women with a negative scan (10).

Controversy surrounds the need to excise lesions seen on breast imaging and diagnosed as papillomas on core biopsy. Although it has been traditional to recommend excision of core biopsy–proven papillary lesions, imaging follow-up rather than excision may be safe providing there is imaging–histopathologic correlation and that all atypical and discordant lesions are excised (14). The use of vacuum-assisted biopsy (VAB) to remove papillomas can avoid the need for surgical excision. In large papillomas, magnetic resonance imaging (MRI) may aid assessment of the presence of malignancy, which is more likely if an enhancing rim is seen. The use of MRI to evaluate the ductal tree is gaining interest but should not be part of the standard investigation of nipple discharge. In one series, MRI was performed in 52 patients with nipple discharge and had a positive predictive value of 56% with a negative predictive value of 87% (11) (Chapter 14).

If clinical examination demonstrates a mass lesion or mammography or ultrasonography identifies an abnormality suspicious of malignancy, then core biopsy of the lesion should be performed and the lesion managed appropriately (Section VII: Management of Primary Invasive Breast Cancer). If no abnormality is found on clinical or mammographic examination, patients are treated according to whether the discharge is from a single duct or multiple ducts (Fig. 5-1). Surgery is indicated in cases of spontaneous discharge from a single duct that is confirmed on clinical examination and has one or more of the following characteristics:

- Is bloodstained or contains moderate or large amounts of blood on testing
- Is persistent and stains clothes (occurs on at least two occasions per week)
- Is associated with a mass
- Is a new development in a woman older than 50 years of age, but is not thick or cheesy

Discharge from multiple ducts normally requires surgery only when it causes distressing symptoms, such as persistent staining of clothes. Some breast units adopt an age-related policy: Patients younger than age 30 years who have serous, serosanguineous, or watery discharge are observed, with microdochectomy reserved for cases in which discharge persists at review; patients older than 45 years of age are treated by a formal excision of the major duct system on the affected side; patients between 30 and 45 years of age are deemed suitable for either approach. The current evidence is that total duct excision is more effective than microdochectomy at establishing a specific diagnosis and has a lower chance of missing any underlying malignancy in women more than 40 years of age (15). Today, many units incorporate ductography and ductoscopy into their management protocols, particularly in younger women (Fig. 5-1). The problem is how to treat a patient with nipple discharge in whom imaging, including ductography or ductoscopy and ductal lavage, fails to identify any serious lesion. Some argue that as discharge from malignant disease is more likely to be bloodstained, there is no place for conservative management of bloodstained discharge and that all patients with bloodstained discharge should undergo duct excision unless investigation has identified a specific benign cause (16). Others argue that in selected patients, who have no clinical

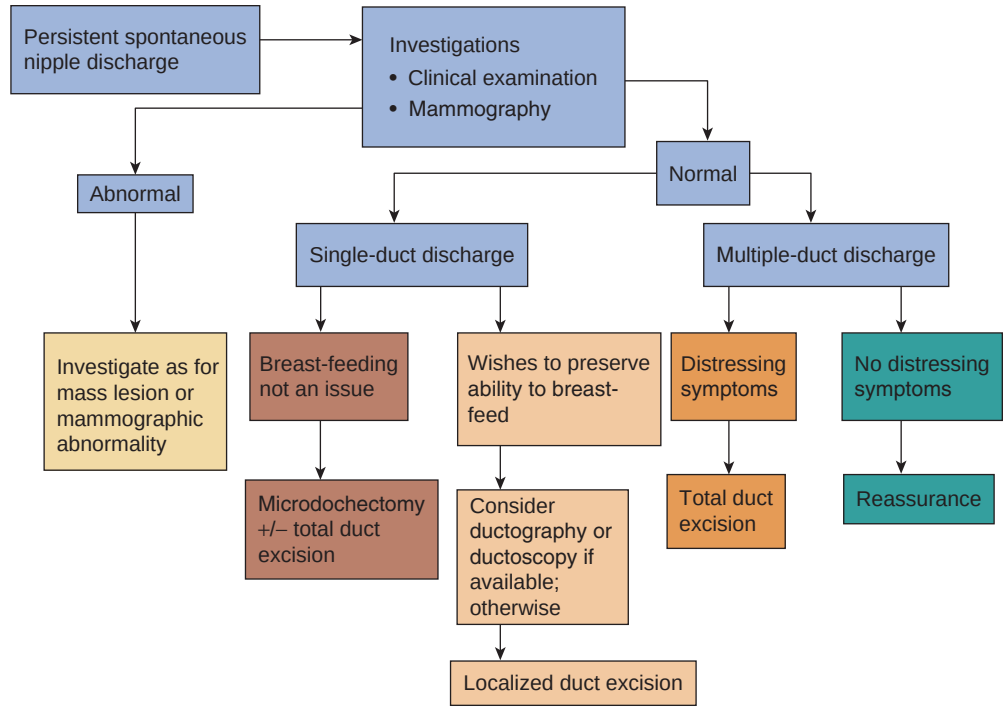

FIGURE 5-1 Investigation of nipple discharge.

or imaging abnormality, short-term observation with repeat evaluation is reasonable (17). A period of observation, particularly in younger women (≤35 years of age), is appropriate if the history of discharge is short but if spontaneous discharge persists (≥2 per week) at review 4 to 6 weeks later and the discharge can be expressed from a single duct on examination, then surgical excision is indicated to establish the cause of the discharge.

Differential Diagnosis of Nipple Discharge

Physiologic Causes

In two-thirds of nonlactating women, a small quantity of fluid can be expressed from the ducts of the nipple if the nipple is cleaned, the breast massaged, and pressure applied. This fluid is physiologic secretion and varies in color from white to yellow to green to brown to blue-black; it is thought to represent apocrine secretion, as the breast is a modified apocrine gland. This physiologic secretion usually emanates from multiple ducts, and the discharge from each duct can vary in color. It is commonly found after pregnancy and is often noticed after a warm bath or after nipple manipulation. The discharge is not usually spontaneous or bloodstained and no specific treatment is required.

Intraductal Papilloma

A true intraductal papilloma develops in one of the major subareolar ducts and is the most common lesion causing a serous or bloody nipple discharge. In approximately half of women with papillomas, the discharge is bloody; in the other half, it is serous (9). Papillomas should be differentiated from papillary hyperplasia, which affects the terminal duct lobular unit and can also cause nipple discharge. Central papillomas consist of epithelium covering arborescent fronds of fibrovascular stroma attached to the wall of the duct by a stalk (Fig. 5-2). The covering epithelium has a two-cell population, with a cuboidal or columnar cell lining covering an underlying layer of myoepithelial cells. A mass may be felt on examination in as many as one-third of cases. Occasionally, the papilloma is so close to the nipple that it can be seen in the orifice of the duct at the nipple. The treatment of choice is microdochectomy. A solitary papilloma is not thought to be a premalignant lesion and is considered by some to be an aberration rather than a true disease process. Papillary lesions can be difficult to characterize on core biopsies.

Multiple Intraductal Papillomas

In approximately 10% of patients with intraductal papillomas, multiple lesions are found; usually, two or three occur, often in the same duct. The term *multiple intraductal papilloma syndrome* is reserved for the rare and distinctive group of patients in whom one duct system contains five or more large and often palpable papillomas with a peripheral distribution. Nipple discharge is less common than in

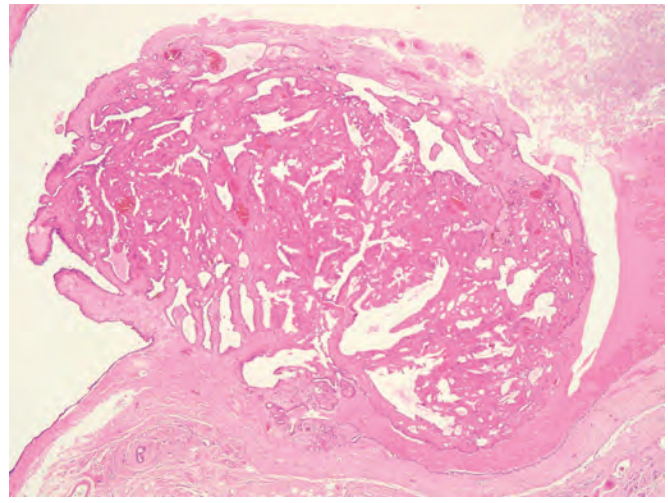

FIGURE 5-2 Histology of duct papilloma.

patients with a solitary intraductal papilloma. In one study, multiple papillomas were reported to be associated with an increased risk of breast cancer, but any increased risk is almost certainly associated with areas of atypical epithelial hyperplasia rather than with the papillomas themselves (18). Repeated excision of papillomas in patients with multiple intraductal papillomas can result in significant breast asymmetry. One option in such patients is to excise such lesions using ultrasound guidance by percutaneous vacuum-assisted biopsy (Fig. 5-3). This provides sufficient material for the pathologist to assess whether lesions are benign and whether atypia is present. Some patients have multiple recurrent peripheral papillomas involving a whole ductal system and in such patients surgery to excise the affected ductal tree should be considered. A segmental excision is often possible with subsequent breast reshaping.

Juvenile Papillomatosis

A rare condition, juvenile papillomatosis, affects women between the ages of 10 and 44 years (19). The common presentation is nipple discharge +/– a discrete mass lesion. In one series of 13 patients, 11 had peripheral and 2 central lesions (19). Three of the 13 presented with nipple discharge; 2 had a palpable peripheral mass lesion, and the remainder had nipple discharge alone. Treatment is by complete excision. Patients with this condition may be at some increased risk of subsequent breast cancer, and close clinical and radiological surveillance of any woman with this condition is indicated.

Carcinoma

An invasive or noninvasive cancer can cause nipple discharge. Only rarely does an invasive cancer cause nipple discharge in the absence of a clinical mass. In most series, DCIS is responsible for up to 10% to 20% of unilateral spontaneous nipple discharges (2). Nipple discharge alone or in association with a mass or Paget's disease is the presenting feature in approximately one-third of symptomatic *in situ* cancers. With the advent of mammography, increasing numbers of noninvasive cancers are being detected and, overall, nipple discharge is the presenting symptom in 7% to 8% of cases of DCIS (Chapter 25). Scant data exist on the frequency with which *in situ* cancers that cause nipple discharge are visible on mammography, but it is recognized that a significant percentage of malignant lesions causing nipple discharge are not visible on mammography. A diagnosis of invasive or noninvasive cancer is often established only by microdochectomy, but this operation is rarely, if ever, therapeutic. Despite a high rate of reported occult nipple–areolar complex involvement (20), a number of studies have demonstrated that breast-conserving surgery with nipple preservation is possible in patients presenting with DCIS or invasive carcinoma who have nipple discharge (21–23). Bauer et al. in 1998 reported that 11 of 43 patients with breast cancer with nipple discharge were successfully treated by breast-conserving surgery. In the study by Cabioglu et al. (20), nipple preserving surgery was successfully performed in one-half of all patients presenting with breast cancer and nipple discharge. There were no local recurrences in those patients who had radiotherapy postoperatively. Concerns about the safety of nipple-preserving breast-conserving surgery in patients with nipple discharge were raised by the retrospective review of Obedian and Haffty (21). Local disease recurrence was noted in 6 of 17 patients with nipple discharge. Patients in this series who underwent central excisions incorporating the nipple had a lower recurrence rate than those patients who had conservation of the nipple–areolar complex. However, this difference did not reach significance. The problem with such retrospective series is that margins were not adequately documented in most patients. It cannot, therefore, be determined whether the high local recurrence rates reported by Obedian were attributable to residual tumor underneath the nipple. Although Cabioglu et al. (21) argue that long-term results obtained from larger series will be required before definitive conclusions can be drawn, they conclude that nipple-preserving breast-conserving surgery can be performed safely providing that negative margins are achieved and appropriate radiotherapy and systemic therapies are administered.

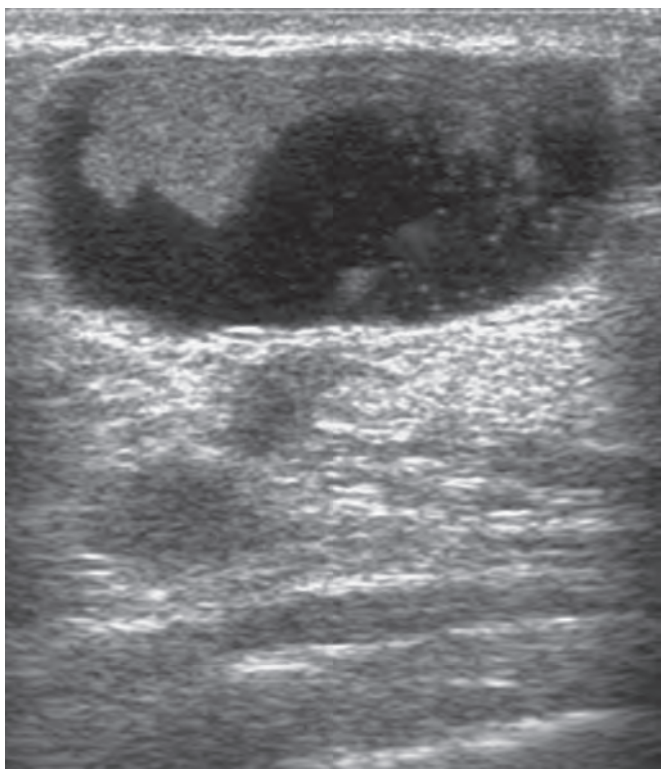

FIGURE 5-3 Ultrasound of an intraduct papilloma characteristic of those seen in multiple papilloma syndrome—such lesions can be excised by mammotomy.

Bloody Nipple Discharge in Pregnancy

Nipple discharge with blood present, either visibly or cytologically, during pregnancy or lactation is common. In 20% of women who experience nipple discharge during pregnancy, blood is evident clinically. The likely cause is hypervascularity of developing breast tissue; it is benign, usually settles quickly, and requires no specific treatment. Only if it persists is investigation required.

Galactorrhea

Galactorrhea is characterized by copious bilateral milky discharge not associated with pregnancy or breast-feeding. Thick, creamy white discharge is not galactorrhea. A careful drug history should be taken because a number of drugs, particularly psychotropic agents, cause hyperprolactinemia. Blood should be taken in patients with galactorrhea to measure prolactin, and if prolactin levels are significantly elevated (≥1,000 mU/L) in the absence of any drug cause, then a search for a pituitary tumor should be instituted. A diagnosis of hyperprolactinemia is suggested

by a history of galactorrhea, amenorrhea, and relative infertility. Galactorrhea disappears after appropriate drug therapy or surgical removal of any pituitary adenoma. Appropriate drug therapy includes administration of cabergoline. Bromocriptine is an alternative, but it is no longer used because it produces significant side effects in up to one-third of patients including, very rarely, strokes (24). For patients with troublesome galactorrhea who are intolerant of medication, bilateral total duct ligation is effective.

Periductal Mastitis and Duct Ectasia

A variety of terms have been applied to the conditions now known as periductal mastitis and duct ectasia. Haagensen first introduced the term *duct ectasia* and considered the condition to be an age-related phenomenon; he believed that breast ducts dilated with age and that stagnant secretions in these dilated ducts leaked into surrounding tissues to cause periductal mastitis. This description of events ignores the findings that periductal inflammation predominates in young women, whereas duct dilatation increases in frequency with advancing age; the sequence of events described by Haagensen is therefore incorrect. If periductal mastitis and duct ectasia are related, then patients with duct ectasia would be expected to have a history of episodes of periductal mastitis. In a study of 186 patients with the clinical syndrome of duct ectasia, only 1 (0.5%) had a history of previous periductal mastitis; in contrast, 97 (70%) of 139 patients with the clinical syndrome of periductal mastitis reported a previous clinical episode of periductal mastitis (25).

Clinical Syndromes

Periductal mastitis is characterized clinically by episodes of periareolar inflammation with or without an associated mass, a periareolar abscess, or a mammary duct fistula. Nipple retraction can be seen early at the site of the affected duct and is often subtle. Nipple discharge can also occur and is often purulent.

The clinical features of duct ectasia include nipple retraction at the site of the shortened duct or ducts and creamy or cheesy, viscous, toothpaste-like nipple discharge. Patients with green discharge from multiple ducts are often diagnosed as having duct ectasia, but most of these have leaking physiologic breast secretion. In one large series, periductal mastitis principally affected women between the ages of 18 and 48 years, whereas most patients who presented with duct ectasia were aged between 42 and 85 years.

Etiology

Aging is an important factor in the cause of duct ectasia. The frequency of the condition increases with age and in one postmortem study, 48% of women aged 60 years or older had pathologic evidence of duct ectasia. Although early studies suggested that the lesions of both periductal mastitis and duct ectasia are sterile, when appropriate transport media are used, bacteria can be isolated from 83% of periareolar inflammatory masses and 100% of nonlactational abscesses and mammary duct fistulae. The organisms isolated are frequently anaerobic. In contrast, in a study of duct ectasia lesions bacteria were identified in only 1 of 11 patients, indicating that these lesions are usually sterile.

An association between smoking and periductal mastitis was first reported in 1988 (26). A subsequent study showed that heavy smokers are more likely to have recurrent infections including abscesses and mammary duct fistulae than light smokers or nonsmokers. Studies with carefully matched cases and controls have shown a significant excess of smokers among patients with clinically diagnosed periductal mastitis, but not in women with clinically diagnosed duct ectasia. How cigarette smoking causes periductal mastitis is unclear. Substances in cigarette smoke may either directly or indirectly damage the wall of subareolar ducts. Accumulation of toxic metabolites—such as lipid peroxidase, epoxides, nicotine, and cotinine—in the breast ducts has been demonstrated to occur in smokers within 15 minutes. Smoking has also been shown to inhibit growth of gram-positive bacteria *in vivo* and *in vitro*, leading to an overgrowth of gram-negative bacteria. This may affect the normal bacterial flora and allow overgrowth of pathogenic aerobic and anaerobic gram-negative bacteria, and would explain the presence of these organisms in the lesions of periductal mastitis. Microvascular changes have also been recorded in smokers and may result in local ischemia (27). The combination of damage caused by toxins, microvascular damage by lipid peroxidases, and altered bacterial flora appears to explain why smokers develop periductal mastitis.

Etiologic data thus suggest that periductal mastitis and duct ectasia are separate conditions with different causes. Duct ectasia appears to be an involutionary phenomenon, whereas periductal mastitis is a disease in which smoking and bacteria are important causal factors.

Other Causes of "Nipple" Discharge

Other diseases of the nipple–areolar complex can present with "nipple" discharge, including nipple adenoma, eczema, Paget's disease, ulcerating carcinoma, and long-standing nipple inversion with maceration. Nipple adenoma is rare, but easy to diagnose (Fig. 5-4). It usually presents with a bloodstained discharge or change in contour or color of the nipple. Occasionally, an ulcer develops. Clinically, there is a nondiscrete mass in the substance of the superficial layer of the nipple. Definitive treatment is complete excision. Eczema or dermatitis can sometimes involve the nipple and is usually caused by irritation from chemicals on clothes or in cosmetics. Eczema can be differentiated from Paget's disease in that eczema affects primarily the areola and only rarely spreads onto the nipple. In contrast, Paget's disease affects the nipple first and only secondarily affects the areola. Treatment for eczema is removal of any aggravating factor, such as perfumed soap or detergents, by the use of hypoallergenic washing materials for clothes and skin, and prescription of topical corticosteroids. Short courses of potent corticosteroids are often more effective at resolving nipple eczema than longer courses of dilute preparations.

Long-standing nipple inversion with maceration is rare but is seen in some elderly people. The injured skin produces a discharge, which can be purulent. Treatment is by careful cleaning of the affected area. Repeated nipple trauma caused by friction from rubbing of clothes on the nipple during jogging and cycling is sometimes sufficiently severe to cause nipple excoriation and bleeding.

NIPPLE INVERSION OR RETRACTION

The terms *inversion* and *retraction* are often used interchangeably, although some call the condition *inversion* only when the whole nipple is pulled in (Fig. 5-5), and use the term *retraction* when part of the nipple is drawn in at the site of a single duct to produce a slit-like appearance (Fig. 5-6). These changes can be congenital or acquired. The acquired causes, in order of frequency, are duct ectasia, periductal mastitis, carcinoma, and tuberculosis.

All patients with acquired nipple inversion or retraction should have a full clinical examination and, if the patient is

FIGURE 5-4 Nipple adenomas.

FIGURE 5-5 Nipple inversion from breast cancer.

FIGURE 5-6 Slit-like nipple retraction from duct ectasia.

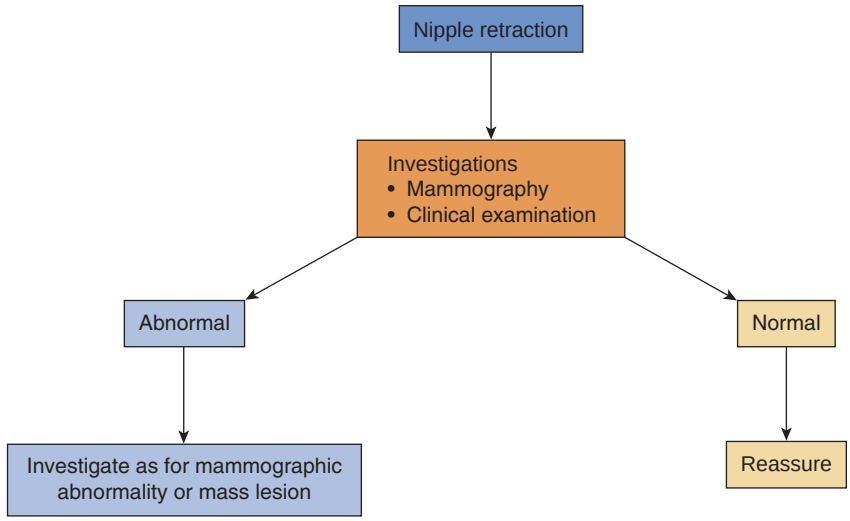

FIGURE 5-7 Management of nipple retraction.

older than 35 years, a mammogram. Management depends on the presence or absence of a clinical or mammographic abnormality (Fig. 5-7). Central, symmetric, transverse slit-like retraction is characteristic of benign disease; nipple inversion occurring in association with either breast cancer or inflammatory breast disease is more likely to involve the whole of the nipple and, in a breast cancer, to be associated with distortion of the areola, which may be evident only when the breast is examined in different positions (Figs. 5-5 and 5-6). Benign nipple retraction requires no specific treatment, but can be corrected surgically if the patient requests it and the surgeon considers the operation appropriate. Division or excision of the underlying breast ducts (total duct division or excision) may be required to evert the nipple; patients should be warned that they will not be able to breast-feed after this procedure and may lose some nipple sensation.

OPERATIONS FOR NIPPLE DISCHARGE OR RETRACTION

Microdochectomy

Microdochectomy is indicated for spontaneous, persistent single-duct discharge and can be performed either through a radial incision across the areola or through a circumareolar incision centered over the discharging duct. A circumareolar incision leaves a better cosmetic scar. The discharging duct is cannulated either with a probe or a blunt-ended needle through which methylene blue can be injected. These various procedures allow the involved duct to be identified under the surface of the nipple. The discharging duct is dissected distally into the breast; a portion of duct over a distance of approximately 5 cm is removed because almost all significant disease affects the proximal 5 cm (9,28). If the remaining duct within the breast appears abnormal and dilated, then the distal duct can be excised or opened and any pathologic lesion in the remaining duct can be visualized and removed. This is an important maneuver because ductoscopy indicates that many significant lesions affect ducts some distance from the nipple. When performing a duct excision directed by ductoscopy, having visualized the abnormality in the duct, transmitted light immediately proximal or at the site of the lesion is used to direct the surgical excision. Once excision has been performed, the nipple should be squeezed gently to ensure that the discharging duct has been removed. Drains are not necessary after this procedure, any significant defect can be closed with mobilization of adjacent breast tissue, and the skin is closed in layers with absorbable sutures. Papillomas visible on ultrasonography can be removed by needle localization or percutaneous vacuum-assisted biopsy.

Total Duct Excision or Division

Total duct excision can be a diagnostic procedure in older patients with nipple discharge and is indicated for multiple troublesome duct discharge or nipple eversion, and as treatment for periductal mastitis and its associated complications. For nipple eversion duct division may be all that is required. Because the lesions of periductal mastitis usually contain organisms (Table 5-1), patients having operations for this condition should receive appropriate perioperative antibiotic treatment. Options for antibiotic therapy include amoxicillin–clavulanate or a combination of erythromycin and metronidazole hydrochloride. Some surgeons prefer total duct excision in older women with single-duct discharge who no longer wish to breast-feed. The reasoning is that is it more likely than single-duct excision to obtain a specific diagnosis (15,16) and if there is a condition, such as duct ectasia, that affects all the ducts underneath the nipple, then any further discharge from the other affected ducts will be prevented. A circumareolar incision based at the six o'clock position is used unless a previous scar exists, in which case the same scar is reused. Dissection is performed under the areola down either side of the major ducts. Curved tissue forceps are passed around the ducts, and these are delivered into the wound. The ducts are secured and then divided from the undersurface of the nipple and, if a total duct excision is being performed, a 2- to 5-cm portion of ducts is excised depending on whether the operation is diagnostic or therapeutic.

For patients having cosmetic nipple eversion, the procedure can be performed through a small incision either at the areolar margin or at the base of the nipple and the ducts are divided sufficiently to ensure that the nipple everts. If the operation is being performed for periductal mastitis, the back of the nipple must be cleared of all ducts up to the nipple skin because recurrence can occur when residual diseased ductal tissue is left. In periductal mastitis only 2 to 3 cm of all the ducts need to be removed as the disease affects only the subareolar ducts. If the nipple was inverted before the operation, it is everted either by dividing the fibrous tissue which is keeping the nipple inverted or manually by firm

TABLE 5-1

Organisms Responsible for Different Types of Breast Infection and Appropriate Antibiotics

Type of Infection	*Organism*	*No Penicillin Allergy*	*Penicillin Allergy*
Neonatal	*Staphylococcus aureus* (rarely *Escherichia coli*)	Flucloxacillin (500 mg four times daily)	Erythromycin (500 mg twice daily)
Lactational	*S. aureus* (rarely *S. epidermidis* and streptococci)	Flucloxacillin (500 mg four times daily)	Erythromycin (500 mg twice daily)
Skin associated	*S. aureus* (500 mg four times daily)	Flucloxacillin (500 mg twice daily)	Erythromycin
Nonlactating	*S. aureus*, enterococci, anaerobic streptococci, *Bacteroides* spp.	Co-amoxiclav (375 mg three times daily)	Combination of erythromycin (500 mg twice daily) with metronidazole (200 mg three times daily)

digital pressure to stretch the tissue stopping the nipple from everting; only rarely are sutures required under the nipple to maintain nipple eversion. No drains are placed, and the wound is closed in layers with absorbable sutures. Patients should be warned before surgery that this operation results in significantly reduced nipple sensitivity in up to 40% of women.

BREAST INFECTION

Breast infection presenting to surgeons is much less common clinically now than it was previously because of early use of antibiotics in the community. It is occasionally seen in neonates, but most commonly affects women between the ages of 18 and 50 years. In the adult, breast infection can be considered lactational or nonlactational. Infection can also affect the skin overlying the breast, and occurs either as a primary event or secondary to a lesion in the skin, such as an epidermoid cyst, or a more generalized condition, such as hidradenitis suppurativa. The organisms responsible for different types of breast infection and the most appropriate antibiotics with activity against these organisms are summarized in Table 5-1 (29). The guiding principle in treating breast infection is to give antibiotics as early as possible to stop abscess formation; if the infection or inflammation fails to resolve after one course of antibiotics, then abscess formation or an underlying cancer should be suspected (30).

Mastitis Neonatorum

Continued enlargement of the breast bud in the first week or two of life occurs in approximately 60% of newborns, and these enlarged buds can become infected, most often by *Staphylococcus aureus*, although the responsible organism is sometimes *Escherichia coli*. In the early stage, antibiotics (flucloxacillin) can control infection; however, if a localized collection is evident on ultrasound, incision and drainage, by aspiration or a small stab incision placed as peripherally as possible so as not to damage the breast bud, is effective at producing resolution.

Lactational Infection

Lactational infection is now less common than it used to be. The infection is usually caused by *S. aureus*, but it can also be caused by *S. epidermidis* and *Streptococcus* species. The first stage is often development of a cracked nipple or a skin abrasion due to nipple trauma from breast-feeding that results in both swelling, which compresses the subareolar breast ducts, and a break in the body's defense mechanisms, which increases the number of bacteria on the skin of the breast. Bacteria then gain access to the breast ducts through the macerated nipple and infect the poorly draining segments. Infection is most common in a first pregnancy during the first 6 weeks of breast-feeding but is also seen during weaning. Symptoms include pain, erythema, swelling, tenderness, or systemic signs of infection. Clinically, the breast is swollen, tender, and erythematous; if an abscess is present, a fluctuant mass with overlying shiny, red skin may be present (Fig. 5-8). Axillary lymphadenopathy is not usually a feature. Patients can be toxic with pyrexia, tachycardia, and leukocytosis. Antibiotics given at an early stage usually control the infection and stop abscess formation. Because more than 80% of staphylococci are resistant to penicillin, flucloxacillin or amoxicillin–clavulanate are given, except in patients with a penicillin sensitivity, for whom erythromycin or clarithromycin is usually effective. Tetracycline, ciprofloxacin, and chloramphenicol should not be used to treat infection in breast-feeding women because they enter breast milk and may harm the child. Patients whose condition does not improve rapidly on appropriate antibiotic therapy require hospital referral and assessment with ultrasonography to determine whether pus is present and to exclude an underlying neoplasm (Fig. 5-9).

Inflammatory cancers can be difficult to differentiate from abscesses. If an abscess is evident on ultrasonography and the overlying skin is not thinned or necrotic, the abscess can be aspirated to dryness following injection of local anesthesia into the skin and the breast tissue and the cavity irrigated with local anesthetic to minimize pain and to dilute thick pus. The abscess should be irrigated until all the pus is evacuated and the fluid aspirated is clear. A combination of repeated aspiration and oral antibiotics is usually effective at resolving local abscess formation and is the current treatment of choice for most breast abscesses (29,30). Aspiration should be repeated every 2 to 3 days until no further pus is obtained. Characteristically, the fluid aspirated changes over a few days from pus to serous fluid and then to milk. If the skin overlying the abscess is thinned and pus is visible superficially on ultrasonography, then after application of local anesthetic cream or infiltration of local anesthetic into the overlying skin, a small incision (mini-incision) is made over the point of maximal fluctuation, and the pus is drained (29). The cavity is then irrigated with local anesthetic solution, which produces some pain relief. Irrigation is continued every few days until the incision site closes. If the skin overlying the abscess is clearly necrotic, the necrotic skin can be excised to allow the pus to drain.

Few lactational abscesses require drainage under general anesthesia. The placement of drains and packing of

FIGURE 5-8 **(A)** Lactational breast infection: large abscess was present on ultrasound which was treated by aspiration with rapid resolution **(B)**.

the wound are unnecessary. Breast-feeding should be continued if possible because this promotes drainage of the engorged segment and helps resolve infection. The infant is not harmed by bacteria in the milk, nor by flucloxacillin, amoxicillin–clavulanate, or erythromycin. Patients who have incision and drainage of their breast abscesses performed under general anesthesia are more likely to stop breast-feeding compared with those treated by mini-incision or aspiration and antibiotic therapy. Only rarely in women with severe and extensive breast infection is it necessary to suppress lactation with cabergoline. Rarely in patients treated with multiple courses of antibiotics a walled-off abscess develops known as an antibioma. Previously these were excised. This is unnecessary and they are aspirated or drained through a small incision until no more pus is present and they resolve, although it can be many months before the mass resolves and the breast feels normal.

FIGURE 5-9 Ultrasound of an abscess.

Nonlactational Infection

Nonlactational infections can be divided into those occurring centrally in the breast in the periareolar region and those affecting peripheral breast tissue.

Periareolar Infection

Periareolar infection is most commonly seen in young women; the mean age of occurrence is 32 years, and most are cigarette smokers. The underlying pathologic process is periductal mastitis (29,31). It can present as periareolar inflammation, with or without a mass, a periareolar abscess, or a mammary duct fistula. A patient presenting with periareolar inflammation without a mass should be treated with antibiotics that are active against both the aerobic and anaerobic bacteria seen in these lesions (Table 5-1). If the infection does not resolve after one course of antibiotics, ultrasonography should be performed to determine whether a localized abscess is present. A patient who presents with or develops an abscess should be treated by recurrent aspiration and oral antibiotics or incision and drainage under local anesthesia (Fig. 5-10). After resolution of the infective episode, patients older than age 35 years should have mammography performed, because very rarely infection can develop in association with comedo necrosis in an area of ductal carcinoma *in situ*. Up to half of patients with periareolar sepsis experience recurrent episodes of infection; the only effective long-term treatment for these women is

FIGURE 5-10 Periareolar abscess with skin necrosis: the abscess can be drained by excision of the necrotic skin.

removal of all the affected ducts by total duct excision. This operation to remove all the subareolar ducts up to the nipple skin is usually curative. Rarely subareolar abscesses can be caused by actinomyces species; these resolve following incision and drainage (32).

Mammary Duct Fistula

A mammary duct fistula is a communication between the skin, usually in the periareolar region, and a major subareolar breast duct (29) (Fig. 5-11). Fistulae occur most commonly after incision and drainage of nonlactational breast abscesses, although they can occur following spontaneous discharge of a periareolar inflammatory mass or after biopsy of an area of periductal mastitis. Patients usually have preceding episodes of recurrent abscess formation and report purulent discharge through the fistula opening. Occasionally, more than one external opening is present usually at the areolar margin, either from a single affected duct or from multiple diseased ducts.

FIGURE 5-11 **Mammary duct fistula.** Bilateral mammary duct fistula. On each side the fistula is discharging in the periareolar region. The affected duct is pulled toward the fistula.

Treatment is surgical, and consists either of opening up the fistula tract and leaving it to granulate (33) or excising the fistula and affected duct or ducts (a total duct excision is also usually required) and closing the wound primarily under appropriate antibiotic cover. The incision to excise the fistula can be radial directly over the fistula tract or circumareolar incorporating the fistula opening. The latter incision produces a superior cosmetic outcome.

Peripheral Nonlactational Breast Abscess

Peripheral nonlactational breast abscesses are less common than periareolar abscesses and have been reported to be associated with a variety of underlying disease states, such as diabetes, rheumatoid arthritis, steroid treatment, and trauma. *S. aureus* is the organism usually responsible, but some abscesses contain anaerobic organisms. Peripheral nonlactational breast abscesses are three times more common in premenopausal women than in menopausal or postmenopausal women and in most no obvious underlying cause is evident; following resolution of infection, mammography is indicated in women older than 35 years to exclude any underlying comedo DCIS. Systemic evidence of malaise and fever is usually absent. Management is the same as for other breast abscesses, with aspiration or incision and drainage (Fig. 5-12).

Skin-Associated Infection

Cellulitis

Cellulitis is an uncommon infection in the breast and can be difficult to distinguish from inflammatory breast cancer or benign erythematous conditions of the breast (Fig. 5-13). Pain is a prominent feature of breast cellulitis associated with erythema, swelling, and warmth. Treatment is with antibiotics (Table 5-1).

Eczema

Patients with eczema involving the skin overlying the breast may develop secondary cellulitis. Appropriate treatments for eczema reduce the likelihood of recurrence.

Epidermoid Cysts

Epidermoid cysts are discrete nodules in the skin that often are referred to as sebaceous cysts, but there is no sebaceous component. These cysts are common within the skin of the breast and can become infected, forming local abscesses that are best treated by mini-incision and drainage rather than aspiration because the material in the abscess is too thick to aspirate.

Hidradenitis Suppurativa

Hidradenitis suppurativa is a condition that affects the apocrine sweat glands and can result in recurrent infection and abscess formation of the skin of the lower half of the breast as well as the axilla (29,32,34–36). It is more common in smokers. Treatment involves keeping the area of skin as clean and dry as possible, draining any abscesses, and stopping smoking. A variety of drug treatments have been tried but are only partially effective. Excision and skin grafting of the affected skin has been tried and has a success rate of up to 50%.

Intertrigo

Intertrigo is inflamed skin in the inframammary folds, often due to moisture and maceration (37) (Fig. 5-14). This can be a recurrent problem in women with large ptotic breasts that make contact with the chest wall. Fungi play

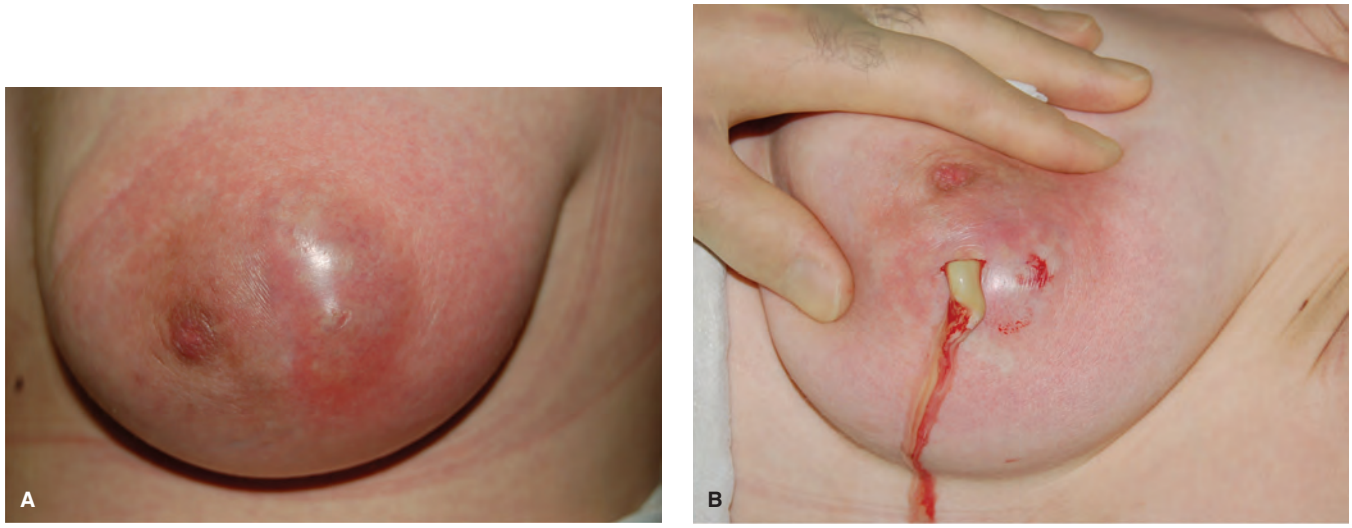

FIGURE 5-12 **(A)** Peripheral abscess: note the shiny thin skin. This abscess was treated by min-incision and drainage with resolution **(B)**.

no aetiological role in this condition. The primary management of intertrigo is to educate the patient about keeping the area as clean and dry as possible. The skin should be washed gently two or more times a day with simple soap, a mild cleansing solution, or hypoallergenic skin wipes, then dabbed dry with a towel or dried with a hair dryer at a low setting (37). Preventive measures include wearing cotton against the skin and keeping the skin dry and clean. Steroids and creams including antifungal agents are not effective; they may aggravate the condition and should be avoided.

Piercing

Nipple rings can result in subareolar breast abscess and recurrent nipple infections, particularly in smokers (38). One study noted that nipple piercing was a significant risk factor for a subareolar breast abscess (OR 10.2 95% CI 1.3–454.4) as is smoking (OR 8.0 95% CI 3.4–19.4) (38).

Pilonidal Sinuses

Pilonidal sinuses affecting the nipple have been reported in hair stylists and sheep shearers because loose hairs penetrate the skin and can result in inflammation and infection (29).

Other Rare Infections

Tuberculosis is rare in Western countries. The breast can be the primary site, but tuberculosis more commonly reaches the breast through lymphatic spread from axillary, mediastinal, or cervical nodes or directly from underlying structures, such as the ribs. Tuberculosis predominantly affects women in the latter part of their childbearing years. An axillary or breast sinus is present in up to 50% of patients. The most common presentation is that of an acute abscess resulting from infection of an area of tuberculosis by pyogenic organisms (29,30). Treatment is with local surgery and antitubercular drug therapy.

Primary actinomycosis (32), syphilis, mycotic, helminthic, and viral infections occasionally affect the breast, but are rare. Actinomycosis organisms can be seen in hidradenitis. *Molluscum contagiosum* can affect the areola and present as wart-like lesions.

Granulomatous Lobular Mastitis

Granulomatous lobular mastitis is characterized by noncaseating granulomata and microabscesses confined to the breast lobule. The condition presents as a firm mass, which is often indistinguishable from breast cancer, or as multiple or recurrent abscesses. Some patients with granulomatous lobular mastitis report that the mass is tender to touch and painful and the overlying skin is sometimes ulcerated (Fig. 5-15). Young women, often within 5 years of pregnancy, are most

FIGURE 5-13 Cellulitis of the breast.

FIGURE 5-14 Intertrigo pre and post.

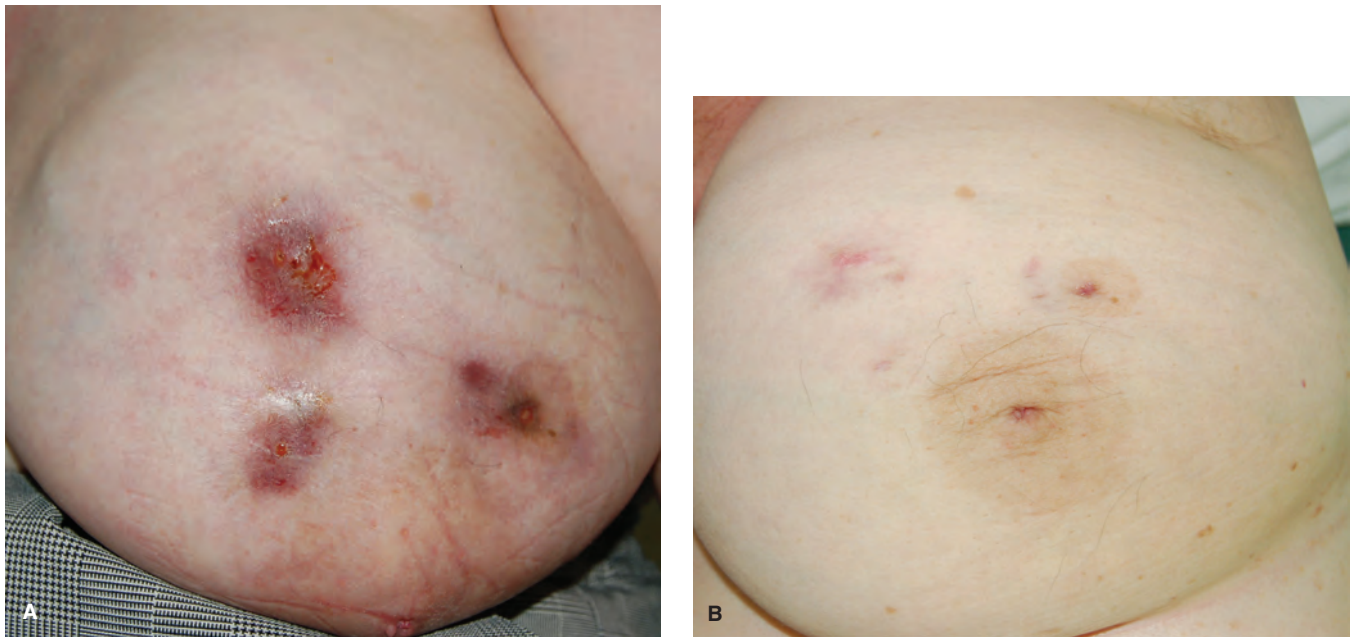

FIGURE 5-15 Granulomatous lobular mastitis at presentation **(A)** and following resolution **(B).**

frequently affected, but not all women with this condition are parous. In contrast to periductal mastitis, it is common in Asian rather than white women and few are smokers. This condition has recently been reported to be associated with hyperprolactinemia (including drug-induced) (39). Prolactin can contribute to a wide variety of physiological and pathological granulomatous cutaneous lesions, and it may do the same in the breast. The frequency of hyperprolactinaemia in women with granulomatosis lobular mastitis is not well documented, so the relevance of this observation is not clear. Rare reported causes of granulomatous mastitis include alpha-1 antitrypsin deficiency and Wegener's granulomatosis. The role of organisms in the etiology of this condition is unclear. One study did isolate corynebacteria from 9 of 12 women with granulomatous lobular mastitis (40). The most common species isolated was the newly described *Corynebacterium kroppenstedtii*, followed by *C. amycolatum* and *C. tuberculostearicum*. These organisms are usually sensitive to penicillin and tetracycline and when antibiotics effective against these organisms have been administered to patients with this condition they do not produce resolution. Any antibiotic treatment should therefore be based on sensitivities as reported by the local bacteriologic service.

A search for the etiology of this condition continues. In patients presenting with a breast mass diagnosed on core biopsy as granulomatous lobular mastitis, excision of the mass should be avoided because it is often followed by persistent wound discharge and failure of the wound to heal. Current treatment involves establishing the diagnosis and observation without any specific treatment because the condition usually resolves slowly over 6 to 12 months. Any abscesses that develop require aspiration or mini-incision and drainage. There is a strong tendency for this condition to recur, but eventually it does resolve spontaneously without treatment (29). Steroids have been tried but without consistent success. More recently, methotrexate as monotherapy given at a dose of 7.5 mg per week, has been claimed to be effective (41). Similar claims were made for steroids. Whether methotrexate alters the course of the condition or merely suppresses the inflammatory component is not clear and given that the condition does resolve spontaneously more studies are required before methotrexate can be considered as an effective therapy for this condition.

Breast Infection after Breast Surgery

Rates of infection after breast surgery vary in relation to the extent of the surgery and risk factors including smoking, obesity, and the presence of diabetes. Rates of infection in excess of 10% are seen after mastectomy (42). Preoperative antibiotics reduce the risk of breast infection by 36% therefore preoperative prophylactic antibiotics in breast surgery patients may be administered routinely. The relative risk of infection if antibiotics are administered in a recent meta-analysis was 0.64, 95% confidence intervals 0.50–0.83, $p < .0005$ (43).

Factitial Disease

Cases of factitious abscess (caused by the patient themselves) are occasionally seen. These patients can have psychiatric problems, but patients appear quite plausible. Factitial disease should be suspected when peripheral abscesses persist or recur despite appropriate treatment. The condition can be difficult to treat because patients are often resistant to help and may be very manipulative.

MANAGEMENT SUMMARY

- Persistent spontaneous nipple discharge accounts for 5% of all symptomatic breast referrals and requires assessment by physical examination and imaging. Surgery is needed for diagnosis in some patients and as many as 20 % will have an underlying malignancy.
- When treating breast infection appropriate antibiotics should be given early to reduce abscess formation. Ultrasound should be performed in patients whose infection does not resolve after a single course of appropriate antibiotics to exclude a breast abscess. Breast abscesses can be treated by repeated aspiration or by incision and drainage.
- Breast cancer should be excluded in patients with an inflammatory lesion that is solid on ultrasound and does not resolve with antibiotics.

CHAPTER 6

Management of Breast Pain

Robert E. Mansel

CHAPTER CONTENTS

Breast pain is one of the most common problems for which patients consult primary care physicians, gynecologists, and breast specialists. Patients mistakenly think the symptom is associated with early breast cancer, but data do not support any strong relationship with breast pain. The Women's Health Initiative Estrogen plus Progestin intervention trials showed no effect on breast cancer risk in women who took estrogens alone, but a mild effect in those taking equine estrogen plus medroxyprogesterone, particularly if baseline breast tenderness was present (hazard ratio [HR] 2.16), but the effect was much less if no baseline breast tenderness was present (1). Once cancer has been ruled out, reassurance alone will resolve the problem in 86% of those with mild and 52% of those with severe mastalgia (2). A survey of screened women in the UK national program revealed that 69% had experienced severe breast pain, although only 3% had sought treatment. Ader et al. in 2001 attempted to establish the prevalence in the community in the United States. In their study, 874 women between 18 and 44 were recruited for interview by random number dialing in Virginia, and 68% reported some cyclical mastalgia, with 22% describing it as moderate or severe (3). Interestingly, patients on the oral contraceptive pill had less trouble, while there was a positive association with smoking, caffeine intake, and perceived stress. A study from the United States (4) showed the impact of breast pain among a population of 1,171 women attending a general obstetrics and gynaecology clinic. Sixty-nine percent suffered regular discomfort and 36% had consulted about their breast pain. A specialist breast clinic in Ghana reported in 2008 that 72% of women attended because of breast pain. Reading of the literature might suggest that the incidence of breast pain is different in many parts of the world, but these differences are mainly cultural in relation to the willingness of women to consult their physicians about breast pain.

The major clinical issue is to exclude cancer and determine the impact on quality of life in patients complaining of breast pain, as this is the primary reason for medication. Only rarely is intervention required, but, after appropriate patient selection, some may derive great benefit from treatment.

ETIOLOGY

Breast swelling is a frequent event in the late luteal phase of the menstrual cycle. Cyclic mastalgia is a more extreme form of this change, and researchers have sought endocrine abnormalities in those with severe breast pain, particularly measuring estradiol, progesterone, and prolactin, but no major abnormalities have been found (5). One hypothesis suggested that inadequate corpus luteal function is an etiologic factor in women with benign breast disease, but this term has been used to include all nonmalignant breast conditions, blurring the distinction between a variety of benign breast conditions. No evidence of progesterone deficiency has been found during the luteal phase in patients with mastalgia. The confusion in the literature between the symptom of breast pain and the large number of variable pathological descriptions of benign breast conditions has resulted in the belief that the condition is a "disease," rather than physiological responses to menstrual cycles. In the aberrations of normal development and involution (ANDI) classification of benign conditions, mastalgia is regarded as a physiologic disorder arising from hormonal activity with little connection to cancer risk, or true pathologic conditions (6). Another suitable term might be *benign breast change* as this does not suggest cancer or premalignancy.

No consistent abnormality of estradiol has been reported in women with cyclic mastalgia; both normal levels and elevated levels have been reported during the luteal phase. Baseline levels of prolactin are either normal or marginally elevated, but increased prolactin release was found after domperidone stimulation in severe cyclic mastalgia, possibly representing a stress response to prolonged pain.

Ecochard et al. measured a range of personal and endocrine variables in 30 women with mastalgia and 70 control subjects (7). Cases were more likely to report foot swelling or abdominal bloating (43% vs. 19%). Women with mastalgia had higher mean luteal levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

No histologic differences have been detected in biopsies from women with and without mastalgia. Immunohistochemical examination of biopsies from 29 women with mastalgia and 29 control subjects revealed no differences in expression of interleukin-6, interleukin-1, and tumor necrosis factor.

CLASSIFICATION

Preece et al. (8) proposed a classification with six subgroups based on a prospective study of 232 patients with breast pain: cyclic mastalgia, duct ectasia, Tietze's syndrome, trauma, sclerosing adenosis, and cancer. This was subsequently simplified into two groups with noncyclic pain: true noncyclic breast pain and those with other causes of chest wall pain (9). Although an accurate diagnosis can be achieved on the basis of history and examination, patients with breast pain can be more simply assigned to one of three groups: cyclic breast pain (around 70%), noncyclic breast pain (20%), or extramammary pain (10%).

Khan and Apkarian (10) studied the differences between cyclic and noncyclic pain using standardized pain questionnaires, including the McGill Pain instrument in 271 women, and found that the level of pain described by the subjects was equivalent to chronic cancer pain, and just less than the pain of rheumatoid arthritis. They noted that women with cyclic pain tended to refer to heaviness and tenderness as found in the Preece study, whereas women with noncyclic pain related the severity to the area of breast involved.

EVALUATION

Important aspects of history-taking include the type of pain, relationship to menses, duration, location, and any other medical problems. The impact of the pain on the everyday activities of the patient, particularly sleep and work, should be established to assess the need for medication.

After inspection, the first aspect of the breast examination should be very gentle palpation of the breasts once the patient has indicated the site(s) of the pain. Having excluded discrete masses, a more probing evaluation should be performed, focusing on the site(s) of pain. After turning the patient half on her side so that the breast tissue falls away from the chest wall, it may be possible to identify that the pain is arising from the underlying rib or costal cartilage. The pain can be reproduced by placing a fingertip on the affected rib and demonstrating to the patient its source.

Nodularity can be associated with mastalgia, but the extent is unrelated to pain severity; in younger women, the finding is so common that it should be considered within the spectrum of normality. If it is apparent that the pain, whether cyclic or noncyclic, is mammary in origin, the decision to treat is based on the subjective assessment of severity, together with the duration of symptoms. This assessment may be facilitated by a daily pain chart that assesses the timing and severity (semiquantitative scale) of the pain. Generally, there should be a history of pain of at least 4 months before hormonal therapy is indicated.

ROLE OF RADIOLOGY

The average age of women entered into trials of treatment for mastalgia is 32 years: In this age group, mammography is not a standard adjunct to clinical evaluation. In the absence of a discrete lump, ultrasonography is also unlikely to give useful information, but any breast lump present requires triple assessment. No specific mammogram findings are associated with breast pain.

Ultrasonography in 212 asymptomatic women and 212 with mastalgia showed the mean maximal duct dilatation was 1.8 mm in normal women compared with 2.34 mm in the 136 with cyclic pain and 3.89 mm in the 76 with noncyclic pain. Dilated ducts were found in all quadrants, but mostly in the retroareolar area, and dilatation did not alter during the menstrual cycle. A highly significant association was found between the extent of ductal dilatation and pain severity.

The meaning of these findings are unclear as no relationship was shown in the cyclic pain patients with the considerable temporal symptoms in this group, but the noncyclic group could be explained by the periductal inflammation often seen in this group.

MONDOR'S DISEASE

Mondor's disease is a rare cause of breast pain, with diagnostic clinical features of local pain associated with a tender, palpable subcutaneous cord or linear skin dimpling. The cause is superficial thrombophlebitis of the lateral thoracic vein or a tributary. The condition resolves spontaneously. Mondor's disease can cause serious alarm because some patients assume that the skin tethering is secondary to an underlying carcinoma, so they are greatly relieved when informed of the benign nature of the condition.

In a series of 63 cases of Mondor's disease, no underlying pathologic process was found in 31 cases. Of the remaining 32, local trauma or surgical intervention was responsible in 15 (47%), an inflammatory process in 6 (19%), and carcinoma in 8 (25%). In view of this, mammography should be performed in women with Mondor's disease who are aged 35 years or older to exclude an impalpable breast cancer.

PSYCHOSOCIAL ASPECTS

Several studies have confirmed that patients with severe mastalgia have psychological morbidity that may be the result rather than the cause of their breast pain. Preece et al. (11) used the Middlesex Hospital Questionnaire to compare patients with mastalgia, psychiatric patients, and minor surgical cases. No significant differences were found between the patients with breast pain and the surgical cases, and both scored significantly lower than psychiatric cases. Only the scores of patients who failed treatment approached those of psychiatric patients. In a small study of 25 women with severe mastalgia, using the Composite International Diagnostic Interview, 45 diagnoses were made in 21 patients (84%): anxiety (n = 17), panic disorder (n = 5), somatization disorder (n = 7), and major depression (n = 16).

A study using the Hospital Anxiety and Depression Scale (HADS) reported high levels of both anxiety and depression in 20 women with severe mastalgia. At Guy's Hospital, HADS was also used to evaluate 54 patients with mastalgia (12). The 33 women with severe pain manifested levels of anxiety and depression comparable with those in women with breast cancer before surgery. Those who responded to treatment had a significant improvement in psychosocial function, but the nonresponders continued to have high levels of distress. Fox et al. (13) conducted a prospective trial in 45 women with mastalgia who kept pain diaries for 12 weeks, with half randomized to listen daily to a relaxation tape during weeks

5 to 8. Abnormal or borderline HADS scores were found at entry in 54%, and a complete or substantial reduction in pain score was measured in 25% of the control subjects and 61% of those randomized to relaxation therapy ($p < .005$).

MASTALGIA AND BREAST CANCER RISK

Because of the lack of precision in classification of benign breast conditions in older studies, it was difficult to determine whether breast pain led to an increased risk of subsequent breast cancer. Foote and Stewart wrote in 1945, "Any point of view that one chooses to take concerning the relation of so-called cystic mastitis to mammary cancer can be abundantly supported from the literature."

Webber and Boyd carried out a critical analysis of the 36 published papers that were available in English before 1984. They set 16 standards, including a description of the study population, a definition of benign disease, follow-up, and a description of the risk analysis. Of the 22 studies reporting an increase in risk, all met more of the standards than the 11 suggesting no increase in risk and the 3 drawing no conclusions.

Since then, a few studies have specifically examined the relation between cyclic mastalgia and breast cancer risk. A French case-control study among premenopausal women—210 younger than 45 years of age with breast cancer, and 210 neighborhood control subjects—matched on year of birth, education level, and age at first full-term pregnancy gave an unadjusted relative risk (RR) for cancer in cyclic mastalgia of 2.66, and after adjustment for family history, prior benign breast disease, and age at menarche, the RR was still significantly elevated at 2.12.

Goodwin et al. (14) recruited 192 women with premenopausal node-negative breast cancer and 192 age-matched premenopausal control subjects. Significant risk variables for breast cancer in the model were marital status, family history, number of years of smoking, prior breast biopsy (before cancer diagnosis), and mean cyclic change in breast tenderness. The odds ratio of cancer for cyclic mastalgia was 1.35, rising to 3.32 in those with severe pain.

Another indication of a possible link between mastalgia and cancer is the relationship between Wolfe grade of mammograms and breast pain. Deschamps et al. (15) determined the Wolfe grades of 1,394 women in the Canadian National Breast Screening Study. All completed a questionnaire, with mastalgia reported by 46%. The extent of dysplasia on mammograms was categorized as Dy2 (25% to 49%), Dy3 (50% to 74%), and Dy4 (≥75%). The odds ratio for a Dy3/4 rating was 1.0 for those who never had breast swelling and mastalgia, whereas it was 2.7 in those reporting both symptoms.

These epidemiologic studies have the problems of recall biases and unknown extent of histologic atypia in the patients who have not had biopsies. In most studies assessing risk using established algorithms, the presence of breast pain is not used as an independent variable in the calculations, unlike prior breast biopsy. That women attend a physician for breast pain, itself results in a higher rate of breast biopsy as noted in the study by Ader et al. (3).

TREATMENT TRIALS

Multiple treatments have been used in women with "benign breast disease," some of whom had nothing more than nodularity without tenderness. Patients with diffusely nodular breasts that are painless require nothing other than exclusion of significant pathology and can be discharged if no other indications for follow-up exist.

Treatment trials for breast pain should have well-documented breast pain classified into cyclic or not, measured with a visual analog scale (VAS) or other rating scales, and ideally using each patient as her own control. Pain should have been present for a minimum of 6 months. Assessment of nodularity should be assessed separately from pain, and has been validated in a study of two experienced blinded physicians assessing 784 women using a VAS giving a highly significant interobserver correlation with a kappa value of 0.865 (16). The overall quality of most published studies has been poor with low numbers of patients recruited, and varying methodologies used. Trials should be of double-blinded, placebo-controlled, randomized design and include a minimum of 20 patients in each arm. Some trials have met these criteria and defined effective drugs or interventions; results are summarized in Table 6-1.

The initial approach by most physicians is to advise reduction in alleged dietary factors associated with breast pain, such as caffeine or saturated fat intake, but the evidence for these interventions is poor. Diuretics are widely used by family physicians to reduce supposed water retention in the luteal phase of the cycle, but are ineffective.

Several agents have been found in controlled trials to be no better than placebo: vitamin E, lynestrenol, mefenamic acid, and caffeine reduction. This is perhaps not surprising because placebo-controlled trials report placebo response rates from 10% to 50%.

As an alternative, more complex approach, reduction in dietary fat can significantly reduce cyclic breast pain. Boyd et al. (17) entered 21 women with a minimum of 5 years of breast pain into a trial in which 11 were shown how to reduce their dietary fat content to 15% of total calories and 10 received general dietary advice. Those in the fat-reduction group had a significant reduction in breast pain. Although a nondrug intervention appeals to many patients, long-term dietary change is a difficult intervention to maintain in premenopausal women with busy lives.

A similar dietary approach of adding the long-chain unsaturated fatty acid gamma-linolenic acid, present in evening primrose oil and starflower oil, provides a nonendocrine approach, but with an efficacy that is questionable. One study entered 103 women with mastalgia into a double-blinded, crossover study comparing evening primrose oil with placebo for 3 months, after which both groups received evening primrose oil capsules for a further 3 months. Cyclic pain was significantly diminished in those given evening primrose oil, but had no effect on noncyclic mastalgia.

However, a systematic literature search by Budeiri to determine the efficacy of evening primrose oil for premenstrual syndrome found no evidence of benefit (18). A more recent Dutch trial also failed to show an advantage for evening primrose oil (19).

In an attempt to resolve this question, one of the largest studies ever performed in both community and hospital patients involving a total of 555 patients was carried out, but with a different placebo arm to the previous trials. This trial failed to show any advantage of the active arms containing gamma-linoleic acid, principally owing to the very large response of 40% reduction in symptoms in the placebo group (20). Despite this, many physicians advise their patients to try this product, which is widely available in nonprescription format, as an initial treatment of breast pain because the incidence of side effects was very low in all the trials. In practical terms it is likely that the patients feel better due to the large placebo effect.

In cyclic mastalgia, most treatments have focused on reduction in estrogen or prolactin drive to the breast cells in the belief that hormonal overstimulation is the predominant

[a]Side effects of sufficient severity that treatment was discontinued.

factor in severe breast pain, although as noted above little evidence exists for this hypothesis.

Danazol, an impeded androgen, may relieve pain in up to 93% of patients, but with side effects that include nausea, depression, menstrual irregularity, and headaches in up to two-thirds of patients, sometimes leading to discontinuation of treatment. To reduce side effects, O'Brien and Abukhali (21) conducted a double-blinded, placebo-controlled trial of luteal-phase danazol in 100 women with premenstrual syndrome, including cyclic mastalgia. Danazol or placebo was given during the luteal phase for three cycles, with a significant pain reduction in those treated and similar side effects in both groups.

As an alternative to drugs, some physicians recommend a more supportive brassiere to relieve mastalgia. In a nonrandomized study of 200 Saudi women with mastalgia, 100 were given danazol 200 mg/day and 100 instructed to wear a sports brassiere. Pain was relieved in 85% of those who wore sports brassieres and in 58% of those given danazol, but of the latter group 42% had side effects and 15% stopped treatment. The results of this trial are difficult to interpret due to its nonblinded, nonrandomized structure.

Bromocriptine, a prolactin inhibitor, was also effective in breast pain in several small preliminary studies. In a multicenter European study of 272 women comparing bromocriptine, 2.5 mg twice daily, with placebo, significant symptom relief occurred in the treated group but 29% dropped out because of side effects, mostly nausea and dizziness (22). A double-blinded comparison study in 47 women with severe breast pain treated with bromocriptine and danazol had significantly better pain relief than the placebo group, but the best response was recorded in the danazol group.

A study using the dopamine agonist lisuride maleate for 2 months in a double-blinded, placebo-controlled trial treated 60 women in a 1:1 ratio. Severity of mastalgia was monitored by VAS, but there was neither run-in period nor any pain severity threshold for trial entry. In patients with less pain, the response rate was 8 of 11 (73%) in the treated and 2 of 15 (13%) in the placebo arm. Among those with more severe pain, the respective response rates were 19 of 19 (100%) and 5 of 15 (33%). The main side effect was nausea, experienced by 17% of the treated and 10% of the control subjects. However, the use of dopamine agents has been limited owing to problematic side effects, and they are currently not being used in breast pain.

The efficacy of progesterone vaginal cream has been investigated in two small randomized trials. In a small study, McFadyen reported a minor, nonsignificant benefit for those women given placebo cream. In a larger trial with 80 participants, a greater than 50% reduction in pain was recorded in 22% of the placebo group and in 65% of those given progesterone-containing cream.

A study of 26 women compared medroxyprogesterone acetate tablets, 20 mg/day in the luteal phase of the cycle, with placebo and found no difference in response rate or side effects. In a multicenter, double-blinded, randomized trial, Peters (23) administered the synthetic 19-norsteroid gestrinone to 73 women and placebo to 72 control subjects. A significantly greater reduction in pain was seen in the gestrinone group, with side effects reported by 44% of the treated cases and 14% of the control subjects.

Tamoxifen, a partial estrogen antagonist and agonist, is effective in treating breast pain. In the first double-blinded, crossover, randomized trial, conducted at Guy's Hospital, pain relief occurred in 71% of those given tamoxifen and 38% of control subjects (24). After 3 months, nonresponders switched to the alternative treatment arm, and pain control was achieved in 75% of the tamoxifen group and 33% of the placebo group. The most common side effect of tamoxifen was hot flashes, occurring in 27%.

A similar placebo response was seen in a more recent trial comparing tamoxifen with danazol, but in the group that received tamoxifen 10 mg, a higher response rate was seen and breast pain was controlled in 89%. In two trials that compared

tamoxifen 10 mg with 20 mg, similar response rates were seen but side effects with the lower dose were substantially reduced (21% vs. 64%). When tamoxifen was compared with danazol, similar response rates were seen, but significantly more side effects occurred in those given danazol (90% vs. 50%). When tamoxifen 10 mg was compared with bromocriptine 7.5 mg daily, pain relief was achieved in 18 of 20 (90%) of the tamoxifen group and in 17 of 20 (85%) of those given bromocriptine. Tamoxifen is now being used extensively in the management of breast pain, as an off-label drug because it is not currently licensed for use in benign breast conditions. The safety of this drug in patients without breast cancer is, however, well documented in the prevention trials involving large numbers of normal high-risk women (25). Furthermore, this review of the prevention trials confirms the reduction in benign breast conditions on the drug, which is consistent with the reduction in symptoms seen in the breast pain trials. Patients who are prescribed tamoxifen should be given a careful explanation that the drug is being used to reduce estrogen drive and is not being used for breast cancer.

Alternative routes of delivery of tamoxifen or selective estrogen receptor modulators (SERMS) may be possible by the transcutaneous route to reduce side effects by avoiding transhepatic passage. This approach has shown some promise using a gel containing 4-hydroxy tamoxifen applied to the breast morning and night (26). A placebo-controlled trial of this gel showed efficacy in cyclic mastalgia, particularly in the late luteal phase of the cycle, and showed a clear blunting of the luteal peak of cyclic breast pain (Fig. 6-1). It is clear that these series of studies of SERMS and the prevention studies confirm the active therapeutic role of these agents in benign conditions of the breast. These new agents are currently not licensed in the treatment of breast pain, and are awaiting further safety data as it is a novel formulation of tamoxifen.

A recent randomized study compared a novel antiestrogen ormeloxifine with danazol and showed that the new agent, which has predominantly antagonist actions, was as effective as danazol but with fewer side effects (27). Pain was assessed by VAS pain scores and ormeloxifine (Centchroman) produced a reduction in median pain scores from 7 at baseline to 2 at 12 weeks.

The relationship of the menstrual cycle in cyclic breast pain was further demonstrated by a randomized trial of the luteinizing hormone-releasing hormone (LHRH) agonist goserelin (Zoladex), which abolishes the menstrual cycle and thus removes the normal fluctuation in estradiol and progesterone. This large placebo-controlled trial of women with cyclic mastalgia treated with Zoladex for 6 months showed significant reduction in breast pain (28). The patients were then followed off treatment for 6 months and the breast pain gradually returned as did menstruation.

In a different approach, Ingram et al. (29) studied isoflavones derived from red clover to determine whether this phytoestrogen could relieve mastalgia. The 18 patients in the trial underwent a 2-month, single-blinded, placebo run-in phase, after which they received either placebo, isoflavone 40 mg, or isoflavone 80 mg. Pain scores for the final single-blinded month and the final double-blinded month were compared. In the placebo group, there was a 13% reduction, for the 40 mg/day group it was 44%, and for

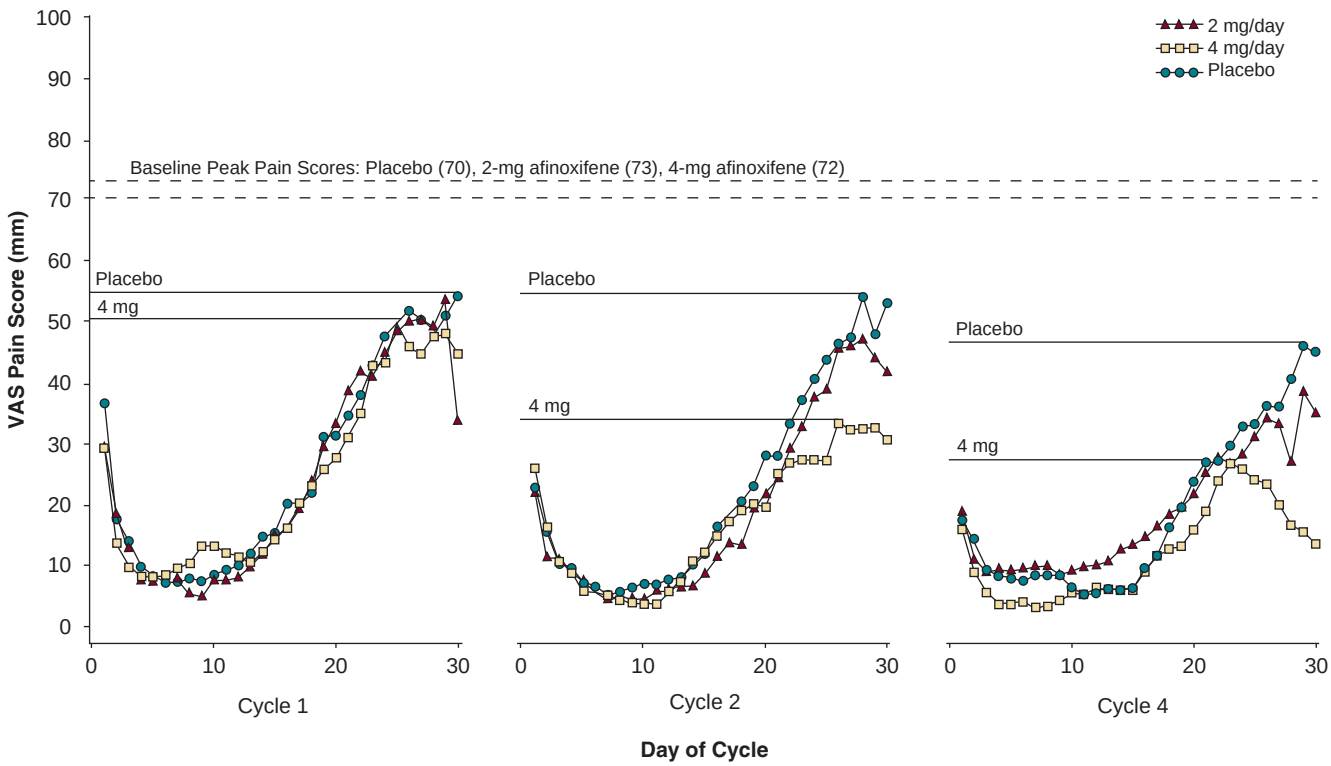

FIGURE 6-1 Effect of topical 4-hydroxy tamoxifen gel on cyclical mastalgia. Randomized trial of 4-hydroxy tamoxifen gel (2 and 4 mg vs. placebo gel) applied to the breast for breast pain. Note the clear cyclical pattern of pain and the reduction of the peak luteal pain in cycle 4 by the 4-mg preparation. (From Mansel R, Goyal A, Nestour EL, et al. and the Afimoxifene [4-OHT] Breast Pain Research Group. A phase II trial of Afimoxifene [4-hydroxytamoxifen gel] for cyclical mastalgia in premenopausal women. *Breast Cancer Res Treat* 2007;106[3]:389–397, with permission.)

the 80 mg/day group it was 31%. No major side effects were reported, but the study needs repeating with larger numbers to determine the true efficacy of isoflavones.

ALTERNATIVE APPROACHES

Acupuncture has been used for the treatment of premenstrual syndrome with some improvement of symptoms, but a recent study from the Mayo Clinic showed that pain scores measured on a 10-point brief inventory scale showed a clinically meaningful improvement in 67% of patients with the worst pain (30). The authors have suggested a randomized trial is required to confirm the findings, but this would be difficult to blind from the patient and placebo responses would be difficult to evaluate. At Guy's Hospital in an open pilot study, applied kinesiology was used in 88 women with self-rated moderate or severe mastalgia present for more than 6 months. This technique uses a type of pressure massage and is a hands-on technique based on improving lymphatic flow. Using self-rated pain scores, there was improvement in 60% and complete resolution in 18%, but as with the acupuncture trials, this trial was not blinded, and the response may have been due to placebo effects.

A randomized trial of *Vitus agnus-castus* extract (castor oil, Mastodynon) showed a modest fall in VAS scores on the plant extract (54% compared with 40% on placebo), with few side effects (Mastodynon).

Ghent et al. (31) investigated the effect of iodine replacement in women with breast pain in three different studies, one of which was a randomized, double-blinded, placebo-controlled trial. The rationale was that iodine deficiency in Sprague-Dawley rats led to mammary epithelial hyperplasia and carcinoma. Participants were treated for 6 months with aqueous molecular iodine 0.07 to 0.09 mg/kg daily, or placebo composed of an aqueous mixture of brown vegetable dye and quinine. Pain improvement occurred in 11 of 33 (33%) of the placebo group and 15 of 23 (65%) of those given iodine. No side effects were reported. More recently Kessler (32) studied supraphysiologic doses of iodine in cyclic mastalgia and reported that approximately 40% of patients obtained more than 50% reduction in breast pain on 3 to 6 mg iodine daily compared with 8% on placebo.

EXTRA MAMMARY PAIN

Pain originating within the thorax or abdomen and referred to the breast area is managed by treatment of the underlying condition. Pain that originates from the thoracic wall (Tietze's syndrome or costochondritis) and localized specific tender areas in the breast (trigger spots) can be managed by injection of steroid and local anesthetic. More recently, nonsteroidal analgesics have been used as topical gel applications and their use is supported by a large randomized trial of 108 women with both cyclic and noncyclic pain, which showed significant reduction in breast pain by diclofenac gel at 6 months compared with placebo gel (reduction in pain measured on visual analog scale from 0 = no pain to 10 = intolerable pain; cyclic 5.87 with diclofenac vs. 1.30 placebo; noncyclic 6.33 diclofenac vs. 1.12 placebo, $p < .001$) (33).

ROLE OF SURGERY

Severely distressed nonresponders to drug therapy may ask for mastectomy. This drastic step should not be undertaken before a full psychiatric assessment has been sought because without careful selection, surgical intervention will damage body image without achieving pain relief. Even after careful psychiatric assessment, excisional surgery should very rarely be undertaken because clinical experience has shown that pain reduction is achieved in only a small number of patients. This is not surprising because the etiology of breast pain is poorly understood, and there are causes of pain that lie outside the breast tissue. In the author's experience the focus on pain will often move to body image after mastectomy and this leaves an unhappy patient who still complains of breast pain, which is clearly therapeutic failure.

A recent overview has considered the role of drugs in the treatment of mastalgia. Srivastava et al. considered the range of drugs available but concluded that the only effective drugs were tamoxifen, bromocriptine, and danazol (34). Many of the studies considered were rejected for poor design or methodology.

The precise mechanisms behind many of the symptomatic presentations of benign breast change remain unclear, but the various hypotheses have been summarized in a review by Santen and Mansel (35).

MANAGEMENT SUMMARY

- The essentials of treatment of women with breast pain are excluding serious underlying pathologic processes, making a diagnosis, and communicating this to the patient to reassure the majority. Only a small proportion (<10%) have problems of such severity and duration that specific treatment is necessary.
- If moderate or severe pain has been present for less than 6 months, a high probability exists of spontaneous remission after reassurance, and no specific treatment should be given.
- In women older than 35 years of age who have not had mammography within the past 12 months and are presenting with a new symptom, mammography should be carried out to exclude abnormalities that may be unrelated to the breast pain.
- The initial approach to therapy should include analgesics, including nonsteroidal antiinflammatory agents, and dietary modifications, although these may work principally through placebo effects.
- The small group with severe, prolonged pain resistant to the above measures should be encouraged to keep a pain chart and return after 6 weeks. If the pain persists, treatment should be started with either tamoxifen or danazol. The former has fewer side effects and can be very effective. Although not licensed specifically for treatment of mastalgia, tamoxifen can be prescribed.
- Treatment should be given at a dosage of 10 mg per day for 3 months. If this achieves pain relief, the dose can be further reduced to 10 mg on alternate days for a further 3 months. For the few who do not respond, a higher dosage of 20 mg per day should be given.
- The very few who do not respond to this treatment should be switched to danazol or goserelin for 4 months.

CHAPTER 7

Abnormalities of the Breast in Pregnancy and Lactation

Richard B. Wait and Holly S. Mason

CHAPTER CONTENTS

Breast disease during pregnancy and lactation can represent a clinical and diagnostic dilemma for the clinician due to the significant change to the breast parenchyma from hormone-related hypertrophy and increased vascularity. These changes affect the clinical breast examination as well as alter the efficacy of the currently available imaging modalities. Added to this is the need to balance concern for the mother with concern for the fetus. Breast cancer remains one of the most common types of cancer to be diagnosed during pregnancy or in the lactational period (1) (see Chapter 67); benign breast disease, however, is even more prevalent during this period. It is critical for the physician to remain as diligent in the evaluation of any breast abnormality in the pregnant or lactating patient as one would in any other woman. This chapter reviews the current state of the diagnosis and treatment of benign breast disease during pregnancy and lactation.

EVALUATION

Clinical Breast Examination

During the course of pregnancy, pregnancy-related hormones (estrogen, progesterone, and prolactin) cause breast tissue to undergo significant changes that lead to increased volume and density (see Chapter 1). During the first trimester, the ratio of fatty tissue to glandular tissue decreases; as the volume of glandular tissue increases, so does the overall volume of the breast. As the pregnancy progresses, these changes intensify and make the evaluation of any breast abnormality more difficult. It is preferred, therefore, for the pregnant patient to have a baseline clinical breast examination during the first trimester before these changes have occurred. As the number of women who become pregnant during their fourth decade increases, it is likely that more women will present already having had a baseline mammogram before becoming pregnant. A prior mammogram and any other imaging study obtained before pregnancy may help facilitate the evaluation of a new mass.

The pregnant patient who presents with a new mass or physical finding should be evaluated and followed very closely. If observation is chosen after completion of the appropriate workup (described later in this chapter), a short interval follow-up examination is indicated because delay in examination may allow pregnancy-related changes (such as an increase in volume or nodularity) to obscure the physical finding. Because the pregnant patient does not undergo the cyclic hormonal changes that the nonpregnant patient experiences, persistence of a mass after a short interval warrants further attention (Fig. 7-1). Ultimately, it is the responsibility of the clinician who identifies a breast mass to rule out a pregnancy-associated breast cancer.

Diagnostic Imaging Issues in Pregnancy and Lactation

When evaluating a pregnant patient, consideration must be given to minimizing exposure of ionizing radiation to the fetus. For this reason, ultrasonography is an ideal first option in the evaluation of a breast mass in this patient population. Ultrasound is a reliable means of differentiating a fluid-filled structure (cyst) versus a solid mass. It can assess the margins and shape of a solid mass or identify shadowing, which may help differentiate a benign mass (e.g., lymph node or adenoma) from a malignancy. Ultrasound can easily guide aspiration of a cyst or percutaneous biopsy of a suspicious mass. An important benefit of ultrasound is that it is less affected by pregnancy-related changes than is mammography. Ultrasound can have 100% sensitivity for identifying malignancy as seen in multiple studies, and high specificity rates are seen as well (Table 7-1). For these reasons, ultrasound is the optimal first imaging study employed for a pregnancy-related breast mass.

The use of mammography in this patient population, on the other hand, remains controversial. There is concern over the potential for exposure of the fetus to ionizing radiation but, with proper abdominal shielding, exposure to the fetus is considered negligible (5). A second issue affecting the use of mammography, however, is the potential for lowered sensitivity owing to the increased density of the pregnant breast and the decrease in adipose tissue-to-breast parenchyma ratio (6), although this is not universally seen

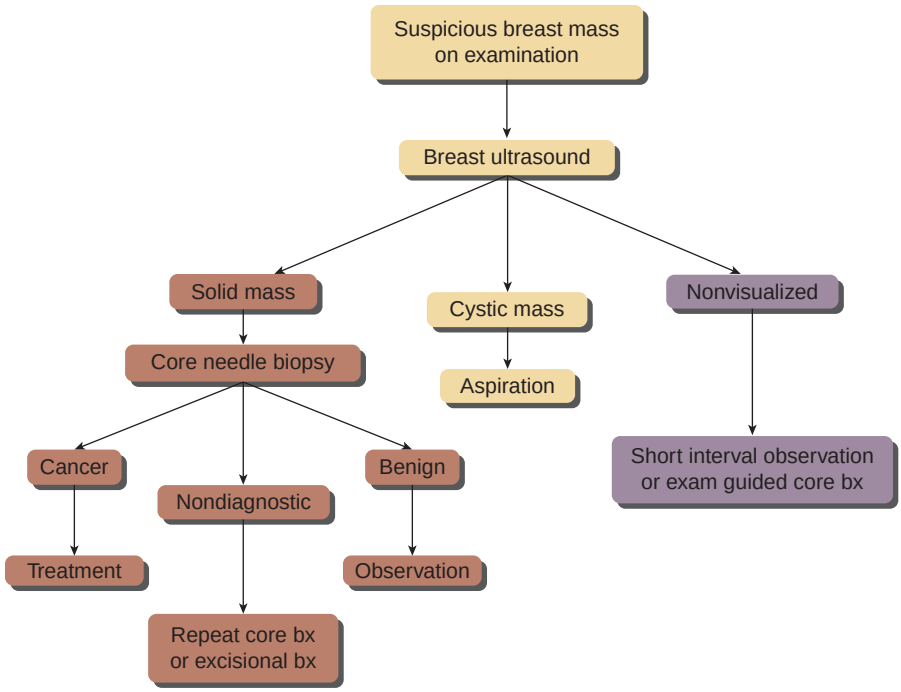

FIGURE 7-1 Flow diagram for management of clinically suspicious breast masses during pregnancy.

(3,7). Yang et al. (2) documented that a malignancy was visualized in 18 of 20 patients (90%) with breast cancer despite the breast density issue. The lactating patient can improve the quality of the mammographic study by emptying her breast either by nursing or pumping immediately prior to the study. In general, mammography should not be the primary imaging tool if there is a suspicious physical examination finding in a pregnant patient. If a patient has a suspicious discrete mass on examination that is not visible on ultrasound, tissue diagnosis with percutaneous biopsy can be performed. Mammography is more useful in the lactating patient or in the newly diagnosed pregnant patient to assess for calcifications or extent of disease.

Magnetic resonance imaging (MRI) of the breast has been used increasingly in the evaluation and treatment of breast cancer. At this time, however, it has not been well studied in the pregnant patient. Pregnancy-associated changes alter the ratio of parenchyma to adipose tissue, causing increased flow and permeability (8). In addition, gadolinium (the contrast agent used in breast MRI) crosses the placenta and, therefore, is a pregnancy category C drug. It is advised to wait until after first trimester if breast MRI is judged to be absolutely necessary (9). Gadolinium uptake in lactating breast tissue can mimic malignancy, however, and result in a false-positive study result (8). MRI is currently not indicated in the pregnant or lactating patient for these reasons.

Tissue Biopsy in the Pregnant and Lactating Patient

Percutaneous biopsy has become the standard of care for tissue diagnosis of any breast mass or imaging abnormality in any patient. Surgical incisional or excisional biopsy for diagnosis necessitates an incision and there is a potential need to return for additional surgery if the biopsy reveals malignancy. Each operation contains risks to both the patient and the fetus that should be minimized if possible. Thus, the clinician must protect the fetus while ensuring appropriate treatment for the patient. A secondary benefit to percutaneous biopsy over surgery for diagnosis should be minimal disruption of the ductal structures of the breast

TABLE 7-1

Sensitivity and Specificity of Ultrasonography and Mammography in Pregnant Women or Lactating Women

Author	*No. of Patients*	*Imaging Study*	
		Ultrasound (Sensitivity/Specificity)	*Mammography (Sensitivity/Specificity)*
Yang et al. (2)	23	100%/NR	90%/NR
Robbins et al. (3)	134	100%/86%	100%/93%
Ahn et al. (4)	22	100%/NR	86.7%/NR

Specificity data are not available in all studies (NR = not reported). There are currently no data on the sensitivity of breast MRI in the pregnant patient.

to facilitate successful lactation. An in-depth discussion of the risks and benefits of biopsy needs to be held with the patient to allow for informed consent.

For many years, fine-needle aspiration biopsy (FNAB) was thought to be the best method of percutaneous tissue diagnosis. In the pregnant or lactating patient, the hormone-mediated hyperproliferation of ductal cells can, however, result in a false-positive diagnosis in the hands of an inexperienced cytopathologist (10). In addition, FNAB can miss the intended target, causing a false-negative result. Percutaneous core biopsy can be more accurate and will provide the cellular architecture needed for a more definitive diagnosis. Excisional biopsy should be undertaken only when there is a lack of concordance between clinical suspicion, imaging result, and percutaneous biopsy result (Fig. 7-1). If an excisional biopsy is intended in the pregnant patient, surgery should be carefully planned to minimize the risk to the fetus from anesthesia, including fetal monitoring if indicated. Local anesthesia alone is the preferred method in these cases.

Care must be taken in this patient population to minimize complications. Gestational or lactational breast tissue is hypervascular, and meticulous hemostasis is mandatory with any intervention to prevent hematoma formation. Breast milk provides a good culture medium for bacteria and, therefore, efforts must be made to minimize the risk of infection. To prevent milk stasis after a biopsy, the lactating patient should either nurse or express milk regularly. If infection should develop, appropriate antibiotics should be administered.

The development of a milk fistula, a tract between a lactiferous duct and the skin, is a potential complication of any percutaneous or surgical intervention. The risk of milk fistula, whether from FNA, core biopsy, or excision, is not well documented, although case reports exist in the literature. Some clinicians suggest breast binding as a means of facilitating cessation of milk leakage, but this is not likely to succeed. Bromocriptine, a dopamine agonist that decreases prolactin levels, can be used to treat a milk fistula, but it is not routinely recommended. Cessation of lactation will allow the fistula tract to heal, and remains the only reliable method to control a milk fistula (11). If possible, the patient should stop lactation 1 week before the biopsy to minimize this risk.

CLINICAL PROBLEMS

Inflammatory and Infectious Problems in Pregnancy

Breast milk represents a lactose-rich culture medium and, thus, inflammatory or infectious problems remain the most common issues for the pregnant patient (12). Milk stasis, or poor emptying of milk from the breast, results from ineffective suckling, restriction of frequency of feeds, or blockage of milk ducts (13). Poor infant attachment to the breast can lead to cracking of the nipple epithelium, which is thought to allow bacteria to enter the breast in a retrograde direction via the terminal ducts, and it has been shown to be a risk factor for mastitis. Milk stasis provides a medium for bacterial growth and injury to the nipple, with subsequent bacterial translocation. This can then lead to a generalized infection (mastitis) with fever, redness, and tenderness, and it may also result in a breast abscess. *Staphylococcus aureus* is the most common organism (Table 7-2) and usually it can be treated with oral antibiotics (14). Other known risk factors for mastitis include advanced maternal age, low parity, difficulty breast-feeding, or employment outside the home (15). It is most important to continue the expression of breast milk to allow for complete emptying of the breast and symptom relief. Education concerning proper emptying, positioning of the infant, and nipple hygiene should be a key component to prevent future episodes of mastitis (13).

TABLE 7-2

Organisms Found in Mastitis or Breast Abscess (in order of frequency)

Staphylococcus aureus
S. epidermidis
Streptococcus (alpha, beta, and nonhemolytic)
Escherichia coli
Candida (rare)

From World Health Organization. *Mastitis: causes and management.* Geneva, Switzerland: WHO/FCH/CAH/00.13; 2000.

A breast abscess will not resolve with antibiotics alone, however, and further intervention is necessary. Ultrasound will help differentiate mastitis from a breast abscess. Repeated aspiration can be successful and it can avoid a disfiguring incision and drainage (16). Aspirate cultures should be taken to ensure appropriate antibiotic coverage. Skin and parenchymal biopsies should be considered to rule out inflammatory breast cancer if no improvement is seen. Despite concerns of the risk to the infant from bacterial contamination in the breast milk, the World Health Organization currently does not recommend cessation of breast-feeding in the presence of a breast abscess (13).

Management of Breast Masses in Pregnancy and Lactation

Most solid masses in the pregnant or lactating patient are benign lesions, such as fibroadenomas and hamartomas, and often predate the pregnancy. Any cause for a breast mass in the nonpregnant woman can also exist in pregnancy or the postpartum period.

Lactating adenomas are the most common cause of breast masses in this patient population and may arise secondary to hormones associated with pregnancy and lactation and are thought to be related to tubular adenomas, fibroadenomas, or hyperplasia (17). Biopsy can determine if a mass is a true lactating adenoma or is caused by lactational change in a preexisting fibroadenoma. Most of these lesions will involute once lactation has stopped, although excision may be required for those that do not. Hemorrhage or infarction will occur in 5% of lactating adenomas owing to vascular insufficiency seen occasionally in pregnancy-induced proliferative breast tissue (18).

Galactoceles are milk-filled cysts, which are thought to occur because of ductal obstruction during lactation. These usually present as tender masses; ultrasound can differentiate a galactocele from a solid mass. Asymptomatic patients can safely be observed. Local breast care, including ice packs and breast support, may help alleviate the discomfort, although aspiration provides the greatest likelihood of symptom relief (12). Rarely, galactoceles can become infected, but they can be effectively treated with repeated aspiration or drain placement in addition to appropriate antibiotics (16).

TABLE 7-3

Frequency of Pathology Types of Pregnancy-Related Breast Masses

Pathology	*Collins et al. (20)*	*Son et al. (6)*	*Slavin et al. (17)*
All nonpregnancy benign neoplasms[a]	4/19	2/29	18/30
All pregnancy-related benign neoplasms	14/19	18/29	12/30
[b]Infection		9/29	
Benign or fibrocystic breast tissue	1/19		

[a]Tubular adenoma, fibroadenoma, hamartoma, adenofibroma, lipoma, papilloma, phyllodes tumor.
[b]Lactating adenoma, lobular hyperplasia, galactocele or other changes "coincident with pregnancy."

Localized breast infarction can occur in the pregnant or lactating breast and often results in a palpable mass that must be differentiated from breast cancer (19). Other benign breast lesions, such as fibroadenomas, lipomas, and papillomas, can occur in these patients and, overall, are just as likely to be the cause of a breast mass as pregnancy-related lesions (6,17,20) (Table 7-3).

Bloody Nipple Discharge

The presence of bloody nipple discharge creates significant patient anxiety because of its association with breast cancer. In the nonpregnant patient, the evaluation of bloody nipple discharge has been well described (see Chapter 6). The workup in the pregnant or lactating patient remains controversial because of the issues with imaging as previously discussed. As in the nonpregnant population, most cases of bloody nipple discharge are of benign etiology.

Bloody nipple discharge can occur as a result of the epithelial proliferation and new capillary formation that occurs during the second and third trimesters (12). A careful clinical breast examination should be performed to identify if the discharge is from a single duct or multiple ducts as multiple-duct discharge is likely to be of physiologic etiology. The location of the draining duct should be carefully documented. The use of cytology is controversial due to low sensitivity rates that can be seen even in the nonpregnant, nonlactating patient (21). Cytology that shows benign ductal cells or is a "nondiagnostic evaluation" should not preclude further evaluation. If the examination does not reveal a palpable mass, retroareolar ultrasound can be undertaken. If retroareolar ultrasound is negative, imaging with mammography and ductography can be performed to identify the lesion location, which then should be biopsied. Terminal duct excision remains an option if all other diagnostic studies are negative, but potential difficulty with postoperative lactation should be discussed with the patient as part of the informed consent.

MANAGEMENT SUMMARY

- Most problems related to the breast in the pregnant or lactating patient are of benign origin; a thorough clinical and imaging evaluation is mandatory, however, to rule out malignancy.
- Ultrasound remains the imaging technique of choice for initial evaluation because of both its safety and sensitivity.
- Percutaneous core biopsy is the preferred method to obtain a tissue diagnosis of a solid mass, although FNA remains an acceptable option. Although not the preferred method of diagnosis, surgical excision may be appropriate in certain circumstances. Surgical excision of a biopsy-proved benign mass should be deferred either until pregnancy or lactation has been completed or until the risk to the fetus and mother can be minimized.
- Infectious or inflammatory problems remain a common cause of breast pathology during the pregnant or lactational period. Repeated aspiration with antibiotic therapy is an acceptable means of treating an abscess. If incision and drainage is undertaken, biopsy of the abscess wall is a reasonable undertaking for histologic evaluation and elimination of malignancy as a possible cause of the abscess.
- The management of bloody nipple discharge remains controversial. It is paramount to utilize imaging to identify the source, but terminal duct excision may be required for accurate diagnosis.

CHAPTER 8

Management of Gynecomastia

Glenn D. Braunstein

CHAPTER CONTENTS

Benign proliferation of the glandular tissue of the male breast constitutes the histologic hallmark of gynecomastia, which, if sufficiently great, appears clinically as palpable or visual enlargement of the breast. This condition, which is exceedingly common, may (a) be a sign of a serious underlying pathologic condition, (b) cause physical or emotional discomfort, or (c) be confused with other breast problems, most significantly carcinoma.

PREVALENCE

Breast glandular proliferation commonly occurs in infancy, during puberty, and in older age. It has been estimated that between 60% and 90% of infants exhibit the transient development of palpable breast tissue owing to estrogenic stimulation from the maternal–placental–fetal unit. This stimulus for breast growth ceases as the estrogens are cleared from the neonatal circulation, and the breast tissue gradually regresses over a 2- to 3-week period, but may persist longer. Although population studies have shown that the prevalence of pubertal gynecomastia varies widely, most have indicated that 30% to 60% of pubertal boys exhibit gynecomastia, which usually begins between 10 and 12 years of age, with the highest prevalence between 13 and 14 years of age (corresponding to Tanner stage III or IV of pubertal development), followed by involution that is usually complete by age 16 to 17 years (1). The percentage of men who exhibit gynecomastia increases with advancing age, with the highest prevalence found in the 50- to 80-year age range (Fig. 8-1). The prevalence of the condition in men ranges between 24% and 65%, with the differences between series being accounted for by the defining criteria and by the population studied (2).

PATHOGENESIS

No inherent differences appear to exist in the hormonal responsiveness of the male or female breast glandular tissue (3). The hormonal milieu, the duration and intensity of stimulation, and the individual's breast tissue sensitivity determine the type and degree of glandular proliferation. Under the influence of estrogens, the ducts elongate and branch, the ductal epithelium becomes hyperplastic, the periductal fibroblasts proliferate, and the vascularity increases. This histologic picture is found early in the course of gynecomastia and is often referred to as the *florid stage*. Acinar development is not seen in the male because it requires the presence of progesterone in concentrations found during the luteal phase of the menstrual cycle (3). Androgens exert an antiestrogen effect on rodent breast cancer models and the human MCF-7 breast cancer cell line; they are thought to antagonize at least some of the effects of estrogens in normal breast tissue (4). Accordingly, gynecomastia is usually considered to represent an imbalance between the breast-stimulatory effects of estrogen and the inhibitory effects of androgens. In fact, alterations in the estrogen-to-androgen ratio have been found in many of the conditions associated with gynecomastia. Such alterations can occur through a variety of mechanisms (Table 8-1; Fig. 8-2).

In men, the testes secrete 95% of the testosterone, 15% of the estradiol, and less than 5% of the estrone produced daily. Most of the circulating estrogens are derived from the extraglandular conversion of estrogen precursors by extragonadal tissues, including the liver, skin, fat, muscle, bone, and kidney (Fig. 8-2). These tissues contain the aromatase enzyme that converts testosterone to estradiol and androstenedione, an androgen primarily secreted by the adrenal glands, to estrone. Estradiol and estrone are interconverted in extragonadal tissues through the activity of the 17-ketosteroid reductase enzyme. This enzyme is also responsible for the interconversion of testosterone and androstenedione. When androgens and estrogens enter the circulation, either through direct secretion from gonadal tissues or from the sites of extragonadal metabolism, most are bound to sex hormone-binding globulin (SHBG), a protein derived primarily from the liver and one that has a greater affinity for androgens than for estrogens. The non-SHBG sex hormones circulate either in the free or unbound state or are weakly bound to albumin. These fractions are able to cross the plasma membrane of target cells and are bound to steroid receptors. Testosterone and dihydrotestosterone bind to the same hormone-responsive element. Each also binds to the hormone-responsive element of the appropriate genes, resulting in the initiation of transcription and hormone

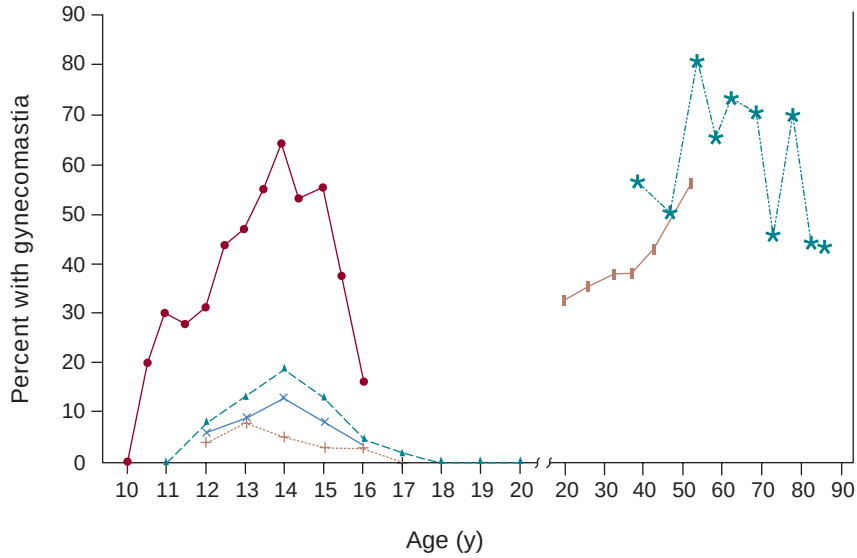

FIGURE 8-1 Prevalence of gynecomastia at various chronologic ages. Data were derived from multiple population studies. (Adapted from Braunstein GD. Pubertal gynecomastia. In: Lifshitz F, ed. *Pediatric endocrinology.* New York: Marcel Dekker, 1996:197–205, with permission.)

TABLE 8-1

Conditions Associated with Gynecomastia and Their Primary Pathophysiologic Mechanisms

Physiologic
- Neonatal
- Pubertal
- Aging

Pathologic
- Idiopathic
- Drug induced (see Table 8-2)
- Increased serum estrogen
  - Increased aromatization (peripheral and glandular)

action. A similar sequence of events occurs after the binding of estradiol or estrone to the estrogen receptor (5).

From a pathophysiologic standpoint, an imbalance between estrogen and androgen concentrations or effects can occur as a result of abnormalities at several levels (Table 8-1; Fig. 8-2). Overproduction of estrogens from testicular or adrenal neoplasms or enhanced extraglandular conversion of estrogen precursors to estrogens can elevate the total estrogen concentration. Such extraglandular conversion can occur directly in the breast tissue. Indeed, increased aromatization of androgens to estrogens has been noted in pubic skin fibroblasts from some patients with idiopathic gynecomastia (6). Elevations of the absolute quantity of circulating free estrogens can occur if estrogen metabolism is slowed or if SHBG-bound estrogens are displaced from the protein. Conversely, decreased secretion of androgens from the testes—caused primarily by defects in the testes or secondary to loss of tonic stimulation by pituitary gonadotropins, enhanced metabolic degradation of androgens, or increased binding of androgens to SHBG—results in decreases in free androgens that could antagonize the effect of estrogens on the breast glandular tissue. As noted previously, androgen and estrogen balance depends not only on the amount and availability of free androgens and estrogens but on their ability to act at the target tissue level. Thus, defects in the androgen receptor or displacement of androgens from their receptors by drugs with antiandrogenic effects (e.g., spironolactone) result in decreased androgen action and, hence, decreased estrogen antagonism at the breast glandular cell level. Finally, the inherent sensitivity of an individual's breast tissue to estrogen or androgen action may predispose some persons to development of gynecomastia even in the presence of apparently normal concentrations of estrogens and androgens.

ASSOCIATED CONDITIONS

Tables 8-1 and 8-2 list the various conditions and drugs that have been associated with gynecomastia. Although the list is relatively long, almost two-thirds of the patients have either pubertal gynecomastia (approximately 25%), drug-induced gynecomastia (10% to 20%), or no underlying abnormality detected (idiopathic gynecomastia, approximately 25%). Most of the remainder have cirrhosis or malnutrition (8%), primary hypogonadism (8%), testicular tumors (3%), secondary hypogonadism (2%), hyperthyroidism (1.5%), or renal disease (1%) (2). For most pathologic conditions, alterations in the balance between estrogen and androgen levels or action occur through several of the pathophysiologic mechanisms outlined in Table 8-1 and Figure 8-2. One of the best examples is the gynecomastia associated with spironolactone. This aldosterone antagonist inhibits the testicular biosynthesis of testosterone, enhances the conversion of testosterone to the less potent androgen androstenedione, increases the aromatization of testosterone to estradiol, displaces testosterone from SHBG (leading to an increase in its metabolic clearance rate), and binds to the androgen receptors in target tissues, thereby acting as an antiandrogen (7). For an in-depth discussion of

the pathophysiology of gynecomastia associated with each of the conditions listed in Tables 8-1 and 8-2, the reader is referred to several reviews (2,3,5,7–15).

EVALUATION

Most patients with gynecomastia are asymptomatic, with the condition detected during a physical examination. Patients with recent onset of gynecomastia owing to drugs or one of the pathologic conditions noted in Tables 8-1 and 8-2, however, may present with breast or nipple pain and tenderness. Approximately 10% to 15% of patients recall a history of breast trauma just before or at the time of discovery of the breast enlargement (15). It is unclear whether breast trauma itself causes gynecomastia. It is likely that, in many patients with an antecedent history of trauma, the breast irritation from the trauma actually led to the discovery of preexisting gynecomastia. Although half of patients have clinically apparent bilateral gynecomastia, histologic studies have shown that virtually all patients have bilateral involvement (16). This discrepancy may be explained by asynchronous growth of the two breasts and differences in the amount of breast glandular and stromal proliferation.

Gynecomastia must be differentiated from other conditions that cause breast enlargement. Although neurofibromas, dermoid cysts, lipomas, hematomas, and lymphangiomas may enlarge portions of the breast, these abnormalities are usually easily distinguished from gynecomastia on historical or clinical grounds. The two conditions that are most important to differentiate are pseudogynecomastia and breast carcinoma. *Pseudogynecomastia* refers to enlargement of the breasts owing to fat deposition rather than to glandular proliferation. Patients with this condition often have generalized obesity and do not complain of breast pain or tenderness. In addition, the breast examination should allow the correct diagnosis (Fig. 8-3). The breasts are examined while the patient is lying on the back with hands behind the head. The examiner places a thumb on one side of the breast and the second finger on the other side. The fingers are then gradually brought together without more than superficial pressure being applied to the skin. Patients with gynecomastia have a rubbery or firm disc of tissue that extends concentrically out from the nipple and that either is easily palpated or offers some resistance to the apposition of the fingers, whereas those with pseudogynecomastia exhibit no such mound of tissue, and no resistance is felt as the fingers are brought together (10). Alternatively, flat palpation with the finger can be used to detect the glandular tissue.

Differentiation of gynecomastia from breast carcinoma usually can be accomplished through careful physical examination. Carcinoma of the breast in men is usually eccentric in location and unilateral (rather than subareolar and bilateral) and is hard or firm, whereas gynecomastia tends to be rubbery to firm in texture. Patients with carcinoma may also exhibit skin dimpling and nipple retraction; they are more likely to have a nipple discharge (10%) than are patients with gynecomastia and may present with axillary lymphadenopathy (15,17). If the two conditions cannot be differentiated on clinical grounds, then mammography, fine-needle aspiration (FNA) for cytologic examination, or core or open biopsy should be done. There is no increased risk of breast cancer in men with gynecomastia followed for 20 or more years (18). Although some epidemiological studies have failed to find an association between Klinefelter's syndrome and breast cancer, the largest study found a 19.2-fold increased incidence compared to the general male population (19).

After a clinical diagnosis of gynecomastia has been made, several causes should be investigated through a thorough history and physical examination. A careful history of medication use is essential, specifically regarding ingestion of the drugs listed in Table 8-2. A history of liver or renal disease, especially if the patient has been receiving hemodialysis for

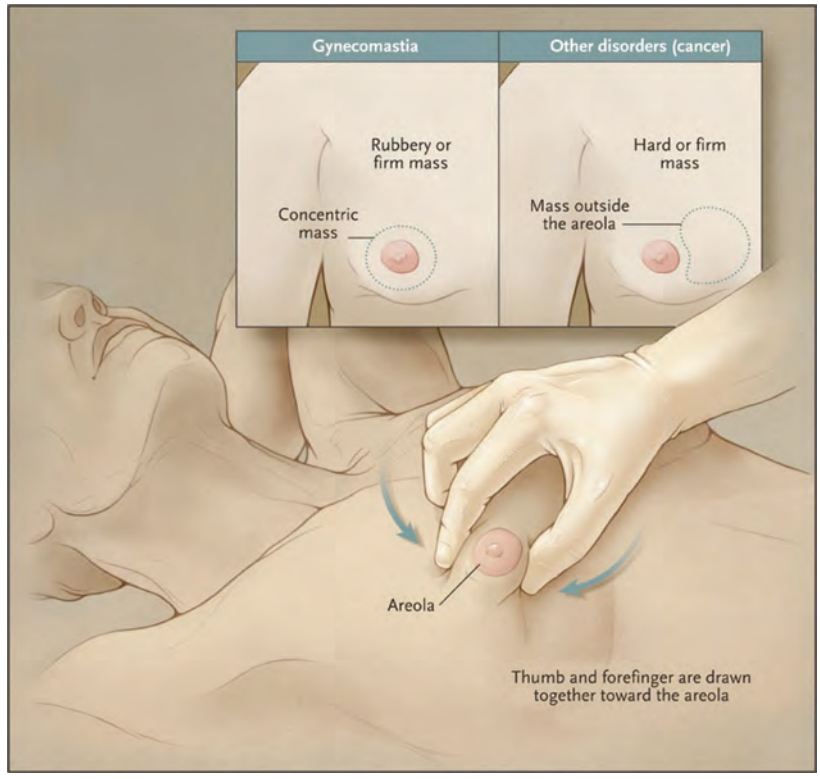

FIGURE 8-3 Differentiation of gynecomastia from pseudogynecomastia and other disorders by physical examination. (From Braunstein GD. Gynecomastia. *N Engl J Med* 2007;357:1229–1237, with permission.)

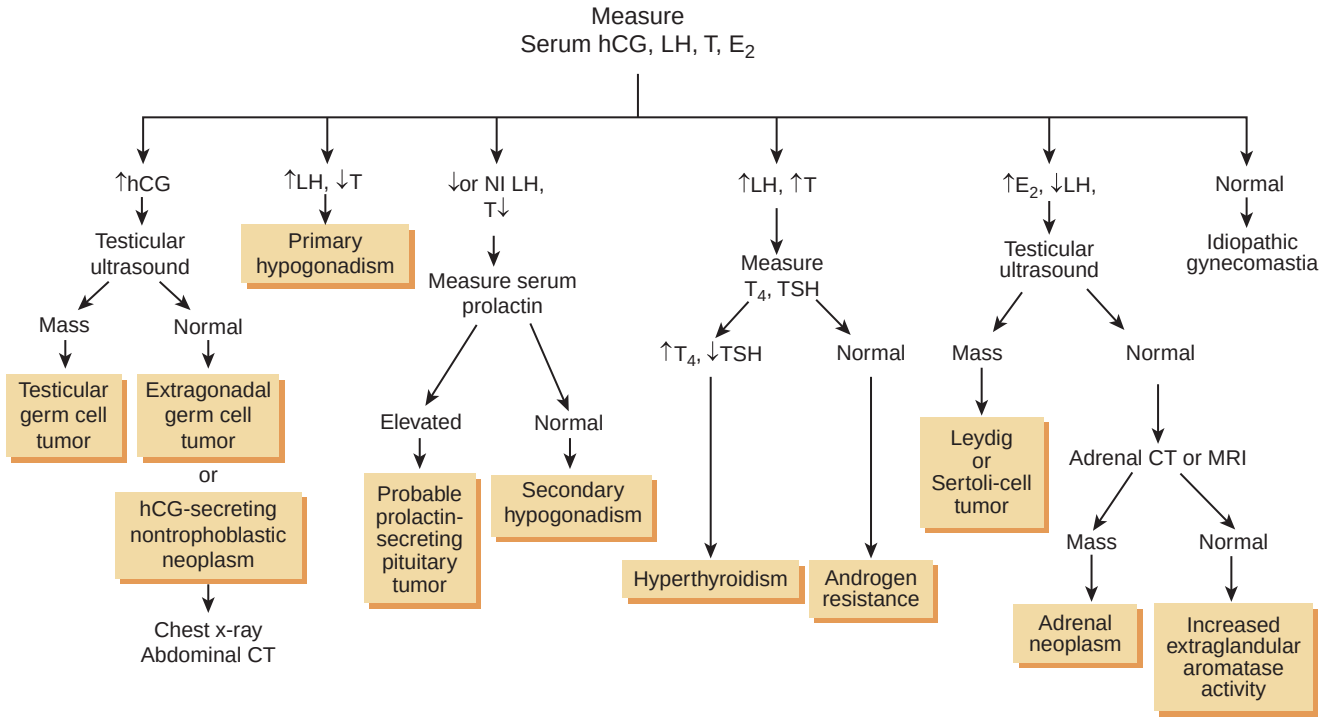

FIGURE 8-4 Algorithm providing interpretation of serum hormone levels and recommendations for further evaluation of patients with gynecomastia. CT, computed tomography; E_2, estradiol; hCG, human chorionic gonadotropin; LH, luteinizing hormone; MRI, magnetic resonance imaging; NI, normal; T, testosterone; T_4, thyroxine; TSH, thyroid-stimulating hormone. (From Braunstein GD. Gynecomastia. *N Engl J Med* 1993;328:490–495, with permission.)

the latter, may point to the underlying cause. A history of weight loss, tachycardia, tremulousness, diaphoresis, heat intolerance, and hyperdefecation, with or without the presence of a goiter, raises the possibility of hyperthyroidism. The patient should be evaluated for the signs and symptoms of hypogonadism, including loss of libido, impotence, decreased strength, and testicular atrophy. A careful examination for abdominal masses, which may be present in nearly one-half the patients with adrenocortical carcinoma, and a meticulous examination for testicular masses are essential parts of the evaluation.

The next step depends on the results of the clinical evaluation. If any of the drugs listed in Table 8-2 have been ingested, they should be discontinued and the patient reexamined in 1 month. If the drug was the inciting agent, then a decrease in breast pain and tenderness should occur during that time. If the patient is of pubertal age and has an otherwise negative general physical and testicular examination, he probably has transient or persistent pubertal gynecomastia. Reexamination at 3-month intervals should determine whether the condition is transient or persistent. At this time, medical or surgical therapy should be considered. If, during routine clinical examination, an adult is found to have asymptomatic gynecomastia without the presence of underlying disease, biochemical assessments of liver, kidney, thyroid function, and testosterone should be performed. In a patient with normal results, no further tests are necessary, but he should be reevaluated in 6 months. Conversely, if the gynecomastia is of recent onset or if the patient complains of pain or tenderness, additional studies—including measurements of serum concentrations of human chorionic gonadotropin (hCG), estradiol, testosterone, and luteinizing hormone—should be done, although the diagnostic yield is often low (20).

The algorithm outlined in Figure 8-4 can be used to discern the underlying abnormality, if any, that is responsible for the breast enlargement (6). An elevated level of hCG in the serum indicates the presence of a testicular or nongonadal germ cell tumor or, rarely, a nontrophoblastic neoplasm that secretes the hormone ectopically. Testicular ultrasonography should be done, and, if no testicular mass is found, a chest radiograph and abdominal computed tomographic scan or magnetic resonance imaging (MRI) study should be performed in an effort to localize an extragonadal hCG–producing tumor. Most nontrophoblastic tumors that secrete the hormone are bronchogenic, gastric, renal cell, or hepatic carcinomas. An elevated serum concentration of luteinizing hormone associated with a low testosterone level is indicative of primary hypogonadism, whereas a low testosterone level and a low or normal luteinizing hormone level suggest secondary hypogonadism owing to a hypothalamic or pituitary abnormality. Serum prolactin concentration should be determined in this situation to rule out a prolactin-secreting pituitary adenoma, which can cause hypogonadotropic hypogonadism. Elevated serum concentrations of luteinizing hormone and testosterone are found with hyperthyroidism and in patients with various forms of androgen resistance caused by androgen receptor disorders. Thyroid function tests can distinguish between these conditions.

If an elevated serum estradiol level is found along with a normal or suppressed concentration of luteinizing hormone, testicular ultrasonography is indicated to rule out a Leydig cell, Sertoli cell, or sex cord testicular tumor. If the ultrasonogram is negative, a computed tomographic scan or MRI scan of the adrenal glands should be done to detect an estrogen-secreting adrenal neoplasm. If both the testes and

adrenal glands appear normal, the increased estradiol level is probably caused by enhanced extraglandular aromatization of estrogen precursors to estrogens. In this situation, estrone levels are often relatively higher than estradiol concentrations. Finally, if all of these endocrine measurements are normal, the patient is considered to have idiopathic gynecomastia.

PREVENTION

Two situations exist in which gynecomastia can be prevented. The first is in patients who require a medication. Avoidance of the drugs listed in Table 8-2 decreases the risk for drug-induced breast stimulation. Also, not all the therapeutic agents in the drug groups listed in the table cause

TABLE 8-2

Drugs Associated with Gynecomastia

Hormones
Androgens and anabolic steroids (**F**)
Chorionic gonadotropin (**G**)
Estrogens and estrogen agonists (**G**)
Growth hormone (**G**)

Antiandrogens or Inhibitors of Androgen Synthesis
Bicalutamide (**G**)
Cyproterone (**G**)
Flutamide (**G**)
Gonadotropin-releasing hormone agonists (**G**)
Nilutamide (**G**)
5α-Reductase inhibitors (**G**)

Antibiotics
Ethionamide (**P**)
Isoniazid (**P**)
Ketoconazole (**G**)
Metronidazole (**P**)
Minocycline (**P**)

Antiulcer Medications
Cimetidine (**G**)
Lansoprazole (**P**)
Omeprazole (**F**)
Rabeprazole (**P**)
Ranitidine (**P**)

Cancer Chemotherapeutic Agents
Alkylating agents (**F**)
Cyclosporine (**P**)
Methotrexate (**P**)
Thalidomide (**P**)
Combination chemotherapy (**F**)

Cardiovascular Drugs
Amiodarone (**P**)
Amlodipine (**P**)
Captopril (**P**)
Clonidine (**P**)
Digoxin (**P**)
Diltiazem (**P**)
Enalapril (**P**)
Felodipine (**P**)
Methyldopa (**P**)
Nifedipine (**F**)
Reserpine (**P**)
Spironolactone (**G**)
Verapamil (**F**)

Psychoactive Agents
Aripiprazole (**P**)
Clozapine (**P**)
Diazepam (**P**)
Duloxetine (**P**)
Fluoxetine (**P**)
Haloperidol (**P**)
Olanzapine (**P**)
Paroxetine (**P**)
Perphenazine (**P**)
Phenothiazine (**P**)
Prochlorperazine (**P**)
Quetiapine (**P**)
Resperidone (**F**)
Sulpiride (**P**)
Thioridazine (**P**)
Trifluperazine (**P**)
Venlafaxine (**P**)
Ziprasidone (**P**)

Drugs of Abuse
Alcohol (**F**)
Amphetamines (**P**)
Heroin (**F**)
Marijuana (**P**)
Methadone (**F**)

Other
Auranofin (**P**)
Diethylpropion (**P**)
Domperidone (**P**)
Etretinate (**P**)
Fibrate (**P**)
Gabapentin (**P**)
Highly active antiretroviral therapy (HAART)
  Efavirenz (**F**)
  Indinavir (**P**)
  Stavudine (**P**)
Metoclopramide (**P**)
Penicillamine (**P**)
Phenytoin (**P**)
Pregabalin (**P**)
Statins (**P**)
Sulindac (**P**)
Theophylline (**P**)

Levels of evidence: Good (**G**), systematic review of randomized controlled trials, or randomized placebo-controlled trials, or prospective cohort studies with or without concurrent controls plus good pathophysiological explanation; Fair (**F**), retrospective studies, or case-control studies, or case series with good pathophysiological explanation; Poor (**P**), isolated case reports.

gynecomastia to the same extent. For example, when considering the use of a calcium channel blocker in an older man, the clinician should remember that nifedipine has been associated with the highest frequency of gynecomastia, followed by verapamil, with diltiazem having the lowest association (7,14). Among the mineralocorticoid antagonists, spironolactone, but not eplerenone is strongly associated with gynecomastia (14,21). Similarly, the incidence of gynecomastia in patients receiving histamine receptor or parietal cell proton pump blockers is highest with cimetidine, then ranitidine, and least with omeprazole (7,14). The second area of prevention occurs among patients with prostate cancer who are about to receive monotherapy with antiandrogens. Numerous studies have shown that prophylactic administration of the antiestrogen tamoxifen is superior to either the aromatase inhibitor anastrozole or low-dose breast irradiation (22,23).

TREATMENT

Discontinuation of the offending drug or correction of the underlying condition that altered the estrogen–androgen balance results in regression of gynecomastia in recent-onset breast growth. As was noted, histologic studies of the breast tissue from men with gynecomastia have shown a marked duct epithelial cell proliferation, inflammatory cell infiltration, increase in stromal fibroblasts, and enhanced vascularity early in the course of the disorder. It is during this proliferative, or florid, stage that patients may complain of breast pain and tenderness. This stage persists for a variable period, but usually lasts less than a year and is followed by spontaneous resolution or enters an inactive stage. There is a reduction in the epithelial proliferation, dilatation of the ducts, and hyalinization and fibrosis of the stroma (16,24). The inactive stage is usually asymptomatic. This histologic picture predominates in men whose gynecomastia is detected during a routine physical examination. When considering therapeutic approaches, it is important to appreciate that, after the inactive stage is reached, the gynecomastia is unlikely spontaneously to regress and is also unlikely to respond to medical therapies. Another important factor to consider is that most gynecomastia regresses spontaneously. Indeed, pubertal gynecomastia develops in a large proportion of boys, but very few exhibit persistent breast glandular enlargement. Similarly, in a group of patients with gynecomastia from various causes, 85% of untreated patients had spontaneous improvement (15). This finding emphasizes the difficulties in assessing the response to any medical intervention.

The indications for therapy are severe pain, tenderness, or embarrassment sufficient to interfere with the patient's normal daily activities. The objectives of surgery are to flatten the chest, eliminate the inframammary fold, align the two nipple-areola complexes, and conceal or contain the scars (25). Surgical removal of the breast glandular and stromal tissue has been the mainstay of interventional therapy. Subcutaneous mastectomy through a periareolar incision with contouring of the breast by suction-assisted lipectomy and ultrasound-assisted liposuction to remove the subglandular adipose tissue are currently the surgical procedure that are usually performed (25). These techniques should be used as primary therapy in patients with long-standing gynecomastia and as definitive therapy in patients who fail to respond to a series of medical therapies.

Three types of medical therapy—androgens, antiestrogens, and aromatase inhibitors—have been tested in patients with gynecomastia. Because this condition has a high frequency of spontaneous regression, the decision of when to treat is often difficult. It is also difficult to assess the use of most medications that have been tried, given the small sample sizes and nonblinded, uncontrolled designs of most studies. Nevertheless, with the exception of early pubertal gynecomastia that has been present for less than 3 months, a trial of medical therapy for patients with moderate to severe symptoms is recommended (26).

Testosterone administration has not been shown to be more effective than placebo in patients with pubertal or idiopathic gynecomastia and it carries the risk of exacerbating the condition by being aromatized to estradiol (15). Micronized testosterone has, however, been shown in a double-blind, placebo-controlled trial to reduce the prevalence of gynecomastia in men with liver cirrhosis after 6 months of therapy (26). Dihydrotestosterone, a nonaromatizable androgen, given either by injection or percutaneously, has been followed by a reduction in breast volume in 75% of patients, with complete resolution in approximately 15% (26). Responders had a decrease in breast tenderness within 1 to 2 weeks without side effects. The androgenic progestogen danazol has also been tried in uncontrolled trials and a single placebo-controlled study, with the latter showing a complete resolution in 23% of patients who received danazol and only a 12% response in those given placebo (26). Although the investigators believed that this drug was safe and well tolerated, other studies using danazol to treat other conditions have noted side effects, including edema, weight gain, acne, nausea, and muscle cramps.

The three antiestrogens that have been tested are clomiphene citrate, tamoxifen, and raloxifene. Response rates of 36% to 95% have been reported for clomiphene citrate, but two of the three systematic studies indicate that less than one-half of patients had a decrease in breast volume of 20% or more or were satisfied with the results (26). No side effects were noted by the investigators when the drug was used in dosages of 50 to 100 mg/day orally. In other settings, the drug has been associated with gastrointestinal distress and visual problems. Tamoxifen, given in dosages of 10 mg orally twice a day, has been studied in several uncontrolled as well as randomized, double-blind studies (26–28). Partial response is found in approximately 80% of the patients studied and complete regression noted in up to 60% of the patients. None of the studies has reported major side effects that are clearly medication-related from tamoxifen given in these doses, and, in view of its safety, the author usually recommends a 3-month trial of the drug for patients with painful gynecomastia. Raloxifene was reported to be partially effective in treating 10 patients with pubertal gynecomastia, but additional studies are needed to assess the true effectiveness of this drug (27).

The aromatase inhibitor testolactone has been given to a small number of patients with pubertal gynecomastia for up to 6 months at a dose of 450 mg/day orally without side effects (29). The authors of this uncontrolled study report a decrease in breast size after 2 months of therapy, but insufficient data currently exist to recommend this drug as a first-line agent. Anecdotal reports of the use of more potent members of this class of medications, such as anastrozole or letrozole, showed some benefit in individual patients (26). A study that examined anastrozole in a large group of patients with pubertal gynecomastia in a randomized, double-blind, placebo-controlled trial failed, however, to show a beneficial effect over placebo (30). In addition, anastrozole was found to be inferior to tamoxifen for preventing gynecomastia in patients with prostate cancer receiving antiandrogen monotherapy (22,23).

MANAGEMENT SUMMARY

- Gynecomastia, with its concentric enlargement of tissue radiating from beneath the nipple–areolar complex, needs to be differentiated from pseudogynecomastia (fatty breasts), cancer, and less common lesions.
- For a lesion that is unilateral, eccentric, or hard, breast cancer must be excluded through mammography or FNA, core, or open biopsy.
- Medications known to be associated with gynecomastia should be stopped or switched to another agent less likely to cause the problem. Breast pain and tenderness should remit within 1 month if the drug was the etiologic factor.
- If the patient is pubertal, a careful general physical and testicular examination should be performed and, if negative, the patient given reassurance, and seen again in 3 months.
- For breast enlargement that is of recent onset, is painful or tender, and hyperthyroidism or liver, adrenal, or testicular abnormalities are not present on physical examination, the clinician should measure serum concentrations of hCG, luteinizing hormone, estradiol, and free testosterone to differentiate among the pathologic causes of gynecomastia.
- If no reversible underlying cause is found and the patient has pain or tenderness or experiences embarrassment over the gynecomastia, a trial of medical therapy with tamoxifen or plastic surgical removal should be offered.

CHAPTER 9

Pathology of Benign Breast Disorders

Laura C. Collins and Stuart J. Schnitt

CHAPTER CONTENTS

The term *benign breast disorders* encompasses a heterogeneous group of lesions that may present as a palpable mass, a nonpalpable abnormality detected on breast imaging studies, or an incidental microscopic finding. Some are discrete lesions, such as fibroadenoma and intraductal papilloma, but a large number of benign breast biopsies exhibit a mixture of microscopic changes affecting the terminal duct lobular units. The two major goals in the pathologic evaluation of a benign breast biopsy are (a) to distinguish benign lesions from *in situ* and invasive breast cancer, and (b) to assess the risk of subsequent breast cancer associated with the benign lesion(s) identified.

BENIGN BREAST DISEASE AND BREAST CANCER RISK: NONPROLIFERATIVE LESIONS, PROLIFERATIVE LESIONS WITHOUT ATYPIA, AND ATYPICAL HYPERPLASIAS

It has been known for many years that some benign breast lesions are more highly associated with breast cancer than others. Two types of studies have evaluated this relationship. In the first type, the prevalence of benign alterations

TABLE 9-1

Categorization of Benign Breast Lesions According to the Criteria of Dupont, Page, and Rogers (3)

Nonproliferative
- Cysts
- Papillary apocrine change
- Epithelial-related calcifications
- Mild hyperplasia of the usual type

Proliferative lesions without atypia
- Moderate or florid ductal hyperplasia of the usual type
- Intraductal papilloma
- Sclerosing adenosis
- Fibroadenoma
- Radial scar

Atypical hyperplasia
- Atypical ductal hyperplasia
- Atypical lobular hyperplasia

in breasts with cancer was compared with their prevalence in breasts without cancer (1). While these studies demonstrated that some benign lesions are more common in cancer-containing breasts, the histologic coexistence of certain benign breast lesions with breast cancer is not sufficient to establish that those benign lesions impart an increased cancer risk.

More recent studies have evaluated the subsequent risk of developing breast cancer in patients who have had a benign breast biopsy and for whom long-term follow-up is available (2–6). In these studies, histologic sections of the benign biopsies were reviewed, and the type of benign lesions present were recorded and related to the risk of breast cancer. In some of these studies, it was also possible to study the interaction of the histologic findings with other factors, such as family history of breast cancer, time since biopsy, menopausal status, and other factors in determining cancer risk. The results of these studies have provided important information regarding the risk of breast cancer associated with benign breast lesions and this information is useful in patient treatment, counseling, and follow-up. These studies have further indicated that terms such as *fibrocystic disease, chronic cystic mastitis*, and *mammary dysplasia* are not clinically meaningful because they encompass a heterogeneous group of processes, some physiologic and some pathologic, with widely varying cancer risks.

The seminal study evaluating benign breast disease and cancer risk is the retrospective cohort study of Dupont et al. (3,7). In their study, the slides of benign breast biopsies from more than 3,000 women in Nashville were reviewed, and the histologic lesions present were categorized using strictly defined criteria (3,7) into one of three categories: nonproliferative lesions, proliferative lesions without atypia, and atypical hyperplasias (Table 9-1). The risk of developing breast cancer was then determined for each of these groups. This system provides a pragmatic, clinically relevant approach to benign breast lesions and has been supported by a consensus conference of the College of American Pathologists (8). Studies from other groups have largely confirmed the initial observations of the Nashville group and have extended these findings by providing important new information regarding benign breast disease and breast cancer risk (2–6) (Table 9-2).

Nonproliferative Lesions

Nonproliferative lesions, as defined by Dupont and Page (3), include cysts, papillary apocrine change, epithelial-related calcifications, and mild hyperplasia of the usual type.

Cysts are fluid-filled, round-to-ovoid structures that vary in size from microscopic to grossly evident (Fig. 9-1). *Gross cysts*, as defined by Haagensen (9), are those which are sufficiently large to produce palpable masses. Cysts are derived from the terminal duct lobular unit. The epithelium usually consists of two layers: an inner (luminal) epithelial layer and an outer myoepithelial layer. In some cysts, the epithelium is markedly attenuated or absent; in others, the lining epithelium shows apocrine metaplasia, characterized by granular eosinophilic cytoplasm and apical cytoplasmic protrusions ("snouts").

Papillary apocrine change is characterized by a proliferation of ductal epithelial cells in which all of the cells show apocrine features as described above. *Epithelial-related calcifications* are frequently observed in breast tissue and may be seen in normal ducts and lobules or in virtually any pathologic condition in the breast. It should be noted that calcifications may also be seen in the breast stroma as well as in blood vessel walls. *Mild hyperplasia of the usual type* is defined as an increase in the number of epithelial cells within a duct that is less than four epithelial cells in depth. In this type of hyperplasia, the epithelial cells do not cross the lumen of the involved space.

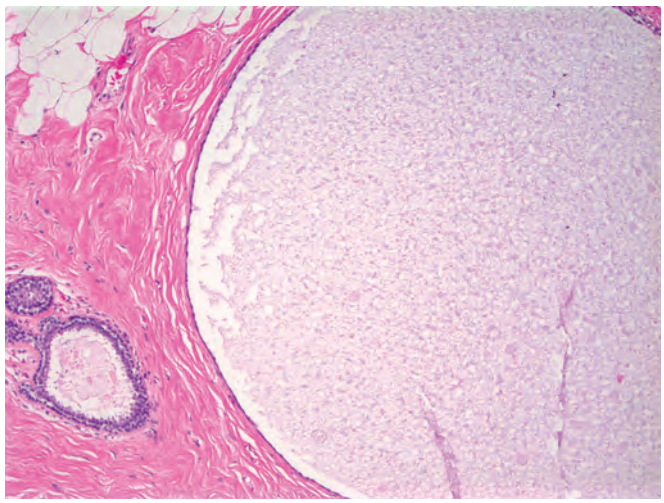

FIGURE 9-1 Cyst characterized by a large, dilated space filled with secretory material and lined by a flattened epithelial cell layer.

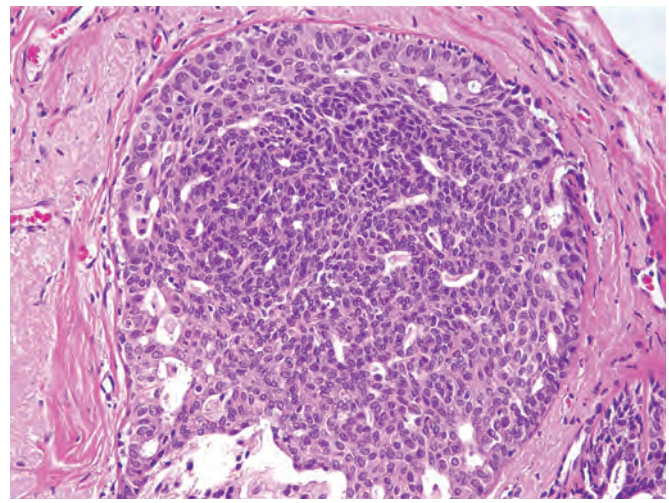

FIGURE 9-2 **Usual ductal hyperplasia.** A proliferation of cytologically benign epithelial cells fills and distends the duct. The nuclei vary in size, shape, and placement. The spaces within the duct are also variable in size and contour.

In the original study of Dupont and Page (3), 70% of the biopsies showed nonproliferative lesions. The risk of subsequent breast cancer among these patients was not increased, compared with that of women who have had no breast biopsy (relative risk [RR] 0.89), even in patients with a family history of breast cancer (in a mother, sister, or daughter). The only group of patients in the nonproliferative category with an increased risk of developing breast cancer was that with gross cysts plus a family history of breast cancer. The relative risk with gross cysts alone was 1.5, but was 3.0 in patients with gross cysts and a family history. It should be noted that, although Dupont and Page initially included fibroadenomas among the nonproliferative lesions, the results of a subsequent study by these investigators indicated a higher relative risk for breast cancer among patients with fibroadenoma than for patients with nonproliferative lesions (10). As a result, fibroadenomas are now included among the proliferative lesions without atypia (see the section on fibroadenomas).

Proliferative Lesions without Atypia

Included within the group of proliferative lesions without atypia are *usual ductal hyperplasia* (11) (also known as *moderate or florid hyperplasias of the usual type*), *intraductal papillomas, sclerosing adenosis,* and *radial scars* (3). As noted above, *fibroadenomas* are now included in this category as well. Women who have had a benign breast biopsy showing proliferative lesions without atypia, as defined previously, have a mildly elevated breast cancer risk, approximately 1.5 to 2.0 times that of the reference population (*intraductal papillomas, radial scars,* and *fibroadenomas* are discussed elsewhere in this chapter).

Usual ductal hyperplasias are intraductal epithelial proliferations more than four epithelial cells in depth. They are characterized by a tendency to bridge and often distend the involved space. The proliferation may have a solid, fenestrated or papillary architecture. If spaces remain within the duct lumen, they are irregular and variable in shape. These spaces are often slit-like and arranged around the periphery of the proliferation, with their long axes parallel to the basement membrane. The cells comprising this type of proliferation are cytologically benign and variable in size, shape, and orientation, and they often are arranged in a "swirling" pattern (Fig. 9-2). It is sometimes possible to discern multiple distinct cell populations, including epithelial cells, metaplastic apocrine cells, and myoepithelial cells (11).

Sclerosing adenosis is usually an incidental finding, but may present as a mammographic abnormality (microcalcifications, distorted architecture) or a mass lesion (also known as *nodular adenosis* or *adenosis tumor*). This lesion is composed of distorted epithelial, myoepithelial, and sclerotic stromal elements arising in association with the terminal duct lobular unit. This lobulocentric pattern is key to the correct diagnosis of sclerosing adenosis and its variants, and is best appreciated at low power microscopic examination (Fig. 9-3). The epithelium in sclerosing adenosis may undergo apocrine metaplasia, and is then referred to as *apocrine adenosis*. The apocrine metaplastic cells may show cytologic atypia, raising the differential diagnosis of invasive carcinoma if the lesion is examined at high microscopic power without accounting for the lobulocentric architecture appreciated at low power (12). Sclerosing adenosis may also be involved by atypical lobular hyperplasia, lobular carcinoma *in situ*, atypical ductal hyperplasia, or ductal carcinoma *in situ* (DCIS). Perineural "pseudoinvasion" may be present in approximately 2% of sclerosing adenosis cases and should not be confused with invasive carcinoma. Because of the distorted glandular pattern of sclerosing adenosis, this lesion may be confused with a low-grade invasive carcinoma, particularly tubular carcinoma. In contrast to the lobulocentric pattern of sclerosing adenosis, tubular carcinoma is infiltrative in nature, however, and does not conform to the normal breast ductal and lobular microanatomy. Although sclerosing adenosis is composed of distorted, elongated, or obliterated glands and tubules, tubular carcinoma is composed of angulated tubules with open lumens. The stroma of sclerosing adenosis is fibrotic or sclerotic compared with the desmoplastic stroma of invasive carcinoma. Importantly, as opposed to tubular carcinoma, sclerosing adenosis contains myoepithelial cells, which may be highlighted by immunohistochemistry.

Atypical Hyperplasias

Atypical hyperplasias have been defined as proliferative lesions of the breast that possess some, but not all, of the features of carcinoma *in situ* and are classified as either ductal

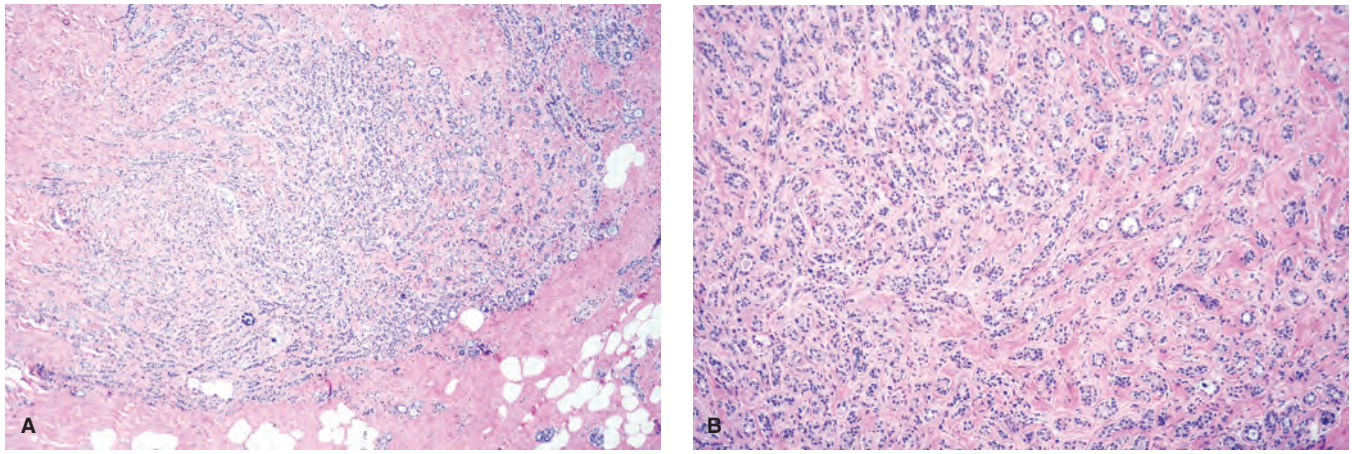

FIGURE 9-3 **Sclerosing adenosis. (A)** Low-power view demonstrates a lobulocentric proliferation of epithelial and stromal elements with scattered calcifications. **(B)** Higher-power view reveals glands and cords of epithelial cells entrapped in fibrotic stroma. The cells are cytologically benign, but the pattern simulates that of an invasive carcinoma.

or lobular type (3,7). *Atypical ductal hyperplasias* (ADH) are lesions that have some of the architectural and cytologic features of low-grade DCIS, such as nuclear monomorphism, regular cell placement, and round regular spaces, in at least part of the involved space. The cells may form tufts, micropapillations, arcades, bridges, solid, and cribriform patterns (11). A second cell population with features similar to those seen in usual ductal hyperplasia is also typically present (Fig. 9-4).

Atypical lobular hyperplasia (ALH) is composed of cells identical to those found in lobular carcinoma *in situ* (LCIS). These cells are monomorphic, evenly spaced, and dyshesive, with round or oval, usually eccentric nuclei and pale cytoplasm often with intracytoplasmic vacuoles (Fig. 9-5). Although criteria for the distinction between ALH and LCIS differ among experts, we utilize the criteria proposed by Page and Anderson (13) and diagnose ALH when the characteristic cells are present but less than one-half of the acini of a lobular unit are filled, distorted, or distended. In addition to involving lobular units, the cells of atypical lobular hyperplasia may also involve ducts (14).

It is important to note that with the increasing use of mammographic screening, atypical hyperplasias are being diagnosed more frequently than in the past. For example, when a biopsy is performed because of a palpable mass, atypical hyperplasia is seen in only about 2% to 4% of cases (3). In contrast, atypical hyperplasia was identified in 12% to 17% of biopsies performed because of the presence of mammographic microcalcifications (15).

Women who have had a benign breast biopsy that demonstrates atypical hyperplasia are at a substantially increased risk for developing breast cancer, approximately 3.5 to 5.0 times that of the reference population. Some studies have suggested that the risk associated with ALH is greater than that associated with ADH (2,7), but others have

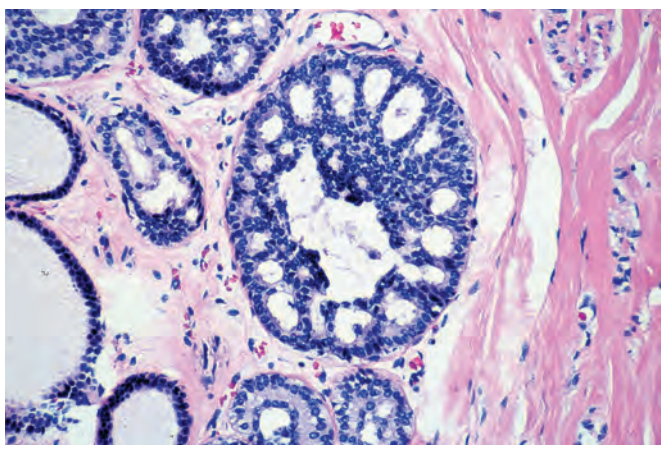

FIGURE 9-4 **Atypical ductal hyperplasia.** Near the center of this space is a proliferation of relatively uniform epithelial cells with monomorphic, round nuclei similar to those seen in low-grade ductal carcinoma *in situ*. However, these cells comprise only a portion of the proliferation within the space.

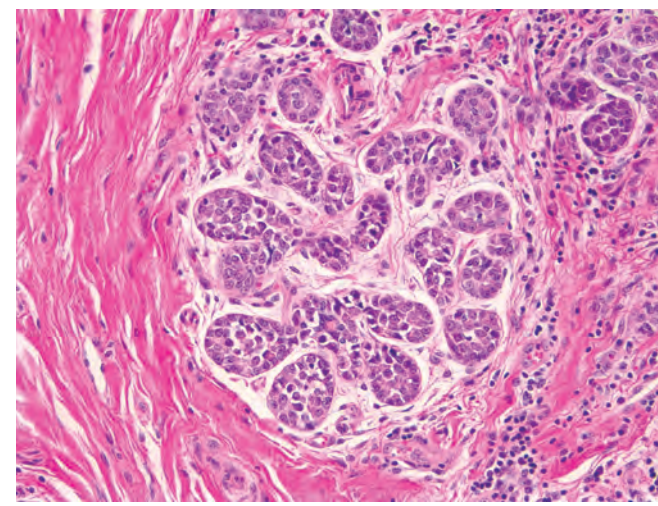

FIGURE 9-5 **Atypical lobular hyperplasia.** The acini of this lobule contain a proliferation of small uniform cells, which are dyshesive, and are identical to the cells that comprise lobular carcinoma *in situ*. However, the acini are not distended by this cellular proliferation.

TABLE 9-3

Relative Risk of Breast Cancer According to Type of Atypical Hyperplasia

Mayo Clinic (16)	3.9 (3.0–4.9)	3.8 (2.5–5.6)	3.7 (2.5–5.3)

[a]Numbers in parentheses represent 95% confidence intervals.

not (16) (Table 9-3); at the present time this issue remains unresolved. Patients whose biopsies showed ALH involving both lobules and ducts had a higher relative risk of developing cancer (RR 6.8) than those with either ALH alone (RR 4.3) or those with only ductal involvement by atypical lobular hyperplasia (RR 2.1) (14).

Columnar Cell Lesions and Flat Epithelial Atypia

Lesions of the breast characterized by enlarged terminal duct lobular units lined by columnar epithelial cells are being encountered increasingly in breast biopsies performed because of mammographic microcalcifications. Some of these lesions feature banal columnar cells in either a single layer (columnar cell change) or showing stratification and tufting, but without complex architectural patterns (columnar cell hyperplasia). In other columnar cell lesions, the lining cells exhibit cytologic atypia, most commonly of the low-grade, monomorphic type. Such lesions were included among lesions originally categorized by Azzopardi as "clinging carcinoma" (monomorphic type) (17), and were more recently included among lesions designated *flat epithelial atypia (FEA)* (11) (Fig. 9-6). The role of columnar cell lesions and, in particular, FEA in breast tumor progression is still emerging. FEA commonly coexists with well-developed examples of ADH, low-grade DCIS, and tubular carcinoma (11). These findings, in conjunction with the results of recent genetic studies (11), suggest that FEA is a neoplastic lesion that may represent either a precursor to, or the earliest morphologic manifestation of, DCIS. The few available clinical outcome studies suggest, however, that the risk of progression of FEA to invasive cancer is extremely low, lower even than that associated with ADH or ALH, supporting the notion that categorizing such lesions as *clinging carcinoma* and managing them as if they were fully developed DCIS will result in overtreatment of many patients (11). Additional studies are needed to better understand the biological nature and the level of subsequent breast cancer risk associated with these lesions.

Factors Modifying Breast Cancer Risk in Women with Biopsy-Proven Benign Breast Disease

A number of factors appear to modify the breast cancer risk associated with biopsy-proven benign breast disease, including a family history of breast cancer, time since biopsy, menopausal status, and the appearance of the background breast tissue.

Family History

There is general agreement that the presence of a family history of breast cancer in a first-degree relative (mother, sister, or daughter) is associated with a slight increase in the breast cancer risk in women with proliferative lesions without atypia (3–7). The influence of family history on breast cancer risk in women with atypical hyperplasia is less clear, however. Dupont et al. (3,7) reported that the risk among patients with both atypical hyperplasia and a family history of breast cancer was twice that of women with atypical hyperplasia without a family history. Similarly, in a study conducted by the Breast Cancer Detection Demonstration Project (BCDDP), the presence of a positive family history substantially increased the breast cancer risk among women with atypical hyperplasia (4). In a recent update of the Nurses' Health Study (6) and in a recent study from the Mayo Clinic (5), the presence of a positive family history was not, however, associated with a further increase in breast cancer risk among women with atypical hyperplasia (Table 9-4). Additional studies are needed to clarify this important issue.

Time since Biopsy

Information regarding the relationship between time since benign breast biopsy and breast cancer risk is available from several studies. In the Nashville study, women with prolifera-

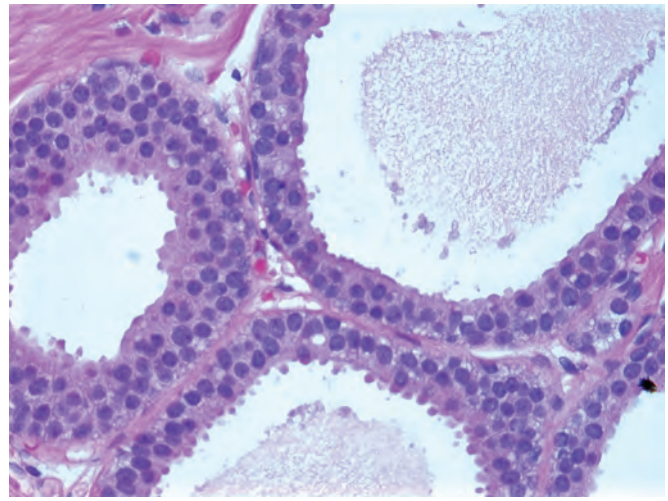

FIGURE 9-6 **Flat epithelia atypia.** The normal epithelial cells in the acini of this terminal duct are replaced by a population of columnar epithelial cells with round, monomorphic nuclei.

TABLE 9-4

Effect of Family History of Breast Cancer on Relative Risk of Breast Cancer

Study	*Proliferative without Atypia*		*Atypical Hyperplasia*	
	No Family History[a]	*Family History*[a]	*No Family History*[a]	*Family History*[a]
Nashville (3)	1.5 (1.2–1.9)	2.1 (1.2–3.7)	3.5 (2.3–5.5)	8.9 (4.8–17.0)
Nurses' Health Study (6)	1.5 (1.1–2.1)	2.5 (1.6–3.7)	4.3 (2.9–6.0)	5.4 (3.0–9.6)
Breast Cancer Detection Demonstration Project (4)	1.7 (0.9–3.2)	2.6 (1.0–6.4)	4.2 (1.4–12.0)	22.0 (2.3–203)
Mayo Clinic (5)	1.6 (~1.4–2.0)[b]	2.2 (~1.5–3.0)[b]	3.0 (~1.7–4.9)[b]	4.0 (~2.0–7.0)[b]

[b]95% confidence intervals estimated from Figure 2 in Ref. (5).

tive lesions without atypia who remained free of breast cancer for 10 years after their benign breast biopsy were at no greater breast cancer risk than women of similar age without such a history. In addition, the breast cancer risk among women with atypical hyperplasia was greatest in the first 10 years after the benign breast biopsy (RR 9.8) and fell to a relative risk of 3.6 after 10 years (18). In contrast, in an analysis of data from the Nurses' Health Study, the breast cancer risk among women with proliferative lesions without atypia was similarly elevated before *and* after 10 years following the benign breast biopsy (RR 1.4 and 1.6, respectively). In addition, the risk associated with atypical hyperplasia was higher after 10 years (RR 5.2) than in the first 10 years after the benign breast biopsy (RR 3.3) (2). Similarly, in the Mayo Clinic study, an excess breast cancer risk was seen among women with biopsy-proven benign breast disease for at least 25 years after the benign breast biopsy (5). Among patients with atypical hyperplasia, the relative risk was persistently elevated beyond 15 years (16). More data are needed to clarify further the relationship between time since biopsy and breast cancer risk for women with benign breast disease, particularly for women with atypical hyperplasia.

Menopausal Status

The risk of breast cancer among women with atypical hyperplasia appears to be influenced by the patient's menopausal status. In the BCDDP study, premenopausal women with a biopsy showing atypical hyperplasia were at a substantially higher breast cancer risk (RR 12, 95% CI 1.0–68) than postmenopausal women with that diagnosis (RR 3.3, 95% CI 1.1–10) (4). In the Nurses' Health Study, the breast cancer risk associated with atypical hyperplasia as a group was similar in premenopausal and postmenopausal women (RR 3.9 and 3.8, respectively). Among premenopausal women, however, the risk associated with ALH was greater than the risk associated with ADH (RR 7.3 and 2.7, respectively). In contrast, the risk associated with ALH and ADH were similar in postmenopausal women (RR 3.4 and 4.0, respectively) (2). Of note, in both the BCDDP study and the Nurses' Health Study, the breast cancer risk among women with proliferative lesions without atypia did not vary according to menopausal status.

Another issue of clinical importance is the influence of postmenopausal hormone replacement therapy on the risk of breast cancer in women with biopsy-proven benign breast disease. Clinical follow-up studies have shown that women who take hormone replacement therapy are at increased risk for developing breast cancer (19). The use of hormone replacement does not, however, appear to further increase the risk in women with proliferative breast disease without atypia or in those with atypical hyperplasia. In an analysis from the Nurses' Health Study among women with proliferative lesions without atypia, the relative risks of breast cancer were similar for those women who never used postmenopausal hormones, who were past users, and who were current users (RR 1.6, 2.1, and 1.9, respectively). Similarly, among women with atypical hyperplasia, the relative breast cancer risks were not significantly different for those who had not used hormone replacement, for past users, and for current users (RR 3.4, 3.0, and 2.5, respectively) (20). Thus, the available data suggest that the use of hormone replacement therapy does not further increase the breast cancer risk among women with a history of biopsy-proven benign breast disease, even among those with atypical hyperplasia.

Background Breast Tissue

A study from the Mayo Clinic has suggested that the presence of lobular involution in the background breast tissue of a benign breast biopsy is associated with a significant decrease in the risk of breast cancer. Furthermore, in that study the presence of lobular involution modified the risk in women with proliferative lesions without atypia and in those with atypical hyperplasia. For example, the relative risk for the development of breast cancer was 7.8 (95% CI 3.6–14.8) for women with atypical hyperplasia without involution in the background breast tissue and 1.5 (95% CI 0.4–3.8) for those with both atypical hyperplasia and complete involution of the background breast tissue (21). Similar results have recently been reported for women enrolled in the Nurses' Health Study (22).

Laterality of Risk

Breast cancers that develop among women with atypical hyperplasia may occur in either breast. Overall, approximately 60% of cancers that develop in women with atypical hyperplasia occur in the ipsilateral breast; an excess of ipsilateral cancers is seen particularly in the first 10 years after the benign breast biopsy (2,5). Among women with ADH, about 55% of cancers occur in the ipsilateral breast (2,5,7). Among those with ALH, about 60% to 70% of the cancers occur in the ipsilateral breast (2). These observations suggest that the concept that atypical hyperplasias represent only risk indicators is overly simplistic and that, in at least some instances, these lesions may act as direct (albeit nonobligate) precursors to invasive breast cancer (23).

Consistency of Histologic Classification

The foregoing data provide compelling evidence that breast cancer risk varies with the histologic category of benign breast disease. They further indicate that the risk among women with biopsy-proven benign breast disease is influenced by other factors as well. To counsel individual patients properly, an understanding of the difference between relative risk and absolute risk is necessary. The *relative risk* for breast cancer represents the incidence of breast cancer among women within a certain subpopulation divided by the incidence of breast cancer in the reference population. The magnitude of the relative risk is highly dependent on the breast cancer incidence in both the study group and the reference population. In contrast, a woman's *absolute risk* of breast cancer is her probability of developing breast cancer during some specified time period. For example, although the relative risk for patients with atypical hyperplasia and a family history of breast cancer in the study of Dupont and Page was 8.9, only 20% of patients in this group had developed breast cancer 15 years after their benign biopsy. Eight percent of patients with atypical hyperplasia but no family history, 4% of patients with proliferative lesions without atypia, and 2% of women with nonproliferative lesions developed breast cancer in 15 years (3).

Given the apparent clinical importance of distinguishing among the various types of benign breast disease, the ability of pathologists to categorize accurately and reproducibly such lesions and to distinguish them from carcinoma *in situ* is a matter of legitimate concern. A study by Schnitt and colleagues suggests that with standardization of histologic criteria among pathologists, interobserver variability in the diagnosis of proliferative breast lesions can be reduced. In that study, six experienced breast pathologists were instructed to use standardized diagnostic criteria (i.e., those of Page et al.) for categorizing a series of proliferative breast lesions. Complete agreement among all six pathologists was observed in 58% of the cases and all but one pathologist arrived at the same diagnosis in 71% (24). The results of this study and others like it indicate that, although the use of standardized histologic criteria improves interobserver concordance in the diagnosis of proliferative breast lesions, even under these circumstances some lesions defy reproducible categorization, particularly the distinction between ADH and limited examples of low-grade DCIS.

Some authors have advocated that qualitative criteria should be supplemented by quantitative criteria to aid in the distinction between ADH and low-grade DCIS. For example, Page et al. (7) require that all of the features of low-grade DCIS be uniformly present throughout at least two separate spaces before DCIS is diagnosed. Lesions that have the qualitative features of low-grade DCIS that do not fulfill this quantitative criterion are categorized as ADH. Tavassoli and Norris (25) have suggested that the risk of breast cancer associated with very small foci of low-grade DCIS (i.e., less than 2 mm) is similar to that of ADH; therefore, they classify lesions that fulfill the qualitative criteria for low-grade DCIS but that are less than 2 mm in size as ADH. The most recent WHO working group did not endorse one approach over another; rather, it pointed out that quantitative criteria are meant to provide "pragmatic guidelines to prevent the overdiagnosis of small low-grade lesions as DCIS," thereby avoiding overtreatment of patients with minimal or equivocal lesions (11).

Newer Methods to Assess Breast Cancer Risk

There is currently an active effort to determine if biological markers in benign breast biopsies might be useful in predicting breast cancer risk, either alone or in combination with histopathology (26). A variety of biomarkers have been studied in this regard including estrogen receptor (ER), angiogenesis, p53 expression, HER2/neu expression, transforming growth factor (TGF)-β receptor II, and cyclooxygenase-2 (COX-2), among others.

In a study of ER expression in benign breast tissue, Khan et al. (27) found that the odds ratio for breast cancer in women with ER positive benign epithelium was 3.2 in comparison with women with ER negative benign breast tissue. In contrast, Gobbi et al. (28) found no significant differences in ER expression in usual-type hyperplasias of women who subsequently developed breast cancer compared with those who did not. Shabban et al. (29) have suggested that the ratio of ERα to ERβ in hyperplasias of the usual type is an important determinant of breast cancer risk. In that study, in women with hyperplasias of the usual type who developed invasive breast cancer the ERα-to-ERβ ratio was significantly higher than in those who did not develop breast cancer (29).

In a small pilot study, Guinebretiere et al. (30) found that increased angiogenesis in benign breast biopsies was associated with a significantly increased breast cancer risk, independent of the presence of atypical hyperplasia. Heffelfinger et al. (31) have also shown that some benign proliferative breast lesions are associated with angiogenesis in the surrounding stroma and that stromal vascularity associated with normal breast epithelium is greater in breasts with invasive cancer than in breasts without cancer. Finally, Viacava et al. (32) have demonstrated higher microvessel density counts in association with usual and atypical ductal hyperplasias than in association with normal mammary glandular structures.

One study has suggested that p53 protein accumulation in benign breast tissue was associated with an increased breast cancer risk (RR 2.6), even after adjustment for other breast cancer risk factors (33). However, a second study from the same group did not substantiate these findings; rather the combination of p53 protein accumulation and p53 nucleotide changes was associated with a nonsignificant fivefold increase in breast cancer risk (34). No significant association was found between HER2/neu protein expression in benign breast tissue and increased breast cancer risk in one study (33), whereas in another study HER2/neu gene amplification in benign breast tissue, as determined by the polymerase chain reaction, was associated with an increase in breast cancer risk, particularly among women with coexistent proliferative breast disease (35).

In another study, women with hyperplasia that showed loss of expression of TGF-β receptor II were found to have a greater risk of breast cancer than those whose hyperplasia showed prominent expression of this receptor protein (36). Recently, Visscher et al. (37) reported that higher levels of COX-2 expression in atypical hyperplasias were associated with greater breast cancer risk.

Insulin-like growth factor receptor-1 (IGF1-R) has recently been evaluated in normal breast terminal duct lobular units. IGF1-R is thought to play a role in breast tumorigenesis and the finding of cytoplasmic distribution of this protein has been shown to be associated with a threefold increase in breast cancer risk (38). This risk is further increased when there is little or no associated membranous staining with IGF1-R, wherein the risk of developing breast cancer is 15 times that of those women not developing breast cancer (38). As with the aforementioned studies, validation of these findings is still needed.

A number of studies have also evaluated loss of heterozygosity, genomic copy number changes, and microsatellite instability in benign breast lesions. These studies have

shown that at least some examples of usual ductal hyperplasia and atypical hyperplasia exhibit a variety of genomic alterations (39,40). The clinical significance of these observations is not yet clear, however. Finally, studies to identify patterns of gene expression or protein expression either in the epithelium or in the stroma using expression profiling and proteomic technologies, respectively, are likely to provide important new insights into the molecular and genetic alterations involved in both neoplastic progression and breast cancer risk in women with benign breast lesions.

A number of follow-up studies evaluating benign breast disease and breast cancer risk have used diagnostic criteria other than those of the Nashville group for categorizing benign breast lesions (41,42). In some of these studies, information regarding the pathology findings in the benign breast biopsies was obtained from a review of the pathology reports only, without a slide review. In general, in these studies, proliferative lesions, particularly those categorized as atypical hyperplasia, have been associated with a higher breast cancer risk than other lesions, although the magnitude of this risk has varied among these studies. In a recent analysis of almost 12,000 women enrolled in the National Surgical Adjuvant Breast and Bowel Project breast cancer prevention (NSABP-P1) trial, women with a history of biopsy-proven "benign breast disease" had a fourfold greater risk of developing breast cancer than women without such a history. Information about the benign breast disease was obtained from review of pathology reports and no further details regarding the nature of the benign breast disease were reported (43).

In summary, the results of clinical follow-up studies indicate that most women who have a benign breast biopsy are not at increased risk for developing breast cancer. A substantially increased breast cancer risk is seen only in the small percentage of patients whose benign breast biopsies show atypical hyperplasia using strictly defined histologic and cytologic criteria. The role of biological and molecular markers to help assess breast cancer risk is not yet well defined but remains an area of active investigation.

SPECIFIC BENIGN LESIONS

Benign Neoplasms and Proliferative Lesions

Fibroadenomas

On gross examination, fibroadenomas are pseudoencapsulated and are sharply delimited from the surrounding breast tissue. They are usually spherical or ovoid, but may be multilobulated. When cut, the tumor bulges above the level of the surrounding breast tissue. The cut surface is most typically gray-white, and small, punctate, yellow-to-pink soft areas and slit-like spaces are commonly observed. Occasionally, the tumor has a gelatinous, mucoid consistency.

Microscopically, fibroadenomas have both an epithelial and stromal component. The histologic pattern depends on which of these components predominates. In general, the epithelial component consists of well-defined, gland-like and duct-like spaces lined by cuboidal or columnar cells with uniform nuclei. Varying degrees of epithelial hyperplasia are frequently observed. The stromal component consists of connective tissue that has a variable content of acid mucopolysaccharides and collagen (Fig. 9-7). In older lesions and in postmenopausal patients, the stroma may become hyalinized, calcified, or even ossified (ancient fibroadenoma). On rare occasions, mature adipose tissue or smooth muscle may comprise a portion of the stroma. The term *intracanalicular* has been used to describe tumors in which the stromal component compresses the glands into slit-like spaces, whereas *pericanalicular* tumors are those in which the rounded configuration of the glandular structures is maintained. In fact, these two patterns often coexist in the same lesion, and this distinction has no clinical significance.

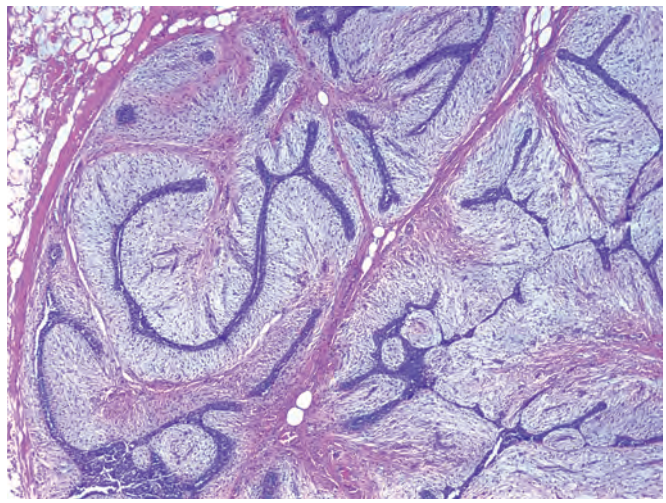

FIGURE 9-7 **Fibroadenoma.** The tumor is well circumscribed and is composed of benign glandular and stromal elements.

Complex Fibroadenomas: Fibroadenomas that contain cysts larger than 3 mm in diameter, sclerosing adenosis, epithelial calcifications, or papillary apocrine change have been designated complex fibroadenomas. In a review of almost 2,500 fibroadenomas, such changes were seen in 23% of the cases. In one clinical follow-up study, complex fibroadenomas were reported to be associated with a greater subsequent breast cancer risk than fibroadenomas that lack such changes (10).

Juvenile Fibroadenomas: Most fibroadenomas in adolescents and younger women are of the usual type seen in older patients. A few present a different clinical and pathologic picture and are termed *juvenile fibroadenomas*. This term, however, has been used by different authors to describe different lesions. Some authors use the term to refer to fibroadenomatous lesions that grow rapidly and may show venous dilatation in the overlying skin. Such lesions may clinically resemble virginal hypertrophy, and only surgical exploration will reveal a circumscribed tumor (44). Microscopically, juvenile fibroadenomas are more floridly glandular and have greater stromal cellularity than the more common adult-type fibroadenoma. Mies and Rosen (45) use the term *juvenile fibroadenomas* to refer to fibroadenomatous lesions that demonstrate severe epithelial hyperplasia which may border on carcinoma *in situ*. Nevertheless, these lesions behave in a clinically benign fashion.

Giant Fibroadenomas: Some tumors that are histologically typical fibroadenomas may attain great size. Several authors have used the terms *giant fibroadenoma* and *benign cystosarcoma phyllodes* synonymously, however, and have created considerable confusion regarding these entities. A lesion that has the microscopic appearance of a conventional fibroadenoma, but that is large, should still be classified as a fibroadenoma and may be treated adequately by enucleation. The major feature that distinguishes a cystosarcoma

phyllodes (preferably called a phyllodes tumor) from a giant fibroadenoma is the cellularity of the stromal component in the former (17). It must be noted, however, that the distinction between these two entities may be extremely difficult in some cases. Because juvenile fibroadenomas may attain great sizes, some authors consider them to be variants of giant fibroadenomas.

Infarction: Fibroadenomas may undergo partial, subtotal, or total infarction. Pregnancy and lactation are the most common predisposing factors. It has been postulated that a relative vascular insufficiency in the face of increased metabolic activity in the breast underlies this phenomenon (17).

Involvement of Fibroadenomas by Atypical Hyperplasia: Atypical hyperplasia of both ductal and lobular types may occasionally be found within a fibroadenoma. In a study of almost 2,000 fibroadenomas, atypical hyperplasia was found in 0.81% of the cases (46). Of note, in that study, the presence of atypia in a fibroadenoma did not predict for the presence of atypical hyperplasia in the surrounding breast tissue, nor was it associated with a significant increase in the risk of subsequent breast cancer.

Involvement of Fibroadenomas by Carcinoma: Infrequently, carcinoma occurs in association with a fibroadenoma. The most frequent type of carcinoma involving fibroadenomas is LCIS, but DCIS, invasive ductal, and invasive lobular carcinomas have also been observed. In almost half of the reported cases, the malignant tumor also involves the surrounding breast tissue. The prognosis of carcinoma limited to a fibroadenoma is excellent.

Adenomas

Adenomas of the breast are well-circumscribed tumors composed of benign epithelial elements with sparse, inconspicuous stroma. The last feature differentiates these lesions from fibroadenomas, in which the stroma is an integral part of the tumor. For practical purposes, adenomas can be divided into two major groups: tubular adenomas and lactating adenomas.

Tubular Adenomas

Tubular adenomas present in young women as well-defined, freely movable nodules that clinically resemble fibroadenomas. Gross examination reveals a well-circumscribed, tan-yellow, firm tumor. On microscopic examination, tubular adenomas are separated from the adjacent breast tissue by a pseudocapsule, and are composed of a proliferation of uniform, small tubular structures with a scant amount of intervening stroma. The tubules are composed of an inner epithelial layer and an outer myoepithelial layer, and resemble normal breast acini, both at the light and ultrastructural level. The tubular lumens often contain eosinophilic material. In some cases, this pattern is admixed with that of a fibroadenoma, suggesting a relationship between the two tumors.

Lactating Adenomas (Nodular Lactational Hyperplasia)

Lactating adenomas present as one or more freely movable masses during pregnancy or the postpartum period. They are grossly well circumscribed and lobulated, and on cut section appear tan and softer than tubular adenomas. On microscopic examination, these lesions have lobulated borders and are composed of glands lined by cuboidal cells with secretory activity, identical to the lactational changes normally observed in breast tissue during pregnancy and the puerperium. Although some authors believe that these lesions are the result of lactational changes superimposed on a preexisting tubular adenoma, others have suggested that they represent *de novo* lesions and are merely nodular foci of hyperplasia in the lactating breast.

O'Hara and Page (47) reviewed 42 breast adenomas that demonstrated lactational changes. They observed an overlapping spectrum of morphologic features in fibroadenomas with lactational changes and in lactating and tubular adenomas. These authors suggested that all these lesions may have a common pathogenesis.

Rarely, adenomatous tumors resembling dermal sweat-gland neoplasms are observed as primary lesions in the breast parenchyma (e.g., clear cell hidradenoma and eccrine spiradenoma) (11) or nipple (e.g., syringomatous adenoma) (11). Pleomorphic adenomas, histologically identical to those seen in the salivary glands and skin, have also been described in the breast (11). Although some of these lesions appear to arise from the breast tissue *de novo*, others appear to represent variants of intraductal papillomas.

Adenomas of the Nipple

Adenoma of the nipple has been described under a variety of names, including florid papillomatosis of the nipple ducts, subareolar duct papillomatosis, papillary adenoma of the nipple, and erosive adenomatosis of the nipple (11). It is not, strictly speaking, a true adenoma of the breast, because of its prominent stromal component.

On macroscopic examination, some adenomas of the nipple appear as solid, gray-tan, poorly demarcated tumors in the nipple and subareolar region; in other cases, no gross lesion is evident. Microscopically, the dominant feature is a proliferation of small gland-like structures. Solid and papillary proliferation of ductal epithelium is also usually evident; however, the papillary pattern may be inconspicuous or totally absent. In advanced lesions, glandular epithelium extends out onto the surface of the nipple. It is this phenomenon that results in the clinically apparent, reddish, granular appearance. Squamous epithelium frequently extends into the superficial regions of the involved ducts, sometimes with the formation of keratinaceous cysts. The lesions usually show considerable stromal fibrosis. This connective tissue may distort and entrap the epithelial elements, resulting in a pattern mimicking invasive carcinoma. The lesion is distinguishable from carcinoma by the preservation of a double layer of epithelium in the proliferating glands (an inner epithelial and outer myoepithelial cell layer), minimal nuclear atypia, absence of necrosis, and the overall low-power configuration. In problematic cases, immunohistochemical stains for myoepithelial cell markers may be of value in distinguishing a nipple adenoma (the glands of which are surrounded by myoepithelial cells) and invasive carcinoma (which lacks a myoepithelial cell component).

A few cases of carcinoma associated with adenomas of the nipple have been reported (48). In most cases, however, adenomas of the nipple are entirely benign. Reports of recurrence most likely represent cases in which the initial resection failed to remove the lesion completely.

Syringomatous Adenoma of the Nipple

Syringomatous adenoma of the nipple is an uncommon benign breast lesion similar in histologic appearance to eccrine syringoma of the skin. The usual clinical presentation is as a mass lesion in the region of the nipple–areola complex. Microscopic examination reveals an infiltrative pattern of epithelial islands that are angulated or comma shaped,

as well as tubular or solid in configuration. The glandular lumens are small or obliterated. Squamous metaplasia is usually present within a variable proportion of epithelial islands, which have an inconspicuous outer myoepithelial layer. The epithelial elements often "invade" into the smooth muscle of the nipple, mimicking invasive carcinoma (11).

It is important to distinguish syringomatous adenoma from the malignant lesions tubular carcinoma and low-grade adenosquamous carcinoma. The glandular structures of tubular carcinoma are mostly angulated with open lumens compared with the epithelial islands of syringomatous adenoma, which have smaller or absent lumens and often have characteristic "comma" or "tadpole" shapes. In addition, the glands of tubular carcinoma are composed of a single cell population as opposed to those of syringomatous adenoma, which have a variable amount of squamous metaplasia. Unlike syringomatous adenoma, tubular carcinoma often has associated DCIS. Low-grade adenosquamous carcinoma is virtually indistinguishable from syringomatous adenoma, but usually involves the deeper parenchyma of the breast. If low-grade adenosquamous carcinoma involves the nipple areola complex, the lesion may be impossible to distinguish from syringomatous adenoma.

Intraductal Papillomas

Intraductal papillomas can be divided into two major categories: solitary (central) papillomas and multiple (peripheral) papillomas.

Solitary (Central) Papillomas

Solitary intraductal papillomas are tumors of the major lactiferous ducts, most frequently observed in women 30 to 50 years of age. These lesions are generally less than 1 cm in diameter, usually measuring 3 to 4 mm. Occasionally, they may be as large as 4 or 5 cm. On gross examination, solitary intraductal papillomas are tan-pink, friable tumors within a dilated duct or cyst. A frankly papillary configuration may or may not be apparent. The tumor is usually attached to the wall of the involved duct by a delicate stalk, but it may be sessile. To identify the papilloma, the involved duct should be opened carefully, using a fine pair of scissors, until the tumor is exposed. Identification of the lesion may be facilitated by the placement of a suture at the end of the involved duct nearest the nipple. Randomly slicing through the excised tissue is not recommended because a small lesion might be missed.

Microscopically, these tumors are composed of multiple, branching, and interanastomosing papillae, each with a central fibrovascular core and a covering layer of cuboidal to columnar epithelial cells. A myoepithelial cell layer is often discernible between the epithelial cells and the connective tissue stalk (Fig. 9-8). In some areas, the complex growth pattern of the papillae results in the formation of glandlike spaces. Variable amounts of fibrosis can result in the entrapment of epithelial elements, producing a pseudoinfiltrative pattern. The lesion designated *ductal adenoma* appears to represent an extensively sclerotic variant of an intraductal papilloma (11). Florid epithelial proliferation is sometimes observed in intraductal papillomas. At times, the epithelial hyperplasia or fibrosis (or both) and the architectural distortion make it extremely difficult to distinguish between benign papilloma and papillary DCIS. Features helpful in making this distinction have been elucidated by Kraus and Neubecker (49) and by Azzopardi (17).

Several additional features of solitary intraductal papillomas deserve emphasis. Papillomas can undergo partial or total infarction, often accompanied by distortion of the adjacent, viable epithelium and production of a pattern that may simulate invasive carcinoma. Squamous metaplasia has been observed in intraductal papillomas. In some cases it accompanies infarction, but it has also been observed in the absence of infarction. This phenomenon may also result in a disturbing growth pattern that can be confused with carcinoma. Finally, some intraductal papillomas exhibit areas of atypia that range from foci resembling ADH to areas qualitatively similar to DCIS, most often low-grade. The classification of such lesions, particularly when the proliferation fulfills the qualitative criteria for the diagnosis of DCIS, varies among different authors. In general, the classification of such lesions has been based largely on the extent of the atypical proliferation within the papillary lesion. For example, Tavassoli uses the designation *atypical papilloma* if the atypical changes involve less than one-third of the

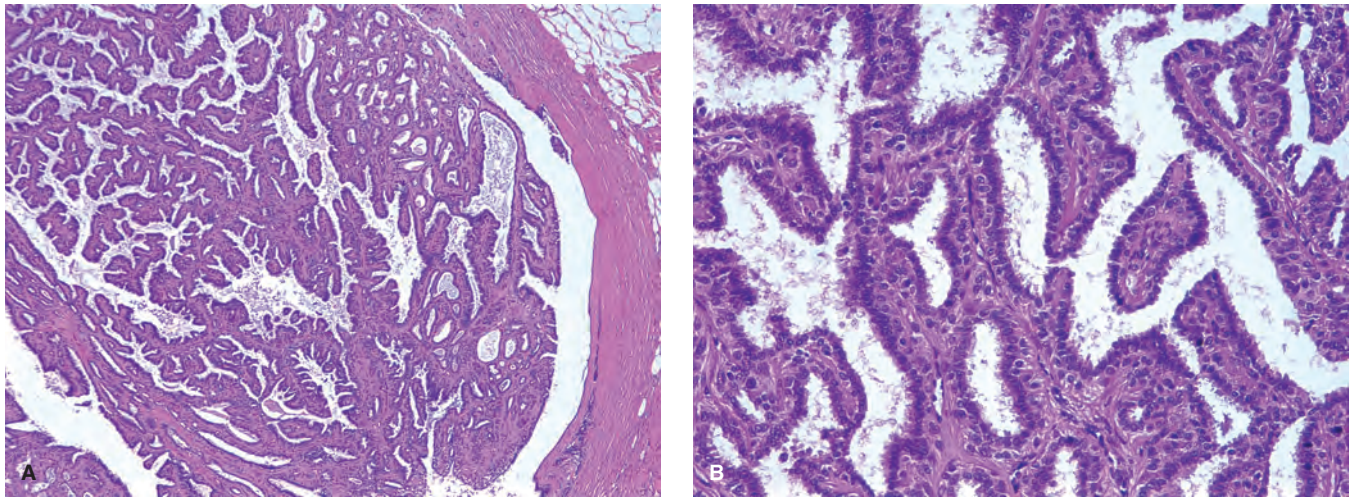

FIGURE 9-8 **Intraductal papilloma. (A)** Low-power view demonstrates the papillary lesion within a dilated duct. **(B)** Higher-power view demonstrates that the papillae are composed of fibrovascular cores covered by an epithelial cell layer (closer to the duct lumen) and a myoepithelial layer (closer to the cores).

papilloma and *carcinoma arising in a papilloma* when the atypical population of cells involves at least a third but less than 90% of the lesion (50). Page et al. (51) have stated that the presence of "any area of uniform histology and cytology consistent with non-comedo DCIS" within a papilloma that is more than 3 mm in size should be considered DCIS within a papilloma, whereas foci with the same qualitative features which measure 3 mm or less in size are classified as a papilloma with atypia. The most recent WHO Working Group recommended use of size/extent criteria as a pragmatic approach for distinguishing papillomas with atypia from papillomas with DCIS (11).

The clinical significance of atypia or DCIS in a papilloma is not well defined. Some authors have reported a substantially increased risk (7.5-fold) for the subsequent development of breast cancer, predominantly in the ipsilateral breast (51), whereas others have found that the level of breast cancer risk associated with papillomas with atypia was similar to that of patients with ADH elsewhere in the breast (four- to fivefold) and that the risk was approximately equal in both breasts (52). Breast cancer risk is reported to be particularly high (sevenfold) among women with multiple papillomas with atypia (52).

The risk of subsequent breast cancer and local recurrence does not appear to be related to the extent of atypia or DCIS within the papilloma. In fact, the most important consideration is the presence of atypia or DCIS in the surrounding breast tissue because this appears to be more closely related to the risk of recurrence than the qualitative features or extent of atypia within the papilloma itself (51,53).

Multiple (Peripheral) Intraductal Papillomas

Compared with solitary intraductal papillomas, multiple intraductal papillomas tend to occur in younger patients; they are less often associated with nipple discharge, are more frequently peripheral, and are more often bilateral. Most importantly, these lesions appear to be particularly susceptible to the development of carcinoma. In Haagensen's (9) series of 68 patients with multiple papillomas, simultaneous or subsequent carcinoma of the apocrine papillary and cribriform types was observed in 22 patients (32%). Another study in which surgically excised specimens from patients with intraductal papillomas were subjected to three-dimensional reconstruction confirms these observations (54). All 16 cases of multiple papillomas in the series were found to originate in the most peripheral portion of the duct system, the terminal duct lobular unit (TDLU). Furthermore, carcinoma was found to be associated with these multiple peripheral papillomas in six cases (37.5%). In contrast, no cases of carcinoma were found to be associated with solitary papillomas involving the large ducts. These findings suggest that peripheral papillomas, in contrast to solitary central papillomas, may be highly susceptible to malignant transformation.

Juvenile Papillomatosis (Swiss Cheese Disease)

This lesion occurs most commonly in adolescents and young women (with a mean age of 23 years), but has been seen in women up to 48 years of age. Patients typically present with a painless mass which, on physical examination, is circumscribed, easily movable, and is most often considered to be a fibroadenoma.

On gross pathologic examination, the lesions range in size from 1 to 8 cm. Multiple cysts of up to 1 cm in diameter are generally apparent. The microscopic features of juvenile papillomatosis are not unique to this entity, and are all components previously described as part of *fibrocystic disease*. The constellation of histologic features, however, forms a characteristic complex. These lesions appear to be well circumscribed, but not encapsulated, and are characterized by the following elements: duct papillomatosis, apocrine and nonapocrine cysts, papillary apocrine hyperplasia, sclerosing adenosis, and duct stasis. The epithelial proliferation in these lesions may be quite marked, and the cytologic and architectural features may approach those of DCIS.

Follow-up studies have suggested that juvenile papillomatosis is associated with an increased risk of breast cancer in the patient's female relatives, and that the patient herself may be at increased risk for developing carcinoma, particularly if the lesion is bilateral and the patient has a family history of breast cancer (55).

Microglandular Adenosis

Microglandular adenosis (MGA) is an uncommon lesion that may be found incidentally in breast tissue excised for other lesions, or it may present as a mass lesion. Most women in whom this lesion has been reported are older than 40 years of age, but patients as young as 28 years and as old as 82 years have been reported to have MGA (11). The importance of this lesion is that it may be mistaken for a well-differentiated (tubular) carcinoma on histological examination.

On gross examination, MGA has generally been described as an ill-defined area of firm, rubbery tissue. Microscopically, the lesion is characterized by a poorly circumscribed, haphazard proliferation of small, round glands in the breast stroma and adipose tissue. Unlike sclerosing adenosis, MGA does not have a lobulocentric, organoid configuration. As with tubular carcinoma, the glands are composed of a single cell layer and lack an outer myoepithelial layer. In contrast to tubular carcinoma, however, the glands are round (not angulated). The single layer of cuboidal epithelial cells has clear to slightly eosinophilic cytoplasm and small, regular nuclei, but the cells lack the apical secretory snouts that are characteristic of tubular carcinoma. The cells stain strongly for S100 protein, and the glands are surrounded by basement membrane material. Eosinophilic secretions are frequently present within the glandular lumina, and are periodic acid-Schiff (PAS) positive. When tubular carcinoma gland lumens contain material, it is usually calcified. As opposed to the desmoplastic stroma associated with tubular carcinoma, the stroma in MGA is typically composed of dense, relatively acellular collagen, which usually demarcates the lesion from the adjacent parenchyma. In some areas, the stroma is minimal and the proliferating glands lie exposed in adipose tissue (Fig. 9-9).

The relationship between MGA and either simultaneous or subsequent carcinoma has been addressed in several studies (56,57). A study by Koenig et al. (58) emphasized the potential importance of atypical MGA as a transitional form between typical MGA and carcinomas arising in this setting. More recent evidence suggests a molecular link between MGA and invasive carcinoma (59). Utilizing array CGH techniques on areas of MGA, atypical MGA and associated invasive carcinomas, Geyer et al. demonstrated that MGA is a clonal lesion with genetic aberrations similar to those found in associated atypical MGA and invasive carcinomas (59). The results of this study, taken together with those reported by others, suggest that some MGA lesions may represent nonobligate precursors to triple negative breast cancers. Further corroboration of these findings in larger studies is still needed.

At the present time, the recommended approach to the treatment of patients with MGA is complete, local excision

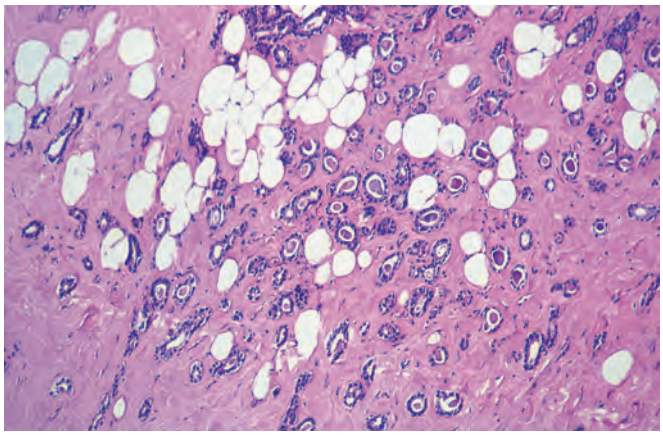

FIGURE 9-9 **Microglandular adenosis**. This adenosis is characterized by a haphazard proliferation of small glands composed of a single layer of epithelial cells. The glands are relatively rounded and many contain eosinophilic secretions in their lumens.

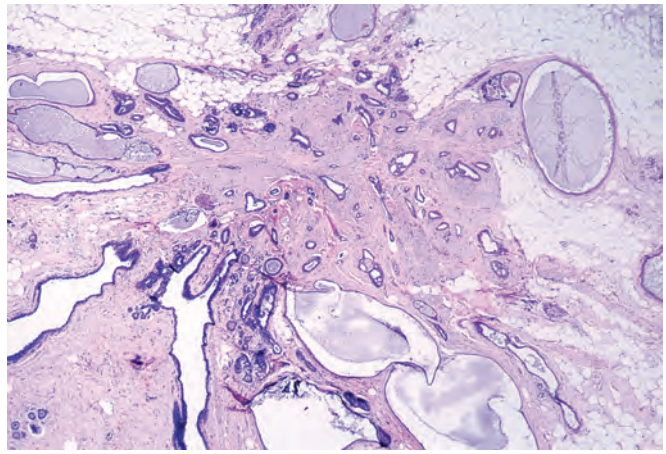

FIGURE 9-10 **Radial scar.** This lesion is characterized by a central fibroelastic core containing entrapped benign glands. Radiating from this core are ducts that show a variety of changes, including cysts and epithelial hyperplasia.

of the lesion and careful follow-up. Those with associated invasive carcinomas should be managed as for the stage of the invasive carcinoma.

Radial Scars

Radial scars were first recognized by Semb in 1928. The name *radial scar* was proposed in 1980, which was a translation of Hamperl's *strahlige narben* introduced in 1975. They have been described in the literature by a variety of other names, including sclerosing papillary proliferation, nonencapsulated sclerosing lesion, indurative mastopathy, and radial sclerosing lesion. The term *complex sclerosing lesion* is sometimes used for similar lesions larger than 1 cm in size or for those lesions with several fibroelastotic areas in close contiguity. The importance of these lesions is twofold. First, they may, on mammographic, gross, and microscopic examination, simulate breast carcinomas. Second, the relationship between the presence of radial scars and subsequent breast cancer has long been a matter of controversy (see discussion below).

Radial scars are most often incidental microscopic findings in breast biopsies performed for other indications (60,61). Some are sufficiently large to be detected mammographically where they appear as spiculated masses that cannot be reliably distinguished from carcinomas. The reported incidence of radial scars varies from 4% to 28% with more contemporary studies closer to the 5% to 7% range (61,62). Several studies have found radial scars to be bilateral and multicentric, with these frequencies reported to be as high as 43% and 67%, respectively (60). They are often multiple, with as many as 31 lesions having been observed in a single breast.

On gross examination, radial scars are irregular, gray-white, and indurated with central retraction—an appearance identical to that of scirrhous carcinoma. On microscopic examination, radial scars are characterized by a central zone of fibroelastosis from which ducts and lobules radiate, exhibiting various benign alterations, such as microcysts, apocrine metaplasia, and proliferative changes, such as florid hyperplasia and papillomas. Within the central area of fibroelastotic stroma, smaller entrapped ducts are present, which are often distorted or angular in appearance (Fig. 9-10). These ducts are lined by one or more layers of epithelium and an outer myoepithelial cell layer. The presence of these myoepithelial cells may be confirmed immunohistochemically with markers such as smooth muscle myosin heavy chain, p63, and calponin. Radial scars may be involved by atypical hyperplasia (either ductal or lobular), and LCIS, DCIS, or invasive carcinoma may rarely be present.

The relationship between radial scars and breast cancer has interested investigators for many years. The observation that the entrapped epithelial elements within the central zone of fibroelastosis in radial scars may mimic tubular carcinoma led several authors to postulate that radial scars represent an early phase in the development of some breast cancers (63). The presence of invasive, *in situ* carcinoma, or both in some radial scars has been cited as further support for the concept of their malignant potential (64). To define further the relationship between radial scars and breast cancer, Sloane and Mayers (64) reviewed 126 radial scars and complex sclerosing lesions. They found that carcinoma and atypical hyperplasia were more common in radial scars larger than 6 to 7 mm than in smaller radial scars and in radial scars in women older than 50 years than in younger women. The similarity in appearance between radial scars and some cancers, and the coexistence of *in situ* or invasive carcinoma within some radial scars, although of interest, does not, however, provide conclusive evidence of a relationship. Studies of the frequency of radial scars in women with breast cancer compared with those without cancer have, however, yielded conflicting results regarding their potential premalignant nature (65).

Until recently, the malignant potential of radial scars postulated in these observational reports had not been validated by clinical follow-up studies. The few available follow-up studies that existed were characterized by small patient numbers and lack of suitable controls. The results of one case-control study suggest that women with a biopsy-proven radial scar are at increased risk for subsequent breast cancer. In that study, the presence of a radial scar was associated with a twofold increase in breast cancer risk, independent of the histologic category of benign breast disease (61). Moreover, the presence of a radial scar further increased the breast cancer risk in women with other types of proliferative breast disease, particularly those with proliferative lesions without atypia. In a subsequent study, the increased breast cancer risk associated with radial scars was observed primarily in women over the age of 50 years and

was largely attributable to the category of coexistent proliferative breast disease. However, two recent studies have not shown an increase in breast cancer risk over and above that associated with the category of proliferative breast disease (62,66). Therefore, radial scars are probably best considered markers of generalized increased breast cancer risk. Given that *in situ* and invasive carcinomas appear to be more common in larger than smaller radial scars (64), the possibility that at least some radial scars represent direct cancer precursors must also be considered. In fact, these two possibilities are not mutually exclusive. Most authorities agree that the finding of radial scar on a core needle biopsy is an indication for excision (67).

The pathogenesis of radial scars is uncertain, as are the reasons for their association with an increased risk of breast cancer. It is attractive to postulate that a disturbance in the normal reciprocal stromal–epithelial interaction exists in radial scars. This may be a reflection of a more generalized perturbation of the interaction between stromal and epithelial cells in the breast, a phenomenon postulated to be important in breast cancer pathogenesis. Jacobs et al. (61) demonstrated by *in situ* hybridization that certain vascular stromal factors found in radial scars were similar to those in invasive carcinomas, raising the possibility that a similar disturbance in stromal–epithelial interactions is present in both lesions.

Granular Cell Tumor

Granular cell tumors are uncommonly found in the breast but, when present, simulate carcinoma on clinical, mammographic, and pathologic examination (68). These tumors occur more commonly in African American than white women, and typically appear between puberty and menopause, implicating some hormonal factor in their development. Granular cell tumors of the breast most commonly occur in the upper, inner quadrant in contrast to carcinomas, which occur most frequently in the upper, outer quadrant. Patients present with a palpable mass that may be associated with skin retraction or fixation to chest wall skeletal muscles. The similarity of granular cell tumors to carcinoma is also evident on mammographic examination, on which they resemble scirrhous carcinoma. Gross examination of the lesion reveals a gray-white to tan firm tumor that may be gritty when cut with a knife; these features further support the impression of carcinoma. Microscopically, these lesions are identical to granular cell tumors in other sites, consisting of a poorly circumscribed proliferation of cells in which the most characteristic feature is prominent granularity of the cytoplasm. On electron microscopic examination, these granules correspond to secondary lysosomes. The nuclei are small and uniform, and lack the features of malignant disease.

Granular cell tumors are almost invariably benign and are adequately treated by wide local excision. Rare cases of malignant granular cell tumors have been reported in both the breast and extramammary sites. Granular cell tumors were initially considered to be myogenic in origin (hence, their earlier designation as granular cell myoblastomas), but ultrastructural and immunohistochemical evidence supports a neurogenic origin for these tumors (68).

Fibromatosis

Fibromatosis of the breast, which is analogous to fibromatosis in other sites (e.g., desmoid tumors of the abdominal wall), is characterized by a locally invasive, nonencapsulated proliferation of well-differentiated spindle cells (69). These tumors have the capacity to recur locally if inadequately excised, but they do not metastasize. Although most cases are sporadic, mammary fibromatosis may be seen in association with familial adenomatous polyposis, Gardner's syndrome, or as part of a hereditary desmoid syndrome (69). There is also an association with prior trauma or surgery, particularly the presence of breast implants.

Patients typically present with a palpable mass which is sometimes associated with skin retraction or fixation to the underlying pectoral muscle. On mammography, these lesions are indistinguishable from carcinomas. Gross pathologic examination reveals an ill-defined, firm, gray-white lesion. Microscopically, fibromatoses consist of interlacing bundles of spindle-shaped cells surrounded by collagen. The cells show minimal to no cytologic atypia, and mitoses are only infrequently encountered. The proliferation tends to surround and entrap preexisting ducts and lobules without destroying them. Fibromatosis may exhibit keloid-like areas where collagen is increased, and the periphery of the lesion may be more cellular, with lymphocytic aggregates also present. The edges of the lesion infiltrate irregularly into the adjacent parenchyma. On electron microscopic and immunohistochemical examination, many of the tumor cells have the features of fibroblasts and myofibroblasts.

The proper treatment for fibromatosis consists of wide local excision. Although metastases have not been reported, lesions may recur locally.

MISCELLANEOUS BENIGN LESIONS

Lipomas

Lipomas consist of encapsulated nodules of mature adipose tissue. Although true lipomas occur in the breast, many lesions designated *lipoma* probably represent foci of fatty breast tissue without a true capsule. *Adenolipoma* is a term that has been applied to a benign fatty tumor of the breast containing entrapped lobular epithelial elements (17); however, such lesions are probably best considered hamartomas.

Vascular Lesions

Benign vascular lesions of the breast parenchyma are relatively uncommon and most often represent incidental microscopic findings. In a series of 550 mastectomy specimens from patients with breast carcinoma, the incidence of benign hemangiomas was 1.2% (70). Benign vascular lesions of the breast can be divided into four major categories: *perilobular hemangiomas, angiomatoses, venous hemangiomas,* and *hemangiomas involving the mammary subcutaneous tissue*. The major significance of these lesions is that they must be distinguished from angiosarcomas. Benign angiomatous lesions are almost always microscopic in size and lack interanastomosing channels, endothelial proliferation, and atypia. Complete excision is recommended for all vascular lesions of the breast. Atypical vascular lesions have been described in the skin of the breast and the mammary parenchyma in women who have been treated with conservative surgery and radiation therapy for breast cancer and these may represent precursors to angiosarcoma of the breast (71,72).

Pseudoangiomatous Stromal Hyperplasia

Pseudoangiomatous hyperplasia of the mammary stroma is a benign stromal proliferation that simulates a vascular lesion. The lesion is often seen as an incidental microscopic finding, but may present as a palpable mass. Microscopic examination reveals complex interanastomosing spaces, some of which have spindle-shaped stromal cells at their margins simulating endothelial cells. Occasionally, the myofibroblasts aggregate together into fascicular bundles that

may simulate a myofibroblastoma. Ultrastructural examinations have demonstrated that the spaces appear to be caused by separation and disruption of collagen fibers and that the associated spindle cells are myofibroblasts. The significance of this lesion is that it must be distinguished from a true vascular lesion, specifically, angiosarcoma.

Chondromatous Lesions

Chondromatous lesions of the breast are uncommon. Although chondromatous changes are most often seen in breast carcinomas and sarcomas, chondroid metaplasia may rarely be seen in fibroadenomas and intraductal papillomas. A few cases of *chondrolipoma* have also been reported, as has a single case of *choristoma* containing cartilage.

Leiomyoma

Leiomyomas of the breast are most often seen in the areolar region and rarely occur in the breast parenchyma (17). The histologic characteristics are the same as those of leiomyomas in other tissue.

Neural Lesions

Neurofibromas and neurilemmomas (schwannomas) are benign nerve sheath tumors. These lesions are most frequently seen in the breast in patients with neurofibromatosis and are most common in the areolar area.

Adenomyoepithelioma

Adenomyoepitheliomas are uncommon lesions considered variants of intraductal papilloma. They present as palpable masses that are grossly circumscribed. Microscopically, these lesions are usually multinodular and are composed of a combination of epithelial and myoepithelial elements. The myoepithelial cells may be polygonal or spindle shaped. These lesions are adequately treated by complete local excision (73). Lesions composed exclusively of myoepithelial cells *(myoepitheliomas)* have also been described (74).

Hamartoma

Hamartomas of the breast present as well-defined masses on physical examination and on mammography. Microscopically, these lesions are composed of an admixture of ducts, lobules, fibrous stroma and adipose tissue in varying proportions. Occasional lesions also contain smooth muscle *(myoid hamartomas)*. These lesions frequently go unrecognized by the pathologist because histologically they resemble other benign or physiologic changes in the breast.

Myofibroblastoma

Myofibroblastomas are uncommon benign mesenchymal tumors. These lesions are typically well circumscribed and are most often composed of a proliferation of relatively uniform-appearing spindle cells in a densely collagenized stroma. The cells comprising the tumor show features of myofibroblasts on ultrastructural and immunohistochemical examination.

Mucocele-Like Lesion

Mucocele-like lesions are composed of mucin-containing cysts that often rupture, with resultant extravasation of mucin into surrounding stroma. The mucoid character of these lesions is usually evident on gross examination. The epithelium lining these cysts can range from benign (including flat or cuboidal epithelium and hyperplasia, including papillary) to atypical ductal hyperplasia to DCIS. The distinction between mucocele-like lesion and mucinous (colloid) carcinoma may be difficult, particularly if there are epithelial cells floating within the mucin. Therefore, these lesions must be completely excised and carefully examined histologically (with multiple sections if necessary) to rule out the possibility of an invasive mucinous carcinoma.

Collagenous Spherulosis

Collagenous spherulosis is most often an incidental microscopic finding in breast tissue removed for another abnormality. This lesion appears to be more frequent in breasts containing sclerosing lesions (e.g., radial scar or sclerosed papilloma). Occasionally, collagenous spherulosis may calcify and present as mammographic microcalcifications. This lesion is characterized by aggregates of eosinophilic fibrillary or hyaline spherules, or both, which are surrounded by an inner myoepithelial layer and outer epithelial layers within the lobules. This arrangement gives rise to an appearance of a fenestrated or cribriform proliferation at low power microscopic examination. The spherules are composed of variable amounts of basement membrane-like material and type IV collagen and are positive for PAS and Alcian blue. This lesion is important to recognize because it must be distinguished from cribriform DCIS and adenoid cystic carcinoma.

REACTIVE/INFLAMMATORY LESIONS

Mammary Duct Ectasia (Periductal Mastitis)

Mammary duct ectasia occurs primarily in perimenopausal and postmenopausal women, and is characterized by dilatation of the subareolar ducts. Considerable controversy exists regarding the most appropriate name for this condition. This controversy has arisen because some authors consider ductal dilatation to be the primary event, whereas others consider the ectatic ducts to be the consequence of prior periductal inflammation.

Duct ectasia is a frequent pathologic finding in breast tissue obtained at autopsy and in surgically excised material. It has been observed on microscopic examination in 30% to 40% of women older than 50 years of age. Clinically evident disease, however, occurs much less frequently (75).

A wide spectrum of pathologic changes is observed in this condition. Cut section of the gross specimen often reveals dilated, thick-walled ducts that contain pasty, yellow-brown secretions. The intervening stroma may be fibrotic. On microscopic examination, some cases show prominent inspissation of lipid-rich material within ducts, accompanied by periductal inflammation. Rupture or leakage of these ducts results in release of this material into the adjacent stroma, with subsequent inflammation and fat necrosis. Plasma cells may be a prominent component of the periductal and stromal inflammatory infiltrate. It should be noted that many cases previously designated as plasma cell mastitis probably represent a stage in the evolution of duct ectasia. In other cases, the histologic picture is dominated by periductal fibrosis and ductal dilatation with minimal inflammation.

As alluded to earlier, the pathogenesis of this condition has not been fully established. Dixon et al. (75) suggested that the primary event is periductal inflammation and that duct ectasia is the ultimate outcome of this disorder. In support of this premise, they observed that inflammation around nondilated ducts predominates in younger patients with this condition, whereas duct dilatation and nipple retraction are more common in older patients (75). Thus,

their postulated sequence of events in the evolution of this disease was that periductal inflammation leads to periductal fibrosis, which subsequently results in ductal dilatation. This group of investigators has also suggested that periductal mastitis and duct ectasia may represent two separate entities, based on differences between women with these two disorders with regard to age, clinical history, and smoking history (76).

Squamous Metaplasia of Lactiferous Ducts (Recurrent Subareolar Abscess, Zuska's Disease)

Keratinizing squamous epithelium normally extends into the orifices of the lactiferous ducts for 1 to 2 mm. If these keratinizing cells extend deeper into the ducts, keratin production can result in ductal distention and eventual duct rupture, resulting in an intense inflammatory response and sterile abscess formation. Secondary bacterial colonization and infection may occur. A fistulous tract may also develop, typically opening at the edge of the areola. Appropriate treatment requires excision of the involved duct, which may also require excision of a portion of the nipple (77).

Fat Necrosis

The importance of fat necrosis is that it may closely simulate carcinoma, both clinically and on mammographic examination.

The macroscopic appearance of fat necrosis depends on its age. In early lesions, there is hemorrhage and indurated fat. With time, a rounded, firm tumor is formed. The cut surface of the lesion at this stage has a variegated, yellow-gray appearance with focal hemorrhage. Cavitation can subsequently occur, owing to liquefactive necrosis. The lesion may eventually be converted to a dense, fibrous scar or may remain a cystic cavity with calcification of its walls.

On microscopic examination, early lesions show cystic spaces surrounded by lipid-laden macrophages and foreign body-type giant cells with foamy cytoplasm (Fig. 9-11). A variable, acute inflammatory cell infiltrate may be present, and there may be focal hemorrhage. With time, there is fibroblastic proliferation with deposition of collagen. Scattered, chronic inflammatory cells are usually present, and focal hemosiderin deposition may be observed. Even in older lesions, scattered, foamy histiocytes and foreign body giant cells are usually discernible. A similar pathologic appearance may be seen after surgical trauma to the breast and after radiation therapy for carcinoma (see the section on pathologic changes associated with radiation therapy, below).

Reactions to Foreign Material

Foreign body-type granulomatous inflammation has been described following injection within the breast of a variety of substances, including paraffin and silicone. Clinically, these lesions generally appear as firm nodules that may be tender.

A variety of tissue reactions has been reported in association with mammary implants (78). One of these is the formation of a fibrous capsule in the surrounding tissue. In 10% to 40% of patients there is contracture of this capsule which results in breast tightness or firmness and deformation of the implant necessitating either capsulotomy or removal of the implant and the surrounding capsule. Histologic examination of the capsular tissue shows varying degrees of fibrosis, chronic inflammation, fat necrosis, granulation tissue, fibrin deposition, histiocytes, and foreign body giant cells, often with demonstrable silicone

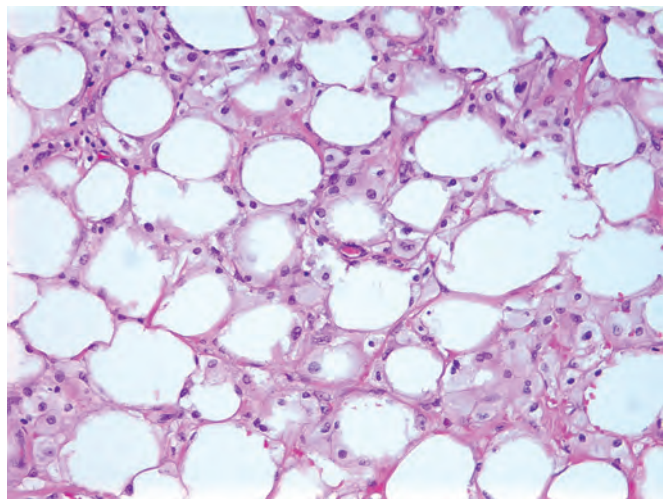

FIGURE 9-11 **Fat necrosis.** The fatty breast tissue is infiltrated by histiocytes containing foamy cytoplasm.

(and in some cases in which it has been used as part of the implant shell, polyurethane). In some cases, the capsule surrounding breast implants develops a cellular lining that histologically, immunohistochemically, and ultrastructurally resembles either normal synovium or synovium with papillary hyperplasia (proliferative synovitis) and has physiologic properties similar to synovium (78). This change has been variably described as *pseudoepithelialization, synovial metaplasia*, and *capsular synovial hyperplasia*. The factors associated with development of synovial-type metaplasia in this setting are not known. Some have suggested that this is a consequence of mechanical forces (e.g., micromotion and friction) between the implant and the surrounding tissue.

A more significant complication of prosthetic implants is the recently described implant-associated T-cell anaplastic large cell lymphoma (ALCL) (79). Patients present 1 to 23 years following implant placement (median time 8 years) with capsule-associated contracture or a late onset seroma. In the few reported cases, there does not appear to be a predilection for a particular implant type (i.e., saline vs. silicone; textured vs. smooth). Microscopic examination of the seroma fluid or the fibrous capsule reveals a relatively cohesive population of large, pleomorphic blasts. The vast majority of implant-associated ALCLs are ALK-negative (anaplastic large cell kinase-negative) (79). Removal of the implant is recommended once the diagnosis is established. Limited data suggest that this lymphoma is relatively indolent, though there are reports of cases with an aggressive clinical course (80).

Mondor's Disease (Phlebitis of the Thoracoepigastric Vein)

Mondor's disease, or phlebitis of the thoracoepigastric vein, has been considered to be rare (81). On pathologic examination, there is phlebitis and periphlebitis. The obliterative endophlebitis is associated with varying degrees of thrombosis, and the adventitia and media may be completely destroyed in advanced cases.

Pathologic Changes Associated with Radiation Therapy for Carcinoma

Breast-conserving surgery, followed by radiation therapy, is now a common treatment for patients with early-stage

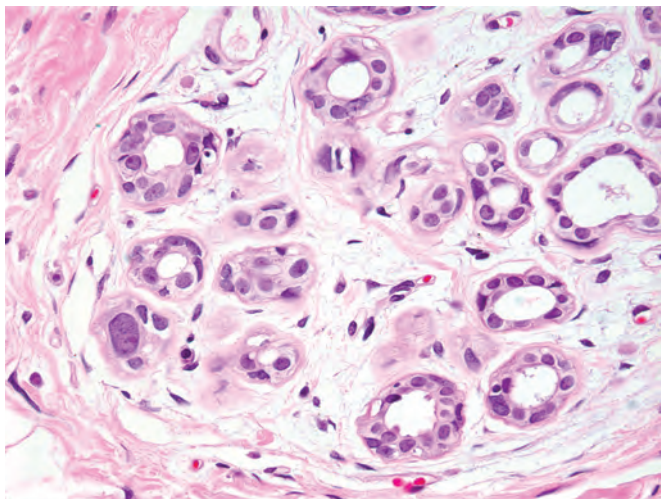

FIGURE 9-12 **Radiation effects.** This terminal duct lobular unit contains scattered enlarged epithelial cells with large, diffusely hyperchromatic nuclei. Cellular polarity is maintained and no evidence of cellular proliferation is present.

breast cancer. The effects of therapeutic doses of ionizing radiation on the skin of the breast have been well described, and are identical to the radiation-induced alterations occurring in skin from any irradiated site.

Fat necrosis can occur in the breast following local excision and radiation therapy for carcinoma. These lesions may be indistinguishable from carcinoma by clinical and radiographic examination, requiring complete histologic examination for accurate diagnosis. The most characteristic pathologic finding in breast tissue excised following primary radiation therapy for carcinoma is epithelial cell atypia in the TDLU, usually associated with varying degrees of lobular sclerosis and atrophy (82) (Fig. 9-12). These changes may be distinguished from carcinoma involving the TDLU by the preservation of polarity and cohesion, and by the absence of cellular proliferation and distention of the involved TDLU in areas of radiation-induced change. Similar epithelial changes have been described in patients treated with preoperative or neoadjuvant chemotherapy (83). Less frequently, epithelial atypia in large (extralobular) ducts, atypical fibroblasts in the stroma, and radiation-related vascular changes may be observed. Interestingly, stromal fibrosis, a characteristic feature of radiation effect in other organs, is so variable among both irradiated patients and nonirradiated control subjects that it is not, by itself, a reliable marker for radiation-induced injury in the breast.

Sarcoidosis

Involvement of the breast by sarcoidosis is rare, but when present, may clinically simulate a neoplasm. Histologically, the lesions consist of typical, noncaseating granulomas with varying numbers of giant cells present in the interlobular and intralobular connective tissue. A diagnosis of sarcoidosis should be made only after the exclusion of other causes of granulomatous inflammation, such as mycobacterial, fungal, and parasitic infections or reactions to foreign materials. Sarcoidosis should also be distinguished from *granulomatous mastitis*, a lesion in which the granulomas are associated with microabscesses and which may respond to corticosteroid therapy.

Lymphocytic Mastitis/Diabetic Mastopathy

Insulin-dependent diabetic patients occasionally develop breast masses that on histologic examination show a characteristic constellation of features. These include dense, keloid-like fibrosis, lymphocytic infiltrates in association with ducts and lobules (lymphocytic ductitis and lobulitis), lymphocytic vasculitis, and epithelioid fibroblasts in the stroma. Although the pathogenesis of this lesion is unknown, it may represent an autoimmune reaction. Similar histologic changes have been described in association with other autoimmune diseases, such as Hashimoto's thyroiditis and in patients with various types of autoantibodies in their serum (84).

IgG4-Related Sclerosing Mastitis

IgG4-related sclerosing mastitis is a benign disease process characterized by discrete, painless breast masses which may be unilateral or bilateral. These lesions are composed of dense lymphoplasmacytic infiltrates with lymphoid follicle formation, a prominent component of IgG4-positive plasma cells, stromal sclerosis, and lobular atrophy. Elevated serum levels of IgG4 are often present as well as the finding of similar lesions in other organs (85,86).

CHAPTER 10

Breast Cancer Screening

Christoph I. Lee and Joann G. Elmore

CHAPTER CONTENTS

INTRODUCTION

Until breast cancer can be prevented, regular screening programs are widely recommended for asymptomatic women. The rationale behind such programs is that early diagnosis through screening can possibly reduce mortality and morbidity more effectively than no screening at all. Nevertheless, even though breast cancer screening has been more thoroughly studied than any other type of cancer screening, questions remain about its overall benefits and potential harms.

Evaluating any screening program is challenging, and breast cancer screening in particular has been a topic of many controversies over the years. In this chapter, we review the general principles of cancer screening that women, clinicians, and health system administrators need to consider before undertaking a breast cancer screening program. We then describe the many modalities that have been studied for possible inclusion in screening programs, including screening mammography, ultrasound, magnetic resonance imaging, breast examination by clinicians, and breast self-examination by individual women. We also review published data from randomized, controlled trials, population studies, and meta-analyses regarding the effects of screening programs on mortality and their potential harms, including false positive and false negative results, overdiagnosis, radiation exposure, anxiety, and economic cost. We then look at data on screening issues in special populations, such as elderly women and women with genetic mutations. We conclude with suggestions on informed decision-making as individual women are the ones who must decide whether to undergo medical screening of any kind.

PRINCIPLES OF CANCER SCREENING

The goal of breast cancer screening is early detection of disease, to be followed by appropriate treatment. Screening tests differ from diagnostic tests insofar as screening identifies subgroups of people who have a high probability of

asymptomatic disease, while diagnostic tests are obtained in symptomatic patients. A positive screening result in an individual rarely provides direct evidence of disease; screening tests must be followed by diagnostic tests to determine whether disease is truly present.

When an apparently healthy population undergoes regular screening, medical professionals have an obligation to show that the benefits of screening outweigh the costs. As we discuss in more detail later in this chapter, a positive screening test result and a diagnosis of breast cancer brings anxiety and treatments with associated morbidities and costs. Screening tests should therefore be safe, with minimal side effects. The minimum requirements for establishing a safe, ethical, and cost-effective screening program involve three areas: the disease targeted by the program, the screening tests needed to detect the disease, and the features of the health care system needed to support the program (1). All the requirements for each of these areas are reviewed in further detail in the following material. If these requirements are not at least partially met, population-wide screening may be ineffective.

Disease Requirements

First, the disease must be serious, with significant morbidity or mortality. Second, an effective therapy for the disease must be available if it is detected as screening would obviously have no value if subsequent treatment would not be beneficial. Third, the natural history of the disease must be understood clearly enough to identify a significant window of opportunity during which the disease is detectable and detection would probably lead to a cure, or at least an effective treatment with less morbidity than the disease itself. Finally, the disease must not be too rare; if it is rare, we can expect an excess of false positive test results, which increases the cost and effort necessary to detect true positives.

Screening Test Requirements and Characteristics

First, a screening test must be reasonably easy and inexpensive to perform. Otherwise, the costs of large-scale screening in terms of time, effort, and money will be prohibitive. This is an important point to remember when considering the relative utility of the many screening modalities now available, as we will discuss in the next section. Second, the screening test must be safe and acceptable both to the individuals undergoing the screening and to their physicians. Finally, the level of accuracy of the screening test must be known and acceptable to the health care system, the physician, and the patient. Its sensitivity, specificity, positive predictive value, and other operating characteristics require careful assessment.

It is critical to understand the characteristics of a given screening test, as well as the interplay of its characteristics with those of the population screened and the clinicians who perform and interpret the test. We present a standard 2×2 table (Table 10-1) comparing the results of screening tests with the disease status of the individuals screened, along with a series of formulas to measure the sensitivity, specificity, and other performance features of the test. The next three paragraphs explain Table 10-1 in more detail.

A positive test result for a person who does not have the disease assessed by a test is called a false positive result while a negative result for a person who actually has the disease is called a false negative result.

Sensitivity refers to the ability of a screening test to detect a disease when it is present and is calculated as $a / (a + c)$. If a test is not sensitive, it will fail to detect disease in some people who actually have the disease; they appear in cell *c*.

Specificity refers to the ability of a screening test to indicate the absence of disease when no disease is present and is calculated as $d / (b + d)$. If a test is not specific, it will falsely indicate the presence of disease in some people who do not have the disease; they appear in cell *b*.

Another important parameter of a screening test is its predictive value, which may be either positive or negative. If a test result is positive, what is the probability that the person tested actually has the disease (i.e., true positive)? If the result is negative, what is the probability that the person does not have the disease (i.e., true negative)? The answers to these questions depend on the sensitivity and specificity of the screening test, as well as on the prevalence of the disease in the underlying population that undergoes screening. Positive predictive value (PPV) is calculated as $a / (a + b)$. Negative predictive value (NPV) is calculated as $d / (c + d)$, indicating the proportion of people with negative test results who are truly free of disease.

Health Care System Requirements

A screening program divides results into positives and negatives. Follow-up within a health care system must be available for everyone who has a positive result to confirm or rule out the presence of disease. Some follow-up testing can be expensive, time-consuming, and painful; it may even entail a degree of risk for the people who receive it. For example, estimates indicate that for every $100 U.S. dollars spent on breast cancer screening, an additional $33 are spent on subsequent diagnostic evaluations stemming from false positive results (2).

Before screening is undertaken, treatment should be available, accessible, and acceptable to people with disease. If a country's resources are too limited to provide treatment in an equitable manner, or if no effective treatment for a given disease is available, it makes no sense, either ethically or in terms of cost-effectiveness, to encourage screening when people in whom disease is actually detected must go untreated.

BREAST CANCER SCREENING MODALITIES

Screen-Film Mammography

Screen-film mammography (SFM) has historically been the standard modality used for breast cancer screening, and the technology studied in all major randomized controlled trials reporting mortality benefit from screening. SFM serves as both image receptor and display medium, thus, requiring images to be processed much like film-based photography prior to digital photography. SFM images need to be developed and fixed chemically, with an image rejection rate due to processing errors exceeding 20% (3). Repeat imaging due to processing errors results in increased examination time, increased patient exposure to ionizing radiation, and increased costs. Thus, full-field digital mammography (FFDM) has quickly replaced SFM, as it does not require chemical image processing and, by enabling real-time contrast and brightness correction, reduces the rate of image rejection due to processing errors.

Digital Mammography

Because SFM serves as both image receptor and display medium, the film must be processed before review, resulting in delayed interpretations and requiring additional resources

TABLE 10-1

Standard 2 × 2 Table Comparing Test Results and Disease Status of Subjects Tested, along with Formulas to Measure Test Characteristics

		TRUE DISEASE STATUS		
		Diseased	*Nondiseased*	*Total*
TEST RESULT	Positive	*a*	*b*	*a* + *b*
	Negative	*c*	*d*	*c* + *d*
	Total	*a* + *c*	*b* + *d*	*a* + *b* + *c* + *d*

Cells:

a = subjects with true positive test results
b = subjects with false positive test results
c = subjects with false negative test results
d = subjects with true negative test results

a + *b* = all subjects with positive test results
c + *d* = all subjects with negative test results
a + *c* = all subjects with disease
b + *d* = all subjects without disease

a + *b* + *c* + *d* = all study subjects

Associated formulas:

a / (*a* + *c*) = sensitivity
d / (*b* + *d*) = specificity
b / (*b* + *d*) = false positive error rate (alpha error rate, type I rate)
c / (*a* + *c*) = false negative error rate (beta error rate, type II rate)
a / (*a* + *b*) = positive predictive value
d / (*c* + *d*) = negative predictive value
[*a* / (*a* + *c*)] / [*b* / (*b* + *d*)] = (*a* / *b*) / [(*a* + *c*) / (*b* + *d*)] = likelihood ratio positive (LR+)
[*c* / (*a* + *c*)] / [*d* / (*b* + *d*)] = (*c* / *d*) / [(*a* + *c*) / (*b* + *d*)] = likelihood ratio negative (LR–)
(*a* + *c*) / (*a* + *b* + *c* + *d*) = prevalence

for image archiving. Full-field digital mammography (FFDM), in comparison to SFM, has been shown to have lower noise, higher contrast, and improved dynamic range (4). In addition, FFDM allows immediate display of digital images on a monitor without film processing, enabling more rapid interpretation (5). Moreover, FFDM makes the use of computer-aided detection (CAD) software, which recognize suspicious image patterns, a possibility.

Large clinical trials comparing FFDM to SFM have generally demonstrated similar accuracy overall, with slight improvements when FFDM is used in certain subpopulations(6–8). For example, the Digital Mammography Imaging Screening Trial (DMIST) compared the performance of FFDM to SFM in asymptomatic U.S. women, finding similar accuracy for breast cancer detection(9). However, FFDM was more accurate than SFM in three subpopulations: pre- or peri-menopausal women, women younger than age 50, and women with mammographically dense breast tissue. Given the growing evidence that FFDM is at least as useful as SFM for screening purposes, FFDM has progressively been adopted over SFM, especially in light of the potential efficiencies inherent in digital image transfer, interpretation, and archiving=(10).

Computer-Aided Detection

Computer-aided detection (CAD) has been found effective for improving the detection of malignancy when it is used in conjunction with both SFM and FFDM (11–13). CAD was initially developed to help radiologists identify small tumors that might otherwise be overlooked, and has been shown to detect 84% to 94% of small malignancies in SFM and FFDM, regardless of whether the malignancies present as masses or as calcifications (11,14,15). Moreover, CAD has been shown to have equal sensitivity for detecting malignancies in women regardless of breast density and histopathologic results (16). However, CAD is also associated with a high false positive rate of between 2 and 5 marks per screening case when the exams include four standard views (by either SFM or FFDM), which may potentially confound radiologic interpretation and lead to unnecessary diagnostic work-up (11,14,15,17). It is currently uncertain what effect the addition of CAD has had on patient outcomes such as mortality. Despite our lack of knowledge, CAD capabilities have become a standard feature of the latest generation of digital mammography workstations.

Ultrasound

Ultrasound serves as a critical adjunct diagnostic modality after abnormalities are noted during mammographic screening, and is increasingly used as a primary diagnostic modality for evaluating focal breast symptoms in women younger than age 40 (18,19). The use of ultrasound to screen asymptomatic women is also rapidly increasing, especially for women found to have extremely or heterogeneously dense breasts on mammography. Dense breast tissue reduces the sensitivity of screening mammography to detect malignancy, and is associated with an increased risk of breast cancer even after adjusting for associated risks such as age and body mass index (20–24). As of early 2013, legislation has been passed in the states of Connecticut, Texas, Virginia, New York, and California to mandate that women with mammographically dense breasts be informed that they may be at higher than average risk for developing cancer, and that they may benefit from supplemental screening tests such as whole-breast ultrasound (25).

Given the wide availability and relatively low cost of ultrasound, it will likely become the most common adjunct screening modality for asymptomatic women with dense breasts. However, current evidence for the effectiveness of ultrasound in breast cancer screening is scarce. To date, the largest trial comparing the addition of screening ultrasound to mammography in women with dense breasts and at least one other risk factor demonstrated a detection rate of 4.3 additional cancers per 1,000 women screened (26). Known as ACRIN 6666, this trial also found that the increased yield of detections came with an unfortunate increase in biopsy rates, from 2% of women screened with mammography alone to 5% of women screened with both mammography and ultrasound. Of the additional biopsies, only 7.4% were positive for cancer, suggesting a very high false positive rate. Because the screening exams studied in ACRIN 6666 were performed by subspecialty radiologists, it is uncertain what the rates of false positives and true positives would be for screening performed by community radiologists under real-world conditions (25). Moreover, no studies have demonstrated the clinical effectiveness of ultrasound screening in asymptomatic women with dense breasts who lack other risk factors.

Recently, automated whole-breast ultrasound (AWBU) was approved for medical use by the U.S. Food and Drug Administration (FDA). It enables the acquisition of ultrasound images of the breast without the need for a hand-held ultrasound exam (27). Early pilot data suggests that AWBU may provide high diagnostic accuracy and operator independence in whole-breast evaluation (28). However, no data from any large trials are currently available to indicate the rates of cancer detection, false positive results, unnecessary diagnostic follow-ups, or image-guided biopsies associated with AWBU.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) of the breast is more sensitive than mammography for identifying malignancies in women with a higher than average risk of breast cancer. Studies have found that the sensitivity of MRI for detecting cancer in this population ranges from 71% to 100%, in comparison to 16% to 40% for mammography (29–31). Currently, annual MRI screening is recommended for women with the gene mutations known as *BRCA1* and *BRCA2*, as well as women whose lifetime risk of breast cancer is higher than 25% (29). The latter group includes women with a strong family history of breast or ovarian cancer and women treated with radiation for Hodgkin disease. Using MRI to perform annual screening of women aged 35 to 54 years who carry the *BRCA1* mutation has been shown to be cost-effective, requiring $55,420 per year of life gained (after adjustment for quality of life) (32).

Insufficient data are available to assess the efficacy of annual MRI screening for women who have either personal histories of breast cancer, previous diagnoses of high-risk breast lesions (e.g., atypical ductal hyperplasia or lobular carcinoma *in situ*), or extremely dense breasts (29). Because the specificity of screening MRI is lower than that of mammography, its use may result in an increase in false positives and associated unnecessary diagnostic workups and image-guided biopsies. Studies suggest that 8% to 15% of all women who receive screening MRI are recalled for additional imaging evaluation, while 3% to 15% of all recipients of screening MRI will ultimately undergo breast biopsies (33 to 35). MRI remains an expensive technology, so its use for screening in the general population is unlikely to be covered by health insurance and will therefore require substantial out-of-pocket expenses for individual patients.

Digital Breast Tomosynthesis

While the sensitivity of FFDM is comparable to that of SFM, FFDM suffers from a masking effect caused by fibroglandular tissue lying directly above and below tumors in two-dimensional images. The masking problem can be partially overcome by digital breast tomosynthesis (DBT). This new technology, which has received approval by the FDA, uses a rotating camera that images the breast from various angles to create a three-dimensional view (36). DBT offers significant advantages over ultrasound and MRI in terms of cost, operation, and ease of use, as it has become an integrated component of the latest generation of digital mammography units (37).

Initial studies comparing DBT to FFDM demonstrated comparable sensitivity and specificity for detecting cancer (38–41). By eliminating the masking problem from screening mammography, adjunct DBT has been reported to produce a 30% to 40% reduction in call-back rates compared to FFDM alone (40–42). Because about 10% of U.S. women are recalled for additional views after screening mammography, DBT may offer substantial cost savings by reducing unnecessary diagnostic workups. As DBT is associated with an additional radiation dose equal to that of routine mammography, the use of adjunct DBT effectively doubles the radiation dose received by patients (43). The clinical and cost-effectiveness of DBT is currently under study in large clinical trials, but no results are available to date.

Molecular Breast Imaging

Molecular breast imaging includes several modalities that use nuclear medicine techniques in combination with radiopharmaceutical agents. Among them are breast-specific gamma imaging (breast scintigraphy) and positron emission mammography, two new technologies that have been approved by the FDA. Some physicians have begun to use molecular breast imaging either as an adjunct diagnostic modality for evaluating abnormalities found on screening mammography or in place of diagnostic MRI for patients with metallic implants or other contraindications for MRI (44). Anecdotally, some facilities also offer molecular breast imaging for screening high-risk patients and women with dense breasts. However, data on the clinical effectiveness of these techniques remain sparse. Nevertheless, as nuclear medicine technologies evolve, these devices may play an increasing role in breast cancer screening and diagnosis.

Clinical Breast Examination

Although screening mammography has been well studied, no research has evaluated clinical breast examination (CBE) by itself, without any other modalities, as a screening modality. The first randomized, controlled trial (RCT) to show breast cancer mortality reduction for combined mammography and CBE was the Health Insurance Plan (HIP) study in the 1960s (45). However, CBE and mammography were studied in combination and not separately. Subsequently, the Canadian National Breast Screening Study compared CBE plus mammography to CBE alone in women aged 50 to 59 years, with CBE conducted by trained health professionals whose performance was periodically evaluated and breast cancer mortality was found to be the same for women in both treatment groups (46). Overall, among the RCTs that evaluated the combination of mammography and CBE compared to usual care, adjunct CBE showed no incremental mortality benefit.

The quality of CBE performed by community clinicians might be less than that in an RCT, especially as the typical duration of an examination in the Canadian trial was 5 to 10 minutes per breast. CBE has also been studied in descriptive, population-based studies, the results of which suggest that it is less accurate than screening mammography. While the specificity may be high in the community, the sensitivity is likely much lower than what has been reported in published trials. For example, the specificity of CBE was 88% among specially trained clinicians in the Canadian trial during the first screening exam (47) and 99% in a U.S. community setting (48). Among women with breast cancer, a false negative CBE was less common in the trial on the first screening exam than in community settings: 17% (47) versus 43% (48), respectively. False negative CBEs result in false reassurance to patients that they do not have cancer, and can delay timely diagnosis and treatment.

Breast Self-Examination

Monthly breast self-examination (BSE) is frequently encouraged, but evidence for its effectiveness is weak (49,50). Research has shown that teaching BSE is not associated with reduced breast cancer mortality. One RCT randomly assigned female workers in Shanghai factories either to an intervention group that received instruction in BSE, with subsequent reinforcement, or to a control group with no intervention (51). After 10 years of follow-up, no difference in breast cancer mortality was found between groups. In addition, formal instruction and encouragement to perform BSE led to more breast biopsies and more diagnoses of benign breast lesions in the intervention group. In this group, the biopsy rate was 1.8%, compared with 1% in the control group. However, a major limitation of the study was that 40% of participants were younger than age 40 at enrollment, a population for whom screening has never been shown to be beneficial.

Case-control studies, nonrandomized trials, and cohort studies on the effectiveness of BSE have returned mixed results, which are difficult to interpret because of possible selection and recall bias. In the U.K. Trial of Early Detection of Breast Cancer, more than 63,500 women aged 45 to 64 years were invited to educational sessions on BSE. However, no difference in mortality was noted when the study sites were compared with other centers without organized BSE education (RR = 1.07; 95% CI, 0.93–1.22) (52). The Canadian National Breast Screening Study noted above also included a nested case-control study based on self-reported BSE, with results suggesting that well-performed BSE may be effective (53).

To improve women's accuracy in performing BSE, a device called the B-D Sensability™ Breast Self-Examination Aid (54) (previously called the Sensor Pad™) has been approved by the FDA. However, no evidence is available on its efficacy in reducing breast cancer mortality.

Thermography

Breast thermography, or digital infrared imaging, is based on the belief that the tissue surrounding a developing breast cancer has higher metabolic activity and vascular circulation compared to normal breast tissue. Supporters of this technology claim that increased regional surface temperature can be imaged and used as a means for identifying breast cancer (55). However, there is no substantial scientific evidence to give credence to this theory and this unproven technology is not endorsed by leading medical societies for breast cancer screening.

BENEFITS OF SCREENING—EFFECT ON BREAST CANCER MORTALITY AND CHALLENGES OF STUDYING SCREENING PROGRAMS

It is difficult to establish the value of a community-based screening program unless an RCT is conducted, as RCTs are less prone to bias than other types of study designs. An improvement in survival among women who have undergone breast cancer screening is often taken to imply that the test saves lives. However, association between receipt of screening and longer survival does not necessarily prove a cause-and-effect relationship, because a study might be limited by various forms of bias (Fig. 10-1) (1). *Selection bias* occurs when most participants in a screening program are healthier than average, so they will likely have a better overall rate of mortality. *Lead-time bias* occurs when screening detects a disease earlier in its natural history than would otherwise have happened, thereby lengthening the time between diagnosis and death. Nevertheless, having additional time during which the diagnosis is known seems unlikely to alter the natural history of the disease, so that no overall reduction in mortality will result. *Length bias* occurs when the full spectrum of a disease includes both indolent and aggressive cases, such that screening participants with less aggressive illness are likely to survive longer after diagnosis, regardless of the treatment they receive.

RANDOMIZED CLINICAL TRIALS OF SCREENING MAMMOGRAPHY

Summary of RCTs

Population-based randomized, controlled trials (RCTs) involving screening mammography have been conducted in North America and Europe with participation by nearly half a million women (46,56–66). These trials differ with regards to design, recruitment, participant characteristics, imaging protocols, management of control groups, compliance with assignment to screening and control group and analysis of outcomes (67). Almost all reported a mortality reduction for women screened by mammography.

Most randomized trials were not set up to specifically evaluate screening mammography for women less than 50 years of age, and the use of age 50 has been considered somewhat arbitrary. The recent AGE trial focused specifically on screening of women 40 to 49 years of age and found

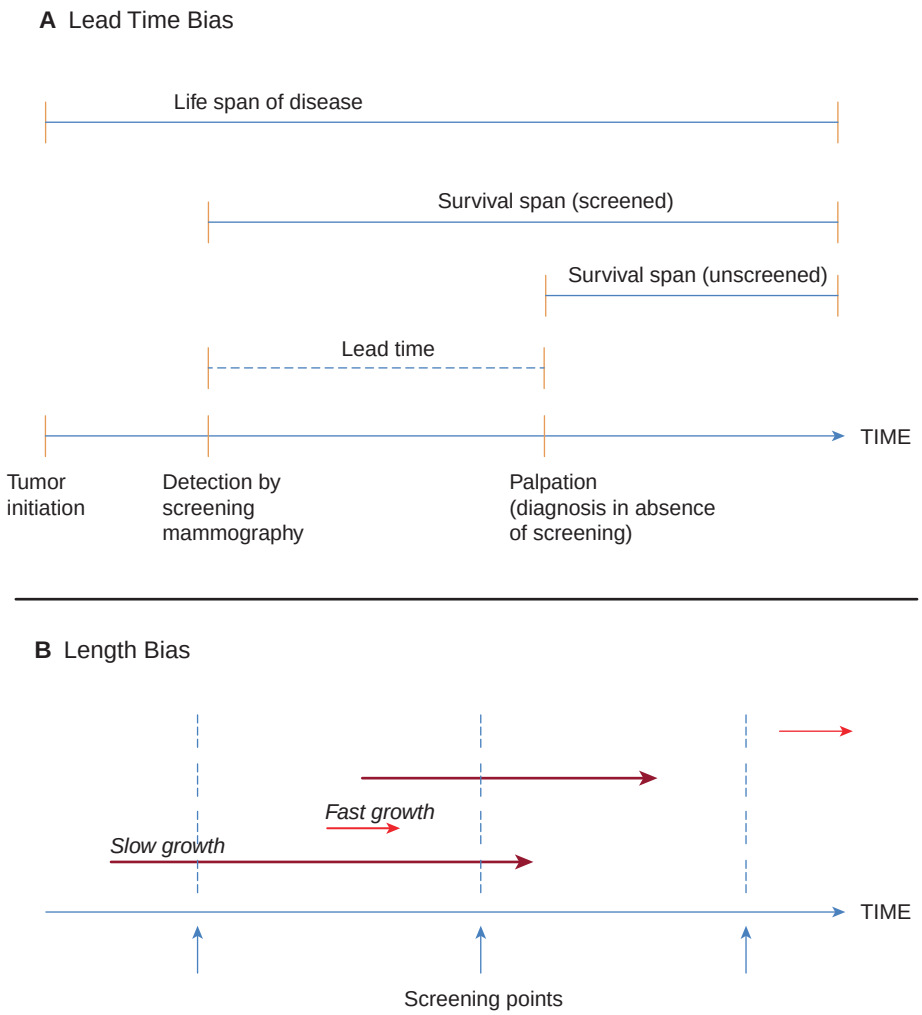

FIGURE 10-1 Lead-time **(A)** and length **(B)** bias. In part B, the length of the arrows represents the time required for the tumor to reach a palpable size. (From Institute of Medicine (IOM). *Mammography and beyond: developing technologies for the early detection of breast cancer: a non-technical summary*. The National Academies Press. http:// www.nap.edu/openbook.php?record_id=10107&page=7)

a small reduction in breast cancer mortality from screening (65). However, the reduction did not reach statistical significance. Thus, the effectiveness of routinely screening women 40 to 49 years of age remains controversial, with concern regarding whether or not the magnitude of benefit from routine screening sufficiently outweighs the harms of false positives and overdiagnosis.

Overview of Individual RCTs

The first RCT, the *Health Insurance Plan of Greater New York* (HIP), was met with great enthusiasm (45,66). In this trial conducted from 1963 to 1966, women aged 40 to 64 years at entry were randomized to screening versus no screening. While there were slight imbalances in the distribution of women between assigned arms with regards to both menopausal status and education, these did not favor the screening nor the control group. The sample size was 30,239 women in the study group and 30,256 women in the control group with the intervention being two-view mammography annually and clinical breast examination (CBE) every 3 years. As in many of the other subsequent RCTs, noncompliance was an issue, with approximately 35% of the invitation-to-screening cohort not attending the first screening. These women who did not attend their initial screening were not re-invited. In this early trial, screening mammography was not readily available outside of the clinical trial, as was often the case leading to contamination of the control groups in other subsequent RCTs. However, it is unclear whether CBE was performed with the same frequency in the two study arms. The follow-up duration for this study was 18 years with a relative risk of breast cancer death of 0.71 at 10 years, and at 0.77 at 15 years. Of note, the mammograms were performed with older equipment and may be of lower quality than current technologies (68). HIP also had differential exclusion between the intervention and control groups of women with a prior history of breast cancer.

The Malmo, Sweden study, which began in 1976, invited women aged 45 to 69 years for mammography screening (69,70). This trial had 21,088 women in the intervention and 21,195 women in the control group, with 74% of women invited to screen attending their first screen, and 70% attending rounds 2 to 5. The intervention was two-view mammography every 18 to 24 months for nine rounds. The control group received mammography at the end of the study, after year 14. It is thought that about 24% of all control women had at least one mammogram. This study had 12 years of follow-up with a subsequent relative risk of breast cancer death at 0.81 (0.62–1.07). This Malmo study, which is often referred to as MMST1 Mammography Screening Trial 1, is often combined with the MMST2 trial for many analyses.

The Swedish Two-County Trial (71–73), which began in 1977, enrolled women 40 to 74 years of age. The randomization was done through geographic clustering with

geographic units designed to be heterogeneous with regards to urban versus rural, population size, and socioeconomic factors. Women with preexisting breast cancer were excluded from both groups. This trial enrolled approximately 80,000 women to screening and just over 39,000 women in the control group from Ostergotland, Sweden, and approximately 39,000 women to screening and 18,000 in the control group from Kopparberg, Sweden. The intervention included one-view mammography every 2 years for women younger than 50 years and every 33 months for women 50 years and older. Contamination was much lower in this study compared to other RCTs; approximately 13% had mammograms as part of routine care, mostly in the later years of the study. The relative risk of breast cancer death for the screened population in the study was reported as 0.82 (0.64–1.05) in Ostergotland and 0.68 (0.52–0.89) in Kopparberg. Concerns have been raised about the randomization methods used as well as the analysis, which required correction for late performance of the control group mammography. However, the group from Sweden has performed subsequent meta-analysis that addressed many of these questions (70,71,74–76).

The Edinburgh (U.K.) Study, which commenced in 1976, enrolled women aged 45 to 64 years from 87 general practices (77). Patients were randomized by clustering based on physician practices. Some randomization assignments were changed after the study began and there was inconsistent recruitment of women within practices, perhaps according to physician judgment about the women's suitability for the trial. There were 28,628 in the intervention group and 26,015 women in the control group. The intervention consisted of two-view mammography and CBE initially followed by single-view mammography every 2 years for the duration of the trial. Compliance was 61% among those screened initially, and decreased to 44% by round 7. Contamination among the control group was not reported. Death was assessed by the Cancer Registry Data. The longest follow-up duration was 14 years, and the ultimate relative risk for the intervention group was 0.84 (0.63–1.12). The lower socioeconomic status and higher all-cause mortality in the control group compared with the screen group suggested inadequate randomization during the study.

The Canada National Breast Cancer Screening Study-1 (NBSS-1), which began in 1980, enrolled women aged 40 to 49 years who volunteered to participate (57). The sample size was 25,214 in the intervention group and 25,216 in the control group. The intervention consisted of annual two-view screening mammography and CBE for 4 to 5 years. Randomization was by blocks after CBE, stratified by the center and 5-year age groups. Compliance was initially 100% and decreased to 85.5% by the fifth screen. Contamination was noted in approximately one out of four women in the control group. The cause of death was ascribed to death certificates reviewed by a blinded panel and cross-referenced with Canadian Mortality Data Base, Statistics Canada. Follow-up over 13 years showed a relative risk of breast cancer death 0.97 (0.74–1.27). This and the later AGE trial are the only trials specifically designed to study women in their 40s. Of note, cancers diagnosed at entry in both of the study arms were included with a disproportionate number in the screened group compared with the control group. This study included evaluation of the technical quality of the mammograms and concerns have been expressed about the mammogram quality, the equipment standardization, and the radiologist's training. A mediolateral view was used in some of the early years for the screening arm instead of the mediolateral oblique view. This trial and the NBSS-2 differ from other RCTS in that women during this time period were also taking adjuvant hormone and chemotherapy following breast cancer therapy.

The Canada National Breast Cancer Screening Study-2 (NBSS-2), which also began in 1980, enrolled women 50 to 59 years of age who volunteered to participate (46). The sample size was 19,711 in the screened group and 19,694 in the control group with the intervention being annual two-view screening mammography and CBE. The control group received annual CBE. As in NBSS-1, all participants in both the control and intervention groups of NBSS-2 were pre-screened and instructed in breast self-examination. In the intervention group, compliance started at 100% and decreased to 87% by the fifth screen. In the control group, compliance initially began at 100% and fell to 85% by screen five. Contamination was lower in this study than in NBSS-1, involving 17% of the control group. There was 11 to 16 years of follow-up, with a relative risk of breast cancer death of 1.02 (0.78–1.33) for the intervention group. The cause of death was ascribed to death certificates that were reviewed by a blinded panel as well as a review with the Canadian Mortality Data Base, Statistics Canada. This trial compared one screening modality to another and does not include an unscreened control group. It also received similar criticisms and reviews as the NBSS-1 study. The quality of the CBE performed at the 15 Canadian centers involved in NBSS-1 and NBSS-2 was likely much higher than that performed in the general community (78).

The Stockholm (Sweden) Study, which commenced in 1981, enrolled women aged 40 to 64 years (79). Patients were randomized based on the birth date; specifically, by day of month. There were two sub-trials with a significant imbalance in the second with approximately 500 more women in the screened group than the control group. The sample size declined from approximately 40,000 to 38,000 in the intervention group and rose from nearly 20,000 to 21,000 in the control group. The intervention consisted of a single-view mammogram every 24 to 28 months. The control group received mammograms during the fifth year. Contamination was noted in approximately one out of four women in the control group. Compliance was 82% screened, and the relative risk of breast cancer death among those screened was 0.80 (0.53–1.22). The follow-up duration was 8 years and the cause of death was obtained by linking to the Swedish Cause of Death Registry. Some concerns have been raised about the randomization of this study, patient exclusions, and the delay in control group mammograms. Inclusion of these data in the Swedish meta-analysis addressed some of these questions (71–73).

The Gothenburg, Sweden Trial, which began in 1982, invited women aged 39 to 59 years old (63,80). The randomization method was complex, with women clustered randomly by their day of birth within their birth year for the older group (50 to 59 years old) and by individual for the younger group (39 to 49 years old). The ratio of study to control varied by the year depending on the mammogram availability. Women with a previous breast cancer diagnosis were excluded from the trial. The sample size included approximately 20,724 women in the screened group and 28,809 women in the control group. The intervention group received an initial two-view mammogram and then a single-view mammogram every 18 months, up to four screens in total. In addition, exams in the later years were double read by two radiologists. The control group received one screening exam approximately 3 to 8 months after the final screen in the study group. Women were followed up to 12 to 14 years. The relative risk of breast cancer death for screened women aged 39 to 59 years was 0.79 (0.58–1.08) in the initial evaluation and 0.77 (0.60–1.00) in the follow-up. The cause of death

was assessed by the Swedish Cause of Death Registry and also an independent endpoint committee. The interpretation of this study is complicated by the delay in performance of mammograms in the control group and by the unequal numbers of women in the invited and control groups.

The AGE Trial enrolled women aged 39 to 41 years from 1991 to 1997, and included 160,921 women (65). Women were randomized to screening with annual two-view mammography until age 48, or usual care for the control group. Patients were randomized based on lists of general practitioners in geographically defined areas of England, Wales, and Scotland; however, the allocation was concealed. Those women who were not invited to the study received usual care. The follow-up method was the intention-to-treat; although all women aged 50 years and older would be offered screening by the National Health Services (NHS). The follow-up duration was 10.7 years and the relative risk of breast cancer death was 0.83 (0.66–1.04). The cause of death was assessed by the NHS central register. The level of contamination of the study groups were not provided, and 70% or fewer women attended screening across the trial. To note, while this trial did not produce statistically significant results, its findings are similar to those of the other RCTs.

Meta-Analyses and Reviews of RCT Data

Meta-analyses of the RCTs have been published by different authors using varying analytic methods, with some authors excluding specific trials due to concerns about quality of the data (50,81–84). In general, most meta-analyses show a reduction in breast cancer mortality with mammography screening among women 40 to 74 years of age, with the greatest absolute risk reduction seen among the older age cohorts. The four trials conducted in Sweden comparing mammography with usual care demonstrated a 9 to 32% reduction in risk of breast cancer death among those screened (56,73). One meta-analysis found little change in the effectiveness of screening mammography in reducing breast cancer mortality after adjusting for differences in patient randomization and adherence to imaging protocols across the trials (Fig. 10-2) (85).

A meta-analysis of RCTs conducted for the U.S. Preventive Services Task Force in 2009, shown in Table 10-2, found that the number needed to invite to screen for 10 years to avoid or delay one death from breast cancer was 1,904 for women in their 40s, 1,339 for women in their 50s and 377 for women in their 60s (81). The meta-analysis demonstrated a pooled relative risk for breast cancer mortality for screening women aged 39 to 49 years of 0.85 (95% CI: 0.75–0.96), indicating a 15% reduction in breast cancer mortality favoring screening. Screening women aged 50 to 69 years was associated with an even lower pooled relative risk for breast cancer mortality of 0.68 (95% CI: 0.54–0.87) (81).

Additional analyses by six Cancer Intervention and Surveillance Modeling Network (CISNET) groups reported that screening every 2 years maintained the majority of the benefit of annual screening with almost half the false-positive results (82). This same group reported that starting biennial screening at age 40 years (vs. age 50 years) reduced

breast cancer mortality by an additional 3%, consumed more health care-related resources, and yielded more false-positive results (82).

An independent U.K. panel was convened to evaluate the benefits and harms of breast screening with a report published in 2012, which concluded that the U.K. breast screening programs confer "significant benefit and should continue." (84) This report describes the results of many of the different meta-analyses and includes a detailed description and review of published data on the topic of overdiagnosis. They report that, for every 10,000 U.K. women aged 50 years invited to screening for the next 20 years, 43 deaths from breast cancer would be prevented and 129 cases of DCIS and invasive breast cancer would be overdiagnosed; in other words, they estimate that there will be one breast cancer death prevented for about every three overdiagnosed cases identified and treated. They estimate that just over 1% of UK women invited to begin screening every year would have an overdiagnosed cancer in the next 20 years.

COMMENTS ON OTHER BENEFITS OF SCREENING

It should be noted that RCTs may underestimate the true benefits of mammographic screening, as mortality reduction is assessed among all women invited to be screened rather than those who actually participated in screening (86). Moreover, beyond mortality reduction, there are other potential benefits of mammographic screening including decreased patient morbidity from less invasive therapies for cancers detected at earlier stages (87). Cancers detected by mammography are statistically more likely to be treated with breast conservation surgery (56% vs 32%) and less likely to receive adjunct chemotherapy (28% vs 56%) (88,89). Women undergoing screening mammography, therefore, experience decreased morbidity by less frequently undergoing mastectomy and complete axillary node dissection, and are provided a wider choice of treatment options than women with cancers who do not undergo routine screening mammography (87). The U.S. preventive services task force (USPSTF) did not consider the increased morbidity associated with treating more advanced stage disease among women not routinely screened during the development of their recommendations.

POTENTIAL HARMS OF SCREENING

False Positive Results and Additional Interventions

Clinicians face the challenge of minimizing the number of women who are unnecessarily called back for diagnostic follow-up after a screening exam while maximizing the likelihood of detecting all potentially lethal cancers. This situation can be compared to the performance of a home smoke detector—you don't want an alarm sounding on a daily basis with no fire, nor do you want to miss an alarm triggered by smoke from a true fire.

Most women who are screened for breast cancer are free of disease. In the United States, approximately one in 10 women who are screened with mammography receive false positive results and are recalled for additional testing, even though they do not have breast cancer (90,91). The availability of prior test results for comparison can help to reassure radiologists that a lesion has been stable over time, and such availability has been associated with lower false positive rates (92). Increased breast density has been associated with lower sensitivity and specificity of screening mammography, with hormone therapy affecting density and, thus, interpretation. However, there are no specific guidelines or protocols for short-term suspension of hormone therapy (in order to optimize mammographic accuracy) that have been shown to be effective (93).

Most data on false positive results in breast cancer screening refer to rates per mammogram instead of rates per woman over the lifespan. This approach ignores the fact that many women undergo screening over a period of decades, and thus could receive 10, 20, or more exams during their lives. A retrospective study published in 1998 highlighted this problem by quantifying the cumulative risk of receiving false positive results. The study followed women who were continually enrolled in a U.S. health plan for 10 years. At the end of this period, one-third of the women who participated in breast cancer screening had received at least one abnormal result requiring additional evaluation, even though none of these women actually had breast cancer (2).

Furthermore, this same study found that the false positive rate associated with mammography was higher than that associated with CBE. The authors estimated that the cumulative risk of receiving at least one false positive result after 10 mammograms was 49.1% (95% CI, 40.3–64.1; see Fig. 10-1),

while the cumulative risk after 10 CBEs was only 22.3% (95% CI, 19.2–27.5). False positive results among study participants led to 870 outpatient appointments, 539 diagnostic mammograms, 186 ultrasound examinations, and 188 biopsies. In one patient, a false positive mammogram prompted a biopsy that resulted in cellulitis, requiring hospitalization for surgical debridement and intravenous antibiotic therapy. The same study also estimated the cumulative rate of breast biopsies, finding that among women without breast cancer, 18.6% (95% CI, 9.8–41.2) underwent biopsies after 10 mammograms and 6.2% (95% CI, 3.7–11.2) underwent biopsies after 10 CBEs. In terms of cost effectiveness, as the authors noted, every $100 spent on initial screening corresponded to an additional $33 spent to evaluate false positive results.

A subsequent study that modeled data from the same cohort of women found that the likelihood of a false positive mammogram varied widely based on characteristics of the women screened, the screening modality used, and the radiologist who interpreted the exam (94). The cumulative risk of receiving at least one false positive result by the ninth mammogram actually varied from 5% to 100%, with increasing risk independently associated with four patient variables (younger age; higher number of previous breast biopsies; family history of breast cancer; current estrogen use) and three radiology variables (longer time between screening; failure to compare the current mammogram with previous mammograms; individual tendency to interpret mammograms as abnormal). The single risk factor most strongly associated with false positive results was the last: the tendency of individual radiologists to find abnormalities on screening.

False positive rates may vary substantially from country to country. One report noted that the recall rate in the United States after screening mammography was twice as high as the rate in the United Kingdom, yet the rate of cancers detected was essentially the same in both countries (95). Another review of 32 community-based screening programs returned similar findings, noting that North American programs appear to interpret a higher percentage of mammograms as abnormal than do programs from other geographical regions, even though rates of cancer detection are similar (except that more cases of ductal carcinoma *in situ* are reported in North America) (96). This review also noted that the percentage of abnormal mammograms varies widely around the world (1.2%–15%), as does the PPV of abnormal mammograms (3.4%–48.7%) and of biopsies (5%–85.2%). Similar variability was noted for other outcomes, including the percentage of cases diagnosed as ductal carcinoma *in situ* (4.3%–68.1%) and the percentage diagnosed with minimal disease (14.0%–80.6%). The large percentage of mammograms judged abnormal in North American screening programs had a negative association with PPV (both $p < .001$) and a positive association with both the frequency of diagnoses of ductal carcinoma *in situ* ($p = .008$) and the number of such cases diagnosed per 1000 screens ($p = .024$). Factors that might explain such international discrepancies are summarized in Table 10-3. A woman's estimated risk of having at least one false positive screening mammogram, according to the total number of screening mammograms performed, is detailed in Figure 10-3.

Most studies on false-positive exams predate the widespread use of such modalities as CAD and MRI in breast screening programs, where the false positive rates may be even higher.

TABLE 10-3

Possible Explanations for the Variability in the Abnormal Interpretation Rate Noted among Published Studies of Screening Mammography

Characteristics of the population screened
Age (e.g., percentage of women <50 yr of age)
Initial versus subsequent screening examination
Presence of risk factors for breast cancer
Presence of breast symptoms
Self-referral versus physician referral
Features of the mammography examination
Equipment type and year
One or two views of each breast
Single or double readings
Technician training
Features of physicians interpreting the mammogram
Experience of the physician
Level of personal comfort with ambiguity
Individual thresholds to label film as abnormal
Features of the health care system
Malpractice concerns
Financial incentives
Private versus academic/public programs
Different stated goals for the percentage of mammograms judged abnormal and positive predictive value
Quality control and auditing procedures
Variability of definitions used to calculate outcomes

From a table in Elmore JG, Nakano CY, Koepsell TD, et al. International variation in screening mammography interpretations in community-based programs. *J Natl Cancer Inst* 2003;95(18):1384–1393.

False Negative Results and False Sense of Security

No medical test is perfect. All the screening modalities that we have discussed can return negative results even when breast cancer is present, either because a lesion was missed by the radiologist or clinician, or because no lesion was visible or palpable on examination. For example, if screening mammography has a sensitivity of 80%, then 20% of mammograms of women who will be diagnosed with breast cancer within 1 year will be interpreted as negative. These women, as well as their primary care physicians, would mistakenly be reassured by such false negative results. To counteract any false sense of security, mammography reports in the United States increasingly note the limitations of the examination and the potential impact of breast density on missed lesions; they also encourage women to seek evaluation if they personally note breast abnormalities despite negative findings on mammography.

Radiation Exposure

Radiation exposure is a known risk factor for developing breast cancer, as documented in observations of women who survived the atomic bombing of Hiroshima and Nagasaki and women who received therapeutic radiation treatments for the chest and upper body (97). Younger age at exposure and higher levels of exposure carry the greatest risk (98,99). Because mammography exposes women to radiation, various efforts have been proposed to minimize harm. These include reducing the amount of radiation required for screening, developing radiation-free screening modalities, and identifying subpopulations that might have heightened vulnerability to radiation (100,101).

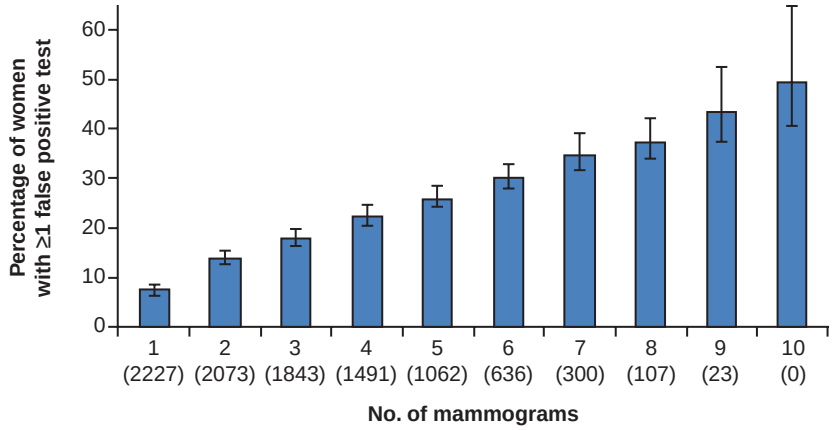

FIGURE 10-3 A woman's estimated risk of having at least one false positive screening mammogram, according to the total number of screening mammograms performed. NOTE: Numbers in parentheses denote numbers of women with at least that many mammograms. I bars indicate 95% confidence intervals. (From Elmore JG, Barton MB, Moceri VM, et al. Ten-year risk of false positive screening mammograms and clinical breast examinations. *N Engl J Med* 1998;338(16):1089–1096.)

In the United States, the mean glandular dose for screening mammography is 1 to 2 mGy (100–200 mrad) per view, which amounts to 2 to 4 mGy (200–400 mrad) per standard two-view examination (97,102). Discussions of the appropriate age to initiate screening often consider the increased lifetime exposure to radiation associated with screening young women.

Discomfort, Anxiety, and Distress

Compression of the breasts is required during mammography in order to create uniform breast density, improve image resolution, and reduce radiation dose. A systematic review of studies examining physical pain and discomfort associated with mammography demonstrates that while most women experience some physical discomfort, few considered the transient pain as a deterrent from screening (103). Pain was often associated with patients' menstrual cycles and anticipation of pain rather than the actual compression itself (103).

In general, women do not react well to hearing that their screening mammogram is "abnormal" and that they might have breast cancer. In such situations, women typically experience a heightened sense of their risk of cancer. Further, when media campaigns publicize that "one in eight women will be diagnosed with breast cancer," some women may misinterpret this message to mean that one in eight women will die of breast cancer. They may also be unaware that a 40-year-old woman is much less likely to be diagnosed with breast cancer than a 60-year-old woman.

Women who receive clear communication of negative mammography results have minimal anxiety about screening (104). Several studies, however, show at least transient levels of anxiety to persistent levels of anxiety for women who are recalled after screening for further diagnostic evaluation (104). One survey of women 3 months after screening mammography found that about one-quarter of those who initially received an abnormal result were still experiencing worry that affected their mood or functioning, even though subsequent testing had already ruled out a cancer diagnosis (105). Such worry and anxiety may have long-term effects. A systematic review of false positive mammograms found that anxiety after receiving a false positive result is associated with more frequent receipt of future screening mammograms (106).

Overdiagnosis

Overdiagnosis of breast cancer refers to the diagnosis of a neoplasm that would never become clinically apparent without screening before a patient's death from other causes (107). Because cancers that will progress cannot be distinguished with certainty from those that will not, any tumor identified by screening is usually treated with surgery and possibly with radiation, chemotherapy, and hormonal therapy. In some cases this regimen might constitute overtreatment because it confers no benefit unless the tumor will actually progress.

Autopsy studies that note breast tumors in women who died of causes unrelated to breast cancer provide some information on the possible rate of underlying breast cancer in the asymptomatic population. An overview of seven autopsy studies found a median prevalence of 1.3% for undiagnosed invasive breast cancer (range 0%–1.8%) and 8.9% for undiagnosed ductal carcinoma *in situ* (range 0%–14.7%) (108,109).

It is difficult to determine the proportion of cancers that are overdiagnosed by existing screening programs. Randomized screening trials might provide the best estimates, but such data are challenging to interpret and not available for all studies. Population-based studies have reported estimates derived from comparing groups with screening against groups without. However, unbiased estimates are possible only if both groups are identical except for screening status. Achieving this level of equivalence is daunting, considering that populations may differ in time, geography, culture, and use of hormone therapy, while investigators may differ in their analyses and handling of the various kinds of bias that affect research outcomes (110,111).

Another method of looking for overdiagnosis would be to conduct an observational, population-based comparison of breast cancer incidence rates before and after the adoption of screening. In the absence of overdiagnosis, we would expect to see a rise in the incidence of breast cancer after screening is adopted, followed by a decrease below the prescreening level, with cumulative incidence remaining stable. However, available findings are more suggestive of the presence of overdiagnosis, as breast cancer incidence rates have historically increased after the initiation of screening, without a compensatory drop in later years (112–117).

The magnitude of overdiagnosis of breast cancer due to screening is controversial, with reported estimates ranging from 7% to 50% of all breast cancer cases possibly being "overdiagnosed." (110,111,118–120) While the precise extent remains debatable, it is highly improbable that no overdiagnosis occurs.

SCREENING CONSIDERATIONS IN SPECIAL POPULATIONS

Women Younger Than 40

No available evidence supports screening in women younger than age 40 years who are at average risk of breast cancer. Because this subpopulation has a low breast cancer rate, a very large number of women would need to be screened to

detect a single case of breast cancer. Younger women are also more likely to have dense breast tissue, which is associated with less accurate screening performance, thus increasing the likelihood of false positives and false negatives.

Elderly Women

Defining the upper age at which breast cancer screening should no longer be recommended is challenging, and this topic is often neglected by guidelines, especially as published RCTs of mammography have not included women older than age 80. In general, a woman's overall state of health should be considered in any decision to undertake or forgo screening.

Women with Limited Life Expectancy

Among women with severe comorbidities who have limited life expectancy, it is critical to balance the potential benefits of screening against the potential harms. Such women might have severe lung disease, such as chronic obstructive pulmonary disease; end-stage renal failure; cardiovascular disease; or metastatic cancer from other organs. Early breast cancer detection and treatment are unlikely to reduce morbidity and mortality in these subpopulations.

It is often assumed that breast cancer screening should be considered for women expected to survive at least 5 more years (121). The harms associated with screening, such as false positives and the attendant anxiety, occur immediately after screening, while the potential benefits are not seen for many years, if at all. In addition, a diagnosis of breast cancer in these women would probably result in a recommendation for treatment, which could impair rather than improve their quality of life without improving their overall survival. Unfortunately, many women with limited life expectancy due to age or health status still undergo screening (122).

Women with Increased Breast Density

Women with extremely dense breast tissue have a three to five times greater lifetime risk of developing breast cancer compared to women with almost entirely fatty breasts, even after adjusting for associated risk factors such as age (21–23). Increased breast density is now regarded as an independent risk factor for breast cancer regardless of the populations studied and the influence of other known risk factors (123). As of 2013, several states including California, Connecticut, Texas, Virginia, and New York require imaging centers to report heterogeneously or extremely dense breast tissue directly to patients, informing them that they may be at increased risk for developing breast cancer. Moreover, some states also require women with dense breasts to receive notice that they may benefit from additional screening studies beyond the mammogram (25). However, there is currently little evidence that adjunct screening, such as with breast ultrasound, would have any additional mortality benefit.

Women with a Family History of Breast Cancer

While breast cancers result from multiple gene mutations, only a small subset are inherited mutations with the majority being sporadic and nonfamilial in nature. Simply having a family member with breast cancer does not play a very large role in determining a patient's lifetime risk of developing breast cancer because the majority of breast cancers are sporadic in nature and not inherited. Currently, major societies do not recommend additional or more frequent screening for women who have a relative with diagnosed breast cancer unless there is greater than 20%–25% lifetime risk for developing breast cancer based on available risk models (124).

Genetic Mutations That Increase Breast Cancer Risk

Women with the *BRCA1* or *BRCA2* mutations are at high risk for breast and ovarian cancer. According to two meta-analyses, the estimated cumulative risk of breast cancer by age 70 is 55% to 65% for carriers of *BRCA1* and 45% to 47% for carriers of *BRCA2* (125,126). Given this heightened risk, some carriers opt for prophylactic mastectomy. Mutation carriers who decide to keep their breasts are advised to consider beginning screening mammography and MRI before age 40.

Unfortunately, preliminary data suggest that mammography is less sensitive for women with *BRCA1* or *BRCA2* than for other women (127). One study found an association between the presence of "pushing margins" (histopathologic terminology for a pattern of invasion) and false negative mammograms in women with *BRCA1* or *BRCA2* (127). In addition, rapid doubling times for tumors in women who carry these mutations may mean that an apparently normal breast examination could be followed shortly afterward by a detectable malignancy (128).

In 1997, the Cancer Genetics Studies Consortium Task Force issued special recommendations for female carriers of *BRCA1* or *BRCA2*. They advised initiating annual mammography at age 25 to 35, performed at a consistent location with prior films available for comparison (129). More recently, the National Comprehensive Cancer Network has recommended annual screening beginning at age 25, while the American College of Radiology recommends annual screening beginning at age 30 (124,130). Meanwhile, the American Cancer Society recommends that initiation of screening be based on individual preferences and circumstances (29).

While *BRCA* mutation carriers may be more prone to radiation-induced breast cancer than women without mutations (131), some studies have not shown an increased risk from radiation (132,133). Any potential benefit of mammographic screening must be carefully weighed against potential risks, particularly in young women (134). However, we have insufficient evidence to suggest that mutation carriers should avoid mammography, particularly as some breast cancers are identified by mammography but missed by MRI.

Several studies have described the outcome of using MRI to screen women at high risk of breast cancer (31,33,35,135–140). These studies are variable in terms of the underlying population studied, the equipment and protocols used, and the calculation and reporting of results. Also, the number of screening rounds is limited, and the distinction between prevalent (first round of screening) and incident cancer detection rates is often unclear.

Despite these caveats, studies consistently demonstrate that breast MRI is more sensitive than either mammography or ultrasound in detecting hereditary breast cancer, although concerns have been raised about the reduced specificity of MRI compared with other screening modalities (31,33,35,138,141,142). Nevertheless, annual MRI screening of *BRCA*1 gene mutation carriers in addition to annual screening mammography has been shown to be cost-effective (143). Alternating MRI and mammography screening at 6-month intervals beginning at age 30 years has been identified as one approach to applying current guidelines in *BRCA1* gene mutation carriers (144).

Women Who Received Thoracic Radiation at an Early Age

Screening has been recommended for women who were exposed to therapeutic thoracic radiation, especially if their exposure occurred before age 30. These women have a much higher incidence of breast cancer (145).

Men

Breast cancer screening is not recommended for men. Even though they may develop breast cancer, such cases are uncommon; only about 1% of all breast cancers occur in men (146). Given this low incidence, no studies to date have addressed breast cancer screening for men.

THE U.S. MAMMOGRAPHY QUALITY STANDARDS ACT

The Mammography Quality Standards Act (MQSA), passed by the U.S. Congress in 1992, requires mammography facilities to meet uniform quality standards (147). The Act sets standards for personnel involved in performing and interpreting mammograms, effective quality control programs for each facility, and medical audit systems for following up abnormal mammograms and obtaining biopsy results. A 1997 report by the U.S. General Accounting Office found that MQSA positively affected mammography quality by ensuring that minimum national standards were met with regard to equipment operation, film processing, image interpretation, and results reporting (148).

It should be noted that MQSA applies only to mammography; mandatory minimum quality standards do not yet exist in the United States for other breast imaging modalities such as MRI and ultrasound (25). Accreditation and certification for operating and maintaining other modalities (e.g., breast ultrasound) remain mostly voluntary and optional. Nevertheless, the American College of Radiology, which is the only organization nationally approved to accredit MQSA, offers nonmandatory accreditation and certification programs for ultrasound, ultrasound-guided biopsy, and stereotactic-guided biopsy (149).

GUIDELINES AND INFORMED MEDICAL DECISION-MAKING

Numerous guidelines on breast cancer screening have been developed, with frequent changes as more evidence appears. The National Guideline Clearinghouse (http://www.guideline.gov) provides free, online access to summaries of evidence-based guidelines for clinical practice (150). This Web-based resource, supported by the U.S. Department of Health and Human Services and the Agency for Healthcare Research and Quality, is updated regularly, enabling comparisons of current recommendations by different groups. Most groups generally recommend mammographic screening for women aged 50 and older and recommend against both CBE and BSE. Nevertheless, recommendations often stress that women should understand and feel comfortable with the contour of their own breasts. Although recommendations for women in their 40s vary, it is clear that initiating screening at age 40 presents more challenges in terms of balancing risks against benefits than does deferring regular screening until age 50. In addition, guidelines over the years have increasingly encouraged clinicians to engage women in informed decision-making so that they can determine which approach to screening is right for them.

CONCLUSION

A breast cancer screening program asks healthy, asymptomatic women to undergo a screening examination in order to detect clinically occult, early-stage breast cancer. While data supports a mortality benefit from screening mammography examinations, the potential harms to individual patients cannot be ignored. Most medical groups currently recommend regular breast cancer screening with mammography for women of average risk, while the available imaging modalities for breast cancer screening and diagnosis continue to expand for women of higher risk. All women should be more fully informed of the balance between the benefits and risks associated with screening mammography, and should take a more active role in making the screening choices that are right for them.

MANAGEMENT SUMMARY

- Regular mammographic screening is widely recommended for asymptomatic women aged 50 years and older.
- Clinicians should engage women in informed decision-making about mammographic screening, weighing the associated benefits and harms, especially among women aged 40 to 50 years.
- Digital mammography is favored over screen-film mammography given its improved accuracy among certain subpopulations of women and in light of workflow and digital data management efficiencies.
- There is currently no evidence to recommend adjunct ultrasound screening in asymptomatic women with dense breasts who are at average risk of developing breast cancer. Adjunct screening breast MRI is recommended for women with *BRCA1* and *BRCA2* gene mutations, as well as women whose lifetime risk of breast cancer is higher than 20% to 25% according to available risk models.

CHAPTER 11

Imaging Analysis: Mammography

Mark A. Helvie and Stephanie K. Patterson

CHAPTER CONTENTS

Mammography is widely practiced in the United States and internationally for screening and diagnostic indications. High-quality examinations and interpretations are necessary for successful practice. Mammography refers to the process of obtaining images of the breast utilizing low energy x-rays. *Breast imaging* is a more general term that encompasses mammography, breast sonography, breast MRI, breast PET scanning, and other emerging technologies. Although it is convenient to discuss mammography independent of other breast imaging modalities, modern practice stresses an integrated approach of various imaging modalities, in particular, mammography, sonography, and more recently MRI.

This chapter will describe the basics of mammographic interpretation and usage in screening and common diagnostic situations. Efficacy of screening mammography, breast sonography, and MRI are covered in Chapters 11, 13, and 14.

Radiography of the breast has been performed for over 95 years. Although palpable breast cancer was often found to have characteristic mammographic findings, the application of mammography into practice was slow. The potential of mammography to detect clinically occult cancer led to international efforts to refine mammographic technique and eventually led to screening trials, primarily in northern European countries and North America. These showed mortality reduction in screened women which formed the basis for the current recommendation for mammographic screening (1). While some controversy exists regarding frequency and age to begin screening, most organizations recommend regular screening mammography. The explosive increase in mammographic screening in the United States in the 1980s and 1990s was associated with extensive public scrutiny and regulation. Breast imaging was first among imaging specialties to develop a standard lexicon and assessment categories to improve quality and communication between radiologist, referring physicians, and patients. Federal law (the Mammography Quality Standards Act [MQSA]) regulates mammographic equipment, quality operations, technologists, and interpreting physicians (2). Direct communication of mammographic results via written reports to patients is required. The Food and Drug Administration (FDA) performs annual on-site regulatory inspections. All sites, equipment, technologists, and reading physicians in the United States require FDA approval to perform and interpret mammograms. Individual states may have additional regulations.

TECHNIQUE

Basic understanding of radiologic physics is necessary for mammographic interpretation. A typical mammographic machine generates low energy (25–32 kVp) x-rays utilizing a small (0.3-mm) focal spot source, such as molybdenum, rhodium, or tungsten. The breast is compressed between an image receptor (film or digital detector) and a transparent plastic compression plate. Compression is used to minimize thickness and motion and is necessary to limit the radiation dose and improve image quality. X-rays are differentially absorbed by different types breast tissue. X-rays that are not absorbed pass through the breast and are detected by an image receptor. There are now two types of FDA approved receptors, film/screen and digital. In film/screen systems, the energy is eventually received by film, which is developed to produce a mammographic image similar to a photographic negative. In contrast, a digital detector receives the x-rays and electronically converts the energy into an electronic data set, which can be projected on a video monitor or printed as a film or stored and manipulated electronically similar to digital photography. Since 2005, there has been a marked trend toward digital mammography. Currently, over 85% of mammography units in the United States are digital. The mammographic appearance of cancer such as calcifications or masses is not different, although each system may offer some theoretical advantages at displaying these findings (3). Dark areas on a mammogram represent areas with minimal absorption (fat) while white areas represent moderate absorption by fibroglandular tissue or extensive absorption by calcium.

Image quality is affected by a host of factors including breast tissue "density," compressed thickness, positioning, motion, focal spot size, detector performance, and radiation dose. Manufacturers attempt to maximize multiple factors to achieve optimum image quality at the lowest possible radiation dose. The FDA limits dose to 3 mGy (300 mrad) for an average thickness breast per exposure. Mammographic technical requirements are mandated by the MQSA. Passing a yearly facility on site inspection by an FDA-approved agent is necessary to maintain operational accreditation. The mammographic technologists play a critical role in insuring quality screening program by optimizing mammographic positioning. The radiologist can interpret only the parts of the breast that have been included in the imaged field, so the skill of the technologist in maximizing positioning is essential for a quality mammogram. The American College of Radiology (ACR) reviews facility mammograms to assess positioning and technique prior to required certification.

SCREENING VERSUS DIAGNOSTIC MAMMOGRAPHY

Screening mammography refers to obtaining routine mammographic images of asymptomatic women in order to detect cancer at a preclinical stage. This is the primary role of mammography. The goal of screening is high sensitivity for early cancer detection. *Diagnostic* mammography refers to mammography used to evaluate abnormal clinical findings such as a breast mass, thickening, or nipple discharge. Diagnostic mammography also refers to obtaining incremental mammographic images (such as magnification views or spot views) for characterization of possible abnormalities detected by screening mammography at time of recall or call back. "Magnification" views employ smaller focal spots (0.1 mm) and larger subject to receptor distances and produce a 2× magnified image. "Spot" compression utilizes smaller compression paddles that focally decrease breast thickness in an area of concern. Unfortunately, the distinctions between screening and diagnostic mammography have been confused by definitions utilized for insurance billing purposes. An insurer may consider a woman with a prior biopsy of "fibrocystic disease" as "diagnostic" mammography for billing even though that individual may have no current abnormal palpable findings. For our purposes, screening mammography refers to the mammographic evaluation of an asymptomatic individual. In the United States, a screening study consists of two views of each breast, craniocaudal (CC) and mediolateral oblique (MLO). Usually screening mammography is performed without the presence of the physician with mammographic interpretation occurring later in a batch reading situation, which improves efficiency and allows for low-cost screening.

Not infrequently, findings noted on screening mammography require additional diagnostic imaging to resolve. Only a small portion of women recalled for diagnostic imaging will have cancer. A simplified U.S. screening pyramid (Fig. 11-1) provides an overview of the screening process. Assuming a cancer incidence of 3 per 1,000 of annually screened women and a recall rate of 8%, the following outcome is expected for 1,000 normal risk women undergoing annual screening mammography: 920 per 1,000 (92%) will be normal and 80 per 1,000 (8%) will be recalled for diagnostic mammography or ultrasound. Of the 80 women who are recalled, 70 per 1,000 (7%) will be normal or probably benign at diagnostic imaging and returned to mammographic screening and 10 per 1,000 (1%) will require tissue diagnosis for a mammographic abnormality. Of the 10 undergoing biopsy, 3 per 1,000 (0.3%) will be found to have cancer (4). These numbers are illustrative but will vary with incidence, screening frequency, recall rate, and biopsy rate.

Digital Breast Tomosynthesis

The major weakness of mammography is the detection of cancer in women with radiographic dense breasts. While nearly all cancers will be apparent in fatty breasts, many fewer will be visible in extremely dense breast. This is due to masking of noncalcified cancers by surrounding dense tissue. Digital breast tomosynthesis (DBT) mammography is a new technology derived from digital mammography that was approved by the FDA in 2011 to improve detection and

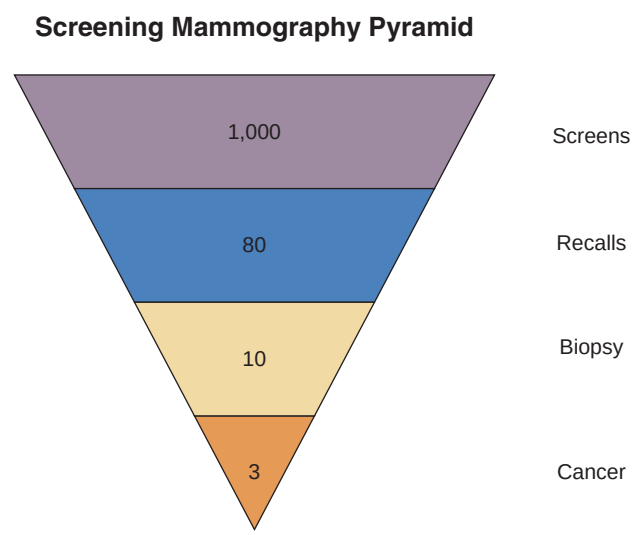

FIGURE 11-1 Simplified screening pyramid showing typical outcomes of 1,000 annually screened women of normal risk.

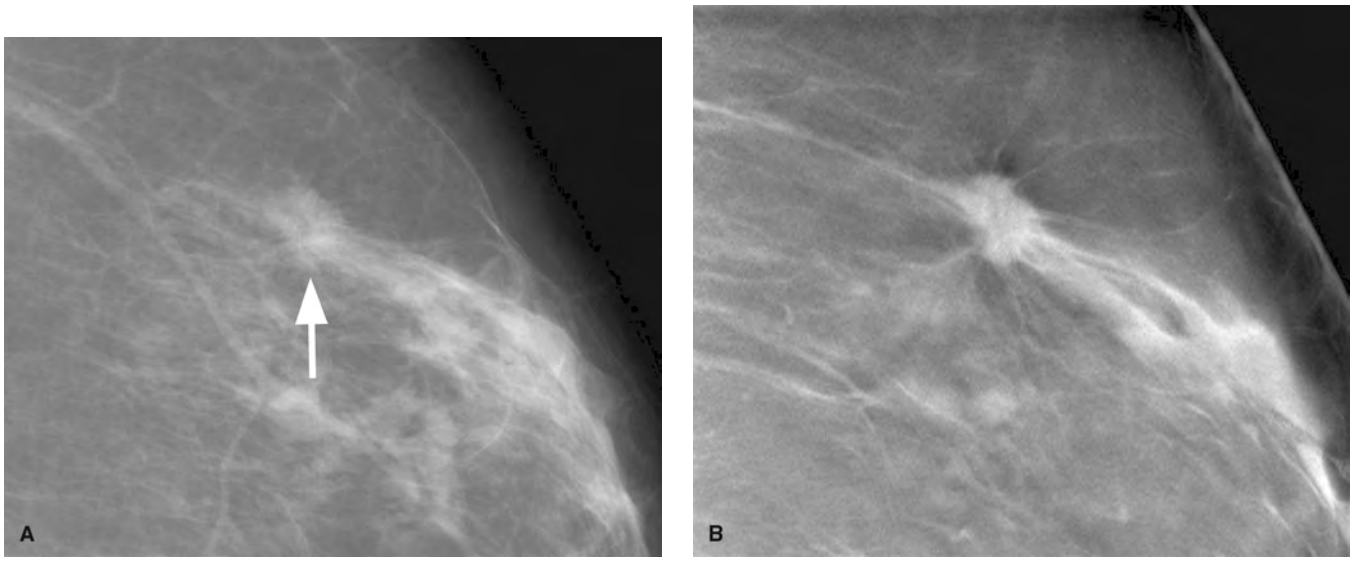

FIGURE 11-2 **(A)** Film screen mediolateral oblique mammography view of a patient with invasive ductal carcinoma *(arrow)*. **(B)** The cancer is better visualized on the 1-mm-thick tomosynthesis image.

characterization of breast lesions especially in women with nonfatty breasts (5). In DBT, the source x-ray tube is moved through a limited arc angle while the breast is compressed and a series of exposures are obtained (6). To a patient, DBT will be very similar to conventional digital mammography except there will be some movement of the x-ray tube head during exposures. These individual exposures are only a fraction of the total dose used during conventional digital mammography. The image data sets are reconstructed and the clinical reader is presented with a series of images (slices) through the entire breast that are read at a workstation analogous to CT or MRI study. Because each reconstructed slice may be as thin as 0.5 mm, masses and mass margins that may otherwise be superimposed with out-of-plane structures may be more visible in the reconstructed slice (Fig. 11-2). This should allow better visualization and characterization of noncalcified lesions. While the basic image interpretation will be similar to conventional mammography, new recall thresholds and probably benign thresholds will be established for DBT specific findings. In early studies, DBT has shown the ability to increase both sensitivity and specificity and has the potential to dramatically change not only how routine "mammography" is performed but also improve the clinical outcome of mammographic screening (5).

MAMMOGRAPHIC INTERPRETATION

Mammographic interpretation is a difficult task that can be dichotomized into two basic processes: detection (perception, visualization) of a possible abnormality and characterization (classification, analysis) of a potential abnormality. The goal of image interpretation by screening is high-detection sensitivity which requires the generation of false positives due to the nonspecific appearance of most small cancers. High sensitivity involves the ability to perceive potential abnormalities, only a fraction of which will prove to be cancer. Careful analysis of recalled patients by additional diagnostic imaging is necessary to evaluate a suspected lesion. With additional diagnostic mammography and ultrasound, a group of abnormalities of sufficient probability for malignancy will be recommended for biopsy. The commonly used U.S. threshold for biopsy is a probability of malignancy greater than or equal to 2% which corresponds to a BI-RADS classification of "suspicious finding" or BI-RADS 4 (7). Experienced readers can assign a reasonable probability of malignancy to a finding recommended for biopsy, but tissue diagnosis is necessary to confirm diagnosis even for lesions of very high probability. Mammographic appearances are seldom tissue specific.

Radiologists' Performance

Interpretation of mammographic images involves the art and science of medicine. While the recognition and characterization of classic large tumors is often straightforward, the detection of the small, subtle lesions can challenge the most expert reader. Interpretive variability exists for screening and diagnostic mammography. Key factors that influence overall performance include physician expertise, recall rates, observation time, biopsy rates, double reading, and CAD. The relationships among these parameters are complex.

Similar to other areas of human endeavor and medicine, differences have been found among radiologists interpreting mammograms (8–14). Beam et al., using an experimental model, found variation among practicing American radiologists with overall sensitivity ranging from 59% to 100% and specificity 35% to 98% (11). Sickles and colleagues reported higher cancer detection rates for specialists than generalists (6.0 per 1,000 vs. 3.4 per 1,000) within a single academic center in a retrospective clinical study (10). Specialists had higher volumes, more frequently participated in CME programs and fellowship training, and more often participated in radiologic–pathologic correlation conferences than generalists. The influence of reading volume on performance has not been consistent. Beam et al. tested 100 radiologists with an enriched study set of 148 mammograms with a 43% cancer incidence (11). They found reading volume not to be tightly associated with improved sensitivity. Rather complex multifactorial processes were found to be associated with expertise. Miglioretti and colleagues reported better performance for readers of diagnostic mammography at academic centers, those concentrating their time in breast imaging, and those performing breast biopsies (14). Volume was not

associated with performance. To date, no definite set of parameters completely predict reader expertise. Common associations with favorable interpretive skills and expertise include concentration in breast imaging, academic practice, continuing education, association with a multidisciplinary breast center, and practice audits (10,12,14). Reading a minimum of 480 mammographic cases per year is required by the FDA to maintain certification.

Sensitivity and specificity are inversely related for any particular reader due to nonspecific appearance of early breast cancer. Sensitivity increases with recall rate over a range of recall rates. High sensitivity can be achieved only when a sufficient number of women are recalled from screening for additional diagnostic mammography and ultrasonography (9,13,15,17). The ideal balance between sensitivity and recall rate is controversial and reflects philosophy, cost, cultural issues, and medical–legal issues. Yankaskas and colleagues demonstrated sensitivity increased from 65% at recall rates of 1.9% to 4.4% and to 80% sensitivity at recall rates of 8.9% to 13.4% in a study of practicing North Carolina radiologists (15). Karssemeijer et al., in an enriched study population, found sensitivity for masses improved from approximately 35% at a 3% callback rate to 59% at a 20% callback rate (9). Gur and colleagues noted improvements in sensitivity with increasing recall over a wide range (7.7% to 17.2%, $p < .05$) at a large clinical practice (17). On average, a 0.22 per 1,000 cancer detection rate improvement occurred for every 1% absolute increase in recall rate. Otten et al., in an experimental situation, found 47% sensitivity improvement when FP rate increased from 1% to 4% (16). In the United States, callback rates of 5% to 15% are common. Rosenberg et al. reported the middle 50% recall rate for practicing U.S. radiologists to be 6.4% to 13.3% (mean 9.8%) for 2.5 million screening studies (13). European callback rates are frequently lower. Dutch breast cancer screening program has reported callback rates as low as 1.1% (9,16). Emphasis on specificity and low cost will limit recall rate. Emphasis on high sensitivity will increase callback rates.

Mammographic sensitivity increases with reader observation time. Nodine and colleagues noted experienced mammographers made 71% of detections in the first 25 seconds but had continued true positive detections for approximately 80 seconds, albeit at a slower rate (18). Krupinski observed the detection of subtle findings occurred later in observation cycle than obvious masses which required longer visual dwell times (19). The threshold to initiate biopsy will influence cancer detection similar to recall rate thresholds. Higher thresholds for biopsy may be associated with higher false-negative (FN) rates and lower sensitivity (14).

Double Reading

Double reading (DR) has been advocated as a method to detect abnormalities overlooked by a single reader. Most independent DR studies have demonstrated improvement in sensitivity at a cost of lowered specificity. A review of clinical independent DR studies shows detection rate improvements of 4% to 15% (20). However, recall rates (FP) increased by 11% to 45%. These divergent trends for DR between sensitivity and specificity tend to balance accuracy. Taplin et al. showed independent DR improved sensitivity by 8.9% and decreased specificity by 13.6% similar to clinical trials (21). Accuracy, as determined by ROC methods, did not change suggesting that independent DR acted to shift the decision threshold towards sensitivity at the expense of specificity. DR with expert or consensus readers as the second reader appears to retain most improvements in sensitivity without large declines in specificity but this outcome may reflect in part the expertise of the second reader.

Computer-Aided Detection (CAD)

CAD systems, commercially available, use artificial computer intelligence in an attempt to act as a second reader. Like DR, most clinical CAD trials have shown improvement in sensitivity but declines in specificity. A CAD system functions as a second reader by placing "marks" on a mammographic site deemed suspicious. The radiologists then characterize these CAD detections. CAD can correctly identify approximately 60% to 80% of cancers with highest performance for microcalcifications. Unfortunately, CAD systems are very nonspecific with 2 to 4 marks placed per every exam. It has been estimated that only 1 in 5,000 CAD marks will reflect a true-positive finding representing a unique cancer missed by the radiologist (20). The interactions between radiologist and CAD are complex but tend to mirror DR studies. Clinical studies with CAD show sensitivity improvements varying from 1.7% to 19.5%, with declines in specificity as noted by increased recall rate of 0.1% to 26% (20). CAD effect on accuracy has often been incompletely reported so the determination whether CAD is increasing accuracy or shifting the threshold toward sensitivity has been questioned. Fenton et al. showed reader accuracy as measured by ROC methods declined with incremental use of CAD in a retrospective clinical study of 684,956 women (22). They showed a nonsignificant 6% improved sensitivity but a 13% significant loss of specificity. Sensitivity improvement for CAD was for DCIS. The reason for this negative result is uncertain but may result from overrelying on CAD, changing radiologists reading patterns, spending less overall time in observation, and radiologists being overwhelmed with the large number of false-positive CAD marks. While CAD remains controversial, CAD is in its infancy and the future of CAD is robust for detection and characterization tasks as a second reader. More effort will be required to improve the human interaction with CAD to reap the theoretical advantages of CAD. Current CAD systems are best viewed as a second reader with moderate sensitivity and poor specificity. Overreliance on CAD should be avoided and may actually degrade overall reader performance if used incorrectly. CAD should never be used to discount a finding deemed by the radiologist to be suspicious.

CHARACTERIZATION OF MAMMOGRAPHIC FINDINGS

Characterization is the process to determine if a suspected mammographic finding represents normal tissue, a benign finding, or potentially breast cancer. The goal of characterization is to establish a probability of malignancy and threshold the finding to determine if tissue sampling is required. This assessment is based on morphologic appearance of a finding and stability or change over time.

Mammography is not tissue specific. Some very low-probability-appearing abnormalities will prove to be malignant and conversely, some high-probability findings will be benign. Distinguishing between what lesions require biopsy and which can be followed involves thresholds. Most U.S. radiologists recommend biopsy for probability of cancer greater or equal to 2% (7). Individual radiologists assess their thresholds by auditing their practice by reviewing the frequency of malignancy for lesions recommended for biopsy (positive predictive value), their false-negative rate for lesions recommended for follow-up, tumor size, and stage. The U.S. Department of Health and Human Services has suggested the following as desirable goals for screening mammography which have been attained by highly skilled

experts: Positive predictive value for biopsy 25% to 40%, recall rate 5% to 10%, incident cancer detection 2 to 4 per 1,000, minimal cancer detection >30%, stage 0, 1 >50%, sensitivity >85%, and specificity >90% (4). Different patient populations will significantly impact on the ability of a screening population to attain these goals.

FDA/BI-RADS FINAL ASSESSMENT CATEGORIES

To provide national uniformity for reporting and assessment of mammographic findings, the American College of Radiology developed a lexicon for final assessment classifications ("BI-RADS") (7). After analyzing a mammogram, radiologists classify their findings into one of five final assessment categories (2,7). MQSA requires the use of final assessment categories paralleling those of the American College of Radiology (2). This lexicon is now used internationally. The final assessment categories are presented in Table 11-1. The categories are as follows:

Category 1: negative
Category 2: benign finding
Category 3: probably benign finding
Category 4: suspicious abnormality
Category 5: highly suggestive of malignancy (risk ≥95%)

Category 4 can be subdivided by risk into 4A (low), 4B (intermediate), and 4C (moderate). Functionally, Categories 1 and 2 represent a normal screening mammogram without

TABLE 11-1

American College of Radiology Breast Imaging Reporting and Data System (BI-RADS) Assessment Categories: Mammography

Complete Final Assessment Categories		
Category 1	Negative	There is nothing to comment on. The breasts are symmetrical and no masses, architectural disturbances, or suspicious calcifications are present.
Category 2	Benign finding	Like Category 1, this is a "normal" assessment, but here, the interpreter chooses to describe a benign finding in the mammography report. Involuting, calcified fibroadenomas, multiple secretory calcifications, fat-containing lesions such as oil cysts, lipomas, galactoceles, and mixed-density hamartomas all have characteristically benign appearances and may be labeled with confidence. The interpreter may also choose to describe intramammary lymph nodes, vascular calcifications, implants, or architectural distortion clearly related to a prior surgery while still concluding that there is no mammographic evidence of malignancy. Note that both Category 1 and Category 2 assessments indicate that there is no mammographic evidence of malignancy. Note that both Category 1 and Category 2 should be used when describing one or more specific benign mammographic findings in the report, whereas Category 1 should be used when no such findings are described.
Category 3	Probably benign finding: initial short interval follow-up suggested	A finding placed in this category should have less than a 2% risk of malignancy. It is not expected to change over the follow-up interval, but the radiologist would prefer to establish its stability. There are several prospective clinical studies demonstrating the safety and efficacy of initial short-term follow-up for specific mammographic findings. Three specific findings are described as being probably benign (the noncalcified circumscribed solid mass, the focal asymmetry, and the cluster of round (punctate) calcifications; the latter is anecdotally considered by some radiologists to be an absolutely benign feature). All the published studies emphasize the need to conduct a complete diagnostic imaging evaluation before making a probably benign (Category 3) assessment; hence it is inadvisable to render such an assessment when interpreting a screening examination. Also, all the published studies exclude palpable lesions, so the use of a probably benign assessment for a palpable lesion is not supported by scientific data. Finally, evidence from all the published studies indicates the need for biopsy rather than continued follow-up when most probably benign findings increase in size or extent. While the vast majority of findings in this category will be managed with an initial short-term follow-up (6 months) examination followed by additional examinations until longer-term (2 years or longer) stability is demonstrated, there may be occasions where biopsy is done (patient wishes or clinical concerns).

TABLE 11-1 *(Continued)*

American College of Radiology Breast Imaging Reporting and Data System (BI-RADS) Assessment Categories: Mammography

Complete Final Assessment Categories		
Category 4	Suspicious abnormality: biopsy should be considered	This category is reserved for findings that do not have the classic appearance of malignancy but have a wide range of probability of malignancy that is greater than those in Category 3. Thus, most recommendations of breast interventional procedures will be placed within this category. By subdividing Category 4 into 4A, 4B, and 4C as suggested in the guidance chapter, it is encouraged that relevant probabilities for malignancy by indicated within this category so the patient and her physician can make an informed decision on the ultimate course of action.
Category 5	Highly suggestive of malignancy: appropriate action should be taken	These lesions have a high probability (95%) of being cancer. This category contains lesions for which one-stage surgical treatment could be considered without preliminary biopsy. However, current oncologic management may require percutaneous tissue sampling as, for example, when sentinel node imaging is included in surgical treatment or when neoadjuvant chemotherapy is administered at the outset.
Category 6	Known biopsy: proven malignancy; appropriate action should be taken	This category is reserved for lesions identified on the imaging study with biopsy proof of malignancy prior to definitive therapy.
Category 0 Incomplete	Need additional imaging evaluation and/or prior mammograms for comparison	Finding for which additional imaging evaluation is needed. This is almost always used in a screening situation. Under certain circumstances this category may be used after a full mammographic workup. A recommendation for additional imaging evaluation may include, but is not limited to, the use of spot compression, magnification, special mammographic views, and ultrasound. Whenever possible, if the study is not negative and does not contain a typically benign finding, the current examination should be compared to previous studies. The radiologist should use judgment on how vigorously to attempt obtaining previous studies. Category 0 should be used only for old film comparison when such comparison is required to make a final assessment.

findings of malignancy. Category 2 may include a normal finding such as a calcified fibroadenoma, normal lymph node, or stable benign appearing calcifications. Category 3, probably benign, represents a finding of such low probability for malignancy that imaging follow-up is recommended instead of biopsy. Multiple studies have established the risk of malignancy to be less than 2% (23). The risk of malignancy expresses itself generally over the first 2 years. Recommended management consists of a follow-up mammogram at 6 months following the initial examination with subsequent follow-up at 12 and 24 months unless biopsy is elected by patient or physician. Diagnostic mammography should be performed prior to using the probably benign category. Category 4 and 5 assessments are abnormalities that require tissue biopsy for diagnosis. These categories represent a broad range (3% to 100%) of risk for cancer and experienced radiologists can render reasonable probability of malignancy estimates.

A category "incomplete" (BI-RADS 0) is used when a screening study requires additional imaging such as recall for diagnostic mammograms or comparison with older exams prior to rendering a final assessment. An incomplete assessment is just that, incomplete. An incomplete exam should not be considered "abnormal" as most will be shown to be normal. Only after diagnostic imaging or comparison with older films can a Category 1 to 5 final assessment be rendered. "Incomplete" has been used to categorize a normal mammogram in a setting of a palpable mass with assessment decision deferred to findings on ultrasonography. Although this is an acceptable use per FDA guidelines, it has led to some confusion in the performance literature based on BI-RADS codes alone. We prefer a definitive mammographic assessment as "negative" in this situation but recommend ultrasound examination of the palpable finding and report the sonographic finding independently. BI-RADS Category 6, "Known biopsy proven malignancy," can be used for cases with known malignant diagnoses.

Although BI-RADS reporting system has been favorably received, confusion can arise from patients and clinicians when a suspicious palpable or sonographic mass has a

"negative" mammogram report. In these situations, tissue biopsy is recommended when the palpable or sonographic findings are suspicious even if the mammogram is "negative." A "negative" mammogram in the presence of a suspicious clinical finding, suspicious USN, or suspicious MRI should never obviate a needed surgical biopsy. Mammography cannot "rule out" cancer.

MAMMOGRAPHIC APPEARANCE OF BREAST CANCER

There is a tendency to limit mammographic analysis to morphologic features. In practice, temporal change on serial mammograms provides a separate axis of analysis from morphologic features. A group of four calcifications that have been present for five years and unchanged may be observed while four new calcifications that were not present on a prior mammogram may be biopsied. Most mammographic cancers appear as masses, calcifications, asymmetry, distortion, or a combination of the four. Masses and calcification account for about 90% of all cancer appearances. Similar to the final assessment categories, a lexicon has been established by the ACR BI-RADS for describing and characterizing morphologic features (7). This lexicon use is not required by MQSA. The following discussion summarized the lexicon. Mammographic interpretation remains a *visual* interpretation process and not a verbal descriptive process. The figures have been chosen to show a range of appearances of breast cancer, not just obvious cases.

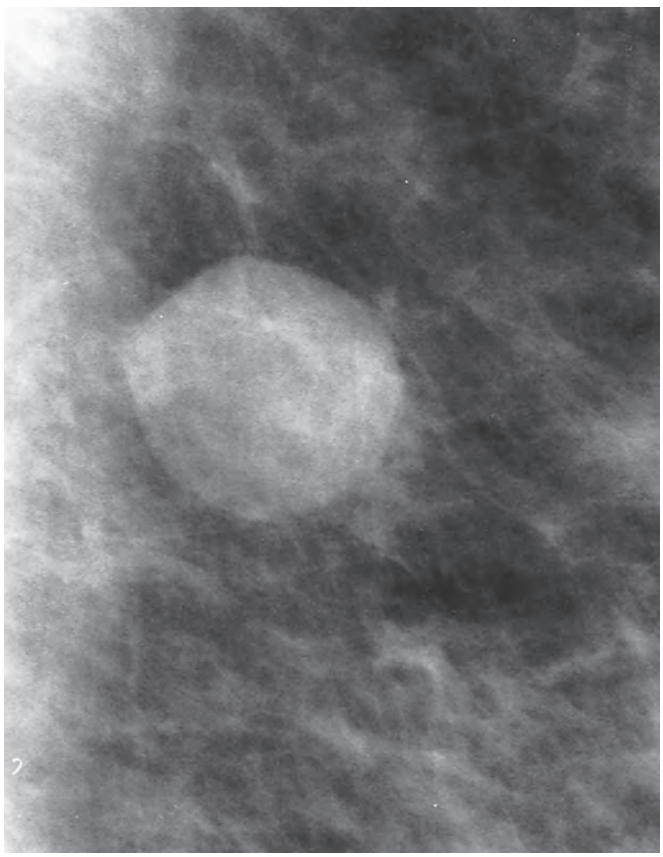

FIGURE 11-3 Smoothly marginated round 14-mm mass. Sonogram demonstrated a simple cyst.

Masses

Masses account for nearly half of all mammographic cancers. Masses refer to space occupying lesions that can be detected in two different projections. If a finding is noted only in a single view same as a CC view, it is referred to as a focal asymmetry. A focal asymmetry may or may not prove to be a "real" finding. Masses are characterized by their shape, margin, and density in order to determine a probability of malignancy.

Shape

Because of the infiltrative biologic nature of most breast cancers, irregular or lobular shaped masses are more likely associated with malignancy than round or oval masses.

Margins

The margin between a mass and the surrounding breast tissue is the key feature for analysis of masses because it relates to the infiltrating pattern of cancer. Often, margins are obscured by breast tissue rendering this evaluation impossible. Circumscribed, well-defined margins tend to represent a benign process (Figs. 11-3 and 11-4) such as cysts or fibroadenomas. Margins that are indistinct or microlobulated suggest infiltration into normal breast tissue and higher risk for malignancy. Smoothly marginated masses are usually subjected to ultrasound interrogation to assess if they represent a breast cyst for which no further intervention is required or a solid mass which often requires biopsy. Masses with indistinct margins may also be interrogated with ultrasound to assess for size, character, and visibility for potential biopsy procedure. Masses with spiculated borders forming a stellate or star-type pattern of radiating lines are associated with the highest risk of malignancy. As shown in Figures 11-3 through 11-7, there is a continuum in appearance of malignant and benign masses.

Mass Density

Lesions that are fat density (black on a mammogram) are benign and do not require tissue diagnosis. These typi-

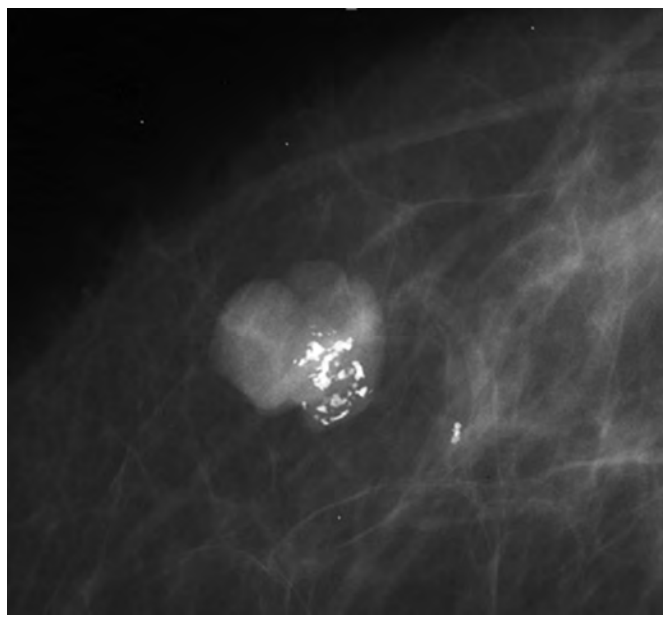

FIGURE 11-4 Spot compression view of a circumscribed mass with associated, very coarse calcifications, typical for a benign, degenerating fibroadenoma.

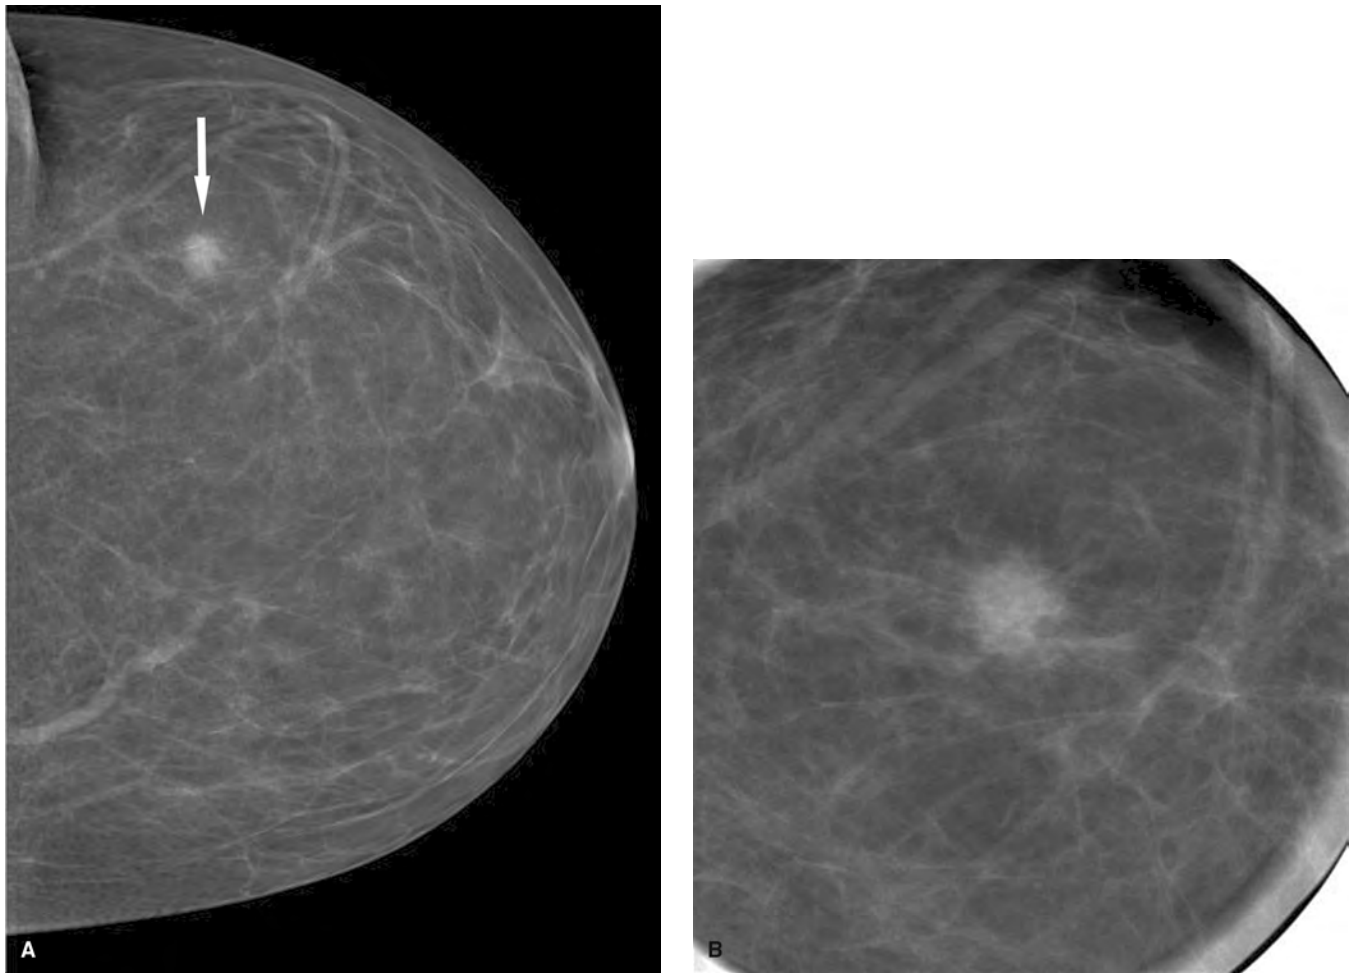

FIGURE 11-5 **(A)** Craniocaudal view shows a new small focal asymmetry in the lateral aspect of the breast *(arrow)*. **(B)** Spot compression magnification view confirms the presence of an indistinct, noncalcified mass: invasive ductal carcinoma.

cally represent lipomas or areas of traumatic fat necrosis with oil cyst formation. Certain circumscribed fat containing and fibroglandular density tissues may have appearance pathognomonic for a benign hamartoma and not require biopsy. Otherwise, density is of limited value in discriminating benign from malignant lesions, although high density is often a suspicious sign.

Calcifications

For reasons not entirely understood, calcifications are formed or are associated with breast carcinoma. Fortunately, calcifications are exquisitely detected by mammography with particles as small as 50 μm being visible. Because calcium absorbs x-rays, they produce a bright white spot on a mammogram. This inherent contrast between calcification and background tissue is a significant reason why mammography is successful in detecting small tumors, especially those associated with ductal carcinoma *in situ*. Calcifications can be seen reasonably well in dense breasts because calcium absorbs more x-ray energy than dense tissue. Unfortunately, many benign conditions such as fibrocystic change also produce breast calcifications that may mimic breast cancer calcifications. Some type of calcification is present on most mammograms. The radiologist is faced with a common problem regarding the nature and significance of calcifications. Magnification mammography is critical in characterizing calcifications. This allows better morphologic assessment of individual particles and clusters. Assessment of microcalcifications includes location, morphology, distribution, number, and biologic stability or progression. All of these factors are important in determining a risk of malignancy.

Location

Calcifications present within the skin may masquerade as parenchymal calcifications. These calcifications are typically small (less than 1 mm) with lucent centers. Radiologists can, with incremental imaging, prove with certainty that calcifications reside in the skin by tangential views. Dermal calcifications require no intervention. Other than dermal calcifications, location is of limited use in assessment.

Morphology

Artery calcifications appear as parallel lines associated with blood vessels and usually when established can be readily distinguished from linear calcifications of carcinoma. Large, coarse peripherally based "popcorn" calcifications are noted with fibroadenomas that are undergoing involution with age (Fig. 11-4). These also can be recognized as a specific benign entity and require no tissue diagnosis. Rod-like linear

FIGURE 11-6 Spot compression view demonstrates the circumscribed margins of an invasive ductal carcinoma, medullary type.

calcifications associated with benign ductal ectasia appear to fill ectatic ducts, are bilateral, and rather homogeneous (Fig. 11-8). In established cases, these calcifications provide no diagnostic dilemma. Early ductal ectatic calcifications may appear indistinguishable from ductal carcinoma in situ. Calcifications containing lucent centers ("eggshell" or "rim" calcifications) are benign and associated with calcified fat necrosis, calcified cysts (Fig. 11-9). Dystrophic calcifications associated with fat necrosis often follow trauma such as surgery and irradiation. They are usually larger than 0.5 mm and have lucent centers. Calcifications which appear to layer with gravity are consistent with sedimenting calcifications within small cysts ("milk of calcium" or "microcystic adenosis"). They are ill defined on the craniocaudal view and are sharply defined on the lateral view with dependent linear calcifications within small cysts. Biopsy is not required.

Most calcifications associated with cancer are small (< 0.5 mm) and often require magnification views for characterization. Malignant calcifications are notable for heterogeneity in size, shape, and geographic clustering. Malignant calcifications vary in appearance from subtle to obvious (Figs. 11-10 through 11-12) and may be associated with mass. Focal areas of amorphous indistinct calcifications are nonspecific in appearance and usually require tissue diagnosis. Positive predictive value for this type of calcification is about 20%.

High probability for cancer calcifications include pleomorphic or heterogeneous calcifications which are fine

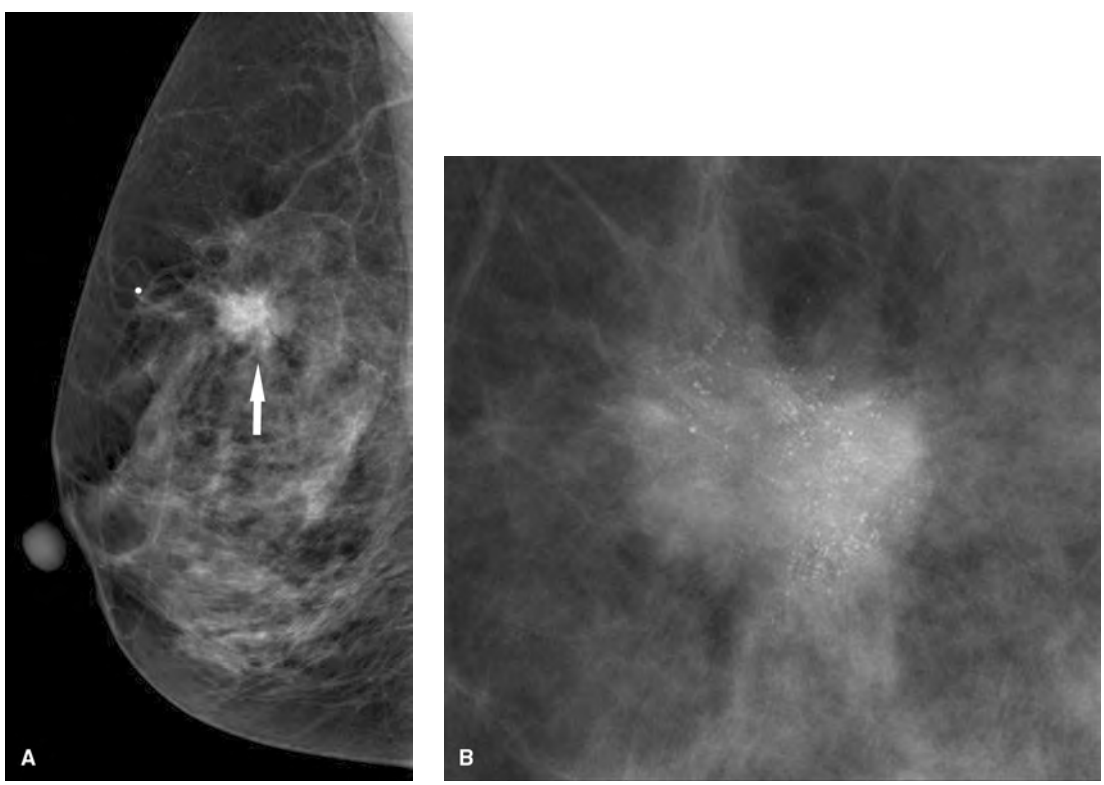

FIGURE 11-7 **(A)** Palpable, spiculated mass with associated microcalcifications *(arrow)*. **(B)** Spot magnification view confirms the presence of the spiculated mass with associated calcifications: invasive ductal carcinoma with DCIS.

FIGURE 11-8 Benign calcifications associated with ductal ectasia. These rod-shaped calcifications are oriented toward the nipple in this postmenopausal woman.

linear or fine linear branching calcifications conforming to a casting pattern of a duct. These calcifications are often associated with high-grade ductal *in situ*, with or without invasive cancer (Fig. 11-11).

Number

Although no number absolutely distinguishes benign from malignant, attempts have been made to determine reasonable thresholds for clinical intervention based on number of calcifications in a cluster. Five or more clustered calcifications not typically benign have been a threshold advocated by some experienced readers for biopsy. Others have noted increased frequency of cancer with increasing number of calcification particles. Most radiologists incorporate number of calcifications in a cluster, morphology and change with time to form an assessment regarding need to biopsy.

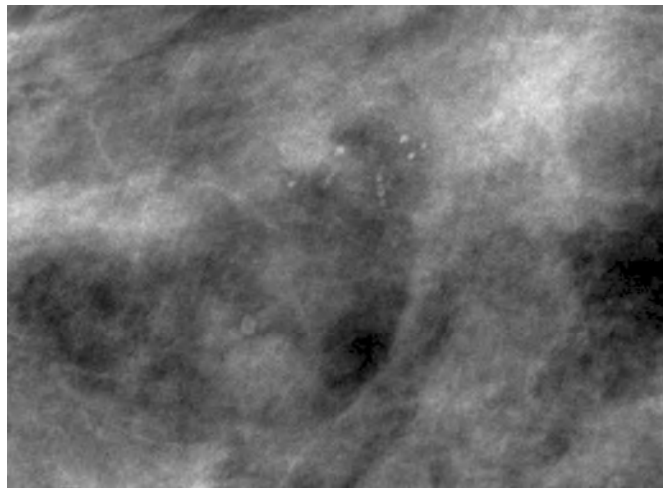

FIGURE 11-10 A 7-mm cluster of amorphous calcifications: ductal carcinoma *in situ*.

Distribution

Distribution of calcifications in addition to morphology, number, and biologic change helps establish a probability of malignancy.

- Grouped or clustered: Clustered calcifications refer to a group of calcifications in a less than 2 cm^3 volume of tissue. Although "cluster" has historically been associated with malignancy, this term can be used as a neutral designator.
- Linear: Calcifications that appear to be arranged within a line or duct imply a ductal origin. This is of moderate suspicion.

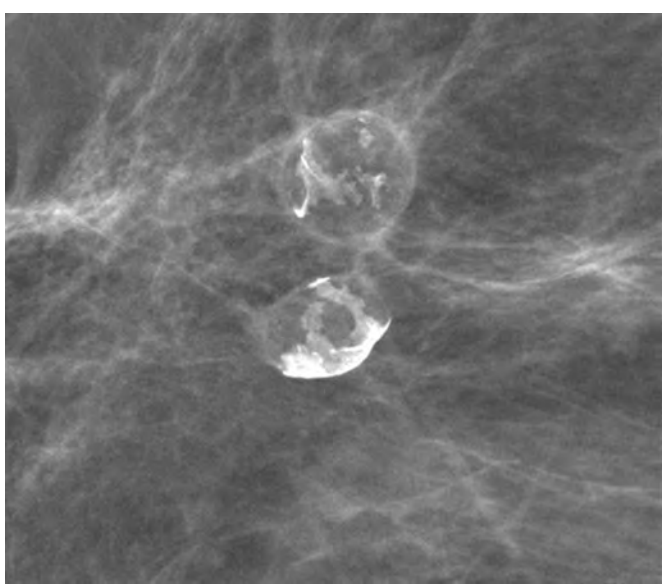

FIGURE 11-9 Benign calcifications associated with lucent masses typical for oil cysts and fat necrosis.

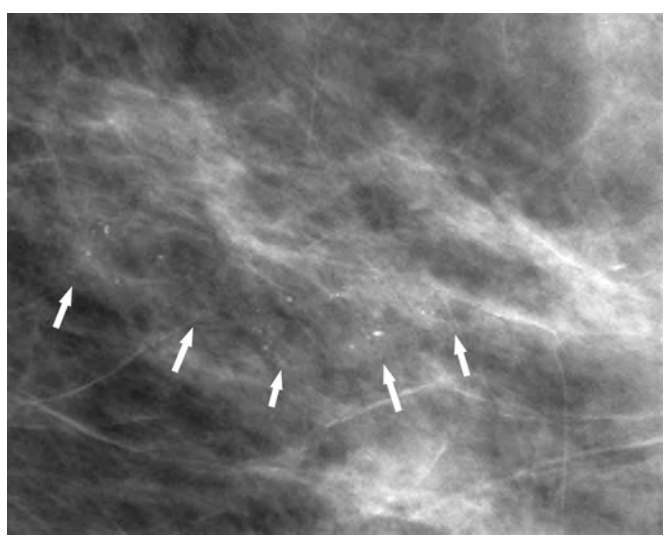

FIGURE 11-11 A 7-cm area of calcifications in a linear distribution *(arrows)*: ductal carcinoma *in situ*.

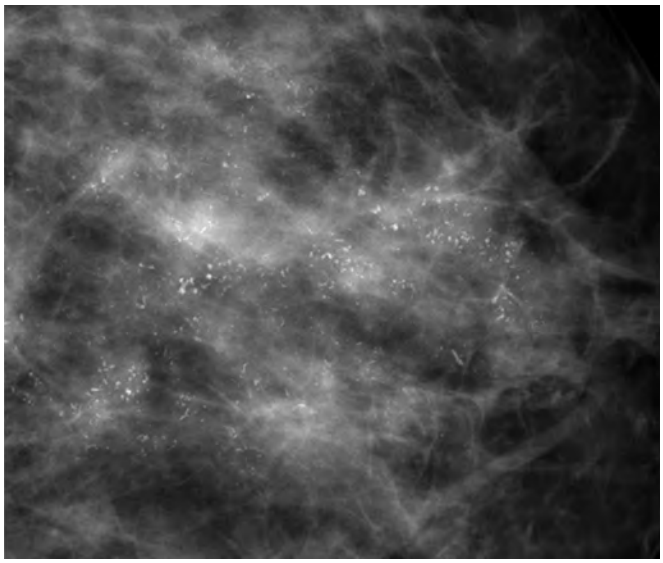

FIGURE 11-12 Magnification view of diffuse, pleomorphic microcalcifications in a heterogeneously dense breast. High-grade DCIS and invasive ductal carcinoma found at pathology.

Segmental: Calcifications restricted to a segment or wedge-shaped portion of the breast may arise within a single ductal system and its branches. This is a distribution frequently associated with malignancy.

Diffuse/scattered: Calcifications that appear to be randomly distributed throughout the breast are referred to as diffuse or scattered. Compared to linear or segmental, scattered calcifications are associated with lower risk of malignancy. By chance, randomly distributed calcification will have areas of higher concentration of calcification particles and areas of fewer not dissimilar to a shotgun pellet pattern. These more concentrated groups are viewed with less suspicion than a similar isolated group of calcification.

Architectural Distortion

Architectural distortion may be a very subjective appearance on a mammogram or a straightforward observation. Architectural distortion refers to an unusual pattern that includes spiculations and retraction (Fig. 11-13). Unless associated with an area of prior biopsy or area of prior infection, architectural distortion requires tissue diagnosis. Benign, radial sclerosing lesions may have this appearance but biopsy is necessary to establish histology. Skin retraction and nipple retraction carry significant risk of malignancy and require tissue biopsy.

Unusual Findings

Focal skin thickening may be associated with benign or malignant ideologies. Malignant causes would include inflammatory carcinoma (Fig. 11-14) and local skin thickening adjacent to a known carcinoma. Skin thickening may be present with benign conditions such as infection and venous obstruction. Clinical management assumes primary importance in these situations.

Focal asymmetry describes an area of asymmetry that lacks the appearance of a true mass. Additional imaging and ultrasound may be required for characterization (Fig. 11-5) but this may be a very subtle manifestation of early breast cancer, especially if a new finding.

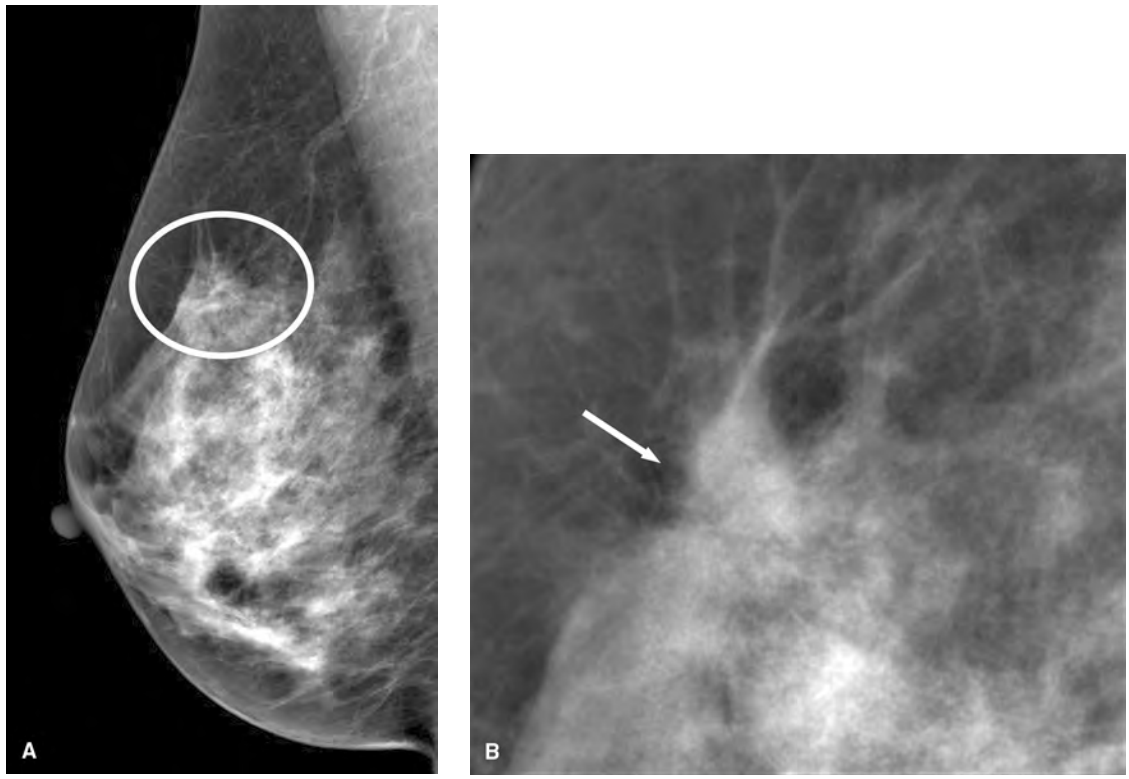

FIGURE 11-13 **(A)** Subtle area of architectural distortion *(circle)*. **(B)** Spot magnification view demonstrates distortion *(arrow)*.

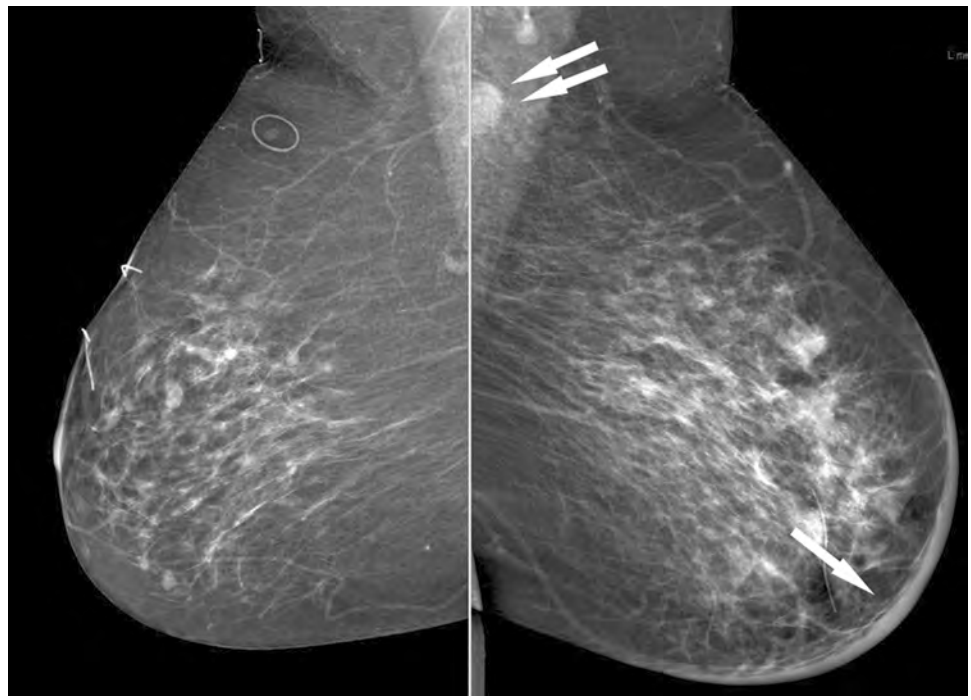

FIGURE 11-14 Bilateral mediolateral oblique views demonstrates skin thickening *(arrow)* of the breast on the right, increased density, as well as a dense axillary lymph node *(arrows)*: inflammatory carcinoma.

FIGURE 11-15 **(A)** Male breast cancer presenting as an irregular, retroareolar mass *(arrow)*. **(B)** Spot compression view demonstrates the irregular mass.

ROLE OF THE MAMMOGRAPHY IN EVALUATION THE SYMPTOMATIC PATIENT

The evaluation of a symptomatic patient is common. Physical examination has poor specificity with only 4% of symptomatic women found to have malignancy (14). The goal of mammography in this setting is to characterize the palpable finding and assess the balance of the breast. Breast ultrasound is used extensively in the setting of a symptomatic patient in addition to mammography. Use of standard practice guidelines is recommended for imaging and management of symptomatic women (24). A suspicious clinical finding should undergo surgical consultation even if imaging is negative.

Palpable Mass or Thickening

Individuals with a palpable breast abnormality such as a discrete mass or focal thickening or nodularity should undergo diagnostic imaging prior to biopsy since biopsy can alter mammographic and sonographic appearances. Women 30 years and older are recommended for mammography and sonography; women younger than 30 are initially evaluated with sonography, although mammography may be necessary in certain circumstances (24). Spot compression views of the palpable area increases sensitivity. Approximately 5% to 15% of patients with a palpable cancer will have a false-negative mammogram. This number is higher for women with extremely dense breasts and lower for women with extremely fatty breasts. An individual clinician may overestimate mammography performance due to the low incidence of cancer in the symptomatic population. Of a typical group of 250 diagnostic patients referred for mammography, there will be 10 cancers. Only 1 of the 250 will have cancer and a false-negative mammogram (assumes a 4 per 100 cancer incidence and a 10% false-negative rate) but this low number is due primarily to the low incidence of cancer rather than the superb mammographic performance. If the mammogram is negative, ultrasound is performed of the palpable area since most cancers with false-negative mammography will be identified as abnormal by sonography. A patient with a negative mammogram and negative ultrasound in the setting of a palpable finding is at very low risk of malignancy. The false-negative rate of combined ultrasound and mammograms at experienced breast centers is 0% to 3% (25–28). The management of patients with palpable findings with negative mammogram and ultrasound depends on the clinical assessment. Suspicious palpatory findings should be biopsied even if imaging is negative. If biopsy is not elected for a very low clinical suspicion palpable findings with negative imaging, short-term clinical follow-up and imaging are recommended to assess for change (24).

Bloody or Serous Discharge

Mammographic sensitivity may be as low as 10% for intraductal cancer presenting as nipple discharge (29). If the mammogram is negative, retroareolar breast ultrasound can be performed to assess for intraductal masses or other findings. If mammogram and ultrasound are negative in the setting of a suspicious discharge, one may proceed with ductography, MRI, or excisional biopsy. Abnormalities on ductography include filling defects, obstructions, and cysts. Characterization of benign and malignant intraductal masses is not sufficient to distinguish benign papilloma from ductal carcinoma *in situ*. Filling defects or stenoses require surgical excision to determine histologic cause. An MR may show areas of abnormal enhancement and possibly intraductal masses. MR size resolution is less than ductogram. Rarely, a ductogram or MR may demonstrate a distal intraductal mass, which may not be reached during routine retroareolar duct surgery. In this situation, the mass can be localized for the surgeon to ensure proper excision. A negative ductogram, mammogram, ultrasound, or MR in a setting of a clinically suspicious nipple discharge should not dissuade surgical excision (24).

Skin Changes or Inflammatory Breast Findings

Women presenting with inflammatory breast findings are referred for diagnostic mammography and often sonography. The distinction between inflammatory cancer and infection is frequently not possible by imaging alone as both may show skin changes, interstitial edema, and abnormal axillary lymph nodes (Fig. 11-14). Unless a suspicious mass or calcifications are found which would direct biopsy, urgent clinical evaluation is recommended. Sonography may detect a fluid collection consistent with abscess which can be confirmed with aspiration. For those women initially treated with antibiotics for suspected mastitis, very short-term clinical reevaluation to ensure resolution is imperative. Early surgical consultation is recommended for nonresponders (24).

Axillary Lymph Node Presentation of Breast Cancer

Less than 1% of women with breast cancer will present with an axillary mass found to represent metastatic breast cancer in axillary lymph nodes with normal breast physical examination. Diagnostic mammography should be performed of both breasts to assess for occult breast cancer. If mammography is negative, breast MR has been advocated. Buchanan et al. found occult cancer by MR in about half of the cases (30).

Symptomatic Pregnant and Lactating Women

Sonography is the initial imaging evaluation of pregnant and lactating women, many whom have never been screened due to young age although mammography may be also useful in some cases to assess for calcifications (31). Due to the extremely low fetal radiation dose, mammography is not contradicted when sonography or physical findings are suspicious for cancer. The radiation dose of a two-view mammogram to the uterus or fetus is less than 1 per 10,000 the breast dose (0.03 μGy or 0.003 mrad) which is further reduced by a factor of 2 to 7 with shielding (32).

NEWLY DIAGNOSED BREAST CANCER

Diagnostic mammography has an important and critical role in evaluating the patient's eligibility for breast conservation therapy. Morrow showed that diagnostic mammography, physical exam, and pathologic analysis could correctly determine 97% of patients' eligibility for breast conservation versus mastectomy (33). Extensive calcifications associated with ductal carcinoma *in situ* by mammography are generally a contraindication to breast-conservation therapy. Multicentric disease by mammography is also a contraindication to breast-conservation therapy. Review of patients' mammograms after histologic diagnosis of breast cancer may change surgical management. Newman et al. reported 10.7% patients had change in management after mammographic review at a multidisciplinary academic center and 7% incremental detection of cancer (34). The impact on

survival is unknown. Magnification mammography is routinely used in the setting of breast cancer manifested as microcalcifications to assess extent. Following lumpectomy with negative pathologic margins, mammography is recommended in cases with malignant calcifications to ensure excision. Suspicious residual calcifications should be subject to reexcision prior to radiation therapy. The use of "staging" MR is controversial and covered in Chapter 14.

BREAST-CONSERVATION-TREATED (BCT) PATIENT SURVEILLANCE

Mammographic surveillance following breast-conservation therapy is typically performed at 6 months, 12 months, and then yearly, although variations exist and the optimal intervals have not been established. Because normal post-BCT changes may mimic cancer by mammography, the first mammogram can serve as a baseline for future evaluations. Typical findings such as mass, edema, and skin thickening are observed. Since these mammographic findings can be signs of malignancy, specificity of mammography is low so aggressive mammographic interpretation at the first post-BCT exam in women with a margin negative cancer is not appropriate. The reported sensitivity of mammography for detection of in-breast recurrence is variable (35). Vapiwala et al. reported 68% of local recurrences (including skin) were positive by mammography (36). The biopsy PPV was higher for mammography than physical exam (65% vs. 40%) and was highest when both mammography and physical exam were abnormal (79%), showing the complementary role of imaging and physical exam. Mammographic surveillance following BCT for ductal carcinoma *in situ* appears reasonable at detection of recurrences, although data are limited. Pinsky and colleagues found 97% of recurrences after BCT for DCIS were apparent by mammography and 91% were minimal cancer at detection (37).

Symptomatic Males

Men presenting with palpable findings may undergo breast imaging, although some clinicians proceed directly to biopsy when the clinical findings are suspicious. The normal male breast is entirely fatty. Gynecomastia presents as retroareolar mammographic density without calcification which may be asymmetric. This often has a characteristic flame-like pattern of distribution and does not appear mass-like. Enlarged breast due to excessive adipose tissue ("pseudogynecomastia") appears as fat on mammography and requires no further evaluation. The mammographic findings of male carcinoma are similar to female cancer but microcalcifications are unusual (Fig. 11-15). Mammography is very sensitive for breast cancer detection due to the lack of breast tissue in most men with negative predictive values of 99% to 100% reported (38). Because some unusual forms of gynecomastia may appear mass-like by mammography, biopsy is required in these cases to establish the diagnosis. Similar to women, a suspicious palpatory finding in the setting of a negative mammogram should not deter biopsy.

SCREENING: SPECIAL SITUATIONS

Screening mammography of high-risk women is performed in a manner similar to routine screening but at an earlier age. Early screening (prior to age 40) has been advocated for women treated with chest mantle radiation during youth, genetic carriers of breast cancer genes such as *BRCA1* and *BRCA2,* other genetic risks, and women with strong premenopausal family history with both annual mammography and MR (24,39). This screening may start as early as ages 25 to 30. There are no randomized control trials to show survival benefit as exists for women aged 40-and older. Mammographic appearance of cancer in some high-risk groups may be similar to the population in general. However, because these are young women, mammography may be less sensitive due to higher frequency of dense breasts and possible aggressive tumor biology. The use of digital mammography in young women with dense breasts may improve sensitivity (3).

MAMMOGRAPHIC ASSESSMENT OF BREAST DENSITY AS A RISK FACTOR

Mammographic breast density is an independent risk factor for breast carcinoma. Fibroglandular tissue attenuates x-rays and produces a white ("dense") area on a mammogram. Fatty areas of the breast do not attenuate x-rays as much and produce a dark (nondense) area on the mammogram. Mammography cannot discriminate between density attributed to fibrotic tissue and that attributed to glandular tissue. Estimation of breast density can be made qualitatively using the four-category BI-RADS classification:

1. Entirely fat
2. Scattered fibroglandular densities
3. Heterogeneously dense
4. Extremely dense (7) (Fig. 11-16)

Approximately 80% of women will have scattered or heterogeneously dense breasts. Only 10% will have extremely dense or fatty breasts (40). This subjective density classification scheme was developed to address the issue of mammographic sensitivity rather than the estimation of risk. More quantitative measurements can be made with computer software programs. Thresholds between the white and nonwhite tissue are not absolute and will influence reproducibility and accuracy. While these classifications have merit, there is variability among readers (41). Although breast density is correlated with risk, changes in breast density may or may not be associated with changing risk. Breast density has not been shown to be a causative factor for breast cancer. Several states have now passed legislation regulating breast density reporting to patients and recommendations for supplemental screening with ultrasound or MR for women with dense breasts. The impact of these laws is unknown, although no randomized control trial exists for supplemental screening of women with dense breasts.

FACTORS AFFECTING MAMMOGRAPHIC SENSITIVITY

The ability of mammography to detect cancer varies greatly among patients. Factors affecting sensitivity and specificity include breast density, age, hormone replacement therapy, biologic subtypes of cancer, and breast thickness.

Breast Density

Breast cancer attenuates x-rays and appears as a white density. A white density against a black (fatty) background is easy to detect (high signal-to-noise ratio). A white density cancer against a white background of fibroglandular tissue is difficult and, in many situations, impossible to detect. The normal dense tissue camouflages the cancer. Extensive breast density has been associated with higher frequency of false-negative mammograms. Whether these

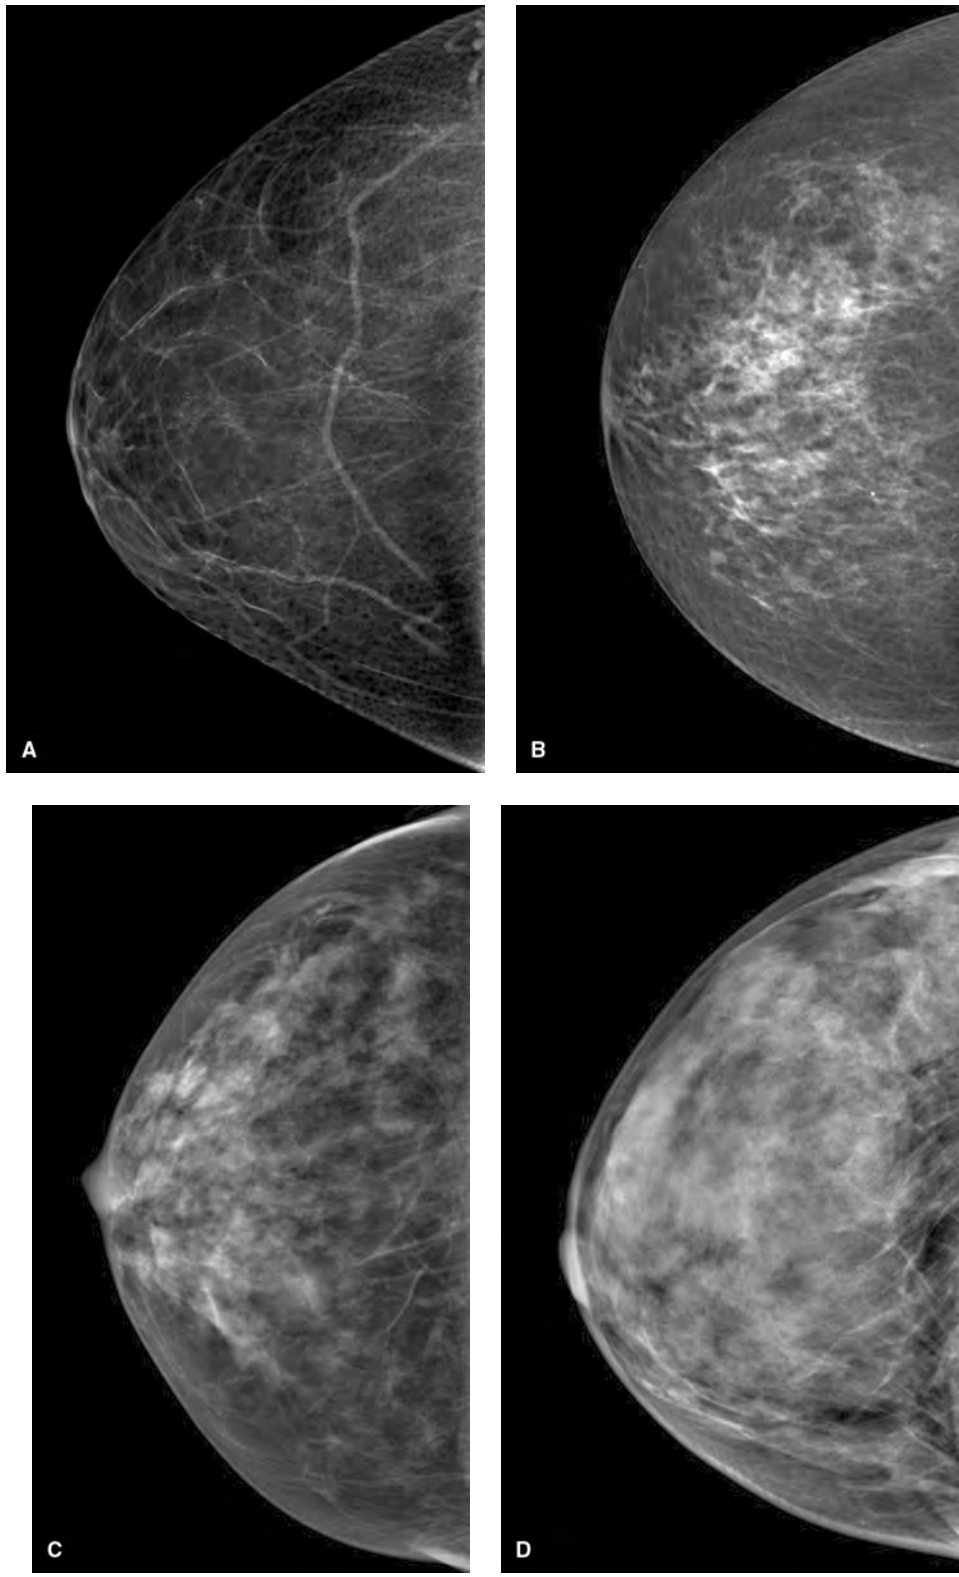

FIGURE 11-16 Spectrum of breast density showing **(A)** fatty; (**B)** scattered fibroglandular; **(C)** heterogeneously dense; and (**D)** extremely dense.

differences relate entirely to imaging by the masking of cancers by dense tissue or to more aggressive tumor biology occurring in women with dense breasts is unknown. The relative insensitivity of mammography in women with dense breasts is a significant limitation of the technique. Alternative methods of imaging these individuals with ultrasound, MRI, tomosynthesis, and digital mammography are ongoing investigations.

Age

Breast density generally declines slowly with age without abrupt change at menopause. Variations exist to defy this trend and postmenopausal hormone replacement therapy can reverse this trend so that age alone rarely is a useful factor in assessing mammographic density. Benign processes that mimic cancers such as fibrocystic changes are less common in older women. For these reasons the accuracy of mammography is highest in that age group compared to younger women (14).

Hormone Therapy

Hormone therapy is associated with increases in breast density in some women, especially those products containing estrogen and progestin. This may mask cancers and limit detection of developing asymmetries. Some drugs such as tamoxifen used for chemosuppression have been associated with a decrease in breast density. Theoretically, this should allow easier detection of malignancy.

Biologic Subtypes

Invasive lobular cancer (ILC) is difficult to detect by mammography prior to clinical presentation. The infiltrative pattern of ILC often does not produce a recognizable mass by mammography when small. Additionally, only 5% of ILC is associated with microcalcifications. Invasive lobular cancer is detected at a larger size than invasive ductal carcinoma and represents a disproportionate number of false-negative mammograms. Invasive mucinous or medullary cancers and some anaplastic cancers may appear as a circumscribed mass mimicking benign conditions such as cysts or fibroadenomas and can produce mischaracterization. Detection is not affected. Sonographic evaluation demonstrates solid masses and biopsy establishes the diagnosis. Triple-negative cancers are more often rounded masses with irregular borders and contain less calcification than other ductal cancers (42).

Patient Factors

Achieving optimal mammographic position requires full patient cooperation. Portions of the breast may not be imaged, especially areas adjacent to the chest wall which become a silent area for mammography. Mammographic image quality declines as breast thickness increases. The decline is due to loss of geometric sharpness, contrast, and increased motion. Breast thickness generally increases with body mass index. Breast implants, especially those placed anterior to the pectoral muscle, may limit mammographic sensitivity even when implant displaced views are performed. The implant absorbs x-rays which precludes mammographic display of portions of the breast.

SUMMARY

High-quality mammography has dramatically changed the evaluation of women for breast cancer in the last 25 years. Age-appropriate routine screening mammography is recommended. Diagnostic breast imaging of symptomatic individuals can assist characterization of palpable findings. However, clinically suspicious abnormalities should be surgically evaluated even when breast imaging examinations are normal.

CHAPTER 12

Imaging Analysis: Ultrasonography

Emily L. Sedgwick

CHAPTER CONTENTS

The use of breast ultrasound for the characterization of breast masses was described as early as 1966 in a Russian journal (1). For many years, the primary indication for sonography was to assess if a breast mass was cystic or solid; however, technological advancements in the resolution and speed of breast ultrasound, in addition to its comparatively low cost, have made breast ultrasound a valuable tool in the evaluation of several breast conditions.

TECHNICAL CONSIDERATIONS

The utility of breast ultrasound depends upon two key factors: equipment and who is performing the ultrasound. Breast ultrasound should be performed with a high-frequency linear transducer, 10 MHz or higher. At a minimum, gray-scale ultrasound (also known as "B mode") is performed, and Doppler ultrasound (either color or Power Doppler) should be used to interrogate for vascularity associated with any lesion. In an effort to better characterize a lesion, such as differentiating a simple from a complicated cyst, harmonic imaging is used. Harmonic imaging takes advantage of the different ultrasound frequencies created by different tissues to create an image (2). Compound imaging is helpful to reduce image graininess and to produce better characterization of a lesion's margins. Compound imaging constructs an image by combining ultrasound waves from different angles (2).

Elastography is another ultrasound tool to help to characterize a lesion. Elastography is the measurement of mass stiffness. In general, a benign mass is stiffer than the adjacent normal breast tissue, and a malignant mass is stiffer than a benign mass. A variety of elastography methods have been proposed. A simple demonstration of elastography is merely applying gentle pressure to the lesion and watching it change in shape or asking the patient to hum during the examination to assess its effect on ultrasound sound waves as they move through the lesion (also known as fremitus). Recently, technological advances have been developed in an effort to standardize elastography performance and interpretation. Formal elastography is not commonly used in most clinical practices, but its use may become more frequent since the new edition of the American College of Radiology (ACR) ultrasound Breast Imaging Reporting and Data System (BI-RADS) is expected in 2014 and may address elastography in image analysis.

IMAGE DOCUMENTATION

The ACR recommends that at least two images be performed of a lesion to document its appearance in orthogonal planes (3). The ACR Practice Guidelines also recommend image labeling to include clock face position, transducer orientation, and distance from the nipple (3). Documenting the presence of any internal vascularity associated with the finding is also recommended.

The person who holds the ultrasound transducer is just as important as the technical parameters of ultrasound. The sonographer identifies a lesion and takes representative images. If the operator is inexperienced or inattentive, the opportunity for early detection and appropriate characterization is lost. In many practices, the primary operator is a technologist who may or may not have advanced training in breast imaging; however, it is recommended that the responsible physician checks the relevant ultrasound findings at the time of ultrasound performance or actually performs the ultrasound (3). Few studies have assessed the accuracy of the different operators; however, interobserver variation exists, especially for lesions smaller than 5 mm (4).

TABLE 12-1

Typical Ultrasound Features of Common Breast Masses

Suspected Diagnosis Based on US features	*Shape*	*Orientation to skin*	*Internal Echotexture*	*Margin*	*Vascularity*	*Posterior acoustic features*
Simple cyst	Oval/Round	Variable	Anechoic	Circumscribed	None	Enhancement
Complicated cyst	Oval/Round	Variable	Hypoechoic (mobile debris)	Circumscribed	None	Variable
Fibroadenoma	Oval	Parallel	Hypoechoic	Circumscribed	Variable	Variable
Lactating adenoma	Oval	Parallel	Hypoechoic	Circumscribed	Variable	Variable
Galactocele	Oval/Round	Variable	Mixed	Circumscribed	None	Variable
Lymph Node	Oval/Round	Variable	Hypoechoic	Circumscribed	Present	Variable
Phyllodes	Oval	Parallel	Hypoechoic	Circumscribed	Present	Variable
Abscess	Round/Irregular	Anti-parallel	Mixed	Noncircumscribed	Present	Variable
Fat Necrosis	Irregular	Anti-parallel	Mixed	Noncircumscribed	Variable	Variable
Invasive Ductal Carcinoma	Irregular	Anti-parallel	Hypoechoic	Noncircumscribed	Present	Shadowing
Invasive Lobular Carcinoma	Irregular	Anti-parallel	Hypoechoic	Noncircumscribed	Present	Shadowing

INTERPRETATION (SEE TABLE 12-1)

Once a lesion has been identified and imaged, the radiologist uses the BI-RADS lexicon to characterize the lesion and form a final impression to guide management. The first edition of the ultrasound BI-RADS lexicon was released by the American College of Radiology in 2003. It was modeled after the mammography lexicon mandated by the Mammography Quality and Standards Act of 1992. The lexicon is organized into major categories: mass, calcifications, special cases, vascularity, and final assessment (5).

The first, and most common, category in the lexicon is "mass." Once a finding has been confirmed in orthogonal planes, it is further characterized by the descriptors of shape, orientation, margin, lesion boundary, echo pattern, posterior acoustic features, and surrounding tissue. Shape is further subdivided into oval, round, or irregular. Each of these has its own positive predictive value (PPV) for malignancy: oval (16%), round (100%), and irregular (62%) (6).

Mass orientation relative to the skin is the second descriptor. A mass that is parallel to the skin is more likely to be benign. A mass with an antiparallel orientation to the skin (common described as "taller than wide") has a PPV for malignancy of 69% (6).

As with mammography and breast MRI, the margin of a mass is most strongly predictive of malignancy. The margin can be described as circumscribed or noncircumscribed. Noncircumscribed margin descriptors include indistinct, angular, microlobulated, and spiculated. Of the four noncircumscribed descriptors, a spiculated margin has the highest PPV for malignancy (PPV = 86%) (6).

The last three descriptors are lesion boundary, internal echogenicity, and posterior acoustic features. These descriptors are important but are not the major criteria in the characterization of a mass found by ultrasound. Occasionally, there may be an echogenic border at the mass lesion boundary; this has been associated with malignancy (7). The internal echogenicity of the mass may be isoechoic, hypoechoic, or hyperechoic relative to the patient's fat. Although other patterns have been reported, the internal echogenicity of cancers is most commonly hypoechoic (6). The final mass descriptor relates to the posterior acoustic features of a mass. Increased through transmission is a fundamental feature of a benign simple cyst; however, the classically described posterior acoustic shadowing has been shown to be a weak predictor for malignancy (6).

The BI-RADS final assessment categories are intended to guide management. If a finding is judged to be BI-RADS 1 (negative) or BI-RADS 2 (benign), routine follow-up is recommended. If a finding is probably benign (BI-RADS 3), short-term follow-up is recommended in 6 months, because the incidence of malignancy in this population is 2% or less (5). If a finding is suspicious for malignancy, the finding is assessed as a BI-RADS 4, where the expected incidence of malignancy is 3% to 94% (5). Subcategories of BI-RADS 4 have been created to stratify malignancy risk; however, more study is needed to further define the subcategories. BI-RADS 5 is used when findings are highly suspicious for malignancy. If the needle-guided biopsy is benign, surgical excision is usually recommended to ensure that malignancy was not missed, because the incidence of malignancy in this group is 95% or greater (5).

CLINICAL INDICATIONS (SEE TABLE 12-2)

Lump in Pregnant or Lactating Woman

The prevalence of breast cancer in this population is relatively low: breast cancer occurs in 1 out of 3,000 pregnancies (8). Although the amount of ionizing radiation from mammography is small, sonography is the first line in the evaluation of breast problems for pregnant women. Common findings in pregnant and lactating women include benign breast tissue (such as axillary breast tissue), simple cysts, fibroadenomas, lactating adenomas, and galactoceles. If the sonographic findings are suspicious for malignancy, a mammogram could be performed after the ultrasound to assess for associated mammographic findings that may support the suspicion for malignancy or help to define the extent of disease (e.g., calcifications associated with ductal carcinoma in situ). Ultrasound resolution is currently insufficient

TABLE 12-2

Assessment and Management Recommendations for Common Breast Masses Seen on Ultrasound

Suspected Diagnosis Based on US features	*BI-RADS Assessment*	*Management*
Lymph Node	2	Annual screening mammogram
Simple cyst	2	Annual screening mammogram
Complicated cyst	3	6-mo, then 12-mo ultrasound for 2 y
Abscess	3	US aspiration, clinical or ultrasound follow-up at 1–2 wk until resolved
Fibroadenoma (<3 cm)	3	6-mo, then 12-mo ultrasound for 2 y
Lactating adenoma	3	6-mo ultrasound
Galactocele	3	6-mo ultrasound
Fat Necrosis	3	6-mo mammogram and ultrasound
Phyllodes	4	Ultrasound guided biopsy
Invasive Ductal Carcinoma	4 or 5	Ultrasound guided biopsy
Invasive Lobular Carcinoma	4 or 5	Ultrasound guided biopsy

to reliably assess for breast calcifications due to ultrasound speckle artifact.

Lump in a Patient Younger than 30 Years of Age

The percentage of breast cancer diagnosed in women in their 20s is less than 1% (9). The vast majority of palpable breast complaints are due to normal breast tissue, simple cysts, or fibroadenomas—lesions that are well characterized by ultrasound alone. For this reason, the ACR and National Comprehensive Cancer Network (NCCN) Practice Guidelines recommend proceeding with a breast ultrasound before mammography in patients under 30 years of age (3,10). If the ultrasound finding is highly suspicious for malignancy, a mammogram can be performed to assess for other sites of disease and suspicious calcifications, as is done with pregnant women.

Recent media attention has created some discussion around the diagnosis of breast cancer in children and teens. The incidence of malignancy in this population is exceedingly low (<1% of all pediatric breast masses) and can be associated with other risk factors (e.g., TP53 genetic mutation) (11). For girls with a breast lump, sonography is the initial imaging modality of choice. Common findings include normal breast tissue, cysts, and fibroadenomas. Fibroadenomas are the most common solid mass in children (11). Large fibroadenomas (greater than 5 cm in any axis) are called giant juvenile fibroadenomas. These masses are usually removed because they are indistinguishable by imaging from phyllodes tumor (the most common breast primary malignancy in children) and because the size of the mass can affect normal breast development. Phyllodes tumors comprise approximately 1% of primary malignant masses in the pediatric population, but most malignant breast masses are due to metastases (11).

An important sonographic finding in the pediatric population is the breast bud. Imaging features of the normal breast bud (irregular shape, irregular margins, posterior acoustic shadowing) may tempt an inexperienced sonographer to recommend biopsy. Biopsy of the breast bud should be avoided, however, because the biopsy may affect breast development. The breast bud can be seen in either girls or boys complaining of a breast lump. Most boys have some breast bud development (gynecomastia) during puberty that resolves spontaneously over a 2-year period (11).

Lump in a Patient Older than 30 Years of Age

For patients older than 30 years of age with a lump, the ACR and NCCN Practice Guidelines recommend mammography prior to ultrasound based on expert opinion (3,10). There is, however, a paucity of data regarding the use of mammography and/or sonography in women aged 30 to 39 years. A recent publication by Lehman et al. found that the sensitivities of mammography and sonography in this age group were 60.6% and 95.7%, respectively (12). The negative predictive value of mammography and sonography were 99.2% and 99.9%, with mammography finding only one malignancy missed by sonography in 1,208 cases (12). They concluded that sonography should be performed before mammography in women aged 30 to 39 years (12).

For women older than 40 years of age, the incidence of breast malignancy increases, and mammography is the first step in imaging a palpable complaint. Mammography can provide important information that may obviate the ultrasound or improve the characterization of an ultrasound finding. For example, fat necrosis can be palpable and is characteristically benign by mammography but may appear malignant by sonography (Fig. 12-1). A second important reason is that it is not uncommon to find a contralateral malignancy when a patient comes in for a lump. If mammography and sonography are negative, the likelihood that the lump represents a cancer is less than 10% (13).

If the palpable abnormality is detected by the physician, it is helpful to show the patient the location of the lump so she may show the radiologist performing the ultrasound. If the ultrasound is to be performed on the same day or next day, it is recommended that the referring physician indicate the palpable area of concern on the patient's skin with a marker so the palpable area can be directly interrogated with ultrasound. It is not infrequent for an ultrasound technologist to image a nearby finding (e.g., a cyst) and assume it corresponds to the palpable complaint. For this reason, it is incumbent upon the radiologist to ensure that the palpable complaint is accurately assessed.

Mammographic Mass

One of the classic indications for a breast ultrasound is for characterization of a mammographic mass. Using the nipple as a landmark on two mammographic views, the radiologist can confidently localize a mass for characterization

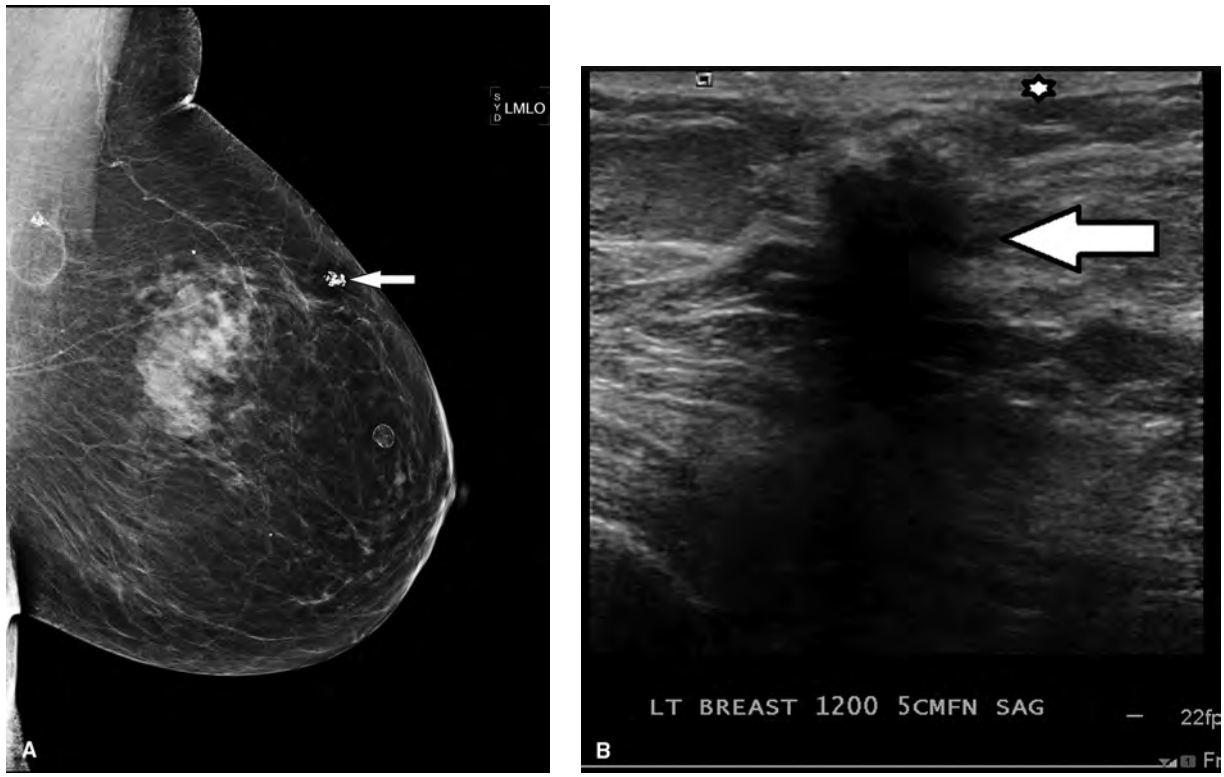

FIGURE 12-1 **(A)** Characteristic calcifications of fat necrosis on MLO mammogram (*arrow*). **(B)** Ultrasound image of corresponding fat necrosis (*arrow*). (Star indicates skin.).

by ultrasound. Once the mass is identified, the radiologist assesses its shape, orientation, internal characteristics (including vascularity), and margin. Commonly encountered masses include simple cysts, complicated cysts, fibroadenomas, lymph nodes, and cancers. A simple cyst is round or oval in shape, usually with parallel orientation, imperceptible wall, increased through transmission, and no internal vascularity (Fig. 12- 2). A complicated cyst is round or oval in shape, usually with parallel orientation, thin wall, and no internal vascularity. Its posterior acoustic features are variable. It has internal echoes, which differentiate it from a simple cyst (Fig. 12-3). A fibroadenoma is oval in shape, with parallel orientation, variable posterior features, and a circumscribed margin with fewer than four gentle lobulations. It may or may not have internal vascularity (Fig. 12-4). It can

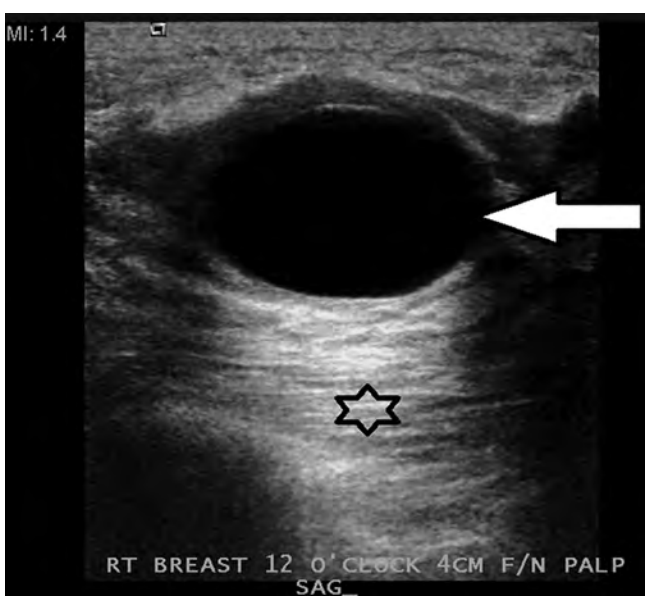

FIGURE 12-2 Simple cyst. Note increased through transmission (*star*). Note imperceptible wall (*arrow*).

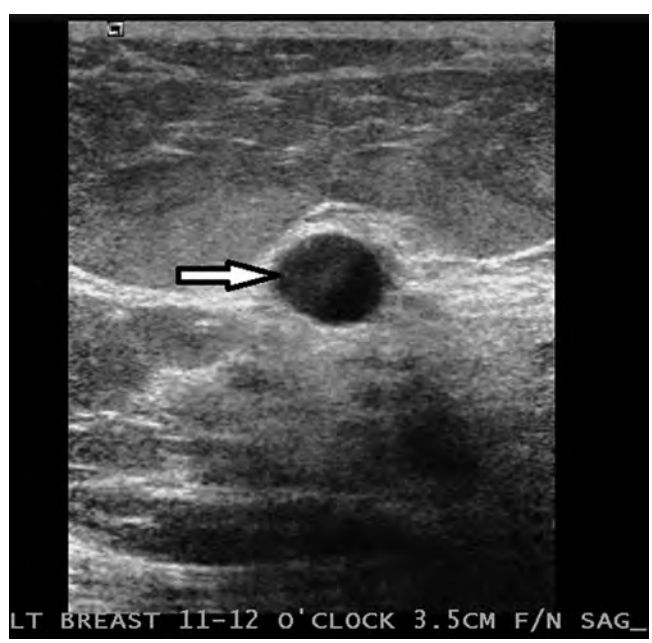

FIGURE 12-3 Complicated cyst. Note internal echoes (*arrow*).

FIGURE 12-4 Fibroadenoma. Note circumscribed margin (*arrow*). It is parallel to skin surface (*star*).

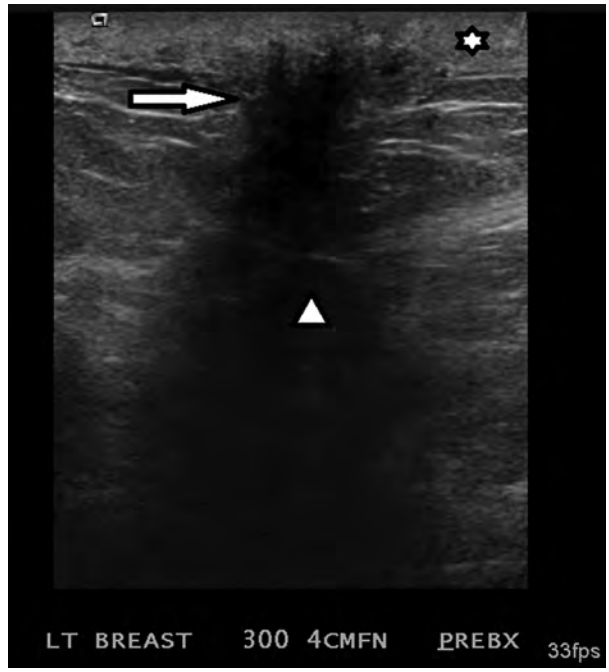

FIGURE 12-5 Invasive ductal carcinoma. Note irregular shape, angulated margin (*arrow*), posterior acoustic shadowing (*triangle*), and anti-parallel orientation to skin surface (*star*).

sometimes be difficult to differentiate a complicated cyst from a fibroadenoma. Since the likelihood for malignancy in both is similarly low, it is reasonable that management for both is the same—6-month follow-up ultrasound (14,15). A lymph node is round or oval in shape, with parallel orientation, echogenic hilum, circumscribed margin; a blood vessel can be seen entering the hilum.

Cancers typically are irregular in shape, with anti-parallel orientation, heterogeneous internal echotexture and vascularity, and a spiculated margin (Fig. 12-5). Although the clinical suspicion for malignancy is high based upon the mammographic features, an ultrasound is recommended for several reasons. First, if there is a sonographic correlate, sonography is better able to identify the area of invasive cancer (16). If a patient has a needle biopsy demonstrating invasive cancer, she will undergo fewer surgical procedures (17). Finally, ultrasound guided biopsy is less expensive and more comfortable for the patient than stereotactic core needle biopsy or wire localization for surgical excision (18).

Cancers may not have all of the classic features as described above. Since approximately 90% of all breast cancers are invasive ductal cancer (IDC), a cancer lacking the typical features is still likely to be an IDC. Lobular cancer may be difficult to perceive on mammography; however, it may be well seen with sonography (Fig. 12-6). Other histologies can have atypical sonographic features but should still be suspicious for cancer because they do not satisfy all of the criteria for benignity. For example, mucinous cancers are round or oval in shape, with lobulated margins; they may have posterior acoustic enhancement (19). Upon close inspection, the margin has multiple lobulations, and the internal architecture is heterogeneous. The latter findings should lead to biopsy (Fig. 12-7).

Suspicious Mammographic Findings without Mammographic Mass

Findings such as pleomorphic calcifications or architectural distortion have a high positive predictive value for malignancy but may have no associated mammographic mass (Fig. 12-8). Ultrasound can be helpful to assess for the presence of an associated mass that may represent an area of invasive cancer and aid in biopsy planning. Finding a sonographic correlate can be especially helpful in the setting of dense tissue on mammography.

Complementary Modality to Breast MRI

In addition to mammography, sonography can be a useful complementary tool to breast MRI. Occasionally, targeted sonography may be beneficial for further characterization of a MRI finding: specifically, an intramammary lymph node. Small enhancing lymph nodes can have suspicious enhancement, and the characteristic fatty hilum may not be resolved on MR imaging. Targeted sonography can often elucidate the characteristic fatty hilum, obviating biopsy.

Sonography can also be helpful if there is a suspicious enhancing mass on MRI for which a biopsy has been recommended. MRI guided breast biopsy has a high cost and relatively low accessibility; consequently, targeted sonography is usually recommended to assess for a sonographic correlate to the MRI finding. LaTrenta et al. found that 43% of lesions with a sonographic correlate were cancer, and 14% of lesions without a sonographic correlate were cancer (20). MRI guided biopsy is therefore recommended if no sonographic correlate is found. If there is a question about whether a sonographic finding correlates to the MRI target, ultrasound guided biopsy with marker placement with an abbreviated follow-up MRI has been reported (21).

Breast Pain

Breast cancer is usually painless (22). Breast pain, however, is one of the most common complaints in the breast imaging department. There is not usually an easily identified anatomic source for the pain unless it is related to fibrocystic changes or infection (abscess). If there is focal pain, an ultrasound can be performed. The sonographic appearance

FIGURE 12-6 **(A)** Invasive lobular carcinoma mammogram. No discrete mass is seen. Note skin thickening (*star*). **(B)** Invasive lobular ultrasound. Note irregular shape (*arrow*), posterior acoustic shadowing (*triangle*), and anti-parallel orientation to skin surface (*star*).

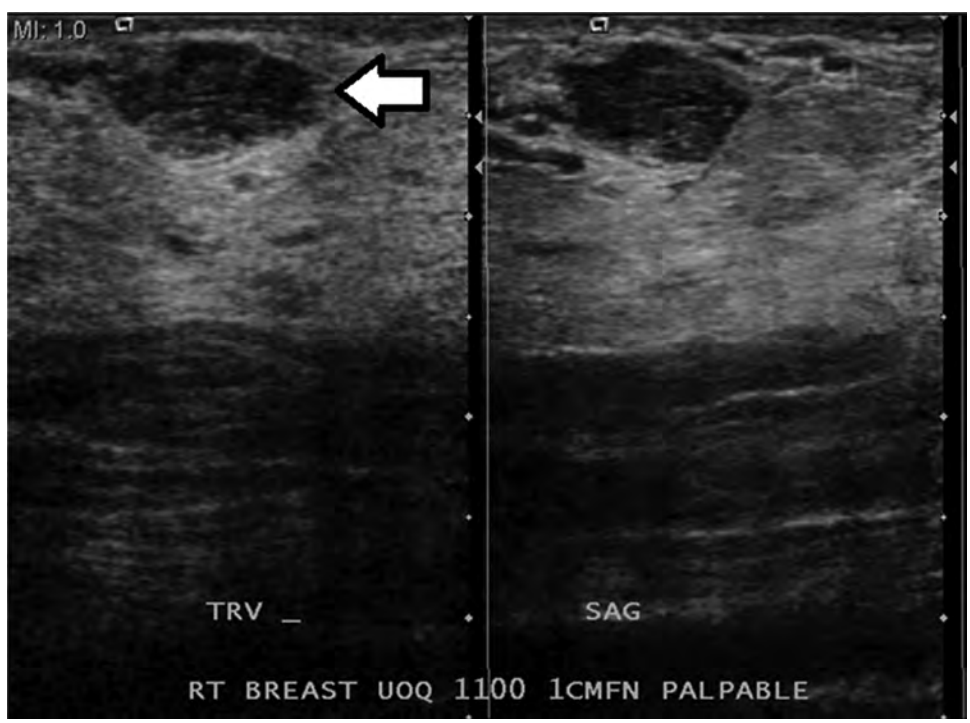

FIGURE 12-7 Mucinous carcinoma. Note the multi-lobulated margin (*arrow*) and heterogeneous internal echotexture, which should prompt a biopsy.

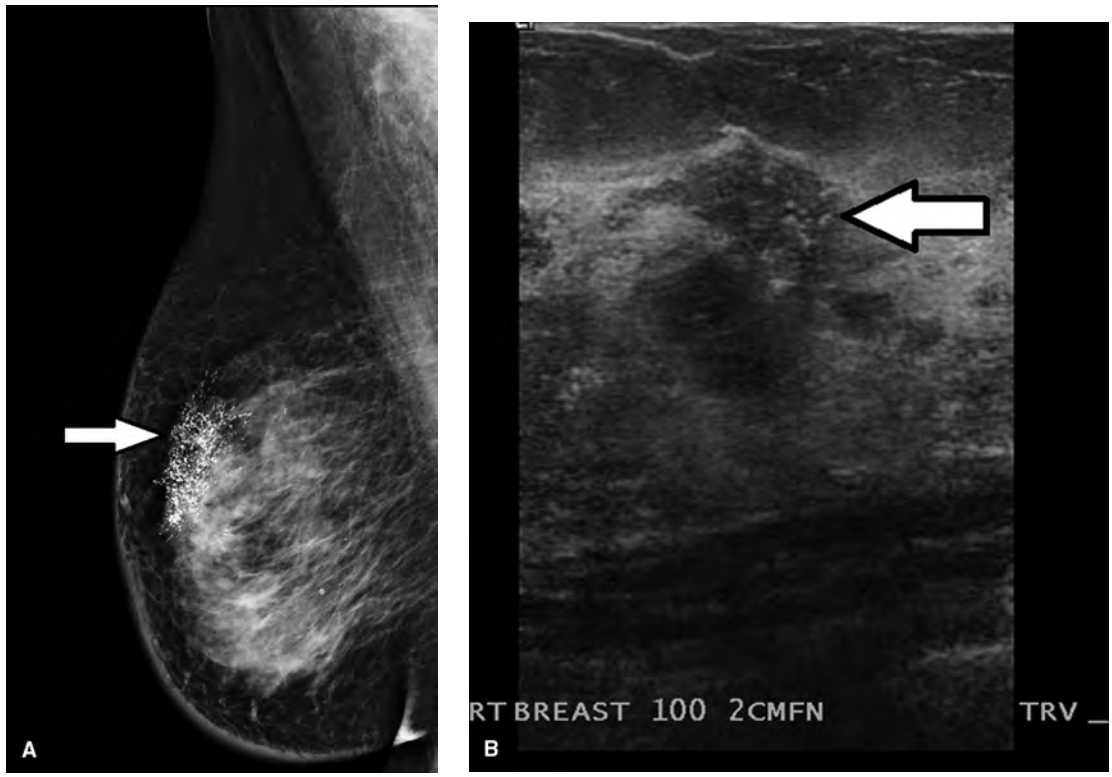

FIGURE 12-8 **(A)** Pleomorphic calcifications on mammography in upper inner right breast without associated mammographic mass (*arrow*). **(B)** Irregular corresponding mass on sonography. Note calcifications (*arrow*).

of fibrocystic changes includes dense tissue and small cysts, often in the upper outer quadrant of the breast. If fibrocystic changes are found, patient reassurance usually resolves the patient complaint. If the patient demonstrates signs or symptoms of infection (e.g., skin redness, painful lump, or fever), she may have an abscess or infected cyst. An abscess is round or irregular in shape with indistinct margins and increased vascularity (Fig. 12-9). Aspiration can be both diagnostic and therapeutic if all or most of the fluid can be withdrawn (23). Aspiration of frank pus prompts immediate treatment with antibiotics. Although the infection is likely due to skin flora, a culture may be helpful in case the patient does not respond appropriately to antibiotic therapy (23).

FIGURE 12-9 Abscess. Note thickened vascular rim (*arrow*).

Nipple Discharge

Nipple discharge is a frequent complaint in the breast imaging department. Nonspontaneous bilateral nipple discharge is of no concern unless it is milky. (Milky discharge may indicate a prolactinoma.) Spontaneous clear or bloody discharge from a single duct may cause clinical concern. Ultrasound has been used in conjunction with mammography to assess for an intraductal mass that may be the cause of discharge from a single duct, such as a papilloma. Ultrasound can also be helpful immediately following a galactogram to assess for an intraductal mass. The patient is transferred to the ultrasound suite with the galactogram cannula in place, so the offending duct can be persistently filled with contrast that may outline the intraductal mass. If the mass can be identified with ultrasound, it can then be biopsied using ultrasound guidance, thereby avoiding blind surgical excision.

Implant Rupture

Saline implant rupture is clinically evident. Silicone implant rupture can be identified by sonography. The "stepladder sign" is where the native wall of the implant can be seen floating in the silicone, which has been confined by the implant capsule (Fig. 12-10A). A stepladder sign is analogous to the "linguini sign," demonstrating intracapsular rupture on breast MRI (Fig. 12-10B). Extracapsular rupture, where silicone is seen outside the confines of the implant capsule, is described as an echogenic mass with echogenic shadowing, known as a "snowstorm" appearance in either the breast tissue or in axillary lymph nodes (Fig. 12-11).

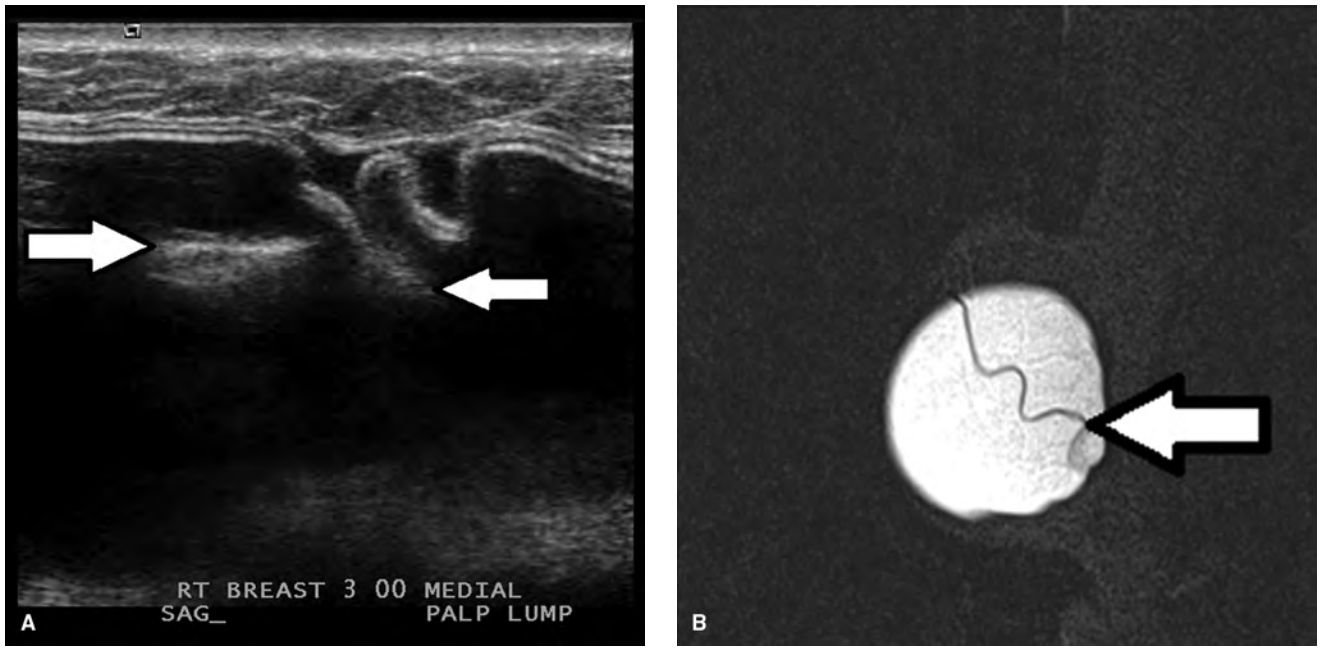

FIGURE 12-10 **(A)** "Stepladder sign" of intracapsular silicone implant rupture (*arrows*). **(B)** Corresponding "linguini sign" seen on breast MRI (*arrow*).

Occasionally, a patient with saline breast implants may complain of a lump that is related to the port. Careful sonography over the area of palpable concern confirms the presence of the valve, and the patient can return to screening mammography (Fig. 12-12).

Extent of Disease

Ultrasound can be useful to define the extent of disease when a patient has a suspected or known breast cancer. Identifying multicentric disease, skin involvement, or adenopathy can help with surgical management and staging. Many practices perform targeted sonography; however, the ultrasound can be expanded to the entire breast and axilla if a suspicious mass is found. Although breast MRI is better than sonography at assessing the extent of disease, MRI is not always paid for by insurance and access to MRI may be limited.

Most of the lymphatic drainage of the breast is to the axilla. Evaluation of the axilla at the time a suspicious breast mass is found is helpful to assess for the presence of locally advanced disease (19). Recently, ultrasound-guided fine needle aspiration (FNA) or core needle biopsy has become more commonly used to stage the axilla. With the recent release of the American College of Surgeons Oncology Group (ACOSOG) Z-0011 trial, the utility of sampling a suspicious axillary lymph node before breast conservation surgery has come into question in patients with early stage breast cancer. The ACOSOG Z-0011 trial found similar local or regional recurrence for patients with one or two positive lymph nodes who had only sentinel lymph node biopsy versus patients who had full axillary dissection (24). Lymph node involvement continues to be an important prognostic

FIGURE 12-11 "Snowstorm" appearance of extraluminal silicone (*arrow*).

FIGURE 12-12 Saline implant valve presenting as palpable complaint (*arrow*). Intact saline implant (*star*).

indicator. The knowledge of axillary lymph node involvement prior to surgery, however, may no longer be necessary since a sentinel lymph node biopsy will be performed at the time of breast conservation surgery.

A few facilities evaluate the supra- and infraclavicular lymph node basins at the time of discovery of a suspicious breast mass (25). Newman et al. found that 29% of 142 patients had suspicious-appearing (but not biopsy-proven) infraclavicular lymph nodes that correlated with lower disease-free and overall survival. They concluded that suspicious infra- or supraclavicular lymph nodes were a useful adverse prognostic factor and advocated routine sonography of these nodal basins in patients with locally advanced breast cancer. Others have advocated evaluation and, if possible, fine needle aspiration of internal mammary lymph nodes, arguing that known internal mammary lymph node involvement would change radiation therapy (26). However, evaluation of nodal basins other than the axilla to define the extent of disease is not a common practice. The reasons for this may be multifactorial: the low likelihood of involved lymph nodes, inexperienced sonographers, uncertain clinical management significance, and lack of reliable cytology for fine needle aspiration of suspicious lymph nodes.

Follow-up of Prior Ultrasound Findings

An increasingly common use of breast ultrasound is in the management of fibroadenomas, one of the most common benign solid masses in women. First published by Stavros et al. in 1995, an oval mass with parallel orientation, circumscribed margin, and fewer than four gentle lobulations may be reliably followed by ultrasound, because the sensitivity for malignancy was 98.4% (27). It was reported that 1.6% of malignant masses were misclassified as benign (27). Harvey et al. demonstrated that palpable lesions that satisfy the above criteria can also be followed with ultrasound, similar to those patients with nonpalpable probable fibroadenomas (14). Since these studies showed a <2% malignancy rate (but not 0%), these authors recommended imaging follow-up. Based on these studies, many radiologists recommend follow-up ultrasounds (at 6 months and 12 months) for 2 years, in line with BI-RADS 3 mammography recommendations developed by Sickles (28). Meticulous attention to technique and management based upon the most suspicious imaging characteristic is fundamental to replicate those results. Although conservative imaging follow-up is not yet the standard of care, this management recommendation is gaining greater traction.

Assessment of Response to Neoadjuvant Chemotherapy

The correlation of the size of an ultrasound mass with the pathology specimen is best for masses 2 cm or smaller (29). The agreement of ultrasound with the pathology specimen falls after neoadjuvant therapy. Ultrasound is still better than clinical exam and mammography with a 35% agreement (30). The agreement of clinical exam and mammography following neoadjuvant chemotherapy are 19% and 26%, respectively (30). Ultrasound is inexpensive, reliable, and contains no ionizing radiation. Although MRI has demonstrated its superiority in assessment of neoadjuvant treatment response with a pathology agreement of 71%, its cost and inaccessibility precludes its widespread use (30).

Ultrasound as a Screening Tool

Screening ultrasound will be addressed in the chapter about screening.

SUMMARY

Breast ultrasound is an important tool in evaluation of breast complaints due to its lack of ionizing radiation and low cost. Its indications include evaluation of clinical complaints (e.g., lump, pain, nipple discharge), further characterization of mammographic and MRI findings, determining extent of disease, and as a guide for breast biopsies. Breast ultrasound is most effective when performed by an experienced operator and used in conjunction with mammography. Further refinements in ultrasound resolution and techniques (e.g., elastography) may expand its utility in the future.

MANAGEMENT SUMMARY

- Ultrasound is often indicated for characterization of a mammographic or palpable finding. For example, ultrasound can further characterize a mammographic mass as a benign cyst or a solid mass.
- Ultrasound is important for biopsy planning. It can identify the invasive component of the cancer.
- Ultrasound guided biopsy can minimize patient expense and discomfort.
- Ultrasound is the first imaging modality for a pregnant woman or a woman less than 30 years of age.

CHAPTER 13

Imaging Analysis: Magnetic Resonance Imaging

Susan P. Weinstein and Susan Orel Roth

CHAPTER CONTENTS

Major advances have been made in the field of MR imaging of the breast since the first report of the use of gadolinium in 1989 to detect breast cancer (1). Technology has kept pace resulting in faster scanning times with greater spatial resolution. The use of gadolinium remains the cornerstone of cancer detection in breast MRI. The formation of neovascularity by malignant lesions results in more rapid uptake and washout of contrast than the surrounding parenchyma. Unlike mammography, which evaluates lesions based on morphology alone, MRI evaluates lesions using both morphologic as well as functional kinetic information with the sensitivity of MRI for invasive breast cancer approaching 100%. Similar to mammography, uniformity in image quality is being promulgated by the American College of Radiology (ACR). Technical requirements for optimal breast imaging including the requirement for a breast MRI biopsy system are now being defined as part of a ACR breast MRI accreditation program. Also, similar to mammography, the ACR BI-RADS (Breast Imaging Reporting and Data System) lexicon for breast MRI has brought uniformity to the interpretation and reporting of breast MRI examinations. With advances in imaging technique, interpretation guidelines, and increasing availability of MRI breast biopsy systems, MR imaging of the breast is now an integral component of breast imaging in clinical practice in both the diagnostic and the screening settings. The clinical indications for MR imaging of the breast have evolved over time, and although controversy exists, MR imaging is currently performed in the clinical settings of high-risk breast cancer screening, response to neoadjuvant chemotherapy, evaluation of equivocal mammographic findings, clinically concerning nipple discharge, and recently diagnosed breast cancer for staging of the ipsilateral breast and screening of the contralateral breast. The roles of breast MRI will continue to evolve as more data become available.

TECHNICAL CONSIDERATIONS

In contrast to mammography, where the techniques for optimal imaging have been well defined for years under the regulation of the Mammography Quality Standards Act (MQSA), overseen by the Food and Drug Administration (FDA) (2), the image quality of breast MRI studies has varied widely until recently. There are many variables that can affect image quality. In an effort to bring uniformity to the quality of breast MRI studies in the United States, the American College of Radiology currently runs a Breast MRI Accreditation program providing guidelines for quality assurance and control, equipment and image quality, as well as staff and radiologist qualifications (3). Initially, this accreditation program was voluntary. Starting in 2012, the MRI accreditation program became mandatory for non-hospital-based imaging centers receiving Medicare reimbursement. This hopefully will bring greater uniformity to breast MRI quality.

MRI Field Strength

Breast MRI studies should be performed on 1.5T magnets or higher. The high field strength allows for rapid acquisition with high-resolution imaging. There is a linear relationship between magnetic field strength and signal-to-noise ratio (SNR). With greater field strength, the SNR is higher, and higher spatial resolution images can be obtained with shorter acquisition times. The high field strength also makes homogeneous fat suppression possible enabling detection of subtle enhancing lesions. Although 1.5T magnets remain the standard in breast MRI imaging, 3T magnets are commercially available. The higher field strength allows for higher SNR, with more rapid imaging speed and resolution. However, there is no definitive evidence that 3T magnets are superior to 1.5T for clinical breast imaging.

Dedicated Breast Coils

A dedicated breast surface coil must be used when performing breast MRI. Many different types of surface coils are commercially available. The coils contain depressions where the breasts lie during the examination. Within each depression, there are receiver coils that detect signal from the breast and transmit information to generate the images. Coils with greater number of receiver coils will have higher SNR. At the Hospital of the University of Pennsylvania, we utilize a bilateral breast multicoil. This type of coil allows for parallel imaging techniques, which can halve the image acquisition time through imaging both breasts simultaneously. The patient is examined in the prone position, which decreases the effects of respiration as well as reducing artifacts from respiration and cardiac motion. The breasts are gently compressed between two plates, which are placed along the medial and lateral sides of the breast. The compression further minimizes patient motion and reduces the number of sagittal slices required to image the breasts and, thereby, reducing imaging time. This configuration also ensures that all of the breast tissue is close to one of the elements of the array, resulting in enhanced SNR. The compression should be applied gently, as firm compression can delay contrast uptake.

Intravenous Contrast

The cornerstone of breast MRI is imaging following the intravenous injection of a paramagnetic contrast agent (gadolinium chelate). Gadolinium is a T1-shortening agent and was first used in breast MR imaging to detect cancer in 1989 (1). Following intravenous injection, accumulation of gadolinium in tissue reflects alterations in vascular density and/or vascular permeability. The neovascularity recruited by cancer cells results in rapid uptake of contrast followed by rapid washout of contrast, and this is the basic premise of MRI cancer detection. Breast cancers will enhance more rapidly and avidly than the normal surrounding tissues, hence the importance of rapid scanning times. The contrast is injected intravenously as a bolus at the dose of 0.1 mmol/kg, followed by a saline flush.

To minimize patient movement during the exam, the IV should be placed and connected prior to positioning the patient in the magnet. Images should be acquired 1 to 2 minutes after administration of contrast with sequential images acquired immediately after. To gather information about lesion kinetics, at least three postcontrast sequences should be acquired. The pre- and postcontrast images are often obtained with fat suppression to increase the conspicuity of the enhancing lesions.

In addition to dynamic gadolinium-enhanced sequences, T2-weighted images and nonfat saturated T1-weighted images should be obtained. Both of these sequences help characterize lesions that may enhance with gadolinium. The images may be acquired in the sagittal or the axial planes, based on preference. At our institution, the images are acquired in the sagittal plane. Subsequently, delayed postcontrast sequences are obtained to better visualize the lateral tissue and the axilla.

The current maximum recommended dose of gadolinium is 0.1 mmol/kg. It was felt for a long time that gadolinium was a very safe contrast agent with fewer contrast reactions than iodinated contrast agents. While gadolinium is still considered a safe intravenous contrast agent, in 2007 the FDA issued a warning regarding the use of gadolinium contrast agents in people with decreased glomerular filtration rate (GFR) due to reported cases of nephrogenic fibrosing sclerosis (NSF) (4). The association with decreased GFR, gadolinium, and NSF was first reported in 1997. Patients with impaired renal function are at increased risk for NSF, a condition that leads to fibrosis of the skin and internal organs (4). Although the condition is rare, to avoid this potential complication it is recommended that patients with GFR ≤30mL/min/1.73m2 not be administered gadolinium.

Fat Suppression

In contrast to mammography where lesion detectabilility is increased in a fatty background, on MRI an enhancing lesion maybe difficult to detect in a background of fat. Therefore, fat suppression will improve the conspicuity of small enhancing lesions. This can be accomplished with either active or passive fat suppression. We prefer using "active" fat suppression where the signal from fat is removed prior to the injection of intravenous contrast. There are a variety of available fat suppression techniques (5). Alternatively, passive fat suppression can be accomplishing with postprocessing image subtraction (subtracting the precontrast from the postcontrast image). This requires that there be no patient motion between the pre- and the postcontrast sequences. Both methods of fat suppression (chemical fat suppression and image postprocessing image subtraction) can be used together, and in our experience does aid in the detection of small enhancing lesions.

High Spatial and Temporal Resolution

Historically, investigators studying the differentiation of malignant from benign breast lesions were divided into two "camps," the first being the "high temporal resolution camp" where lesion characterization was based on contrast enhancement kinetics which required high temporal resolution, and the "high spatial resolution camp," where lesion morphology was critical and required high spatial resolution. Unfortunately, high temporal and high spatial resolution are competing strategies, and choosing one was at the sacrifice of the other. Sensitivity for the detection of small enhancing foci improves with increasing spatial resolution, but this requires longer imaging times. On the other hand, the high temporal resolution needed for dynamic contrast enhancement is obtained at the cost of a loss of spatial resolution, signal to noise, and/or volume of the breast imaged. For optimal spatial resolution, a pixel size of less than 1.0 mm in each in-plane direction is necessary with 3-mm or less slice thickness. For optimal temporal resolution, the first postcontrast images should be obtained in less than 2 minutes following contrast injection, with subsequent scans obtained over the following 5 to 7 minutes to evaluate the shape of the enhancement curve. Different methods may be utilized to optimize these two competing factors. One is using a higher field strength magnet. 3T magnets are available for commercial use. Theoretically, compared to 1.5T magnet, a 3T magnet should provide double the SNR and therefore allowing for faster image acquisition. However, there is no conclusive clinical evidence that 3T is superior to 1.5T in terms of diagnostic performance. Image acquisition time may also be reduced while preserving spatial resolution by using parallel imaging. Parallel imaging allows for simultaneous acquisition of spatial information from both coils, thus reducing the time to acquire the spatial information. Combination of imaging methods may be used as well. Parallel imaging techniques may be further optimized on a 3T magnet.

Diffusion-Weighted Imaging

In addition to evaluating lesion morphology and kinetic information, diffusion-weighted imaging (DWI) may be used to increase the specificity of MRI. Although DWI should not

be the primary method used for lesion analysis, it can be helpful when the other imaging parameters such as lesion morphology and kinetic information are equivocal. The concept of diffusion is based on random and thermal motion of water in tissue, also known as Brownian motion. Tissues with high cellularity restrict the motion of water whereas tissues with low cellularity allow for more free movement of the water molecules. Tumors tend to have higher cellularity and hence have restricted motion. On DWI, the restricted motion results in a higher signal intensity (Fig. 13-1). The technique that is most commonly used to generate DWI imaging is T2-weighted echo planar imaging. Due to the higher cellularity of carcinomas, there is restricted diffusion in invasive cancers relative to benign lesions and normal parenchyma, resulting in relatively brightness of malignant lesions compared to benign lesions. Different diffusion gradients, b, are applied. The signal loss from the different gradients is exponentially proportional to the amount of diffusion of the water molecules. The apparent diffusion coefficient (ADC) can be calculated from at least two diffusion weighted image sets at different b values. Restricted diffusion and high cellularity results in lower ADC values.

Various studies have shown that using an ADC cutoff value can aid in discriminating between benign and malignant lesions (6,7). However, there is no standardization of diffusion techniques. Different ADC cutoff values and diffusion gradients are used from institution to institution. In addition, although most carcinomas have high cellularity and low ADC values, some benign lesions can exhibit these characteristics. Likewise, some malignant lesions can

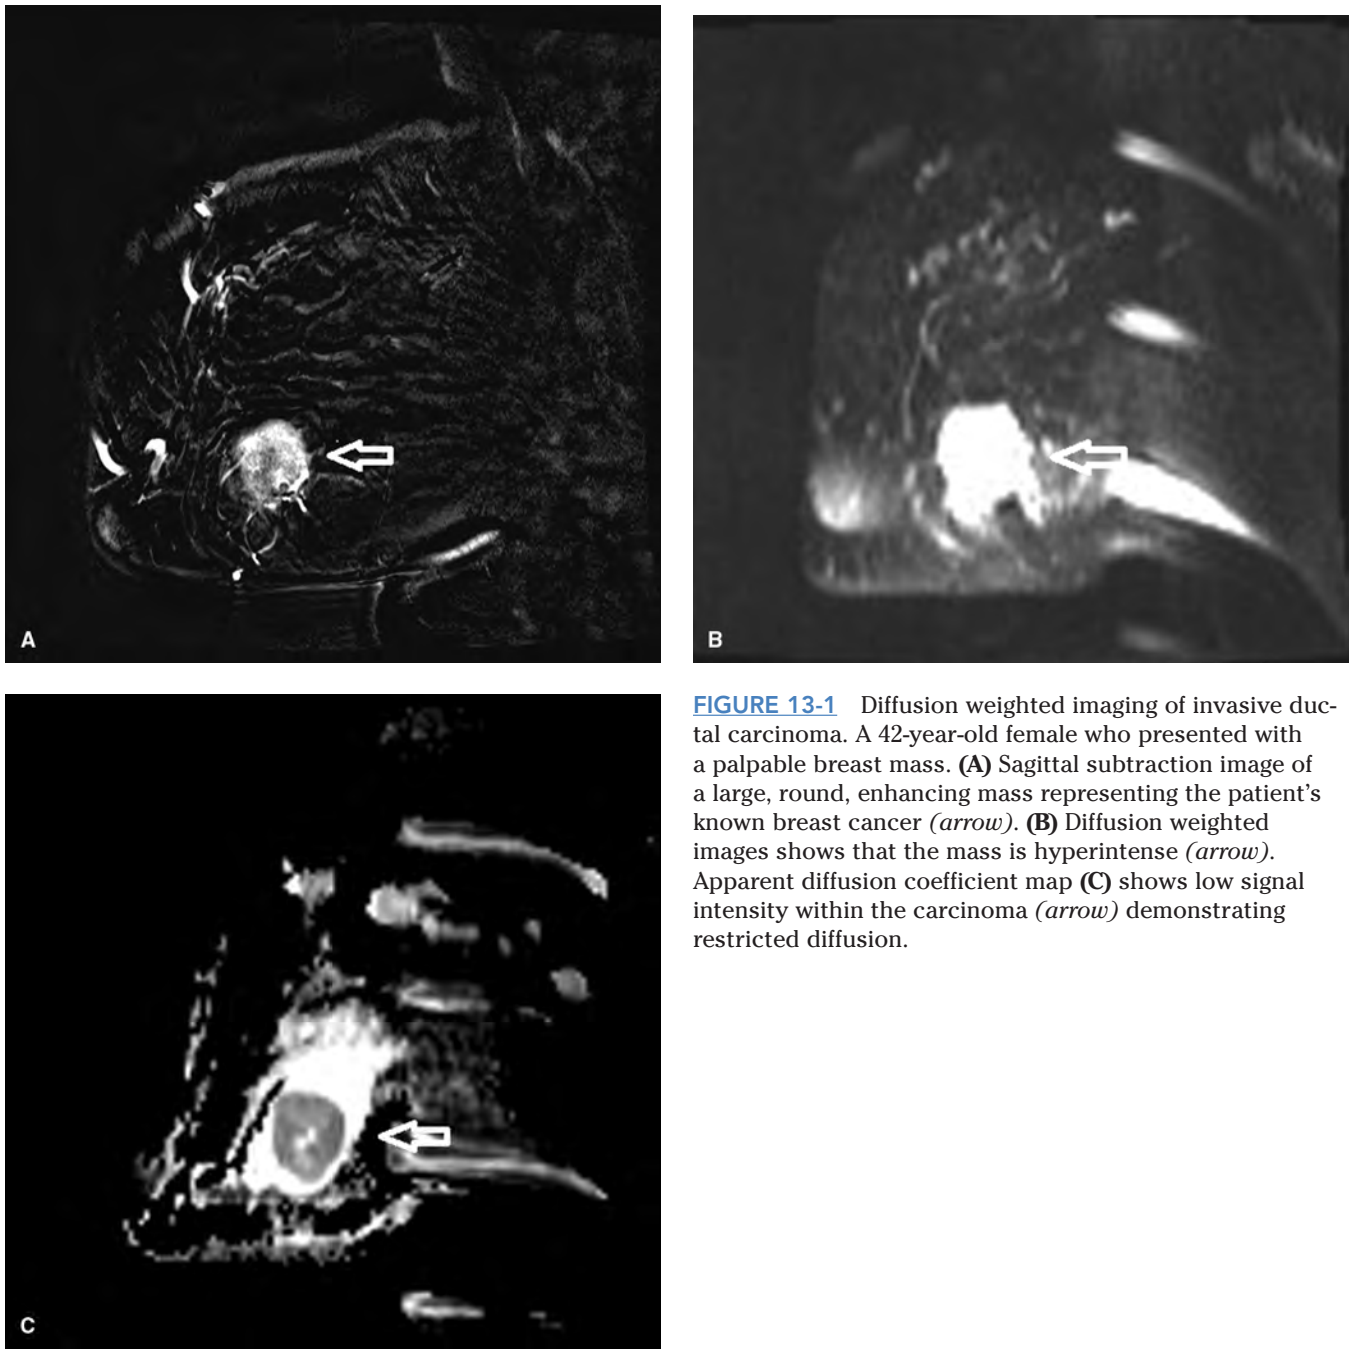

FIGURE 13-1 Diffusion weighted imaging of invasive ductal carcinoma. also demonstrate benign features on DWI such as necrotic tumors, tumors with cystic components, and mucinous tumors. At this time, given these limitations and overlap with benign and malignant features, one cannot reliably use DWI alone to differentiate benign from malignant lesions but rather use this information in combination with morphologic features and kinetic information.

MRI-Guided Localization or Biopsy Capability

The ability to perform MRI-guided interventional procedures is an integral part of MRI imaging. A requirement of the ACR breast MRI accreditation program, the facility performing breast MRI must either have the capacity to perform MRI-guided breast interventional procedures or to create a referral arrangement with a cooperating facility that will provide these services (3). There will be malignant lesions detected on MRI that will be occult on mammography, sonography, and clinical examination, hence the need to perform MRI-guided biopsies. With a technique that is highly sensitive but not highly specific, a needle localization or core needle biopsy system is needed to differentiate true positive enhancing malignant lesions from false positive benign enhancing lesions. The two available options are MRI-guided core needle biopsy and MRI-guided needle localization.

Historically, MRI-guided intervention was limited to needle localization followed by excisional biopsy. Currently, many different MRI-compatible core biopsy systems are commercially available. MRI-guided core needle biopsy is a safe and accurate way to biopsy MRI detected lesions (Fig. 13-2). Similar to ultrasound-guided core needle biopsy, the advantages of MRI-guided core biopsy over excisional biopsy are the less invasive nature of the procedure, minimizing the number of surgical procedures in patients diagnosed with breast cancer, and reduced costs.

A major limitation of MRI-guided needle localization and core biopsy remains the inability to verify successful lesion removal or lesion sampling. In the case of needle localization,

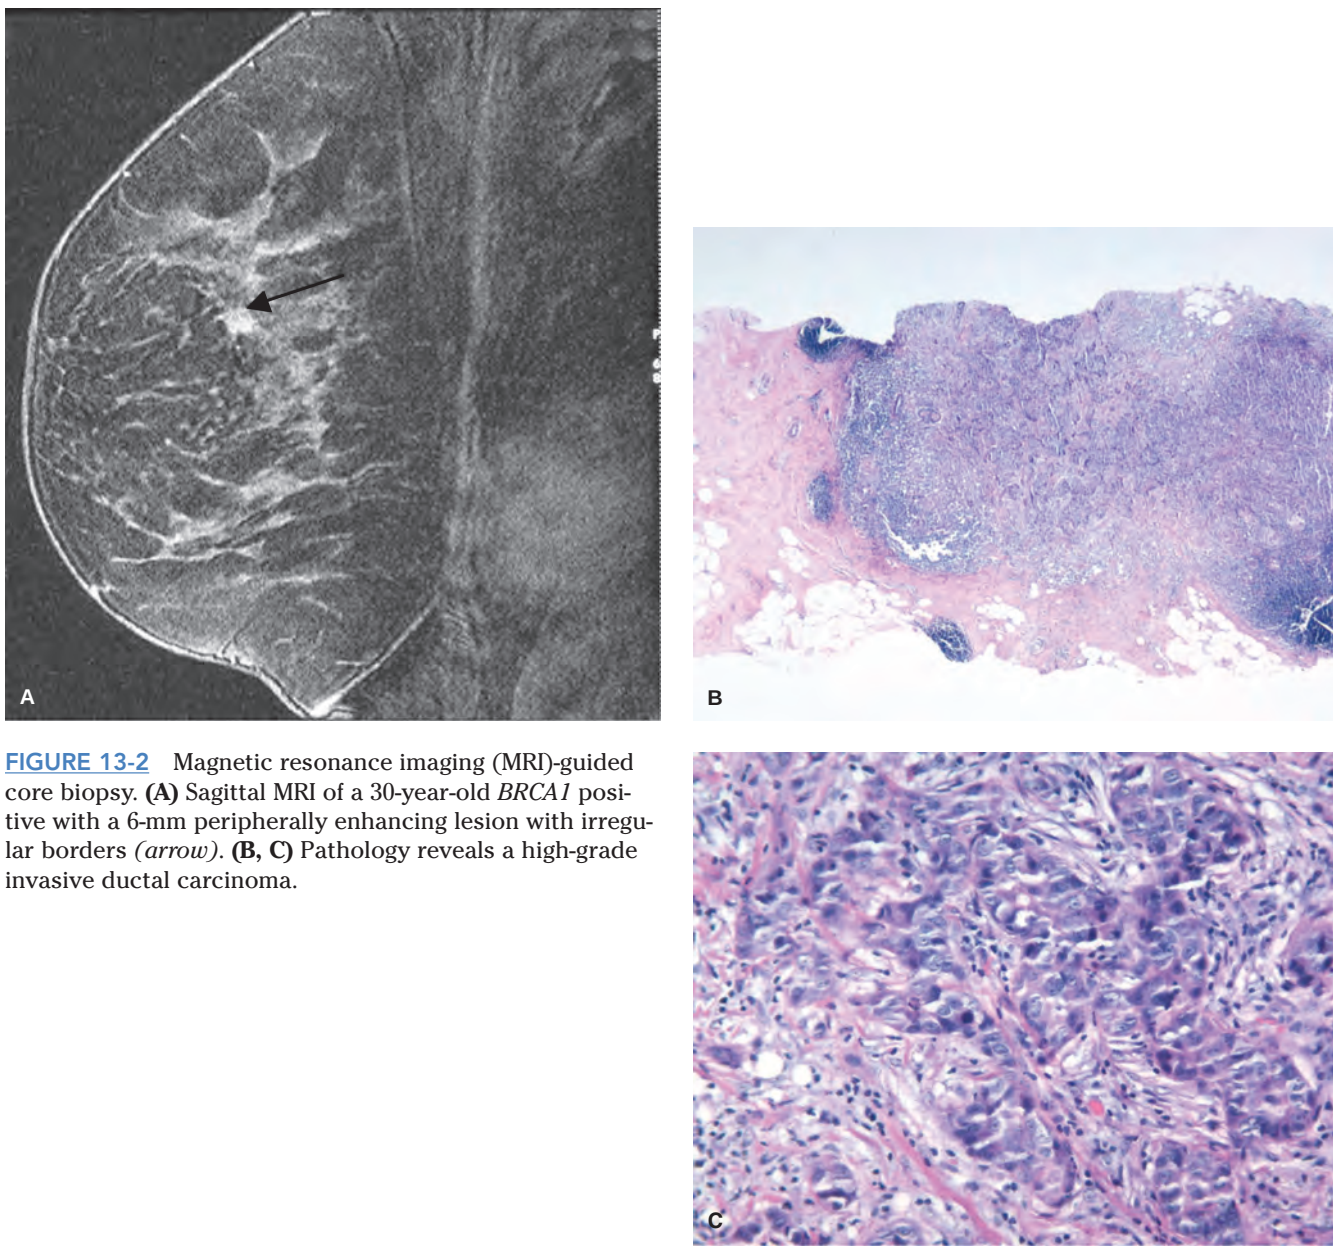

FIGURE 13-2 Magnetic resonance imaging (MRI)-guided core biopsy. **(A)** Sagittal MRI of a 30-year-old *BRCA1* positive with a 6-mm peripherally enhancing lesion with irregular borders *(arrow)*. **(B, C)** Pathology reveals a high-grade invasive ductal carcinoma.

the lesion localized with MRI guidance is usually not visible with mammographic specimen radiography. In the case of core biopsy, the ability to document successful sampling can be impossible due to the washout of contrast during the procedure. While a clip is placed following most MRI core biopsies, documentation of accurate clip placement can be difficult if the lesion is not visible at the end of the procedure. In such situations where there is washout of contrast, correlation with anatomic landmarks is recommended to confirm appropriate biopsy site and clip placement. Careful radiologic–pathologic correlation is needed to determine if the pathology findings are concordant with the imaging findings. In any case where the MRI finding is highly suspicious but the pathology is benign, immediate repeat MRI is required. Repeat MRI shortly after the biopsy is needed to confirm that the lesion has been adequately been sampled. If the targeted lesion is still present on the follow-up MRI, repeat MRI percutaneous biopsy or excisional biopsy would be necessary. However, when there is concordant benign histology, the management can vary from routine follow-up to a 6-month follow-up MRI. Whether short interval MRI follow-up should be performed in all cases with a nonspecific benign pathology result (i.e., fibrocystic changes or benign breast tissue) remains to be defined.

For a MRI-detected lesion, a targeted ultrasound examination or second-look ultrasound may be done in correlation with the MRI findings. The likelihood of visualizing the MRI-detected lesion on sonography is dependent on lesion morphology, size, and pathology (8,9). Greater success will be had with enhancing masses than nonmass enhancement. In addition, malignant lesions were more likely to be visible than benign lesions. Also, the larger the lesion size, the more likely it will be visible on targeted sonography. The success rate of targeted second-look ultrasound has been reported to be 23% to 89%.

If the MRI-detected lesion is sonographically visible, ultrasound-guided biopsy is the preferred method of biopsy. It is cheaper, faster, and more readily available when compared to MRI, with greater patient comfort. However, intermodality correlation is essential to confirm the sonographic lesion correlates with the MRI lesion. This involves correlation of the lesion size, depth in the breast, and location relative to other anatomic structures. Due to differences in patient positioning, supine for breast ultrasound and prone for breast MRI, occasionally this can be challenging. Meissnitzer et al. found on follow-up of 80 histologically benign cases that were biopsied under ultrasound and felt to be concordant to the MRI lesions, the sonographic mass did not correlate with the MRI lesion 12% of the time (10). Careful correlation is needed and follow-up imaging should be considered.

Image Interpretation

MRI has emerged as an important imaging technique for the detection, diagnosis, and staging of breast cancer. The value of MRI in this setting is derived primarily due to high sensitivity for the detection of breast cancer, with reported sensitivities ranging from 88% to 95% (11). However, high reported sensitivities have been tempered by relative low specificity, with reported specificities reports rates widely ranging from 37% to 97% (12). The low specificity is due to the overlap in morphologic appearances and enhancement behavior of benign and malignant lesions. Contrast enhancement has been seen not only in cancer, but also in fibroadenoma, fibrocystic changes including sclerosing adenosis, fat necrosis, radial scar, mastitis, atypical ductal hyperplasia, and lobular neoplasia (Fig. 13-3). In addition, presumably normal breast tissue may enhance following contrast enhancement. This enhancement has been shown to vary with different phases of the menstrual cycle, being greatest in weeks 1 and 4, lowest in week 2 (13) (Fig. 13-4). When using enhancement kinetics alone, it was shown in one study that up to three-fourths of enhancing lesions with suspicious enhancement kinetics were no longer visible when the study was repeated at a more optimum time in the menstrual cycle (13).

The characterization of enhancement as normal, benign, or concerning for malignancy remains a challenge. Historically, image interpretation was complicated by two fundamentally different methods for performing breast MRI; one utilizing three-dimensional high spatial resolution scans to assess lesion morphology, and the other utilizing rapid, dynamic imaging to assess enhancement kinetics. As discussed earlier, advances in both software and hardware now permit imaging with high spatial resolution and high temporal resolution so that both morphology and enhancement kinetics can be evaluated in the same study. While it has become increasing apparent that both architectural features and enhancement characteristics may yield greater accuracy than using either alone, characterization of morphologic features appears to be more predictive of malignancy than is characterization of the enhancement kinetic cure (14–16).

Numerous morphologic and dynamic enhancement curve criteria for classifying an enhancing lesion as benign or suspicious for malignancy have been described in the literature. In an effort to bring uniformity to breast MRI reports, an MRI breast imaging lexicon (BI-RADS) has been created through the efforts of the Susan Komen Foundation, the Public Health Service Office on Women's Health, and the American College of Radiology (ACR) (17). The first version of the MRI breast lexicon was published by the ACR in 2003, with the second edition due out in 2013. Results from many studies that evaluated the positive predictive value of morphologic and kinetic feature were incorporated into the first edition of the lexicon, and findings from more recent studies will be added to the second edition. One addition to the second BI-RADS MR imaging lexicon will be the description of background parenchymal enhancement (BPE), which refers to the presumably normal enhancement of the fibroglandular tissue identified on the first contrast-enhanced series. BPE is thought to be related to endogenous hormone status and fluctuates with the menstrual cycle, highest during weeks 1 and 4 and lowest during week 2 as noted above. It has been found to increase in postmenopausal women undergoing hormone replacement therapy, and to decrease in women treated with tamoxifen or aromatase inhibitors (18). Currently the degree of BPE is subjective, and is reported as minimal (less than 25%); mild (26% to 50%); moderate (51% to 75%); and marked (greater than 75%) (Fig. 13-5). It has been postulated that the degree of BPE may decrease the sensitivity of breast MRI by obscuring enhancing malignancies. Investigators evaluating BPE and impact of the diagnostic performance of MRI have reported that increasing background enhancement is associated with younger patient and age and higher abnormal interpretation rate (BI-RADS Category 3, 4, or 5), but found no significant difference in positive biopsy rate or cancer detection rate among the BPE categories (19,20).

Following the description of BPE, an area (or areas) of abnormal enhancement is then described using lesion descriptors (morphology and enhancement kinetics). Enhancing lesions are divided into three main categories: focus or foci, mass, and nonmasslike enhancement (NMLE) (Fig. 13-6). A focus (foci) is defined as enhancement measuring less than or equal to 5 mm that cannot be otherwise characterized due to size. A mass is a 3-D lesion that occupies a

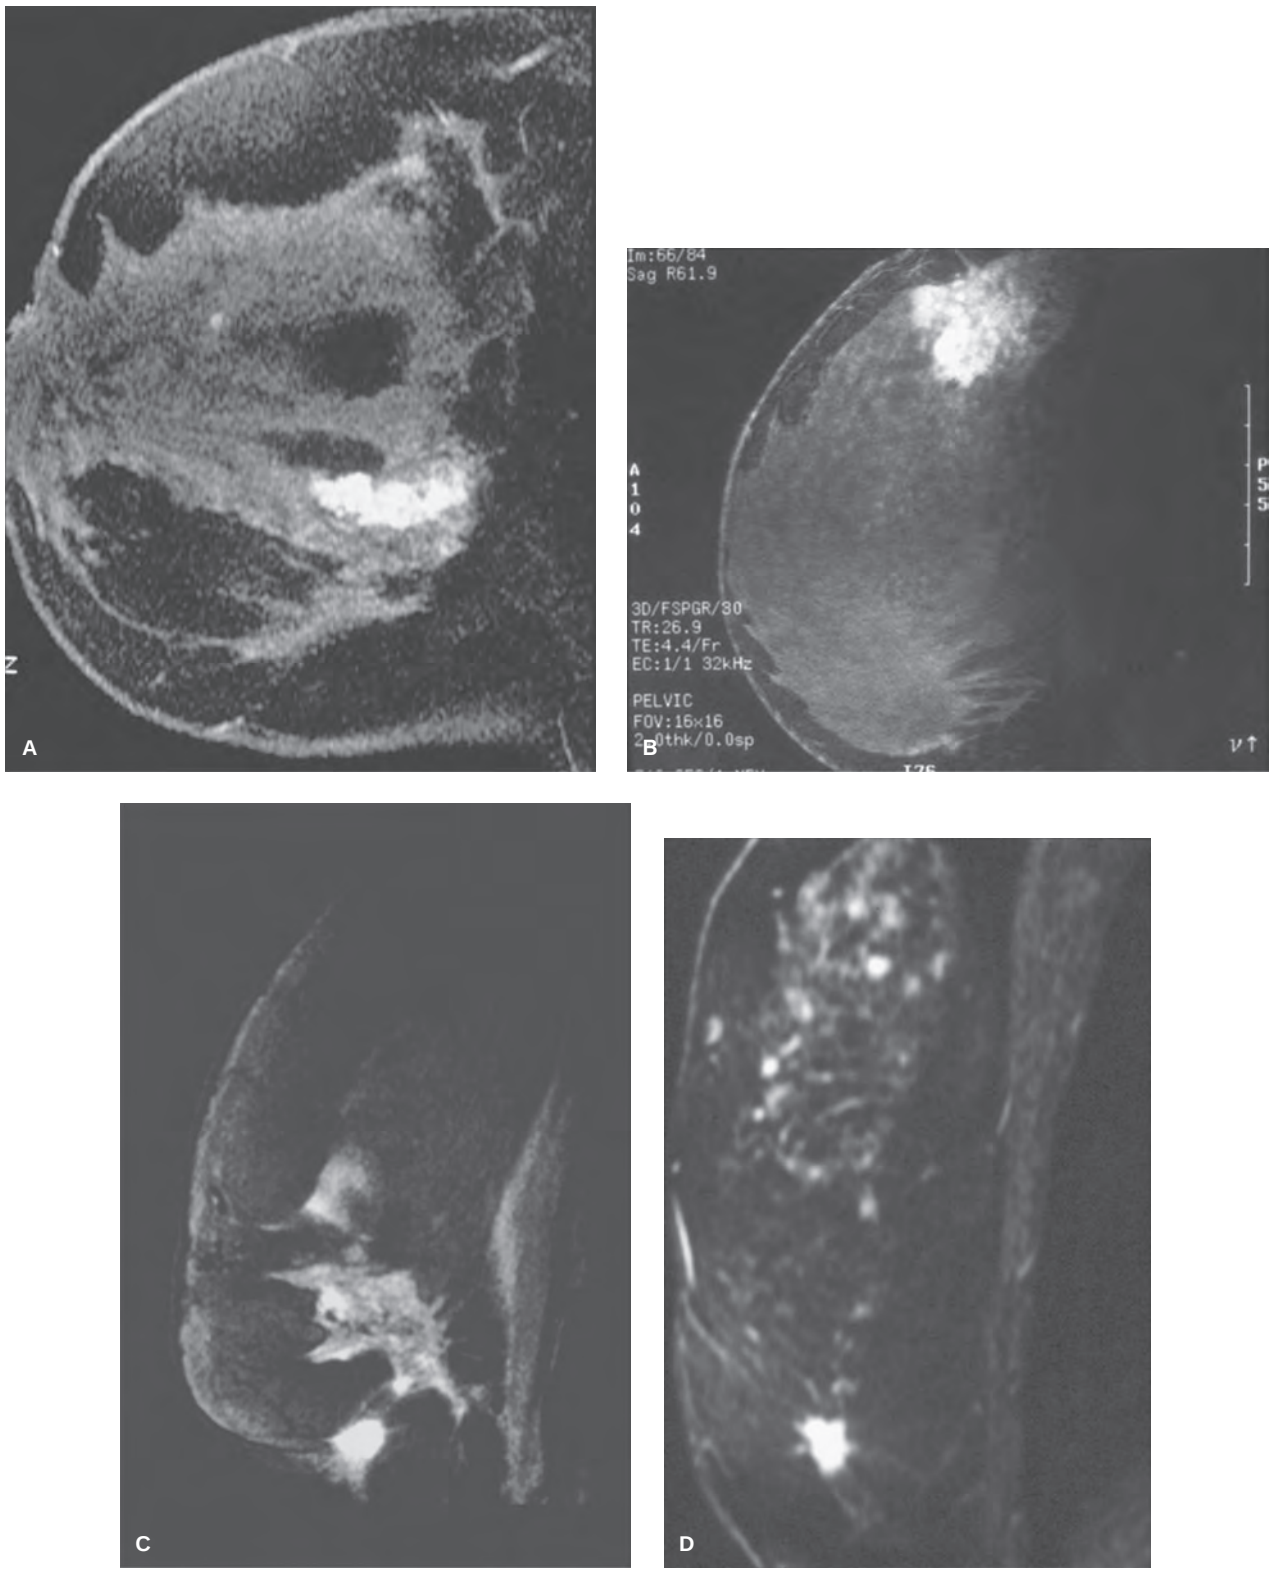

FIGURE 13-3 False-positive enhancing lesions. Contrast enhancement is demonstrated in **(A)** sclerosing adenosis, **(B)** chronic mastitis, **(C)** fat necrosis, and **(D)** radial scar.

space in the breast, and is described in terms of shape, margin, and internal enhancement. NMLE is an area of enhancement without an associated mass (space occupying lesion) and is characterized by distribution, internal enhancement, and symmetry. Enhancement curve assessment includes the initial enhancement phase in first 2 minutes (slow, medium, or rapid), and the delayed phase (persistent increasing, plateau, or washout) (Fig. 13-7).

Architectural features reported to be highly predictive of benign disease include masses with smooth or lobulated

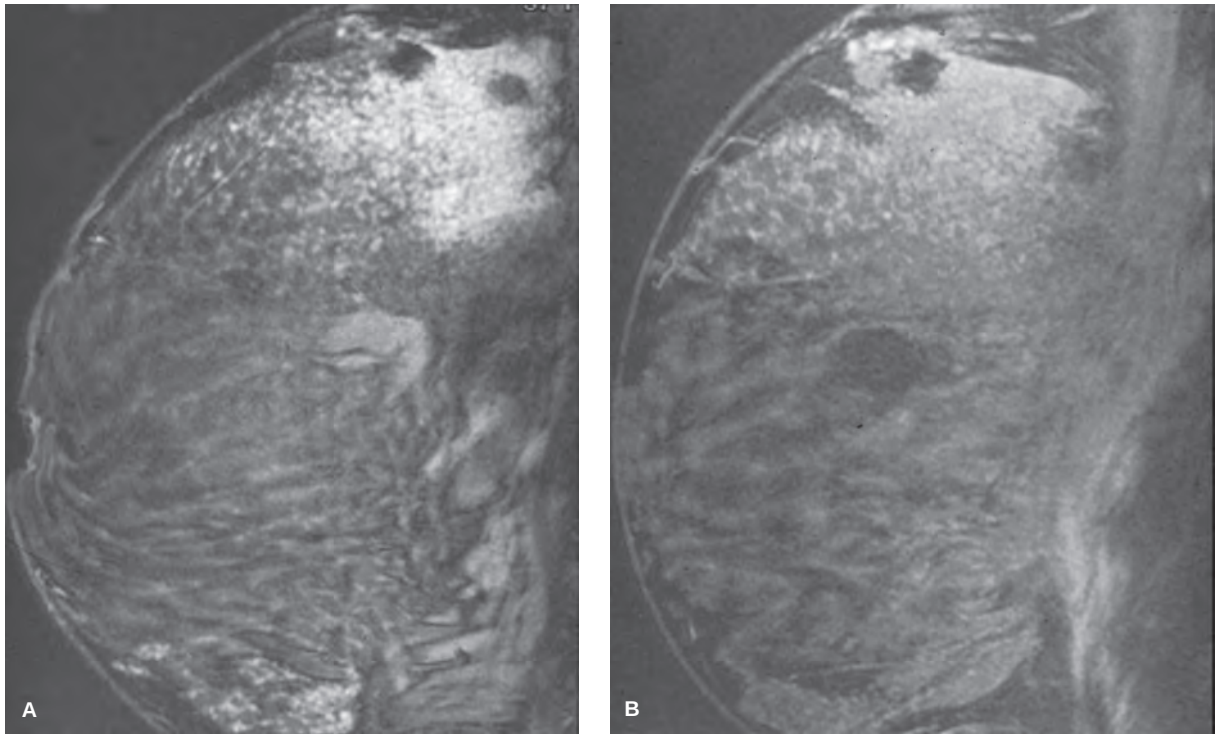

FIGURE 13-4 Hormonal variability of contrast enhancement. Sagittal magnetic resonance image of a patient with a family history of breast cancer reveals an area of regional enhancement in the superior breast, which was no longer present when the patient was imaged at a different time in her menstrual cycle.

borders, the absence of mass enhancement, and a circumscribed mass with nonenhancing internal septations, which in some reports was specific for the diagnosis of a fibroadenoma (14,21). While circumscribed borders on mammography are associated with a 2% likelihood of cancers (22), it has been suggested that this morphologic feature may not be a reliable indicator of benignity on MRI for several reasons including the circumscribed borders of some cancers in high-risk patients, and the perception of margin smoothness which is dependent on spatial resolution and window and level settings (16,23,24). This can be especially problematic in masses smaller than 1 cm in size. In a study of positive predictive value of various morphologic and kinetic features, Liberman et al. reported that 17% of smoothly marinated masses in their series were malignant (16). In contrast, Gutierrez et al. reported that masses of 1 cm or greater with smooth margins and homogeneous enhancement in their series had the lowest predicted probability of malignancy of 3% (24). However, this was not the case with smaller masses, where the likelihood of malignancy for small masses (less than 1 cm in size) with smooth margins and homogeneous enhancement was 16%. Histologic subtypes that may have smooth margins include mucinous cancer, intracystic papillary cancer, and some high-grade tumors, such as triple-negative cancer (25). Despite smooth margins, these malignant lesions often display other concerning morphologic features including heterogeneous enhancement, rim enhancement, and/or an enhancement kinetic curve showing contrast washout over time.

Architectural features with highest PPV for malignancy include a mass with spiculated or irregular margins, irregular shape, marked internal enhancement, and/or rim enhancement (11,12,14–16). These findings suggest the presence of an invasive cancer. For NMLE, the features with highest PPV for malignancy include segmental or clumped linear enhancement (11,12,14–16,24) and suggest the diagnosis of DCIS. The enhancement kinetics with the highest PPV is rapid initial enhancement with delayed phase showing plateau or washout (11,12,14–16). However, as noted previously, kinetic information is less predictive of malignancy than is morphologic characterization. This is especially true with NMLE, where DCIS not uncommonly displays suspicious ductal or segmental morphology, but with benign kinetic curves (24).

The overall impression and final recommendation categories are virtually identical to the BI-RADS mammography lexicon. A BI-RADS Category 0 study is incomplete, where comparison with a previous MRI study or correlation with mammography and/or ultrasound is needed. A BI-RADS Category 1 study is negative. A BI-RADS Category 2 study demonstrates benign findings such as postsurgical/postradiation changes, cysts, or an enhancing lesion(s) with benign MRI characteristics. Reported NPV for BI-RADS Category 1 examination (no abnormal enhancement was cancer found) have ranged from 88% to 99% (11,15). Mahoney at el. reported an NPV of 100% in their BI-RADS Category 2 cases (15). A BI-RADS Category 3 study demonstrates an enhancing lesion (or lesions), which is deemed to be probably benign, and short-term interval follow-up, usually at 6 months, is recommended. At the present time, approaches for what type of enhancing lesion should be placed into the probably benign category are intuitive. The type of enhancement that should be classified as probably benign as opposed to normal, benign, or suspicious remains unclear. In mammography, findings that should be placed into the probably benign category have been well studied. In clinical investigation, it has been demonstrated that the likelihood of a lesion classified as probably benign, BI-RADS Category 3 on mammography, but ultimately prove to be malignant should be less

FIGURE 13-5 Background enhancement. than 1% to 2% (22). In contrast to mammography, there has been very little published on the outcome of lesions placed into the BI-RADS Category 3 (23). There is a wide variation in the use of probably benign assessment, which has been applied in 6.6% to 25% of examination (23). The cancer yield in cases placed into BI-RADS 3 has also been widely variable, ranging from 0% to 10%. The wide discrepancy in reported results is likely due to differences in inclusion criteria for patient population: screening high-risk women only, screening and diagnostic MRI, and BI-RADS 0 mammographic and sonographic workup. Further investigation is needed to determine if there are distinct morphologic and/or kinetic characteristics that can be deemed appropriate for short interval follow-up with an acceptable cancer yield and maintain favorable prognosis. In addition, overall cost must be considered when interpreting a breast MRI as probably benign. In contrast to mammography, where placing a patient into short interval follow-up was a relatively fast and inexpensive alternative to surgical excision, one or more 6-month follow-up MRI examinations are very expensive. The cost–benefit of short interval follow-up MRI (how often and for how long) relative to how readily available MRI-guided

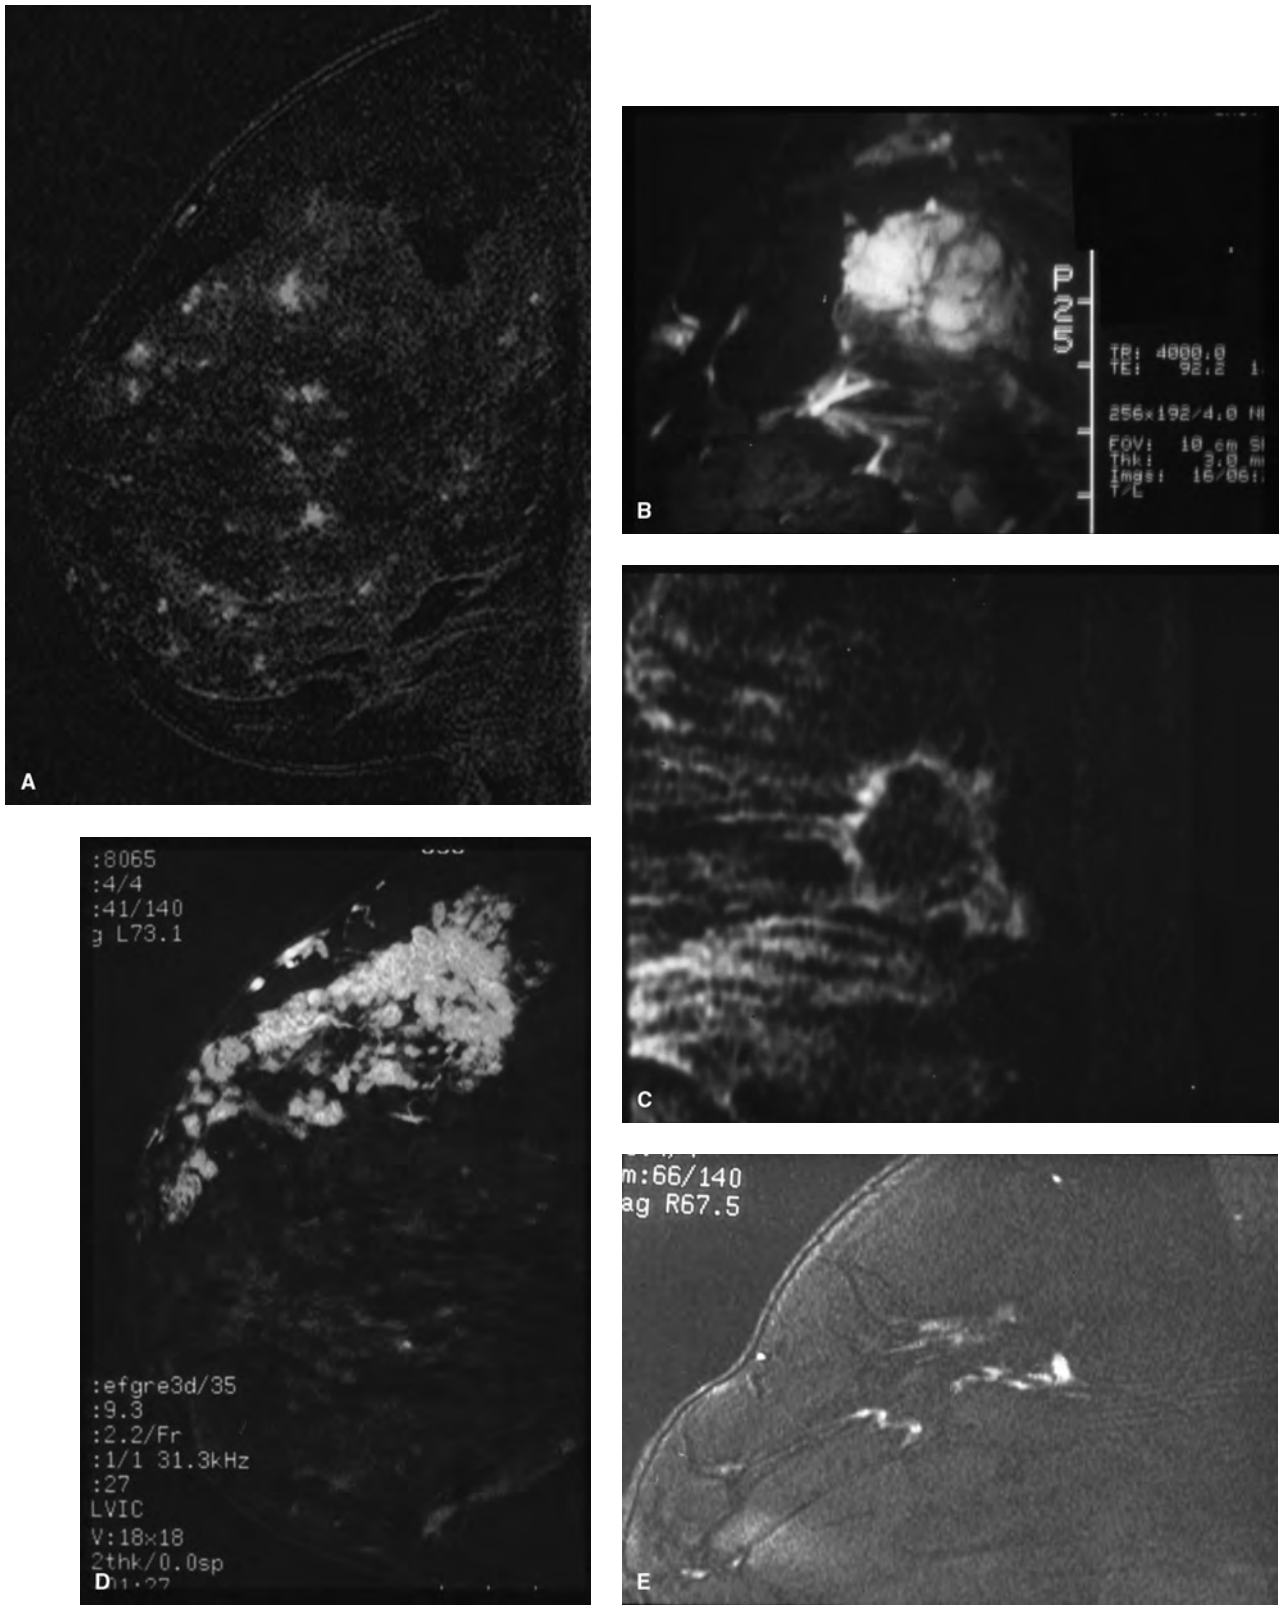

FIGURE 13-6 Architectural features: **(A)** scattered foci (less than 5 mm) of enhancement, **(B)** lobulated enhancing mass with nonenhancing internal septations in fibroademoma, **(C)** peripheral enhancement and spiculated borders in invasive ductal carcinoma, **(D)** clumped segmental nonmass enhancement in DCIS, and **(E)** linear nonmass enhancement in DCIS.

core needle biopsy is needs to be studied. Finally, BI-RADS Category 4 (suspicious) and 5 (highly suspicious) studies demonstrate an enhancing lesion (or lesions) for which a biopsy is recommended. The biopsy can be performed with MRI guidance if seen only on MRI, or with ultrasound guidance in those cases where the MRI finding can be identified on a directed ultrasound study. In those cases where targeted ultrasound is recommended for possible guidance for biopsy, these should be categorized as BI-RADS 4, biopsy recommended (MRI-guided biopsy if ultrasound is negative), not BI-RADS Category 0. Reported PPV for BI-RADS Category 5 lesions have ranged from 67% to 71% while reported PPV for BI-RADS Category 4 lesions have ranged from 19% to 21% (15,16).

CLINICAL INDICATIONS

Problem Solving: The Equivocal Mammogram, Ultrasound, or Physical Examination Finding

Breast MR imaging can be used as a problem-solving tool in the setting of equivocal imaging (mammography and/or ultrasound) findings (26–28). MR imaging can be a very useful clinical tool when breast cancer is suspected but the diagnosis cannot be established by means of conventional methods. MRI, however, should never be used in place of a full mammographic and sonographic evaluation. A thorough conventional imaging evaluation should be completed prior to recommending a MRI. In one study, the most common mammographic findings that led to the recommendation for MRI were architectural distortion and asymmetries, findings seen only on one view (29). No suspicious enhancement was seen in the region of the mammographic abnormality in 87% of the cases. However, correlative enhancing masses were seen in 13% (15 per 115) cases with biopsy of all 15 cases yielding 6 cancers (6 per 115, 0.5%) (29). Based on results of several studies demonstrating sensitivity of MRI for the detection of invasive cancer approaching 100%, it has been suggested that a negative MRI examination image in the setting of equivocal imaging or physical examination findings virtually excludes the presence of invasive cancer. However, there have been multiple reports (30–33) documenting false-negative MRI cases, not only of noninvasive cancer but of invasive ductal cancer as well, including invasive lobular cancer and invasive ductal cancer. The reported false-negative rates of MRI range from 4% to 12% (30–33), although up to 47% of the cases may be attributed to differences in image perception and interpretation rather than true false negatives (34). Regardless, as is true with a negative mammogram or a negative ultrasound study, in a patient with a suspicious palpable abnormality, a negative MRI study should not preclude biopsy.

Another potential problem-solving tool that was FDA approved in 2011 and rapidly gaining clinical acceptance is tomosynthesis imaging. Tomosynthesis is 3-D imaging of the breast based on the digital platform. One of the main advantages of tomosynthesis is that, similar to breast MR, the 3-D imaging decreases the superimposition of fibroglandular tissue that may obscure lesions. The 3-D imaging also allows for improved triangulation, or localization of mammographic findings seen in one view, and lesion analysis and thus can be used as problem-solving tool (35). In addition, there is current ongoing research to add contrast to tomosynthesis imaging. It is feasible that tomosynthesis may decrease the role of MRI in the evaluation of inconclusive mammographic findings in the future. This remains to be seen.

Axillary Node Malignancy and Unknown Site of Primary Tumor

Occult primary breast cancer presenting as malignant axillary adenopathy represents less than 1% of breast cancers. Traditionally, treatment offered to these women was mastectomy and axillary node dissection. Pathologic evaluation of the mastectomy specimen in such situations has demonstrated the primary cancer in only one-third of the time. The ability of mammography to identify a primary breast cancer in this clinical setting has been disappointing, with reported rates ranging from 0% to 56%. In contrast, MRI has demonstrated very high sensitivity for the detection of an ipsilateral breast cancer primary (36,37) in these patients. In a review of six studies, the overall sensitivity of MRI was 94% with a specificity of 94% to 100% and estimated PPV was 90% (37). The results of these studies support the clinical use of MRI as the imaging study of choice in the clinical setting of malignant axillary adenopathy and unknown site of primary tumor. In this patient population, MRI offers the potential for breast cancer detection as well as staging, which can then be used to guide treatment planning. The identification of localized disease may offer some patients the option of breast conservation therapy as an alternative to mastectomy. If MR does not demonstrate the primary breast cancer, options include mastectomy or whole breast radiation followed by systemic therapy.

Monitoring Response to Chemotherapy

In patients presenting with locally advanced cancers, preoperative chemotherapy is necessary prior to surgical therapy. Decreasing the size of the tumor also can allow for less radical surgery, converting a clinically indicated mastectomy to potential breast-conserving therapy. However, monitoring clinical response can be challenging. The resulting fibrotic response from chemotherapy may sometimes make clinical breast evaluation difficult. There are also limitations to mammography as overlying glandular tissue can make assessment difficult. Studies have shown that MRI is superior to mammography and clinical breast examination in establishing a baseline tumor extent and in monitoring these patients (38,39). In addition, it has been shown that MRI can

provide evidence of response to therapy as early as after one cycle of chemotherapy with tumor volumetric measurement being the superior method to monitor change than tumor diameter measurement (38). Given that MRI can detect early response, it is equally important to identify patients who do not respond to therapy so appropriate chemotherapy regimen changes may be made. However, it has been shown that MRI may over- and underestimate tumor response. In some cases, MRI following treatment demonstrates no residual enhancing tumor, yet residual tumor nests, which may be extensive, are found at excision. The absence of enhancement even in the presence of residual invasive tumor is likely secondary to chemotherapy-induced decreased tumor vascularization and/or decreased vascular permeability. It has also been demonstrated that the underestimation of residual tumor burden on MRI may vary with the chemotherapeutic agent. Tumors treated with a taxane-containing regimen are often underestimated (40). It is postulated that the underestimation of tumor volume by MRI is secondary to the numerous nests of tumor left following the taxane regimen compared with a more concentric tumor shrinkage with other chemotherapeutic agents. As there can be "complete imaging response," placement of a clip at the original tumor site is recommended prior to neoadjuvant treatment so the tumor site can be identified and localized at the time of surgery. If there is no residual enhancement at completion of therapy, the clip can be localized at the time of surgery.

The imaging pattern of response may depend on the original appearance of the tumor. In cases of focal disease, there is concentric shrinkage of the tumor in responders, which can be easy to follow. However, when tumor presents as multifocal or multicentric disease, response to therapy can result in residual small foci of tumor scattered in the breast, some of which may be below the threshold of imaging.

In addition to contrast-enhanced MRI, studies have shown the diffusion-weighted imaging may have a role in monitoring response to chemotherapy (41). As diffusion-weighted imaging measures movement of water molecules at the cellular level, these studies have reported increases in ADC reflect damage at the cellular level in response to the chemotherapy prior to morphologic changes became detectable. Pickles et al. found increase in ADC values to be statistically significant after one cycle of chemotherapy but comparison was made to lesion diameter rather than volume (41), whereas Hylton and colleagues found tumor volume measurement to be a more sensitive measure than diameter (38). The role of diffusion-weighted imaging in monitoring response to chemotherapy remains to be seen, but it may have a valuable role in patients with renal dysfunction or gadolinium allergy as intravenous contrast is not needed.

Despite its limitations, MRI does appear, at the current time, to be the most accurate imaging methods for evaluating response to chemotherapy. While it is superior to mammography and clinical breast examination, potential over- and underestimation of tumor burden should be taken into account when incorporating MRI in this clinical setting.

Breast Cancer Screening in Women at High Risk

In the 1990s, the first prospective, nonrandomized studies were initiated in The Netherlands, the United Kingdom, Canada, Germany, the United States, and Italy to determine the benefit of adding annual MRI to mammography for women at increased risk for developing breast cancer including women with *BRCA1* or *BRCA2* mutations or women with at least a 20% to 25% lifetime risk of developing breast cancer (42–47). In a review of 8 of these trials, Lehman et al. reported that 144 cancers were detected in 4,271 women for a cancer yield of 3% (48). Despite substantial differences in patient population (i.e., age, risk) and MRI technique, all reported significantly higher sensitivity for MRI compared with film mammography (or any of the other modalities). Overall, the studies reported a high sensitivity for MRI, ranging from 71% to 100% versus 0% to 40% for mammography in high-risk populations (48).

In August 2006, the American Cancer Society convened an expert panel to review the literature on MRI high-risk screening published between 2002 and 2006 with the intent to develop guidelines for adding MRI to mammography for screening of women at elevated risk for developing breast cancer. Based on evidence (reported results of prospective, nonrandomized studies), the panel concluded that annual screening MRI should be added to annual screening mammography in *BRCA1* or *BRCA2* mutation carriers, for first-degree relatives of *BRCA1* or *BRCA2* mutation carriers but were not themselves tested, or based on risk assessment had a lifetime risk of 20% to 25% or greater for developing breast cancer (49) (Fig. 13-3). Based on expert consensus, given limited published experience, the panel recommended annual screening MRI in patients who received radiation to the chest between ages 10 and 30, patients with Li-Fruameni syndrome and first-degree relatives, and those with Cowden and Bannayan-Riley-Ruvalcaba syndromes and first-degree relatives (49).

When screening with MRI should begin, how often it should be performed, and when it should be stopped remain unclear. In a statement published in 2010, The Society of Breast Imaging and the American College of Radiology recommend that screening MRI be performed annually, beginning by age 30, but not before age 25 in *BRCA1* or *BRCA2* mutation carriers or first-degree relatives (50). For women with 20% or greater lifetime risk, annual MRI is recommended to begin by age 30 (not before 25) or 10 years before the age of the youngest affected first-degree relatives. For those with a history of chest irradiation (ages 10 to 30 years), annual MRI beginning 8 years after treatment, but not before age 25 is recommended. The age to stop MRI screening in the United States has yet to be defined. In the United Kingdom, the National Institute for Health and Clinical Excellence (NICE) guidelines for MRI screening of women at increased risk are as follows: Annual MRI should be offered to women who are *BRCA1* and *BRCA2* mutation carriers aged 30 to 39; TP 53 carrier greater beginning at age 20; women aged 30 to 39 with greater than 8% 10-year risk; women aged 40 to 49 years with greater than 20% 10-year risk or greater than 12% 10-year risk with dense breasts on mammography; MRI should not be offered to women older than age 50 (51).

The ACS panel found insufficient evidence to recommend annual screening MRI in patients with lifetime risk of 15% to 20%; a history of biopsy proven LCIS, ALH, or ADH; those with a personal history of breast cancer; or those with heterogeneously or extremely dense breasts on mammography. However, single-institution, retrospective studies published after the ACS guidelines were defined have reported cancer detection rates on screening MRI in patients with a history of LCIS or a personal history of breast cancer similar to detection rates in women with a *BRCA1* or *BRCA2* mutation or those with greater than 20% lifetime risk, suggesting that screening MRI may be of value in these patients as well (52,53). The Society of Breast Imaging (SBI) and the American College of Radiology (ACR) suggest that MRI screening be considered in women with between 15% and 20% lifetime risk of breast cancer on the basis of personal history of breast or ovarian cancer or biopsy-proven

neoplasia or ADH (50). The ACS guidelines (and the SBI and ACR) recommend against MRI screening in women at less than 15% lifetime risk.

While it has become increasing clear that MRI is a highly sensitive imaging technique to detect mammographic and clinically occult cancer in selected high-risk populations, there are two major interrelated limitations that need to be addressed, the first being limited specificity of MRI resulting in false-positive findings and the second being potential high costs related to the actual screening MRI costs and the potential downstream costs when an abnormality is detected. In terms of specificity, reported callback rates for additional imaging following screening MRI have ranged from 8% to 17% (average 10%), and biopsy rates ranged from 3% to 15% (average 5%) (48,49). However, it has been reported that recall rates decreased in subsequent rounds of screening, where the prevalence screens had the highest false-positive rates, which subsequently dropped to less than 10% (44,48,49). While the callback and biopsy rates of MRI were higher than for mammography in high-risk populations, the proportion of biopsies yielding a malignant diagnosis (positive predictive value) in these studies was also higher for MRI, ranging from 20% to 40% (44,48,49).

The potential for heightened patient anxiety following a false-positive MRI examination remains of concern. Results of relatively small studies have demonstrated variable degrees of elevated anxiety in women following a false-positive MRI examination. In a study looking at the psychological impact and acceptability of MRI and mammography in the United Kingdom national study for MRI screening of women at familial high risk of breast cancer (MARIBS), women were assessed psychologically 4 weeks before mammography and MRI, immediately after, and then 6 weeks after (54). Women reported that both mammography and MRI were acceptable with high levels of satisfaction and low psychological morbidity, but women reported that MRI was more distressing, they had higher anticipatory anxiety before MRI, the anxiety persisted at 6 weeks, and they stated they were more likely to return for mammography than MRI. In the Canadian screening trials, the authors reported that MRI did not have a detrimental psychological impact on women with a *BRCA* mutation, and that recalling these women for further imaging after a false-positive MRI temporarily increased global anxiety (55).

There has been anecdotal evidence that a false-positive MRI screening examination in a woman at high risk for the development of breast cancer may result in the request for prophylactic mastectomy. The actual frequency of prophylactic mastectomy secondary to a false-positive MRI study remains to be determined. Hoogerbrugge et al. reported their experience in a study of 196 *BRCA* mutation carries that underwent screening with MRI (56). In this study, 41% (81 per 196) of women had at least one positive MRI or mammogram. The probability that a positive MRI result was a false positive was 83%. In patients with a prior preference for mastectomy, prophylactic mastectomy was performed in 89% in those with a false-positive MRI versus 66% with a negative MRI ($p = .06$). No significant difference was found in women with prior preference for surveillance (63).

High cost, in large part related to false-positive findings, remains perhaps the greatest barrier to the implementation of widespread screening MRI of women at high risk. The costs associated with MRI include the initial MRI cost, but additional "downstream" costs when the MRI examinations yield false-positive results leading to immediate recall MRI studies, short interval follow-up MRI studies, additional mammogram and ultrasound studies, and benign breast biopsies. Several cost-effectiveness studies have been published. Each study has used a different computer model taking into account breast cancer risk, sensitivity, and specificity of MRI; cost of MRI; and cost per quality-adjusted life-year (QALY) gained with MRI. Using QALY in the range of $50,000 to $100,000, several studies have demonstrated that MRI does appear to be cost-effective. Plevritis et al. concluded that the cost per QALY saved for annual MRI plus film mammography, compared with annual film mammography alone, varied by age and was more favorable in carriers of a mutation in *BRCA1* than *BRCA2* because *BRCA1* mutations confer higher cancer risk, and higher risk of more aggressive cancers, than *BRCA2* mutations (57). Estimated cost per QALY for women aged 35 to 54 years was $55,420 for women with a *BRCA1* mutation and $130,695 for women with a *BRCA2* mutation. The most important determinants of cost-effectiveness were breast cancer risk, sensitivity of mammography, cost of MRI, and quality of life gains from MRI. An evaluation of the cost-effectiveness in the United Kingdom (based on MARIBS study) showed that the incremental cost per cancer detected for women at approximately 50% risk of carrying a *BRCA* gene mutation was $50,911 for MRI combined with mammography over mammography alone (58). For known mutation carriers, the incremental cost per cancer detected decreased to $27,544 for MRI combined with mammography, compared with mammography alone. Taneja et al. also reported that MRI appeared cost-effective in *BRCA1* or *BRCA2* mutation carries (QALY $25,277) and might be cost-effective in other high-risk groups depending on expected prevalence of disease (QALY $45,566 [300 cases], $310,616 [50 cases]) (59). In a cost-effectiveness study of MRI and mammography for screening *BRCA1* mutation carriers, Lee et al. concluded that combined annual screening with mammography and MRI provided the greatest life expectancy and was likely to be cost-effective when the value placed on gaining an additional QALY was in the range of $50,000 to $100,000 (60). In contrast to these reports, Moore et al., in a cost-effectiveness analysis of MRI compared to mammography for breast cancer screening in young women at high risk, found that although MRI may provide health benefits when compared to mammographic screening for some high-risk women, it did not appear to be cost-effective even at a willingness to pay thresholds above $120,000 (61).

Nipple Discharge

Nipple discharge is a relatively common complaint, with a reported incidence of 2% to 5%. Although most nipple discharge is caused by benign processes such as papillomas and duct ectasia, the risk of cancer among patients presenting with nipple discharge has been reported to be 5% to 21%. There have been a few reports, with relative small numbers of patients, demonstrating the potential of MR imaging to identify both malignant and benign lesions in this clinical setting. One of the earliest studies to evaluate the role of MRI for patients with nipple discharge described 22 patients with nipple discharge and negative mammography of whom 14 underwent excisional biopsy following the MRI (62). The authors reported that the MRI findings correlated with histologic findings in 10 of 14 (71%) cases that underwent surgical excision, including the identification of 5 of 6 underlying malignancies. More recent experience also supports the potential of MRI in the setting of clinically concerning nipple discharge. In a retrospective study of 306 patients with negative mammography who underwent ductography (DG) ($n = 163$) and /or MRI ($n = 52$), the overall incidence of malignancy was 10% (63). DG had a PPV of 19% and NPV of 63% while MRI had a PPV of 56% and NPV of 87%. The authors concluded that ductography is a poor indicator of underlying

pathology and cannot exclude underlying malignancy while MRI offered higher predictive values and thereby may allow for improved patient selection and treatment planning, but on the other hand, MRI should not replace major duct excision as the gold standard to exclude malignancy in patients with clinically concerning nipple discharge. In a subsequent report from the same institution, in a retrospective review of a highly select group of 475 patients presenting with ND, where the incidence of underlying cancer/high-risk pathology was high (36%), the sensitivity and specificity of MRI was 70% and 44%, respectively, and when performed after a negative standard evaluation, MRI detected 75% of otherwise occult malignant/high-risk lesions (64). However, in all of these cases the lesions were in the central region of the breast that would have been encompassed by standard duct excision. The authors thus concluded that while MRI may have a role in the evaluation of suspicious ND, the low specificity of MRI and the potential to detect "incidental" enhancing lesions that would require follow-up or biopsy should be considered before implementing routine use of MRI in this setting. In 2010, in a report of European Society of Breast Cancer Specialists (EUSOMA) working group on potential indications for the use of breast MRI, the authors found insufficient evidence of benefit to recommend the routine use of MRI in the clinical context of suspicious nipple discharge, recommending systematic reviews and meta-analysis of published studies (65).

Imaging in the Setting of Newly Diagnosed Breast Cancer

The generalized use of MRI in the clinical setting of newly diagnosed cancer remains controversial. The literature is replete with single institution and multicenter, nonrandomized retrospective studies performed over the past 15 years to evaluate MR imaging for preoperative ipsilateral breast cancer staging and contralateral breast cancer screening in patients with newly diagnosed breast cancer. Based on the results of these studies, there is overwhelming evidence that MRI is more sensitive than mammography, ultrasound, and physical examination in the assessment of tumor size and the detection of multifocal or multicentric disease in the ipsilateral breast and detecting unsuspected contralateral synchronous disease. In a recent meta-analysis of 50 such studies (n = 10,811 women) performed between 1996 and 2011 (total of 2,243 studies reviewed), MRI detected additional cancer in the ipsilateral breast in 20% of women and in the contralateral breast in 5.5% of women (66). In another meta-analysis of 22 studies that reported contralateral malignancies detected only by MRI, MRI detected a suspicious finding (TP plus FP) in 9.3% of women, with PPV of 47.9% and TP: FP of 0.92. In 35.1% of cases, the MRI detected cancers were DCIS and in 64.9% were invasive cancer (67).

Given the potential of MRI to detect unsuspected multifocal or multicentric cancer and synchronous bilateral cancer, it has been suggested that MRI should be part of the preoperative assessment of patients with newly diagnosed breast cancer. The assumptions behind adopting MRI in this role include the short-term goal of improved surgical planning, with reduced rate of reexcision surgery in those patients who will ultimately require mastectomy, and the long-term goals of reduced in-breast local recurrence and improved overall survival. At the current time, there is little evidence that preoperative MRI achieves any of these goals. In terms of improving surgical management, while MRI may detect more disease than was suspected based on conventional imaging or clinical examination, limited specificity remains problematic, with false-positive findings resulting in additional benign biopsies, wider excisions, and unnecessary mastectomies. In the aforementioned meta-analysis of 50 studies evaluating MRI for ipsilateral staging, the summary PPV of ipsilateral additional disease was 67% (95% CI 59% to 74%) and for the contralateral breast, the PPV was 37% (95% CI 27% to 47%) (66). While true positive MRI prompted "appropriate" conversion from local excision to wide local excision (WLE) in 4.5% or to mastectomy in 8.3%, the proportion of women with inappropriate conversion to more extensive surgery due to false-positive MRI findings was 4.5% (WLE) and 1.7% (mastectomy).

There remains an ongoing concern that a connection exists between the increasing use of breast MRI for breast cancer staging and increasing rate of mastectomies. At the Mayo Clinic in Rochester, Minnesota, in a study of 5,405 patients who underwent breast cancer surgery between 1997 and 2006, patients who had an MRI were more likely to undergo mastectomy than those who did not. However, mastectomy rates increased from 2004 to 2006 predominantly in patients who did not undergo MRI, suggesting that other factors influencing surgical management are involved (68). In a recent meta-analysis examining the effect of preoperative MRI compared with standard preoperative assessment on surgical outcomes, summary of evidence showed that MRI significantly increased mastectomy rates and suggested an unfavorable harm–benefit ratio for routine use of preoperative MRI in breast cancer staging (69).

In addition to more extensive surgery in the ipsilateral breast, there is also evidence that the use of preoperative MRI may correlate with an increased rate of contralateral prophylactic mastectomy (70–71). In a study of 3,606 women who underwent preoperative staging bilateral breast MRI, women who underwent MRI were nearly twice a likely to have a contralateral prophylactic mastectomy than those who did not undergo MRI (9.2% vs. 4.7%; $p < .001$) (71).

There are multiple potential biases inherent in the nonrandomized trials included in these meta-analyses, making it clear that randomized control trials are needed to gain a clearer understanding of the effects of preoperative breast MRI. The results of the first of such trials, the COMICE (comparative effectiveness of MRI in breast cancer) trial, were published in 2010 (72). This randomized-control multicenter trial, which evaluated the effectiveness of MRI in reducing reexcision rates, enrolled 1623 women in 45 UK centers, with biopsy-proven primary breast cancer that were scheduled for wide excision after triple assessment (clinical, radiological [mammography and ultrasound], and pathological assessment). Patients were randomly assigned to receive either MRI or no further imaging. The addition of MRI was not significantly associated with a reduced reexcision rate, with 19% needing reexcision in the MRI group versus 19% in the no-MRI group. The results of a second randomized control study, the MONET (MR mammography of nonpalpable breast tumors), was published in 2011 (73). This study, performed at four sites in the Netherlands, enrolled 418 patients with a nonpalpable BI-RADS Category 3 to 5 lesion, randomized to MRI versus no MRI. The primary endpoint was the rate of additional surgical procedures in patients with nonpalpable breast cancer. The authors reported that the addition of MRI was paradoxically associated with an increased reexcision rate (reexcision rate performed because of positive margins of resection after primary breast conserving surgery was 18 per 53 [34%] in the MRI group vs. 6 per 50 [12%] in the control group). Based on these results, the authors suggested that breast MRI should not be used routinely for preoperative workup patients with nonpalpable breast cancer.

Thus, at the present time, the short-term goal of MRI, namely improved surgical management with reduced number of surgical procedures, has not been demonstrated. While data are clear that MRI permits detection of mammographically, sonographically, and clinically occult multifocal cancer in selected patients with presumed unifocal disease and detect synchronous contralateral disease, what is not known is whether this will translate into a decreased rate of local recurrence, improved relapse-free survival, and overall survival. Should treatment (i.e., BCT vs. mastectomy) be altered because MRI detects additional foci of cancer, especially in those cases where the foci prove to be tiny areas of DCIS? Would these foci of cancer identified on MRI be successfully treated with postoperative radiation therapy? In those cases where the additional foci of cancer detected on MRI are subsequently excised, might not these patients be ideally suited to BCT? The reported rate of MRI-detected additional foci of cancer of 20% is substantially higher than the rate of recurrence after breast-conserving surgery plus definitive radiation therapy. Presumably, in many cases the additional foci of cancer detected on MRI would have been included in standard breast-conserving surgery or the residual disease would have been treated with postsurgical radiation therapy. To date, there have been no published results from prospective randomized control trials designed to answer these questions. The only information on the impact of staging MRI on outcome comes from single-institution, retrospective studies. In a study of 346 patients, 65% of whom underwent BCT, Fischer et al. reported a reduced rate of local failure for patients who underwent staging MRI compared with those who did not (1.2% vs. 6.5%; $p < .001$) (74). This study, however, is limited by failure to adjust for differences in tumor size, nodal status, and the use of systemic chemotherapy between groups. In a more recent study Solin et al., in a retrospective study of 756 women who underwent BCT (28% of whom had a staging MRI), reported no significant difference in 8-year rates of relapse-free survival (3% with MRI vs. 4% without MRI) and no significant difference in the 8-year rates of overall survival (94% with MRI vs. 95% without MRI) (75). There are limitations to this study. It was a nonrandomized, retrospective study. There was a potential for bias as patients who underwent MRI tended to be young and tended to have dense breast tissue on mammography. The value of MRI may have been underestimated as patients with extensive disease detected on MRI were excluded. Given the low rates of local failure, it may have been difficult to show an improvement in outcome in a single-institution study.

The clinical significance of MRI-only-detected synchronous contralateral cancer also remains unclear, especially the cases that are noninvasive. In approximately one-third to one-half of cases, the MRI-detected contralateral disease was DCIS. Would the contralateral cancers detected on MRI be successfully treated in those patients who undergo systemic chemotherapy and thus never become clinically apparent? Furthermore, the detection of these contralateral cancers must be weighed against the added time, expense, and costs associated with MRI and MRI-guided biopsy in those cases where the MRI-detected lesions prove to be benign.

While published data do not support staging of all patients with newly diagnosed breast cancer, are there subgroups of patients who are most at risk for having multifocal or multicentric cancer and would benefit most from MR imaging? Van Goethem et al. found that unsuspected multifocal or multicentric disease was most often observed in young or perimenopausal women or patients with larger (greater than 5-cm) lesions, dense breast tissue on mammography, a first-degree family history, and invasive lobular cancer (37). The EURSOMA working group suggested potential subgroups that might benefit from staging MRI including patients with newly diagnosed invasive lobular cancer, patients at high risk for breast cancer, and patients under age 60 with a discrepancy in size of greater than 1 cm between mammography and ultrasound with expected impact on treatment decision (65). There are also emerging data that MRI may be of clinical benefit in patients being evaluated for partial-breast irradiation (PBI). In retrospective studies, up to 20% of patients initially considered to be candidates for PBI proved to be unsuitable as a result of the MRI (76–77). One of the major criticisms of MRI staging of breast cancer is that the reported rate of additional foci of cancer detected on MRI is much higher than the reported rate of local recurrence following breast-conservation therapy with lumpectomy followed by whole-breast radiation. However, if whole-breast radiation is replaced with partial-breast radiation, then the additional foci of tumor detected by MRI may become clinically important.

Based on the current success of breast-conserving surgery, it is unlikely that MR imaging of the breast is warranted in all patients with newly diagnosed breast cancer. Furthermore, given the high cost and limited availability of breast MRI, it is unlikely that all patients with newly diagnosed breast cancer will have access to MRI. Even if the cost of MR imaging could be reduced and these imaging modalities do become widely available, which patients with breast cancer should undergo and MRI study prior to surgery? And for those who do undergo this examination, what is the risk–benefit ratio? Additional carefully designed prospective clinical investigation is needed in attempt to find answers to these questions.

Given the uncertainties surrounding the use of MRI in women with newly diagnosed breast cancer, there are two issues that remain paramount. First, it is critical that women are informed of the potential benefits and risks of preoperative MRI and their personal preferences be taken into account prior to ordering the study. Second, MRI-only-detected suspicious lesions require MRI-guided core biopsy or needle localization and excisional biopsy, as the majority of such lesions will prove benign.

MANAGEMENT SUMMARY

- MRI has very high sensitivity for the visualization of both invasive carcinoma and DCIS, and MR imaging can detect breast cancer that is mammographically, sonographically, and clinically occult. MRI, however, has a low specificity leading to a substantial rate of false-positive biopsies. False-positive findings may be minimized by timing MRI appropriately in the menstrual cycle.
- Questions surrounding clinical indications for breast MRI remain. MRI appears to be indicated as an adjunct to mammography in the settings of equivocal mammographic, sonographic, or physical examination findings, malignant axillary adenopathy with unknown site of primary tumor, and monitoring response of locally advanced cancer to chemotherapy.
- Annual screening MRI in addition to annual screening mammography is indicated in women with a known *BRCA1* or *BRCA2* gene mutation, a greater than 20% to 25% lifetime risk of developing breast cancer, or a history of radiation to the chest for Hodgkin disease.

- In other women at increased risk for the development of breast cancer including those with a personal history of breast cancer and those with a history of atypia or LCIS, there is insufficient evidence to recommend routine screening MRI at this time.
- The use of MRI for breast cancer staging remains controversial. MRI is currently the most accurate imaging method for determining extent of disease in the ipsilateral breast. The size of the MRI-detected cancers are also similar to mammographically and sonographically detected breast cancers. However, the detection of additional foci of breast cancer has not translated into a decreased rate of positive margins or improved selection for breast-conserving therapy (BCT). In those patients who do undergo BCT, it remains to be determined if preoperative staging with MRI will result in a decrease in the local recurrence rate. More data are needed. However, MRI detects significantly more disease than current rates of local recurrence. Similar issues exist for contralateral cancer detection.

CHAPTER 14

New Breast Imaging Techniques

Maxine S. Jochelson

CHAPTER CONTENTS

More than ever before, the cost of medical care and concern for radiation exposure are being taken into account in the process of deciding which tests and treatments we recommend for our patients. These concerns certainly apply to breast imaging particularly because the examinations we perform are repeated regularly over the course of a woman's lifetime contributing to cumulative radiation exposure. Additionally many of the newer technologies are costly; we need to learn which ones are worth the cost. Fortunately, there is a great deal of research and development in the field of breast imaging geared toward improved diagnostic capability while keeping cost and radiation exposure in mind. This chapter will review the current status of the current and more advanced breast imaging techniques.

Despite the seemingly never-ending controversies regarding its use, screening mammography remains the only breast imaging examination that reduces overall breast cancer mortality. This decrease in mortality is approximately 30%. Mammography is inexpensive and widely available. While there is radiation exposure, it is relatively low: The radiation dose has decreased from analog to digital mammography and is now 3.91 mGy to the breasts and 0.47 mSv to the whole body. The cost of mammography per life saved is less than that of seat belts, approximately $18,000.00.

The overall sensitivity of mammography is 70% to 85%. However, this sensitivity is dramatically decreased in women with denser breast tissue. As medicine becomes more personalized, screening recommendations are adjusted based on individual patient characteristics. Currently patient risk is arbitrarily divided into three categories. Average or normal risk is defined as less than 15% lifetime risk of developing breast cancer. Women at normal risk should begin screening mammography at the age of 40 and have yearly exams until their life expectancy is less than 5 years. Screening should begin earlier in women at intermediate (15% to 20%) risk and high risk (greater than 20%), generally 10 years earlier than the youngest family member who had breast cancer. If the increased risk is due to prior chest radiation, screening should begin 7 years after the completion of radiation therapy. With the application of these recommendations, there are many younger women having mammograms, and they generally have denser breast tissue. Sensitivity of mammography in these higher-risk women with dense breasts is only 30% to 50% (1,2). Boyd et al. have shown that there is a 17.8-fold increase in interval cancers in women with extremely dense breasts compared with women with fatty breasts (3).

In addition to mammography, two other breast imaging tools are commonly used: ultrasound and breast MRI. Ultrasound has primarily been used to further evaluate clinical or mammographic findings and image-guided biopsies. It is inexpensive and widely available. Additionally there is no radiation exposure. Breast ultrasound is increasingly being used for screening in conjunction with screening mammography. However, it is time-consuming, operator dependent, and has a low positive predictive value (PPV). Ultrasound is not useful for the detection of DCIS and breast calcifications.

Breast MRI is an exquisitely sensitive method of breast evaluation with no radiation exposure. As opposed to mammography and breast ultrasound, which only evaluate anatomy, MRI combines physiologic with anatomic evaluation. Contrast-enhanced MRI enables detection of the neovascularity associated with breast cancer, sometimes before a discreet mass can be detected which is why it is so sensitive for detection of breast cancers and for staging cancers within the breast. It is also the most accurate method for following patients after neoadjuvant chemotherapy. However, MRI is very expensive and good-quality MRI is not universally

available. Claustrophobic patients and patients with certain implanted metallic clips and devices are unable to undergo breast MRI. Suboptimal specificity is also a limitation of breast MRI.

Clearly there is a need to develop better technologies for breast cancer detection. Two types of advances have been made. The first type of advancement builds on the standard technologies described above. These include the advance from analog mammography to digital mammography, and, based on the template of digital mammography: tomosynthesis and contrast-enhanced mammography. Advances in ultrasound include automated whole breast ultrasound (AWBU) and elastography. Microbubbles have been used as a contrast agent for ultrasound in various organs and have also been evaluated for breast imaging. MRI advances include improved interpretation criteria by the development of an MRI-specific BI-RADs system. Imaging sequences such as diffusion-weighted imaging and spectroscopy may improve specificity.

The second type of advancement in breast imaging includes new platforms for imaging the breast. These include radionuclide breast imaging, CT of the breast, and optical breast imaging. Both types of advancements will be discussed in this chapter.

MAMMOGRAPHY

Xeromammography was the standard breast imaging modality until the early 1980s. Film screen (analog) mammography replaced xeromammography, leading to improvement in ability to detect soft-tissue lesions. Digital mammography has largely replaced film screen technique. In the United States approximately 70% of mammograms are performed with digital technique. Digital mammography has been shown to improve accuracy in breast cancer detection in women under 50, women with dense breast tissue, and premenopausal and perimenopausal women but has fallen short in improving overall accuracy (4). Radiation exposure is decreased and the interpreting radiologist is able to manipulate the images for better visualization. No hard-copy films are required. Moreover, the digital mammographic technology is the platform on which more advanced breast imaging techniques have been developed. These include digital breast tomosynthesis (DBT) and contrast-enhanced spectral mammography (CESM).

Tomosynthesis

Sometimes referred to as 3-D mammography, this technique was called the most exciting new technology in breast imaging in 2011. DBT is a purely anatomic evaluation of the breast. Multiple projections of the compressed breast are obtained using an x-ray tube that moves along an arc with a stationary detector. Image slices are reconstructed in the plane parallel to the detector both in a mediolateral oblique (MLO) or craniocaudal (CC) plane. A "3-D" volume can be reconstructed when both views are imaged. The theory behind this technique is that by performing these tomographic images, one can peel away the overlying breast tissue that may be obscuring lesions or their characteristics. This improves lesion conspicuity and margin feature analysis (Fig. 14-1). Additionally, false-positive lesions are seen on mammography due to superimposition of breast tissue and DBT can exclude an abnormality in this situation. Because of these capabilities, DBT can be more sensitive and specific than routine mammography. DBT produced by a single vendor is currently FDA approved to be performed in addition to a full-field digital mammogram (FFDM). Other vendors are applying for FDA approval.

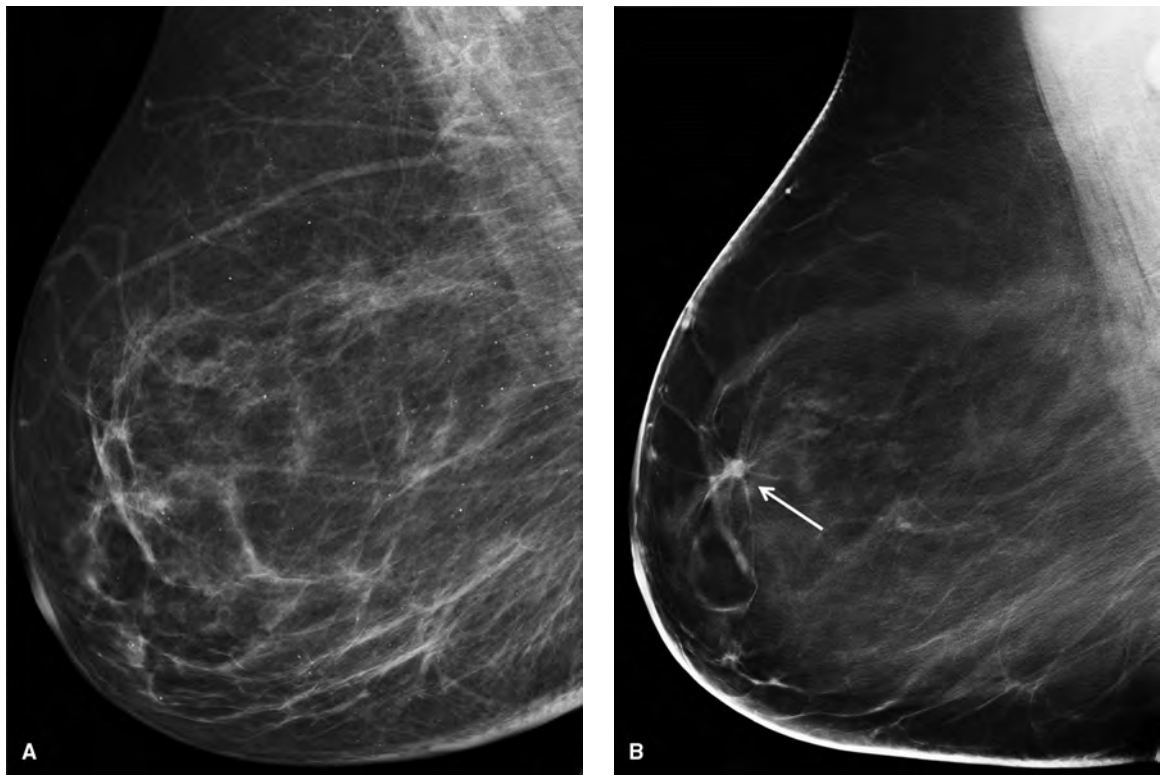

FIGURE 14-1 Tomosynthesis: 61-year-old woman with predominantly fatty breast. **(A)** RMLO: negative mammogram. **(B)** Spiculated cancer detected on tomosynthesis in the MLO view *(arrow)*. (Courtesy of Dr. Gisella Gennaro.)

DBT has been shown to reduce the number of patients called back for additional imaging 40% of the time (4,5). This would be advantageous if DBT alone could be utilized for screening. Used in addition to a screening mammogram, it is essentially a callback of 100% of the patients merely performed at the same time. Noroozian et al. demonstrated that DBT images showed equivalent mass characterization when compared to routine spot films. In 67 patients, DBT detected 7 additional cancers as well as 5 additional false-positive findings (6). Rafferty et al. compared FFDM alone to FFDM plus DBT in two multi-institutional reader studies of 1,192 subjects. Diagnostic accuracy for the combination of tomosynthesis with DBT showed a statistically significant improvement of 6.8% and 7.2% in the two studies (7). Of interest, in a test set of 130 women, two-view tomosynthesis had significantly better accuracy than FFDM but only for readers with the least experience in mammographic interpretation (8).

The benefits of DBT are seen only with soft-tissue lesions. Identification and characterization of calcifications is more problematic. This is partially due to the very thin slices (1 mm) and the blurring inherent to tomosynthesis. Spangler et al. showed superior sensitivity (84% vs. 75%) and specificity (71% vs. 64%) of FFDM over DBT (9). Technological improvements have been made to improve on this, but this remains an area where DBT does not currently offer an advantage over FFDM.

There are many issues to be resolved before any official recommendations can be made for use of DBT. The radiation dose of tomosynthesis is 4 to 8 mGy so that doing both routine mammography and DBT exams doubles or triples overall dose. In an effort to keep radiation dose to a minimum, studies have been and are being performed using various combinations of the two exams: FFDM with a single-view (MLO) tomosynthesis examination was performed in 200 women (376 breasts evaluated). The clinical performance of a single-view tomo was not significantly different from routine mammography (10). Other options being considered include a single-view tomo (i.e., MLO) with the other view (CC) digital mammogram. Another option would be to replace the digital mammogram with a mammogram synthesized from the tomosynthesis examination. Additional research is required to determine the approach with the least radiation and the highest yield.

DBT takes 50% to 70% longer to read than routine mammography which is clearly a significant limitation. Reimbursement does not reflect the additional time expenditure. Storage and display issues must also be resolved. Additionally, it is unclear whether DBT is best used as a screening tool in all patients, screening in selected patients, or as a diagnostic tool after an abnormal screening mammogram. A planned American College of Radiology Imaging Network (ACRIN) trial will address this question. However, it is clear that it will be decades before we are able to determine if screening with DBT will provide reduction of mortality from breast cancer over and above that of routine mammographic screening.

Contrast-Enhanced Mammography

Breast MRI is the most sensitive technique for breast cancer imaging with sensitivities reported to be nearly 100%. The excellent sensitivity is due to its ability to detect abnormal blood flow in a breast cancer in addition to identifying the mass itself. MRI may show vascular enhancement in tumor vascularity even when no discrete mass can be identified: an entity termed nonmass enhancement. With the advent of digital mammography, it was hypothesized that the addition of intravenous contrast to digital mammography could potentially approximate this capability of MRI. Contrast-enhanced mammography would therefore combine physiology with anatomy.

Initial studies were performed using temporal subtraction technique and iodinated contrast material. Patients were injected following a baseline image while the breast was compressed and up to seven additional images were obtained after injection. Subtraction was performed yielding both kinetic curves and a contrast enhanced image. Although this technique was able to detect enhancement associated with breast carcinoma in most patients, there were technical limitations. Motion artifact due to long imaging times limited the quality of the images. Additionally only a single view of one breast could be imaged per injection.

An alternative solution utilizing dual-energy imaging was proposed. Hardware and software adaptations to a digital mammography unit automate the dual-energy technique. Approximately 3 minutes after the injection of iodinated contrast material a mammogram is performed. For each exposure, two images are obtained in each view: a low-energy image that is below the K-edge of iodine (33.2 keV) and a high-energy image that is just above. The two images are combined and processed so that the background breast tissue is subtracted out, maximizing the ability to see the iodine enhancement. The low-energy image is essentially a digital mammogram, although at the moment it cannot be used as such. This procedure was initially called dual-energy contrast-enhanced digital mammography (DE CEDM) and is now called contrast-enhanced spectral mammography (CESM). Using this technology, Dromain et al. compared contrast-enhanced mammography plus noncontrast mammography to mammography alone or to mammography with ultrasound in the evaluation of 142 lesions in a single breast in 120 patients. Sensitivity for contrast-enhanced mammography with mammography was 93% versus 78% for mammography alone ($p < .001$). Specificity was unchanged. There was a trend toward improvement in sensitivity and specificity when DE CEDM plus mammography was compared to ultrasound with mammography, but this did not reach statistical significance (11).

Jochelson et al. then evaluated the feasibility of performing bilateral contrast-enhanced mammography in 10 patients with known carcinoma using the same technique described above. Bilateral DE CEDM was easily accomplished and well tolerated. The order in which the images were obtained did not matter. The bilateral examination was completed within 8 to 10 minutes. While contrast enhancement in MRI washes out quickly, contrast enhancement with DE CEDM remained for up to 10 minutes after injection. It is presumed that this may be due to the use of a different type of contrast material. Radiation dose from this dual-energy technique is 20% more than a routine digital mammogram or the equivalent of one extra mammographic image.

Once feasibility was demonstrated, DE CEDM was compared to breast MRI and digital mammography for the ability to identify the primary tumor in 52 patients with untreated unilateral breast cancer. Contrast-enhanced mammography was also compared to MRI for its ability to stage the cancer within the breast. DE CEDM and breast MRI were equivalent in their ability to detect the index tumors: 50 per 52 (96%) and significantly better than mammography 42 per 52 (81%) at $p < .05$ (Fig. 14-2). The lesions detected by DE CEDM ranged from 4 to 67 mm, median 17 mm. The size of the lesions approximated pathologic size in all but two patients in whom DE CEDM overestimated the size of the lesions. The two cancers not seen on DE CEDM included a 2-cm infiltrating lobular carcinoma (ILC) and a 5-mm infiltrating ductal carcinoma with ductal carcinoma *in situ* (IDC and DCIS). The two lesions

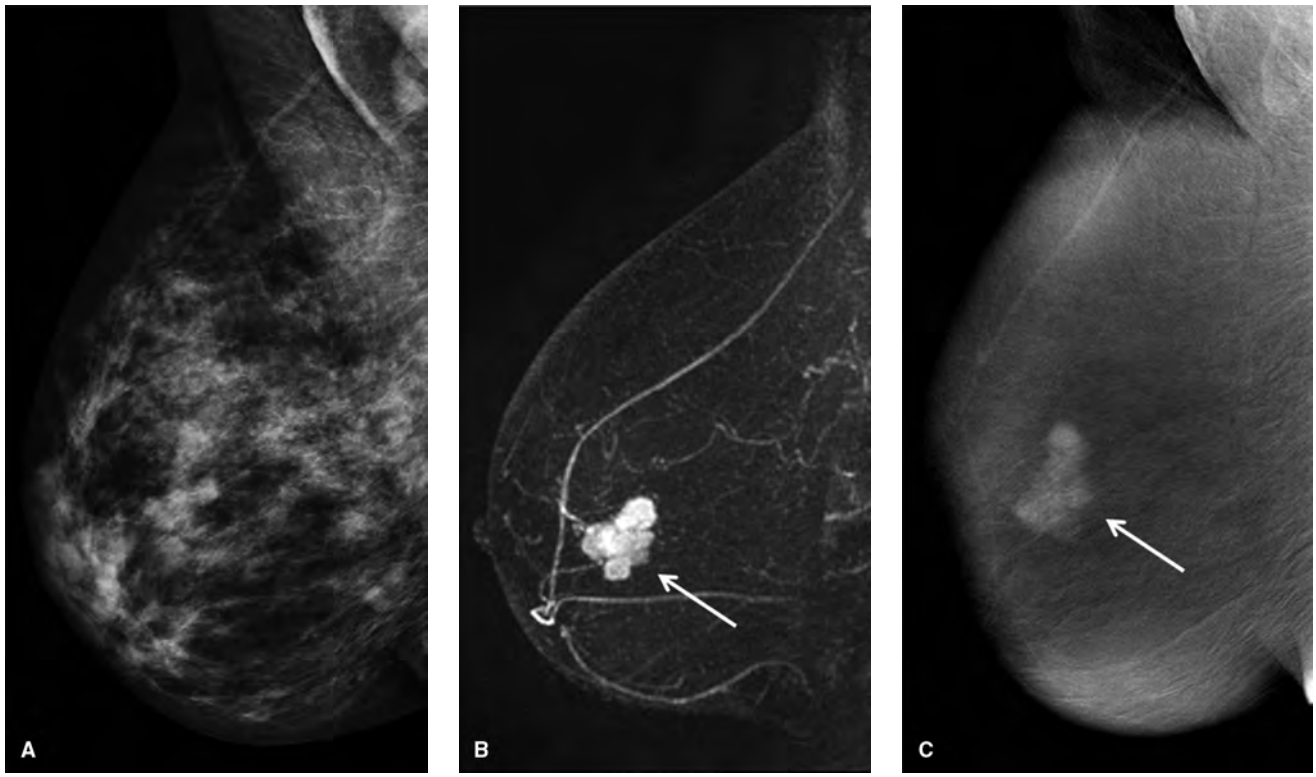

FIGURE 14-2 Contrast-enhanced mammography: 51-year-old woman with a palpable mass that was mammographically occult. Cancer detected on ultrasound. **(A)** Right MLO: negative mammogram. **(B)** Sagittal subtraction view from breast MRI demonstrates enhancing lobulated breast cancer *(arrow)*. **(C)** Contrast-enhanced mammogram; mediolateral oblique projection demonstrates lobulated breast cancer similar to MRI *(arrow)*.

occult on MRI, which were in patients whose cancers were detected on DE CEDM, included a 7-mm IDC/DCIS and an area of DCIS that measured 14 mm on DE CEDM. The only contralateral cancer was Paget's disease which was not evident on either DE CEDM or MRI, but was detected when the patient underwent a prophylactic contralateral mastectomy.

MRI surpassed DE CEDM in the ability to detect additional sites of malignancy. Sixteen patients had multifocal or multicentric cancers and MRI detected 15 per 16 (94%) while DE CEDM detected additional disease in 9 per 16 (56%). Twenty-five additional lesions were detected in these 16 patients. MRI detected 22 per 25(92%) and DE CEDM 14 per 25 (56%). The clinical impact of this difference in detection of additional lesions was seen in three patients who were originally thought to be candidates for breast conservation, but were demonstrated to have multicentric disease thus requiring mastectomy. The addition of DE CEDM or MRI to digital mammography conveyed a considerable advantage in the determination of which women required mastectomy.

One of the greatest limitations of MRI is its low specificity. DE CEDM was more specific than MRI in this series: 4% of patients undergoing DE CEDM had one false-positive finding while 25% of patients undergoing MRI had one false-positive finding. Two patients demonstrated false-positive lesions in the ipsilateral breast on DE CEDM, and biopsy of both of these lesions was also recommended on the corresponding MRI. On pathology, one was a radial scar and the other a fibroadenoma. No contralateral false-positive lesions were found on DE CEDM. There were 13 false-positive findings on MRI: 8 in the ipsilateral breast and 5 in the contralateral breast. Eight core biopsies and 8 additional surgical procedures were performed as a result of these false-positive findings on MRI. Biopsies yielded the following: 1 radial scar, 2 fibroadenomas, 2 papillary lesions, 3 cases of ADH, 1 ALH, and 4 cases of benign tissue. None of the high-grade lesions were upgraded at surgery.

An enhancing lesion seen on DE CEDM was significantly more likely to be malignant than one seen on MRI, with a positive predictive value for DE CEDM of 97% (64 per 66) and for MRI of 85% (72 per 85) ($p < .01$) (12).

Since the initial trials, improvements to the software, hardware, and filters of the CEDM unit have been made. It is now FDA approved and called contrast-enhanced spectral mammography (CESM) because there is the potential to use more than two energies. With these changes, there is less time needed between exposures enabling a shorter examination time and less chance for motion. The processing mechanism has also been improved yielding better images. It remains to be seen if the improved technique will improve accuracy. At this time the ability of CESM to detect cancers in a pure screening setting has not been tested, but that study is underway.

Contrast-Enhanced Digital Breast Tomosynthesis

The natural next step from the latter two technologies is to combine them. Chen et al. performed a pilot study involving 13 patients with BI-RADS 4 or 5 lesions using tomosynthesis performed in the MLO projection and temporal subtraction technique (13). Ten of 11 cancers were detected. Neither of the two benign lesions enhanced. More recently, Carton et al. (14)

performed both temporal subtraction and dual-energy contrast enhancement with DBT on a single breast with a known cancer. The cancer was identified with both contrast techniques and was found to correlate with MRI images in that same patient. Not surprisingly there was less motion artifact when using dual-energy technique when compared to temporal subtraction. Dual energy also allowed for both breasts to be imaged. As this chapter is being written there is ongoing development of this promising technology.

ULTRASOUND

Targeted breast ultrasound is a standard method of evaluating mammographic and clinical breast abnormalities. It is used to characterize a mass seen on mammography as cystic or solid and may distinguish malignant from benign features. Ultrasound is also used to investigate a mammographically occult palpable mass and to guide core biopsies.

Screening ultrasound has gained increasing popularity as an adjunct to screening mammography, particularly in women at increased risk for breast cancer. It is a method of cancer detection that is predominantly anatomic. Ultrasound is relatively inexpensive and widely available. There is no radiation exposure. Since ultrasound is operator dependent, reproducibility is suboptimal.

ACRIN trial 6666 evaluated the performance of screening breast ultrasound in addition to mammography in over 6,000 women who had dense breast tissue in at least one quadrant of the breast and at least one other risk factor. Interpretation was blinded to mammographic findings. There were 4.2 mammographically occult cancers detected per 1,000 women. These were primarily invasive cancers. Ultrasound was not shown to be useful for the detection of DCIS or microcalcifications. In this study, biopsy was recommended in 9% of the women and short-term follow-up was recommended in another 9%. PPV was only 9% (15).

In the last few years many states have passed legislation requiring patients to be directly informed that they have dense breasts with an associated increased risk for breast cancer. Additional imaging will likely be suggested or desired by the patient and currently this has primarily been screening ultrasound. The first state to enforce this legislation was Connecticut. Weigert et al. have reported the first data regarding the use of screening ultrasound in women with dense breast tissue and no other risk factors. In this retrospective study of six practices there were 72,030 mammograms and 8,647 screening ultrasounds. Twenty-eight cancers were diagnosed with an additional cancer detection rate of 3.25 per 1,000. PPV was only 6.7%, 9% of patients were called BI-RADS 3 requiring 6-month follow-up. 5% were BI-RADS 4 or 5. In their population the average cost of a breast ultrasound was $250 for which average insurance reimbursement was $72. Professional fee was $85 and reimbursement was $30. Ultrasound core biopsies were $2,400. Using these numbers the cost per breast cancer found was $110,241 (16).

Automated Whole Breast Ultrasound (AWBU)

AWBU is a technique developed to decrease the operator dependency of handheld ultrasound and thereby improve reproducibility. The device is placed over the breast and static images are obtained in a standard fashion which also allows 3-D reconstruction. The static images do not need to be interpreted in real time. This may improve efficiency, but patients will need to be called back if there are findings requiring additional evaluation. Kelly et al. reported their experience with the performance of AWBU with mammography in 6,425 studies in women with dense breasts. They demonstrated an improvement in cancer detection from 3.6 per 1,000 with mammography alone to 7.2 per 1,000 by the addition of AWBU. In their hands the PPV of AWBU was 38.4% versus 39% for mammography. Twenty-one cancers less than 10 mm were detected by ultrasound versus 7 by mammography (17). Shin et al. evaluated 55 patients with 121 lesions detected with handheld ultrasound. An additional 36 lesions were detected with AWBU. Lesion detection rate increased with size. It was 92% when mean lesion diameter was greater than 1.2 cm. Their false-positive detection rate was 6% (18). Should these data be confirmed in larger studies, this technology could potentially provide improved screening results with a more efficient method of imaging.

Elastography

Differentiation of benign and malignant ultrasound masses is based on mass and margin characterization. Malignant appearing masses have irregular margins, microlobulation, posterior shadowing, and a heterogeneous echo pattern. They are classically taller than wide or have a round shape. Vascularity is increased. Despite these seemingly adequate criteria, specificity remains a major limitation. Another characteristic of breast cancer that may potentially improve lesion characterization is that cancers are generally harder or stiffer than the surrounding breast tissue. Elastography is a technique that can be used to better differentiate benign from malignant masses using this attribute. There are two different types of elastography: static and shear strain.

Static or compressive elastography uses manual compression to detect tissue "hardness." The operator compresses the breast and a color map that reflects tissue hardness is generated. Fluid-filled lesions have a trilaminar appearance, benign or soft tumors are green, and malignant tumors are blue and may appear larger than their size on the B-mode scan itself. However, the accuracy depends on the degree of compression, rendering this an operator-dependent technique. Chang et al. performed a prospective study of 312 breast masses: 245 benign and 67 malignant. Fifty percent of the static exams were either technically inadequate or low quality. Multivariate analysis revealed that breast thickness in the location of the target lesion was the most important factor that affected quality. The ability to differentiate benign from malignant lesions differed significantly (p = .015) between high-quality exams (87%) and lower-quality exams (56.8%) (19). Yi et al. compared B-mode ultrasound to elastography in 1,786 women. They showed that B mode was more sensitive (98.5% vs. 93.2%) and elastography more specific (42.6% vs. 16.3%) (20). Cho et al. combined elastography with Doppler, improving the area under the receiver operating characteristic (ROC) curve from 0.771 to 0.844. When both tests were negative, the specificity of the ultrasound exam improved from 25% to 34% (p < .001). They concluded that an anatomically low suspicion mass with a negative elastogram and Doppler interrogation could be called probably benign and undergo 6-month follow-up rather than biopsy (21).

Shear-wave elastography is less operator dependent and more reproducible. It is also quantitative. It works by measuring the propagation of the speed of the sound waves which is directly related to tissue stiffness. Chang et al. studied 158 consecutive women with this technique and demonstrated that mean elasticity values were significantly higher in malignant masses than in benign masses (p < .0001) (22). Berg et al. performed a multinational trial evaluating 939 breast masses, 289 of which were malignant. Median mass size was 12 mm and 837 of the masses were greater than or equal to BI-RADS 3. By using the visual color generated by the stiffness

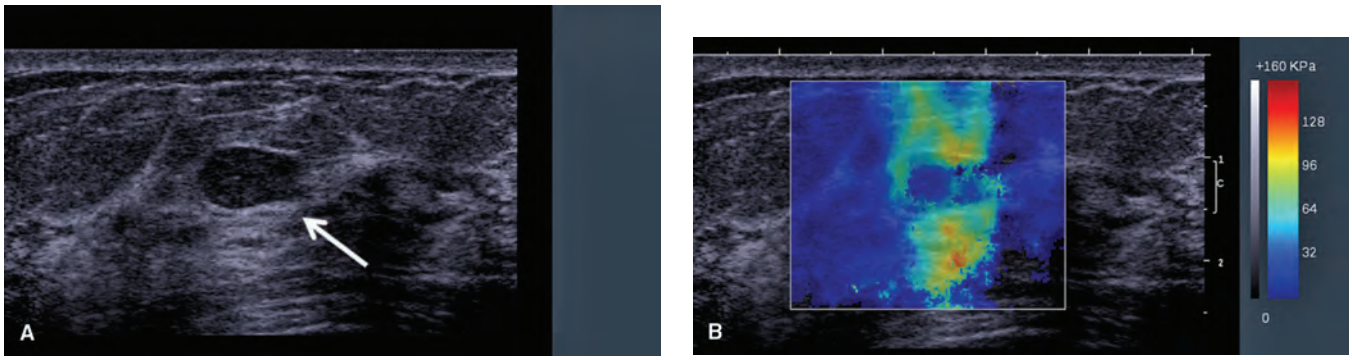

FIGURE 14-3 Shear-wave elastography: 53-year-old woman. **(A)** Predominantly circumscribed mass on standard B-mode ultrasound *(arrow)* originally called probably benign BI-RADS 3. **(B)** Surrounding tissue was shown to be stiff on shear-wave elastography. Therefore, biopsy was performed. Pathology revealed grade 1 infiltrating ductal carcinoma with ductal carcinoma *in situ*. (Courtesy of Dr. Christophe Tourasse via Dr. Wendie Berg.)

measurement to upgrade BI-RADS 3 and using lack of stiffness to downgrade BI-RADS 4a masses, specificity improved from 61.1% to 78.5% ($p < .001$). Area under the curve improved from 0.950 to 0.962 ($p = .005$) (23) (Fig. 14-3).

Contrast-Enhanced Ultrasound (CEUS)

Evaluation of tumor angiogenesis with ultrasound has primarily been performed with Doppler flow imaging. However, specificity remains suboptimal due to demonstration of vascularity within benign tumors. Gas microbubbles within lipid microspheres have been injected in an attempt to improve sensitivity and specificity of ultrasound. The microbubbles oscillate and emit signals that can be detected by the ultrasound probe. This type of contrast is different from iodinated contrast in that the microbubbles do not diffuse from the blood vessels into surrounding tissues. Newer ultrasound imaging techniques have been developed to better image these microbubbles. These include intermittent power Doppler and pulse inversion harmonic imaging. Early studies have shown improved sensitivity of up to 100% using this technique, but with specificities of 5.6% to 100%. Limitation of specificity is likely due to increase in the detection of small, nonmalignant vessels.

Liu et al. have recently reported results in 104 patients with known breast masses in whom the results of contrast-enhanced ultrasound (CEUS) correlated with histologic features (24). Possible applications include the follow-up of patients after neoadjuvant chemotherapy or as a method to deliver drugs directly to a tumor site.

While potentially very exciting, the use of microbubbles is currently limited due to the technical difficulty involved in performing this procedure.

BREAST MRI

Breast MRI is among the most commonly used breast imaging modalities. With regard to sensitivity, it is the examination against which all other breast imaging exams are compared. There is no radiation exposure. Images are obtained prior to and at several time points after infusion of a gadolinium chelate contrast material (except when evaluating implants). Subtraction images are produced and kinetic information is generated. Technology has continued to evolve with magnet field strength increasing from 1.5T (tesla) to 3T for current routine use. Exploration of the utility of a 7T magnet has begun as well.

A full discussion of MRI can be found elsewhere in this book. There are a few new concepts and techniques that bear mentioning.

MRI Screening

It is well known that breast MRI is more sensitive for the detection of breast cancer in women at increased risk for breast cancer than clinical breast exam, mammography, and ultrasound combined. However, its use is limited by cost and availability. Cost is high due in part to contrast material, length of time for examination, and interpretation. Studies are being performed to determine if the time involved in scanning and interpreting breast MRI can be decreased. Kuhl et al. prospectively read 932 breast MRIs for screening or assessment. Interpreting the first postcontrast subtraction views took 58 seconds to read with a sensitivity of 98.7% and specificity of 92.9%. Interpretation of the subtraction MIP took 2 seconds to read. Sensitivity was 88.6% and specificity 85.7% (25). Mango et al. evaluated the sensitivity and timing of interpretation of three postcontrast MRI sequences in 100 women with known breast carcinoma by two readers. When interpreted with no history or prior examinations, one reader detected 98% of the cancers on the first postcontrast images and first postcontrast subtraction images while the second reader detected 95% and 93%. Sensitivity for the subtraction MIP was 96% and 84% for these two readers. Results improved to 100% detection with history and prior examinations. The time to perform these limited sequences is approximately 15 minutes, reduced from the full protocol which takes 30 to 40 minutes. Interpretation time was 0.5 to 3 minutes (mean 56 seconds) (26). This is a promising area of exploration, although a great deal more work needs to be done.

Diffusion-Weighted Imaging (DWI)

While the sensitivity of MRI is exquisite, reportedly close to 100%, specificity is moderate—in the 70% range. Improvements in specificity have occurred in part with the adoption of BI-RADS for MRI which is a combination of both morphologic and kinetic features as well as the use of standardized descriptors. Morphologic criteria include mass shape and margin characteristics. Lesions with irregular, microlobulated, or spiculated margins are more likely to be malignant. Rim enhancement also suggests malignancy. Segmental or ductal distribution of nonmass enhancement also increases the likelihood of malignancy. Kinetic characteristics assess

the rapidity of initial enhancement and the changes in enhancement afterwards. Rapid initial enhancement followed by washout of contrast is more highly suggestive of carcinoma compared to a plateau or continual increase in enhancement.

Despite the use of these criteria, there remains a need for improved specificity. Diffusion-weighted imaging (DWI) has been evaluated in this regard. DWI is a sequence that is available on most MRI scanners. However, results are felt to be better with greater field strength. Imaging time is short and importantly, no contrast is required. DWI has been used successfully in many other organs including the brain. It is a pulse sequence that essentially measures the random motion of water molecules within a lesion. Motion is affected by cellularity and extracellular characteristics such as viscosity, membrane permeability, and blood flow. In addition to the DWI, diffusion can be quantified by apparent diffusion coefficient (ADC) characteristics. An ADC map can be generated, although accurate mapping can be technically challenging. This is particularly true in smaller lesions.

The ADC value is inversely proportional to cellularity, edema, viscosity, and the presence of extensive fibrosis which all restrict the movement of water molecules. Since most cancers are cellular (with the exception of the rare mucinous cancers), they classically have lower ADC values. Kul et al. investigated the contribution of DWI added to dynamic contrast-enhanced MRI in 84 patients with 47 breast cancers. They demonstrated an improvement in specificity of breast MRI from 75.7% to 89.2% (p = .063) when adding DWI (27). Ei Khouli et al. showed improved characterization of breast lesions using ADC normalization by using glandular tissue rather than an absolute ADC value. They demonstrated an improvement in the area under the receiver operating curve from 0.89 to 0.98 and a decrease in the false-positive rate of MRI from 36% to 24% in 93 patients (28) (Fig. 14-4).

Investigators are attempting to further characterize the meaning of ADC values. Martincich et al. showed that ADC values varied among different breast biomarkers. They demonstrated that patients with more aggressive subtypes of breast cancer had lower ADC values. They proposed that this could be due to the more aggressive tumors having increased mitotic activity and therefore cellularity which would decrease ADC values (29). In a similar vein, Parsian et al. evaluated ADC values of benign and high-risk lesions in 165 women. They demonstrated that high-risk lesions were more likely to have a lower ADC value while other lesions such as many fibroadenomas, fibrosis, usual ductal hyperplasia, and inflammation had higher values (30). If this study is validated with larger patient populations, DWI could be used in conjunction with contrast-enhanced MRI to differentiate which benign-appearing lesions require biopsy.

Data suggest that DWI may also improve the ability to assess treatment response in patients undergoing neoadjuvant chemotherapy. However, limitation in accuracy of DWI with smaller tumors and current technical complexity in obtaining accurate mapping limit its widespread application at this time. Therefore use of this sequence remains primarily investigational. An ACRIN trial has been designed to further assess the utility of DWI for breast imaging.

MR Spectroscopy

Another MRI tool with the potential to improve specificity is MR spectroscopy (MRS). This is a technique of molecular breast imaging that is currently a measurement of the total composite choline (tCho) within a breast lesion detected on MRI. This function is based on the fact that choline is a precursor of phosphatidylcholine which composes cell membranes and increases with tumor growth. It has been well established that choline peaks can be detected in most breast cancers and generally not in normal breast tissue. This knowledge can potentially be used to improve the positive predictive value of breast MRI. There is, however, some overlap in choline values between benign and malignant tumors. Using primarily 1.5T MRI units sensitivities of 70% to 100% and specificities of 67% to 100% have been reported. Recently, Mizukoshi et al. have shown that using quantitative MRS provides higher specificity than qualitative MRS when differentiating benign from malignant breast tumors. In their evaluation of 208 breast lesions (169 malignant and 39 benign), sensitivity decreased from 84.6% to 68.1% while specificity increased from 51.3% to 79.4% using the quantitative measurements (31).

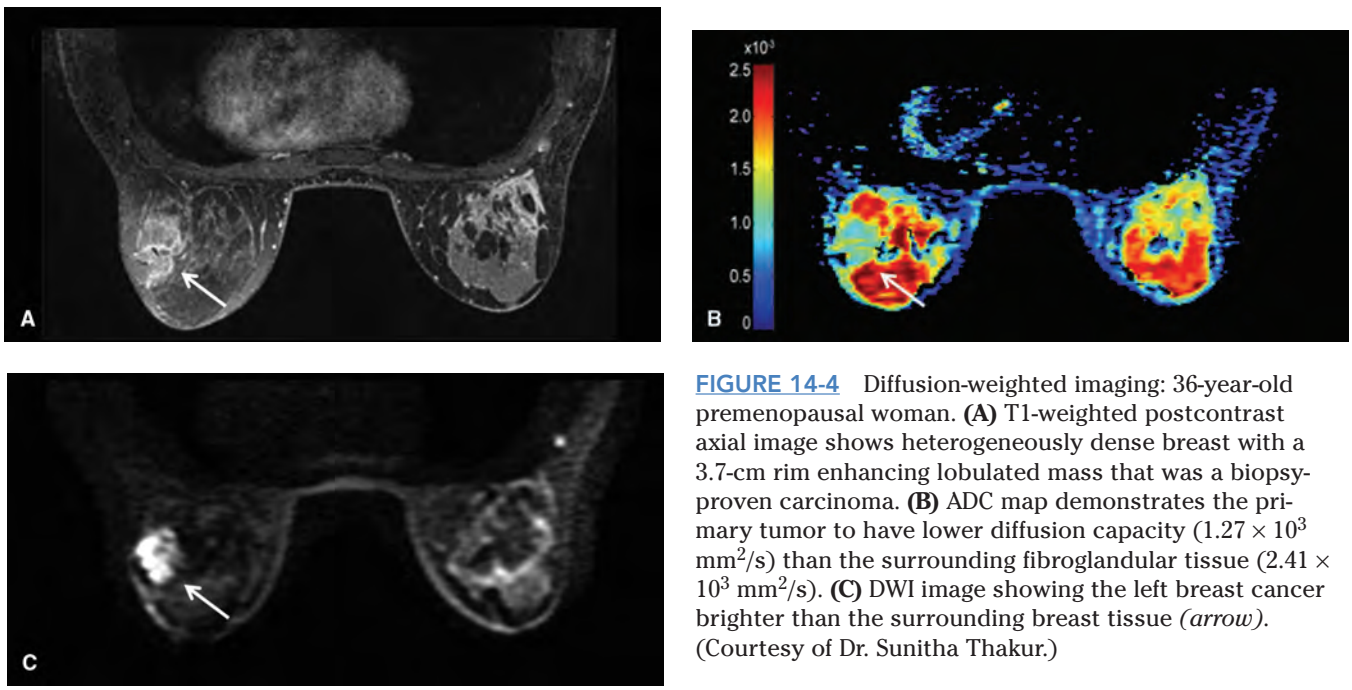

FIGURE 14-4 Diffusion-weighted imaging: 36-year-old premenopausal woman. **(A)** T1-weighted postcontrast axial image shows heterogeneously dense breast with a 3.7-cm rim enhancing lobulated mass that was a biopsy-proven carcinoma. **(B)** ADC map demonstrates the primary tumor to have lower diffusion capacity (1.27×10^3 mm^2/s) than the surrounding fibroglandular tissue (2.41×10^3 mm^2/s). **(C)** DWI image showing the left breast cancer brighter than the surrounding breast tissue *(arrow)*. (Courtesy of Dr. Sunitha Thakur.)

Tozaki et al. demonstrated that choline levels correlated with standardized uptake values obtained with PET/CT. They also found that both results correlated significantly with nuclear grade, estrogen receptor negativity and triple-negative lesions (32).

As intellectually promising as MRS seems, there are limitations precluding routine use. In order to measure tCho, it is necessary to place a volume of interest in the region of the suspected cancer seen on MRI. Lipid signals from the surrounding adipose tissue may contaminate this measurement and precise placement requires the breast imager to be available to determine the area to be measured at the time of scanning which can hamper use in a busy clinical setting. The possibility of automating this process is under consideration. Measurements in lesions under a centimeter are likely to be inaccurate limiting use in both the diagnostic setting as well as the evaluation of residual disease after treatment.

Wijnen et al. have reported quantification of levels of phosphorylated metabolites rather than tCho using a 7T magnet. They have shown that there is less likely to be contamination from surrounding tissues using this technique with the different metabolites which would therefore not require such precise identification of the area to be measured. Thus, smaller lesions could theoretically be measured as well (33). In conclusion, MRS is currently primarily a research tool. A great deal more investigation is required to make this a viable routine clinical adjunct to breast MRI.

RADIONUCLIDE BREAST IMAGING

Radionuclide breast imaging is a method of detecting breast abnormalities that is independent of breast density and images physiology over anatomy. There are currently two tracers commonly used: sestamibi (MIBI) and 18F-fluorodeoxyglucose (18F-FDG).

MIBI or Gamma Imaging

In the early 1990s incidental breast and other cancers were occasionally detected during cardiac imaging with technetium-99m-sestamibi (MIBI). Attempts at dedicated imaging of the breasts with MIBI at that time were limited by the large collimators that were distant from the breasts. Sensitivity was excellent (greater than 90%) for large lesions but abysmal for small lesions. Thus MIBI imaging of the breast was stalled until new technological advances enabled high-quality dedicated breast imaging to be performed. There are two different systems using high-resolution detectors: molecular breast imaging (MBI) using a semiconductor base and breast-specific gamma imaging (BSGI) which uses a scintillating crystal detector. There does not appear to be a significant clinical difference between the two technologies. Both may detect cancers occult on mammography and both may detect additional cancers within the breast once cancer is diagnosed (Fig. 14-5). With both techniques the breasts are positioned as with mammography using mild breast compression.

Although MIBI imaging is independent of breast density, it is dependent on the patient's hormone status. Therefore it is ideal to image premenopausal women between days 2 and 14 of their cycles. The patient receives between 740 and 1,110 MBq of tracer. Imaging begins 10 minutes after tracer administration. Each of the four routine images requires 5 to 10 minutes of imaging and if axillary views are necessary an additional 10 to 20 minutes are needed.

The group at the Mayo Clinic has reported on its use of a dedicated semiconductor-based gamma camera system: molecular breast imaging (MBI). The detector is made of cadmium zinc telluride elements (CZT). Initially a single gamma camera was used but Mayo now uses a dual-head system. Sensitivity for breast cancer detection improved from 85% overall and 29% for tumors 5 mm or less to 91% overall and 69% for tumors 5 mm or less (34) in 150 women prior to their breast biopsies (34). Rhodes et al. screened 936 women with dense breast tissue and at least one other risk factor with both mammography and MBI. There were 11 cancers. Yield of mammography was 3.2 per 1,000, yield of MIBI imaging was 9.6 per 1,000, and combining both technologies had a detection rate of 10.7 cancers per 1,000 women (35).

Breast-specific gamma imaging (BSGI) is the other modality employed for MIBI imaging. This uses a scintillating crystal detector with a single camera. Initial work performed by Brem et al. showed a sensitivity of 96.4% overall but slightly less for lesions less than 1 cm, 88.9%. Specificity was only 59.5% (36). Multiple other studies also reported sensitivities of approximately 90% and specificities of approximately 60%. In a BSGI multicenter registry that included 1,042 patients, Weigert et al. reported a sensitivity of 91% and a specificity of 77%. However, in this report high-risk lesions such as atypical ductal hyperplasia, lobular carcinoma *in situ*, radial scars, and papillomas were classified as true positives, not false positives, as they are in other breast imaging studies. This is likely to account for the improved specificity (37).

Indications for performing MIBI imaging have included high-risk screening, evaluation of extent of disease in known breast cancers, problem solving, and imaging patients for whom MRI is recommended but can't be done. However, it is important to note that at the dose of tracer currently in use, while patients receive only 2 mGy to the breast (compared to 3.91 from a digital mammogram), they receive 8.9 to 9.4 mSv as a whole body effective dose (compared with 0.47 mSv from a digital mammogram) and in particular 50 mGy to the lower large intestine. These high extramammary doses should obviate repeated use of this technology for an individual patient (i.e., use as a yearly screening tool). Preliminary studies suggest possible equivalency at a reduced dose, but even at half the dose the radiation exposure is considerable.

Positron Emission Mammography (PEM)

Whole body PET/CT using 18F-fluorodeoxyglucose (18F-FDG) is widely used for staging and follow up of lymphomas and multiple solid tumors including breast carcinoma. Investigations of its ability to detect the primary breast cancers were disappointing with sensitivity as low as 30%, even though most breast cancers are FDG avid. As with MIBI imaging, this was due to the distance of the collimators from the breasts. PEM was developed to better image the breast with FDG. As with MIBI imaging, PEM involves positioning patients in the same manner as with mammography. The breasts are gently compressed between two collimators and the detectors have high (1.5 to 2.0 mm) spatial resolution. The results of PEM imaging are independent of breast density and hormone status.

Preparation for PEM is similar to whole body PET scans. Patients fast for 4 to 6 hours prior to injection of approximately 10 mCi (403.3 MBq) of 18F-FDG. They rest for 1 hour after which imaging is performed with 10-minute acquisitions per view. Tomographic slices are provided with 12 images for each view of the breast providing a three-dimensional set of images. PEM can also be performed after a single FDG dose following a whole body examination and there are data to suggest that the longer period of time after injection may actually improve specificity. Unfortunately, PEM following whole body imaging is not reimbursed as a separate study.

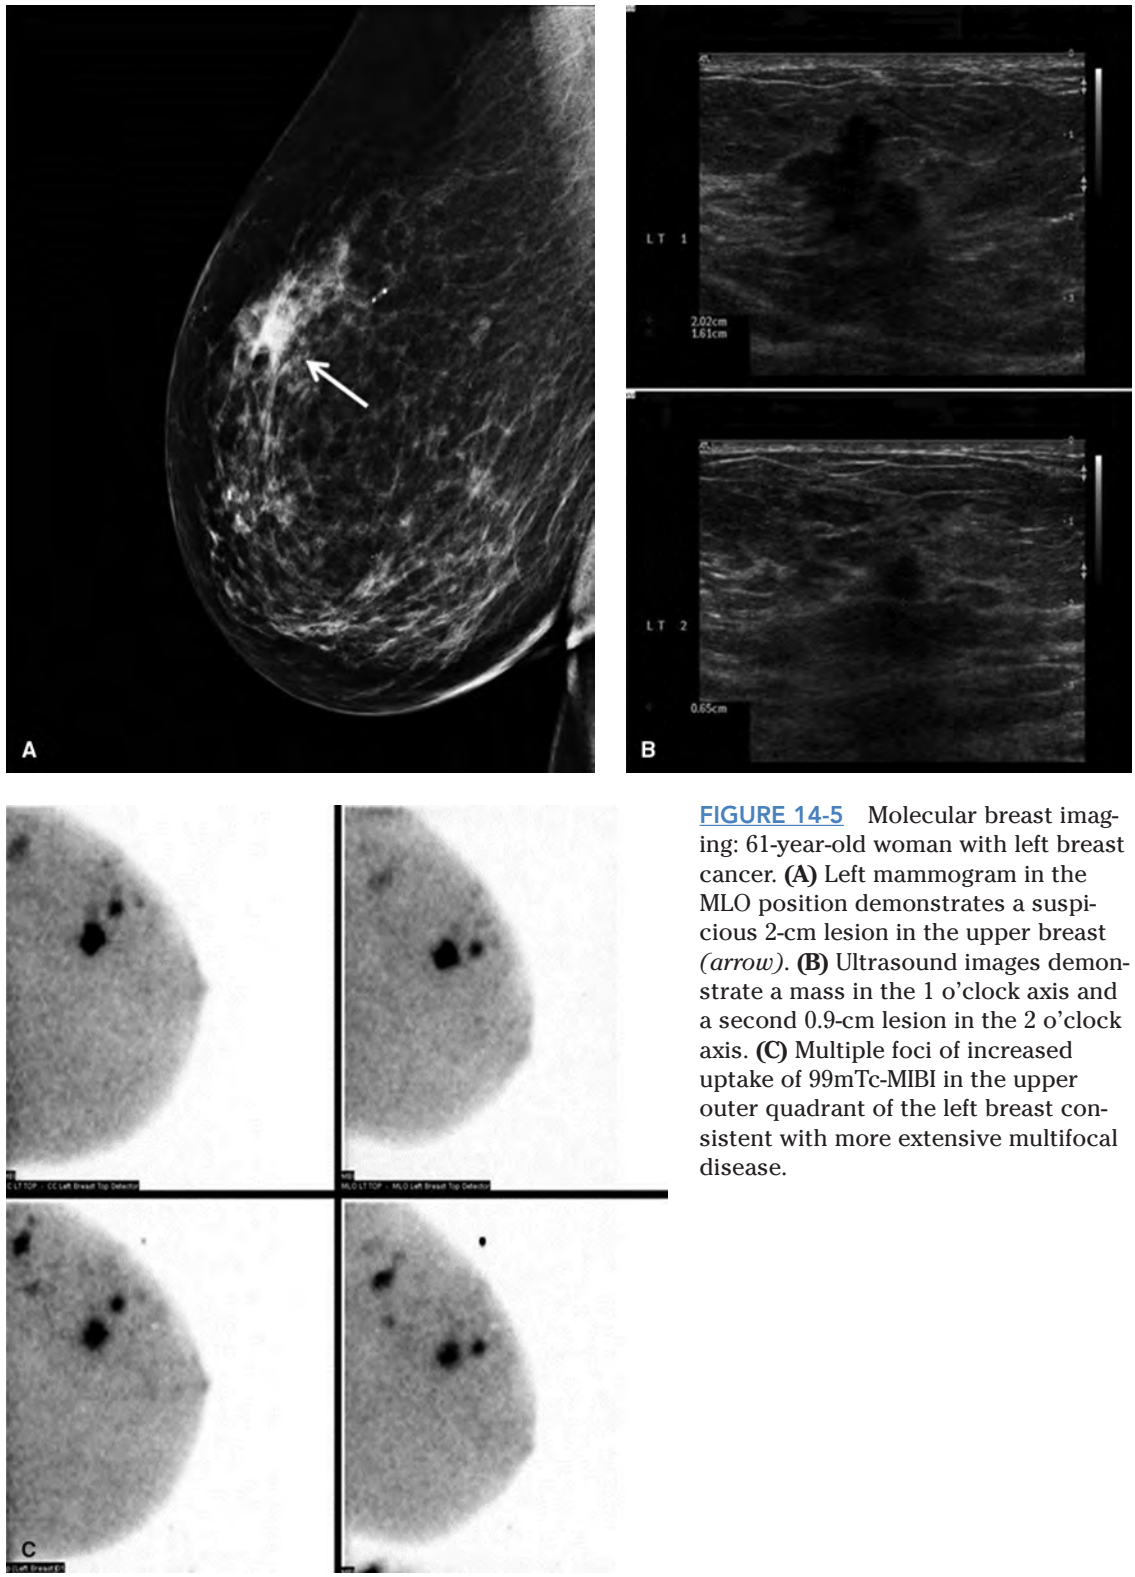

FIGURE 14-5 Molecular breast imaging: 61-year-old woman with left breast cancer. **(A)** Left mammogram in the MLO position demonstrates a suspicious 2-cm lesion in the upper breast *(arrow)*. **(B)** Ultrasound images demonstrate a mass in the 1 o'clock axis and a second 0.9-cm lesion in the 2 o'clock axis. **(C)** Multiple foci of increased uptake of 99mTc-MIBI in the upper outer quadrant of the left breast consistent with more extensive multifocal disease.

PEM differs from whole body evaluation in that there is no correlative CT to provide attenuation correlation or anatomic correlation. Therefore the units of uptake for PEM are not standard uptake value (SUV). The unit used for PEM is the PEM uptake value or PUV, which measures uptake in a lesion against the background of the breast itself.

Schilling et al. have reported PEM to have a sensitivity of 90% for the detection of DCIS and 93% for invasive cancers, even for small lesions (38). Berg et al. reported their experience comparing PEM to MRI in staging the breast in 388 patients with recently diagnosed breast cancer. They demonstrated that the two modalities had comparable breast level sensitivity while MRI was more sensitive at the

lesion level. However, PEM was more specific at both the patient and lesion levels. The positive predictive value of PEM was 66%, which was significantly better than that of MRI, which was 53% (p = .016) (39). In a group of 367 patients with known breast cancer, PEM was less sensitive in detecting cancers in the contralateral breast. Fifteen (4.1%) patients were found to have contralateral breast cancer. PEM diagnosed 3 of 15 (20%) prospectively. Uptake in three other cancers had been called benign and two other cancers were visible retrospectively. On a blinded retrospective review 11 of 15 (73%) were called suspicious (40).

Whenever a new technique is developed that can detect a breast cancer not seen on any other breast imaging test, a mechanism for biopsy is critical to document that the abnormality is actually cancer. PEM was the first of the radionuclide imaging modalities to develop a technique for breast biopsy. The technique is performed with the patient seated, but is otherwise similar to the method employed with stereotactic and MRI guided biopsies: in this case the lesion is targeted and guided by FDG uptake. Once the samples are obtained, they can be placed under the detector to confirm adequate sampling of the hypermetabolic lesion.

Although PEM appears to be a sensitive and specific modality for detection of cancer(s) within the breast, its use must also be limited due to radiation dose. Just as with MIBI dose to the breast is low: 2.5 mGy. However, at current tracer doses whole body dose is 6.2 to 7.1 mSv with 59 mGy to the bladder wall. Manufacturers are evaluating whether adequate results can be obtained using lower tracer doses, but even so regular use of this technology as for yearly screening is not warranted. Other uses for radionuclide breast imaging might include follow-up after neoadjuvant treatment using either FDG or other tracers, staging the breast once a diagnosis of cancer has been made or for problem solving when other clinical and or imaging parameters are indeterminate.

Breast CT

Dedicated computerized tomography (CT) of the breast is another tool developed to evaluate breast tissue without the interference of overlying structures; in principal similar to tomosynthesis. The patient lies prone on the scanning table. One breast is scanned at a time. No breast compression is used. The scan field of view is approximately 21 cm, which is large enough to accommodate most breasts. Since there is no breast compression, patients find breast CT more comfortable than mammography. Scans of each breast take approximately 17 seconds.

O'Connell et al. evaluated a cone-beam CT system to evaluate dose, breast coverage, and image quality compared with conventional mammography. They demonstrated overall equivalent radiation doses ranging from 4 to 12.8 mGy, mean 8.2, compared with mammography 2.2 to 15mGy with a mean of 6.5. Breast coverage was superior with CT except in the axilla and axillary tail. Overall detection of masses and calcifications was similar (41).

Adding physiology to this otherwise purely anatomic technique, Prionas et al. evaluated the performance of breast CT after administration of nonionic iodinated intravenous contrast material. Fifty-four lesions (25 benign and 29 malignant) in 46 patients were analyzed. Not surprisingly, malignant masses were significantly better seen after contrast enhancement than on nonenhanced CT and mammography. Previous studies showed inferior detection of calcifications on nonenhanced CT when compared with mammography. In this study, malignancies presenting as microcalcifications were significantly better seen on contrast-enhanced CT than on non-contrast-enhanced CT but not better than on mammography, while benign calcifications remained better detectable on mammography than on CT either enhanced or nonenhanced (42).

CT of the breast is a potentially promising technology that is better tolerated by patients due to lack of compression and shows equivalent radiation exposure as mammography. More work is required to improve the spatial resolution necessary to detect smaller lesions and microcalcifications.

Optical Imaging of the Breast

Optical imaging is a primarily physiologic method of evaluating the breast that utilizes near infrared light to detect breast lesions based on determination of differential light absorptions of tissue hemoglobin and oxygen saturation. Malignant tumors develop neovascularity and therefore have increased concentration of hemoglobin which is detected with optical scanning. The hemoglobin concentration correlates well with mean vessel density (MVD). Despite the increased vascularity, however, there is decreased oxygen saturation also theoretically detectible by diffusion imaging. The scanner has poor spatial resolution and is unable to penetrate into deeper breast tissues at this time. Therefore, while a few small studies show tumor detection rates of up to 90%, optical imaging cannot currently be used as a stand-alone examination.

Investigators have evaluated using optical imaging to supplement other imaging tests such as ultrasound and breast MRI for both diagnosing breast cancer and evaluation of response to treatment. Moon and colleagues performed a prospective study combining optical diffusion breast imaging with ultrasound in 193 women with 217 breast lesions. The group was evenly divided between benign and malignant lesions. Ultrasound alone showed 100% sensitivity, 27.5% specificity, PPV of 57.8%, and NPV of 100% in distinguishing benign from malignant lesions. With the supplemental use of optical imaging, sensitivity was 98%, specificity 41.3%, PPV 62.4%, and NPV 95.7%. The investigators found that utilization of the hemoglobin level was superior to utilization of oxygen saturation. When evaluating patients with a BI-RADS 4A, the addition of optical imaging improved specificity from 27.5% to 76.1% (43).

Early data have shown that using optical imaging as a surrogate biomarker can predict for pathologic complete response in women receiving neoadjuvant chemotherapy for locally advanced breast cancer since it measures hemoglobin/MVD within the tumors: CD-105 is a glycoprotein expressed on the surface of highly proliferating endothelial cells that is not detected in normal breast tissue. Pakalniskis et al. demonstrated that there was a significant correlation between the MVD of pretreatment biopsy CD-105 expressing vessels and pretreatment hemoglobin levels in women achieving pathologic complete response, not those with a partial response. There was also a significant difference in the MVD of CD-105 expressing vessels and mean levels of hemoglobin after treatment in patients achieving a complete pathologic response (44).

The use of optical imaging has also been investigated during surgery, but again results are premature. It is a technology with early promise particularly if used as an adjunct with other imaging modalities, but at the moment requires validation of early results before it can be brought into routine use. A comparison of this and the various technologies discussed above is provided in Table 14-1.

In conclusion, I have described an array of promising breast imaging modalities that are currently to be considered primarily as adjuncts to the three standard breast imaging tools: mammography, ultrasound, and MRI. These modalities are in varying stages of development. It is not feasible to perform every test on every patient, and rigorous scientific

TABLE 14-1

New Imaging Techniques: Characteristics and Potential Benefits

Technique	*Characteristics*	*Potential Benefits*
Mammography		
Tomosynthesis	Thin slices peel away overlying tissue.	Improved lesion conspicuity and margin analysis; decreased callbacks.
Contrast mammo	Neovascularity can be visualized by contrast enhancement.	Can visualize mammographically occult cancers even without discrete mass; improved sensitivity.
Contrast tomo	Combines tomosynthesis with contrast.	Improved analysis of characteristics of enhancing lesions.
Ultrasound		
Automated US	Machine performs static images with 3-D reconstruction.	Not operator dependent; improved reproducibility; no need to interpret in real time.
Elastography	Differentiates lesions based on their hardness or stiffness.	Improved specificity of ultrasound; decreased biopsies.
Contrast US	Gas microbubbles with neovascularity can be detected by ultrasound probe.	Improved sensitivity; ability to assess response to chemotherapy; potential mechanism for drug delivery.
MRI		
Diffusion weighted	Can quantify random motion of water molecules within a lesion.	Improved specificity when evaluating breast lesions.
Spectroscopy	Measures total composite choline within breast lesions.	Improved specificity of MRI.
Radionuclide Imaging		
BSGI/MBI	Tumors are detected by uptake of sesta-MIBI.	Sensitive method to detect cancer limited by whole body radiation exposure.
PEM	Tumor detection is related to uptake of FDG.	Sensitive and specific method of breast cancer detection limited by whole body radiation exposure.
Other		
Breast CT	Can evaluate tissue without overlying structures; no breast compression; IV contrast improves sensitivity.	Sensitive and more tolerable method to evaluate for breast cancer.
Optical imaging	Near infrared light is used to detect breast lesions based on tissue hemoglobin and oxygen saturation related to neovascularity.	Used as adjunct to ultrasound or MRI to improve specificity; may aid in assessment of response to therapy.

principals must be applied to determine which of these will be the most useful in each clinical situation (screening, diagnosis, staging, response to treatment, and follow-up) while also trying to limit costs, unnecessary biopsies, and radiation dose. Perhaps with greater knowledge of tumor biology and genetics, we will be able to tailor our approach to the use of specific tests for specific biologic situations.

CHAPTER 15

Image-Guided Biopsy of Nonpalpable Breast Lesions

Janice S. Sung and Christopher E. Comstock

CHAPTER CONTENTS

IMAGE-GUIDED BIOPSY OF NONPALPABLE BREAST LESIONS

The increasing use of mammography, ultrasound, and breast MRI to screen asymptomatic women has resulted in the increased detection of clinically occult, nonpalpable breast lesions. Despite technological advances and improvements in image resolution, the imaging features of most breast lesions remain indeterminate, requiring tissue sampling for definitive diagnosis. Initially, surgical excision following image-guided needle localization was the gold standard for biopsy. However, because up to 70% to 80% of lesions for which biopsy is recommended represent benign etiologies, newer cost effective methods were investigated as alternatives to surgical biopsy (1).

Nonpalpable breast abnormalities were initially sampled using fine-needle aspiration (FNA). FNA is a fast, relatively inexpensive technique that patients tolerate well. However, significant limitations of FNA include the frequency of insufficient sampling, frequency of false positives, and limited accuracy compared to core biopsy or surgical excision. In the multicenter randomized Radiology Diagnosis Oncology Group V trial, there was a 35% insufficient sample rate with FNA of nonpalpable breast lesions, and the accuracy rate for ultrasound-guided FNA was 77% compared to 98% with ultrasound-guided core biopsy (2,3). In addition, distinguishing between *in situ* or invasive carcinoma and determining receptor status may be difficult on cytology from FNA. For these reasons, FNA is primarily used to sample axillary nodes or lesions not amenable to core biopsy, including lesions that are superficial or abutting the chest wall.

Simple and complicated cysts are benign and do not require aspiration except when requested for symptomatic relief. In general, the fluid should be discarded due to the frequency of false positives unless the aspirate is not typical of cyst contents. Ciatto et al. examined the cytology following aspiration of 6,782 consecutive cysts and found that the 5 papillomas detected in this series all had bloody aspirates. Therefore, the fluid from a cyst aspiration is typically discarded and cytology obtained only with bloody aspirate (4). In cases when the ultrasound findings cannot distinguish between a complicated cyst versus a solid mass, initial aspiration is recommended for those masses that would require biopsy if solid (i.e., new or enlarging). Complete resolution with aspiration confirms that the lesion in question represented a complicated cyst. If a suspected cyst does not completely resolve with aspiration, the fluid should be discarded and the procedure converted to a core biopsy due to its increased accuracy.

In the late 1980s and 1990s, automated large core needle biopsy using stereotactic or ultrasound guidance was demonstrated to be an accurate method to sample imaging-detected abnormalities with comparable results to surgical biopsies and decreased costs and patient morbidity (1). Stereotactic biopsy is most commonly used to sample mammographic microcalcifications. Less frequently, stereotactic biopsy is performed to sample a mammographic mass, asymmetry, or area of architectural distortion with no sonographic correlate. However, stereotactic biopsy of noncalcified lesions should be performed only after a thorough high-quality breast ultrasound has been performed, as these may be more difficult to target using stereotactic guidance. A focused ultrasound should also be performed if mammographic calcifications are associated with a mass or increased density as targeting the associated soft tissue density has a higher likelihood of diagnosing an invasive component (Fig. 15-1). Percutaneous biopsy using ultrasound guidance is the preferable method for sampling any lesion that is evident sonographically.

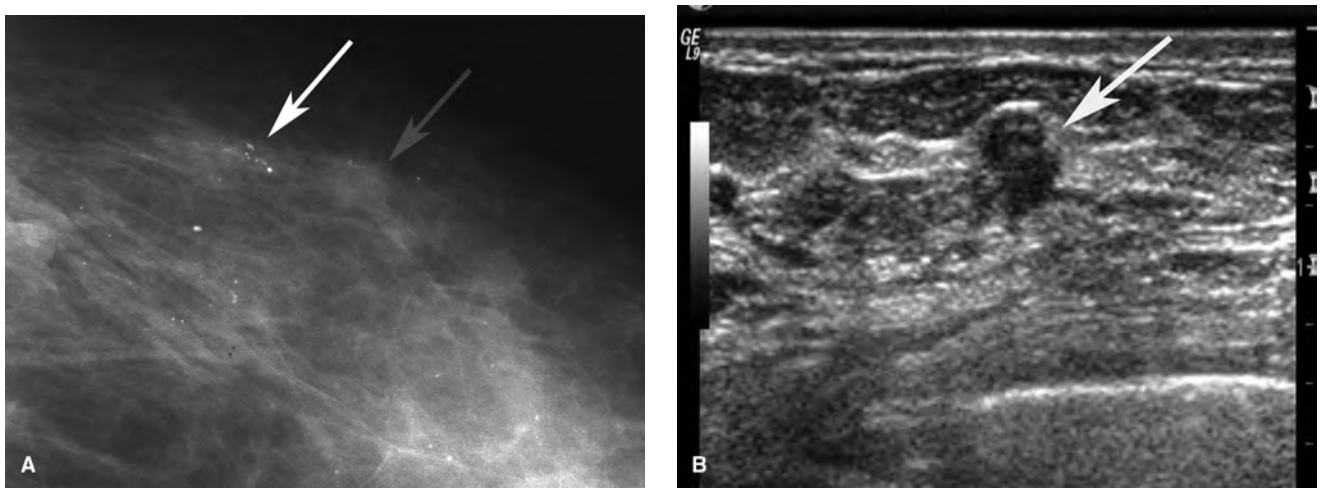

FIGURE 15-1 Ultrasound-guided biopsy of an invasive ductal carcinoma. **(A)** Mammogram demonstrates calcifications (*white arrow*) and adjacent soft tissue mass (*grey arrow*). **(B)** Targeted ultrasound identified a sonographic correlate to the mammographic density (*arrow*). Ultrasound-guided biopsy yielded invasive ductal carcinoma with DCIS. Calcifications were associated with the DCIS.

Compared to stereotactic or MRI-guided biopsy, ultrasound-guided biopsy is faster, more comfortable for the patient, and allows greater access to breast tissue, especially for far posterior and medial lesions that may not be amenable to either stereotactic or MRI-guided biopsy. In addition, adequate sampling is more consistently obtained because the needle can be seen traversing the target in real time. Parker et al. first described the accuracy of ultrasound-guided core biopsy using a 14-gauge automated needle. In this study, there was 100% concordance between the pathology obtained with ultrasound-guided core biopsy of 49 lesions and subsequent surgical excision. Of the 132 benign ultrasound-guided biopsies, no malignancies were identified at 12- to 36-month follow-ups (5).

Subsequently, vacuum-assisted devices were developed that improved diagnostic accuracy compared to automated devices and are now routinely used in all stereotactic percutaneous biopsies. Automated and vacuum-assisted devices were also modified to sample lesions detected only on MRI. Percutaneous biopsy using imaging guidance has been demonstrated to be a safe, accurate, less deforming, less invasive, and less expensive alternative to surgical biopsy and is the preferred method for sampling nonpalpable breast lesions. However, accurately performing percutaneous biopsies requires an understanding of all breast imaging modalities and an ability to correlate spatially between them despite differences in technique and patient positioning.

This chapter will review the indications and techniques for performing biopsies using stereotactic, ultrasound, and MRI guidance as well the potential pitfalls in both performing these procedures and the management of the pathology obtained from percutaneous biopsy.

PATIENT SELECTION AND PREPARATION

Patient Selection

Mammography, ultrasound, and breast MRI examinations are classified using the American College of Radiology Breast Imaging Reporting and Data System (BI-RADS), which gives a final assessment category indicating the level of suspicion for malignancy for each study (6).

BI-RADS 3 lesions have imaging features that suggest a less than 2% chance of malignancy. The criteria of a BI-RADS 3 mammographic lesion are largely based on two studies that collectively include over 80,000 mammograms (7,8). In these studies, a 6-month follow-up mammogram identified interval progression of those few BI-RADS 3 lesions that were actually malignant and diagnosed these cancers early enough to maintain a favorable prognosis (9). At the same time, close follow-up of BI-RADS 3 lesions reduces the false negative rate of biopsy and decreases health care costs. Examples of BI-RADS 3 mammographic lesions include a nonpalpable low-density solid mass with a round or oval shape and predominantly circumscribed margins on a baseline mammogram or clustered microcalcifications with a punctate morphology on a baseline study. New or enlarging solid masses should not be categorized as BI-RADS 3 lesions but should undergo biopsy.

The BI-RADS lexicon for lesions detected on ultrasound and MRI are less widely validated than for mammography. Stavros et al. initially developed a classification scheme to differentiate benign from malignant lesions on ultrasound with a 98.4% sensitivity and a 99.5% negative predictive value for malignancy (10). Subsequent studies have confirmed the low rate of subsequent malignancy in BI-RADS 3 masses (11,12). An incidental homogeneously hypoechoic oval mass with circumscribed margins and parallel orientation is an example of an ultrasound BI-RADS 3 lesion.

The specific morphologic and/or kinetic features of lesions appropriate for a BI-RADS 3 recommendation on MRI have not been well established but are generally based on the principles used to characterize BI-RADS 3 lesions on mammography. The cancer yield of BI-RADS 3 lesions on MRI has varied between 0% and10% (13,14). Eby et al. evaluated the characteristics of probably benign MRI lesions and found that foci, defined as lesions less than 5 mm in size that are too small to further characterize, comprise 46% of BI-RADS 3 lesions (14). Liberman et al. also found a 3% malignancy rate in suspicious lesions less than 5 mm in size (15). Studies have suggested that unique foci with a high T2 signal intensity correlate may safely be followed on a 6-month follow-up MRI given the low rate of malignancy of these lesions.

BI-RADS 4 lesions have between a 2% and 95% chance of representing malignancy and can be further subdivided

into BI-RADS 4a (low suspicion of malignancy), 4b (moderate suspicion), and 4c (high suspicion) categories. BI-RADS 5 lesions are highly suspicious with a greater than 95% chance of malignancy. Percutaneous biopsy is recommended for all examinations with BI-RADS 4 or 5 recommendations. Percutaneous biopsy is most useful for BI-RADS 4 lesions because surgery can be avoided in 70% to 80% of cases where biopsy yields benign and concordant pathology. Percutaneous biopsy of BI-RADS 5 lesions is recommended due to improved surgical outcomes at lumpectomy, including decreased positive margin rates (16).

Patient Preparation

Patients are asked to discontinue aspirin, warfarin, nonsteroidal anti-inflammatory agents, vitamin E, or other anticoagulation or antiplatelet drugs for at least 5 days prior to the procedure. However, patients who are anticoagulated for a medical reason are advised to consult their ordering physician to determine whether the medication can be safely discontinued. Studies have demonstrated that core biopsy can safely be performed without clinically significant complications if anticoagulants cannot be discontinued or if urgent results are required (17). Premedication with antibiotics in patients with prosthetic valves or joint replacements is generally not necessary.

SELECTION OF BIOPSY DEVICE

Both the gauge of the biopsy needle and the type of biopsy device are important factors to consider when performing percutaneous core biopsies. Percutaneous biopsies should be performed using a 14-gauge or larger bore needle due to increased accuracy compared to 16- or 18-gauge needles (18).

Two types of biopsy devices are available: automated spring-loaded devices or vacuum-assisted biopsy devices. Vacuum-assisted devices are standard for stereotactic or MRI-guided biopsies. Vacuum-assisted devices are faster and more accurate due to the larger size of specimens and the ability to obtain contiguous samples. The median specimen weight is approximately 17 mg with a 14-gauge automated needle, 35 mg with a 14-gauge vacuum-assisted biopsy probe, and 100 mg using an 11-gauge vacuum-assisted needle (1). Successful calcification retrieval rate and the rate of histologic underestimation are improved using a vacuum-assisted device compared to a 14-gauge automated large core biopsy device.

Although vacuum-assisted devices are routinely used during stereotactic and MRI-guided biopsies, most ultrasound-guided biopsies can be accurately performed using an automated spring-loaded device (19). A vacuum device may be preferred when sampling complex masses when lesion conspicuity may decrease due to loss of the fluid component once the needle is inserted or in cases of a suspected fibroepithelial lesion or papilloma when larger specimens may improve pathologic accuracy.

BIOPSY METHODS

Stereotactic Biopsy

Stereotactic biopsy may be performed on either dedicated prone tables or an upright add-on unit. Add-on units convert a standard diagnostic mammography unit, and the biopsy is performed with the patient in a sitting or decubitus position. Add-on units require less space, are less expensive, and allow the room to be used for routine mammography when a biopsy is not being performed, but they are associated with an increased risk of vasovagal reactions. Advantages of prone tables include that the biopsy is performed out of the patient's view, that vasovagal reactions are uncommon, and that more working space between the biopsy gun and the patient is permitted (1). The cost and space requirement for a dedicated room make prone tables impractical for centers that perform a low volume of stereotactic biopsies, and both types of units are considered acceptable and commonly used.

The technique for performing stereotactic biopsy is similar regardless of the type of unit used. The direction of approach is selected based on lesion location and/or visibility. A scout image is taken with the target centered in a cutout compression plate. A stereotactic pair in which images are taken at +15 and –15 degrees from a center line is obtained. Stereotactic biopsy is based on the concept that a lesion can be localized in three dimensions—the *x*, *y*, and *z* axes—based on the apparent change in position on the stereotactic pair (parallax). Once the target is selected, the housing unit is moved to the x and y coordinates. The skin is cleansed and anesthetized, and the biopsy needle inserted into the breast to the predetermined depth. Another stereotactic pair is obtained with the needle in the prefire position to confirm accurate targeting, and then the needle is typically fired (Fig. 15-2). A postfire stereotactic pair may be obtained to confirm needle position prior to sampling. If the target is calcifications, a specimen radiograph is taken to confirm retrieval of some of the targeted calcifications. If the target is a mass or asymmetry, a postfire image should be obtained to confirm that the needle trough is within the mammographic abnormality. Finally, a localizing clip is placed at the biopsy site and an image obtained to confirm clip deployment. After completion of the biopsy, a 2-view mammogram is performed to confirm clip placement and position relative to the biopsy site. This postbiopsy mammogram is also useful to confirm sampling of a mammographic mass or asymmetry, although these may be obscured by postbiopsy change.

Pitfalls of Stereotactic Biopsy

Several factors may complicate successful stereotactic biopsy, including the following:

- Error in targeting: Localization requires targeting the same lesion on both stereotactic pairs. Targeting two different lesions on the stereotactic pairs will miscalculate the depth (*z* axis), resulting in unsuccessful retrieval of the target.
- Skin calcifications: Skin calcifications mistakenly may be thought to be within the breast parenchyma. The possibility that the target represents skin calcifications should be considered when the calculated Z value (depth) is approximately 5 mm (Fig. 15-3).
- Negative stroke margin: Stroke margin is the distance between the postfire needle position and image receptor. A negative stroke margin indicates that the breast thickness is insufficient and that the needle will strike the image receptor when fired (Fig. 15-4). Standard biopsy needles typically have a needle trough of 18 to 20 mm, and the calculated depth (Z value) centers the target within the needle trough. With thin breasts, devices with a shorter cutting chamber of 12 mm and a blunt tip may be employed. However, these petite devices decrease the sample size and require more precise targeting. Minimizing compression to ensure maximal breast thickness may also permit sampling in thin breasts. If the stroke margin error is only a few millimeters because the calculated Z value

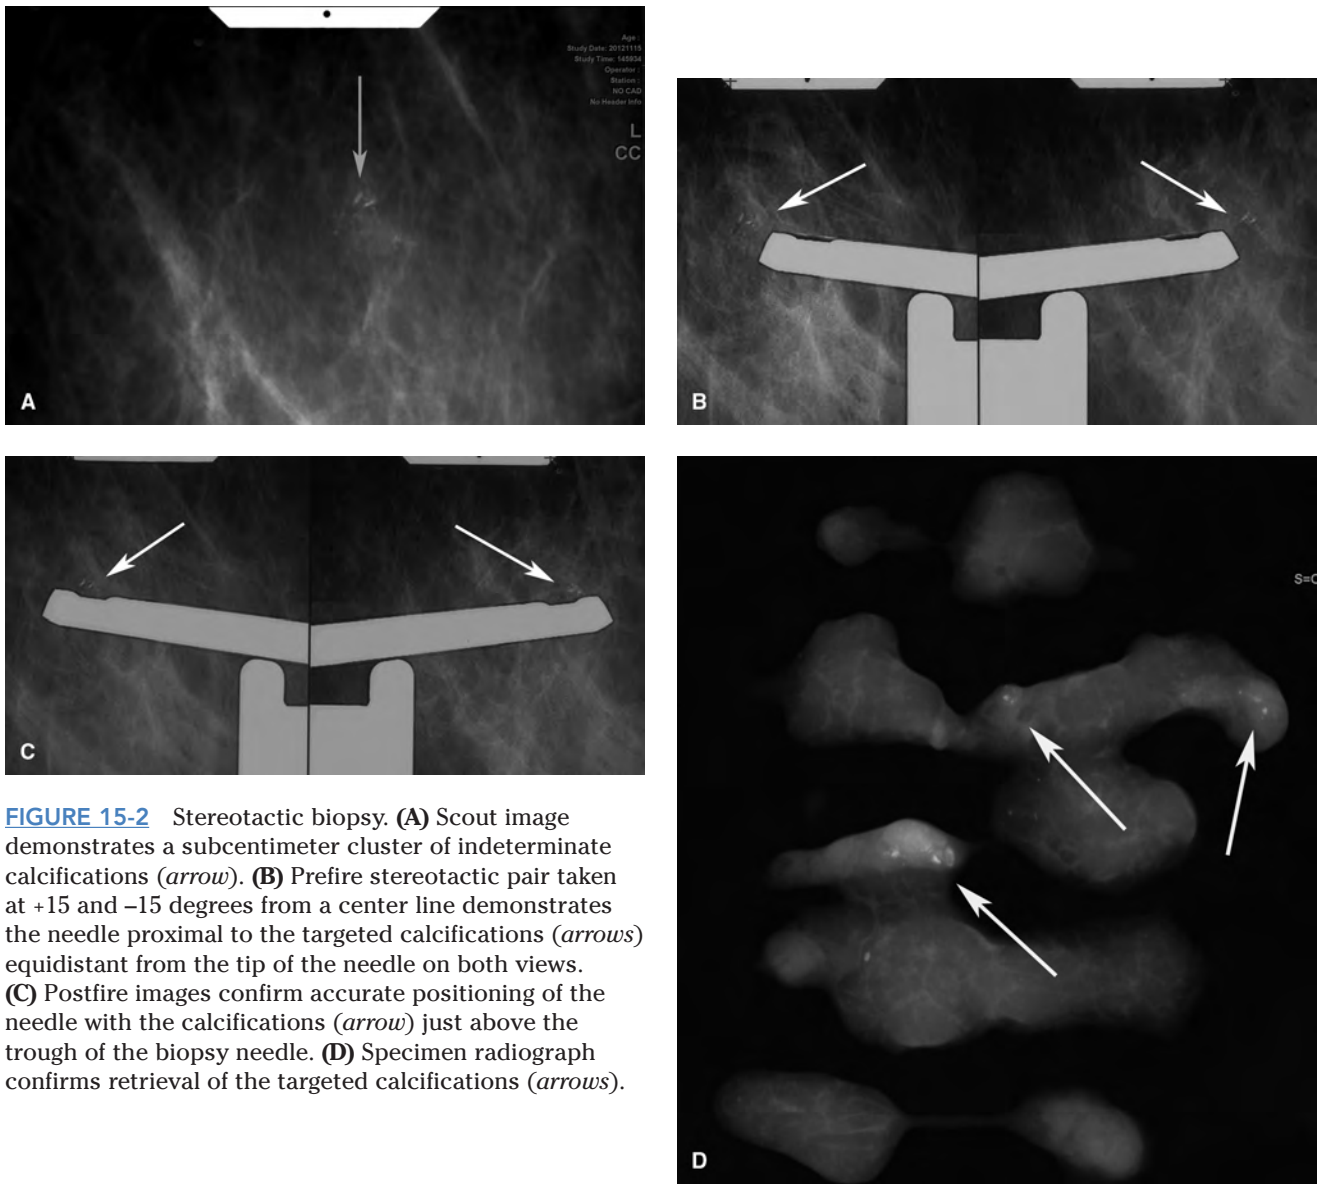

FIGURE 15-2 Stereotactic biopsy. **(A)** Scout image demonstrates a subcentimeter cluster of indeterminate calcifications (*arrow*). **(B)** Prefire stereotactic pair taken at +15 and –15 degrees from a center line demonstrates the needle proximal to the targeted calcifications (*arrows*) equidistant from the tip of the needle on both views. **(C)** Postfire images confirm accurate positioning of the needle with the calcifications (*arrow*) just above the trough of the biopsy needle. **(D)** Specimen radiograph confirms retrieval of the targeted calcifications (*arrows*).

centers the target in the middle of the needle trough, which is typically 18 to 20 mm, the needle can be pulled back to prevent the tip from striking the image receptor while keeping the target within, but not centered in, the trough. A reversed compression paddle, which has an aperture allowing tissue to push through, also may be placed on the far side of the breast to increase breast thickness.

- Axillary tail or posterior lesions: Lesions in the posterior breast may be difficult to target. Positioning the patient in an oblique position may facilitate access to the posterior parenchyma. Targeting the anterior edge of the lesion with preferential sampling posteriorly can be attempted. Alternatively, biopsy can be performed with the patient's arm and shoulder positioned through the table aperture and supported in order to better access the axillary tail (Fig. 15-5).
- Calcifications on specimen radiograph but not identified by pathology: Mammographic calcifications representing calcium oxalate may be difficult for pathologists to visualize and may require analysis with polarized light to improve their conspicuity. In addition, after tissues cores are embedded into paraffin, only a small proportion is sectioned into slides for analysis. If no calcifications are identified, the paraffin blocks can be x-rayed to determine whether additional sections are needed (Fig. 15-6).

Despite these maneuvers, some lesions will not be amenable to stereotactic biopsy, usually due to lesion location or breast thickness. In these situations, mammographic-guided localization prior to excisional biopsy will be required.

Ultrasound Guided Biopsy

Ultrasound-guided core biopsy is the preferable method for sampling any lesion that is evident sonographically. Ultrasound-guided biopsy is more technically challenging than either stereotactic or MRI-guided biopsy as hand-eye coordination is required to accurately target the lesion while the breast is mobile and not compressed.

During an ultrasound-guided core biopsy, the patient is positioned either in the supine or supine oblique position with the ipsilateral arm raised over the head. The skin is

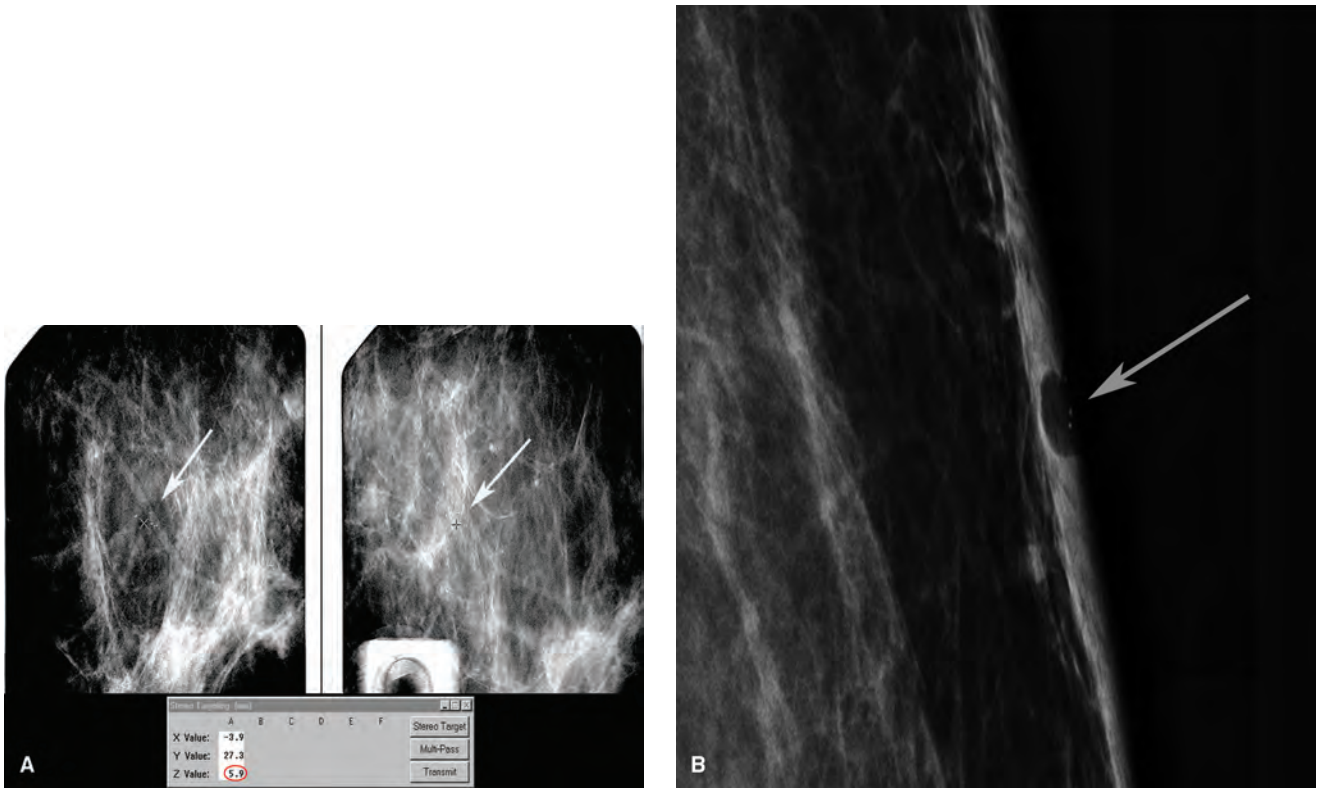

FIGURE 15-3 Stereotactic biopsy of dermal calcifications. **(A)** Initial targeting localizes a cluster of calcifications (*arrow*) to a depth of 5 mm (*red circle*), suggesting that the calcifications are within the skin. No calcifications were present on the specimen radiograph. **(B)** Tangential view postbiopsy confirms that the calcifications are within the skin, which now contains postbiopsy changes including air (*arrow*).

cleansed, and local anesthesia injected. After a skin incision is made, the needle is inserted parallel to the long axis of the transducer so that the entire length of the needle is visualized as it is advanced to the target. With automated core biopsy devices that are fired into biopsy position, the needle tip should be positioned just proximal to the lesion edge before it is fired. With a nonfiring vacuum-assisted device, the needle is typically positioned deep to the target. The angle of the needle greatly affects visualization, and the needle should be directed parallel to the transducer and chest wall to avoid injury.

Pitfalls of Ultrasound-Guided Biopsy

The major limitations to ultrasound-guided biopsy are as discussed below:

- Lesion visualization: A lesion must be sonographically evident to undergo ultrasound-guided biopsy. Therefore, ultrasound-guided biopsy may not be feasible for calcifications or small masses for which no sonographic correlate can be identified.
- Inaccurate targeting: An advantage of ultrasound-guided biopsy is that the biopsy needle can be seen in real time traversing the desired target. However, when sampling subcentimeter lesions, the needle may appear to be accurately positioned through the target, but, due to volume averaging, the needle is actually in the adjacent tissue. Turning the transducer in the orthogonal plane to image the needle in cross section through the target confirms accurate targeting.
- Injury to the chest wall: The core biopsy needle should always be positioned parallel to the chest wall. With automated core biopsy devices, the tip of the needle should be visualized at all times and when firing the needle. There must be adequate distance away from vital structures to accommodate the throw of the needle once fired. A rare but potential complication of ultrasound-guided biopsy is pneumothorax.
- Inaccurate identification of a sonographic correlate to a mammographic abnormality: When sampling a potential sonographic correlate to a mammographic abnormality, a localizing clip should be placed in the biopsied lesion. The postbiopsy mammogram should confirm correlation between the biopsied lesion and the mammographic abnormality (Fig. 15-7).
- Inaccurate identification of a sonographic correlate to a MRI abnormality: Targeted ultrasound is often performed to evaluate for a sonographic correlate to a MRI finding in order to facilitate biopsy. A potential correlate is more frequently identified for enhancing masses compared to nonmass enhancement (20,21). However, true ultrasound-MRI correlation can be confirmed only if a follow-up MRI is performed, demonstrating the localizing clip placed at the time of ultrasound-guided biopsy within the area of enhancement on MRI. One study found that the presumed sonographic correlate biopsied yielding a benign, concordant diagnosis did not correspond to the lesion originally detected on MRI in 12% of cases (21). For this reason, a 6-month follow-up MRI is recommended following benign concordant biopsy of a sonographic correlate to a

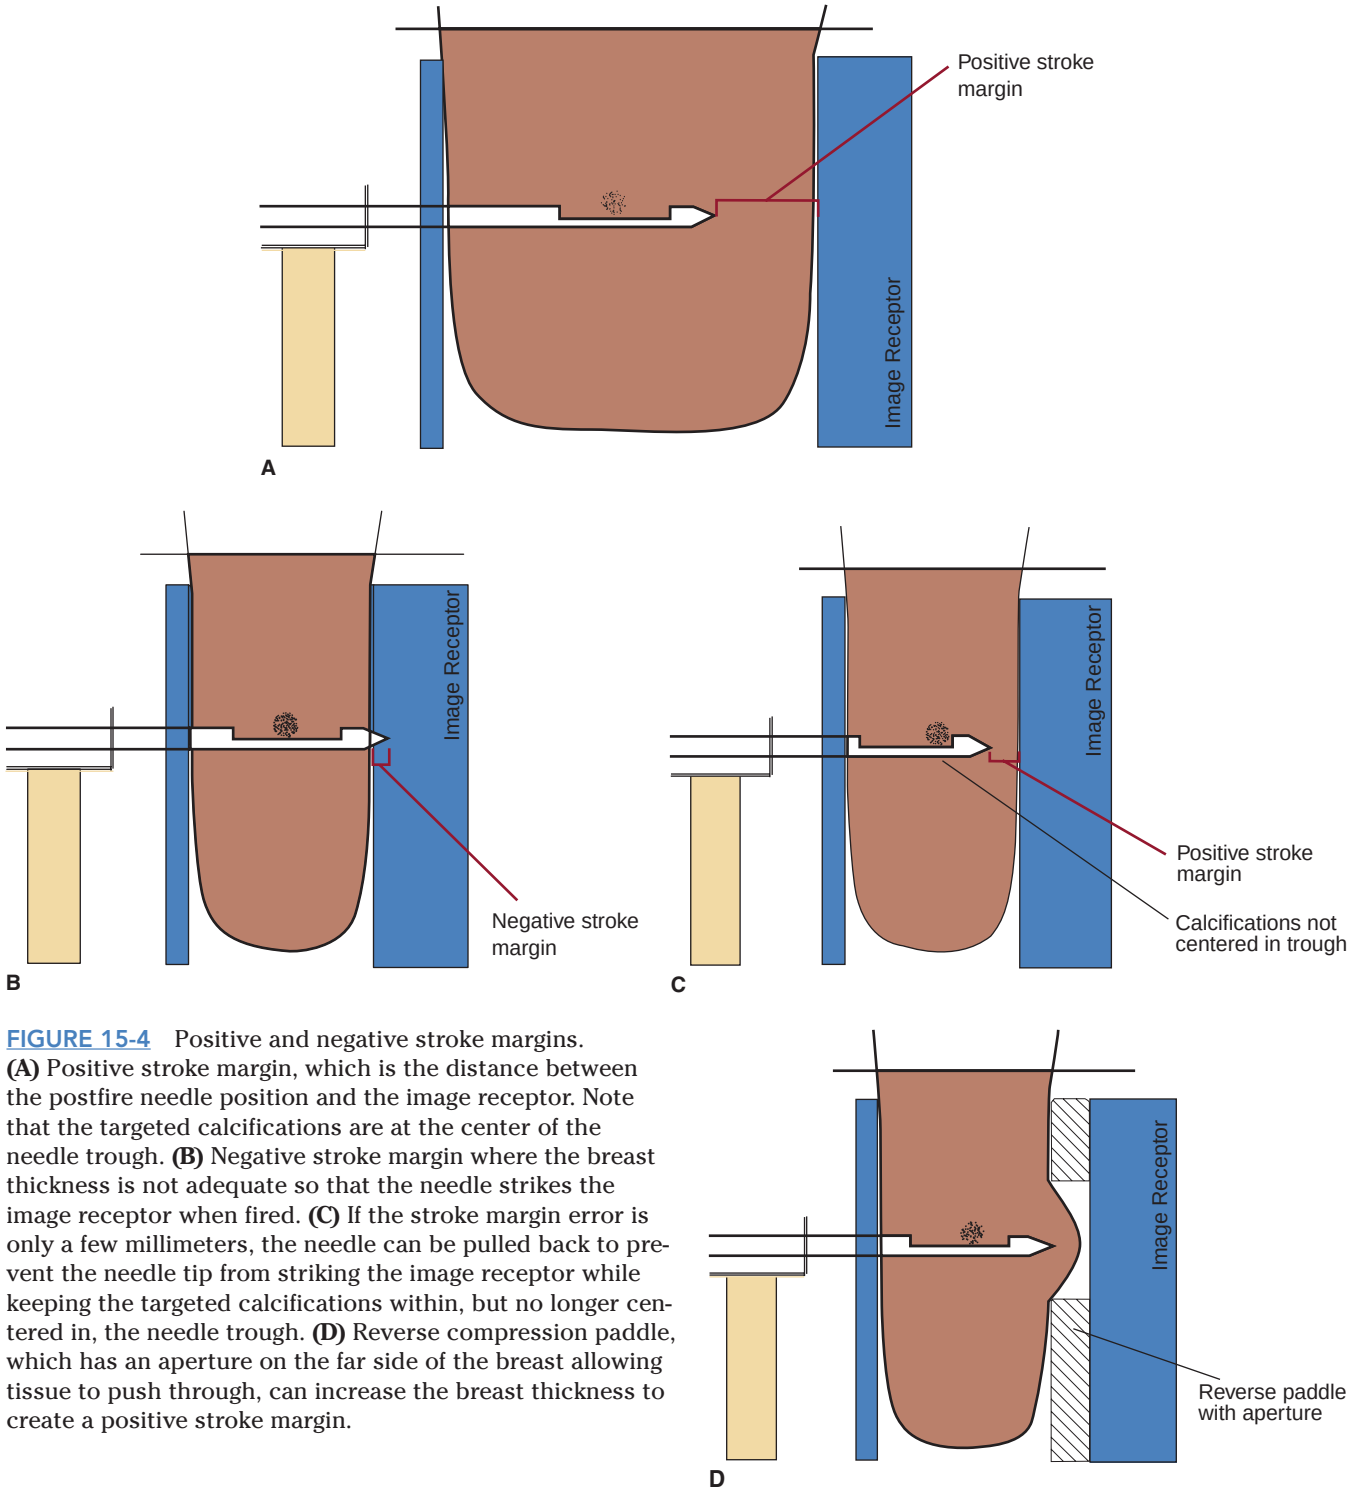

FIGURE 15-4 Positive and negative stroke margins. **(A)** Positive stroke margin, which is the distance between the postfire needle position and the image receptor. Note that the targeted calcifications are at the center of the needle trough. **(B)** Negative stroke margin where the breast thickness is not adequate so that the needle strikes the image receptor when fired. **(C)** If the stroke margin error is only a few millimeters, the needle can be pulled back to prevent the needle tip from striking the image receptor while keeping the targeted calcifications within, but no longer centered in, the needle trough. **(D)** Reverse compression paddle, which has an aperture on the far side of the breast allowing tissue to push through, can increase the breast thickness to create a positive stroke margin.

MRI-detected lesion (22). This pitfall likely is related to differences in patient positioning with the patient positioned prone during the MRI but supine and oblique during the ultrasound.

MRI-Guided Biopsy

Breast MRI is increasingly being performed as an adjunct to mammography to screen patients who are at high risk for developing breast cancer. The sensitivity of breast MRI for detecting invasive and *in situ* breast cancer is high, but the specificity is lower (23,24), necessitating the use of percutaneous biopsy for a definitive diagnosis.

Breast MRI should be performed on only a 1.5 or 3.0 T magnet using a dedicated breast coil. During biopsy, the patient is positioned prone and the breast immobilized in light compression. Tight compression may inhibit blood flow and is not recommended. Depending on the location of the target, either a medial or lateral approach is selected. Pre- and postcontrast images are first obtained to identify

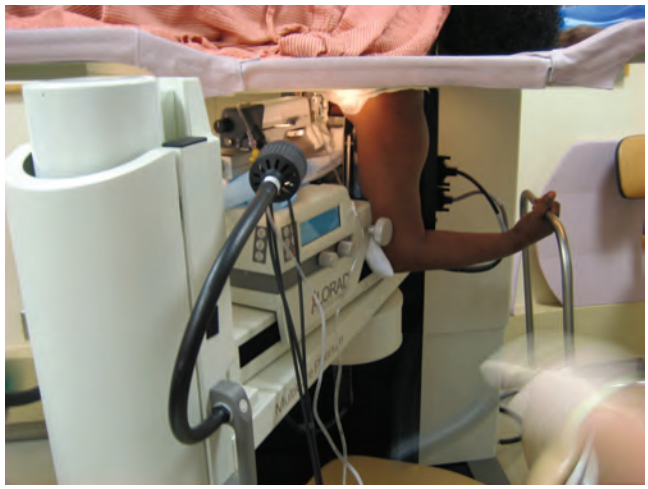

FIGURE 15-5 The patient's arm and shoulder can be positioned through the table opening to facilitate access to posterolateral lesions. The patient's arm should be stabilized during the procedure to minimize motion.

the target. The skin overlying the lesion is cleansed and anesthetized. A sheath is placed over a trocar and inserted to the appropriate depth. The trocar is removed, a plastic obturator inserted, and repeated imaging performed to confirm accurate positioning. Samples are obtained using a vacuum-assisted device. A postbiopsy series is then obtained to confirm biopsy site changes. Following biopsy, a localizing clip is placed at the biopsy site. A postbiopsy mammogram is obtained to confirm clip placement and position with respect to biopsy site changes.

Pitfalls

Potential factors complicating accurate MRI-guided biopsy include the following:

- Lesion nonvisualization: Cancellation of MRI-guided biopsy occurs in approximately 8% of patients. Factors associated with a higher cancellation rate include moderate or marked parenchymal enhancement and lesion size less than 1 cm (25). Lesion nonvisualization may be due to excessive compression of the breast parenchyma. Therefore, if a target is not identified at the time of biopsy, compression is reduced and delayed sequences obtained. If the target is still not visualized, the biopsy is canceled and a 6-month follow-up MRI should be obtained (22,25).
- Decreased lesion conspicuity: Decreased lesion conspicuity is likely related to compression, which is applied only at the time of biopsy and may alter perfusion and the appearance of the target. If a lesion is visualized but appears less conspicuous at the time of MRI-guided biopsy, biopsy should still be performed.
- Errors in targeting: Unlike ultrasound-guided biopsy where the needle is seen traversing the target in real time or stereotactic biopsy where the specimen radiograph confirms sampling of the targeted calcifications, confirmation of accurate sampling during MRI-guided biopsy is less accurate and relies on identifying postbiopsy changes at the expected location of the target (Fig. 15-8). One study reports a 2.5% false negative rate of MRI-guided biopsy

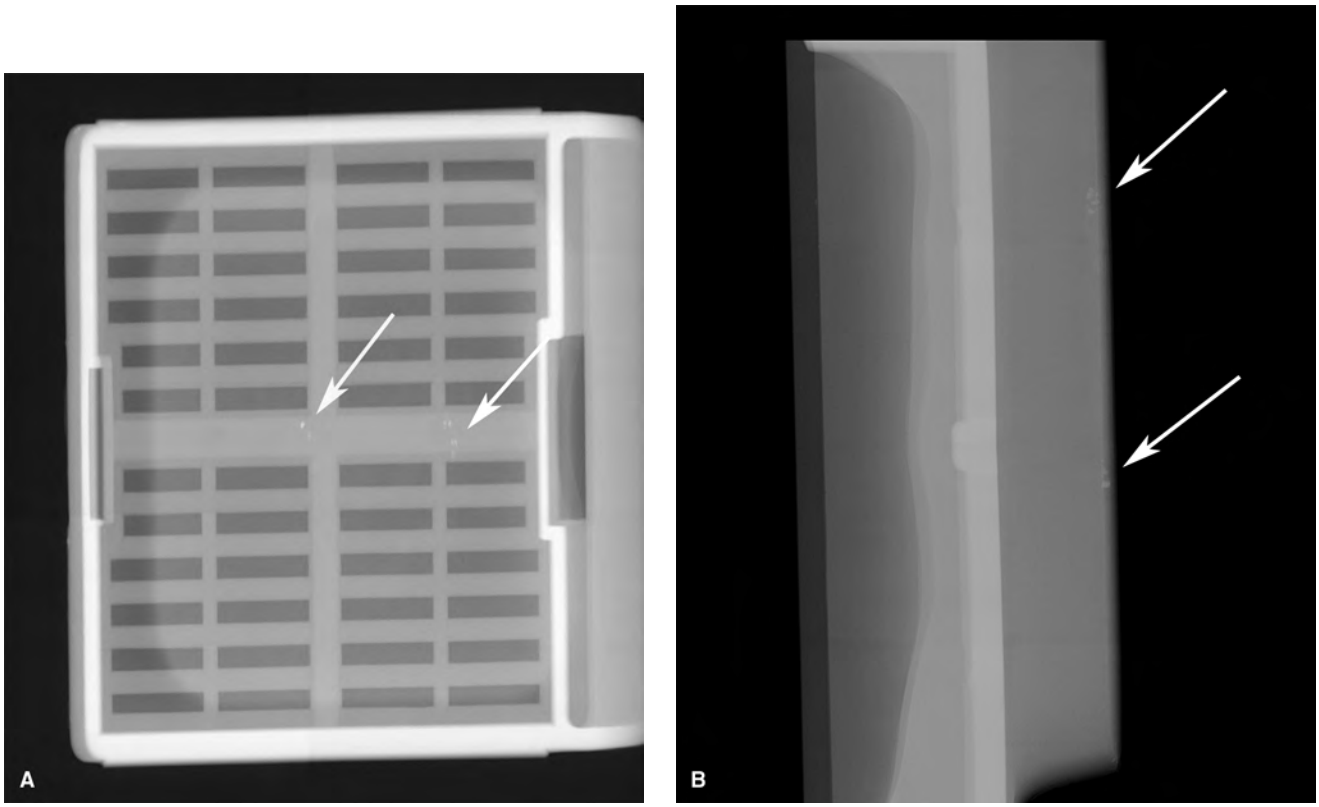

FIGURE 15-6 Imaging specimen paraffin blocks. Frontal (**A**) and lateral (**B**) x-rays of specimen blocks confirm the presence of calcifications (*arrows*) retrieved on stereotactic biopsy. Additional sections can be obtained from those blocks containing calcifications.

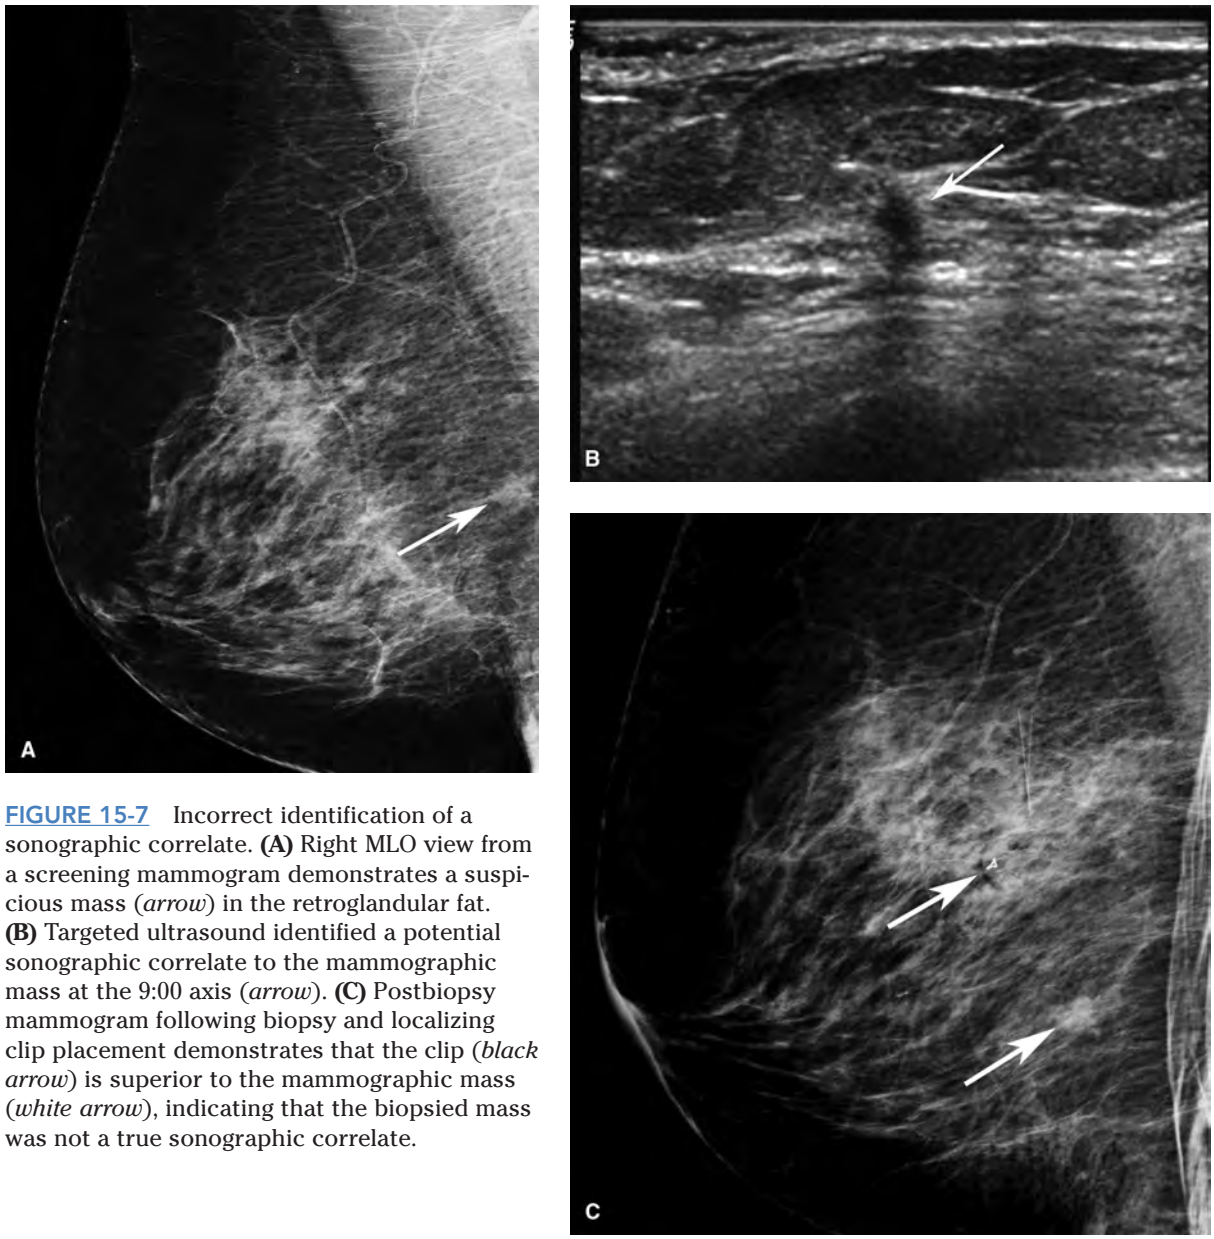

FIGURE 15-7 Incorrect identification of a sonographic correlate. **(A)** Right MLO view from a screening mammogram demonstrates a suspicious mass (*arrow*) in the retroglandular fat. **(B)** Targeted ultrasound identified a potential sonographic correlate to the mammographic mass at the 9:00 axis (*arrow*). **(C)** Postbiopsy mammogram following biopsy and localizing clip placement demonstrates that the clip (*black arrow*) is superior to the mammographic mass (*white arrow*), indicating that the biopsied mass was not a true sonographic correlate.

(22,26). Therefore a 6-month follow-up MRI is recommended after benign concordant MRI-guided biopsy to confirm accurate targeting and sampling.

CLIP PLACEMENT

A localizing clip should routinely be placed during almost all percutaneous biopsies, particularly for subtle lesions or lesions that are less conspicuous or no longer evident after sampling. Clip placement also assists in correlating lesions between modalities. A postbiopsy mammogram should be performed following clip placement in order to document clip deployment and the position of the clip relative to the expected location of the targeted lesion. Clip displacement when the clip position is significantly distant from the site of the imaging abnormality is an infrequent complication. This occurs predominantly during stereotactic or MRI-guided biopsies along the biopsy tract when the breast is released from compression. If a clip is displaced and surgical excision is necessary, the original imaging abnormality (i.e., residual calcifications) can be targeted if still visible following biopsy. Otherwise, localization can be performed by targeting anatomic landmarks and the location of biopsy changes, which are best assessed on the immediate postbiopsy mammogram.

COMPLICATIONS

Complications following percutaneous biopsy procedures are infrequent. Bleeding is the most common complication and has been reported in up to 3% of cases using an 11-gauge vacuum-assisted system. Hemostasis can usually be obtained with direct compression for 10 to15 minutes. Hematomas are rarely clinically significant and can be managed conservatively. Infection is another potential but rare complication.

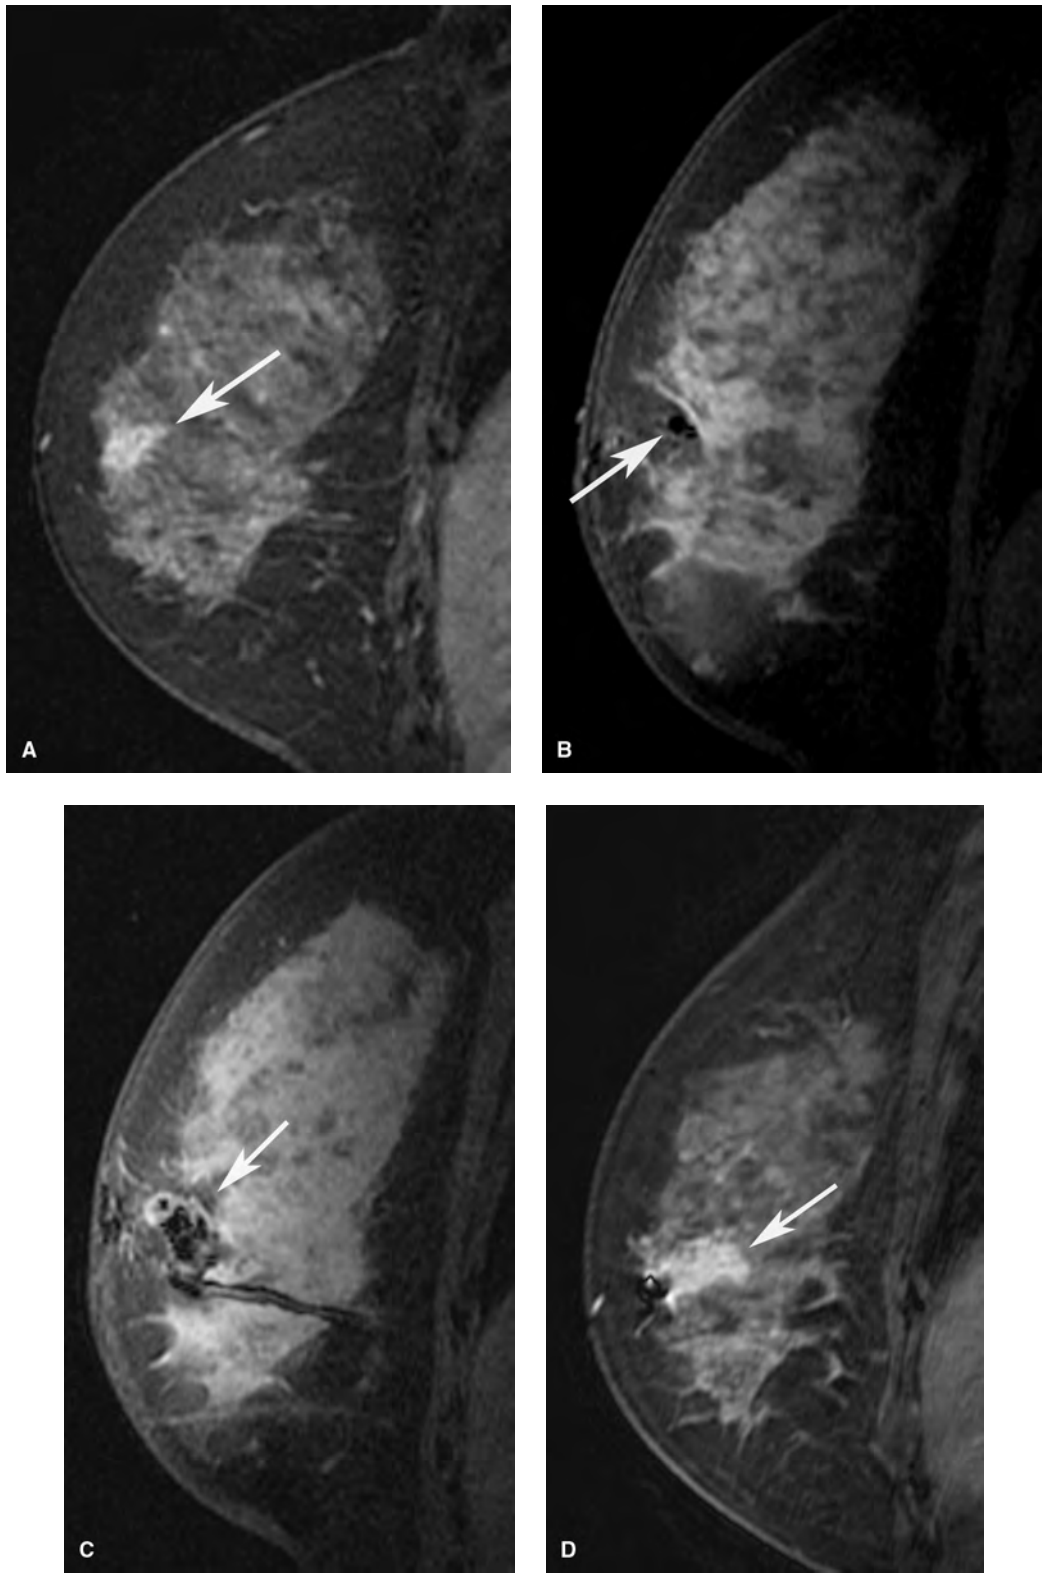

FIGURE 15-8 False negative MRI-guided biopsy. **(A)** Biopsy was recommended for an indeterminate area of nonmass enhancement (*arrow*) on screening breast MRI. **(B)** Sagittal fat saturated T1-weighted image demonstrates low signal from the obturator (*arrow*) at the anterior aspect of the nonmass enhancement that has become difficult to visualize. **(C)** Sagittal fat saturated T1-weighted image demonstrates expected postbiopsy changes (*arrow*) after sampling. Pathology-yielded stromal fibrosis, which was thought to be concordant. **(D)** Sagittal fat saturated T1-weighted image on the 6-month follow-up MRI demonstrates the localizing clip at the anterior aspect of the area of nonmass enhancement (*arrow*), which has now increased in size. Repeat MRI-guided biopsy yielded invasive ductal carcinoma.

HISTOPATHOLOGIC CONCORDANCE

Correlation of the imaging appearance of a biopsied lesion with the histopathology is an integral part of percutaneous breast biopsy to maintain high accuracy and a false negative rate comparable to surgical excision. Communication with the pathologist may be helpful in cases of questionable imaging-pathologic concordance.

Benign breast histopathology encompasses a broad range of conditions, including nonspecific findings such as fibrocystic change, apocrine hyperplasia, sclerosing adenosis, stromal fibrosis, and ductal hyperplasia. Examples of more specific benign histology include fibroadenoma, lymph nodes, and fat necrosis. The mammographic and sonographic features of many of these pathologies have been well described.

There is no consensus regarding the follow-up imaging protocol after benign concordant percutaneous biopsy, and practices vary by institution. Lee et al. recommended a 6-month follow-up for nonspecific benign results on stereotactic biopsy and yearly screening mammography if specific benign results were obtained; another retrospective study recommended imaging at 6, 12, and 24 months after all benign concordant biopsies (27,28). A more recent study reported that a 6-month imaging follow-up did not impact either cancer detection or rebiopsy rates and therefore yearly follow-up may be more appropriate (29).

At our institution, the patient returns to routine annual screening mammography after benign and concordant stereotactic biopsy of calcifications if the calcifications appear to be adequately sampled on the specimen radiograph. If multiple morphologically similar clusters of calcifications are present and sampling of one representative cluster yielded benign and concordant pathology, a 6-month follow-up mammogram is recommended to confirm stability of the remaining clusters. A 6-month follow-up mammogram is also recommended after obtaining benign, concordant pathology after stereotactic biopsy of masses or asymmetries as assessing for adequate sampling may be more difficult than with biopsy of calcifications. Similarly, a 6-month follow-up ultrasound is also sometimes recommended after ultrasound-guided biopsy of a low-suspicion lesion that yields a benign but nonspecific pathology.

Determining histopathologic concordance following MRI-guided biopsy is more challenging as all of these lesions can appear as focal areas of enhancement, distinct from the remainder of the breast parenchyma. Because there is considerable overlap in the morphologic features of benign and malignant lesions on MRI, it is possible that a lesion thought to be benign and concordant is, in fact, malignant. Therefore, a 6-month follow-up MRI is routinely performed following benign concordant MRI-guided biopsy.

HIGH RISK LESIONS DIAGNOSED AT CORE BIOPSY

Controversy exists regarding the need for surgical excision after percutaneous core biopsy yielding certain high risk lesions, including atypical ductal hyperplasia, lobular neoplasia, radial scar, and papillary lesions. Excision of a high risk lesion is often recommended (Table 15-1) due to potential histologic underestimation when a high risk lesion diagnosed at percutaneous biopsy is upgraded to either *in situ* or invasive carcinoma at the time of surgery.

Atypical Ductal Hyperplasia

Atypical ductal hyperplasia (ADH) is the most common of the high risk lesions, identified in approximately 5% of all biopsies and in up to 20% of biopsies performed for amorphous calcifications (3). Histologic underestimation of ADH diagnosed on stereotactic biopsy is reduced by acquiring a larger volume of tissue. The upgrade rate of ADH to carcinoma at excision is approximately 20% to 56% when using a 14-gauge automated core biopsy device but is reduced to 20% with an 11-gauge vacuum-assisted device (1). This upgrade rate is high enough that surgical excision is generally recommended.

Surgical excision is also recommended when ADH is diagnosed on MRI-guided biopsy. Although histologic underestimation is reduced to approximately 20% with an 11-gauge vacuum-assisted device using stereotactic guidance, studies have reported a 38% upgrade rate of ADH diagnosed at MRI-guided biopsy using a 9-gauge vacuum-assisted biopsy device (30). This higher rate may reflect the increased risk of malignancy in patients undergoing a breast MRI, which is usually performed for either high risk screening or preoperative staging.

TABLE 15-1

Management Recommendations of High Risk Lesions on Percutaneous Biopsy

High Risk Lesion	*Management Recommendation*
Atypical ductal hyperplasia	Excision
Lobular neoplasi(a)	
- ALH	Controversial
- Classic LCIS	Controversial
- Pleomorphic LCIS	Excision
Radial scar/ Radial sclerosing lesion	Excision
Papilloma	Excision
Microscopic radial scar and papilloma	Controversial

Lobular Neoplasia

Lobular neoplasia (LN) includes both atypical lobular hyperplasia (ALH) and lobular carcinoma *in situ* (LCIS). ALH and LCIS are often considered to be along a spectrum of a disease. Currently LN is thought to represent a marker for increased risk of breast cancer at any site in either breast as opposed to a true precursor of malignancy.

Lobular neoplasia can be subdivided into classical and pleomorphic types with the pleomorphic type having a higher likelihood of upgrade to malignancy (31). The upgrade rate for lobular neoplasia varies widely in the literature—between 0% and 50%. This wide range is likely related to the fact that most of these studies are retrospective, have small numbers of patients included due to the low incidence of the pathology, and do not include radiologic-pathologic concordance. In one of the largest retrospective studies that included 278 cases of lobular neoplasia from 14 institutions, Brem et al. reported a 23% upgrade rate (32). Conversely, Hwang et al. reviewed 136 cases of LN and reported a 2% upgrade rate of ALH and 23% upgrade rate of LCIS (33). However, the upgrade rate of LCIS was reduced to less than 2% when nonclassic or pleomorphic variants of LCIS or cases with imaging-pathology discordance were excluded. Another consideration is whether the LN represents an incidental finding or is related to the imaging abnormality. Given the conflicting

data, surgical excision for classic LCIS and ALH continues to be controversial. Surgical excision is recommended for all cases of pleomorphic LCIS.

Radial Scar

Radial scars are rare—reported in less than 1% of all percutaneous biopsies. These may present mammographically as spiculated masses, classically with a lucent center, or as incidental microscopic lesions unrelated to the imaging abnormality for which biopsy had been performed. Historically, the standard management of radial scars diagnosed at core biopsy has been excision due to a reported association with DCIS and invasive carcinomas. A multiinstitutional trial published in 2002 reported an overall upgrade rate of 8% at surgical excision (34). The upgrade rate was higher if there was associated atypia on core biopsy. There was no upgrade if at least 12 specimens were obtained at stereotactic biopsy using an11-gauge vacuum-assisted device, if there was no associated atypia, and when the mammographic findings were concordant. Microscopic radial scars also have a low upgrade to malignancy and may not require excision (35). Although the data are limited, some institutions reserve surgical excision for radial scars that are mammographically evident or for radial scars associated with atypia.

Benign Papillomas

Papillary lesions are diverse, ranging from benign papillomas to papillary lesions with atypia to invasive papillary carcinomas. Papillary tumors are found in up to 4% of percutaneous biopsies (36). Papillomas are considered atypical papillomas if there are foci of ADH or DCIS. Atypical papillomas or papillomas with DCIS warrant excision. However, there is continuing controversy as to whether surgical excision is required for a benign papilloma on core biopsy. Surgical excision has traditionally been recommended due to the limited sample obtained and concern that percutaneous biopsy might sample a nonrepresentative portion of the lesion. Similar to other high risk lesions, the reported upgrade rate of papillomas ranges widely in the literature between 0% and 25%, largely due to the small number of patients included in each study, their retrospective design, and differences in assessing imaging-pathologic concordance (31,36). Most of these studies involved papillomas diagnosed at either ultrasound or stereotactic biopsy. Communication with the pathologist is important to distinguish microscopic papillomas that are entirely contained within the core specimens as these may not require excision (35). Surgical excision is recommended when papilloma is obtained on MRI guided biopsy due to a 5% upgrade rate in papillomas without atypia (36).

CONCLUSION

Image guided percutaneous breast biopsy has become the preferred method for evaluating nonpalpable lesions in the breast. Percutaneous core biopsy is a safe, less invasive, and less costly alternative to surgical biopsy with comparable accuracy. However, understanding potential pitfalls that may occur with image guided biopsy is important in order to maintain its effectiveness. Accurate targeting is critical with any image guided biopsy in order to minimize false negative rates. In addition, imaging-pathologic concordance is essential after biopsy. Management of high risk lesions continues to be debated, and additional studies need to be performed to standardize management of these lesions.

MANAGEMENT SUMMARY

- Most nonpalpable breast lesions can be successfully and accurately biopsied using imaging guidance.
- Ultrasound-guided biopsy is the preferred method of percutaneous biopsy for any sonographically evident lesion as it is faster, less expensive, and more comfortable for the patient compared to stereotactic or MRI-guided biopsy. Ultrasound-guided biopsy also avoids radiation exposure or intravenous contrast administration.
- Definite indications for surgical excision following percutaneous biopsy include malignancy, pathology that is discordant from the imaging appearance, and certain high risk lesions, such as ADH, radial scars, and papillomas.

SECTION IV

Epidemiology and Assessing and Managing Risk

CHAPTER 16

Inherited Genetic Factors and Breast Cancer

Alan Ashworth

CHAPTER CONTENTS

Although much remains to be learned about the heritable factors involved, enormous strides have been made in the past two decades in understanding inherited susceptibility to breast cancer. These advances are based on the discovery and characterization of a number of high-risk, relatively uncommon genes responsible for the clustering of breast cancer in certain families. More recently, a large number of common variants having a modest effect on individual risk have been defined by the use of genome-wide association studies. As clinical utility is currently largely restricted to high-risk genes, this chapter will focus largely on this category but in the future it seems possible that low-risk common variants will also be utilized to inform risk and management of breast cancer. Other relevant information can be found in Chapter 17.

One measure of familial clustering is the familial relative risk (FRR) which is defined as the ratio of the risk of breast cancer for a relative of an affected individual to that of the general population. Multiple observations including simulation and twin studies suggest that the FRR for breast cancer largely reflects the genetic influence on the disease.

Although genetics are clearly important, there is a tendency to assume that familial clustering of disease invariably results from inherited predisposition. However, other explanations for familial clustering of breast cancer should be considered including (a) geographically limited environmental exposure to carcinogens, which might affect an extended family living in close proximity; (b) culturally motivated behavior that alters risk factor profile, such as age at first live birth; and (c) socioeconomic influences that, for example, might result in differing dietary exposures. In addition, multiple, complex inherited genetic factors likely influence the extent to which a risk factor for breast cancer plays a role in any one individual; such modifying effects are likely to be shared among genetically related members of an extended family.

HISTORICAL EPIDEMIOLOGIC STUDIES OF FAMILIAL BREAST CANCER

The first attempts to determine the influence of family history on breast cancer risk were published in the first half of the twentieth century (1,2). Although many of these studies have methodological flaws, they consistently demonstrated a twofold to threefold increase in breast cancer risk in mothers and sisters of patients with breast cancer. The first large population-based study to estimate breast cancer risk associated with a family history was conducted in Sweden and involved 2,660 women (3). Within this study cohort, women with an affected relative had an increased breast cancer risk of 1.7 compared to those without. Anderson (4) suggested that a small subset of families with a very high risk of developing breast cancer due to a single genetic defect might be obscured in studies in which most breast cancer cases were multifactorial in origin. By 1980, a significant

body of evidence had accumulated supporting the presence of inherited factors responsible for familial clustering of breast cancer, and efforts shifted to determining the inheritance pattern of breast cancer within these families. In 1984, Williams and Anderson (5) provided the first evidence for an autosomal dominant breast cancer susceptibility gene with age-related penetrance finding supported by Newman et al. (6) in 1988.

MODE OF INHERITANCE

To date, all studies of inherited susceptibility to breast cancer suggest that breast cancer susceptibility is transmitted in an autosomal dominant mendelian fashion, and the identification of an increasing number of genes has born out this modeling (7,8) (Table 16-1). With a pattern of autosomal dominant inheritance, an individual can have one of three possible genotypes: carrier of two nonmutant alleles (homozygous normal), or carrier of one (heterozygous) or two (homozygous) mutant alleles. The actual risk of developing breast cancer in a mutation carrier is based on the penetrance of the gene. Penetrance is the likelihood that the effect (phenotype) of a mutation (genotype) will become clinically apparent. Individuals carrying two copies of an autosomal dominant disease–related gene are rare, partly because of the relative rarity of heterozygotes and partly because of the potential for a lethal defect in a homozygous affected fetus. However, biallelic (homozygous) deleterious mutations in *BRCA2* have been reported in patients with Fanconi anemia type D1, a rare recessive disorder characterized by leukemia and birth defects (9). Finally, there are several reports of individuals who have both *BRCA1* and *BRCA2* mutations (10). Anecdotal observations suggest that these women develop more frequent and earlier cancers than single mutation carriers, but the number of such individuals identified is too small for definitive studies.

There is a 50% chance that an individual offspring will inherit a mutant copy of any given gene from a heterozygous parent. Therefore, on average, 50% of the related individuals in a family carry the mutant gene being transmitted. If the penetrance of the gene is high, the pedigree pattern for an autosomal dominant disease is quite striking, with vertical inheritance and half the children of an affected parent also being affected, whereas none of the offspring of a homozygous normal parent are affected. This pedigree pattern also

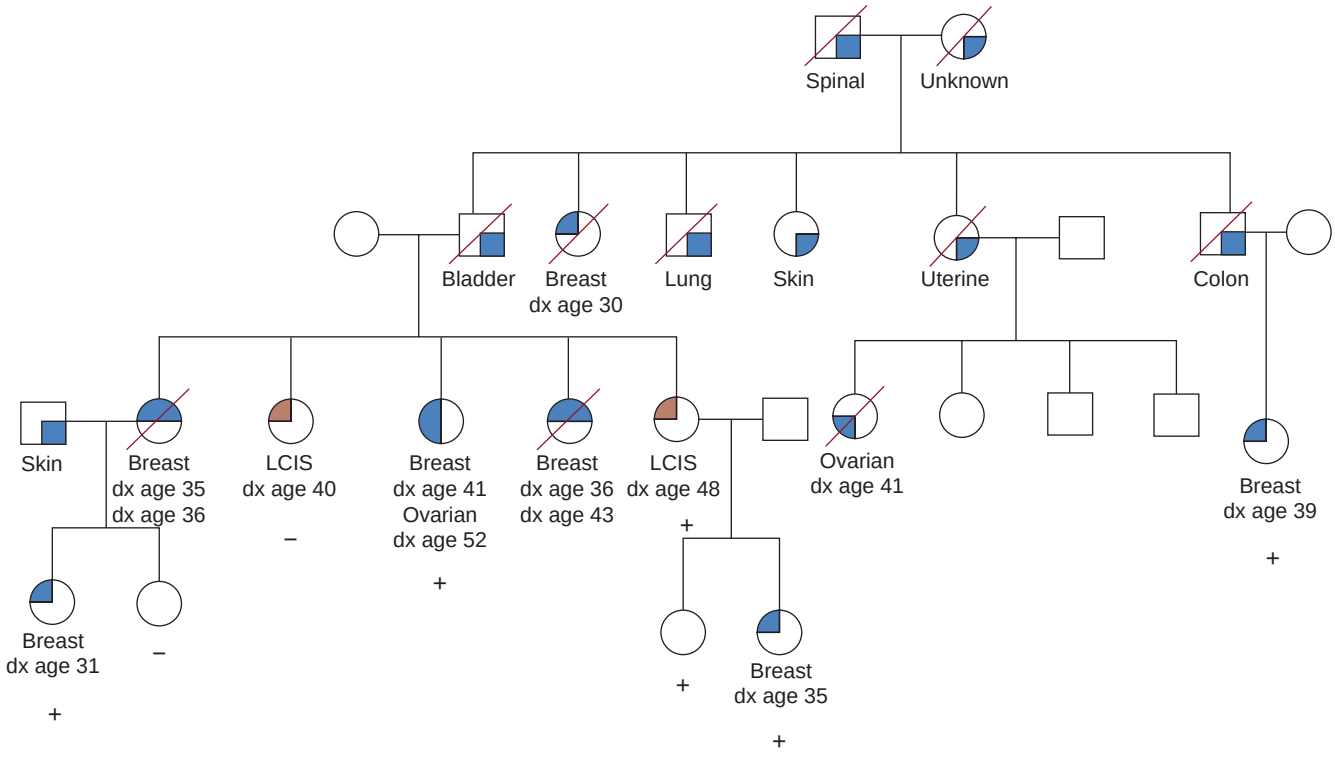

FIGURE 16-1 A kindred with a *BRCA1* mutation. □, Unaffected cancers are indicated with dark shading of symbols;(+), known *BRCA1* mutation carriers;(–), individuals who tested negative; all others are untested. Deceased individuals are indicated with a diagonal line through the symbol. One family member with lobular carcinoma *in situ* (LCIS) tested positive, and the other tested negative, consistent with previous reports suggesting LCIS is not a component of *BRCA1*-related cancer susceptibility.

presupposes a low risk in the general population, which is not the case for breast cancer. As a result, breast cancer in women from families that have a known *BRCA1* mutation but who do not themselves carry the mutation is not uncommon. Such women are termed *phenocopies,* because they have the phenotype associated with the gene mutation but are noncarriers. This situation is illustrated in the pedigree shown in Figure 16-1, a typical pedigree of a family known to carry a mutation in *BRCA1.* As long as the gene being examined is not on the X or Y sex-related chromosomes, the sex of the carrier is irrelevant. However, in the case of autosomal dominant inheritance of breast cancer, significant sex-related differences in the penetrance of mutations exist. Therefore, although mutations occur equally in male and female populations, breast cancer is much more common in women with *BRCA1* or *BRCA2* mutations than in men, but male breast cancer is part of the spectrum of both *BRCA1* and *BRCA2.*

TUMOR SUPPRESSOR GENES

Two fundamental types of genetic alterations responsible for the development of the malignant phenotype are found in cancer cells: (a) activation of protooncogenes producing a "gain of function" in the affected cell and (b) inactivation of tumor suppressor genes producing a "loss of function" in the cell. Some tumor suppressor genes are important in cell-cycle regulation, normally functioning as checks on cell growth; others are critical elements in the cellular response to DNA damage, preventing the propagation of mutations in other critical genes. Mutated tumor suppressor genes lose these regulatory functions, leading to malignant transformation. However, because all individuals are born with two alleles of every gene, an explanation was needed for the development of cancer in large numbers of individuals who had only a single inherited mutation in a tumor suppressor gene. In 1971, Knudson (11) put forward the "two-hit hypothesis," suggesting that cancer arises as a result of two genetic events occurring in the same cell, inactivating both copies of a given tumor suppressor gene. In the case of sporadic cancer (i.e., cancer occurring in women without a family history of the disease), the likelihood that two events would occur in the same gene in the same cell is quite low. However, individuals from "cancer families" inherit an inactivating mutation in one allele of the implicated tumor suppressor gene in all cells (i.e., a germline mutation); therefore, only one somatic (noninherited) event is required to inactivate the single remaining copy, making the development of cancer a much more common event than in individuals born without the "first hit." Of particular relevance to breast cancer are the tumor suppressor genes *TP53, BRCA1,* and *BRCA2.*

HEREDITARY BREAST CANCER SYNDROMES

The study of clinical syndromes that include an increased incidence of breast cancer has provided insight into the mechanisms by which genetic mutations result in the development

of cancer. The most frequently identified pedigrees contain site-specific breast cancer (i.e., breast cancer in these families is not found in association with inherited susceptibility to other cancers, such as ovarian) and are thought to represent the effect of a single genetic abnormality; *BRCA1* and *BRCA2* are the best studied examples. Breast cancer also has been noted to occur in association with other cancers. The occurrence of breast cancer in association with diverse childhood neoplasms in the Li-Fraumeni/SBLA (*soft-tissue* and bony sarcomas, *b*rain tumors, *l*eukemias, and *a*drenocortical carcinomas) (12) syndrome and the association between breast and ovarian cancer represent some of the most intensively studied examples. An elevated frequency of breast cancer may occur in patients with hereditary syndromes that include nonmalignant manifestations as well, such as Cowden's disease and Muir-Torre syndrome (13–15). An increasing number of moderate-risk genes—*ATM, CHEK2, PALB2,* and *BRIP1*—are being identified that lead to an increased risk of cancer of twofold to fourfold (8). Finally, numerous common variants (population frequency 5% to 50%) in genes, which cause a very modest (1.1–1.5 fold) elevation in risk, are just starting to become part of the landscape of breast cancer susceptibility (8) (Table 16-1).

BRCA1 and *BRCA2*

In 1990, chromosome 17q21 was identified as the location of a susceptibility gene for early onset breast cancer, now termed *BRCA1* (16). Shortly thereafter, linkage between the genetic marker D17S74 on 17q21 and the appearance of ovarian cancer in several large kindreds was also demonstrated (17). Initial estimates suggested that *BRCA1* mutations were responsible for more than 90% of breast cancer cases in families with apparent autosomal dominant transmission of breast cancer and at least one case of ovarian cancer, and 45% of cases in families with breast cancer only. However, the percentage of site-specific breast cancer cases attributed to *BRCA1* mutations rose to almost 70% if the median age at onset of breast cancer in the families was younger than 45 years (18), demonstrating the critical importance of the characteristics of a family to the likelihood that a *BRCA1* mutation will be detectable. The *BRCA1* gene was identified in 1994 (19) and encodes a novel protein now known to be important in the cellular response to DNA damage (20).

Initial progress toward the identification of a second breast cancer susceptibility gene came from a linkage analysis of 22 families with multiple cases of early onset female breast cancer and at least one case of male breast cancer. Linkage between male breast cancer and polymorphic genetic markers on chromosome 13q12-13 identified the *BRCA2* locus (21). In 1995, the partial sequence of *BRCA2* and six germline mutations that truncated the putative *BRCA2* protein were identified (22). Shortly thereafter, the complete structure of the *BRCA2* gene was published (23).

BRCA1 is composed of 24 exons (coding regions) and is translated into a protein consisting of 1,863 amino acids (Fig. 16-2A). The coding region of *BRCA2* is 11.2 kb in length and is made up of 26 exons that produce a protein of 3,418 amino acids. The size of these genes is important from a clinical standpoint in the context of genetic testing, because this has made screening for mutations technically demanding and costly. Furthermore, the *BRCA1* gene contains a large number of repetitive elements that facilitate the generation of large deletions and duplications. For example, disease-associated deletions account for 36% of *BRCA1* mutations in the Netherlands (24). However, the use of modern next-generation DNA sequencing methodologies are already overcoming these technical and cost issues.

More than 500 coding region sequence variations have been detected in *BRCA1* and 250 in *BRCA2*. A listing and description of most known mutations is available on the Breast Cancer Information Core (BIC) website (research.nhgri.nih.gov/bic/). Several similarities between *BRCA1* and *BRCA2* are apparent. No mutation hot spots in either have been detected. Most unequivocally confirmed mutations reported to date are truncating mutations, adding little in the way of clues for defining functional regions. Finally, few mutations have been identified in either gene in sporadic breast cancers. However, it has been suggested that the pathways in which the *BRCA1* and *BRCA2* proteins act may be disrupted in sporadic cancer, a phenotype that has been termed "BRCAness" (25).

Estimates of *BRCA1* and *BRCA2* mutation prevalence in unselected patients with breast cancer are in the range of 2% to 3%. In a large population-based study of white and black cases (n = 1,628) and controls (n = 674) in North America for ages 35 to 64, *BRCA1* mutations were detected in 2.4% of cases and 0.04% of controls while *BRCA2* mutations were detected in 2.3% of cases and 0.4% of controls. *BRCA1* mutations were more common in white (2.9%) than black (1.4%) of cases, while *BRCA2* mutations were slightly more frequent in black (2.6%) than white (2.1%) cases (7).

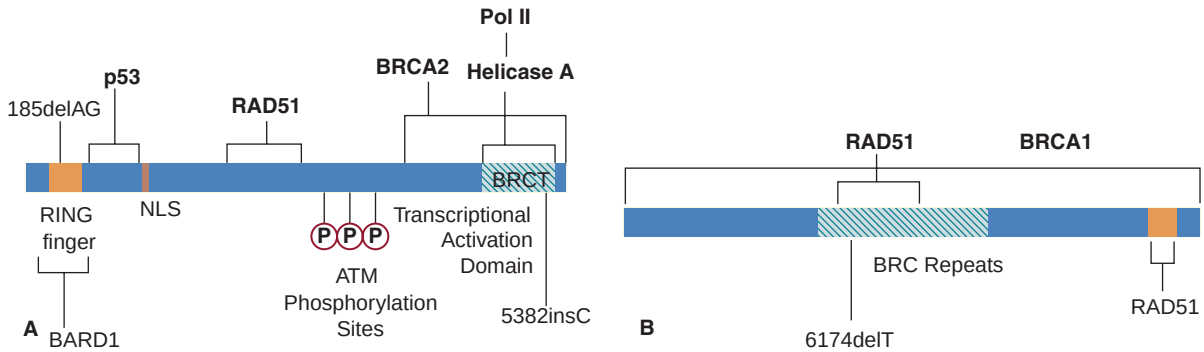

FIGURE 16-2 **(A)** Functional domains of *BRCA1*. An idiogram of the 220-kd *BRCA1* protein depicting known functional domains. Domains are shown as filled areas within the diagram. The two common mutations found in the Ashkenazi Jewish population (185delAG and 5382insC) are indicated. **(B)** Functional domains of *BRCA2*. The carboxy terminal RAD51 binding site, and the central RAD51 binding BRC repeats are as depicted. The common mutation (6174delT) found in the Ashkenazi Jewish population is indicated (51,52).

In families identified through clinics treating high-risk breast cancer, *BRCA1* and *BRCA2* mutations are found in up to 55% of families with both breast and ovarian cancer and up to 75% of families with both breast and ovarian cancer in the same individual, underscoring the importance of the family history in determining the likelihood that a *BRCA1* mutation is present (26). Population-based DNA sequencing studies, now feasible due to new technology, should give much more accurate estimates of mutation prevalence.

Population Genetics of BRCA1 *and* BRCA2

The population genetics of *BRCA1* and *BRCA2* reflect several basic evolutionary principles. Each gene has undergone multiple independent mutations and these mutations have migrated with the populations in which they originally occurred. Certain "founder mutations" are known to exist in *BRCA1* and *BRCA2,* which have occurred in specific ethnic populations many generations in the past. They persist because the development of disease usually occurs after childbearing age, so individuals carrying these mutations are able to pass them on to subsequent generations with little impact of the mutated alleles on survival of the species.

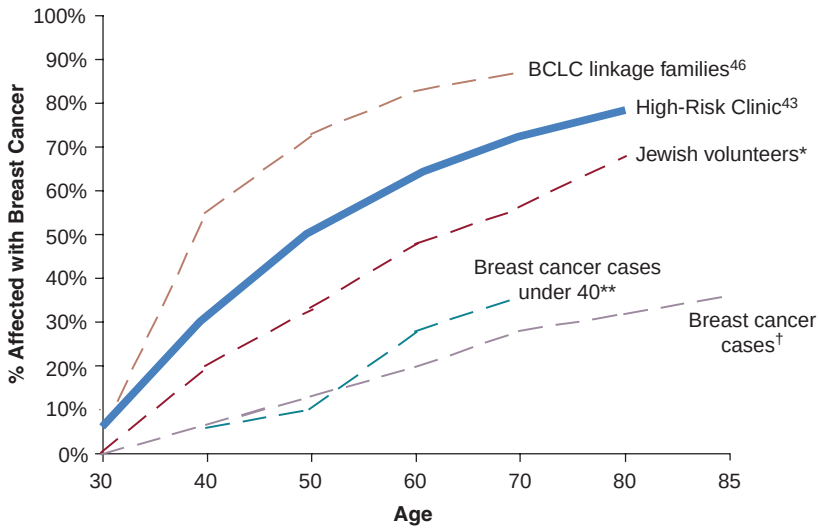
Founder mutations have been identified in a number of populations. A comprehensive review by Szabo and King (27) reveals the similarities and differences in mutation rate, penetrance, and nature of the mutations among various population groups. The proportion of high-risk families with breast or ovarian cancer appears to vary widely by population group. Mutations in *BRCA1* are most common in Russia (79% of families with breast and/or ovarian cancer), as compared to Israel (47% of families) and Italy (29%). *BRCA2* mutations appear to be more common than *BRCA1* mutations only in Iceland, where a single mutation accounts for virtually all of the *BRCA2*-associated breast and ovarian cancer cases (28).

BRCA1 and *BRCA2* mutations among the Ashkenazi Jewish population are among the most intensively researched, as the presence of founder mutations facilitates these studies. The two Ashkenazi Jewish founder mutations in *BRCA1* are 185delAG and 5382insC, occurring in 1 in 8 and 1 in 12 individuals of Ashkenazi descent, respectively (29,30). One of these two mutations, 6174delT in *BRCA2,* occurs in more than 2% of the Ashkenazi Jewish population. When compared to the estimated frequency of *BRCA1* mutations in an unselected white population of about 0.1% (31), this finding suggested the presence of a "founder effect" in the Ashkenazi Jewish population, documented with haplotype studies (32). Analysis of germline *BRCA1* mutations in several cohorts of Jewish women suggests that more than 20% of Jewish women developing breast cancer before age 40 carry the 185delAG mutation (33). Even more strikingly, estimates suggest that 30% to 60% of all Ashkenazi Jewish women with ovarian cancer carry one of the *BRCA1* or *BRCA2* founder mutations (34). Up to 90% of mutations identified in women of Ashkenazi Jewish descent are one of the three founder mutations, although other *BRCA1* and *BRCA2* mutations have also been detected (35). Based on these data, individuals of Ashkenazi descent choosing to undergo genetic testing should first be tested for the three Ashkenazi Jewish founder mutations. Full sequencing can be reserved for those individuals at particularly high risk of having a *BRCA1* or *BRCA2* mutation.

Though still limited, data are now available on the prevalence of *BRCA1* and *BRCA2* mutations in some nonwhite populations. Interestingly, many *BRCA1* and *BRCA2* mutations in African Americans appear unique to this ethnic/racial group (36) and in addition, genetic testing for *BRCA1* and *BRCA2* mutations in the African American population is complicated by a high rate of variants of unknown significance. More data are also becoming available from the Hispanic population, with similar features predicting pathogenic mutations (37). Comprehensive data from other ethnic groups or geographic areas are lacking.

Cancer Risks for BRCA1 *and* BRCA2 *Mutation Carriers*

Cancer risk estimates for *BRCA1* and *BRCA2* mutation carriers have been controversial (38). Estimates based on the highly penetrant families used to find these genes are high (as they were selected to be), likely due to coexistent genetic and environmental modifiers that may increase the risk of disease. However, in studies of lower-risk cohorts, such as population-based studies or cohorts of women with breast cancer unselected for family history, the lifetime risk of breast cancer was much lower (39). For this reason, the estimation of the risk of breast cancer in *BRCA1* mutation carriers has been variable with an estimate of pooled data of 65% (40) (Fig. 16-3). Estimates of contralateral breast cancer occurrence are as high as 60% (41). Cumulative risk of ovarian cancer in *BRCA1* carriers has been reported to be



*Data from Struewing JP, Hartge P, Wacholder S, et al. *N Engl J Med* 1997;336:1401–1408.
**Data from Fodor FH, Weston A, Bleiweiss IJ, et al. *Am J Hum Genet* 1998;63:45–51.
†Data from Hopper JL, Southey MC, Dite GS, et al. *Cancer Epidemiol Biomarkers Prev* 1999;8:741–747.

FIGURE 16-3 Breast cancer risk estimates associated with *BRCA1* mutations vary depending on sample ascertainment. Breast cancer risks (penetrance) will be highest in families selected to have multiple affected family members for use in linkage studies (27) and lowest in population-based ascertainments (29). Sample sets collected in breast cancer risk evaluation clinics would be expected to be intermediate between these two ascertainments; recent data have confirmed that hypothesis (30). An ascertainment of Ashkenazi Jewish volunteers also falls between high- and low-risk penetrance estimates, again because this sample is likely a mix of population-based ascertainment and individuals who volunteer because they were aware of a strong family history (31).

between 27% (40) and 45% (42,43), and there is also a significantly increased risk of fallopian tube cancer and reports of an increase in uterine and cervical cancer, stomach cancer, a twofold to threefold increase in pancreatic cancer, a possible twofold increase in colon cancer, and a 17-fold risk of testicular cancer (43,44); however, these risks have not been consistently seen across studies. Prostate cancer risk does not appear increased, although the disease may occur at an earlier age. Male breast cancer is also seen in association with *BRCA1* mutations (43).

BRCA2 has a cancer risk profile similar, but not identical, to *BRCA1*. Lifetime breast cancer risk for *BRCA2* mutation carriers is estimated to be 45% to 84%, with lifetime ovarian cancer risk in the range of 10% to 20% (40,45) and *BRCA2* mutations are associated with a 6% lifetime risk of male breast cancer (7). Male *BRCA2* mutation carriers have an increased risk of prostate cancer. Pancreatic cancer also is associated with *BRCA2* mutations (46), with an RR of 3.5. The incidence of *BRCA2* germline mutations in patients with familial pancreatic cancer (two first-degree relatives with pancreatic cancer) may be as high as 20% (47). *BRCA2* mutation carriers also appear to have an increased risk of stomach cancer (RR = 2.6), gallbladder and bile duct cancers (RR = 5.0), and malignant melanoma (RR = 2.6) (46).

Modifiers of BRCA1 *and* BRCA2 *Mutations*

Although germline mutations in *BRCA1* and *BRCA2* confer a high risk of breast cancer, a great deal of variability in cancer risk among individuals both between and within families has been observed. The discovery of environmental or genetic factors that modify the penetrance of *BRCA1* and *BRCA2* mutations may clarify our understanding of their mechanism of action and provide additional information with which to counsel individuals with *BRCA1* and *BRCA2* mutations. Furthermore, factors that affect familial breast cancer risk in the general population could presumably affect breast cancer risk in *BRCA1* and *BRCA2* mutation carriers. By far the most important modifiers identified for *BRCA1* and *BRCA2* mutation carriers are prophylactic oophorectomy and the use of tamoxifen for chemoprevention. Prophylactic oophorectomy decreases the risk of ovarian cancer by 95% but importantly also decreases the risk of breast cancer by 50% (48,49). The magnitude of the benefit of oophorectomy (and estrogen deprivation) on breast cancer risk is seen in both in *BRCA1* and *BRCA2* mutation carriers, despite that 90% of *BRCA1*-related breast cancers are ER negative. In retrospective studies, tamoxifen has been shown to decrease the risk of contralateral breast tumors by 50% in both *BRCA1* and *BRCA2* mutation carriers (50). To date, many reproductive factors have been examined as modifiers in *BRCA1* and *BRCA2* mutation carriers, including parity, age at first pregnancy, oral contraceptive use, and tubal ligation (51). Of all these, perhaps the most clinically relevant are the protective effects of oral contraceptives on ovarian cancer risk.

Genetic factors are likely to modify the risk of cancer in *BRCA1* and *BRCA2* mutation carriers. However, most studies examining this have been limited in size and statistical power. Convincingly validated modifiers of *BRCA1* and *BRCA2* penetrance have yet to be identified. However, consortia of investigators are now being established to systematically investigate candidate genetic modifiers. One such group, the Consortium of Investigators of Modifiers of *BRCA1* and *BRCA2* (CIMBA), contains about 30 affiliated groups who together have collected DNA and clinical data from approximately 10,000 *BRCA1* and 5,000 *BRCA2* mutation carriers (52). Initial results have provided support for the role of a number of gene variants in affecting penetrance in mutation carriers. The identification of proven genetic modifiers of breast cancer risk for *BRCA1* and *BRCA2* mutation carriers may prove useful for the determination of individualized risk of cancer among carriers.

Biological Function(s) of BRCA1 *and* BRCA2

BRCA1 and BRCA2 Proteins: BRCA1 is a nuclear protein with two important regions of sequence similarity to known functional motifs. These regions are the RING domain at the beginning of BRCA1 and the BRCT motif at the carboxyl terminus (Fig. 16-4A). The 42 amino acid RING domain (so called because it was initially described in a *R*eally *I*nteresting *N*ew *G*ene) near the amino terminus of BRCA1 binds zinc (7). RING domains mediate interactions between proteins involved in polyubiquitination, a key cellular process regulating protein degradation that is essential in cell growth and differentiation (53). The BARD1 (BRCA1-associated RING domain-1) protein binds the BRCA1 RING domain (54) which confers substantial ubiquitin ligase activity on the complex. The BRCA1–BARD1 heterodimer can therefore add polyubiquitin chains to specific lysine residues of target proteins, targeting those proteins for modification and degradation (55). The BRCT (*br*east *c*ancer-1 *t*erminus) domain was first recognized as a cellular motif by its presence in BRCA1, but it is now known to be highly evolutionarily conserved and present in more than 40 other proteins involved in response to DNA damage, including scRAD9 in yeast and BARD1; this domain functions as a phospho-protein docking motif (56).

Like BRCA1, BRCA2 is a nuclear protein. However, the structure of BRCA2 initially provided fewer insights into its function (Fig. 16-2B). Subsequently, major structural motifs recognized in BRCA2 are the eight tandem BRC repeats in the central portion of the protein which mediate

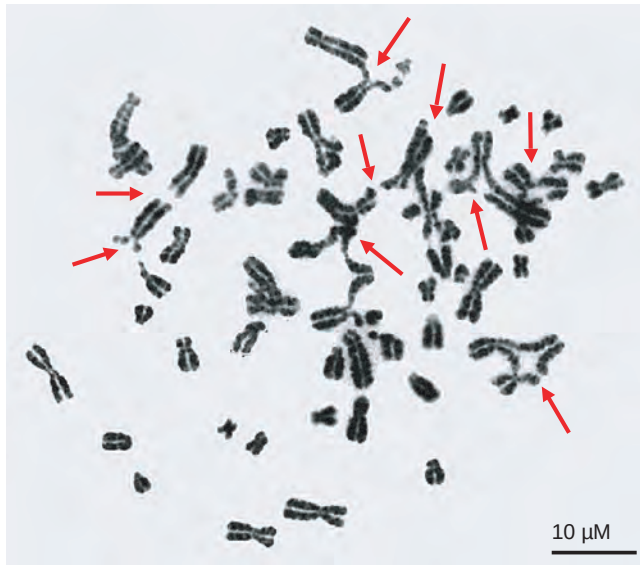


FIGURE 16-4 *BRCA2*-deficient cells are highly sensitive to DNA cross-linking agents. Cells defective in *BRCA2* function show a high degree of chromosome instability, including chromosome breaks and radial chromosomes (51,52,139). These aberrations accumulate spontaneously but are highly exascerbated by DNA-damaging agents that induce DSBs, in particular DNA cross-linking agents. Shown here are the effects of treating CAPAN1 cells, which carry a loss of function c.6174delT *BRCA2* allele and no wild-type allele, with the DNA cross-linking agent mitomycin C. *Arrows* indicate chromosomal aberrations.

the critical interaction of BRCA2 and RAD51 (22,23). TR2, another binding site for RAD51 exists at the carboxyl terminus of BRCA2 (57). The structure of a large portion of the C-terminus of *BRCA2* has been determined, which revealed the presence of a single-strand and double-strand DNA binding domain (58).

Roles of BRCA1 and BRCA2 in the Response to DNA Damage: The *BRCA1* and *BRCA2* genes encode large proteins that likely function in multiple cellular pathways including transcription, cell cycle regulation (59). However, it is the roles of BRCA1 and BRCA2 in the maintenance of genome stability DNA repair that have been best documented (20). Both proteins suppress illegitimate recombination and play important roles in the repair of double-stranded DNA breaks as a central part of this function. BRCA1 participates more broadly in this process than BRCA2, with a role both in sensing and signaling the presence of damaged DNA and in assisting in repair of the damage locally. When present in normal cells, BRCA1 enhances transcription of other important genes in the process, regulates the S, G_1, and G_{2M} checkpoints, ensuring that cells with damaged DNA damage do not replicate, alters chromatin structure and nucleosome organization at the local site of damage, facilitating access by repair complexes, and promotes use of the error-free repair pathway of homologous recombination (HR) -mediated repair rather than the error-prone process of nonhomologous end joining (NHEJ) (20).

BRCA2 has a more limited role in maintaining genome stability, functioning only at the local site of repair by regulating the activity of RAD51, an essential component of error-free HR-mediated repair of double-stranded breaks (20). In particular, BRCA2 affects the choice between the two HR subpathways—the conservative gene conversion (GC) mechanism and the error-prone single-strand annealing (SSA). In BRCA2 mutant cells, GC is suppressed leading to the preferential use of NHEJ and SSA. The physical interaction between BRCA2 and RAD51 is essential for error-free DSB repair. BRCA2 is required for the localization of RAD51 to sites of DNA damage, where RAD51 forms the nucleoprotein filament required for recombination. Foci of RAD51 protein are apparent in the nucleus after certain forms of DNA damage and these likely represent sites of repair by HR; BRCA2-deficient cells do not form RAD51 foci in response to DNA damage (60).

For both BRCA1 and BRCA2 it is the failure to faithfully repair DNA breaks that underlies the genomic instability in BRCA1 and BRCA2 mutant cells (Fig. 16-5). Cells defective in BRCA1 and BRCA2 function show a high degree of chromosome instability, including chromosome breaks and radial chromosomes (60–62). These aberrations accumulate spontaneously but are exacerbated by DNA damaging agents that induce DSBs, in particular DNA cross-linking agents (Fig. 16-4). These observations eventually provided critical information for the identification of *FANCD2*, mutated in Fanconi's anemia type D2, as BRCA2 (9). This discovery was made in part due to the observation that cells from patients from the Fanconi complementation group D2 have the same unusual chromosomal structures seen in BRCA2-deficient cells.

Other Functions of BRCA1: The role of BRCA1 as a transcriptional coactivator—a protein that facilitates transcription of genes in the presence of direct transcriptional activators—is a critical component of its ability to transduce signals, activating DNA damage response pathways. In unraveling this function, BRCA1 first was shown to interact with two key components of the cell transcription machinery of the cell including the RNA polymerase holoenzyme (63). In addition, the carboxy-terminus BRCT repeats act as transcriptional activation domains (64). *BRCA1* has been shown to be an important factor in the transcriptional regulation of ER (65). In the absence of functional *BRCA1* ER is no longer expressed and this is could be the explanation of the ER negative, basal, phenotype of tumors arising in *BRCA1* mutation carriers (25). Recently additional novel functions have been proposed (66).

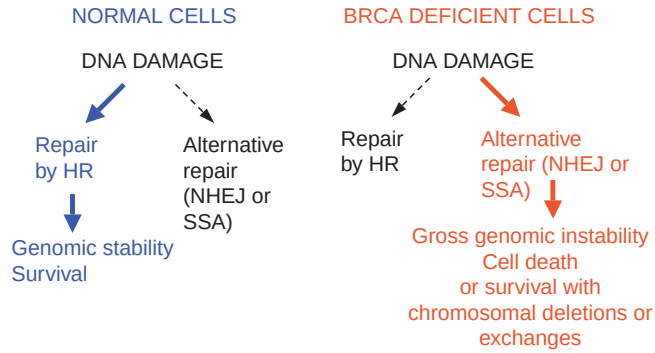

FIGURE 16-5 Loss of functional BRCA1 or BRCA2 affects the choice of DNA double-strand break repair pathway. DNA DSBs are repaired in normal cells, in part, by HR-based mechanisms. Functional *BRCA1* and *BRCA2* proteins are required for efficient repair by HR and genomic stability. In the absence of BRCA1 or BRCA2 alternative repair pathways, such as NHEJ and SSA, are utilized leading to cell death or survival with genomic damage (20).

CLINICAL FEATURES OF HEREDITARY BREAST CANCER

Breast cancers caused by mutations in high-penetrance susceptibility genes have several distinctive clinical features: Age at diagnosis is considerably younger than in sporadic cases, the prevalence of bilateral breast cancer is higher, and associated tumors are noted in some families. Associated tumors may include ovarian, colon, prostate, pancreatic, and endometrial cancers, among others, as well as sarcomas and breast cancer in male family members. Evidence reviewed later in this chapter also supports the notion that tumors arising in the setting of inherited mutations in susceptibility genes have different characteristics with regard to grade, estrogen receptor (ER) status, and molecular profile. Whether these cancers respond differently to treatment or are associated with a worse prognosis than sporadic tumors remains controversial.

Histopathology of *BRCA1*- and *BRCA2*-Associated Breast Tumors

In contrast to sporadic breast cancers, those arising in *BRCA1* mutation carriers are frequently, although not exclusively, negative for the estrogen receptor (ER) and the growth factor receptor, HER2, but mostly express basal cytokeratins (67–68). In support of this, gene expression profiling analysis indicates relative downregulation of ER response genes and the upregulation of proliferation associated genes and basal cytokeratins. This phenotype leads to the clustering of these tumors with sporadic cancers of the basal-like subtype (25,69). A mechanism by which loss of *BRCA1* function likely mandates lack of ER and ER regulated

gene expression has been suggested. Functional *BRCA1* appears necessary for the expression of ER by directly binding and transactivating the *ER* gene promoter. When *BRCA1* is lost in tumors, ER can no longer be expressed and, as a result, resistance to tamoxifen and other ER-directed therapies arises (65).

BRCA2 mutation associated breast cancers are typically quite different to those arising in *BRCA1* mutation carriers and are generally much more similar to sporadic cases. Specific morphological features such as pushing margins and a greater degree of tubule formation have been noted. The ER and HER2 status of tumors, are not obviously different from the spectrum of sporadic cancers invasive ductal cancers (70). However, a recent study has suggested that *BRCA2* associated tumors are of higher grade, are more frequently ER positive and are less likely to overexpress HER2 compared to control sporadic tumors matched for age and ethnicity. In summary *BRCA2* cancers tend to be a high grade proliferative form of luminal breast cancer.

Influence of *BRCA1* or *BRCA2* Mutation Status on Breast Cancer Prognosis

This remains a controversial issue in part because of the diversity of the design of the studies that have been used. A review of most of these concluded that there was no convincing data, in women with breast cancer, that *BRCA1* or *BRCA2* mutation status conferred adverse prognosis, other than for contralateral breast cancer occurrence (71). Since this review was published two other relevant studies have been reported. Moller et al. (72) studied patients who developed breast cancer while enrolled on prospective breast cancer surveillance programs because of strong family history of breast cancer and mutation status was confirmed by re-sequencing. *BRCA1* mutation was associated with worse prognosis even in classically low risk node negative patients. Rennert et al. (73) conducted a very large population study in Israel in which all new cases of invasive breast cancer in the country in 1987 and 1988 were sought. Case records and pathology samples were available on 1545 women and tumor DNA was extracted and analyzed for the three Ashkenazi founder mutations in *BRCA1* and *BRCA2*. No difference in overall or breast cancer specific survival was noted for *BRCA1* or *BRCA2* mutation carriers when compared with non-carriers.

Influence of *BRCA1* or *BRCA2* Mutation Status on Response to Therapy

Rennert et al. noted two important observations in subgroups of their large Israeli study (73). First, there was a statistically significant correlation between *BRCA1* mutation status and a more favorable prognosis in women receiving adjuvant chemotherapy when compared with non-carriers. Second, women presenting with tumors less than 2 cm had a worse prognosis if they were *BRCA1* carriers. This is intriguing given the similar results of another retrospective study of similar design conducted in 505 Jewish women in New York and Montreal with small tumors suitable for breast conserving surgery (74). Robson et al. (74) found the presence of an Ashkenazi founder mutation in *BRCA1* to be associated with adverse breast cancer survival when compared with non-carriers (62% at 10 years versus 86%; $p < .0001$). *BRCA1* status predicted breast cancer mortality only among women who did not receive chemotherapy (hazard ratio 4.8, 95% confidence interval 2.0–11.7; $p = .001$). Whether this phenomenon relates directly to *BRCA1* gene function or some other aspect of the basal-like breast cancer phenotype associated with *BRCA1* mutated breast cancer is not clear. A similar adverse prognosis normalized by an apparent increase in sensitivity to chemotherapy in sporadic "basal-like" breast cancer has also been reported in a small study (75) and sporadic "basal-like" breast cancers have been noted to have high response rates to anthracycline based chemotherapy, in common with the other major ER negative subtype, the HER2 positive cancers (76). There are few data relating to *BRCA1* or *BRCA2* genotype specific effects on normal tissue chemotherapy toxicity. Retrospective data suggest no evidence of increased complications (77). Taken together these data suggest that *BRCA1* mutation carriers who present with small and node negative breast cancers may be at more significant risk of micro-metastatic breast cancer than noncarriers. This may explain a worse prognosis if chemotherapy is avoided in what is regarded as a classically lower-risk population. A greater sensitivity to adjuvant chemotherapy seems to correct for any adverse baseline prognosis.

A potential concern, because of the role of *BRCA1* and *BRCA2* in the DNA damage response, is response to radiotherapy. A mature analysis of *BRCA1* and *BRCA2* carriers and matched controls treated with breast-conserving therapy and radiotherapy and followed for a median of 6 to 8 years has shown no increase in ipsilateral breast tumor recurrence in carriers who had had a prophylactic oophorectomy when compared to matched controls. An increase was noted in women who did not have prophylactic oophorectomy (78). As stated above, contralateral breast cancers were significantly more common in *BRCA1* and *BRCA2* mutation carriers than controls whether or not prophylactic oophorectomy was performed. There is, however, no evidence of increase in normal tissue radiation toxicity associated with carrier status (78,79).

What Is the Most Effective Chemotherapy for *BRCA1*- and *BRCA2*-Associated Breast Cancer?

A number of clinically used agents appear to be selective for killing cells defective in *BRCA1* or *BRCA2*. These include the DNA cross-linking agents (e.g., carboplatin, cisplatin, and mitomycin C) (60). This suggests an increased sensitivity to lesions that damage DNA in ways that interfere with DNA replication forks and which subsequently require DNA repair by homologous recombination for fork restart. This is consistent with the key role that *BRCA1* and *BRCA2* play in the Fanconi anaemia network (66), the hallmark of which is extreme cellular sensitivity to DNA cross-linking agents. The sensitivity of *BRCA1*- and *BRCA2*-deficient cancers to platinum salts is strongly supported by observations in genetically modified mice (80).

It has been suggested that *BRCA1* may be required to mediate paclitaxel induced cell death as loss of *BRCA1* function leads to microtubule stabilizing agent resistance (81). This contention is supported by uncontrolled retrospective data from patients treated with taxane-based neoadjuvant therapy (82). An randomized phase II clinical study testing the efficacy of carboplatin and docetaxel in *BRCA1* and *BRCA2* carriers with advanced breast cancer (www.breakthrough.org.uk/researchcentre/clinical_trials/brca_trial/index.html)(60) is ongoing.

New Therapeutic Approaches to the Treatment of *BRCA1*- and *BRCA2*-Associated Cancers

New therapeutic strategies, based on synthetic lethality, have recently been put forward for the treatment of cancers arising in carriers of mutations in *BRCA1* or *BRCA2* (20,83).

Synthetic lethality is defined as the situation when mutation in either of two genes individually has no effect but combining the mutations leads to death (20). This effect can arise because of a number of different gene–gene interactions. Examples include two genes in separate semiredundant or cooperating pathways and two genes acting in the same pathway where loss of both critically affects flux through the pathway. The implication is that targeting one of these genes in a cancer where the other is defective should be selectively lethal to the tumor cells but not toxic to the normal cells. In principal, this should lead to a large therapeutic window (20).

The synthetic lethal pair in the approach that is being developed is the interaction between HR and the single-strand break (SSB) DNA repair pathway (84). Endogenous base damage, including SSBs, is the most common DNA aberration and it has been estimated that the average cell may repair 10,000 such lesions every day. Base excision repair (BER) is an important pathway for the repair of SSBs and involves the sensing of the lesion followed by the recruitment of a number of other proteins. PARP-1 (Poly[ADP]Ribose Polymerase) is a critical component of the major "short-patch" BER pathway. PARP-1 is an enzyme, discovered over 40 years ago (20), that produces large branched chains of poly(ADP) ribose (PAR) from NAD^+ which senses and binds to DNA nicks and breaks. This results in activation of catalytic activity causing poly(ADP) ribosylation of PARP-1 itself as well as other acceptor proteins such as histones. This modification potentially signals the recruitment of other components of DNA repair pathways as well as modifying the activity of proteins (84).

PARP-1 inhibition causes failure of the repair of SSB lesions but does not affect DSB repair (20). However, a persistent DNA SSB encountered by a DNA replication fork will cause stalling of the fork and may result in either fork collapse or the formation of a DSB (20). Therefore, loss of PARP-1 increases the formation of DNA lesions that might be repaired by GC. As loss of function of either *BRCA1* or *BRCA2* impairs GC, loss of PARP-1 function in a *BRCA1* or *BRCA2* defective background likely results in the generation of replication-associated DNA lesions normally repaired by sister chromatid exchange. This is likely to be the explanation of the observation that small molecules PARP inhibitors are highly selectively lethal to cells lacking functional *BRCA1* or *BRCA2* (Fig. 16-6).

These observations suggested a potential new mechanism-based approach for the treatment of patients with *BRCA1*- and *BRCA2*-associated cancers. In these patients, tumor cells lack wild-type *BRCA1* or *BRCA2* but normal tissues retain a single wild-type copy of the relevant gene potentially providing a large therapeutic window. This difference provides the rationale for inhibiting PARP to generate specific DNA lesions that require functional *BRCA1* and *BRCA2* for their repair. This approach is likely to be more specific and to have fewer side effects than standard cytotoxic chemotherapy, as PARP inhibitors are relatively nontoxic and do not directly damage DNA. A number of PARP inhibitors are in clinical development (20).

Phase 1 studies have established the safety of olaparib, a potent PARP inhibitor, as a single agent and shown that significant and durable antitumor responses can be established in patients with BRCA-mutant breast, ovarian, or prostate tumors (85). Furthermore, olaparib does not seems to cause many of the side effects associated with standard chemotherapies. In subsequent phase 2 clinical studies, 40% of patients with breast or ovarian cancer with germline BRCA mutations had a favorable response to the drug (86,87). This is a particularly high response given that the patients in these trials had been heavily pretreated and had become resistant to a range of chemotherapies. Such work has led to a series of additional PARP inhibitors being tested in clinical trials (20). Not all of these trials have shown positive results, which in part may be due to differences in the pharmacological properties of the PARP inhibitors used, the nature of the study population and the trial design (20).

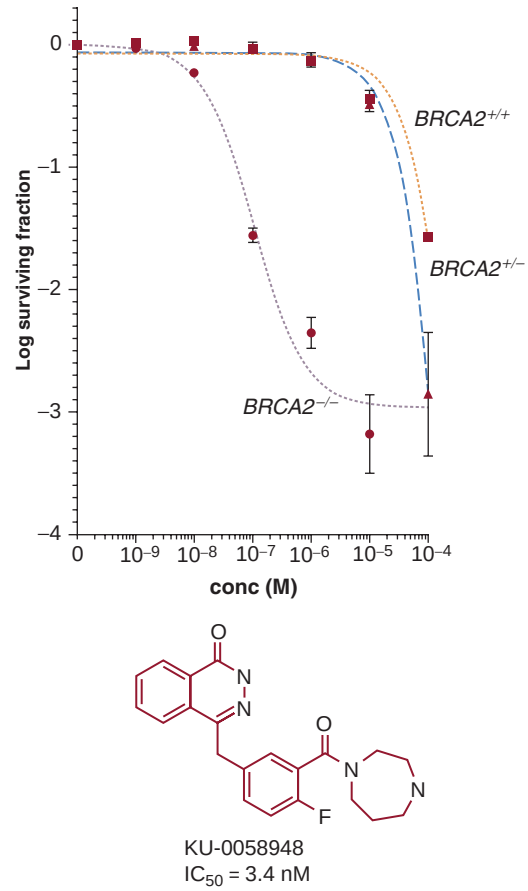

FIGURE 16-6 *BRCA2* mutant cells are exquisitely sensitive to a potent PARP inhibitor (20,83). Clonogenic survival curves of *BRCA2* wild-type, heterozygous, and deficient mouse ES cells after exposure to a range of concentrations of the potent PARP inhibitor KU0058948. *BRCA2*-deficient cells are over 1,000-fold more sensitive than wild-type or heterozygous cells. KU0058948 is based around a phthalazin-1-one core and is a competitive inhibitor with respect to the PARP substrate NAD+ (20).

Mechanisms by which *BRCA2* mutated cells can acquire resistance to PARP inhibitors and platinum salts have been studied (88). These experiments have shown that mutagenic DNA pathways that are up-regulated in the absence of *BRCA2* function may drive intragenic deletion events. These can rarely correct the effect of mutation on the open reading frame and restore expression of a functional *BRCA2* gene (88). These rare events may then be selected for over time in a sensitive population. This potential mechanism of resistance to PARP inhibitors has now been observed clinically in humans (89).

OTHER BREAST CANCER SUSCEPTIBILITY GENES

TP53

Germline mutations in *TP53* result in Li-Fraumeni syndrome (LFS), which was first identified in 1969 in four kindreds with multiple childhood sarcomas and excessive cancer risks (12). Subsequent epidemiologic efforts have identified the major component neoplasms, including breast cancer, soft-tissue sarcomas and osteosarcomas, brain tumors, leukemia, and adrenocortical carcinomas; several additional tumor types are likely to merit inclusion (90). Segregation analysis confirmed the autosomal dominant pattern of transmission of cancer susceptibility, with age-specific penetrance estimated to reach 90% by age 70 years (91). In 1990, germline *TP53* mutations were identified as the cause of LFS (92); approximately 50% of carefully defined families have alterations in *TP53*. The prevalence of germline *TP53* mutations in women with breast cancer diagnosed at younger than 40 years has been estimated at approximately 1%. Although an initial report suggested *CHEK2* mutations were responsible for some cases of LFS and LFS-like syndrome, this finding was not supported by much larger studies showing that *CHEK2* is a low-penetrance cancer susceptibility gene (93).

ATM

Ataxia-telangiectasia is an autosomal recessive disorder characterized by oculocutaneous telangiectasias, cerebellar ataxia, immune deficiency, and a predisposition to leukemia and lymphoma. Both copies of *ATM* (*A-T*, mutated) are mutated in patients with ataxia-telangiectasia (94). *ATM* is a member of a large family of protein kinases, and functions as a checkpoint in response to DNA damage, phosphorylating *TP53* and *BRCA1* in the presence of damaged DNA (94). Conflicting data have existed about whether female *ATM* heterozygotes have an increased risk for breast cancer. Initial studies examining family members of patients with ataxia-telangiectasia observed an increased number of breast cancer cases in obligate and predicted heterozygotes (95). However, the controls in the two largest studies had an unusually low incidence of breast cancer. Other studies have been inconclusive due to two factors: only small numbers of cases were included and in general the whole *ATM* gene was not screened due to its large size. In an attempt to overcome these limitations, Renwick et al. (96) screened the whole *ATM* gene in 443 *BRCA1 and BRCA2* mutation negative familial breast cancer cases and 521 controls. Significantly more *bona fide* ataxia-telangiectasia causing mutations were found in the cases than the controls. These results convincingly establish *ATM* as a breast cancer susceptibility gene.

One controversy that has emerged as a result of the question of breast cancer risk in *ATM* heterozygotes is the use of mammography in women younger than 50 years. Concern over repeated mammography was raised based on data that *ATM* homozygotes (i.e., that have ataxia-telangiectasia) have increased DNA damage from ionizing radiation. This biological defect suggested that the use of mammography for cancer detection should be weighed against the possibility of inducing cancer as a result of radiation exposure. However, *ATM* mutations do not appear to contribute to breast cancers diagnosed following radiation therapy for Hodgkin disease (97) and do not seem to play a role in recurrence following radiation for breast cancer (98). Therefore, magnitude of increased risk for breast cancer due to mammography in *ATM* heterozygotes is unknown and presumably small, and the benefit of detecting a neoplasm in its early stages is large. There has, thus, been almost uniform agreement that screening mammography should be initiated when clinically appropriate regardless of concern over the presence of *AT* mutations.

PTEN

Cowden's syndrome is a rare inherited syndrome in which mutations in *PTEN* are transmitted in an autosomal dominant pattern with variable penetrance. Malignant and benign lesions of the breast along with hamartomas in the gastrointestinal tract; mucocutaneous lesions (including trichilemmomas, papillomatosis of the lips and oral mucosa, and acral keratoses); thyroid abnormalities including goiters, adenomas, and follicular cancer; macrocephaly; uterine fibroids; and ovarian cysts and carcinomas characterize Cowden's syndrome (13). Approximately 75% of affected women have either fibrocystic breasts or mammary fibroadenomas. A marked increase in breast cancer incidence as compared to the general population was first observed in a series of cases of families with Cowden's disease, and subsequently it has been estimated that up to 25% to 50% of women with Cowden's disease may develop invasive breast cancer (13). Male breast cancer also has been reported in families with Cowden's syndrome, although infrequently (13).

STK11 LKB

Peutz-Jeghers syndrome, first described in the 1920s, is characterized by the occurrence of hamartomatous polyps in the small bowel and pigmented macules of the buccal mucosa, lips, fingers, and toes (99). It is an autosomal dominant disorder that has been reported to occur in approximately 1 in 20,000 live births. More recently, it has been associated with an excess incidence of tumors involving the breast, gastrointestinal tract, ovary, testis, and uterine cervix (99). The gene mutated in Peutz-Jeghers syndrome has been identified on chromosome 19 (100) and is *STK11/LKB1,* a tumor suppressor gene that encodes a protein kinase. Two studies have attempted to define the degree of cancer risk associated with the syndrome. Giardiello et al. (99) described a cohort of 31 patients followed from 1973 to 1985. Forty-eight percent of the patients developed cancer during that interval: Four developed gastrointestinal tract cancer and 10 developed non–gastrointestinal tract cancer, representing an RR 18 times that of the general population (99). An elevated risk of breast and gynecologic cancers has been reported in women with Peutz-Jeghers syndrome (101).

CHEK2

CHEK2 is located on chromosome 22, and encodes a cell-cycle checkpoint kinase that is implicated in DNA repair. An initial study suggested that families with LFS that lacked an identifiable *TP53* mutation had germline *CHEK2* mutations (93). However, there are now data providing strong evidence that *CHEK2* is not a high-penetrance cancer susceptibility gene in these families (101). The possibility that *CHEK2,* specifically the *CHEK2* 1100delC mutation, is associated with an increased risk of breast cancer was explored in a large multi-institutional study (102). Of those individuals with familial non-*BRCA1* and *BRCA2* breast cancer, 5.1% carried a *CHEK2* 1100delC mutation, compared to 1.4% of sporadic breast cancers, and 1.1% of controls ($p < 10^{-7}$) providing evidence that germline *CHEK2* mutations confer a twofold risk of breast cancer (95% CI). In addition, *CHEK2* 1100delC was found in 13.5% of individuals with breast cancer from families known to be negative for *BRCA1* or *BRCA2* mutations with at least one male breast cancer case (102). Thus, this mutation is associated with an RR of 10 for male breast cancer.

MLH1 and *MSH2*

Muir-Torre syndrome, a variant of hereditary nonpolyposis colon cancer (HNPCC, also called *Lynch syndrome type II*), is the eponym given to the association between multiple skin tumors and multiple benign and malignant tumors of the upper and lower gastrointestinal and genitourinary tracts (103). Many of the manifestations of Muir-Torre syndrome are common lesions (basal cell carcinomas, keratoacanthomas, and colonic diverticula) in distributions similar to that in the general population but with earlier age at onset in affected individuals. Women with the syndrome reportedly have an increased tendency to develop breast cancer, particularly after menopause, although lifetime risk has not been calculated (104). Multiple genes responsible for HNPCC have been described, including *MLH1* and *MSH2* (104). Mutations in these genes are thought to lead to the development of HNPCC through accumulation of DNA replication errors and associated subsequent genome instability (104).

PALB2

PALB2 was originally identified as a protein which interacts with the N-terminal region of *BRCA2* (105). This association is essential for *BRCA2* function and *PALB2* deficient cells are defective in double-strand break repair HR and sensitive to DNA cross-linking agents. These properties resemble genes involved in the Fanconi Anemia network and in fact biallelic mutations in *PALB2* cause Fanconi Anemia type N (106). A role for *PALB2* mutations in breast cancer susceptibility was established in two studies. Rahman et al. (107) identified five different monoallelic *PALB2* truncating mutations in 10 individuals with familial breast cancer; it was estimated that these mutations conferred a 2.3-fold elevated risk of breast cancer. In a separate study, a founder *PALB2* mutation in Finland was identified which appears to be associated with an approximately fourfold risk (108).

BRIP1

BRIP1 is a nuclear *BRCA1* interacting protein originally referred to as *BACH1* (109). This protein is a helicase and interacts with *BRCA1* via the BRCT-motif and contributes to its DNA repair functions. Like *PALB2, BRIP1* is implicated in Fanconi anaemia; *BRIP1* is the *FANCJ* gene. Seal et al. (110) identified constitutional truncating mutations of the *BRIP1* gene in individuals with breast cancer from *BRCA1 and BRCA2* mutation-negative families. These were significantly more common in this group than in a control population. It was estimated that *BRIP1* mutations confer a relative risk of breast cancer of about 2.

Low-Penetrance Breast Cancer Susceptibility Genes

Large collaborative studies using genome-wide association studies in thousands of breast cancer patients have led to the discovery of multiple genetic variants (SNPs) conferring relatively small risks of breast cancer on individuals. Some of these are within or near known genes such as *FGFR2, TOX3, MAP3K1,* and *RAD51L1* whereas others are present in regions of the genome distant from the nearest gene such as the SNPs on 2q35 and 8q24 (111) (Table 16-1). All of the SNPs so far identified confer small increases in risk of no less than 1.5-fold. Together, the variants so far identified explain around 10% of the overall familial risk suggesting that many more risk variants are to be found. Interestingly, some variants such as those in *FGFR2* confer elevated risk of ER-positive but not ER-negative breast cancers. Currently, the clinical utility of typing individuals for these variants is limited but may increase as more risk SNPs are identified and technology to analyze genomes becomes simpler and cheaper (111).

FUTURE DIRECTIONS IN BREAST CANCER GENETICS

Following the identification of *BRCA1* and *BRCA2,* there is an improved understanding of cancer risks associated with these genes, and management strategies to reduce cancer risks based on clinical evidence have been developed. Further elucidation of the basic mechanisms involved in the pathogenesis of *BRCA1*- and *BRCA2*-related breast cancers may allow more targeted interventions to eliminate risks in individuals with germline mutations and may provide critical information regarding the development of sporadic tumors. The influence of modifying factors, both genetic and environmental, is being addressed as families with identical mutations can have marked variation in cancer phenotype. However, known breast cancer susceptibility genes account for less than 25% of the familial aggregation of breast cancer. Many other variants with moderate or low penetrance, some of them common, will be discovered by utilization of new rapid and cheap methods of DNA sequencing. This will have considerable implications for risk assessment. The hope is that these advancements will improve the diagnosis and treatment of breast cancer in women affected with both inherited and sporadic forms of the disease.

CHAPTER 17

Genetic Testing and Management of Patients with Hereditary Breast Cancer

Susan M. Domchek, Beth N. Peshkin, Marc D. Schwartz, and Claudine Isaacs

CHAPTER CONTENTS

Genetic counseling and testing are increasingly an integral component of the management of women with newly diagnosed breast cancer, particularly if they have a family history of breast and/or ovarian cancer. Because breast cancer is such a common disease in North America and northern Europe, it is not uncommon to encounter families in which two or three women have had this disease. Such clusters may be typical of *familial* breast cancer, particularly when the ages of onset are postmenopausal. In the majority of such familial clusters there is no clear single genetic etiology. *Hereditary* breast cancer, which is much less common, is usually characterized by two or more generations affected with breast and related cancers (e.g., ovarian cancer), often with a predisposition to early ages of onset. As discussed in this chapter, specific features of an individual's personal and family history can provide substantial clues about potential etiology. When family histories are suggestive of hereditary risk, women and their family members may benefit from genetic counseling and testing. Women at high risk can reduce their risk of cancer-related morbidity and mortality through increased surveillance and adoption of risk-reducing strategies. Noncarriers of known familial risk-conferring mutations may be relieved of persistent worry and avoid unnecessary interventions. Pre- and posttest genetic counseling ensure that individuals have appropriate information about the risks, benefits, and limitations of genetic testing, as well as how to use results for clinical management.

Although genetic counseling and testing for breast cancer, particularly with regard to *BRCA1* and *BRCA2* mutations, have diffused into mainstream oncologic care, questions regarding individualized cancer risks, the long term impact of management options, and how best to use this information to treat breast cancer patients remain. While risk reduction and early detection strategies have been extensively studied in individuals with *BRCA1* and *BRCA2* mutations, much less is known regarding management of individuals with mutations in rare high penetrance cancer susceptibility alleles (e.g., *PTEN, TP53, STK11, CDH1*). An additional layer of complexity stems from the discovery of a host of moderate penetrance genes (e.g., *CHEK2, BRIP, BARD*) for which there are particular concerns regarding clinical utility. These limitations in our knowledge create challenges for providers who must counsel patients about clinical management and for the patients who face the decisions to undergo genetic testing. This chapter provides an overview of the medical and psychosocial issues that are relevant to this process. The focus of this chapter is on patients at high risk who have family histories consistent with inherited susceptibility to breast cancer.

CLINICAL CHARACTERISTICS OF HEREDITARY BREAST CANCER

Approximately 5% to 10% of breast cancers arise as a result of an inherited susceptibility owing to alterations in a single highly penetrant gene. Most cases of hereditary breast cancer, and particularly hereditary breast and ovarian cancer, are attributable to mutations in *BRCA1* and *BRCA2 (BRCA1/2)* (1). Other hereditary breast cancer syndromes,

caused by mutations in highly penetrant genes (noted in parentheses), account for less than 1% of all cases of breast cancer each and include Li-Fraumeni syndrome (*TP53*) (2), Cowden syndrome or *PTEN* hamartoma syndrome (*PTEN*) (3), Peutz-Jeghers syndrome (*STK11*) (4), and hereditary diffuse gastric cancer syndrome (*CDH1/E-cadherin*) (5) (see Table 17-1 for details on these as well as associated cancer risks). Recently it has been demonstrated that women with Lynch Syndrome (Hereditary Non-Polyposis Colorectal Cancer Syndrome, HNPCC) also have an elevated risk of breast cancer (6). However, in contrast to the very elevated risk of colon cancer associated with mutations in *MLH1, MSH2*, and *MSH6*, the risk of breast cancer is only modestly elevated. Thus, mutations in these genes are highly penetrant for colon cancer, but only moderately penetrant for breast cancer (6). Multiple other moderate penetrance genes for breast cancer are also known, for example *CHEK2, ATM, BRIP, BARD*, and *PALB2* (7). These genes are associated with increased risk of breast cancer of 2–5 fold. Mutations in some of these genes have been clearly associated with other cancer risks, such as the association of *PALB2* mutations and pancreatic cancer risk (8). For most of the others, associated cancer risks are uncertain.

For most women with or at increased risk for breast cancer, genetic testing for *BRCA1/2* mutations is the most clinically useful and informative strategy. The reasons for this are that i) mutations in these genes are the most common of the highly penetrant genes, ii) the associated, significantly increased risk of ovarian cancer has major implications for clinical management, and iii) data exist to guide clinical management for mutation carriers and their family members. Mutation testing for the other high penetrance susceptibility genes is generally reserved for families in which there is suspicion for these distinct clinical syndromes (see Table 17-1). However, the landscape of genetic testing for cancer susceptibility is rapidly changing. Next generation sequencing (also known as massively parallel sequencing) allows for rapid genetic testing of multiple genes. Several multiplex panels incorporating moderate and high penetrance genes are now commercially available with more expected in the near future (see Table 17-2). In addition, panels of low penetrance single nucleotide polymorphisms (SNPs) are also commercially available. In addition to all of this, the costs of whole exome and whole genome sequencing have rapidly decreased. These rapid technical advances in germline sequencing currently exceed our ability to apply results to clinical practice and will be discussed further later.

In this chapter, we will focus on cancer risks and management strategies associated with mutations in *BRCA1/2*, but we will also discuss issues related to genetic counseling and management issues related to other genes.

BRCA1 and *BRCA2* Cancer Risks

Breast and Ovarian Cancer Risks

The literature addressing cancer risks in *BRCA1* and *BRCA2* mutation carriers reveals a wide range of potential risks for breast and ovarian cancer which are considerably elevated over the U.S. general population risks of 7% and less than 1%, respectively, to age 70. When reviewing these studies, it is important to consider various sources of ascertainment (e.g., through linkage testing versus direct genotyping, clinic-based versus unselected or population-based series, and selection through affected or unaffected cases or probands) and the relative advantages and limitations of specific study designs. Most of these studies are retrospective in nature, therefore yielding less robust estimates of cancer risk than prospective cohorts. In consideration of these factors, it is appropriate to inform patients about a range of reported risks in mutation carriers that is based on analysis of several studies. For example, the largest meta-analysis of studies published by Antoniou et al (9). combined data from 22 international studies comprising more than 8,000 index cases affected with female (86%) or male (2%) breast cancer or epithelial ovarian cancer (12%). To be included, index cases were

sampled independently of family history. The average cumulative breast cancer risk to age 70 years in *BRCA1* carriers was 65% (95% CI, 51%–75%), versus 45% (95% CI, 33%–54%) in *BRCA2* carriers. Interestingly, when families were ascertained through an index case diagnosed with breast cancer at an early age, especially before age 35 years, cumulative cancer risks were about 20% higher for *BRCA1* carriers (i.e., 87% risk of breast cancer [95% CI, 67%–95%] and 51% risk of ovarian cancer [95% CI, 9.1%–73%] versus 61% risk of breast cancer [41%–74%] and 32% for ovarian cancer [11%–49%] for families containing an older proband with breast cancer). When the index case was older, the *BRCA1*-associated breast cancer risks were similar to those identified through ovarian cancer probands. Similarly, in *BRCA2* families, the breast cancer risks were higher in families with breast cancer index cases versus ovarian cancer probands. Although breast cancer incidence was not impacted by the age of the index patient, *BRCA2*-associated ovarian cancer risks were higher when the proband had breast cancer before age 35. Another notable finding from these analyses was that the breast cancer incidence in *BRCA1* carriers increased with age, but starting at 50 years the incidence remained somewhat constant. In *BRCA2* carriers, however, the incidence of breast cancer continued to rise. These data also confirmed that ovarian cancer rates in women younger than 30 years are very low, but after that, risk rises more dramatically, especially for *BRCA1* carriers. Specifically, Antoniou et al. reported the lifetime risk of ovarian cancer in *BRCA1* carriers to be 39% (95% CI, 22%–51%) and 11% (95% CI, 4.1%–18%) in *BRCA2* carriers but for both *BRCA1* and *BRCA2* mutation carriers the risk of ovarian cancer prior to age 40 was less than 3% (9).

Chen et al. (10) performed a meta-analysis of ten international mixed-ascertainment studies that included data from families at high risk as well as population-based series. The cumulative risks to age 70 for breast cancer were 57% (95% CI, 47%–66%) for *BRCA1* and 49% (95% CI, 40%–57%) for *BRCA2* and ovarian cancer risks of 40% (95% CI, 35%–46%) for *BRCA1* and 18% (95% CI, 13%–23%) for *BRCA2* mutation carriers. These data are roughly consistent with the findings of Antoniou et al. (9) and provide reasonable parameters for clinical use. In addition, Chen and Parmigiani derived age-specific predicted mean breast and ovarian cancer risks for currently unaffected *BRCA1/2* mutation carriers based on their current age (20–60 years) (10). These data, published in tabular form, may be useful in clinical counseling. For example, based on the table, it is estimated that a 30-year-old, unaffected *BRCA1* carrier has a cumulative risk of breast cancer to age 40 of 10%; to age 50 it is 28%; to age 60 is 44%; and to age 70 it is 54%. In addition, her cumulative risk of ovarian cancer to age 40 is 2.2%; 8.7% to age 50; 22% to age 60; and 39% to age 70. Age-specific risks may be one important component to guide decisions about the timing of risk management procedures, such as prophylactic surgery.

Finally, investigators associated with the EMBRACE (Epidemiological study of *BRCA1* and *BRCA2* mutation carriers) consortium recently published one of the largest prospective studies of cancer risk in 978 *BRCA1* and 909 *BRCA2* mutation carriers from the United Kingdom (11). Using Kaplan-Meier estimates, they reported that the average cumulative breast cancer risk to age 70 in *BRCA1* and *BRCA2* carriers was 60% (95% CI, 44%–75%) and 55% (95% CI, 41% –70%), respectively. The average ovarian cancer risk to age 70 in *BRCA1* and *BRCA2* carriers was 59% (95% CI, 43%–76%) and 16.5% (95% CI, 7.5%–34%), respectively.

Considering these three studies together, the average cumulative risk of breast cancer in *BRCA1* and *BRCA2* carriers to age 70 is between 57% and 65% and 45% and 59%, respectively. The average cumulative risk of ovarian cancer to age 70 in *BRCA1* and *BRCA2* carriers is between 39% and 55% and 11% and 18%, respectively. In several instances, these average ranges encompass confidence intervals from different studies. It is also important to bear in mind that the life expectancy for most mutation carriers without cancer is greater than age 70, so these risks need to be extrapolated to older ages.

Importantly, primary fallopian tube cancer and primary peritoneal cancer are part of the tumor spectrum associated with *BRCA1* and *BRCA2* mutations (12) and are often included under the category of "ovarian cancer." A related question that arises, particularly for surgical treatment, is whether carriers face an elevated risk of uterine cancer. Overall, it does not appear that *BRCA1/2* mutation carriers have an excess risk of this malignancy unless they have used tamoxifen either as treatment or primary prevention (13).

These data underscore the complexity in providing an individualized risk assessment for *BRCA1/2* carriers. It is important, however, to counsel individuals about features of the pedigree that may hamper risk assessment, such as small family size, few women in the family, limited or unverifiable cancer history data, and so forth. Recent studies also suggest that more recent birth cohorts have an increased risk of breast cancer (14) In addition, variation in risk is likely to be attributable in part to genetic and nongenetic risk factors, as addressed later in this chapter. Validated comprehensive risk models to provide more individualized risk assessment are needed.

Second Malignancies after Breast Cancer

A hallmark of hereditary cancer is the predisposition toward multiple primary cancers. For example, *BRCA1/2* carriers who are affected with breast cancer have a 40% to 65% cumulative risk of contralateral breast cancer (12,15,16). These risks appear to differ depending on the age at first breast cancer diagnosis and mutation type (i.e. *BRCA1* vs. *BRCA2)* (15). For example, the 10 year risk of contralateral breast cancer is estimated to be 31% for *BRCA1* carriers whose first breast cancer was diagnosed at age less than 40, as compared with 8% for those who were initially diagnosed at age greater than 50 (15). The overall risk of contralateral disease in women diagnosed with breast cancer prior to age 40 at 25 years is estimated to be approximately 63% in *BRCA1* and *BRCA2* carriers (15). The risk of contralateral breast cancer may be reduced substantially with the use of tamoxifen, oophorectomy, or both (oophorectomy in premenopausal women) (17). This is discussed in greater detail in the section on management of mutation carriers with breast cancer. Of note, women with sporadic breast cancer have a 0.5% to 1.0% annual risk of contralateral breast cancer, leveling off at 20% at 20 years of follow-up. Although specific risks are difficult to quantify, it does appear that, over the long term, mutation carriers are at elevated risk of developing metachronous ipsilateral breast cancer (18).

A significant concern for *BRCA1/2* breast cancer survivors is the threat of developing ovarian cancer. Metcalfe et al. (19) reported that the 10-year actuarial risk of ovarian cancer in such patients was 12.7% and 6.8% for *BRCA1* and *BRCA2* carriers, respectively. Similar findings were seen by Domchek et al. with a risk of ovarian cancer following breast cancer of 7.8% in *BRCA1* carriers and 3.3% in *BRCA2* carriers with a median follow up of approximately 4 years (20). Of note, the development of ovarian cancer was the cause of death in one-fourth of the patients with stage I breast cancer in the Metcalfe study, underscoring the importance of considering the impact of mutation status in individuals who present with a malignancy.

Second Malignancies after Ovarian Cancer

An additional clinical concern is the risk of breast cancer following a diagnosis of ovarian cancer in *BRCA1/2* mutation carriers. Two studies have examined this issue and have found a low risk of breast cancer within 5 years of the diagnosis of ovarian cancer, which may be due in part to the impact of ovarian cancer treatment. At the same time, the risk of developing recurrent ovarian cancer was quite high. Specifically, Vencken et al. reported that women with *BRCA*-associated ovarian cancer had lower 5-year and 10-year risks of primary breast cancer (6%, and 11%, respectively) compared with unaffected mutation carriers (16%, and 28%, respectively); in addition, those with ovarian cancer had significantly higher mortality rates. The risk of death in those with ovarian cancer at 2, 5, and 10 years were 13%, 33%, and 61%. In comparison, the corresponding risks of death in carriers unaffected at the start of follow up were 1%, 2%, and 2%, respectively; $p < .001$). Similar findings were seen in Domchek et al. in which the 5- and 10-year breast cancer free survivals for *BRCA1/2* mutation carriers following ovarian cancer were 97% (95% CI = 0.92, 0.99) and 91% (95% CI = 0.82, 0.95), respectively. The 5- and 10-year overall survival rates were 85% (95% confidence interval [CI] = 0.78, 0.90) and 68% (95% CI = 0.59, 0.76), respectively. This information can help guide women making decisions about breast cancer management, but suggests that particularly in the first 5 years after diagnosis, conservative (non-surgical) management is reasonable (21,22).

Other Cancers

Several studies have reported an association between pancreatic cancer and *BRCA2* and *BRCA1* mutations (23,24), although the risk is more elevated in the former. The overall number of carriers with pancreatic cancer in these studies is low, but with this limitation, relative risks (RR) have been estimated at 2 to 3 for *BRCA1* and 2 to 6 for *BRCA2*. Despite the clear elevation in RR, the risk of pancreatic cancer in the general population is relatively low and thus even in *BRCA2* mutation carriers the lifetime risk estimates for pancreatic cancer appears to be 5% or less. There is concern that individuals in *BRCA*-families with multiple cases of pancreatic cancer have higher risks but these are difficult to quantify.

With respect to colon cancer risk in mutation carriers, some studies have identified elevated risks (12,25) and others have not (26). Thus, it is likely that if an elevation in risk exists, it appears to be small. In addition, increased risks of other cancers such as melanoma, uveal melanoma, and gastric cancer (particularly in *BRCA2* carriers) (12,25,27,28), have been seen but additional studies are needed to better quantify such risks. There may be a modest global risk in cancer in general.

Cancers Affecting Males

Multiple studies have demonstrated that prostate cancer risks are elevated in *BRCA2* mutation carriers with RR as high as 8 (28,29) with cancers often occurring younger than age 65 (25,27). The lifetime risk to age 65 is approximately 15% (29). *BRCA2*-associated prostate cancer appears to be more aggressive with higher risk disease and poorer survival. Male mutation carriers also have a substantially elevated risk of developing breast cancer. For example, a retrospective study utilizing data from 1,939 families, including 97 men with breast cancer, revealed that the cumulative risk of breast cancer at age 70 was 1.2% (95% CI, 0.22%–2.8%) and 6.8% (95% CI, 3.2%–12%) in *BRCA1* and *BRCA2* carriers, respectively (30). Although these absolute risks are low, the relative risks, particularly up to age 50, are sizable.

Summary: BRCA1/2-Associated Cancer Risks

In summary, given the wide confidence intervals reported in most studies and the range of risks found in different populations, it is difficult to define the precise cancer risks for individual mutation carriers. While it is known that genotype–phenotype correlations, genetic modifiers, and family history impact the risk of breast cancer it is uncertain how to translate these factors into clinical risk assessment (see Cancer Risk Modifiers). Nonetheless, although exact cancer risks for an individual are not known, it is clear that women with *BRCA1* and *BRCA2* mutations face a substantially elevated risk of early onset breast and ovarian cancer, with increased risks that persist throughout their lifetime.

Breast and Ovarian Cancer Risks in *BRCA1/2*-Negative Families

When an individual tests negative for *BRCA1/2* mutations, the first question that should be asked is whether there is a known mutation in the family. Several studies have demonstrated that individuals who test negative for a known mutation in the family (a "true negative") are at approximately the same risk for developing breast and ovarian cancer as women in the general population (in the absence of independent risk factors) (31–34).

In individuals with negative *BRCA1/2* testing and no known mutation in the family, testing is uninformative. Cancer risks in these families are dependent on the strength of the family history. In clinical practice, uninformative results from *BRCA1/2* testing are the most commonly encountered outcome and it is important to provide cancer risk assessments that factor in these results. Not surprisingly, relatives of *BRCA1/2* negative probands with early onset breast cancer or a strong family history of breast cancer still face increased risks of breast cancer, perhaps as much as three- to fourfold (34). However, of significant importance is that studies have also shown that there is no excess risk of invasive ovarian cancer in high risk *BRCA1/2* negative families ascertained through a breast cancer proband. (35,36) For example, a large study of 8,005 women from 895 families in the United Kingdom found the RR of ovarian cancer to be 0.37 (95% CI, 0.01–2.03) in uninformative *BRCA1/2* families (35). However, Lee et al. (37) found that if a family is ascertained through a woman who has *ovarian cancer*, her close relatives have an elevated risk of ovarian cancer, with a standardized incidence ratio of 1.9. Together, these studies suggest that members of *BRCA*-negative families, especially those with many cases of breast cancer, have an increased incidence of breast cancer, but are likely not at a significantly increased risk for ovarian cancer. Several computer models (e.g., BRCAPRO, BOADICEA, and IBIS—models which will be discussed shortly—allow the clinician to impute *BRCA1/2* test results (in this case, negative or uninformative) and obtain an estimate of breast and ovarian cancer risks in consideration of such test results and the individual's personal and family history. For families with at least one documented case of ovarian cancer, the possibility must be considered that an undetected mutation in *BRCA1/2* exists, there is a mutation in a different gene, or less likely, that the proband tested may be a phenocopy, as discussed later in this chapter.

Cancer Risk Modifiers

Genotype–Phenotype Correlations Within BRCA1 *and* BRCA2

Patients frequently ask whether mutation-specific data are available that may help individualize *BRCA1* or *BRCA2* risks. Although studies have suggested that genotype–phenotype correlations may exist, these data are not yet sufficiently

substantiated to integrate into clinical counseling. For example, a study of 164 families found that mutations occurring within the central region of the *BRCA2* gene, called the ovarian cancer cluster region (OCCR), was associated with a lower risk of breast cancer (RR = 0.63, 95% CI, 0.46–0.84) and a higher risk of ovarian cancer (RR = 1.88, 95% CI, 1.08–3.33) (38). Interestingly, in another study of unselected *BRCA2* carriers with ovarian cancer, first-degree relatives had ovarian, colon, stomach, pancreatic, or prostate cancer only when the proband's mutation was within the OCCR of exon 11, and an excess of breast cancers was observed when the mutation was outside of the OCCR (39). These findings suggest that mutations within the OCCR in *BRCA2* may confer a diminished risk of breast cancer (i.e., not necessarily a higher risk of ovarian cancer) and that mutations within the region may be associated with a broader tumor spectrum altogether.

Further studies in *BRCA1* and *BRCA2* carriers are needed before these data can be used to refine risk estimates in the clinic. In addition, an understanding of putative molecular mechanisms for differential risks will further contribute to our understanding of genotype–phenotype correlations.

Modifier Genes

As discussed earlier, it is possible that specific mutations in the *BRCA1/2* genes are associated with variable cancer risks. An increasing body of research is focusing on how polymorphisms in other genes impact *BRCA1/2* cancer risks. To generate sample sizes with sufficient statistical power to detect effects of modifier genes, an international consortium of more than 60 groups has been formed, known as CIMBA (Consortium of Investigators of Modifiers of *BRCA1* and *BRCA2*). By pooling data from approximately 30,000 mutation carriers, this group has found multiple genetic modifiers which impact breast risk in *BRCA1* and *BRCA2* mutation carriers. Interestingly, and importantly, it appears possible that the addition of single nucleotide polymorphism (SNP) panels could aid in individual risk prediction for *BRCA1/2* mutation carriers. In one study examining 7 risk-associated SNPs in *BRCA2* mutation carriers, the 5% of *BRCA2* carriers at highest risk were predicted to have a probability between 80% and 96% of developing breast cancer by age 80, compared with 42% to 50% for the 5% of carriers at lowest risk (40). Although as yet unknown, it is possible that these risk differences might be sufficient to influence the clinical management of mutation carriers.

In the future, it is very possible that individuals seeking information about their cancer risk may undergo a series of genetic tests that could help better personalize their risks. Thus, information about penetrance may be derived from data specific to an identified *BRCA1* or *BRCA2* mutation as well as SNPs or variants in other genes. In addition, other factors, such as a woman's reproductive history, hormone use, environmental risk factors, and utilization of risk-reducing measures, may be integrated into estimates of lifetime cancer risk. Integrative models are needed.

Reproductive Factors

A central question has been whether reproductive factors that affect risk in the general population are applicable to *BRCA1/2* carriers. Although data are limited, several studies have suggested that early menarche may confer slightly elevated risks for breast cancer among *BRCA1/BRCA2* carriers (41,42). Data on parity and breast cancer risk are less consistent. Some studies have demonstrated an increased risk of breast cancer with increased pregnancies among *BRCA1* carriers (41) and *BRCA2* carriers (42); with others showing a protective effect (43). Several studies have demonstrated a protective effect of breast-feeding among *BRCA1* carriers (41,44). However, other studies have failed to detect such an effect (43).

The impact of parity on risk of ovarian cancer is inconsistent and controversial. Contrary to studies of the general population, several studies have suggested that increased parity might be a risk factor for ovarian cancer among *BRCA1/2* carriers. For example, in a matched case-control study with 794 cases and 2,424 controls, parity was associated with a 33% reduction in the odds of ovarian cancer among *BRCA1* carriers, but an increase of the odds of ovarian cancer among *BRCA2* carriers (45). However, consistent with literature in the general population, there have also been studies reporting a protective effect of increasing parity among mutation carriers (46).

Oral contraceptive use has been shown to significantly reduce the risk of ovarian cancer, and some studies have shown that use may be associated with a modest increased risk of breast cancer (45,47) although others have not. Tubal ligation may also reduce the risk of ovarian cancer in mutation carriers (48).

In summary, despite a growing literature on reproductive risk factors, the limited research to date and the inconsistent nature of the results preclude definitive conclusions or concrete integration into risk assessments. Thus, clinical recommendations may not be affected by these factors.

GENETIC COUNSELING AND RISK ASSESSMENT

Criteria for Genetic Counseling Referral

In general, it is recommended that individuals with a suggestive personal and/or family history of breast cancer be referred for genetic counseling, which includes a detailed risk assessment and discussion about the potential likelihood that genetic testing will provide informative results for medical management or for clarifying relatives' cancer risks. A 10% *BRCA1/2* carrier probability has been suggested as a possible threshold for recommending genetic testing (49). However, quantitative estimates combined with clinical judgment form the optimal basis for referral and risk assessment in clinical practice. Indeed, many organizations have published statements about the importance of genetic counseling for individuals at elevated cancer risk, and some contain specific criteria for genetic counseling referral. These groups include the American Society of Clinical Oncology (ASCO), the National Society of Genetic Counselors (NSGC), the National Comprehensive Cancer Network (NCCN), the United States Preventive Services Task Force (USPSTF), the National Institute for Health and Clinical Excellence (NICE), and others (49,50). In the United States, some third-party payers have established their own criteria for genetic counseling and testing which are used in decisions regarding insurance coverage for testing. We provide sample criteria for referral for consideration of *BRCA1/2* testing in Table 17-3. Notably, the criteria for who is considered a "good" candidate for genetic testing has expanded significantly since genetic testing became commercially available in the late 1990s. This is due, in part, to the understanding that in certain clinical situations individuals have a high enough pre-test chance ("prior probability") of having a gene mutation that there is no need to also have a strong family history. These situations include women diagnosed with breast cancer under 40, women with triple negative breast cancer, women with high grade serous ovarian cancer, men with breast cancer,

TABLE 17-3

Criteria for Referral for Genetic Counseling of Individuals at Increased Risk for *BRCA1/2*-Associated Hereditary Breast Cancer[a,b]

- Personal history of breast cancer diagnosed ≤45
- Personal history of breast cancer and Ashkenazi Jewish ancestry
- Personal history of breast cancer diagnosed ≤50 and at least one first- or second-degree relative with breast cancer ≤50 and/or epithelial ovarian cancer
- Personal history of breast cancer and two or more relatives on the same side of the family with breast cancer
- Personal history of breast cancer and one or more relatives with epithelial ovarian cancer
- Personal history of epithelial ovarian cancer, diagnosed at any age, particularly if Ashkenazi Jewish
- Personal history of male breast cancer, particularly if at least one first- or second-degree relative with breast cancer and/or epithelial ovarian cancer
- Personal history of triple negative breast cancer ≤60
- Relatives of individuals with a deleterious *BRCA1/2* mutation

[a]Close relatives of individuals with the history mentioned in the table are appropriate candidates for genetic counseling. It is optimal to initiate testing in an individual with breast or ovarian cancer prior to testing at-risk relatives.
[b]Criteria modified from NCCN Version 2.2013 (50).

and Ashkenazi Jewish individuals with breast or ovarian cancer. More liberal application of genetic testing has also been aided by a significant decrease in the rate of detection of variants of uncertain significance (discussed in more detail in the next section).

The Genetic Counseling Process

Genetic counseling is an important component of the risk assessment and genetic testing process. In the latter, pre- and posttest counseling is important because of complexities in test result interpretation and discussion of medical management options, as well as the potential implications for family members. The process of genetic counseling, which encompasses everything from initial history taking to a review of the potential benefits, limitations, and risks of testing, is comprehensive in nature and is designed to facilitate informed decision-making (51).

Initial or pretest genetic counseling sessions involve a detailed review of the patient's family and medical history. The family history may be conveniently recorded in the form of a pedigree and should be updated periodically. Pedigrees should include information about maternal and paternal relatives encompassing at least three generations, if possible. It is important to record all cancer or precancerous diagnoses, ages at diagnosis, laterality, treatment, and history of prophylactic or other related surgery. Review of pathology reports is important, not only to verify diagnoses but also to confirm whether certain histologies are present. For example, nonepithelial ovarian cancers, such as germ cell cancers, are not part of the tumor spectrum observed in *BRCA1/2* mutation carriers. Relevant environmental and exposure history is also important to note, as well as ethnic ancestry. It is important to document specifically whether individuals are of Ashkenazi (Eastern or Central European) Jewish ancestry. In addition, current ages, or ages at and causes of death, as well as other chronic medical conditions in unaffected and affected individuals, should also be indicated on the pedigree. For example, women who undergo oophorectomy at an early age who also have a positive family history of heart disease or osteoporosis may consider a more in-depth assessment of their own personal risk factors for these conditions so that they can discuss appropriate management options.

Analysis of the pedigree for hallmark features of hereditary cancer provides the basis for an accurate risk assessment. The two approaches to pedigree analysis are (a) a qualitative impression and (b) a quantitative estimate of carrier probability. A qualitative analysis is helpful to determine if a family history contains features suggestive of hereditary breast cancer, especially syndromes not attributable to *BRCA1/2* mutations. For example, early onset breast cancer in the presence of a sarcoma, adrenocortical cancer, or childhood cancer is suggestive of Li-Fraumeni syndrome (see Table 17-1) (2). In addition, it can be determined if factors in the family history may make it difficult to discern a pattern of hereditary cancer, thus limiting the utility of some quantitative models of risk assessment. Small family size, few women in the family, premature deaths, and lack of knowledge regarding medical history, are all potential limitations of pedigree analysis. For example, Weitzel et al. (52) found that in families containing a proband with breast cancer before age 50 and a limited family structure, three commonly used risk assessment models did not accurately predict *BRCA1/2* carrier probability.

Assessing *BRCA1/2* Carrier Probability

Cancer risk assessment encompasses several factors, including the likelihood that an individual or family harbors a gene mutation, the chance that an individual is a gene carrier based on Mendelian analysis, and the cancer risks derived from estimates of gene penetrance. As discussed in the section The Genetic Counseling Process, qualitative impressions of the pedigree are invaluable, particularly for identifying rare syndromes associated with hereditary breast cancer. However, for most women at moderate to high risk presenting for genetic counseling, consideration of *BRCA1/2* testing will be most appropriate. In this section, quantitative models for estimates of *BRCA1/2* carrier probability will be reviewed.

Several models are available to provide estimates for gene carrier probability. Most of the models discussed here are available to run on the internet or are downloadable at no cost. Probabilities generated by many models vary based on which person is chosen for the analysis, so for some patients it might be more appropriate to run the model on the person most likely to harbor a mutation (or who has the most affected relatives who will be captured within the model) and then Mendelian probabilities can be calculated for other relatives.

Two of the most widely validated models are BRCAPRO and BOADICEA (53–55). BRCAPRO was developed in the United Sates and uses Bayesian theory and family history information (e.g., affected status for breast or ovarian cancer, ages of affected and unaffected first- and second-degree relatives) to estimate *BRCA1/2* carrier probabilities as well as breast cancer risk (53). The model, which is included in CancerGene (54) and is frequently updated, also incorporates data about *BRCA1/2* mutation frequency and a range of *BRCA1/2* mutation penetrance figures based on published estimates. In addition to providing *BRCA1/2*

probability estimates, this model also generates a pedigree, and age-specific risks for breast cancer (primary and contralateral) and ovarian cancer based on positive and uninformative negative test results. Breast cancer risks are also calculated using Gail model parameters and breast density. Other strengths of the model include the ability to integrate multiple pieces of additional information into *BRCA1/2* carrier probability estimates, such as Jewish ancestry, race, age at oophorectomy and/or bilateral prophylactic mastectomy, genetic testing results (for residual probability in the person tested or to account for the possibility of a phenocopy or uninformative result in an unaffected person), and breast tumor marker status, including estrogen and progesterone receptors, HER-2/neu, and cytokines CK14 and CK5/6. Tumor markers indicating the triple negative or basaloid phenotype are predictors of *BRCA1* positivity. Of note, however, despite the establishment of ductal carcinoma *in situ* (DCIS) as part of the *BRCA1/2* tumor spectrum (56), at present, the program does not count DCIS as breast cancer (i.e., it factors in cases of invasive breast cancer only); therefore, carrier probability may be underestimated. Users may therefore wish to enter DCIS cases as invasive.

The BOADICEA (Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm) model was originally developed using segregation analysis of breast and ovarian cancer in families identified through population-based series of breast cancer cases and multiple case families in the United Kingdom, and has since been extensively updated to include data from over 2,700 families (57). Unique strengths are that risk estimates computed by the model take into account the polygenic nature of hereditary breast cancer (i.e., implicating genes other than *BRCA1* and *BRCA2*), other cancers associated with *BRCA1/2* mutations (i.e., prostate and pancreatic), and the effect of birth cohort on cancer risk (58). Although the online model allows for imputation of any family size and pedigrees may be imported, data input for each family member can be time consuming as, for example, year of birth must be entered. The program will generate a full pedigree. Like BRCAPRO, *BRCA1/2* test results are considered; however, oophorectomy status and breast pathology is not included and the model was not developed with *in situ* cancers in mind. BOADICEA also can be used to predict mutation carrier probabilities as well as cancer risks. This model is widely used in the United Kingdom, and is one of the models suggested for use by the NICE guidelines (49).

Researchers at the University of Pennsylvania developed a model known as Penn II, which is based on 966 *BRCA1/2* tested families with at least two cases of breast or ovarian cancer from four high-risk breast cancer screening clinics, and uses logistic regression analysis to determine the likelihood of finding a *BRCA1* or *BRCA2* mutation in an individual and family (59). Data input consists of answers to 11 short questions (e.g., providing the answers yes/no, the number of affected relatives, and the age of the youngest breast cancer case). Strengths of the model include the incorporation of third-degree relatives in the risk assessment (e.g., first cousins) as well as other *BRCA*-associated cancers (e.g., pancreatic, prostate, and male breast). If the proband is not affected, carrier probability can be determined by Mendelian calculations. As expected, predictors of finding a mutation include the presence of breast cancer before age 50, male breast cancer, breast–ovarian double primaries, ovarian cancer, and Ashkenazi Jewish ancestry. This model is easy to use in clinical practice and appears to perform well (60). It does not calculate cancer risks.

The Myriad model uses data derived from empirical rates of *BRCA1/2* mutation prevalence in over 180,000 consecutive gene analyses performed in their commercial laboratory (61,62). Mutation carrier probability is calculated based on the age at diagnosis of breast cancer (<50 or ≥50 years), the presence of ovarian cancer or male breast cancer, and the presence or absence of Ashkenazi Jewish ancestry. Like other models, these data also underscore that the presence of ovarian cancer in the family increases the probability of testing positive and, in many cases, as other models substantiate, with comparable family history, Jewish individuals are more likely to harbor a *BRCA1/2* mutation than non-Jewish individuals. In families with multiple cases of breast and ovarian cancer, however, the impact of Jewish ancestry has a less significant effect on the likelihood of detecting a mutation. Of note, family history used for inclusion in these data was limited and often not verified. This model is included in the CancerGene package and online (62), and is very easy to use.

The Manchester scoring system was developed based on empiric data from 921 non-Jewish British families, and has been updated to include extensive breast pathology from 2,156 samples (63). This model was developed to ascertain families with at least a 10% prior probability of having a *BRCA1* or *BRCA2* mutation for the purposes of clinical triage. The model assigns a score for *BRCA1* and *BRCA2* based on the presence of various cancers (e.g., female and male breast cancer, ovarian, prostate, and pancreatic), the age range in which cancer was diagnosed, and breast pathology and receptor status information (63). No information about unaffected relatives is considered, nor are data about race or Jewish ancestry. Families with a combined score of at least 16 can be used as a 10% threshold, and 20 points as a 20% threshold (63). Limitations of the model include its lack of applicability to Ashkenazi Jewish individuals and that it may underestimate risk in small families or single affected breast cancer probands diagnosed at a young age. This tool is widely used in the U.K. and is incorporated into the NICE guidelines as a tool for selecting candidates for genetic testing (20% or higher) and various management strategies (49). This model, along with others, performs reasonably well in discriminating mutation carriers from noncarriers in validation studies (49).

Finally, a model based on the International Breast Cancer Intervention Study is referred to as IBIS or Tyrer-Cuzick (64). Of importance, this model is applicable only to unaffected women. It considers a family history of breast or ovarian cancer in first-, second-, and third-degree relatives, including a father or brother with breast cancer, and uses Bayesian calculations, *BRCA1/2* penetrance data from the Breast Cancer Linkage Consortium, and assumptions about the existence of a dominantly inherited, low penetrance gene in calculating gene carrier probability. The model is also used frequently to calculate breast cancer risk, and in addition to family history it also incorporates personal risk factors, such as age at menarche and menopause, age at first live childbirth, parity, height, and body mass index, use of hormone replacement therapy, and history of breast conditions that may elevate risk (e.g., atypical hyperplasia and lobular carcinoma *in situ* [LCIS]). The model has been shown to accurately predict breast cancer risk in some populations, but significantly overestimates it in women with atypical hyperplasia (65). Genetic test results can be entered, but the model assumes that sensitivity for *BRCA1/2* mutation detection is 100% because the residual probabilities after testing are always zero. Table 17-4 summarizes the *BRCA1/2* mutation probabilities for probands in three

different pedigrees as determined by commonly used probability models.

Pedigree 1 (Fig. 17-1) is an example of a high-risk family, in that it contains four cases of breast cancer (one bilateral and two under the age of 50 years) in three generations and one case of ovarian cancer. Regardless of ancestry, BRCAPRO gives the highest carrier probability estimate (50% or 72% if non-Jewish or Jewish, respectively). If the ovarian cancer patient is used as the proband for BRCAPRO, the prior probabilities increase further.

Pedigree 2 (Fig. 17-2) is also a highly suggestive family, with four cases of breast cancer, three under age 50 years, in three generations.

Finally, Pedigree 3 (Fig. 17-3) is an example of a moderately suggestive family history of the type commonly encountered in clinical practice. If the family is non-Jewish, all models yield a relatively low probability that the proband (III-1) will test positive, whereas, as expected, the probabilities are higher if the family is Jewish. Interestingly, if breast cancer tumor markers indicative of the basaloid phenotype are entered for the proband (e.g., estrogen and progesterone receptor negative, HER-2 negative), the probability of testing positive is substantially increased based on the BRCAPRO model. This finding underscores the importance of considering breast cancer pathology in addition to family history, especially because this is a small family with few females in it.

These examples demonstrate several important concepts. First, quantitative probability estimates of *BRCA1/2* status may be highly variable, so it is important to understand the features of each model that could account for some of these differences, as well as the strengths and limitations of each model. Thus, carrier probability estimates must be interpreted in addition to a qualitative impression of the pedigree. In some cases, it might make more sense to calculate carrier probability for someone in the family other than the proband. Such an approach might be useful if the proband is unaffected with breast or ovarian cancer (i.e., by calculating carrier probability for an affected individual, Mendelian analysis can then be used to derive risks), or if there is a "higher risk" proband in the family (e.g., a woman with ovarian cancer, or who was diagnosed with breast cancer at a younger age). Finally, Jewish ancestry significantly impacts carrier probability, so it is critical to ascertain ethnic background when taking the pedigree. As pedigrees 1 and 2 underscore, paternal family history is also critical to ascertain.

Another critical aspect of pretest counseling is a psychosocial assessment, along with a discussion about the review of the possible benefits, risks, and limitations of genetic testing. Although no individual can imagine fully how he or she might react on learning a test result, having this discussion beforehand can at least begin to prepare individuals for different responses and enable them to mobilize coping, support, and informational resources ahead of time. It is also helpful to clarify expectations about what the patient hopes to learn from genetic testing, and how he or she may handle uncertainties associated with test result interpretation.

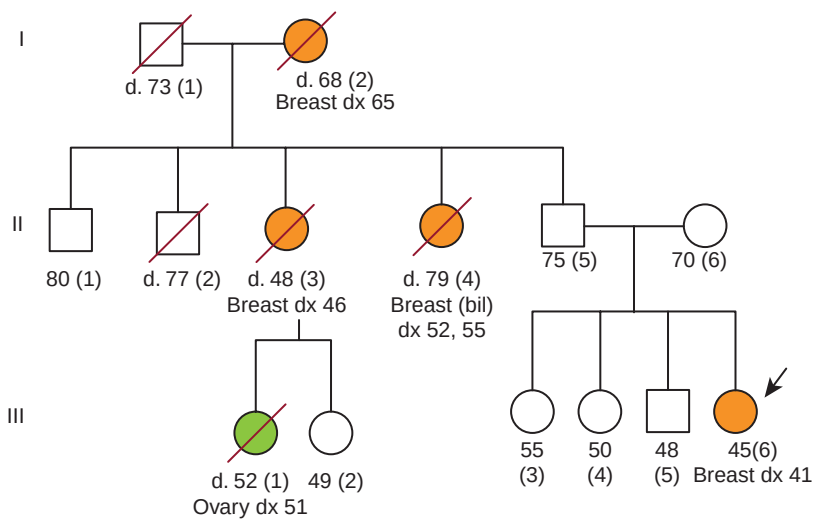

FIGURE 17-1 Pedigree 1, high risk breast/ovarian cancer family.

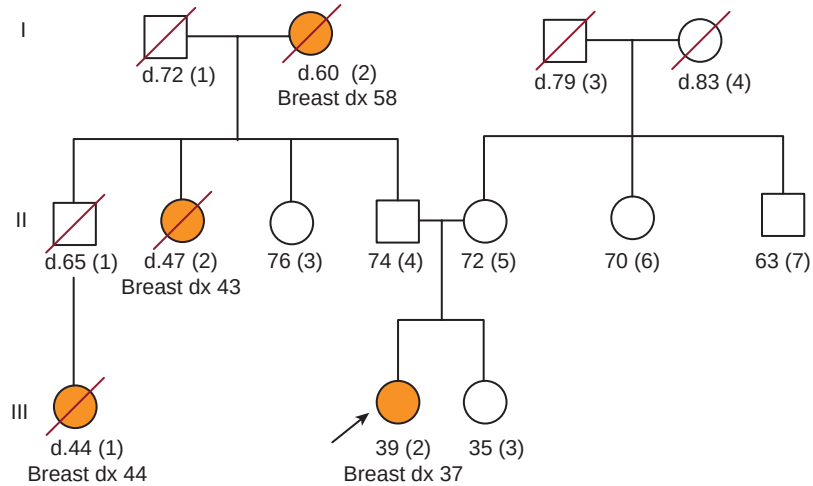

FIGURE 17-2 Pedigree 2, high risk site-specific breast cancer family.

Discussing risk perception, attitudes toward cancer screening and risk reduction, past health behaviors, impact of relatives' diagnosis, and current and past psychiatric history can help frame discussions about goals, coping strategies, and decision-making.

Potential benefits of testing include the reduction of uncertainty because of increased knowledge. In addition, results may help facilitate more informed decision-making about medical options, including risk reducing surgery or definitive surgery in newly diagnosed breast cancer patients.

Frequently, the choice to be tested may also be motivated by a desire to obtain information for other family members. For patients with cancer who are very ill or actively in treatment, this reason may be their main motivation for pursuing genetic testing, because the medical implications for them may be very limited. Among individuals of childbearing age, concern about transmitting their mutation to future children may also exist. It is important to address reproductive concerns in the context of genetic counseling, especially as options such as prenatal and preimplantation genetic testing are available, although requests for these types of testing are uncommon. Decision-making around these issues can be very complex and fraught with ethical dilemmas; thus, genetic counseling can be instrumental in helping patients clarify their own values and preferences.

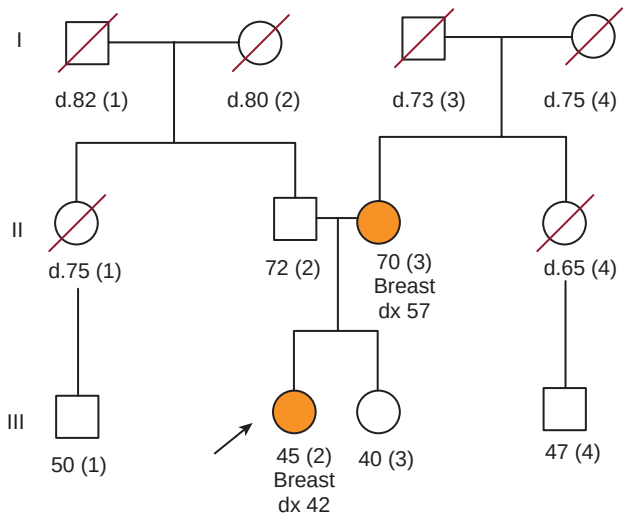

FIGURE 17-3 Pedigree 3, moderate risk site-specific breast cancer family.

A limitation of testing is the possibility that results may not be informative. Although no significant physical risks are associated with genetic testing, psychosocial risks must be taken into consideration. Although few cases of genetic discrimination have been documented, it is important to inform individuals considering genetic testing about current national and state laws that address this concern. In May 2008, the Genetic Information Nondiscrimination Act (GINA) was signed into law in the United States, which provides many protections against discrimination based on genetic information for those with individual and group health insurance plans, and in employment settings (66). For some individuals and depending on the status of their insurance plan, genetic counseling and testing for *BRCA1/2* mutations is also a covered service under the Affordable Care Act (67). It is also encouraging that *BRCA1/2* testing, which can cost up to approximately $4,000, is often a covered expense by many insurance companies in the United States.

Although studies have not demonstrated significant adverse emotional effects of testing, as described in the section on psychosocial outcomes, it is not uncommon for mutation carriers to experience some feelings of distress, anxiety, or sadness, which is usually manageable without clinical intervention and which dissipates over time. Although many individuals pursue testing for the sake of obtaining information for family members, the decision to disseminate one's test results and the ensuing ramifications can cause strain among relatives. It is not uncommon for those with true negative results to feel a combination of relief and survivor guilt for being spared a burden that other relatives may experience. In addition, the role of information gatekeeper may be overwhelming for some individuals as they try to attend also to their own needs for support. Through the process of genetic counseling, at-risk individuals can be identified from the pedigree, and the process of family communication may be facilitated with the provision of educational material and, for example, sample letters that can be modified and sent to relatives, for those wishing to use that means of notification.

Thus, in considering the complexities involved in genetic counseling and testing, and the potential for testing to have a significant impact on an individual and his or her family, an integral part of the informed consent process involves discussion of these issues before genetic testing. Posttest genetic counseling provides an opportunity to review pertinent information and may serve to help individuals begin to assimilate their results.

Genetic Testing Process and Results Interpretation

Regardless of which hereditary breast cancer syndrome is suspected within a family, the degree to which testing will be informative is always maximized by first testing an individual in the family who is most likely to carry a mutation (e.g., a woman diagnosed with breast cancer before age 50 or with ovarian cancer). The sensitivity and specificity of testing are important considerations when selecting a laboratory. *BRCA1/2* testing is the most frequently ordered test for hereditary breast or ovarian cancer susceptibility, with more than 1 million tested altogether (68). Of note, other variants may also be identified and may be classified as follows: *suspected deleterious*, which are likely but not definitively proven to be risk conferring; *favor polymorphism*, which are likely but not definitively proven to be of no clinical consequence; and those of *uncertain significance* where insufficient data exist for classification (69). Although unclassified variants are relatively uncommon, occurring in 5% to 10% of clinical samples, and the rates of such variants have been falling, they may occur with increased frequency in specific ethnic groups (e.g., 14% in African American or Caribbean probands) (70). It is critical that providers counsel patients appropriately about these results and retain the ability to recontact them if the variant becomes reclassified.

In addition to sequencing, testing for other large rearrangements in *BRCA1* and *BRCA2* is available, which further increases the sensitivity of testing. The National Comprehensive Cancer Center Network recommends that large genomic rearrangements be part of routine comprehensive *BRCA1/2* testing (50). Large rearrangements in general account for up to 10% of mutations identified, and while they are more prevalent in patients of Latin American/Caribbean ancestry relative to other ethnicities, they are very rare in the Ashkenazi Jewish population (71).

When a deleterious mutation is not identified in the proband after full testing, such results are considered to be indeterminate or uninformative. If an affected individual at high risk is the first to be tested in the family, a negative result could arise owing to a number of possibilities, such as

1. A mutation could be present in the gene/s analyzed, but was not detectable by the method/s used.
2. A rare mutation in another gene or mutations in multiple genes could be implicated, for which testing may or may not be available.
3. The individual tested developed sporadic cancer.

With respect to the latter possibility, it is important to bear in mind that phenocopies can occur within families as breast cancer is a common disease. That is, a proband with breast cancer who tests negative for *BRCA1/2* mutations may represent a sporadic occurrence within a hereditary breast cancer family particularly when the breast cancer is at a later age. However, ovarian cancer is less likely to be a phenocopy given that it occurs much less frequently than breast cancer and is a significant predictor of finding a deleterious mutation. Whenever possible, testing should begin in affected individuals who have the highest chance of testing positive for a *BRCA1/2* mutation. For example, it is preferable to test a 32-year-old with bilateral breast cancer, or her mother with ovarian cancer, not the grandmother with breast cancer at 70, as the latter could be a phenocopy.

Founder Mutations in Ashkenazi Jews and Other Ethnic Groups

Targeted testing for specific mutations may also be appropriate based on a patient's ethnicity. The occurrence of recurrent or "founder" mutations is pronounced in individuals of Ashkenazi (central or eastern European) Jewish descent. In this population, three mutations occur with increased frequency: 187delAG and 5385insC in *BRCA1* and 6174delT in *BRCA2*. Whereas the general population frequency of *BRCA1/2* mutations in the United States is estimated at 1/500, in Ashkenazi Jews, the incidence of these founder mutations is 1/40 (10). Not surprisingly, the incidence of these founder mutations is substantially higher when selected Jewish populations are studied, such as patients with breast or ovarian cancer (72). Although double heterozygotes are rare, owing to this possibility individuals with a relative who carries one of these mutations should still be tested for all three mutations if they have Ashkenazi Jewish ancestry on both sides of their family (73). Of note, these three founder mutations do not occur exclusively in Ashkenazi Jews, and nonfounder mutations have been reported in this ethnic group, although they are rare. For example, Myriad reported that among 926 Ashkenazi Jewish individuals who underwent comprehensive *BRCA1/2* analysis, 110 had a nonfounder mutation (12%) and 4 had a large rearrangement (<1%, all of whom were high risk) (71). At this time, it is not possible to predict which features of the family history will make it more likely that a nonfounder mutation will be identified. However, individuals who have a high prior probability of testing positive based on models such as BRCAPRO (e.g., if calculated as though the family was non-Jewish), or who have qualitative features within the family history that are highly suggestive of a mutation (e.g., more than one case of ovarian cancer, male breast cancer, or pancreatic cancer) should consider pursuing comprehensive testing after three founder mutations are ruled out. Myriad Genetics offers an Ashkenazi Jewish panel with the three common mutations which is significantly cheaper than comprehensive analysis. Therefore, it is suggested testing in individuals start with this panel prior to comprehensive analysis. Founder mutations have also been described in other European and non-European populations, such as those with Icelandic, Norwegian, Dutch, or French Canadian ancestry. It is important for clinicians to determine whether targeted testing is appropriate. For most non-Ashkenazi Jewish individuals in the United States, targeted testing is not indicated.

Testing for a Familial Mutation

Finally, once a mutation in a cancer susceptibility gene is identified, relatives may be offered testing for only the single mutation. As mentioned, one exception to this is for Ashkenazi Jewish individuals, who should generally be tested for all three founder mutations regardless of which one is segregating in the family. In general, testing for a familial mutation yields definitive information: A deleterious (positive) test result is obtained, with the attendant cancer risks, or the result is classified as a true negative, in which the patient can be reassured that cancer risks are thought to be close to those observed in the general population. It is critical, however, to assess other potential risk factors, such as environmental factors and the history on the side of the family in which the mutation is not segregating (i.e., the family history of the other parent). If cases of cancer are present, and especially if these are suggestive of an inherited predisposition, the patient may still have an elevated risk of cancer and his or her medical management plan may need to take this into account.

Examples of Results Interpretation

To illustrate concepts in result interpretation, consider Pedigree 2 (Fig. 17.2). If the proband (III.2) underwent full *BRCA1/2* testing, including testing for large rearrangements, and no mutation was identified, this finding is considered to be uninformative given that this family history is strongly consistent with hereditary breast cancer. Although the

likelihood is low that the proband's cancer is a phenocopy (given her young age at diagnosis), this possibility could be further discounted if her affected cousin had also tested negative for *BRCA1/2* mutations.

If the affected proband (III.2) in Figure 17.2 was found to carry a variant of uncertain significance, and it was subsequently not identified in her father, this finding suggests that the mutation is not likely to be associated with heightened cancer risks as it is not segregating on the side of the family with multiple cases of breast cancer. If this observation can be replicated in numerous families, the accumulation of such data in conjunction with statistical approaches, would add further credence to this assumption. Except to assist in the determination of a variant's significance, at-risk relatives should not be offered testing for a variant because it provides no further information about their risk of developing cancer.

If individual III.2 is found to harbor a *BRCA2* mutation, and her sister (III.3) subsequently tests negative for this mutation (true negative), the sister's chance of developing breast or ovarian cancer is reduced to that observed in the general population. This example underscores the importance of offering genetic testing to an affected individual first. If, however, the proband's sister (III.3) was the first person in the family to undergo *BRCA1/2* testing and tested negative, at that point, it would not be clear whether this result would be attributable to the fact that she did not inherit a mutation segregating in her family or whether a *BRCA1* or *BRCA2* mutation does not exist in this family. In this scenario, rather than a test result providing reassurance, the patient would have to be counseled that she is still considered to be at high risk for breast cancer.

In summary, there are several possible outcomes of genetic testing. There are two types of definitive test results: (a) a *positive* result refers to the identification of a deleterious mutation associated with increased cancer risks; and (b) a *true negative* result means that a mutation previously identified in a blood relative has been ruled out. Even among highly selected probands the most commonly obtained result is one that is *indeterminate* or *uninformative*. These classifications mean that a deleterious mutation has not been identified in the family and the possibility of an inherited susceptibility cannot be definitively ruled out. Given the complexities in test result interpretation, it is important that it be done in the context of an individual's medical and family history, especially given that critical medical management may hinge on an accurate risk assessment.

Psychosocial Outcomes of *BRCA1/2* Genetic Testing

The advent of *BRCA1/2* testing was accompanied by considerable concern about the potential for adverse psychosocial outcomes in this already distressed population. Many women have now undergone genetic testing for *BRCA1/2*. A growing literature has begun to evaluate both the immediate and long-term psychosocial impact of learning one's *BRCA1/2* mutation status.

Studies evaluating the short-term impact of genetic testing demonstrate substantial decreases in distress and anxiety among women who learn that they do not carry a *BRCA1/2* mutation (74). The short-term impact on women who receive positive test results is less consistent. Although many studies suggest increased distress and anxiety in the months immediately following receipt of a positive *BRCA1/2* test result (74,75), others demonstrate stable levels of distress and anxiety (76). This combination of decreased distress among those receiving negative test results and stable or increased distress among those who receive positive results yields significant short-term differences in distress between these groups. These differences typically remain stable or even dissipate during the year following testing (77,78).

There have now been several cross-sectional and prospective studies that have evaluated the long-term psychosocial outcomes of *BRCA1/2* testing. Two small studies that focused on individuals unaffected with cancer found no differences on psychosocial outcomes between carriers and noncarriers at three years or five years posttesting (78). In contrast, a more recent small study found that distress increased in the two years following receipt of a positive *BRCA1/2* test result (79). A recent cross-sectional study reported statistically significant, but not clinically significant, genetic testing distress in *BRCA1/2* carriers compared with noncarriers at 7 years posttest (80). Similarly, in a prospective study with an average follow-up of over five years posttesting, Graves and colleagues found modest but significantly increased distress among *BRCA1/2* carriers compared to women who received negative or uninformative test results (81). These long-term studies suggest that, while a positive *BRCA1/2* result may remain salient over the long term, distress related to testing rarely reaches a clinical level. These studies also highlight the potential modifying role of risk reducing surgery on psychosocial outcomes. Specifically, *BRCA1/2* carriers who opted for risk reducing mastectomy or risk reducing oophorectomy reported lower levels of distress and perceived risk over the long term (79,81).

Although these studies are reassuring, need for caution exists in interpreting these results owing to the wide variability in emotional responses to testing and the select nature of research samples to date. For example, a number of studies have shown that individuals who report high levels of distress, poor quality of life, or who have inaccurate perceptions of their likelihood for carrying a mutation before testing are more likely to report ongoing distress following a positive test result (82,83). Further, more research is needed to determine whether the largely positive outcomes associated with genetic testing in controlled research programs can be replicated in community settings in which extensive genetic counseling may not always be provided or where genetic counseling is provided via telephone or the internet (84). Finally, the participants in most of these studies have been overwhelmingly white, well-educated, and of high socioeconomic status. However, limited reports that have focused on the impact of *BRCA1*/2 among black patients suggest comparable outcomes to previous studies (85).

Ethical Issues in Genetic Counseling and Testing for Hereditary Breast Cancer

Genetic counseling and testing for hereditary cancer risk often raises many complex issues because of the uncertain but often predictive nature of information obtained; potential risks and limitations of testing; and because genetic test results, especially positive results, have implications, not just for the persons tested, but for their family members as well. In this section, the following major themes will be highlighted: (a) the importance of informed consent; (b) predictive testing in children; (c) duty to warn; and (d) duty to recontact.

First, to maximize the likelihood that patients make fully autonomous decisions about genetic testing, including a full appreciation of the potential benefits, limitations, risks, and implications of testing, it is imperative that informed consent is obtained before testing. The process of genetic counseling affords patients with an opportunity to make informed decisions and to actively consent to genetic testing. It is comprehensive in nature, not only encompassing information,

potential implications, and options, but it also includes a discussion of the psychosocial and familial aspects of testing (86). Documentation of this discussion should be made, and, if required, patients should sign a written consent form prior to genetic testing.

An issue that continues to garner a significant amount of attention is the issue of testing children for susceptibility to adult onset cancers. Most professional societies agree that, in general, genetic testing for minors should occur when medical benefits accrue in childhood (87). However, individual circumstances, including the maturity of the minor and his or her ability to provide assent/consent, and the family concerns should all be explored during the process of genetic counseling and with the involvement of other providers such as the pediatrician and a psychologist. With respect to hereditary breast cancer syndromes, childhood cancers are a feature of Li-Fraumeni syndrome and, although no approach for screening of the associated cancers has proven efficacy, a case for *TP53* testing could be made to relieve parental worry and unnecessary medical procedures in an at-risk child. With respect to *BRCA1/2* testing, however, other factors may play into testing decisions, such as the child's motivation, readiness for, and interest in genetic testing, particularly for "mature minors"; the impact on the family unit and relationships with parents and siblings; the desire to obtain relief from true negative test results (which of course must be balanced against the possibility of testing positive for a familial mutation); and the impact on autonomous decision-making for the child once he or she reaches adulthood. *BRCA1/2* testing in minors remains controversial and, to date, is a rare event. However, it is important for clinicians to explore the issue of family communication about genetic testing and to be sensitive to concerns that parents and adolescents may have about future cancer risk and the associated implications.

Another matter related to family communication concerns what responsibilities individuals have to inform their relatives about genetic risk and the ethical obligations of clinicians to ensure that relatives of the tested patient are informed about this risk (i.e., the "duty to warn"). Studies have shown that the rate of *BRCA1/2* test result disclosure to adult relatives, especially first-degree relatives, is generally high, although underserved, minority, and older patients may have lower rates of disclosure (88). However, the clinician's role in informing at-risk relatives when the tested individual does or will not is unclear. On one hand, patient autonomy and respect for privacy are critically important, but there are circumstances when it might be argued that providing benefit (e.g., the potential to reduce worry and distress and to provide information for medical management) and avoiding harm (e.g., avoidance of unnecessary screening or risk-reducing surgery) may be compelling ethical arguments for overriding patient autonomy. From a legal standpoint, the well-known Tarasoff case set the precedent for a breach of confidentiality between health care provider and patient when imminent harm is foreseeable and preventable (89). In this case from 1976, a patient discussed with his psychotherapist his intention to kill a woman, which he ultimately did. The therapist in this case did not warn the woman of impending danger, but this ruling allows for patient confidentiality to be overridden to avoid harm. However, subsequent case law in the United States has not been consistent with respect to whether a clinician's obligation is fulfilled by informing patients about potential risks to relatives or whether relatives need to be informed directly (89). Indeed, the logistics of identifying and directly contacting relatives often prove to be prohibitive. In the United States, another legal consideration is raised by the HIPAA Privacy rule, which prohibits disclosure of "individually identifiable health information," which would include genetic testing results (89). It is not clear how this regulation impacts public health mandates to override confidentiality in the setting of a serious health threat (90). If it becomes necessary to override a patient's wishes about disclosure, consultation with an ethics committee or legal counsel should be considered.

Although several organizations worldwide have developed guidelines that outline the exceptional circumstances in which it may be permissible to override patient confidentiality to disclose genetic test results, guidance from organizations such as the American Medical Association and the American Society of Clinical Oncologists is very practical (91,92). These guidelines stress the importance of pre- and posttest counseling as an opportunity for providers to explain risks to relatives and their expectations about family disclosure, and to offer assistance to patients to accomplish this goal. In addition, consent forms can include language about the role that the provider and patient will play in identifying and notifying at-risk relatives, including circumstances, if any, under which patient confidentiality may be breached. It is helpful to reiterate implications to relatives in a summary letter to the patient, as well as facilitating the process of disclosure by giving patients resources to help accomplish this goal (e.g., educational material, sample letters, or text for e-mails) and contact information for genetic counselors convenient to relatives.

Finally, given the many developments in cancer genetics, the issue of whether or when to recontact patients has been raised. For example, many women were tested prior to the availability of commercially available large rearrangement testing and received "negative" or uninformative *BRCA1/2* genetic testing. Or, more recently, providers are grappling with whether high risk patients who received uninformative results should be recontacted about the availability of multi-gene panel testing. Changes in management recommendations may also prompt questions about whether and which patients to recontact. These questions raise the issues of whether and when there is a requirement to recontact patients when technology changes, and how to determine whether patients want to be informed about ongoing developments. At a minimum, patients need to be recontacted if the interpretation of their result changes (for example, a variant of uncertain significance that is reclassified to a deleterious mutation). Thus, it is important that clinicians encourage patients to maintain up-to-date contact information with their office. In addition, summary letters to patients can specify that patients check in with the clinic at defined time intervals or that they should check reliable resources for important updates.

In summary, genetic counseling and testing for hereditary cancer risk may yield many potential benefits to individuals and their families. In some instances, however, patient values and preferences and the possibility of adverse outcomes need to be balanced carefully when considering ethically challenging issues.

MANAGEMENT OF HEREDITARY BREAST CANCER

Over the past few years, significant data have emerged regarding the benefit of various screening and prevention options in those with a known inherited susceptibility to cancer and other women at high risk. This section summarizes current knowledge regarding the benefits and limitations of these interventions. The management options for unaffected *BRCA1/2* mutation carriers will be discussed first, followed

by a review of the impact of *BRCA1/2* status on treatment of patients with breast cancer, and finally we will summarize management options for those with other hereditary breast cancer syndromes. It is important to note that most of the recommendations for screening or risk reduction in this group of women at high risk are based on nonrandomized data or expert opinion (50).

Management of Unaffected *BRCA1/2* Carriers

In general, management options for women at increased risk for hereditary breast cancer include screening, prevention interventions, or both.

Breast Cancer

Screening Options: The current breast cancer screening guidelines for women with a known inherited susceptibility to cancer include education about monthly breast self-examinations beginning at age 18, semiannual clinician-performed breast examinations beginning at age 25, and annual mammograms and MRI beginning at age 25 or individualized based on earliest age of onset in the family (49,50) Studies from a number of different countries in Europe and North America demonstrated the benefit of MRI in women at increased risk for breast cancer, and specifically in *BRCA1/2* mutation carriers. MRI had a sensitivity of 71% to 100% and specificity of 81% to 97%, whereas mammography had sensitivity of 33% to 59% and specificity of 93% to 99.8% (Table 17-5). However, these studies also noted that false-positive MRI results were quite frequent, with MRI having a positive predictive value that ranged from 7% to 63%. Optimal breast MRI requires a dedicated breast coil, a well-established imaging technique, radiologic expertise in the interpretation of these studies, and the ability to perform MRI-guided biopsies. Additionally, to further minimize the likelihood of false-positive findings in studies, breast MRI in premenopausal women should be performed on days 7 to 14 of the menstrual cycle. Screening breast MRI in combination with mammogram has shown to be cost effective in *BRCA1/2* mutation carriers (93).

A number of outstanding issues remain. Although studies have demonstrated that breast cancers detected by MRI tend to be small and frequently node negative (94–97), no randomized data exist on the impact of this screening modality on breast cancer mortality. Breast MRI has been shown to be associated with a decreased risk of advanced stage breast cancer (98). In addition, data from 1,275 *BRCA1/2* mutation carriers in a combined analysis of several studies were used to develop natural history models. These models predicted a 50% to 62% decrease in breast cancer mortality with the use of combined mammogram and MRI (99). Therefore, it is felt likely that breast MRI will decrease breast cancer specific mortality despite an absence of randomized data. Although initial studies in women at high risk suggested that MRI was not as sensitive for the detection of DCIS as is mammography (94–96); a subsequent single institution study of more than 7,000 women not selected for family history referred for breast MRI found that MRI detected 92% of the cases of pure DCIS, whereas mammography diagnosed only 53% ($p < .0001$) (100). Whether mammogram and MRI should be staggered every 6 months or be performed simultaneously is also not clear (101).

An additional unresolved issue is the concern that radiation exposure, either in the form of prior chest x-ray or mammograms, may increase the risk of breast cancer in mutation carriers (102–104). Several studies specifically examining mammograms do not support this association (105,106), while others have demonstrated a non-statistically significantly elevated risk (103). In contrast, several studies have demonstrated that radiation exposure prior to age 20 (not mammography) appears to be particularly associated with risk, with the role of mammography between ages 25 and 30 less certain (102,103). It is worth noting that the benefit of mammograms in women 25 to 30 may also be limited due to significant breast density; therefore, while mammograms in women 25 to 30 may not be associated with significant risk, they also may not be associated with significant benefit. Consistent with this, the current NCCN guidelines contain a footnote that states: "The best screening strategy for women 25 to 30 is uncertain with some data suggesting that mammogram be added to MRI only after age 30" (50).

Risk Reduction Options: Many women at increased risk for hereditary breast cancer choose prevention interventions as an alternative to screening or in addition to screening. Options for unaffected women include risk-reducing or prophylactic surgery and chemoprevention. The two surgical options for risk reduction are bilateral mastectomy and risk-reducing salpingo-oophorectomy.

Risk-Reducing Mastectomy Studies have examined the role of risk-reducing mastectomy (RRM) in mutation carriers and demonstrated that this is a very effective means of breast cancer prevention. The Prevention and Observation of Surgical End Points (PROSE) study group has examined the impact of prophylactic mastectomy in a prospective cohort. *BRCA1/2* mutation carriers with breast tissue intact at the time of ascertainment were prospectively followed. With a mean follow-up of 3.1 years, 0 of 172 carriers who underwent risk-reducing mastectomy developed breast cancer (4 incidental cancers were detected at the time of prophylactic surgery). In contrast, breast cancer was diagnosed in 64 of

787 (8.1%) who did not undergo prophylactic mastectomy with median followup of more than 3 years (20). The group at the Rotterdam Family Cancer Clinic has reported their experience with risk-reducing bilateral or contralateral mastectomy in 358 women with either known *BRCA1/2* mutations (N = 236) or at risk for hereditary breast cancer (N = 122) (107). The women in this study underwent skin-sparing mastectomy often accompanied by immediate reconstruction. With a median follow-up of 4.5 years, 1 case of metastatic breast cancer developed in a previously unaffected woman who had undergone risk-reducing mastectomy. The mastectomy specimens were carefully examined for the presence of occult malignancy, which was identified in 10 of the 358 women (2.8%). Invasive cancer was detected in three, whereas DCIS was seen in five and LCIS in two. These cases were equally distributed among women with known *BRCA1/2* mutations and those at increased risk with no known heritable condition, and in women previously affected and unaffected with breast cancer.

Given the risk of occult malignancy, it has been suggested that mutation carriers planning RRM undergo the sentinel node procedure. Studies examining the rate of occult invasive malignancy in prophylactic mastectomy specimens (108) and modeling studies, suggest that routine the sentinel node procedure in this setting is neither cost-effective nor would it minimize the risk of complications. Thus, at present, the routine sentinel node procedure is not recommended in those undergoing RRM.

A number of surgical techniques are available, including total or simple mastectomy which involves removal of both breasts and the overlying skin; skin-sparing mastectomy in which both breasts are removed but the overlying skin is preserved; nipple sparing mastectomy entailing removal of both breasts with preservation of overlying skin and nipple and areolar complexes. Although long-term outcomes on nipple sparing prophylactic mastectomy are not yet available, data have suggested low rates of early local recurrence in those undergoing nipple sparing mastectomy for cancer treatment or prophylaxis (109,110).

Risk Reducing Bilateral Salpingo-Oophorectomy A number of studies have evaluated the impact of risk-reducing salpingo-oophorectomy (RRSO) on subsequent risk of breast cancer and demonstrated that *BRCA1/2* carriers who underwent this procedure had a significant reduction in their breast cancer risk (111–114). In 2002, two important papers were published simultaneously. A prospective study from Memorial Sloan-Kettering Cancer Center of 170 *BRCA1/2* carriers followed for a median of 2 years found that 3 of the 98 carriers who underwent salpingo-oophorectomy developed breast cancer as compared with 8 of the 72 women who chose surveillance (p = .07) (113). Similarly, a multi-institution study of 241 *BRCA1/2* carriers from the PROSE study followed for about 8 years observed that breast cancer developed in 21% of those who had undergone bilateral salpingo-oophorectomy as compared with 42% of those who had not undergone this procedure (HR = 0.47, 95%, CI, 0.29–0.77) (111).

An important question is whether there is a differential protective effect of this procedure on breast cancer risk in *BRCA1* versus *BRCA2* carriers. A prospective study of 368 *BRCA1* and 229 *BRCA2* carriers found that RRSO resulted in a 72% reduction in risk of breast cancer in *BRCA2* carriers (HR = 0.28, 95% CI, 0.08–0.92, p = .036) as compared with a non-significant 39% reduction in *BRCA1* carriers (HR = 0.61, 95% CI, 0.30–1.12, p = .16) (17). However, a retrospective, international case-control study of 1,439 *BRCA1/2* carriers with breast cancer and 1,866 *BRCA1/2* unaffected *BRCA1/2* carriers, found that prior history of oophorectomy conferred greater protection against breast cancer for *BRCA1* carriers than *BRCA2* carriers (56% reduction in *BRCA1* carriers [OR = 0.44, 95% CI, 0.29–0.66] vs. 46% reduction in *BRCA2* carriers [OR = 0.57, 95% CI, 0.28–1.15]) (112). More recently, the PROSE study examined the impact of RRSO on breast cancer risk by *BRCA1* and *BRCA2* mutation status in a large prospective cohort. RRSO was associated with a reduction in breast cancer risk both in previously unaffected *BRCA1* (N = 869; HR 0.63 [0.41–0.96]) and *BRCA2* (N = 501; HR 0.36 [0.16–0.82]) (20). Therefore, there does appear to be breast cancer risk reduction for both *BRCA1* and *BRCA2* mutation carriers following RRSO. Further work is required to determine whether the magnitude of risk reduction is truly different between those with *BRCA1* versus *BRCA*2 mutations. Importantly, RRSO was also shown to be associated with a significant reduction in breast cancer–specific mortality (HR, 0.44 [95% CI, 0.26–0.76]) (20).

BRCA1/2 carriers who choose to undergo prophylactic oophorectomy at a young age frequently consider taking hormone replacement therapy (HRT) to deal with the consequences of premature menopause. Data from the PROSE study group suggest that short-term use of HRT did not alter the protective effect of RRSO on breast cancer risk. Of the 155 carriers who underwent RRSO, 60% reported use of HRT, most of whom were under age 50, and these women had a 63% reduction in their risk of breast cancer as compared with a 62% reduction for the group as a whole (114). In addition, the Hereditary Breast Cancer Clinical Study Group conducted a matched case-control study of 472 postmenopausal women with a *BRCA1* mutation to examine HRT use and subsequent breast cancer risk. The risk of breast cancer with ever use of HRT compared with never use was 0.58 (95% CI, 0.35–0.96; p = .03) (115). Thus, mutation carriers who undergo RRSO before the age of natural menopause can consider short term HRT after an appropriate discussion of the potential risks and benefits, but such therapy should not extend beyond age 50, the age after which it has been shown to increase breast cancer risk in the general population (116). Additionally, nonhormonal interventions to reduce menopausal symptoms and the management of other medical issues, such as bone health, should be considered.

Chemoprevention Data from the national surgical adjuvant breast and bowel project (NSABP) P1 Breast Cancer Prevention Trial, the International Breast Cancer Intervention Study (IBIS-I), and the Study of Tamoxifen and Raloxifene (STAR) demonstrate that 5 years of the selective estrogen receptor modulators (SERM) tamoxifen and raloxifene reduce the risk of breast cancer by 30% to 50% in healthy women at increased risk for this disease based on a family history, age, and certain high-risk conditions, such as LCIS or atypical hyperplasia (104,117–119). Similarly, exemestane has also been demonstrated to decrease the risk of breast cancer in women with LCIS or a Gail 5 year risk of breast cancer of more than 1.66% (120). However, limited information exists regarding the role of such agents in reducing the risk of breast cancer in *BRCA1/2* mutation carriers. Given that SERM have only been demonstrated to decrease the risk of hormone receptor positive breast cancer in these studies, it has been postulated that these agents may be more effective in *BRCA2* carriers who tend to develop hormone receptor positive breast cancer as opposed to *BRCA1* carriers who more frequently have hormone receptor negative disease. This hypothesis was supported by a study in which genetic analysis was performed on 288 of the NSABP P1 participants who developed breast cancer (121). Only 19 (6.6%) were found to carry disease-conferring mutations. Tamoxifen was associated with

a decrease in risk of breast cancer among *BRCA2* carriers (RR = 0.32, 95% CI, 0.06–1.56), but no reduction in risk among *BRCA1* carriers (RR = 1.67, 95% CI, 0.32–10.7). Of note, the study included only small numbers of carriers (8 *BRCA1* and 11 *BRCA2* carriers) and, thus, was not powered to address adequately the impact of tamoxifen in *BRCA1/2* carriers.

In contradistinction, other studies support the notion that endocrine interventions that reduce estrogen levels result in a lower risk of breast cancer in both *BRCA1* and *BRCA2* carriers. As previously described, bilateral salpingo-oophorectomy significantly reduces the risk of breast cancer in both *BRCA1* and *BRCA2* carriers (17,20,111–113). Additionally, a number of studies have found that tamoxifen significantly reduced the risk of contralateral and ipsilateral breast cancer in *BRCA1* and *BRCA2* carriers. A case-control study by Gronwald et al. (122) matched 285 *BRCA1/2* carriers with bilateral breast cancer with 751 carriers affected with unilateral breast cancer, and demonstrated that the use of tamoxifen was associated with a 55% reduction in the odds of contralateral breast cancer (OR = 0.45, 95% CI, 0.29–0.70). This protective effect of tamoxifen was noted both for *BRCA1* carriers (OR = 0.48, 95% CI, 0.29–0.79) and *BRCA2* carriers (OR = 0.39, 95% CI, 0.16–0.94). Additionally, a retrospective cohort study of mutation carriers undergoing breast-conserving therapy performed by Pierce et al. (18) also noted that tamoxifen use resulted in a significant reduction in the rate of contralateral breast cancer (HR = 0.31, p = .05).

In summary, when counseling mutation carriers about the use of tamoxifen as a risk-reducing agent, it is important that they be informed that insufficient data currently exist to define clearly the benefit of such therapy. At present, no data exist regarding the potential benefit of raloxifene or aromatase inhibitors in mutation carriers.

Ovarian Cancer

Screening Options: It is recommended that mutation carriers who have not had prophylactic oophorectomy undergo concurrent semiannual transvaginal ultrasound (TVUS) and CA-125 beginning at age 30 or 5 to 10 years younger than the earliest age of onset of ovarian cancer in the family. For premenopausal women, it is recommended these studies be performed between days 1 and 10 of the menstrual cycle (49,50). It is important to note, however, that the benefit of such interventions is currently unclear. A number of completed and ongoing trials are addressing the utility of screening with CA-125 and TVUS, both in the general population and in women at high risk. CA-125 has typically been considered abnormal if over 35 U/mL. It has also been suggested that the change over time of CA-125 compared with the patient's baseline (the risk of ovarian cancer algorithm or ROCA) may be a more accurate indicator of risk. In the United States, the Prostate, Lung, Colorectal, and Ovarian (PLCO) screening trial performed a randomized controlled trial of 78,216 women aged 55 to 74 years assigned to undergo either annual screening with CA-125 and TVUS (for varying numbers of years) or usual care. There was no difference in ovarian cancer mortality and there were serious complications seen following false positives (123). On the basis of this information, routine ovarian cancer screening in the general population is not recommended. More recently, a study of 3,563 women with an estimated lifetime risk of ovarian cancer of more than 10% underwent frequent screening with some evidence suggesting early stage tumors were detected using this approach (123,124). Several other studies have completed accrual and results are pending. Further data from these large prospective trials are needed to shed light on the utility of CA-125 screening in this high-risk group of women. In the absence of these data, however, it is still recommended that mutation carriers who have not undergone salpingo-oophorectomy perform the screening outlined above. Additionally, studies are evaluating the utility of novel serum markers and several trials have prospectively collected serum for such analyses.

Risk Reduction Options

Risk-Reducing Bilateral Salpingo-Oophorectomy Risk-reducing bilateral salpingo-oophorectomy is strongly recommended for mutation carriers between ages 35 and 40 and once childbearing is complete. Two pivotal studies published in 2002 demonstrated the strong protective effect of this intervention. Among 551 *BRCA1* and *BRCA2* carriers followed for more than 8 years, fallopian tube or ovarian cancer, or primary peritoneal carcinomatosis developed in 8 of the 259 (3.1%) subjects who had undergone RRSO as compared with 58 of the 292 (19.9%) who had not undergone this procedure (HR = 0.04, 95% CI, 0.01–0.16) (14). Similarly, in a prospective study of 170 *BRCA1* and *BRCA2* carriers over the age of 35 followed for 2 years, cancer of the fallopian tubes or ovaries or primary peritoneal carcinomatosis was diagnosed in 5 of the 83 women choosing surveillance as opposed to 1 of the 98 women who underwent salpingo-oophorectomy (p = .04) (113). In a subsequent analysis with data from the above two studies, 498 *BRCA1* carriers and 294 *BRCA2* carriers were prospectively followed for a median of 38 months. An 88% reduction in risk of *BRCA*-associated gynecologic malignancies was noted in those electing RRSO (3 of 509) as compared with surveillance (12 of 283) (HR = 0.12, 95% CI, 0.03–0.41). In this study, no post-RRSO cancer was seen in *BRCA2* mutation carriers (17). Additionally, an international study of 1,828 *BRCA1/2* carriers demonstrated that, with a median follow-up of 3.5 years, RRSO was associated with an 80% reduction in risk of *BRCA*-associated gynecologic malignancies (HR = 0.20, 95% CI, 0.07–0.58; p = .003) (125). Of note, this study estimated a 4.3% cumulative incidence of peritoneal carcinomatosis at 20 years in those undergoing RRSO. Recently the PROSE study group examined the impact of RRSO on ovarian cancer risk with specific analysis not only by gene (*BRCA1* vs. *BRCA2*) but also by breast cancer status (prior breast cancer vs. none). No post-RRSO peritoneal cancers were seen in *BRCA2* mutation carriers either in those with or without prior breast cancer. For *BRCA1* mutation carriers, RRSO decreased the risk of ovarian cancer in both unaffected mutation carriers and those with prior breast cancer (20).

In addition to the residual risk of peritoneal carcinomatosis after RRSO, which appears to be higher in *BRCA1* compared to *BRCA2* mutation carriers, studies have demonstrated that occult malignancies, including cancer of the fallopian tubes, occur in 2% to 10% of women at the time of risk-reducing surgery (111,113,126). This finding underscores the importance of removal of the fallopian tubes at the time of risk-reducing surgery as well as the significance of careful examination of the specimen for occult malignancy.

Studies have also demonstrated that RRSO is associated not only with a reduction in breast and ovarian cancer incidence but also a reduction in disease related mortality. Following an initial small study in 2006, the PROSE study group reported on 2,482 prospectively followed *BRCA1* and *BRCA2* mutation carriers. RRSO was associated with a significant decrease in breast cancer specific (HR 0.44 [95% CI, 0.26–0.76]), ovarian cancer specific (HR 0.21 [95% CI, 0.06–0.80]), and overall mortality (HR 0.40 [95% CI, 0.26–0.61]) (20). These data confirm the critical importance of RRSO in

the management of *BRCA1/2* mutation carriers. Further data are needed on the optimal timing of oophorectomy.

Commonly questioned is the role of hysterectomy in mutation carriers at the time of RRSO. Given the risk of fallopian tube cancer, concern has been raised that a small portion of the proximal fallopian tube remains if hysterectomy is not performed, thus resulting in a residual increased risk of fallopian tube cancer. However, two studies examining fallopian tube cancers indicate that more than 90% occur in the distal or mid-portion of the tube (127), suggesting that the occurrence of a proximal fallopian tube cancer would be a very unlikely event. Some reports have suggested an increased incidence of uterine carcinoma in mutation carriers, whereas others have not confirmed an elevated risk of serous uterine cancer. A case-control study suggested that any increased incidence of uterine cancer among mutation carriers was related to the use of tamoxifen (13); this was confirmed in a more recent study by the same group of 4,456 *BRCA1/2* mutation carriers. Even with tamoxifen use the excess risk of endometrial cancer was small, with a 10 year cumulative risk of 2% (13). In addition, the use of tamoxifen can be minimized at this time given the options of raloxifene for breast cancer prevention (which does not increase the risk of uterine cancer) (128) and aromatase inhibitors for treatment of postmenopausal breast cancer. Therefore, based on our current understanding risk of uterine cancer is not a singularly compelling reason to consider hysterectomy at the time of RRSO.

A final issue to be considered centers on the type of HRT after RRSO. Findings from the Women's Health Initiative have shown an increased risk of breast cancer with combination hormone replacement therapy (estrogen plus progesterone) but not estrogen alone (129). In carriers undergoing hysterectomy, estrogen alone could be used; however it is unclear if the findings from the Women's Health Initiative apply to mutation carriers undergoing premature menopause for whom a brief duration of HRT is being considered. Thus, carriers should consider this information at the time they are undergoing RRSO, but at present, hysterectomy is not routinely recommended.

It has been proposed that the majority of ovarian cancers arise in the fallopian tube (130). Therefore, the concept of salpingectomy only (with delayed oophorectomy—potentially as late as the time of natural menopause) has been proposed as an option for *BRCA1/2* mutation carriers in an effort to avoid premature menopause. However, given the substantial data demonstrating benefit of RRSO, this approach should be viewed as experimental (131,132).

Chemoprevention Oral contraceptives are known to decrease the risk of ovarian cancer in the general population. As discussed previously in the section on cancer risk modifiers, a large case-control study demonstrated that oral contraceptive use reduced the risk of ovarian cancer in *BRCA1* and *BRCA2* carriers (45). However, data from The International *BRCA1/2* Carrier Cohort Study, a retrospective study of 1,593 mutation carriers, indicate that both current and past use of oral contraceptives was associated with an increased risk of breast cancer (HR = 1.47, 95% CI, 1.16–1.87) (47). Other studies have not shown this association (133). Therefore, women and their physicians should consider both the benefits (ovarian cancer risk reduction, prevention of unintended pregnancy, and others) and the risks (potential increased risk of breast cancer, deep venous thrombosis, and others). On the basis of the current data, there is no recommendation specifically for or against the use of oral contraceptives.

Male Breast Cancer

It is recommended (based on expert opinion rather than direct evidence) that male *BRCA1/2* carriers consider monthly breast self-examination, undergo semiannual clinical breast examination starting at age 35, and consider undergoing baseline mammogram at age 40 followed by annual mammogram if gynecomastia is present or baseline study reveals parenchymal or glandular breast density (50). Data regarding the optimal clinical management of male mutation carriers are lacking.

Prostate Cancer

The United States preventative services task force (USPSTF) now recommends against prostate cancer screening in the general population. Given the increased risk of prostate cancer in *BRCA2* mutation carriers, prostate specific antigen (PSA) screening can still be considered, and guidelines suggest that male mutation carriers should *consider* prostate cancer screening starting at age 40 (50). The IMPACT study, a multicenter prostate cancer screening study in *BRCA1* and *BRCA2* mutation carriers and controls ("true negatives"—men who test negative for the known familial *BRCA1* or *BRCA2* mutation) will provide significant information on this issue (134).

Other Cancers

The management of pancreatic cancer risk is uncertain and evolving. Studies in familial pancreatic cancer patients (which generally have included *BRCA2* mutation carriers with at least one first- or second-degree relative with pancreatic cancer) have reported that screening with endoscopic ultrasound, abdominal MRI, or both can detect presumed precursor lesions, namely intraductal papillary mucinous neoplasm (IPMN) (135). However, it is uncertain whether this results in a decrease in pancreatic cancer mortality. A recent multicenter study has suggested that, if pancreatic cancer screening is considered, the earliest age of initiation should be 50 or 10 years prior to earliest pancreatic cancer in the family (136). Novel strategies are also being evaluated. Additionally, it is often recommended that *BRCA2* carriers undergo annual skin examination with a dermatologist for the increased risk of melanoma.

Management of *BRCA1/2*-Associated Breast Cancer

Breast Cancer

Phenotype: Histopathologically, *BRCA1*-associated breast cancers have been consistently noted to be both more frequently high grade and more frequently estrogen and progesterone receptor negative (137–139). In addition, these tumors exhibit more lymphocytic infiltration and continuous pushing margins than is typically seen in sporadic breast cancer (140) and more frequently have medullary or atypical medullary features. On molecular analyses, *BRCA1*-associated breast cancers showed an increased incidence of *p53* mutations (137), but a decreased incidence of overexpression of *erb*B-2 (137). Studies examining *BRCA2*-associated breast cancers have demonstrated that these appear to be similar to sporadic breast cancer with respect to hormone receptor status (139). In addition, in contrast to *BRCA1, BRCA2*-associated breast cancers did not exhibit any differences in expression of *p53* or *erb*B-2 (137).

More detailed molecular analyses from the Cancer Genome Atlas have demonstrated that *BRCA1*-associated breast cancers are often of the basal phenotype and have

confirmed a high rate of *p53* mutations (141). In addition, *BRCA1/2*-associated tumors appear to have a distinct profile of deletions as well as a characteristic signature of substitution mutations (142).

Breast Cancer Prognosis

Investigations have focused on whether the observed phenotypic differences between sporadic and *BRCA1/2*-associated breast cancers have prognostic implications. There has been variability in the findings of these studies, as well as the methodologies employed. Some studies have sought to overcome survival biases that could hinder the interpretability of the findings by genotyping tumor blocks from all Jewish women diagnosed over a specified timeframe and correlating the findings with clinical outcome. Rennert et al. (139) obtained data on all incident cases of invasive breast cancer diagnosed between January 1987 and December 1988 in the Israeli National Cancer Registry. DNA was extracted from available blocks and tested for the three founder mutations in those of Ashkenazi Jewish descent. A total of 1,545 subjects had tumor specimens available for analysis as well as clinical and pathologic records. *BRCA1* or *BRCA2* mutations were identified in 10% of the subjects. The 10-year survival rate was 49% for *BRCA1* carriers, 48% for *BRCA2* carriers, and 51% for noncarriers. The hazard ratio for death from breast cancer adjusted for age, tumor size, and nodal status, did not differ between *BRCA1* carriers (HR = 0.76, 95% CI, 0.45–1.30, p = .31), or *BRCA2* carriers (HR = 1.31, 95% CI, 0.8–2.15, p = .28) compared with noncarriers. Interestingly, among those receiving chemotherapy, a nonstatistically significant trend was seen for improved survival in *BRCA1* carriers (10-year survival of 71% in carriers vs. 46% in noncarriers; HR = 0.48, 95% CI, 0.19–1.21, p = 0.12) and the interaction term between *BRCA1* status and chemotherapy was significant for overall survival (p = .02). Additionally, a survival disadvantage was seen for *BRCA1* carriers with tumors less than 2 cm in size (p = .04). In a study by Robson et al. (143), tumor blocks of 496 Jewish women diagnosed between 1980 and 1995 who underwent breast-conserving surgery were analyzed. Founder mutations were identified in 11% of the women and 10-year breast cancer specific survival was significantly worse in *BRCA1* carriers than noncarriers (62% vs. 86%, p < .001), but not in those with *BRCA2* mutations (84% vs. 86%, p = .76). However, *BRCA1* status predicted for a worse outcome only in those not receiving chemotherapy. Other studies have also demonstrated no differences in breast cancer specific survival in *BRCA1/2* carriers versus noncarriers. Based on these data, mutation status should currently not be viewed as an independent predictor of clinical outcome.

Local Treatment

Although the increased risk of contralateral breast cancer in *BRCA1/2* mutation carriers with breast cancer is well-established, it is less clear whether *BRCA1/2* carriers incur greater risks for ipsilateral cancer if treated with breast-conserving therapy. Additionally, concerns regarding increased radiation sensitivity and potential impact on cosmesis in mutation carriers have been raised. A comprehensive review article noted that among 17 studies examining the risk of in-breast tumor recurrence in genetic cohorts as opposed to those with sporadic disease, 5 noted an increased risk, whereas 12 did not (145). Many of these studies however, did not factor in the impact of either tamoxifen or oophorectomy on subsequent risk of breast cancer. In a study by Pierce et al. (18), which compared 160 *BRCA1/2* carriers with breast cancer who underwent breast-conserving therapy with 445 matched controls with sporadic breast cancer, no overall difference in rate of ipsilateral recurrence at 10 years was noted. However, when women who had undergone prophylactic oophorectomy were excluded from the analysis, mutation carriers had significantly higher rates of ipsilateral recurrence (p = .03). The metachronous ipsilateral breast cancers in carriers were more commonly located in a quadrant other than that of the primary lesion and tended to be associated with longer time to recurrence, suggesting that these represented second primary cancer rather than an in-breast tumor recurrence. Additionally, in this study no negative impact on cosmesis was observed.

A second study by Pierce et al. examined 655 women with known *BRCA1/2* mutations diagnosed with breast cancer who underwent either breast conservation (N = 302) or mastectomy (N = 353) and were followed. There were no differences seen in regional or systemic recurrences between the breast conversation therapy and mastectomy groups, and no difference in overall survival. However, women undergoing breast conservation therapy had an elevated risk of a second in-breast event (largely felt to be second primary tumors) that was significantly reduced by chemotherapy (144).

Thus, breast-conserving therapy is an appropriate local treatment option for mutation carriers with newly diagnosed breast cancer. Nonetheless, it is important that these women understand that they face increased risks for both contralateral and ipsilateral new breast cancers. Thus, some mutation carriers with a newly diagnosed breast cancer may wish to consider bilateral mastectomy to minimize their risk of developing a new primary.

Systemic Treatment

As discussed, current data regarding the impact of *BRCA1*/2 status on breast cancer related prognosis suggest that the details of the breast tumor (stage and hormone receptor status) and not *BRCA1/2* status should remain the main determinants regarding systemic therapy. It is possible that, in the future, choice of systemic therapy may be influenced by genetic information because preclinical and early clinical data suggest that *BRCA*-associated breast cancers may have enhanced sensitivity to certain chemotherapeutic agents such as platinum (146). The increased efficacy of platinum agents is thought to be a possible explanation for the improved survival seen in *BRCA*-associated ovarian cancers as compared with sporadic disease (147). Small, single arm studies of cisplatin chemotherapy in *BRCA1* mutation carriers have demonstrated high response rates in both the metastatic and neoadjuvant settings (148). However, it has also been demonstrated that *BRCA*-mutation associated breast cancers appear sensitive to chemotherapy in general (not just to cisplatin) with improved responses compared with sporadic breast cancers in both the metastatic and neoadjuvant (149,150) setting. Studies are underway to compare platinum-based chemotherapy to standard chemotherapy in *BRCA*-associated breast cancer to directly address whether there is difference in outcome. In addition, hope is that a novel class of drugs Poly(ADP-ribose) polymerase-1 (PARP-1) inhibitors, may be particularly effective in *BRCA* mutation-associated breast cancer. PARP-1 is an enzyme involved in the repair of single-strand DNA (ssDNA) breaks through base excision repair. In PARP-1 deficient states, ssDNA breaks may go on to become double strand DNA (dsDNA) breaks. The repair of dsDNA breaks is dependent on *BRCA1*- and *BRCA2*-mediated processes. Thus, in *BRCA*-deficient cells, it is hypothesized that PARP-1 inhibition will

result in accumulation of dsDNA breaks, ultimately leading to apoptosis (151,152). Clinical trials of PARP inhibitors in *BRCA*-associated breast and ovarian cancers have demonstrated encouraging results and multiple studies are ongoing (153,154).

Screening and Risk Reduction Options for Second Malignancies

Mutation carriers with a breast cancer diagnosis are at increased risk of developing a second breast cancer and ovarian cancer (see section on Clinical Characteristics). As previously noted, up to 25% of mutation carriers with stage I breast cancer will subsequently succumb to ovarian cancer. Thus, it is recommended that the screening and prevention guidelines for breast and ovarian cancer as described in the prior section on management of unaffected mutation carrier, be utilized. It is important to note that these must be individualized and balanced, incorporating information on the underlying prognosis related to the breast cancer. Two separate studies have examined the risk of breast cancer following the diagnosis of ovarian cancer. In both of these studies, the risk of developing breast cancer within five years of an ovarian cancer diagnosis was quite low (while unfortunately the risk of relapse and death due to ovarian cancer was not). Thus, conservative management of breast cancer risk following the diagnosis of ovarian cancer in *BRCA1/2* mutation carriers is suggested (18,19).

Management of Individuals with Other Hereditary Breast Cancer Syndromes

Li-Fraumeni Syndrome

Li-Fraumeni syndrome (LFS) is a rare, highly penetrant autosomal-dominant condition characterized primarily by soft tissue sarcomas, osteosarcomas, leukemias, brain tumors, adrenocortical malignancies, and early onset breast cancer (Table 17-1) (2). Specific testing criteria based on these features have been published which include women diagnosed with breast cancer at age 35 or younger with a negative *BRCA1/2* test result (50). Mutations in the tumor suppressor gene *TP53* occur in at least 70% of families with LFS (2). It is estimated that 50% of carriers will develop a LFS-associated cancer by age 30 years and the lifetime risk of cancer exceeds 90% (2). Individuals are also at high risk for developing multiple primary cancers (2). In particular, the occurrence of breast cancer in these families is remarkable in that the median age of diagnosis in women is in the early 30s; male breast cancer, however, is rarely reported. Owing to concerns about increased risks for cancer in the field of radiation treatment, mastectomy is recommended over lumpectomy; alternatively bilateral mastectomy may be the treatment of choice. Management guidelines from the National Comprehensive Cancer Network indicate that, for women, the recommended surveillance for breast cancer consists of consideration of monthly breast self-examination beginning at age 18; semiannual clinical breast examinations beginning at age 20 to 25 or 5 to 10 years before the age of occurrence of the first breast cancer in the family; and annual breast MRI starting at age 20 to 25 (46). Mammography can be added at the start of MRI screening or at age 30 as MRI only may be sufficient between ages 20 and 30. Risk-reducing mastectomy should also be discussed on an individual basis. Beginning at age 20 to 25 years, an annual comprehensive physical examination is recommended with particular focus on rare cancers (50). Early studies have suggested that intensive surveillance may aid in the early detection of malignancy. Recent data on an intensive screening regimen including full body MRI and brain MRI, which has the advantage of avoiding radiation, have been encouraging. Participation in clinical trials with novel imaging is encouraged. Colonoscopy should be considered by age 25, and be repeated every 2 to 5 years (50). Pretest counseling is imperative in testing for *TP53* mutations given the significant implications of a positive result, including for children.

Cowden Syndrome

Cowden syndrome is a rare, although potentially underrecognized, autosomal-dominant condition characterized by macrocephaly; multiple hamartomatous lesions; characteristic skin findings; benign lesions of the breast, uterus, and thyroid; and an increased risk of early onset breast cancer, as well as cancers of the thyroid (usually follicular), endometrium, kidney (renal cell), colorectum, and skin (melanoma) (Table 17-1) (3). Specific criteria for testing are available, in which up to 85% of individuals who meet these criteria have a mutation in the *PTEN* gene. The lifetime risk of breast cancer is between 25% and 50%, with most cases diagnosed before age 50 (3). Recent data have suggested a lifetime risk of breast cancer as high as 85%; however, this penetrance estimate may have been high due to the study design and ascertainment bias (155). In addition, up to 75% of women with Cowden syndrome have been observed to have a variety of benign breast conditions, including ductal hyperplasia, intraductal papillomatosis, adenosis, lobular atrophy, fibroadenomas, and fibrocystic changes (3). Management guidelines from the National Comprehensive Cancer Network indicate that, for women, the recommended surveillance for breast cancer consists of consideration of monthly breast self-examination beginning at age 18; semiannual clinical breast examination beginning at age 25 or 5 to 10 years before the age of occurrence of the first breast cancer in the family; and annual mammogram and breast MRI starting at age 30 to 35 or 5 to 10 years younger than the earliest known breast cancer in the family. Risk-reducing mastectomy and hysterectomy should also be discussed on an individual basis. Additional screening should include annual comprehensive physical examination beginning at age 18, with particular focus on breast and thyroid examinations, colonoscopy beginning at age 35, baseline thyroid ultrasound at age 18 with consideration of annual examination, and annual dermatologic examination. Screening strategies for endometrial cancer and renal cell cancer are not clearly defined at this time.

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome (PJS), arising predominantly from mutations in the *STK11* (*LKB1*) gene, is an autosomal-dominant condition characterized by hamartomatous polyps in the gastrointestinal tract and by mucocutaneous melanin deposits in the buccal mucosa, lips, fingers, and toes (Table 17-1) (4). With respect to extraintestinal cancers, the most significant risk is for breast cancer, with a lifetime risk estimated to be 45% to 50%. Although overall few cases have been reported, onset before age 50 years and bilateral disease is not uncommon. The risk of ovarian cancer, estimated at about 20%, is significant, but many of these are nonepithelial sex cord tumors (4). Women also face elevated risks for colon, stomach, pancreatic, small intestine, cervical, uterine, and lung cancers. Management guidelines from the National Comprehensive Cancer Network indicate that women with PJS should be managed by a specialized team and consider participation in clinical trials (50). They recommend that women undergo annual mammography and breast MRI

starting at about age 25, colonoscopy and upper endoscopy every 2 to 3 years starting in the late teens, as well as consideration of other gastrointestinal and gynecologic screening. Many of these guidelines are provisional, and may be modified based on an individual's family history.

Hereditary Diffuse Gastric Cancer

Hereditary diffuse gastric cancer is an autosomal-dominant cancer predisposition syndrome associated with diffuse gastric cancer (signet ring carcinoma or isolated cell-type carcinoma) and female lobular breast cancer. Up to 50% of affected individuals harbor a mutation in the *CDH1* gene; in other cases, the causative gene mutations remain unidentified. Based on multi-case families, it is estimated that the lifetime risk of gastric cancer is 80%, and the average age of onset is before age 40 (range 14 to 69 years). The lifetime risk of breast cancer in women is between 39% and 52%, and the average age of onset is 53 years; however, this risk estimate assumes that women do not develop gastric cancer or that they survive it long term (5). It is important to note that lobular breast cancers are typically difficult to detect on mammography and MRI may be more accurate in this setting. Thus, annual mammography and breast MRI from the age of 35 years is recommended for women (156). Given that lobular carcinomas are frequently hormone receptor positive, chemoprevention with tamoxifen or raloxifene is a very reasonable option. Additionally, risk-reducing mastectomy can be considered.

Moderate Penetrance Genes

A number of "moderate" penetrance genes have been identified, mutations in which are associated with a relative risk of breast cancer of 2 to 5. Multiplex panels (described in Table 17-2) are increasingly commercially available and may be appropriate to consider for women with breast cancer or a family history of breast cancer who have tested negative for *BRCA1/2* mutations. Despite the availability of these panels, it remains uncertain how the presence of a moderate penetrance breast cancer susceptibility allele should change clinical management. Multiple studies are ongoing to attempt to address this issue. In addition, as demonstrated in Table 17-2, these commercial multiplex panels contain both high penetrance and moderate penetrance genes. The mix of moderate and high penetrance alleles in a single panel raises concerns about appropriate counseling and consent. For many of the moderate penetrance genes on these panels, very limited information is available on breast cancer risk estimates and associated risks of other cancers. In addition, because many genes are being analyzed, it is very likely that variants of uncertain significance will be detected, further complicating the interpretation of results. Finally, significant caution should be taken prior to counseling family members as "true negatives" of moderate penetrance gene mutations. Different counseling models are needed prior to wide use of these panels (7). Here, we discuss two of the moderate penetrance genes for which the most information is available, *CHEK2* and *PALB2*.

CHEK2: CHEK2 (cell cycle checkpoint kinase 2) plays a role in cell-cycle arrest and DNA repair. One of the most commonly identified variants in the *CHEK2* gene is a small deletion (1100delC), which is found predominantly in individuals of northern and eastern European descent (157). A recent meta-analysis of breast cancer risk associated with this specific mutation reported that, among pedigrees with "familial breast cancer" (i.e., one case of female breast cancer with one or more relatives with breast cancer, including male breast cancer, or ovarian cancer), the cumulative risk of breast cancer to age 70 was 37% (95% CI, 26%–56%) (157). Although this risk roughly compares with those reported in lower end of the range for *BRCA1* and *BRCA2* carriers, it is important to bear in mind that the studies used in the analysis used a variety of ascertainment methods, which may have biased estimates of penetrance (157,158). Mutation type and type of cancer in the proband may impact the cancer risks in relatives (159); and the full spectrum of cancers associated with this and other specific variants in *CHEK2* is not fully defined (157,158). Moreover, it is unclear whether other low penetrance genes could contribute to familial breast cancer risks in *BRCA1/2*-negative families in addition to potential *CHEK2* mutations and what management strategies are optimal. Given that most *CHEK2*-related breast cancers are hormone receptor positive (160), chemoprevention with the selective estrogen receptor modulators (SERM) tamoxifen or raloxifene could be considered; however, whether such testing information impacts uptake of SERM use is unknown. Recent data have suggested a worse outcome of breast cancer associated with germline *CHEK2* mutations, but it is not clear if this is independent of other tumor features (such as gene expression profiles from Oncotype testing in ER positive, node negative breast cancer patients) (161). In summary, *CHEK2* is a known, although uncommon, moderate penetrance breast cancer susceptibility allele, but how to best use knowledge of mutation status in clinical practice is evolving.

PALB2: Truncating mutations in the *PALB2* gene on chromosome 16p12.2 have been described in individuals with familial breast cancer. Such mutations have not been seen in controls and thus the relative risk of breast cancer is estimated to be 2–3. Heterozygous *PALB2* mutations have also been associated with pancreatic cancer (8). In this study, 3 of 96 familial pancreatic cancer patients had truncating *PALB2* mutations, and no mutations were found in control subjects. However, *PALB2* are not frequently found, even in families with both breast and pancreatic cancer. Further work is needed on penetrance estimates for pancreatic cancer and to better understand the utility of pancreatic cancer screening.

SUMMARY

Most individuals with a family history of breast cancer have a familial rather than hereditary basis to their disease. For women with hereditary breast cancer, *BRCA1* and *BRCA2* mutations account for most cases. Mutations in these genes are associated with a significantly elevated risk of early onset breast and ovarian cancer. In addition, other cancers may be seen with an increased frequency in mutation carriers. Models based on cancer history, family history, and ethnic background are available to guide clinicians in estimating the likelihood that an individual harbors a risk-conferring mutation. Data from prospective studies have emerged demonstrating a strong protective effect of bilateral salpingo-oophorectomy and bilateral mastectomy on cancer incidence. Additionally, it is now recommended that women with a hereditary predisposition to breast cancer alternate annual breast MRI with mammogram. Because of the complexities involved in decision-making about genetic testing and medical management, genetic counseling is recommended before and after undergoing testing. Further studies on genetic and environmental cancer risk modifiers, genotype–phenotype correlations, and the impact of cancer screening and prevention options are underway and will continue to provide greater insight into the features and management of individuals at high risk.

MANAGEMENT SUMMARY

- *BRCA1/2* carriers face significantly elevated risks of early onset breast and ovarian cancer as well as increased risk of pancreatic, prostate, and male breast cancer.
- Decisions regarding more intensive screening versus prevention (particularly risk reducing surgery) are often personal, based on a careful balancing of the relative risks and benefits of the various options.
- Breast cancer screening recommendations include annual mammogram alternating with annual breast MRI.
- Breast cancer prevention options can be combined with more intensive screening and include RRSO, risk reducing mastectomy, and chemoprevention (with tamoxifen, raloxifene, or exemestane).
- For management of ovarian cancer risk, bilateral salpingo-oophorectomy between ages 35 and 40 and once childbearing is complete is strongly recommended. Short-term HRT before age 50 can be considered.
- For women who have not undergone salpingo-oophorectomy, semiannual CA-125 and TVUS are recommended, beginning at age 30 or 5 to 10 years younger than the earliest age of onset of ovarian cancer in the family. However, few data support a benefit of screening for ovarian cancer.
- Male mutation carriers should perform monthly breast self-examination, have semiannual clinical breast examination, and consider annual mammography. Prostate cancer screening can be considered, particularly in *BRCA2* mutation carriers.
- *BRCA2* mutation carriers may consider annual skin examination, on an individualized basis, and consider participating in studies on pancreatic cancer screening.
- Mutation status does not impact early stage breast cancer systemic management in *BRCA1/2* carriers at this time, but mutation carriers need to consider their risks of second malignancy and should follow similar guidelines to those outlined previously for unaffected carriers.
- Recommendations for management of members of hereditary breast cancer families who have undergone genetic testing and tested negative for *BRCA1/2* mutations need to be individualized based on their personal and family history.

CHAPTER 18

Nongenetic Factors in the Causation of Breast Cancer

Walter C. Willett, Rulla Tamimi, Susan E. Hankinson, Aditi Hazra, A. Heather Eliassen, and Graham A. Colditz

CHAPTER CONTENTS

Breast cancer has an enormous impact on the health of women. Approximately 227,000 women are diagnosed with invasive breast cancer annually in the United States, accounting for approximately 29% of all incident cancers among women (1). Each year, 40,000 women die of breast cancer, making it the second leading cause of cancer deaths among U.S. women, after lung cancer, and the leading cause of death among women aged 40 to 55 years. Breast cancer is rare among men, with only 2,190 incident cases and 410 deaths estimated for the United States in 2012 (1). The lifetime risk of being diagnosed with breast cancer through age 85 years for an American woman is approximately 1 in 8, or 12.15%, whereas the lifetime risk of dying from breast cancer is approximately 3.4% (2).

This chapter begins with a description of the marked variations in breast cancer rates among populations and over time. Decades of research have led to a substantial understanding of the factors involved in the development of breast cancer; known and suspected risk factors are reviewed and considered in relation to etiologic mechanisms leading to breast cancer. The contribution that known risk factors make to the existing variations in rates is considered; this contribution is central to the question of whether unidentified pollutants or dietary factors explain the current high rates in the United States. Because of the major investments in breast cancer research, the means for preventing a substantial fraction of breast cancer now exists; strategies that can be adopted by individual women, their healthcare providers, and societies and governments as a whole are examined.

DESCRIPTIVE EPIDEMIOLOGY OF BREAST CANCER

High- and Low-Risk Populations

The incidence of female breast cancer varies markedly between countries, being highest in the United States, western and northern Europe, intermediate in southern and eastern Europe and South America, and lowest in Asia and Africa (3). In 2008, the age-adjusted incidence rate of breast cancer varied by about a factor of five across countries worldwide (Fig. 18-1) (3). However, incidence rates have been rising in traditionally low-incidence Asian countries, particularly in Japan, Singapore, and urban areas of China as these regions are making the transition toward a Western style of economy and pattern of reproductive behavior (4,5). As a result of unfavorable trends in these countries, the international gap in breast cancer incidence has narrowed since 1970 (6).

Age–Incidence Curve of Breast Cancer Risk

Breast cancer is extremely rare among women younger than 20 years and is uncommon among women younger than 30 years. Incidence rates increase sharply with advancing age, however, and become substantial before age 50 years. From 2000 to 2009, the incidence of breast cancer among American women aged 30 to 34 years was 26 per 100,000 and increased to 188 per 100,000 among women aged 45 to 49 years (1). The rate of increase in breast cancer incidence continues throughout life but slows somewhat around ages 45 to 50 years, strongly suggesting the involvement of reproductive hormones in breast cancer etiology because non–hormone-dependent cancers do not exhibit this change in slope of the incidence rate curve around the time of menopause (7). By age 70 to 74 years, the incidence of breast cancer among American women rises to 425 per 100,000 (8). The shape of the age–incidence curve in low- and intermediate-risk populations is similar to that of the United States, although the absolute rates are lower at each age (9) (Fig. 18-2).

Racial/Ethnic Groups within the United States and Studies of Migrants

According to recent data from the Surveillance, Epidemiology, and End Results (SEER) registries (1), the lifetime risk of breast cancer for white women in the United States is 12.8%, approximately 1 in 8, whereas that for black women is 10.1%, approximately 1 in 10. Between 2000 and 2009, the overall age-adjusted incidence rate of breast cancer among white women in the United States averaged 127 per 100,000 women, whereas the corresponding rate among black women averaged 121 per 100,000 women (1). However, these age-adjusted figures conceal a crossover pattern in which the risk of breast cancer at a young age is modestly higher among black women than white women. At older ages, incidence rates for white women are substantially higher than those among black women (Fig. 18-2).

Unlike that of most other illnesses, the lifetime risk of breast cancer is positively associated with higher socioeconomic status. This association is largely explained by the known reproductive risk factors (10); women in lower socioeconomic strata are more likely to have more children and to have them at younger ages than women in higher socioeconomic strata. It is likely that much, if not all, of black/white differences in breast cancer rates among older women reflect racial differences in social class distribution (11) and, thus, in the distribution of established reproductive risk factors. The modestly higher incidence rates of breast cancer among young black women relative to young white women are consistent with the hypothesis of a short-term increase in breast cancer risk immediately following pregnancy, although the overall lower lifetime risk of breast cancer among black women is consistent with the hypothesis of a long-term benefit of early and repeated pregnancy (12). The effect of these reproductive factors on breast cancer risk is described in greater detail in the following section on

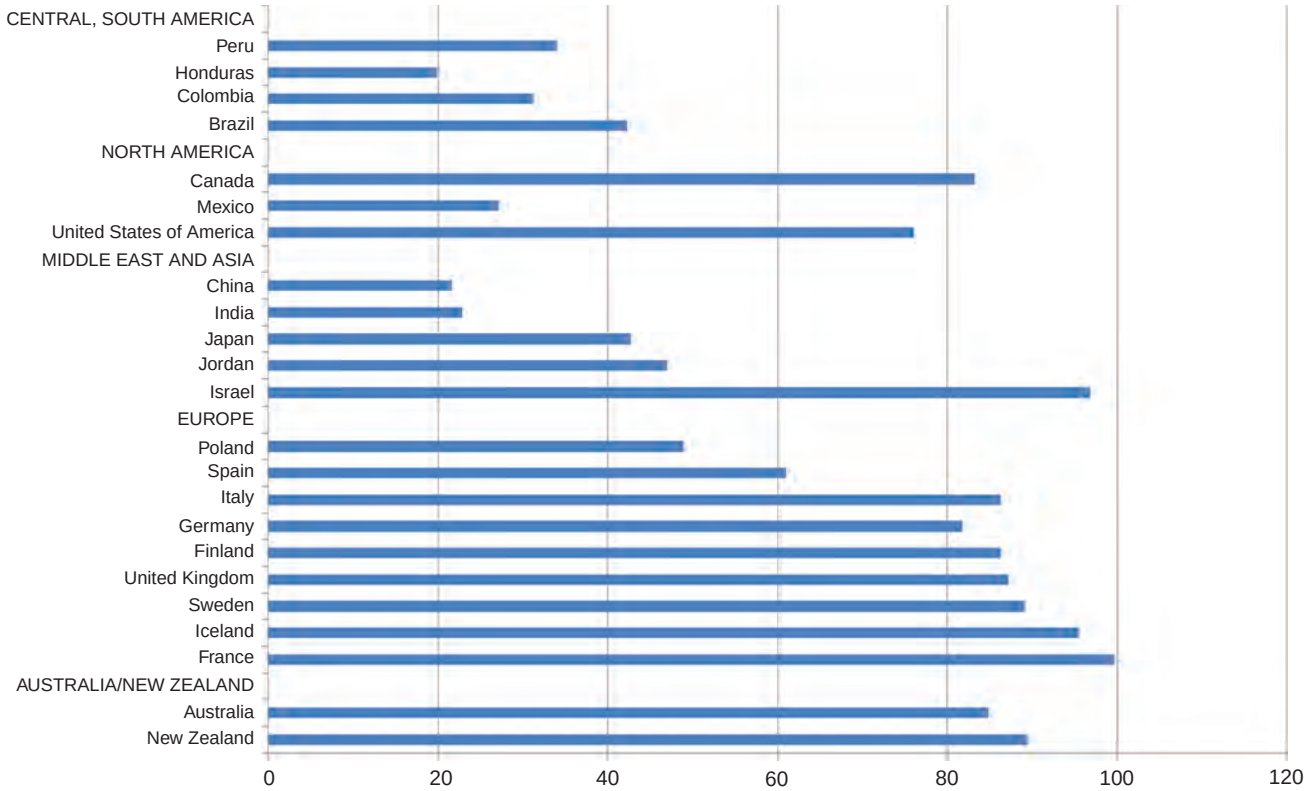

FIGURE 18-1 International variation in breast cancer incidence among women in 2008, per 100,000 women-years, age adjusted to the world standard. (Data from GLOBOCAN 2008. Ferlay J, Shin HR, Bray F, et al. *Cancer incidence, mortality and prevalence worldwide*. Lyon, France: IARC Press, 2010.)

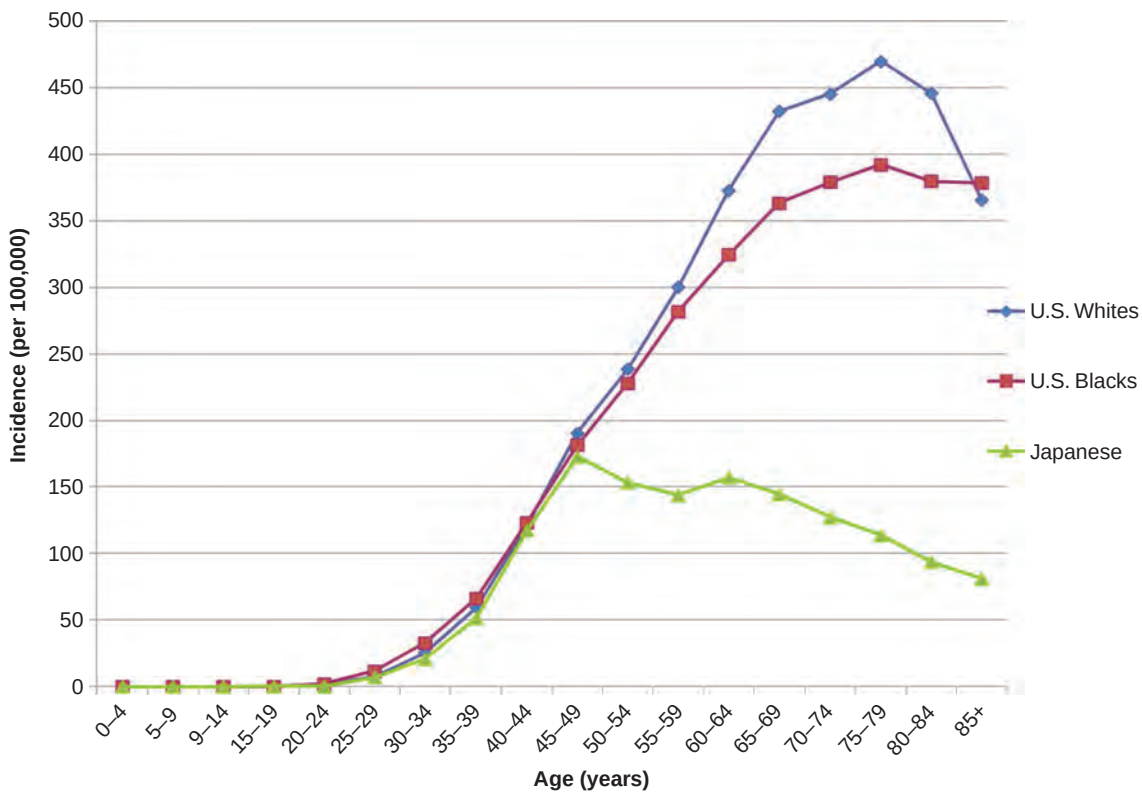

FIGURE 18-2 Age-specific breast cancer incidence rates, white and black U.S women (2000–2009) and Japanese women (2006). (Data from U.S. women from Surveillance, Epidemiology, and End Results (SEER) Program (www.seer.cancer.gov), National Cancer Institute, DCCPS, Surveillance Research Program, Cancer Statistics Branch; data for Japanese women from Cancer Statistics in Japan (http://www.ncc.go.jp.))

modeling. Although black women have a lower probability of developing breast cancer over their lifetime, their risk of dying from breast cancer is the same or perhaps even slightly higher than white women (3.26% compared to 2.86% for black and white women, respectively) (13). Black women have poorer 5-year survival rates from breast cancer at all ages of diagnosis compared to white women (2). This poorer survival can be attributed, in part, to the tendency of black women to be diagnosed at later stages of disease (2). In addition, there is evidence that molecularly defined subtypes of breast cancer associated with poor prognosis, specifically basal-like tumors, are more likely to occur among black women (2).

Breast cancer incidence rates among Asian, Hispanic, and American Indian women in the United States are considerably lower than those of (non-Hispanic) white women (2). The magnitude of the difference in incidence rates among various ethnic groups often depends on migrant status. For instance, breast cancer incidence for Chinese American and Japanese American women from 1973 to 1986 was about 50% lower for those born in Asia and about 25% lower for those born in the United States compared to U.S.-born white women (14). Among Filipino residents of the United States, the incidence rate of breast cancer was nearly identical between foreign-born and U.S.-born women, and both were less than half that of U.S.-born white women. Compared with Chinese women living in the mainland, Singapore, and Hong Kong, Asian-born Chinese women living in the United States had an almost twofold higher annual rate of breast cancer, and U.S.-born Chinese women had a higher rate still (14,15). The pattern for Japanese women was similar (14).

These findings are consistent with a large body of literature showing increases in breast cancer incidence following migration from a low-risk country to the United States (16–21). Ziegler et al. (21) noted a six-fold gradient in risk of breast cancer among Asian women, depending on recency of migration. Asian American women with three or four grandparents born in the West were at highest risk, whereas women who were born in rural areas of Asia and whose length of residence in the United States was a decade or less were at lowest risk. Although the studies of breast cancer risk among migrants have focused almost exclusively on migrants from low-risk to high-risk countries and have shown convergence of rates, there are also data suggesting that a convergence of rates similarly occurs when migrants move from high-risk to low-risk countries. For instance, Kliewer and Smith (22), reporting on immigrants to Australia and Canada, note that immigrant groups coming from countries where breast cancer mortality rates were higher than those of native-born women often showed a decrease in mortality. Such findings strongly suggest that factors associated with the lifestyle or environment of the destination country influence breast cancer risk and are consistent with a positive relationship between length of time in the destination country and adoption of that country's lifestyle. For example, among immigrants, the fertility rate and the average number of children born tend to converge to the rates of the destination country (23,24).

Geographic Variation in the United States

Breast cancer incidence and mortality rates vary within the United States, although to a much smaller degree than among countries. During the 1980s, the incidence of breast cancer in the San Francisco Bay Area was somewhat higher than that for the rest of the United States, and international comparisons based on data from this decade led to an often-quoted statement that white women in the San Francisco Bay Area had the highest incidence of breast cancer in the world (15,25). Based on the most recent SEER data (1) and the National Cancer Institute (Fig. 18-3A), incidence of breast cancer is above the national average among women in the Pacific Northwest and the northeastern United States (age-adjusted incidence rate for Connecticut is 137 per 100,000 and for Washington is 132 per 100,000) (1). Previous reports have concluded that the high incidence of breast cancer in the San Francisco area and in the Northeast can likely be accounted for by regional differences in the prevalence of known risk factors, including parity, age at first full-term pregnancy, age at menarche, and age at menopause (25–29). Among the 17 SEER registry sites, the lowest age-adjusted incidence rates among women are found in Arkansas (109 per 100,000), Utah (108 per 100,000), and New Mexico (110 per 100,000) (1,9). Again, regional differences in reproductive risk factors largely explain these lower rates.

Geographic differences in breast cancer mortality across the United States vary by approximately 1.5 comparing areas of highest versus lowest mortality (1). Figure 18-3B illustrates these regional differences from 2005 to 2009. Although incidence rates are highest in the Pacific Northwest and Northeast, these regions tend to have lower breast cancer mortality rates than the national average. These differences may be due to regional differences in breast cancer risk factors, mammographic screening, and treatment. Geographic differences in the prevalence of established risk factors explain much of the geographic differences in mortality. In 1987, age-adjusted mortality ratios among women 50 years and older were 1.15, 1.18, and 1.30 in the West, Midwest, and Northeast, respectively, compared with the South. After adjustment for established breast cancer risk factors, these mortality ratios fell to 1.13, 1.08, and 1.13, respectively (29).

Trends in Incidence and Mortality

Incidence rates of breast cancer have steadily increased in the United States since the 1930s, when formal record keeping began in Connecticut, until 2000. Between 1950 and 2000, the age-adjusted incidence rate rose by an average of 1.4% per year in this state (30), which has the oldest cancer registry in continuous operation. This represents a cumulative increase of about 70% over the 50 years. During the 1980s, incidence rates rose more sharply. Data from the SEER program, which began collecting data from different registries across the country in 1973, confirm the trends in incidence portrayed in the Connecticut registry since that time (Fig. 18-4). Increases have occurred in all age groups since 1935, although the magnitude of increase has been greater for older women. Between 1975 and 2000, incidence rates among black women younger than 50 years increased by 22% compared to a cumulative increase of 10% for white women younger than 50 years (8). Among women 50 years and older, the cumulative increase was 40% for both black and white women. Between 2001 and 2004, incidence rates of breast cancer decreased by approximately 3.5% per year. Between 2005 and 2009, incidence rates among white women have remained relatively constant; while among black women incidence rates have increased.

Several studies have examined whether the increase in breast cancer incidence in the United States has been due to the increasing use of screening mammography (31–36). Because screening causes at most a transient increase in incidence, and because its use was limited before the 1980s, it can explain little of the long-term increase between the 1930s and the 1980s. However, during the 1980s, the

increased incidence was almost entirely due to an increase in localized disease and in tumors measuring less than 2 cm in diameter; the incidence of tumors 2 cm or larger remained stable. These findings suggest that the increase in use of screening mammography accounts for part of the recent increase in breast cancer incidence (34,37). A recent analysis of SEER data suggests that 31% of breast cancers diagnosed in 2008 are due to overdiagnosis and in the absence of mammographic screening would have never been clinically detected (38). Although this study was limited by making a number of assumptions, including that the underlying incidence was constant over this time and was unable to distinguish between DCIS and regional disease, the results are in line with other studies suggesting that a substantial amount of breast cancers are overdiagnosed with mammographic screening (39). The continued increase in breast cancer rates during the 1990s may be due in part to increased use of hormone replacement therapy, obesity, and mammography screening. The decline in rates observed between 2001 and 2004 likely reflect decreases in both mammographic screening and postmenopausal hormone use after publication of results from the Women's Health Initiative (WHI) randomized trial in 2002 (30,40). Since 2005, breast cancer rates have plateaued in the United States, Canada, Australia, and parts of Europe (3).

Trends in breast cancer mortality are of major public health interest, but their interpretation is complex because they reflect the combined effects of trends in underlying risk of breast cancer, changes in screening practices, and effectiveness of treatment. Also, the divergence between breast cancer incidence and mortality rates began in the United States even before the use of mammography or chemotherapy (Fig. 18-5), suggesting that awareness of breast cancer and earlier use of simple surgical treatment have also influenced mortality rates (41). Further, mortality rates lag behind changes in breast cancer incidence, screening, and treatment by at least 5 to 10 years (42). Age-adjusted mortality rates in the United States were relatively stable between the 1950s and the mid-1980s, when an overall decline was first noted (37). Mortality rates in the late 1980s began to decline slightly (about 1% per year). Rates through the 1990s declined somewhat more (3% decline per year) (8,43), perhaps because of enhanced treatment and screening. These overall trends obscure important variation by age and race, however. Since the 1970s, mortality rates have fallen for younger white women, and this decline has accelerated since

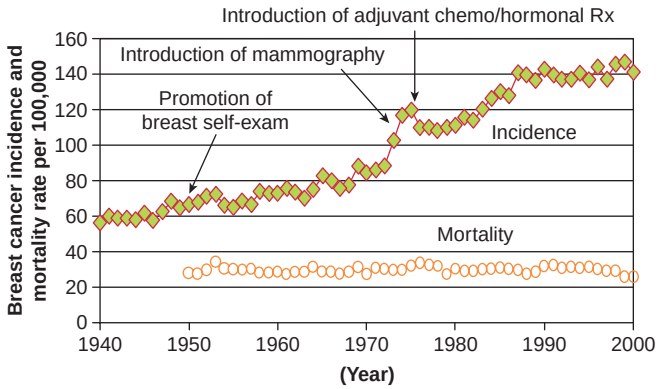

FIGURE 18-5 Breast cancer incidence and mortality in the United States, based on the Connecticut SEER database, 1940-2000. (From Shulman LN, Willett W, Sievers A, Knaul FM. Breast cancer in developing countries: Opportunities for improved survival. *J Oncol* 2010; 2010:595167, with permission.)

the late 1980s. From 1973 to 1995, the cumulative decline in mortality rates for white women younger than 60 years has been more than 20%, with much of this decline occurring since 1988. In contrast to these trends among younger white women, mortality rates for white women 60 years and older increased slowly during the 1970s and 1980s, although since the late 1980s, mortality has also begun to decline in this group (37,42). The trends in breast cancer mortality among black women have been unfavorable; between the 1970s and 1990, mortality rates increased for black women in all age groups (42), and only recently is there evidence of a decline, but to a lesser extent than what is observed in white women (Fig. 18-6). From 1992 to 2009, breast cancer death rates have declined by 1.8% per year in whites compared with 1.0% in black women (1).

Trends in Incidence and Mortality around the World

Since the 1950s, breast cancer incidence has been increasing in many of the lower risk countries and in high-risk Western countries. Some of the recent increases in incidence in high-risk populations may be due to greater use of mammography, as in the United States. This appears to be the case in Sweden (44) and in England and Wales (45). Breast cancer incidence rates have nearly doubled in recent decades in traditionally low-risk countries such as Japan (4,9) and Singapore (5) and in the urban areas of China (46). Dramatic changes in lifestyle in such regions brought about by growing economies, increasing affluence, and increases in the proportion of women in the industrial workforce have had an impact on the population distribution of established breast cancer risk factors, including age at menarche and fertility, as well as nutritional status (47). These changes have resulted in a convergence toward the risk factor profile of Western countries (47).

Trends in breast cancer mortality around the world have largely paralleled the trends in incidence. Between the 1970s and 1990s mortality increased in both high-risk and lower risk populations, although since the 1990s mortality has declined moderately in the United Kingdom, the Netherlands, and Sweden, similar to the decline observed in the United States (3,48,49). As in the United States, some of the downturn in mortality in these countries may be due to more widespread use of screening mammography, adjuvant chemotherapy during the 1980s (48,50), and more recently targeted therapies (51). Countries with mortality rates that are still increasing tend to be those with the lowest mortality (48). For instance, Russian Federation, Republic of Korea, and Japan all have breast cancer mortality rates that are continuing to increase (3). Thus, a convergence of breast cancer mortality rates may be occurring internationally, in part reflecting an international convergence of reproductive and behavioral risk factors (48).

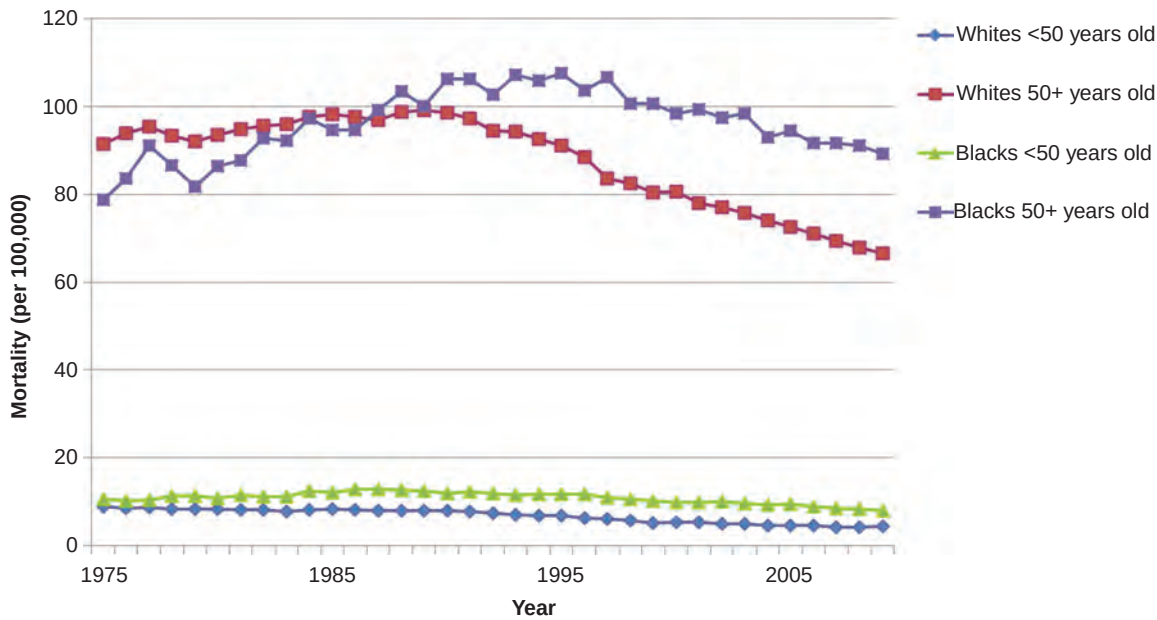

FIGURE 18-6 Trends in breast cancer mortality for white and African American women in the United States by age-group. (Data from National Cancer Institute. Surveillance Epidemiology, and End Results Program, Cancer Incidence and Mortality Statistics. National Cancer Institute, DCCPS, Surveillance Research Program, Cancer Statistics Branch, Accessed December 2012.)

REPRODUCTIVE FACTORS

This section addresses reproductive factors during the course of a woman's life in relation to the risk of breast cancer. An underlying concept is that ovarian hormones initiate breast development and that subsequent monthly menstrual cycles induce regular breast cell proliferation. Puberty is a critical period during breast development. The onset of puberty is marked by a surge of hormones that induce regular breast cell proliferation. This pattern of cell division terminates with menopause, as indicated by cessation of ovulation and menstrual periods.

Menarche

Menarche represents the development of the mature hormonal environment for a young woman and the onset of monthly cycling of hormones that induce ovulation, menstruation, and cell proliferation within the breast and endometrium. Earlier age at menarche has been consistently associated with increased risk of breast cancer (52). Most studies suggest that age at menarche is related to both premenopausal and postmenopausal breast cancer, although the magnitude of effect appears to be greater for premenopausal than postmenopausal women (53). In a pooled analysis of 7,764 premenopausal women and 16,467 postmenopausal women, each additional year in delay of menarche was associated with a 9% decrease in premenopausal breast cancer and a 4% decrease in postmenopausal breast cancer (54). In addition, age at menarche is inversely associated with both estrogen receptor positive (ER+)/progesterone receptor positive (PR+) and estrogen receptor negative (ER-)/progesterone receptor negative (PR-) breast tumors, although the protective effect of late age at menarche is greater for hormone receptor positive tumors (55). More recently, studies have evaluated the association between reproductive factors and molecular subtypes of breast cancer. At least four major categories of invasive breast cancer have been reproducibly identified by gene expression profiling: luminal A, luminal B, HER2-type, and basal-like (56). Large-scale epidemiologic studies have used immunohistochemical markers as proxies to characterize tumors into these subtypes. These studies have tended to show an association with increasing age at menarche and reduced risk of luminal A tumors (57,58).

Although menarche is most clearly related to the onset of ovulation, some studies suggest that hormone levels may be higher through the reproductive years among women who have early menarche (59). In addition, early menarche may be associated with earlier onset of regular ovulatory menstrual cycles and hence greater lifetime exposure to endogenous hormones (60). Whether the levels of ovarian hormones or their cyclic characteristics are the underlying influence on breast cancer risk is unsettled (7); both likely play a role.

Menstrual Cycle Characteristics

Shorter cycle length has been quite consistently related to greater risk of breast cancer (52), although not all studies support this relation (61). Shorter cycle length during ages 20 to 39 years may be associated with higher risk of breast cancer, perhaps because the shorter cycle length is associated with a greater number of cycles and more time spent in the luteal phase when both estrogen and progesterone levels are high. Long and irregular cycles may also be related to reduced risk of breast cancer (61).

Ovulatory infertility, an indicator of infertility due to hormonal causes, has not been consistently related to risk of breast cancer, although one cohort study suggested a substantially lower risk among women with this condition (relative risk [RR] = 0.4 compared to women with no infertility history) (61). The significant inverse association seen in this study may be related to the young age of the cohort and thoroughness of investigation of the cause of infertility in this group of health professionals.

Pregnancy and Age at First Full-term Pregnancy

Nulliparous women are at increased risk of breast cancer compared to parous women. This risk is evident after age 40 to 45 years, but not for breast cancer diagnosed at younger ages. In the majority of epidemiologic studies, a younger age at first full-term pregnancy predicts a lower lifetime risk of breast cancer (52). The reduction in risk following pregnancy compared to nulliparous women is not immediate but takes approximately 10 to 15 years to manifest (62). In fact, risk of breast cancer is increased for the first decade following first pregnancy (12,63,64). The proliferation of breast cells during the first pregnancy results in differentiation into mature breast cells prepared for lactation; this may also lead to growth of mutated cells and excess risk over the next decade. Epidemiologic evidence for the transient excess risk after the first pregnancy is consistent. Less clear is the presence of a transient increase in risk after subsequent pregnancies; some studies suggest an adverse effect (65) but others do not (64).

The first pregnancy is associated with permanent changes in the glandular epithelium and with changes in the biologic properties of the mammary cells. After the differentiation of pregnancy, epithelial cells have a longer cell cycle and spend more time in the G_1 phase, the phase that allows for DNA repair (66). The longer the interval from menarche to first pregnancy, the greater the adverse effect of the first pregnancy (12). The later the age at first full-term pregnancy, the more likely that DNA mistakes have occurred that will be propagated with the proliferation of mammary cells during pregnancy. The susceptibility of mammary tissue to carcinogens decreases after the first pregnancy, reflecting the differentiation of the mammary gland. This is also seen in the age-dependent susceptibility of the breast to radiation, reviewed later in this chapter.

Number and Spacing of Births

A higher number of births is consistently related to lower risk of breast cancer; each additional birth beyond the first reduces long-term risk of breast cancer. Although in some analyses, this has not been independent of earlier age at first birth, the overall evidence indicates an independent effect of greater parity (67). In addition to a protective effect of higher parity, several studies now indicate that more closely spaced births are associated with lower lifetime risk of breast cancer (64,68). This may be due to the breast having less time to accumulate DNA damage before it attains maximal differentiation by repeated pregnancies.

Lactation

As early as 1926, it was proposed that a breast never used for lactation is more liable to become cancerous (69). There are two major biologic mechanisms proposed to induce the protective effect: Breast-feeding may result in further terminal differentiation of the breast epithelium, and lactation delays the resuming of ovulatory menstrual cycles after pregnancy. Ecological studies demonstrate a consistency with the patterns of international variation in breast cancer incidence: Rates are lower in populations where breast-feeding is both

common and of long duration. The overall evidence from case–control and cohort studies supports a reduction in risk with longer duration of breast-feeding, but the findings have varied substantially in the level of risk reduction. Some of the differences may relate to the pattern of breast-feeding, for example, whether feeding was exclusively from the breast or supplemented with other food; this needs to be evaluated further. A pooled analysis from almost 50 studies in 30 countries reported an overall 4% reduction in risk per 12 months of breast-feeding for all parous women (70). The authors estimate that if women in developed countries had the number of births and lifetime duration of breast-feeding of women in developing countries, cumulative incidence of breast cancer by age 70 years would be reduced by as much as 60%. About two-thirds of this reduction would be related to breast-feeding (70).

Recent studies have examined the association between lactation in relation to breast cancer subtype. In the Black Women's Health Study, ever breast-feeding was associated with a nonsignificant reduced risk of ER-/PR- breast cancer (Hazard ratio [HR]=0.78, 95% confidence Interval [CI], 0.60–1.03), but not ER+/PR+ breast cancer (HR=1.13; 95% CI, 0.91–1.42) (71). This study also found that higher parity was associated with an increased risk of ER-/PR- breast cancer and that breast-feeding appeared to ameliorate the increased risk. In addition, three recent studies have reported inverse associations between breast-feeding and reduced risk of basal-like breast cancers defined using immunohistochemical markers ranging from 20%–40% reduction comparing 4+ months of breast-feeding to never breast-feeding (57,72,73). In the Nurses' Health Study, 4+ months of breast-feeding relative to never breast-feeding was associated with a 40% reduced risk of basal-like tumors (RR = 0.6; 95% CI, 0.4–0.9) and a 20% reduced risk of luminal A tumors (RR = 0.8; 95% CI, 0.7–1.0) (57). Given that there are only a few studies that have assessed this relation and all three studies had less than 300 basal-like cases, additional studies are needed to better understand the association between lactation and tumor subtypes.

Spontaneous and Induced Abortion

Close to one-fourth of all clinically identified pregnancies in the United States end as induced abortions (74), and for women whose pregnancies continue for 8 to 28 weeks, the probability of spontaneous abortion ranges from 8% to 12% (75). It has been suggested that breast cells are the most vulnerable to mutation when breast tissue consists of rapidly growing and undifferentiated cells, such as during adolescence and pregnancy. In early pregnancy, the number of undifferentiated cells increases as rapid growth of the breast epithelium is taking place. If the pregnancy continues to term, these cells differentiate by the third trimester, thus, the number of cells susceptible to malignancy decreases. The interruption of the differentiation of breast cells that takes place as the result of spontaneous and induced abortions has been hypothesized to increase a woman's risk of developing breast cancer (76). This hypothesis appears to be supported by a meta-analysis that included data from 28 published reports on induced abortion and breast cancer incidence (77). However, this analysis, based largely on case-control studies, contains the underlying serious potential for bias in retrospective studies of the relation between abortion and breast cancer. Induced abortion can be an extremely sensitive topic, and reporting on abortion history by women with a life-threatening condition such as breast cancer may be more complete than reporting by women without breast cancer.

By far the largest study on the association between breast cancer and abortion was a population-based cohort study made up of 1.5 million Danish women born April 1, 1935, through March 31, 1978 (78). Of these women, 280,965 (18.4%) had one or more induced abortions. After adjusting for potential confounders of age, parity, age at delivery of first child, and calendar period, the risk of breast cancer for women with a history of induced abortion was not different from that of women who had not had an induced abortion (RR = 1.0; 95% CI, 0.94–1.06). In addition, there was no trend in risk with increasing number of induced abortions in a woman's history. Similarly, no association between induced abortion and breast cancer incidence was observed in four prospective cohort studies including the Iowa Women's Study (79), the Shanghai Textile Workers Study (80), the European Prospective Investigation into Cancer and Nutrition (81), and the Nurses' Health Study II (82). Taken as a whole and accounting for the limitations of the case-control study design, the available evidence does not support any important relation between induced abortion and risk of breast cancer. In 2003, the Early Reproductive Events and Breast Cancer Workshop, convened by the National Cancer Institute to assess the state of evidence between reproductive factors and breast cancer, recognized that spontaneous and induced abortions are not associated with breast cancer risk (83).

Age at Menopause

Early studies of age at menopause and risk of breast cancer focused on women who had undergone bilateral oophorectomy at a young age; these women have a greatly reduced risk of breast cancer (84,85). Women with bilateral oophorectomy before age 45 years have approximately half the risk of breast cancer compared to those with a natural menopause at 55 years or older. On average, the risk of breast cancer increases by some 3% per year of delay in age at menopause. Although some studies suggest the effect of age at menopause decreases with advancing age at breast cancer diagnosis (86), this may reflect greater error in recall of age at menopause as women are further removed from the event (87). Adjustment for error in recall removes this apparent decrease in the effect of menopause with advancing age.

The reduction in risk of breast cancer with early menopause is likely due to the reduction of breast cell division with the termination of menstrual cycles and the decline in endogenous hormone levels, which become substantially lower than during the premenopausal years.

Models of Reproductive Factors and Breast Cancer Incidence

Biomathematical models are derived by translating a series of hypotheses about the biologic process involved in carcinogenesis into mathematical terms. The classical models of carcinogenesis proposed by Armitage and Doll (88) and by Moolgavkar and Knudson (89) are the best known. Armitage and Doll noted that the gradient of 6 to 1 (i.e., 6 units increase in the logarithm of death rate per unit increase in logarithm of age) was more or less consistent across 17 cancer sites, but also noted a deficit in mortality from breast cancer among older women. They attributed this to a reduction during middle life in the rate of production of one of the later changes in the process of carcinogenesis (88). Pike et al. (63) reviewed the epidemiologic evidence in the early 1980s and proposed a model of tissue aging that accounted for the relation between reproductive risk factors and breast cancer incidence. Ultimately, models will ideally be developed that take into account all known risk factors.

The mathematical model proposed by Pike et al. (63) was based on the observed age-incidence curve and on the known relations of ages at menarche, first birth, and menopause to the risk of breast cancer. The model proposed by Pike et al. (63) is built on earlier work by Moolgavkar et al., who fitted mathematical parameters to breast cancer incidence data from several countries. The Pike et al. model related breast cancer rates to the growth of the breast. The model allowed a short-term increase in risk with first pregnancy followed by a subsequent decrease in risk accumulation. Finally, at menopause the breast begins an involutional process that is thought to reflect a decrease in cell turnover and eventual disappearance of epithelium. The original Pike et al. model, however, did not include terms for the second or subsequent births or for the spacing of pregnancies, nor did it easily accommodate pregnancies after age 40 years. Type of menopause was not considered either (bilateral oophorectomy vs. natural menopause). Although there has been controversy about whether the bearing of additional children beyond the first reduces the risk of breast cancer, substantial evidence reviewed earlier indicates that both the number of births and their spacing are associated with risk: The greater the number of births and the closer they are spaced, the lower a woman's risk of breast cancer.

An extension of the Pike et al. model of breast cancer incidence utilized prospective data from the Nurses' Health Study (12,64,90) and added a term to summarize the spacing of births. Nonlinear models produced parameters that were difficult to interpret (64), but a subsequent modification allowed ready estimation of RRs (12), thus making the results more accessible to epidemiologists and clinicians familiar with the RR as measure of the relation between an exposure and disease. Prior to menopause, the incidence of breast cancer increased 1.7% for a 1-year increase in age at first birth. Closer spacing of births was related to significantly reduced risk of breast cancer. For each additional year of delay between the first and second births, for example, the risk of breast cancer increased by 0.4%. The increase in risk with first pregnancy originally observed with this modified Pike model has since been documented in a prospective study from Sweden (65) and in an analysis from an international case-control study (91). The effect of age at first and subsequent births on breast cancer incidence was still greater after menopause (Fig. 18-7).

According to the extended Pike et al. model, a parous woman with a single birth at age 35 years has a 34% increase in breast cancer incidence at the time of the birth relative to a nulliparous woman. The excess risk goes down very slowly over time. Even at age 70 years such a woman has excess risk versus a nulliparous woman. In sum, the cumulative risk to age 70 is 16% greater than that of a nulliparous woman. Conversely, a parous woman with an early age at first birth (20 years of age) and multiple births conceived at a young age has a slight excess risk immediately after the first birth relative to the nulliparous woman (RR = 1.10), which slowly diminishes over time, reaching equality at age 32 years and continuing to decline until menopause (age 50 years), at which time the RR is 0.82. Since the relationship between breast cancer incidence and reproductive history changes with age, cumulative incidence, rather than age-specific incidence, is a useful summary (see Fig. 18-7). Compared to a nulliparous woman, a woman with one birth at age 35 years has a 16% excess risk over the age period 30–70 years, while the woman with births at ages 20, 23, and 26 years has a 27% decrease in risk over the similar age period (90).

In the original Pike et al. model (63), factors associated with reduced risk of breast cancer were each considered to slow the rate of breast tissue aging, which correlates with the accumulation of molecular damage in the pathway to breast cancer. In the Rosner and Colditz (12,90) extension of the Pike et al. model, the rate of tissue aging was highest between menarche and first birth, consistent with the hypothesis that this is the period when the breast is most vulnerable to mutagenesis. The transient increase in the risk of breast cancer associated with the first pregnancy is followed by a 20% decrease in the rate of breast tissue aging (12). This observation helps explain the cross-over effect in certain subgroups of women: Around menopause, rates of one subgroup that were initially higher drop below rates of a second subgroup. For instance, using data from New York State, Janerich and Hoff showed a cross-over in breast cancer incidence between single and married women at age 42, such that married women had a higher incidence before this age and lower mortality thereafter (92). A similar cross-over of incidence has been reported for black and white women in the United States (11,93), consistent with the distribution of age at first birth by race. Over many decades, pregnancy rates have been higher and age at first birth has been younger for black women than for white women (94).

The age-incidence curve from biomathematical models of reproductive events and breast cancer incidence also mirrors the observed patterns of breast cancer incidence across many countries. In China and many developing countries, the estimated number of births in the early 1960s was 6.5 births per woman (95), which is not associated with a late age at first birth. Also, the average age at menarche in China was about 17 years, even through the 1960s (96). Fitting the Rosner and Colditz model with menarche at age 16 years, first birth at age 19 years, six births spaced a year apart, and age at menopause 50 years, we estimate an annual rate of breast cancer incidence for 65-year-old Chinese women is 93.6 per 100,000. For the cohort of U.S. women born between 1921 and 1925, the average age at menarche was approximately 13.5 years, the median age at first birth was 23 years, the mean number of children was three, and the mean interval between births was 3 years (97). Considering these characteristics, and holding age at menopause constant at 50 years, the annual rate of breast cancer incidence predicted for 65-year-old U.S. women is 279 per 100,000—close to the observed SEER rate of 300 per 100,000 for women of

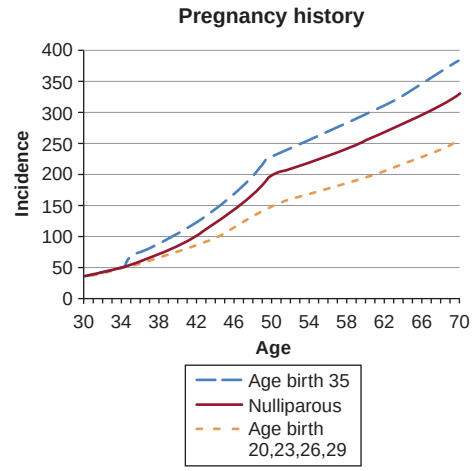

FIGURE 18-7 Age-specific incidence of breast cancer for three hypothetical women. (Data from Colditz G, Rosner B. Cumulative risk of breast cancer to age 70 years according to risk factor status: data from the Nurses' Health Study. *Am J Epidemiol* 2000;152:950–964.)

this age, and approximately three times the rate for Chinese women. Applying this model to typical reproductive patterns for women from low-incidence countries suggests that reproductive factors alone account for more than half of the international variation in the risk of breast cancer (98). These results were confirmed when the model was applied to data from a Chinese cohort (99).

The extension of the Rosner and Colditz model to include history of benign breast disease, height, weight, alcohol intake, and type of postmenopausal hormone used, in addition to reproductive factors and family history, gives a model that compares favorably to the Gail model for risk prediction (100). In a meta-analysis of breast risk prediction models that have been validated, the Gail model and the Rosner model have equivalent performance with area under the curve or c-statistic values of 0.63 (101). Furthermore, this extended Rosner model has been applied to the evaluation of risk factors for ER+ and ER- breast cancer. Incidence of ER+/PR+ tumors increases at 11.0% per year during premenopausal years and at 4.6% per year after natural menopause. In contrast, the incidence of ER-/PR- tumors increases at 5.0% per year during premenopausal years and 1.3% after natural menopause. The one-time adverse effect of first pregnancy is present for ER-/PR- breast cancer but not ER+/PR+ tumors. Parity shows a strong inverse association with ER+/PR+ tumors (RR = 0.6 for four births at 20, 23, 26, and 29 versus nulliparous), but not ER-/PR- tumors (RR = 1.1 for four births vs. nulliparous). Other risk factors, including benign breast disease, family history of breast cancer, alcohol use, and height, show consistent relations with both ER+/PR+ and ER-/PR- breast cancer, while body mass index after menopause is related to incidence of PR+ but not PR- tumors. The concordance statistic (indicating predictive ability of the model) adjusted for age was 0.64 (95% CI, 0.63–0.66) for ER+/PR+ tumors, and for ER-/PR- the concordance statistic was 0.61 (95% CI, 0.58–0.64) (102). Addition of circulating estrogen levels to the model adds further to the performance (103) as does refining benign breast disease (BBD) to consider atypical hyperplasia and proliferative disease without atypia (104).

Risk Prediction

Breast cancer incidence models have been applied to predict the risk of breast cancer over a defined time period, say 5 or 10 years. The larger the number of risk factors considered, the higher the likelihood the prediction model will separate those at risk of disease from those who are not as likely to develop disease. However, as Wald notes (105), to be useful as a screening test or an individual marker of risk or to identify those who will develop disease and those who will not, the magnitude of association for a predictor must be on the order of 10 or higher comparing extreme quintiles for a detection rate of 20%. No prediction models for breast cancer have achieved this level of discrimination to date. The Rosner model generates a relative risk of 6 or more comparing top versus bottom decile of risk among women in each 5-year age group.

Ottman et al. published a simple model in 1983 that calculates a probability of breast cancer diagnosis for mothers and sisters of breast cancer patients (106). They used life-table analysis to estimate the cumulative risks to various ages based upon two groups of patients from the Los Angeles County Cancer Surveillance Program, then derived a probability within each decade between ages 20 and 70 for mothers and sisters of the patients, according to the age of diagnosis of the patient and whether the disease was bilateral or unilateral.

Because risk factors may change over the life course (weight gain, change in alcohol intake, menopausal status, use of postmenopausal hormones for some years, etc.), it becomes more helpful to consider the impact of all these risk factors on breast cancer cumulative risk up to a given age, say 70 or 75. This approach has been developed for breast cancer risk according to family history (107), and the prediction of BRCA1 carrier status (108,109), but more general applications joining carrier status and lifestyle factors remain limited (110).

The complex nature of breast cancer incidence, with many possible time-dependent risk factors, requires prediction models that account for this variation over time. These are now shown to outperform traditional approaches that fit indicator variables with fixed effects across time (100). In addition, the log-incidence model of Rosner and Colditz performs significantly better than the commonly used Gail model for total breast cancer incidence that includes only five variables (age, age at menarche, age at first birth, number of benign breast biopsies, and family history). Growing emphasis is placed on mammographic breast density as a contributor to risk prediction (111,112), and while some models have incorporated this measure, none yet also include the details of reproductive risk factors, specific type of postmenopausal hormone therapy used, and breast cancer incidence.

The efficacy of chemoprevention for breast cancer is clearly shown for ER+ disease reducing risk by 50% (113). Given the need to balance risks and benefits when implementing a tamoxifen-based chemoprevention strategy (114), a model that successfully identifies women at increased risk of ER+ breast cancer will, therefore, improve the risk benefit ratio. Rosner and Colditz have applied their log-incidence model to breast cancers classified according to receptor status and reported that the area under the ROC curve adjusted for age was 0.630 (95% CI, 0.616–0.644) for ER+/PR+ tumors and was 0.601 (95% CI, 0.575–0.626) for ER-/PR- tumors, indicating adequate discriminatory accuracy. On the other hand, when we fit the Gail model to the same data set, it had performance characteristics that were somewhat lower than the Rosner and Colditz model with values of 0.578 for total cancer and 0.57 for ER+/PR+ tumors. The difference between the area under the ROC for the Rosner and Colditz model versus the Gail model for total breast cancer was statistically significant ($p < .0001$), indicating that the more complete modeling of risk factors across the life course could be more useful for discriminating among those women at high and low risk for breast cancer.

The clinical application of risk prediction models with performance evaluation showing improved patient satisfaction with decision-making, improved health outcomes, or cost-effectiveness of care remains the gold standard for evidence of clinical utility (115). To date, none of the breast risk prediction models have been evaluated in this routine use setting to show such benefits for women.

ENDOGENOUS SEX HORMONES AND RISK OF BREAST CANCER

Several lines of evidence have long suggested that sex hormones play a central role in the etiology of breast cancer. As noted earlier, rates of breast cancer increase rapidly in the premenopausal years, but the rate of increase slows sharply at the time of menopause, when estrogen levels decline rapidly. In addition, several reproductive variables that alter hormone status affect risk of breast cancer; for example, early age at menarche and late age at menopause

are associated with increased risk of breast cancer while parity is inversely associated with risk. After menopause, adipose tissue is the major source of estrogen, and obese postmenopausal women have both higher levels of endogenous estrogen and a higher risk of breast cancer (116). In animals, estrogens, progesterone, and prolactin all promote mammary tumors. Also, hormonal manipulations such as anti-estrogens (e.g., tamoxifen) are useful in the treatment of breast cancer and reduce breast cancer incidence in high-risk women (117–119).

Methodologic Issues in Studies of Endogenous Hormones and Breast Cancer Risk

In contrast to clinical needs where discerning grossly abnormal from normal hormone levels is the focus, epidemiologic studies are usually aimed at detecting modest differences within the normal range of levels. Considerable laboratory error has been reported in studies of assay reproducibility, with several hormones being measured quite poorly by some laboratories (120,121). Low reproducibility could result in true (and important) exposure/disease associations being missed. Varying sensitivities and specificities of different laboratory assays also have made comparison of results between studies difficult (122,123). For example, in studies of postmenopausal plasma estradiol, mean levels in control subjects have ranged from 9 (124) to 28 (125) pg/ml. Although these differences may result in part from differences in characteristics of study subjects (i.e., differences in adiposity), a substantial component is likely due to the use of varying laboratory methods. Increasing efforts by the CDC and several professional organizations are addressing these measurement issues (e.g., testosterone) (126).

Several hormones, particularly estrogens, fluctuate markedly over the menstrual cycle. In some early studies, hormone levels were measured in samples collected without regard to the menstrual cycle phase, thus adding considerable "noise" to the comparison of hormone levels between breast cancer cases and controls. This noise could mask true associations or, because of chance differences in the distribution of cycle phase between cases and controls, could result in associations that do not truly exist. More recent studies have tended to collect all samples at approximately the same time in the cycle, have matched on cycle day, or have carefully controlled for cycle day in the analysis—all appropriate strategies.

For both logistic and financial reasons, in most epidemiologic studies only a single blood sample can be collected per study subject. Whether a single sample can reflect long-term hormone levels (generally the exposure of greatest etiologic interest) is therefore an important issue. In several studies, repeated blood samples were collected over a 1- to 3-year period in postmenopausal women and the correlation between the samples calculated. Overall, steroid hormones were reasonably stable, with intra-class correlations ranging from 0.5 to 0.9 (127–130). This level of reproducibility is similar to that found for other biologic variables such as blood pressure and serum cholesterol measurements, all parameters that are considered reasonably measured and that are consistent predictors of disease in epidemiologic studies. Data on premenopausal women are more limited, although follicular or luteal estrogens were reasonably reproducible over a 3-year period (131), and androgens have been reasonably correlated over a several-year period (128,129,131). Data on circulating levels of insulin-like growth factors also indicates substantial stability over a several-year period (131,132).

Over the last decade a number of well-conducted prospective studies have assessed the role of circulating hormone levels and breast cancer risk; their findings are summarized below.

Estrogens

Estradiol, considered the most biologically active endogenous estrogen, circulates in blood either unbound ("free") or bound to sex hormone–binding globulin or albumin. Free or bioavailable (free plus albumin-bound) estradiol is thought to be readily available to breast tissue and thus may be more strongly related to risk than total estradiol. Postmenopausally, estrone is the source of most circulating estradiol, and estrone sulfate is the most abundant circulating estrogen (133). Both normal and malignant breast cells have sulfatase and 17-beta-dehydrogenase activity (134). Thus, estrone and estrone sulfate could serve as ready sources of intracellular estradiol.

In 2002, a pooled analysis was published consisting of all prospective studies of endogenous estrogens and androgens in postmenopausal women that had been available at that time (135). Data were from nine prospective studies with a total of 663 breast cancer cases and 1,765 healthy controls; none of the women were using exogenous hormones at blood collection. The risk of breast cancer increased with increasing estrogen levels. For example, the relative risks (95% CI) for increasing quintiles of estradiol level, all relative to the lowest quintile, were 1.4 (1.0–2.0), 1.2 (0.9–1.7), 1.8 (1.3–2.4), and 2.0 (1.5–2.7). Estrone, estrone sulfate, and free estradiol were similarly related to risk. No significant heterogeneity in results was noted between the studies. Subsequent to the pooled analysis, several additional prospective studies have been published and all have supported these findings (136–138). Further, urinary hormone levels have been assessed in relation to breast cancer in two prospective studies (139,140) and in each, positive associations were observed.

The association between circulating estrogens and breast cancer risk appears stronger for ER+ and PR+ tumors, with relative risks ranging from 2.0–2.6 comparing the extreme 20–25% of levels (141–143). Data are sparse and less consistent for ER- tumors. In the only two studies with more than 100 ER- cases, the association of estradiol with ER-/PR- tumors was similar to that observed for ER+/PR+ tumors in one (143) and considerably weaker than that observed in ER+ tumors in the second (142). The association with ER+ tumors is in line with findings from the tamoxifen and raloxifene trials, where risk of only ER+ tumors was reduced (118,144) and also from epidemiologic studies of obesity and breast cancer where stronger associations have been noted for ER+ tumors.

Whether the association between plasma estrogens and postmenopausal breast cancer is similar in women at varying levels of breast cancer risk has been addressed in two studies. The first was conducted in the high-risk population of the National Surgical Adjuvant Breast and Bowel Project Cancer Prevention Trial (P-1) with 89 cases and 141 non-cases enrolled in the placebo arm of the trial (145). In P-1, high risk was defined as having at least a 1.66% 5-year risk of breast cancer as estimated from the Gail model (146). No association was observed between estradiol levels and breast cancer risk: The relative risk for the top (vs. bottom) quartile of levels was 0.96 (95% CI, 0.47–1.95). In contrast, in the Nurses' Health Study cohort (with over 400 cases and 800 controls) (147), women were classified as high or low risk in several ways: according to family history of breast cancer, by their 5-year modified Gail risk score, and by their 5-year Rosner and Colditz risk score (90). Overall, the associations of plasma estrogens with breast cancer were robust across risk

categories regardless of which metric was used to define risk. Thus, the data from this larger cohort suggest that circulating estrogens are predictive of risk in women at low and at high risk of breast cancer; however, confirmation in other studies is needed.

Two prospective studies have addressed whether circulating estradiol levels are associated with breast cancer risk even in women using postmenopausal hormones (estrogen only or estrogen plus a progestin) (148,149). In the first and largest study, modest positive associations with estradiol and free estradiol were observed (top versus bottom quartile RR for estradiol = 1.3; 95% CI, 0.9–2.0, p-trend = 0.20 and RR for free estradiol = 1.7; 95% CI, 1.1–2.7, *p*-trend = 0.06) (148). In the second study, similar associations were observed between circulating estrogens and breast cancer, regardless of postmenopausal hormone use (149). Thus, although women using postmenopausal hormones have a different hormonal profile than non-users, plasma estradiol concentrations appear to be associated, albeit possibly more modestly, with breast cancer in this group of women.

Data on premenopausal estrogen levels and breast cancer risk are more limited, in large part because of the complexities related to sampling during the menstrual cycle. Eight prospective studies have been published to date, although 6 of the 8 had fewer than 100 cases (range 14–98 cases) and, not surprisingly, no significant associations with plasma estrogens were observed in the 6 small studies (150–155). Two much larger studies have recently been published. In the first, conducted in the European Prospective Investigation into Cancer and Nutrition (EPIC) cohort, with 285 breast cancer cases and 555 controls, one blood sample was collected per woman, and the day in the menstrual cycle was recorded (156). Controls were matched to cases on age and phase of the menstrual cycle at blood collection (defined in 5 categories). Comparisons between case and control hormone levels were based on residuals from spline regression models; the residuals indicated how much an individual's hormone level deviated from the predicted hormone levels on that day. Overall, no association was observed for either estradiol or estrone (e.g., top to bottom quartile comparison [RR = 1.0; 95% CI, 0.7–1.5] for estradiol). In the second large prospective study, conducted within the NHSII, both early follicular and mid-luteal samples were collected from each woman (157). The analysis included 197 cases with 394 controls also matched on age and luteal day. Follicular, but not luteal, total and free estradiol were significantly associated with breast cancer risk (top to bottom quartile comparison [RR = 2.1; 95% CI, 1.1–4.1] for follicular total estradiol). No association was observed with either estrone or estrone sulfate (in either phase of the cycle). Clearly, additional data, with careful matching of cases and controls and detailed evaluation by timing in the menstrual cycle, are needed.

To date, only one study has examined the role of circulating estrogen levels during pregnancy and subsequent breast cancer risk (158). Among 536 cases and 1,049 controls, higher levels of serum estradiol and estrone in the first trimester of first pregnancies were not associated with higher breast cancer risks overall, but were associated with higher risk of breast cancers diagnosed before age 40 (top vs. bottom quartile RR (95% CI) estradiol = 1.81) (1.08–3.06), *p*-trend = 0.03; estrone = 1.63 (1.01–2.60), *p*-trend = 0.04).

Estrogen Metabolites

A woman's pattern of estrogen metabolism also has been hypothesized to influence her breast cancer risk. Estradiol and estrone can be metabolized through several pathways, including the 2-, 4-, and 16-hydroxylation pathways (159). Products of these pathways have markedly different biologic properties, and opposing hypotheses have been proposed concerning their influence on risk (159). Several epidemiologic studies have examined estrogen metabolites and breast cancer risk, but many have assessed only 2-hydroxyestrone, 16α-hydroxyestrone, and the 2:16α-hydroxyestrone ratio. In three prospective assessments among premenopausal women, nonsignificant inverse associations with the 2-:16α-hydroxyestrone ratio were observed in each (160–162). Six prospective studies of either urinary (161–163) or circulating (164,165) metabolite levels among postmenopausal women who were not using postmenopausal hormones also observed no significant associations for 2-hydroxyestrone, 16α-hydroxyestrone or their ratio and breast cancer risk. While these data do not support an important relationship with these metabolites and risk, these studies do not include other biologically active metabolites.

Two recent studies have measured estrogen metabolites in urine (166) or serum (167), using a high performance liquid chromatography/tandem mass spectrometry (LC/MS-MS) assay that measures 15 estrogens and metabolites simultaneously, including parent estrogens and metabolites in the 2-, 4-, and 16-hydroxylation pathways (168). In premenopausal women, urinary levels of estrogen metabolites, measured in the mid-luteal phase of the menstrual cycle, were assessed among 247 cases and 485 controls (166). Higher levels of one metabolite in the 16-hydroxylation pathway, 17-epiestriol, were associated with higher breast cancer risk (top vs. bottom quartile RR = 1.74; 95% CI, 1.08–2.81, *p*-trend = 0.01). However, higher levels of the parent estrogens, estradiol and estrone, were associated with lower risks of breast cancer (top vs. bottom quartile RR for estradiol=0.51; 95% CI, 0.30–0.86); RR for estrone 0.52; 95% CI, 0.30–0.88). Generally, although not significantly, inverse associations were observed with metabolites in the 2- and 4-hydroxylation pathways. Associations were unchanged with adjustment for plasma estrogens, suggesting women with increased urinary excretion of estrogens are at reduced risk. In postmenopausal women, serum levels of 15 estrogen metabolites were investigated in 277 cases and 423 controls (167). Although several metabolites were individually positively associated with breast cancer risk, none of the associations remained after adjustment for unconjugated estradiol, which was associated with a two-fold increased risk, consistent with other studies. The ratios of 2-hydroxylation pathway:parent estrogens and 4-hydroxy catechols:methylated catechols remained significantly associated with risk after adjustment for unconjugated estradiol: interdecile comparison RR (95% CI) 0.72 (0.52–1.00) and 1.31 (1.03–1.61), respectively.

Androgens and Breast Cancer Risk

Androgens have been hypothesized to increase breast cancer risk either directly, by increasing the growth and proliferation of breast cancer cells, or indirectly, by their conversion to estrogen (60). In animal and *in vitro* experiments, androgens either increase or decrease cell proliferation, depending upon the model system (169). Dehydroepiandrosterone (DHEA) administered to rodents can decrease tumor formation. In humans, DHEA may act like an antiestrogen premenopausally but an estrogen postmenopausally in stimulating cell growth (170); in part because of the estrogenic effect of its metabolite, 5-androstene-3b,17b-diol also can bind to the estrogen receptor (171).

In postmenopausal women, the best summary of evidence on circulating androgens and breast cancer risk is from the pooled analysis of nine prospective studies described

above (135) along with the recently published report from the EPIC study (136). In the pooled analysis, testosterone was positively associated with breast cancer risk: The relative risks (95% CI) for increasing quintile category (all relative to the lowest quintile of levels) were 1.3 (1.0–1.9), 1.6 (1.2–2.2), 1.6 (1.1–2.2) and 2.2 (1.6–3.1). Findings were generally similar for several other androgens measured. In EPIC, similar positive associations were observed for each of the androgens assessed. In each of these analyses, when estradiol was added to the statistical models, relative risks for the androgens were only modestly attenuated, suggesting some independent effect of circulating androgens on breast cancer risk. As with estradiol, associations with androgens and breast cancer have tended to be stronger for ER+ tumors than for ER- tumors (141–143). Whether this differential is because androgens are serving as a source of estrogens at the breast, or because ER+ tumors are more likely to also be AR+ is unclear. Interpretation of these data is complicated because of possible differences between estradiol and the androgens in terms of assay precision, hormone stability within woman over time, and intracellular conversion of androgens to estrogens that cannot be accounted for in epidemiologic analyses.

The association of plasma testosterone levels and subsequent breast cancer risk also was positive and of the same general magnitude in women using postmenopausal hormones (148). In the two studies previously described, the association between circulating testosterone and breast cancer across categories of predicted breast cancer risk has been addressed. No association was observed between testosterone levels and breast cancer risk in the P-1 trial with 89 cases and 141 non-cases (RR for top versus bottom quartile = 0.5; 95% CI, 0.2–1.1) (145), although the association was noted to be quite robust in the larger NHS cohort (147).

Among premenopausal women, although data are much more limited, prospective nested case-control studies are quite consistent in showing a positive association of similar magnitude to that reported among postmenopausal women between circulating androgen levels and risk of breast cancer (153,155–157,172,173).

Progesterone

Progesterone exerts powerful influences on breast physiology and can influence tumor development in rodents (174). Based largely on indirect evidence, progesterone has been hypothesized both to decrease breast cancer risk by opposing estrogenic stimulation of the breast (174) and to increase risk because breast mitotic rates are highest in the luteal (high progesterone) phase of the menstrual cycle (60). In three large prospective studies, results have not been consistent with inverse (156,172) and no association (157) reported. However, progesterone levels vary substantially throughout the menstrual cycle and are difficult to measure in the context of large epidemiologic studies, hence further assessments with better measures are warranted. In postmenopausal women, only a single prospective study has been conducted and no association found (138).

Prolactin

Prolactin receptors have been found on more than 50% of breast tumors (175), and prolactin can increase the growth of both normal and malignant breast cells in vitro (176). Cumulatively, substantial laboratory evidence suggests that prolactin could play a role in mammary carcinogenesis (177) by promoting cell proliferation and survival (178–181), increasing cell motility (182), and supporting tumor vascularization (177,183). Because prolactin is influenced by both physical and emotional stress (184,185), levels in women with breast cancer may not reflect their predisease levels. Thus, evaluation of this association in prospective studies is particularly important.

Prolactin levels and risk of breast cancer have been evaluated in several studies to date (137,150,151,186–190). Most, though not all (137), studies have observed a significant positive association, with case numbers ranging from 26 (151) to 1,539 (188). In by far the largest study to date, an updated analysis within the NHS and NHSII cohorts with 1,539 cases (premenopausal and postmenopausal women combined), a modest but significant association was observed across quartiles of prolactin level, with a top (versus bottom) quartile RR = 1.4; 95% CI, 1.0–1.9, p-trend = 0.05 (188). In this analysis, the association of prolactin with breast cancer did not differ by menopausal status (p = 0.95). The association was stronger for invasive cases (top vs. bottom quartile RR = 1.4; 95% CI, 1.1–1.7, p-trend = 0.001) than in situ cases (comparable RR = 1.2; 95% CI, 0.8–1.6, p-trend = 0.43). In addition, the association was significantly different by ER/PR status of the tumor (p-heterogeneity=0.03) with RRs for top versus bottom quartiles of 1.6; 95% CI, 1.3–2.0, p-trend <0.001 for ER+/PR+, RR = 1.7; 95% CI, 1.0–2.7, p-trend = 0.06 for ER+/PR-, and RR = 0.9; 95% CI, 0.6–1.3, p-trend = 0.70 for ER-/PR-. Cumulatively, epidemiologic data support a role for prolactin in the etiology of breast cancer.

Insulin-like Growth Factor

Insulin-like growth factor I (IGF-I) is a protein hormone with structural homology to insulin. The growth hormone–IGF-I axis can stimulate proliferation of both breast cancer and normal breast epithelial cells (191). Rhesus monkeys treated with growth hormone or IGF-I show histologic evidence of mammary gland hyperplasia. In addition, positive associations have been observed between breast cancer and birth weight as well as height, which are both positively correlated with IGF-I levels (192). These associations were carefully evaluated in a large pooled analysis, combining data from 17 prospective studies and including 4,790 cases and 9,428 controls (193). Overall, a modest but statistically significant positive association was observed (top vs. bottom 20% of IGF levels RR = 1.28; 95% CI, 1.14–1.44) that did not vary by menopausal status at blood collection. Associations were apparent among ER+ tumors (comparable RR = 1.38; 95% CI, 1.14–1.68) but not ER- tumors (comparable, RR = 0.80; 95% CI, 0.57–1.13; p for heterogeneity = 0·007). The primary IGF binding protein IGFBP-3 was not independently associated with breast cancer risk, and the IGF-I association did not vary by level of IGFBP-3. In addition, the association between IGF-I levels during pregnancy and the mother's subsequent risk of breast cancer has been assessed. Of two large prospective studies, a positive association was observed in one (194), while no association was seen in the second (195). Reasons for these differences are not clear. Cumulatively, data point to a modest positive association between circulating IGF-I levels and breast cancer risk.

Insulin

Insulin is a known mitogen and circulating levels have been evaluated in relation to subsequent breast cancer risk. Some studies evaluated insulin levels in fasting or nonfasting subjects; others assessed c-peptide levels, which is a marker of insulin secretion. Among premenopausal women, overall no consistent associations have been observed (132,196–198). Similarly, in postmenopausal women, where at least 10 studies with over 2,500 postmenopausal cases have been published, no consistent associations have been reported (132,197–205).

Melatonin

Laboratory evidence in conjunction with recent epidemiologic data suggests a possible relation between melatonin and breast cancer risk. In vitro studies, although not entirely consistent (206), find that both pharmacological and physiologic doses of melatonin reduce the growth of malignant cells of the breast (207–211). In rodent models pinealectomy boosts tumor growth (212), whereas exogenous melatonin administration exerts anti-initiating (213) and oncostatic activity (214–217) in various chemically induced cancers. The hormone could influence risk through antimitotic or antioxidant activity (218), by modulating cell-cycle length through control of the p53-p21 pathway (211) or by reducing estrogen levels (219,220).

To date, five prospective studies have assessed the association between urinary 6-sulfatoxymelatonin levels (a metabolite of melatonin) and breast cancer risk. In the first, where a 24-hour urine sample was collected, no association between levels and breast cancer were observed (221). In three subsequent analyses conducted in the Nurses' Health Studies and the ORDET cohort and utilizing either a first morning urine or a 12-hour overnight urine, consistent inverse associations were observed, with 30–40% lower breast cancer risk seen among women with the highest (versus lowest) melatonin levels (222–224). In the most recent prospective analysis (225), no significant association was observed overall. However, in this study, a significant positive association was observed in the first two years of follow-up, and a significant inverse association was seen with longer follow-up, suggesting that time from urine collection to diagnosis may be important. Additional studies are clearly needed. There is relatively consistent indirect evidence from observational studies for an association between night work and breast cancer risk (226). Night work is associated with substantially reduced melatonin levels (227,228). Two retrospective studies of flight attendants with occupational exposure to light at night linked employment time to an increased breast cancer risk (229,230). Two nationwide record linkage studies (231,232) and a retrospective case-control study (219) associated night work with an approximately 50% higher breast cancer risk. In the only two prospective studies, working 20 to 30 or more years of rotating night work as a nurse was associated with an increased risk of breast cancer (233,234).

Other Hormones and Hormone Scores

In one prospective study, the influence of multiple hormones, considered simultaneously, on postmenopausal breast cancer risk was evaluated (235). Postmenopausal levels of estrone, estradiol, estrone sulfate, testosterone, androstenedione, dehydroepiandrosterone (DHEA), DHEA sulfate, and prolactin and, secondarily, IGF-I and c-peptide, were evaluated among 265 cases and 541 controls. Several hormone scores were evaluated, including ranking women by the number of hormones above the age- and batch-adjusted geometric mean. Having seven or eight compared to zero hormones above the geometric mean level was associated with total (RR = 2.7; 95% CI, 1.3–5.7, p trend <0.001) and ER+ (RR = 3.4; 95% CI, 1.3–9.4, p trend <0.001) breast cancer risk. Overall, these results suggest that multiple hormones with high circulating levels substantially increase the risk of breast cancer, particularly ER+ disease.

Anti-Müllerian hormone (AMH; also called Müllerian inhibiting substance [MIS]) is produced in ovarian granulosa cells and plays a key role in regulating folliculogenesis (236). Circulating levels vary over a woman's life, being low or undetectable before puberty, peaking from puberty through the premenopausal years, and becoming undetectable after menopause. Although limited laboratory data suggest a protective role of AMH in breast carcinogenesis, the one prospective study to date observed a significant positive association between circulating AMH and breast cancer risk (237). With 105 cases and 204 matched controls, RR (95% CI) with increasing quartile categories were 1.0, 2.8, 5.9, 9.8 (3.3–28.9). Associations appeared somewhat stronger among women ≥55 versus <55 years of age at diagnosis (top vs. bottom quartile RR [95% CI]: <55 years = 3.9 [0.9–16.3]; ≥55 years = 9.6 [2.8–33.3]). This strong association deserves further study, because AMH has not been assessed in any other prospective studies to date.

ORAL CONTRACEPTIVES

Since oral contraceptives were first introduced in the 1960s, they have been used by millions of women (238). Most combined oral contraceptives contain ethinyl estradiol (or mestranol, which is metabolized to ethinyl estradiol) and a progestin. The estrogen dose in oral contraceptives has ranged from at least 100 mg in 1960 to 20–30 mg, the doses most commonly used today; during this same time period, at least nine different progestins have been used (239,240). Patterns of use also have changed considerably over time, with both increasing durations of use and a trend toward earlier age at first use. Over 70 epidemiologic studies have evaluated the relationship between oral contraceptive use and breast cancer risk.

Any Use and Total Duration of Use

Most studies have observed no significant increase in breast cancer risk even with long durations of use. Individual data from 54 epidemiologic studies were collected and analyzed centrally (86). In this large pooled analysis, in which data from 53,297 women with and 100,239 women without breast cancer were evaluated, no overall relationship was observed between duration of use and risk of breast cancer. Similar findings were generally observed when long-term use was evaluated among either postmenopausal women or women over the age of 45 years.

Recency of Use

In the pooled analysis (86), current and recent users of oral contraceptives had an increased risk of breast cancer (for current vs. never-users, RR = 1.24). This increased risk disappeared within 10 years of stopping oral contraceptive use (relative risk by years since stopping use vs. never use: 1–4 years, 1.16; 5–9 years, 1.07; 10–14 years, 0.98; more than 15 years, 1.03) (Fig. 18-8). When the investigators evaluated both time since last use and duration of use, they observed a modestly increased risk only among current and recent users, and no independent effect of long duration of use on the risk of breast cancer even among very young women. In more recent studies, past use of oral contraceptives (generally use in the more distant past) also has not been associated with breast cancer mortality (241–243). Thus, the increased risk of breast cancer observed among young, long-term users of oral contraceptives in past individual studies (and meta-analyses) appears due primarily to recency of use rather than to duration. These data suggest that oral contraceptives may act as late-stage promoters. Importantly, current and recent users, the women who appear to have a modest increase in risk, are generally young (under 45 years of age) and thus have a low absolute risk of breast cancer. Hence, a modest increase in their risk will result in few additional cases of breast cancer. Nevertheless, this apparently

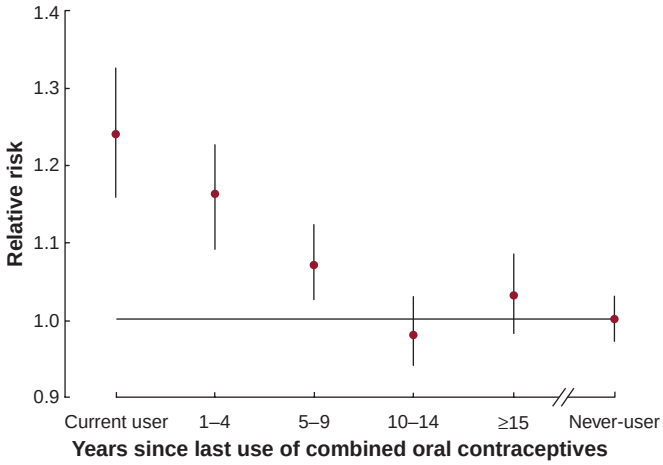

FIGURE 18-8 Relative risk of breast cancer by time since last use of combined oral contraceptives. (Reproduced from Collaborative Group on Hormonal Factors in Breast Cancer. Breast cancer and hormonal contraceptives: collaborative reanalysis of individual data on 53,297 women with breast cancer and 100,239 women without breast cancer from 54 epidemiological studies. *Lancet* 1996;347:1713–1727, with permission.)

increased risk among current and recent users should be considered in deciding whether to use oral contraceptives. On the basis of these data in conjunction with supporting laboratory evidence, the International Agency for Research on Cancer (IARC) classified oral contraceptives as carcinogenic to humans (i.e., group 1 carcinogens) in 2005 (244).

Use before a First Pregnancy

Because any influence of oral contraceptives on the breast has been hypothesized to be greatest prior to the cellular differentiation that occurs with a full-term pregnancy (245), a number of investigators have evaluated the effect of oral contraceptive use prior to a first full-term pregnancy. In two meta-analyses, the summary relative risk indicated a modest increase in risk with long-term use (246,247). In the pooled analysis (86), a significant trend of increasing risk with first use before age 20 years was observed. Among women ages 30–34 years, the relative risk associated with recent oral contraceptive use was 1.54 if use began before age 20 years and 1.13 if use began at age 20 years or older. Overall, there was no consistent evidence of a differential effect according to type or dose of either estrogen or progestin, but few studies had examined this issue (60).

Risk according to Breast Cancer Risk Factor Profile

Possible interactions with other breast cancer risk factors were evaluated in detail for the first time in the collaborative pooling project (86). In this study, the investigators defined oral contraceptive use in terms of recency and age at first use, rather than "ever use," as done in most previous individual studies. Overall, the relationship between oral contraceptive use and breast cancer did not vary appreciably by family history of breast cancer, weight, alcohol intake, or other breast cancer risk factors. In a recent meta-analysis among women with BRCA1 and BRCA2 mutations (248), neither ever use nor duration of use was associated with breast cancer risk. However, use of oral contraceptives prior to 1975 was associated with a modest increased risk while use after 1975 was not associated with risk, suggesting possible differences by formulation.

Receptor Status and Histologic Subtypes of Breast Cancer

Few studies have addressed possible differences in these associations by estrogen receptor status or by intrinsic molecular subtype (e.g., luminal A, luminal B subtypes). Ever use of oral contraceptives was assessed by hormone receptor status in eight case-control studies (249). Results were inconsistent, and only one study reported a significantly stronger association for ER- than for ER+ breast cancer. Only three of these studies evaluated time since last use, and again results were mixed. Recently, in the Black Women's Health Study, ever use of oral contraceptives was significantly stronger for ER-/PR- breast cancers (ever versus never use RR = 1.7; 95% CI, 1.2–2.3) than for ER+/PR+ breast cancers (comparable RR = 1.1; 95% CI, 0.9–1.4) (250). In the Women's Health Initiative, no association was observed between total duration of use and triple negative breast cancer; recent or current use could not be examined in this older population. In case-case analyses, compared to luminal A breast cancers, luminal B cases were less likely to ever use oral contraceptives in one study (251) but not in a second study (252); no differences were observed with triple negative, basal-like or HER-2 breast cancers, although case numbers were small. More data are needed to determine if oral contraceptives differentially influence breast cancer subtypes.

Newer Oral Contraceptive Formulations and Specific Formulations

Until the time of the large pooled analysis published in 1996, limited data existed regarding the influence of the newer oral contraceptive formulations on breast cancer risk (86) and data on specific formulations was particularly sparse. In a study that assessed risk by hormonal dose/potency, the relative risks associated with recent use of lower dose formulations were generally lower than relative risks associated with higher dose formulations (253). Further, associations appeared to vary by type of progestin used (with borderline significant positive associations observed for levonorgestrel, ethynodiol diacetate, and norethindrone acetate) although these differences were based on small numbers. In the population based Women's CARE case-control study (254), overall no increased risk of breast cancer among current users or former users was observed regardless of estrogen or progestin dose. Among specific formulations, an increased risk was observed for current use of ethynodiol diacetate, and no association was seen with levonorgestrel formulations. In the Nurses' Health Study II, the only prospective cohort to examine newer generation oral contraceptives as well as specific formulations, current use of any oral contraceptives was associated with a modest increase in risk (RR = 1.33; 95% CI, 1.03–1.73) (255). However, this association was largely accounted for by use of a single type of preparation, triphasic contraceptives with levonorgestrel (comparable RR = 3.05; 95% CI, 2.00–4.66). Although no firm conclusions can yet be drawn, accruing data suggest that specific oral contraceptive formulations indeed may have a differential impact on breast cancer risk.

Progestin-only Contraceptives

Progestin-only contraceptives include progestin-only pills ("mini-pill"), depot-medroxyprogesterone (DMPA, an injectable contraceptive), and implantable levonorgestrel

(Norplant); very few epidemiologic studies have evaluated their association with breast cancer risk. Longer-term users of the progestin-only pill have been observed to have either a similar or lower risk of breast cancer than never-users (256). Four of five case-control studies reported relative risks of 1.5–2.2 associated with recent use of DMPA versus non-use (257–259), while a fifth study found no association regardless of recency or duration (260). As with other contraceptives, the risk appears to subside several years after stopping use. In the only study to have assessed these associations, the relative risks didn't vary by tumor hormone receptor subtype or histologic subtype. Norplant, a long-acting contraceptive that is implanted subdermally, was introduced in the United States only in 1990. In the CARE study, no association was observed for ever Norplant use, although only 12 women were exposed (260). Further epidemiologic research is needed for each of these drugs.

POSTMENOPAUSAL HORMONE USE

Postmenopausal estrogens have been used for more than half a century. By the mid-1970s, almost 30 million prescriptions were being filled annually in the United States (261). A challenge in studying the relationship between postmenopausal hormones and breast cancer is the substantial variation in formulations and patterns of use that has occurred over time. By the time sufficient use of one type of hormone has occurred to allow a detailed epidemiologic evaluation, new formulations are already being introduced.

The possible relation between postmenopausal estrogen use and risk of breast cancer has been investigated in more than 50 epidemiologic studies over the past 40 years. Most of these studies focused on unopposed estrogen and have been summarized in meta-analyses (262–267) and a large pooled analysis (268). More recently, data from randomized controlled trials have confirmed the epidemiologic relations of combination estrogen plus progestin hormone therapy to increased risk of breast cancer, and IARC has now classified estrogen plus progestin therapy as a human carcinogen (269). On the other hand, the Women's Health Initiative randomized trial did not observe an increase in risk with short term use (median 5.9 years) of unopposed estrogen (270), although the duration of use was shorter than in the epidemiologic studies that continue to show increased risk with longer durations of unopposed estrogen therapy (15 plus years of current use) (271). A summary of these findings, plus a more detailed discussion of several of the most important and most recent studies, is provided below. Particular attention is focused on use of estrogen alone versus estrogen plus progestin therapy.

Any Use

All meta-analyses have concluded that overall, ever users of postmenopausal estrogens have little or no increase in risk of breast cancer compared with women who have never used this therapy. Depending on the inclusion criteria for the meta-analyses, the RR estimates across studies range from 1.01 to 1.07. The RR observed in the pooled individual patient data analysis was 1.14 (268). However, as for oral contraceptives, ever use is a poor measure of exposure because it fails to distinguish between short and long duration and recent and past users, nor does it distinguish type of hormone therapy used.

Duration of Use

In the meta-analyses, significant increases in risk of approximately 30% to 45% with more than 5 years of use have been observed. In updated results from the Nurses' Health Study (272), with 1,935 breast cancer cases, an excess risk of breast cancer was limited to women with current or very recent use of postmenopausal hormones. Within this group, the risk increased with longer duration of use and was statistically significant among current users who have used for 5 or more years (e.g., compared to never users of postmenopausal hormones, RR for ≥10 years of use =1.47; 95% CI, 1.22–1.76) (272). While the WHI with median duration of use of unopposed estrogen (5.9 years) shows no excess risk of breast cancer (270), longer durations in epidemiologic studies show significant increase in risk (273). With over 5,600 invasive breast cancer cases in the Nurses' Health Study, Chen et al. show that risk is significantly increased beyond 10 years of current use and continues to increase with longer durations (274).

Risk is greater for users of estrogen plus progestin compared to users of estrogen alone (275–277). These epidemiologic results were corroborated by the Women's Health Initiative, a randomized controlled trial of estrogen plus progestin use that showed a significant increase in risk of breast cancer with duration of use of this hormone combination (40). Given the high dropout and noncompliance with therapy during the trial (approximately 40% stopped taking drug or placebo in each arm), analysis of compilers showed a substantially greater increase in risk with duration of therapy (278), closer to that observed in epidemiologic studies that by their nature evaluate risk among compliers or users of hormone therapy.

Recency of Use

Data on recency of use have been sparse because many studies do not distinguish current from past users. One meta-analysis calculated an RR for current use of 1.63 for women with natural menopause and 1.48 for women with surgical menopause. In a second, the summary RR was 1.40 (95% CI, 1.20–1.63) comparing current to never users. In the report from the Nurses' Health Study cohort (272), an excess risk of breast cancer was limited to women with current or very recent use of postmenopausal hormones. In the Breast Cancer Detection Demonstration Project (BCDDP) cohort, a positive association with invasive breast cancer was noted among current users with ≥5 to 15 years of use (279). In the U.K. Million Women Study, risk was likewise substantially larger among current users than past users, and returned to the risk of never users within 4 years of stopping use (280).

These relationships were evaluated in considerable detail in the pooled analysis that combined results of 51 epidemiologic studies (268). Importantly, in these analyses, women with an uncertain age at menopause were excluded (e.g., women with simple hysterectomies) because inadequate accounting for age at menopause in the analysis can lead to substantial attenuation of the observed relationships between postmenopausal hormone use and breast cancer risk (281). The median year of case diagnosis was before 1990 in the majority of studies and accordingly few recorded type of hormone used. The vast majority of use across these 51 studies was unopposed estrogen, but type of hormone therapy was not addressed in the overall assessment of these data. The investigators observed a statistically significant association between current or recent use of postmenopausal hormones and risk of breast cancer; the positive association was strongest among those with the longest duration of use (Fig. 18-9). For example, among women who used postmenopausal hormones within the previous 5 years (compared to never users of postmenopausal hormones), the RRs for duration of use were 1.08 for 1 to 4 years

Duration of use and time since last use	Cases/controls	RR (FSE)
Never used	12,467/23,568	1.00 (0.021)
Last use <5 years before diagnosis		
Duration <1year	368/860	0.99 (0.085)
Duration 1–4 years	891/2,037	1.08 (0.060)
Duration 5–9 years	588/1,279	1.31 (0.079)
Duration 10–14 years	304/633	1.24 (0.108)
Duration ≥15 years	294/514	1.56 (0.128)
Last use ≥5 years before diagnosis		
Duration <1 year	437/890	1.12 (0.079)
Duration 1–4 years	566/1256	1.12 (0.068)
Duration 5–9 years	151/374	0.90 (0.115)
Duration ≥10 years	93/233	0.95 (0.145)

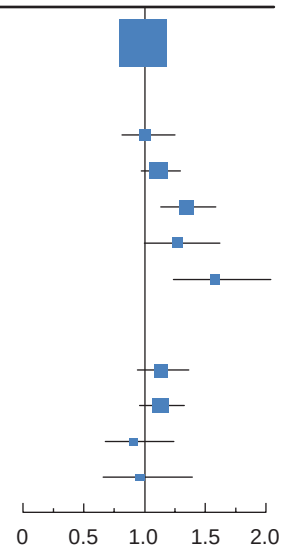

FIGURE 18-9 Relative risk (RR) of breast cancer for different durations of use of hormone replacement therapy. Relative risk is shown in comparison with that of those who never used hormone replacement therapy, stratified by study, age at diagnosis, time since menopause, body mass index, parity, and the age of the woman at the time her first child was born. "Last use ≥5 years before diagnosis" includes current users. Floated standard error (FSE) and floated CI (FCI) were calculated from floated variation for each exposure category. Any comparison between groups must take variation into account. Each analysis is based on aggregate data from all studies. Black squares indicate relative risk, area of which is proportional to amount of information contributed (i.e., to inverse of variance of logarithm of relative risk). Lines indicate 99% FCI (lines are white when 99% FCIs are so narrow as to be entirely within width of square). (Reproduced from Collaborative Group on Hormonal Factors in Breast Cancer. Breast cancer and hormone replacement therapy: collaborative reanalysis of data from 51 epidemiologic studies of 52,705 women with breast cancer and 108,411 women without breast cancer. *Lancet* 1997;350:1047–1059, with permission.)

of use, 1.31 for 5 to 9 years, 1.24 for 10 to 14 years, and 1.56 for 15 years or more of use. No significant increase in breast cancer risk was noted for women who had quit using postmenopausal hormones 5 or more years in the past, regardless of their duration of use. Whether this holds true for all types and durations of use of hormone therapy remains to be evaluated more precisely.

Type, Dose, and Mode of Delivery of Estrogen

Limited data are available regarding the effects of dose or type of estrogen on breast cancer risk. Again, the best data come from the pooled analysis (268). No significant differences in the RRs were observed according to either the type of estrogen used (conjugated estrogen vs. other) or the estrogen dose (<0.625 versus ≥1.25 mg), although some modest differences in estimates suggested that further evaluation is warranted.

Although the effect of estrogen use on breast cancer risk could be reasonably hypothesized to vary by mode of estrogen delivery (e.g., patch estrogen, by avoiding the first pass effect in the liver, does not increase SHBG to the extent that oral preparations do), no important differences are observed in the largest study to date; the Million Women Study included over 40,000 users of transdermal estrogen and observed no significant difference in relative risk of breast cancer (1.24) compared to that among the 60,000 users of oral therapy (1.32) (277).

Time since Menopause, Initiating Use of Hormone Therapy, and Risk

Considerable evidence has recently accumulated addressing timing of use of hormones and the magnitude of the adverse effect on breast cancer risk (282). A rigorous analysis of the U.K. Million Women Study shows risk is substantially greater among women who start hormone therapy before or less than 5 years after menopause. This effect is observed for estrogen alone and for combination estrogen plus progestin (280). The U.K. Million Women Study contrasts with the WHI where 90% of women in the estrogen-only arm of the trial were more than 5 years beyond menopause at randomization.

Risk according to Breast Cancer Risk Factor Profile

The risk associated with postmenopausal hormone use was assessed in a number of specific subgroups in the pooled analysis (268). Risk did not appear to vary according to reproductive history, alcohol intake, smoking history, or family history of breast cancer. However, the RRs associated with 5 or more years of postmenopausal hormone use were highest among the leanest women (*p* for

heterogeneity = 0.001); this interaction has been consistently observed (271,277,283). Risk for unopposed estrogen therapy is also more clearly observed to increase with duration of use among women with bilateral oophorectomy than those without (271), again consistent with precise statistical control for underlying risk of breast cancer because age at menopause is more accurately assessed in women undergoing bilateral oophorectomy than in those who have hysterectomy without oophorectomy (284). This consistent finding that risk of unopposed estrogen is attenuated among overweight and obese women may account for the apparent lower risk of breast cancer among women in the WHI trial of unopposed estrogen, given the overweight and obese population included in the trial (285).

Use of Estrogen Plus Progestin (E & P)

The addition of a progestin to estrogen regimens became increasingly common through the 1990s because it minimizes or eliminates the increased risk of endometrial hyperplasia and cancer associated with using unopposed estrogens. In the United States, by the mid-1980s, almost 30% of postmenopausal hormone prescriptions included a prescription for progestin (286). The impact of an added progestin to the risk of breast cancer has been evaluated only in the last 25 years.

Two of the first studies to assess this relationship suggested that the addition of a progestin could decrease breast cancer risk (287,288). However, these studies were small and potentially important confounders (e.g., age and parity) were not accounted for in the analyses. Since this time, several additional studies have assessed this relationship and together indicate that a protective effect of typical doses used in postmenopausal hormone therapy can be ruled out (268). Prospective studies reporting on this relationship had similar findings. Bergkvist et al. (289) observed an RR of 4.4 (95% CI, 0.9–22.4) among women who used estrogen plus progestin for 6 or more years compared to never users. Women using hormones for a shorter duration did not appear to be at increased risk, but CIs again were wide and did not exclude either a modest increase or a decrease in risk. In findings from the Nurses' Health Study (272), in which among women using progestins, about two-thirds used 10 mg of medroxyprogesterone for 14 or fewer days per month, the RR associated with current estrogen plus progestin use versus never use was 1.4 (95% CI, 1.2–1.7). The BCDDP found that the risk of breast cancer went up by about 1% for every year that women took estrogen alone and about 8% for every year that they took estrogen plus progestin (290). Although these yearly increases in risk seem minimal, their accumulation over time is of concern. For example, if women take estrogen with progestin for 10 years, their risk of breast cancer will be 80% higher than if they had never used hormones (291). For both types of therapy, however, this increase in risk begins to drop after hormone use stops (268). In the pooled analysis (268), data on the postmenopausal hormone formulation were available from only 39% of women, and only 12% of these reported using estrogen plus a progestin. The RR associated with 5 or more years of recent use, relative to never use, was 1.53. More recent case-control studies also support this increase in risk with combination estrogen plus progestin (292,293). The Women's Health Initiative randomized controlled trial of estrogen plus progestin versus placebo among 16,608 postmenopausal women with an intact uterus, ages 50 to 79, stopped early at the recommendation of the data safety monitoring board (DSMB) in part due to the prespecified harm boundary for breast cancer (40). At an average of 5.2 years of follow-up, women randomized to estrogen plus progestin had a significantly elevated risk of breast cancer, RR compared to placebo 1.26 (95% CI, 1.00–1.59), and analysis accounting for adherence showed an RR of 1.49 for estrogen plus progestin. Importantly, the trend for increasing risk with increasing duration of use of estrogen plus progestin was also significant. These results among women adherent to use of estrogen plus progestin at an average of 5 years of use are consistent with the epidemiologic data, which also shows the trend in risk with duration of use continuing to increase beyond 5 years and no evidence of a plateau (274).

In addition to their effect on breast cancer, postmenopausal hormones also have a major impact on other aspects of women's health. Results from the Women's Health Initiative (a large randomized clinical trial) definitively show that after 5 years of use, estrogen plus progestin does more overall harm to women than good (40), although the Women's Health Initiative studied only one type and dose of estrogen plus progestin (Prempro); because widespread use of estrogen plus progestin is relatively recent, few data are available to evaluate the effect of different formulations, doses, or schedules of use of progestin on risk of breast cancer (294,295). The British Million Women Study with over 9,000 cases of breast cancer during follow-up again confirmed the excess risk of breast cancer among women currently using combination estrogen plus progestin and noted this is significantly greater relative risk than among women using estrogen alone. Risk increased with duration of use but did not vary significantly according to the progestagen content or whether use was sequential or continuous (277). The possibility remains that dose of progestagen is important, including total monthly exposure, but variation in studies to date has not allowed rigorous and valid comparisons. Despite issues such as dose of progestagen that remain open research questions, additional follow-up of the WHI trial participants shows excess breast cancer mortality among the women receiving estrogen plus progestin compared to placebo with almost double the risk of death from breast cancer through 11 years of follow-up (296).

Receptor Status and Histologic Subtypes of Breast Cancer

Consistent evidence from larger epidemiologic studies shows combination estrogen plus progestin and unopposed estrogen therapy are associated with increased risk of ER+ breast cancer (297). While the WHI did not observe any significant difference in the distribution of invasive cancer by receptor status, the trial had limited power to detect an association with fewer than 500 cases of breast cancer. Some have suggested that risk is limited to lobular subtypes of breast cancer (298), but the majority of evidence does not support this claim. Also, given the higher proportion of receptor positive tumors in lobular rather than ductal cancers, a stronger relative risk observed for lobular cancer (297) would be expected for this subset of breast cancers. This is confirmed in the Million Women Study with over 8,000 cases of invasive ductal and over 1,500 invasive lobular cancers, where significant increases in risk of ductal carcinoma are observed for estrogen alone and for combination therapy (273).

Decline in Breast Cancer Incidence

Numerous studies in the United States and internationally have reported on the decline in breast cancer incidence after 2002. Based on data from the San Francisco mammography registry, prescribing of E&P peaked in 1999. Before publication of the Heart and Estrogen/progestin Replacement Study (HERS) the use of hormone therapy was increasing at 1% per quarter, but declined by 1% per

quarter after the publication (299). This decline in prescribing continued until the publication of the WHI in 2002, at which point a more substantial decline of 18% per quarter was observed. The peak and decline through 1999 to 2002 is concordant with the HERS report (300) in 1998 showing a significant increase in coronary heart disease (CHD) in the first year of therapy among women with prevalent coronary disease, and in addition, no long-term benefit in reducing CHD (301). The growing epidemiologic evidence published since 2000 on the adverse effects of combination therapy on breast cancer added further evidence against the use of this therapy. Based on a prevalence of use of E&P in California, Clarke et al. estimated a population attributable risk (PAR or the proportion of cases caused by E&P) of up to 11% based on a prevalence of use of 30% and a relative risk of 1.4 (302). Given that substantially higher relative risks of 2 or more have been reported (277), this estimate of the PAR is conservative. Assuming a prevalence of use of 17.5%, the average reported for California in 2001 (302), a relative risk of 1.49 gives a PAR of 7.9% and a relative risk of 2.0 gives a PAR of 14.9%.

Evidence for breast cancer incidence rates now clearly shows a parallel drop in breast cancer consistent with the pattern of decreased prescribing. The rigorous, state-of-the-art analysis by Jemal et al. (303) using joint point analysis and drawing on SEER incidence data from 1975 through 2003 shows that there is a significant decrease in incidence of invasive breast cancer from 1999 to 2003 in all 5-year age groups from 45 years and above, and a sharp decrease largely limited to ER positive tumors in age groups 50 to 69 between 2002 and 2003. Furthermore, while others have suggested that a 1% to 3% drop in screening mammography may account for this drop in incidence, Jemal et al. show strong evidence against this. If screening was to account for a drop in incidence, rates of *in situ* disease would also need to drop because they are almost only detected by mammography. Prior to screening becoming widespread, Jemal et al. show *in situ* rates were low and rose with the uptake of screening to plateau from 1999 through 2003. The lack of a drop in *in situ* cancer offers compelling evidence that a reduction in screening does not account for the drop in incidence of invasive breast cancer.

Others have analyzed SEER data over a shorter period (30) or draw on the unique resources of the California tumor registry and the health maintenance organization (HMO) data sets (304) to show similar relations between change in hormone therapy and a decrease in breast cancer incidence. Robbins and Clarke (305) have also evaluated the change in prescribing as estimated from the California Health Interview Survey (CHIS) for almost 3 million non-Hispanic white women aged 45 to 74 against the change in breast cancer incidence across 58 counties in California. This thoughtful analysis shows that from 2001 to 2004, incidence declined by 8.8% in the counties with the smallest E&P reductions, by 13.9% in those with intermediate reductions, and by 22.6% in counties with the largest reductions in combination postmenopausal hormone therapy (305). Between 2001 and 2003, CHIS data did not show any significant change in the proportion of women who reported having a mammogram in the previous two years adding further evidence against this as a plausible major explanatory factor in the observed declines in incidence. Analysis of women undergoing routine mammography in San Francisco rules out a drop in screening as a cause of the decrease in incidence and confirms other reports of the changes in incidence of invasive breast cancer (306). Even more evidence in support of this relation between decrease in E&P and breast cancer comes from declines in incidence that parallel those in the United States as reported in New Zealand (307), Australia (308), and Germany (309). Based on these data and the IARC classification of estrogen plus progestin as a carcinogen, we can conclude that removal of estrogen plus progestin acting as a promoter accounts for this rapid drop in incidence (310).

Summary of Postmenopausal Hormone Use and Breast Cancer Risk

Although some aspects of the relationship between postmenopausal hormones and breast cancer risk remain unresolved, several areas of clear agreement have emerged. The finding of no increase in risk comparing ever users to never users is consistent and reassuring. However, much of that observation reflects the experience among short-term users and hormone use in the past, predominantly unopposed estrogen.

Overall, the findings also indicate an increased risk in two important subgroups of users: users of long duration and current users. These increases are particularly marked among women beginning use within 5 years of menopause. In general, users of long duration are more likely to be current users, so in many studies these two groups overlap substantially. From a biological perspective, these are the groups one would most expect to demonstrate a relation with breast cancer risk, because exogenous estrogens appear to act as a promoter at a late stage.

The increase in breast cancer risk associated with estrogen plus progestin use appears considerably greater than that for use of estrogen alone. Combination estrogen plus progestin therapy increases mortality from breast cancer, not just incidence of disease. The impact on risk of differing progestins and patterns of use of progestins remains to be resolved.

GENETIC SUSCEPTIBILITY TO BREAST CANCER

Hereditary Syndromes

Family history of breast cancer is an accepted risk factor for breast cancer; however, the proportion of breast cancer estimated to be due to rare highly penetrant genes such as *BRCA1* and *BRCA2* is less than 10% (311), perhaps as low as 3% (312). A few highly penetrant genes and hereditary syndromes for breast cancer are described below; however, a more extensive discussion of this topic is covered in Chapter 17, Inherited Genetic Factors and Breast Cancer. Among 2,389 incident cases of breast cancer occurring in the Nurses' Health Study between 1976 and 1988, the age-adjusted RR associated with having a maternal history of breast cancer was 1.8 (95% CI, 1.5–2.0) (313). This risk rose to 2.1 if the mother's breast cancer was diagnosed before age 40. Having a sister with breast cancer was associated with a RR of 2.3, and this rose to 2.5 for having both and mother and a sister with breast cancer. Risk of developing breast cancer by age 70 for a 30-year-old woman with both a mother and sister history of breast cancer was estimated to be 17.5%. Segregation analyses of breast-cancer-prone families showed that inheritance in these families is consistent with an autosomal dominant mode of inheritance (314). These families represent a heterogeneous group of syndromes such as the Li-Fraumeni syndrome (a disorder that includes predisposition to sarcomas, lung cancer, brain cancer, leukemia, lymphoma, and adrenal-cortical carcinoma), Cowden disease (a syndrome involving mucocutaneous and gastrointestinal lesions and breast cancer), and a syndrome called by some "early onset breast cancer" (314) in which

breast cancer often occurs in the 20s and 30s. The molecular basis for certain of these syndromes is associated with high penetrance mutations. The Li-Fraumeni syndrome is due to germline mutations in the *p53* gene (315). Cowden syndrome is due to germline mutations of the *PTEN* gene (316). The breast cancer susceptibility gene on chromosome 17q was called *BRCA1* and was cloned in 1994 (317). A second breast cancer susceptibility locus, *BRCA2*, was localized on chromosome 13q and cloned in 1995 (318). Estimates of the cumulative lifetime risk of breast cancer in *BRCA1* and *BRCA2* carriers range from about 85% (estimated from the families selected for linkage analysis) to 50% or even less (estimated from population-based studies) (311). The higher estimates from the linkage analysis studies could be due to higher penetrance mutations in these families or to ascertainment bias resulting in failure to select families in which *BRCA1* and *BRCA2* mutations are present but do not give rise to a sufficiently striking breast cancer predisposition to qualify for enrollment into the linkage studies. In case series from "high-risk" clinics to which women with a notable family history of breast cancer are referred, *BRCA1* mutations may be responsible for 20% to 30% of early-onset breast cancer (319). However, estimates in unselected breast cancer cases are much lower, in the range of 2% to 3% (319,320). Estimates for *BRCA2* tend to be lower (319). In unpublished data from the Nurses' Health study, only 2 of 192 consecutive cases had truncation mutations in *BRCA1*, and 1 of 192 had a truncation mutation in *BRCA2*. Genetic testing and management of patients with highly penetrant mutations is discussed in Chapter 19. Moderate penetrance genes with minor allele frequencies (MAFs) ranging from .0005–.01 such as *CHEK2* (rare deletion mutation) and *PALB2* also increases breast cancer risk (321).

"Sporadic" and Later-onset Breast Cancers

As the high-penetrance genes responsible for single gene disorders have been found, the field of genetic epidemiology has seen a shift to studies using unrelated controls, often described as "association studies." This has been largely motivated by the lack of power in family-based studies if allele penetrance is low, as few members of even large families will be affected. There are additional parameters that can be calculated in association studies; for instance, to assess the population attributable risk for alleles associated with familial risk or specific allelic variants, it is necessary to screen population-based case series.

Low-penetrance Alleles and Breast Cancer Risk

Until recently, the main method used in the search for these low-penetrance alleles has been the "candidate gene" approach in which polymorphic variants in genes that plausibly influence breast cancer risk are assessed in conventional epidemiologic studies (i.e., case-control or cohort studies). The principal candidates studied have been genes involved in steroid hormone metabolism, carcinogen metabolism genes, and genes that may influence cell proliferation. Despite a large number of positive reports of association in a single study, few of these reports have been replicated (322). The failure to replicate initially positive findings has been ascribed to a variety of factors including publication bias, the "winner's curse" phenomenon (the first report of an association is often more positive than subsequent studies), underpowered studies, multiple comparisons, and genetic heterogeneity (322). The major problem with candidate gene studies may be the low prior probability associated with any specific candidate gene chosen from among the approximately 24,000 human genes. Despite this, when all published studies are combined, approximately 20% to 30% of association studies yield statistically significant pooled estimates, usually of modest effects (322,323). Until recently, none of these replicated positives have applied to breast cancer. Recent results from the Breast Cancer Association Consortium suggest that a nonsynonymous polymorphism in a coding variant (D302H) in Caspase 8 (*Casp8*) is associated with lower risk of breast cancer (324).

Genome-wide Scans and Cancer Susceptibility

Advances in genotyping technology coupled with decreases in genotyping cost have enabled genome-wide association studies (GWAS) in large-scale study populations. In contrast to the candidate gene approach, GWAS offer the potential to conduct a comprehensive and unbiased search for modest associations (325). The generation of a draft sequence of the human genome led to subsequent efforts to define the spectrum of variability in the sequence. These efforts include the International HapMap and 1000 Genomes Project.

The International HapMap provides a database of common SNPs (single nucleotide polymorphisms; defined as SNPs with minor allele frequency, MAF, >5%) at an average spacing of every 1,250 bases across the 3 billion base pairs of genomic sequence (326). Analysis of this dataset indicates that over 90% of the nearly 10 million common SNPs estimated to exist are highly correlated with at least one other SNP (a phenomenon known as linkage disequilibrium). This observation suggests that much of the information on genetic variation can be extracted with the genotyping of a carefully chosen subset of SNPs called tagSNPs, which can serve as surrogates for untested SNPs. The informativeness of a set of tagSNPs can be increased by selecting SNPs that maximize the r^2 to untyped SNPs in a region, and further increased by ranking SNPs according to the number of proxies they have (327). The extent of diversity in population genetics history is evident in the substantial differences in patterns of linkage disequilibrium between the multiple continental populations studied in HapMap 1 included European, East Asian, and West African populations. Draft 1 of the HapMap 3 data release includes 1,301 samples from 11 populations.

The 1000 Genomes Project provides an extensive catalog of SNPs, structural variants and their haplotype context. Using the next generation sequencing technologies, this international collaboration will sequence genomes from approximately 2,500 individuals from about 25 populations around the world. The Phase I data, an integrated release of genetic variation from 1,092 human genomes is currently available.

Replication in Whole Genome SNP Studies

However, testing 500,000 or more independent SNPs at conventional levels of statistical significance will generate a very large number of "statistically significant" results. Consideration of other factors, such as whether an SNP is in a known candidate gene pathway or network or a candidate genomic region (identified for instance, by previous linkage analyses or cytogenetic abnormalities in tumors) might be useful in advancing SNPs of interest, but since so little is known about the majority of the genes in the genome, this exercise will only apply to a small portion of genic regions. Thus, while there is considerable novelty for the first whole genome scan conducted for a specific disease, the reality is that it does not do much more than identify a list of SNPs for further testing in follow-up replication studies.

Fortunately, simulations have shown that carefully designed multistage studies in large consortia in which the best candidate SNPs identified in the first stage are advanced in subsequent studies of comparable cases and controls maintain high statistical power and enable a substantial decrease in genotyping cost (328,329).

Results from Genome-wide Scans of Breast Cancer

Results from 12 GWAS for sporadic breast cancer were published from 2007-2012 (330-337). The studies identified 25 loci as strongly associated with overall breast cancer risk, eight of which contained genes (*FGFR2, TOX3, MAP3K1, LSP1, ESR1, RAD51L1, TERT* and *PTHLH*) plausibly related to breast cancer. The *ESR1* variant is located upstream of the exon 1 transcription start site. *ESR1* encodes the ER-alpha gene involved in regulation of estrogen signaling pathways. However, several loci are located in non-genic regions such as 8q24. Variants in *FGFR2, MAP3K1,* 8q24, and 5p are associated with ER+ breast cancer. Studies on ER- breast cancer have identified three loci (TERT, Chr 19, MERIT40*)* (336,337). Additional studies by breast cancer molecular subtype are ongoing. Collectively, the 25 variants explain approximately 9% of the heritability of breast cancer. A meta-analysis of nine GWAS that includes over 10,000 breast cancer cases and over 12,000 controls of European ancestry have been conducted to identify new variants. Replication of the new variants is ongoing. The variants identified to date have modest effect sizes (RR = 1.05–1.6 per allele), emphasizing the need for large-scale replication. Studies have also been mainly conducted in postmenopausal breast cancer cases. In the CGEMS-NHS (331), the RRs for SNPs in 10q26 of intron 2 of *FGFR2* for premenopausal women in the Nurses' Health Study II were similar to those in postmenopausal and older-onset breast cancer case series, demonstrating the generalizability of the findings for this gene to premenopausal cases.

These findings, and additional loci that will almost certainly be discovered in further follow-up of these and further GWAS, have established new loci that collectively are likely to robustly identify a much larger fraction of women at modest genetic risk of breast cancer than the very small fraction at very high risk identifiable through analysis of the high penetrance genes such as *BRCA1* and *BRCA2.* Deriving the appropriate risk prediction models, integrating SNPs with molecular phenotypes, and then understanding how they can be applied clinically will be a substantial challenge over the next several years.

Since many of the GWAS SNPs identified to date are located in non-coding regions of the genome, future collaborative investigations will require functional follow-up to uncover the mechanistic association with breast cancer (338). A recent study shows that GWAS SNPs associated with breast cancer risk are located in enhancer regions and alter binding affinity for the pioneer factor FOXA1 (339). Efforts to link the risk alleles in non-coding regions to genes using expression quantitative trait analyses and to identify the causal alleles using next-generation sequencing are in progress.

DIETARY FACTORS

Nutritional factors have been prominent among the hypothesized environmental determinants of breast cancer that account for the large variation in breast cancer incidence around the world and the large increases in rates among the offspring of migrants from countries with low incidence to countries with high incidence. The dominant hypothesis has been that high fat intake increases risk. In this section, evidence for this relationship is reviewed and alternative hypotheses are suggested.

Dietary Fat and Breast Cancer

Animal Studies

High-fat diets have long been known to increase the occurrence of mammary tumors in rodents. However, the interpretation of these and other animal data is controversial. Fat is the most energy-dense macronutrient (9 kcal/g compared with 4 kcal/g for protein and carbohydrate); thus, high-fat diets tend to be higher in energy intake unless care is taken to keep energy intake constant. Many animal experiments have not done this, resulting in confounding of fat consumption by energy intake. In a meta-analysis of diet and mammary cancer experiments in mice, Albanes (340) observed a weak inverse association with fat composition (adjusted for energy), whereas total energy intake was positively associated with mammary tumor incidence. Freedman, Clifford, and Messina (341) conducted a similar meta-analysis of experiments in both rats and mice and reported that both higher fat intake and higher caloric intake independently increase mammary tumor incidence. In studies specifically designed to determine the independent effects of fat and energy intake, the effect of fat was either weak in relation to that of energy intake (342) or nonexistent (343). Furthermore, the relevance to human experience of rodent models in which animals are given high doses of specific carcinogens, to which humans are rarely exposed, is questionable. Notably, in a very large study of rats and mice fed substantially different amounts of corn oil without administration of a carcinogen, no effect of fat intake was found on spontaneous mammary cancer incidence (344). In a case-control study in dogs, fat intake, which ranged from 10% to 70% of energy, was not associated with risk of breast cancer (345). The clearest message from the animal data is the importance of total energy intake and the need to consider energy balance in epidemiologic studies.

International Correlation (Ecologic) Studies

The dietary fat hypothesis is largely based on the observation that national per capita fat consumption is highly correlated with breast cancer mortality rates (346). A serious problem with ecologic comparisons of diet and breast cancer is the potential for confounding by known and unknown breast cancer risk factors. National fat consumption per capita is highly correlated with level of economic development; thus, any factor that characterizes affluent Western countries would also be correlated with national rates of breast cancer. Prentice et al. (347) found that the ecologic relation between fat consumption and breast cancer incidence rates was still statistically significant after adjustment for Gross National Product (GNP) per capita and average age at menarche. However, other breast cancer risk factors such as low parity, late age at first birth, greater body fat, and lower levels of physical activity are more prevalent in Western countries and would be expected to confound the association with dietary fat. Thus, there is good reason to question whether the international correlation between fat intake and breast cancer represents a causal relationship.

Secular Trends

Estimates of per capita fat consumption based on "food disappearance" data (the food available rather than the amount actually eaten), and breast cancer incidence rates have both increased substantially in the United States during the twentieth century. However, surveys based on measures of actual individual intake, rather than food disappearance, indicate

that consumption of fat as a percentage of energy has declined in the last several decades, a time during which breast cancer incidence has increased. Higher dietary fat consumption has been implicated in the increase in breast cancer incidence in Japan since 1950. However, this increase could also be due to the increasing prevalence of reproductive and other lifestyle risk factors that characterize Western populations.

The famine that occurred in Norway during World War II provided a natural experiment on the effects of nutritional deprivation on breast cancer risk (348). Women who were adolescents during the famine have subsequently experienced a reduction in breast cancer risk (about 13% lower) at all ages. These data on time trends indicate the sensitivity of breast cancer rates to nutritional and lifestyle factors but do not specifically support a role of dietary fat.

Data from special populations with distinct dietary patterns are valuable, because adherence to a particular diet over many years may represent a more stable long-term exposure than that applicable to most free-living adults whose diet may change substantially over time. Because these populations often have unusual distributions of potential nondietary risk factors such as alcohol consumption, smoking, and reproductive behavior, care must be taken in attributing differences in cancer rates to diet alone. Seventh-Day Adventists, who consume relatively small amounts of meat and other animal products, have substantially lower rates of colon cancer, but only slightly lower breast cancer rates than other U.S. white women of similar socioeconomic status (349). Breast cancer rates among British nuns who ate no meat, or very little meat, were similar to rates among single women from the general population (350), also suggesting there is no substantial association between animal fat and risk of breast cancer.

Case-control Studies

In a typical case-control study of diet and breast cancer, the diet before diagnosis reported by women with breast cancer (cases) is compared with the diet reported by women who have not been diagnosed with breast cancer. An early large study was that of Graham et al. (351), who used a food frequency questionnaire to compare the fat intake of 2,024 women with breast cancer to that reported by 1,463 female controls seen at the hospital with benign conditions. Animal fat and total fat intake were almost identical in the two groups. In a meta-analysis, Howe et al. (352) summarized the results from 12 smaller case–control studies including 4,312 cases and 5,978 controls. The overall pooled RR for a 100-g increase in daily total fat intake (an unrealistic change) was 1.35; the risk was somewhat stronger for postmenopausal women (RR= 1.48). The main concern with this finding is that associations in case-control studies of diet may easily be due to selection bias (the controls are drawn from a population with a different distribution of fat intake than the distribution in the population that gave rise to the cases) or recall bias (the cases, knowing their diagnosis, differentially misreport their prediagnosis diet) (353). We now have many examples in which findings from case-control studies of diet and cancer have not been confirmed in prospective studies (354).

Cohort Studies

In a cohort (prospective) study, the diets of a large group of women are measured, and the subsequent rates of breast cancer among those with different levels of dietary factors are compared. Selection bias should not be a problem because the population that gave rise to the cases is known (the starting members of the cohort), and recall bias should not occur because dietary information is collected before knowledge of disease. The results for postmenopausal breast cancer (for which fat intake has been hypothesized to be strongest because the international differences are largest for this group) from prospective studies with at least 200 incident cases of breast cancer are shown in Table 18-1 (355–366). The number of breast cancer cases in some of

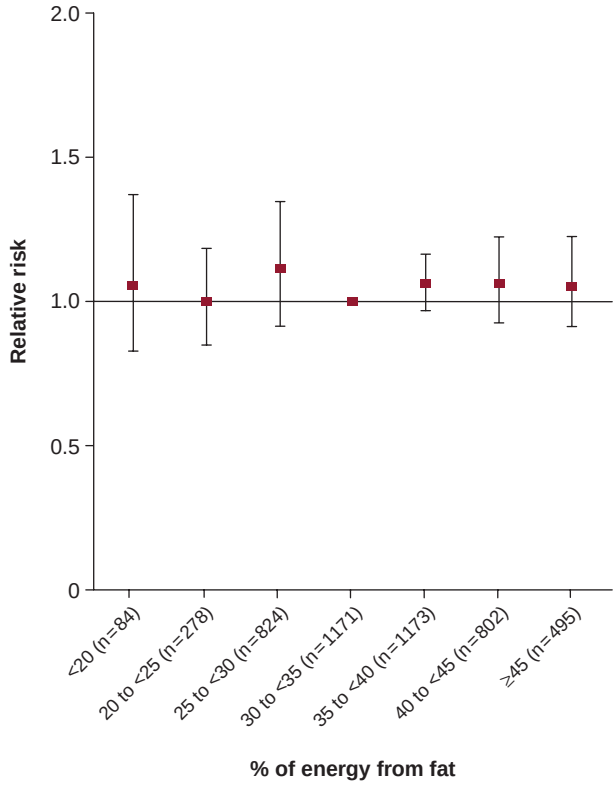

FIGURE 18-10 Pooled relative breast cancer risk and 95% CIs associated with percentage of energy derived from fat intake. (Reproduced from Hunter DJ, Spiegelman D, Adami HO, et al. Cohort studies of fat intake and the risk of breast cancer: a pooled analysis. *N Engl J Med* 1996;334:356–361, with permission.)

these studies far exceeds the number in the pooled analysis of case-control studies referred to earlier, and the size of the comparison series (i.e., noncases) is much larger. Only in the AARP study was a weak positive association between fat intake and risk of breast cancer observed (comparing highest with lowest category of intake, RR = 1.11 (95% CI, 1.00–1.24) (362). In all other studies no significant association was seen. A collaborative pooled analysis has been conducted that included most of the prospective studies shown in Table 18-1 that included 4,980 cases of breast cancer among 337,819 women (367). In addition to providing great statistical precision, the pooled analysis allowed standard analytic approaches to be applied to all studies, an examination of a wider range of fat intake, and a detailed evaluation of interactions with other breast cancer risk factors. Overall, no association was observed between intake of total, saturated, monounsaturated, or polyunsaturated fat and risk of breast cancer. As noted in Figure 18-10, no reduction in risk was seen even for fat intakes as low as 20% of energy. When the relatively few women with fat intake lower than 15% of energy were examined, their risk of breast cancer was actually increased twofold; this could not be accounted for by other dietary or nondietary factors.

Substudies were available for each cohort in the pooled analysis in which the measurement errors of the dietary questionnaires were quantified and these were used to adjust the overall RRs and CIs to take into account errors in measuring diet. Without correction, the RR for a 25-g/day increment in fat intake was 1.02 (95% CI, 0.94–1.11). After accounting for measurement error, the RR was 1.07 (95% CI, 0.86–1.34). The upper bound of the adjusted 95% CI excludes the RR of 1.4 to 1.5 predicted by the international correlations. In calculations based on a series of theoretical assumptions, Prentice has claimed that the pooled analysis of breast cancer failed to find a positive association because the measurement error correction did not account for underreporting of fat by more obese women. However, actual studies do not support this assumption, and the other predictions based on this theoretical model are also not supported by the data (368). In analyses with extended follow-up of these cohorts (7,329 cases of breast cancer), the lack of association with total fat intake was confirmed (RR for an increment of 5% of energy from fat per day = 1.00 (95% CI, 0.98–1.03) (369). Based on a small cohort (168 cases) in which a positive association with fat intake was reported when assessed with a 1-week dietary record but not when assessed with a food frequency questionnaire, Bingham et al. suggested that the lack of association seen in the large cohort studies was due to the use of the latter method (370). However, in a recent analysis that combined four cohorts that used both methods, including extended follow-up of Bingham's cohort, the two methods yielded almost identical weak inverse associations between fat intake and incidence of breast cancer (371). In the Nurses' Health Study, additional analyses have been conducted with 20 years of follow-up (3,537 postmenopausal cases) (372); up to six assessments of fat intake were available, which substantially improves the measurement of long-term dietary intake. The RR for a 5% increase in percentage of energy from total fat was 0.98 (95% CI, 0.95–1.00), and no suggestion of any reduction in risk was seen for fat intakes even lower than 20% of energy (356). Thus, the prospective studies provide strong evidence that no major relation exists between total dietary fat intake over a wide range during midlife and breast cancer incidence. It remains possible that total fat intake during childhood and/or early adult life may affect breast cancer risk decades later. Notably, in the Nurses' Health Study II, which was established to evaluate the influence of dietary and other potential risk factors earlier in life, intake of animal fat (but not vegetable fat) before menopause was positively associated with risk of breast cancer (373). This finding, which needs to be replicated, was mainly due to consumption of red meat and high-fat dairy products. In this same cohort, a large subset of women also completed a detailed questionnaire about their diet during high school. A marginally significant association was seen between total fat intake and risk of premenopausal breast cancer (RR = 1.35; 95% CI, 1.00–1.81) (374), but this could not be clearly distinguished from intake of red meat, which was also associated with increased risk (375).

Intervention Studies

Some have suggested that the relation between dietary fat and breast cancer can be established only by randomized trials of fat reduction. In the Women's Health Initiative, 48,835 women were randomly assigned either to reduce their total fat intake to 20% of calories from fat or to their regular diet (376). After 8 years of follow-up, the relative risk for the low fat compared to the control group was 0.91 (95% CI, 0.83–1.0, p = .09), indicating no significant benefit of the intervention. However, as has been the experience in other large dietary intervention trials (377), maintaining compliance with a diet very different from prevailing food consumption habits proved to be difficult, and the reported difference in fat intake between groups was only 8% of energy at year 6 rather than the 14% of energy anticipated. Moreover, self-reported compliance in dietary intervention studies tends to be overreported, and no differences were seen between groups in blood levels of HDL cholesterol or triglycerides (378). Because reduction in dietary

fat would be expected to reduce HDL cholesterol and increase triglycerides (379), this lack of effect on blood lipids suggests that the WHI did not really address the dietary fat and breast cancer hypothesis, despite being the most expensive study ever conducted (380). Prentice et al. suggested that, even though not significant, the slightly lower (9%) risk of breast cancer in the low fat group may represent a real effect of fat reduction that may become significant with longer follow-up. However, even if a significant effect were to be seen, it would not be possible to conclude that this was due to reduction in dietary fat because there was an approximately 1.5-kg weight loss in the low fat group, which is typically seen with intensive dietary interventions independent of percentage of energy from dietary fat (381). This degree of weight loss, although modest, could account for most of a 9% difference in breast cancer risk (382). Furthermore, as pointed out by the Women's Health Initiative investigators, women in the dietary intervention group were counseled to adopt a dietary pattern that is high in fruits, vegetables, and grain products and low in total fat and saturated fat (383). Thus, the trial is unable to distinguish between a decrease in risk due to increased intake of fruits, vegetables, and grains or a decrease due to lower fat intake. Also, this trial could not address whether dietary fat reduction at an earlier age may reduce breast cancer risk. The lack of association with fat intake in the 20-year follow-up of the Nurses' Health Study (372) suggests that insufficient follow-up time is not a likely explanation for the nonsignificant results of the WHI trial. A second trial of dietary fat reduction was conducted in Canada among women with elevated risk of breast cancer (384,385); after an average of 10 years of follow-up, there was a nonsignificant 19% increase in risk of breast cancer among those on a low-fat diet. In contrast to the WHI trial, women assigned to the low-fat diet experienced the expected changes in blood lipid levels. Although this trial was consistent with findings from prospective cohort studies, it could not exclude an effect of diet earlier in life.

Type of Fat

In addition to overall fat intake, specific types of fat could differentially affect risk of breast cancer. In most animal studies, diets high in polyunsaturated fat (linoleic acid), but typically at levels beyond human exposure, have increased the occurrence of mammary tumors. As noted earlier, however, a positive association has not been found in prospective epidemiologic studies (369).

Some animal studies have suggested that monounsaturated fat, in the form of olive oil, may be protective relative to other sources of energy (386); the abundant antioxidants in this oil could contribute to this effect. In a Spanish study specifically undertaken because of the high consumption of olive oil and low breast cancer rates in this population, no association was observed with total fat intake (387). However, higher intake of olive oil was associated with reduced risk of breast cancer. Similar inverse associations with olive oil or monounsaturated fat were seen in case-control studies in Greece, Italy, and Spain (388). In the pooled analysis of cohort studies (369), saturated fat (compared to carbohydrate) was weakly associated with higher risk of breast cancer (RR for 5% of energy=1.09; 95% CI, 1.00–1.19), and compared to monounsaturated fat, the RR was 1.18 (95% CI, 0.99–1.42).

High intake of N3-fatty acids from marine oils has inhibited the occurrence of mammary tumors in animals. However, case-control and cohort studies have in general not found intake of N3-fatty acids or fish (the major source of long-chain N3-fatty acids) to be associated with lower risk of breast cancer (356,388).

Height, Weight, and the Risk of Breast Cancer

As noted earlier, energy restriction powerfully reduces mammary tumor incidence in rodents (340,341). This relationship is difficult to evaluate directly in humans because estimates by adults of their energy intake, especially during childhood, are unlikely to be sufficiently precise and any analysis would need to also account for physical activity with high accuracy. However, because children who experience energy deprivation during growth do not attain their full potential height, attained height may be used as a proxy for childhood energy intake, although this is not a specific indicator as protein restriction and genetic factors also affect stature. In Japan, for instance, a substantial increase in average height has occurred during the twentieth century, presumably because of improved nutrition. Among countries, height is positively correlated with breast cancer rates (389), supporting the hypothesis that childhood and adolescent energy intake may influence breast cancer rates decades later.

Most of the case-control and cohort studies of attained height and risk of breast cancer suggest a modest positive association (390). In a follow-up of the National Health and Nutrition Examination Survey-I (NHANES-I) population in which women at risk for malnutrition had been oversampled, a nearly twofold increase in risk was observed across the range of height (391). In a pooled analysis of large cohort studies (4,385 cases among 337,819 women), the RRs for an increment of 5 cm of height were 1.02 (95% CI, 0.96–1.10) for premenopausal women and 1.07 (95% CI, 1.03–1.12) for postmenopausal women (392) (Fig. 18-11) and in a meta-analysis of 15 published cohort studies, the relative risk for a 5 cm

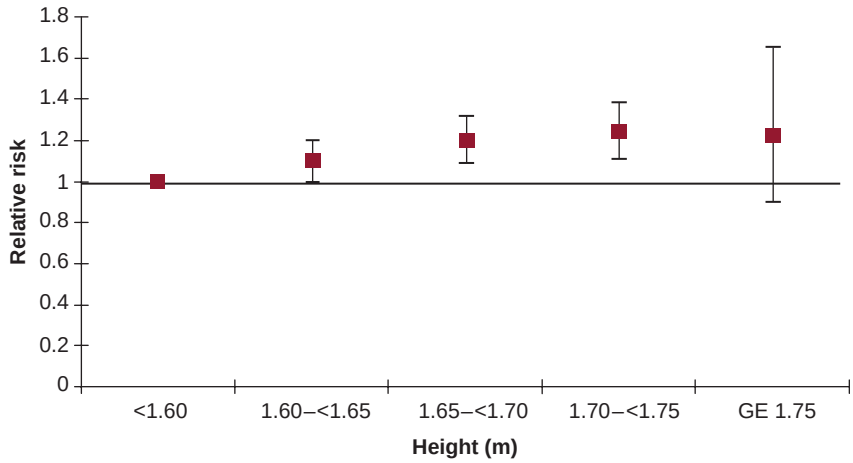

FIGURE 18-11 Results of prospective studies of the association between height and breast cancer. (Adapted from van den Brandt PA, Spiegelman D, Yaun SS, et al. Pooled analysis of prospective cohort studies on height, weight, and breast cancer risk. *Am J Epidemiol* 2000;152:514–527.)

increment was 1.11 (95% CI, 1.09–1.13) among postmenopausal women and 1.09 (95% CI, 1.05–1.14) among premenopausal women (393). In the studies of Vatten and Kvinnsland (394,395), the positive trend between height and risk of breast cancer was most nearly linear in the birth cohort of women who lived through their peripubertal period during World War II (1929–1932), a time in which food was scarce and average attained greater height reduced. Collectively, these data provide convincing evidence that attained greater height is associated with a modest increased risk of breast cancer.

Age at menarche, an established risk factor for breast cancer, provides a second indirect indicator of energy balance during childhood. Nutritional factors, in particular energy balance, appear to be the major determinants of age at menarche. In prospective studies among young girls, the major predictors of age at menarche were weight, height, and body fatness (396–399). A marginally significant inverse association between dietary fat and age at menarche was seen in one study (398), but no relation was observed in others. The potential for energy balance to influence breast cancer risk through age at menarche is greater than might be appreciated by examining the distribution of this variable in modern Western countries. Although the average age at menarche in these countries is now 12 to 13 years, in rural China the typical age has been approximately 17 to 18 years (400), similar to that of Western countries 200 years ago. An effect of growth rate on breast cancer risk may begin even before birth, because an inverse relation between birth weight and breast cancer risk has been observed mainly in premenopausal women (401,402).

The relation between preadolescent body fatness and risk of breast cancer appears to be complex; even though greater adiposity reduces the age at menarche, adiposity at this age has been associated with lower rather than greater risk of breast cancer (401,403). Notably, in the Nurses' Health Study II cohort, women who were the most overweight at ages 5 and 10 had only half the risk of breast cancer before menopause compared to those who were the leanest at these ages (403), and adjustment for age at menarche had little effect on this association. This finding has been hypothesized to be due to earlier differentiation of breast tissue and reduced susceptibility to carcinogens (401), but further examination of these relationships is needed.

The mechanisms by which age at menarche and attained height are related to risk of breast cancer are probably multiple. Early onset of menstrual cycles exposes the breast to ovarian hormones at a younger age and for a longer duration over a lifetime. Also, in several studies, an early age at menarche has been associated with higher estrogen levels at later ages (404). Height has been suggested to be a surrogate for mammary gland mass (405), which may be related to higher risk, or it may be a surrogate for exposure to high levels of IGF-I or other anabolic hormones during childhood. IGF-I is directly involved in regulation of growth during childhood and is hypothesized to increase risk of breast cancer, although the relation of blood levels during adulthood to cancer risk is complex and remains unsettled (406). IGF-I levels are in part determined by genetic factors, but energy restriction reduces IGF-I levels, and infusion of IGF-I appears to negate the effects of energy restriction tumorigenesis in animals (407). Also, high consumption of dairy products increases blood levels of IGF-I (408–414), and in addition it appears to accelerate growth in height (413,415,416). However, data on milk consumption during childhood and risk of breast cancer are limited.

Weight and Weight Change during Adulthood

Attained weight and weight change in adults provide sensitive measures of the balance between long-term energy intake and expenditure. Although the relation between these variables and breast cancer risk has been complex and confusing, recent findings provide a coherent picture and indicate a major contribution of weight gain during adulthood clearly contributes importantly to risk of postmenopausal breast cancer risk. Two reproducible findings have been particularly enigmatic: (a) In affluent Western populations with high rates of breast cancer, measures of body fatness have been *inversely* related to risk of premenopausal breast cancer; and (b) body fatness after menopause has been only weakly related to postmenopausal breast cancer risk despite strong associations between body fat and endogenous estrogen levels.

The inverse relation between body weight (typically used as body mass index [BMI], calculated as weight in kilograms divided by height in meters squared, to account for variation in height) and incidence of premenopausal breast cancer has been consistently seen in recent prospective studies (283,392,393). In the most recent meta-analysis the relative risk for a 2-unit increment in BMI was 0.94 (95% CI, 0.92–0.95) (393). Little relation of BMI to breast cancer mortality has been observed in premenopausal women, probably because delayed detection and diagnosis in heavier women counterbalances the lower incidence among heavier women. Heavier premenopausal women, even at the upper limits of what are considered to be healthy weights, have more irregular menstrual cycles and increased rates of anovulatory infertility (417), suggesting that their lower risk may be due to fewer ovulatory cycles and less exposure to ovarian hormones. Increased rates of menstrual irregularity and anovulatory infertility are also seen among very lean women, but such women are uncommon in Western populations. Although irregular menstrual cycles have been associated with reduced risk of breast cancer (61), adjustment for details of menstrual characteristics accounted for little of the inverse relation between BMI and risk of premenopausal breast cancer (418). This suggests that other factors, yet to be determined, account for most of the lower risk of breast cancer among overweight premenopausal women.

In both case-control and prospective studies conducted in affluent Western countries, the association between BMI and risk of breast cancer among postmenopausal women has often been only weakly positive or nonexistent (352,390,392). The lack of a stronger association has been surprising because obese postmenopausal women have plasma levels of endogenous estrogens nearly twice as high as those of lean women, because of conversion of androstenedione to estrogens in adipose tissue, and levels of SHBG are lower (419). The lack of a stronger positive association appears to be due to two factors. First, like the protective effect of early pregnancy, the reduction in breast cancer risk associated with being overweight in early adult life appears to persist through later life (283,420). Thus, an elevated BMI in a postmenopausal woman represents two opposing risks: a protective effect due to the correlation between early weight and postmenopausal weight and an adverse effect due to elevated estrogens after menopause. For this reason, weight *gain* from early adult life to after menopause should be more strongly related to postmenopausal breast cancer risk than would attained weight. Indeed, the relation between weight gain and risk of postmenopausal breast cancer has been consistently supported by both case-control (421–423) and prospective studies (283,393,420,424,425). A second reason for failing to appreciate a greater adverse effect of excessive weight or weight gain on risk of postmenopausal breast cancer is that the use of postmenopausal hormones obscures the variation in endogenous estrogens due to

adiposity and elevates breast cancer risk regardless of body weight (283,425). To appreciate fully the impact of weight or weight gain, an analysis should be limited to women who never used postmenopausal hormones. Thus, among women who never used postmenopausal hormones in the Nurses' Health Study, those who gained 25 kg or more after age 18 years had double the risk of breast cancer compared with women who maintained their weight within 2 kg (283) (Fig. 18-12). In this population, the combination of either using postmenopausal hormones or gaining weight after age 18 years accounted for one-third of postmenopausal breast cancer cases. Greater BMI has generally been more strongly associated with breast cancer mortality than with incidence (283,426). This may relate to greater difficulty in detecting small tumors in fatter breasts, which could influence prognosis, as well as the greater endogenous estrogen levels.

The relation between body weight and breast cancer risk among lower risk mainly non-Western countries is somewhat different in higher risk countries (427). In general, the inverse relation between weight and premenopausal breast cancer risk has not been observed, and the association between weight and postmenopausal risk has been stronger. This difference is likely to be due to the lower prevalence of overweight among premenopausal women in these low-risk countries; few women are likely to be sufficiently overweight to cause anovulation and a reduction in premenopausal breast cancer risk. As a result, BMI after menopause would only reflect the adverse effects of high endogenous estrogens, unopposed by a residual protective effect due to correlation with overweight in early adult life.

In summary, as in animal studies, energy balance appears to play an important but complex role in the causation of human breast cancer. During childhood, rapid growth rates accelerate the occurrence of menarche, an established risk factor, and result in greater attained stature, which has been consistently associated with increased risk. During early adult life, overweight is associated with a lower incidence of breast cancer before menopause, but no reduction in breast cancer mortality. However, weight gain after age 18 years is associated with a graded and substantial increase in postmenopausal breast cancer that is seen most clearly in the absence of hormone replacement therapy.

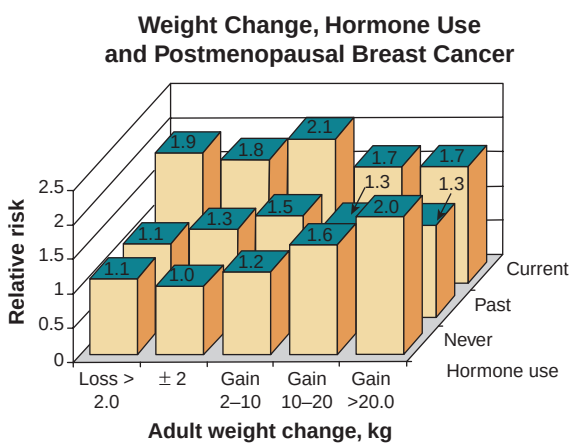

FIGURE 18-12 Relative risk (RR) of breast cancer by adult weight change and hormone use among postmenopausal women. (Reproduced from Huang Z, Hankinson SE, Colditz GA, et al. Dual effects of weight and height gain on breast cancer risk. *JAMA* 1997;278:1407–1411, with permission.)

Carbohydrates, Glycemic Index, and Glycemic Load

Higher intakes of carbohydrates increase blood insulin levels, which have been hypothesized to promote tumor growth. Glycemic index (GI) is a measure of carbohydrate quality, referring to the incremental elevation in blood glucose levels after a standard amount of carbohydrate, and glycemic load (GL) combines the amount of carbohydrate in a food or diet and its glycemic index (428). The adverse metabolic response to glycemic load is augmented by underlying insulin resistance in epidemiologic studies often represented by BMI (429). Among premenopausal women, carbohydrate intake and glycemic load tended to be inversely related to risk of breast cancer among lean women, but positively associated with risk among postmenopausal women (430). In a recent meta-analysis of prospective studies, greater glycemic index, but not glycemic load or carbohydrate intake, was associated with a small increase in risk of breast cancer (429,431). In the large EPIC study, GI, GL, and carbohydrate intake were not related to overall risk of breast cancer. However, among postmenopausal women, GL and carbohydrate intake were significantly associated with an increased risk of estrogen receptor-negative tumors (comparing highest vs. lowest quintiles for glycemic load RR = 1.36; 95% CI, 1.02–1.82; p-trend = 0.01), and for carbohydrate intake the relative risk was 1.41 (95% CI, 1.05–1.89; p-trend = 0.009) (432). Because these are potentially important findings, further examination of these relationships by hormone receptor status is needed.

Dietary Fiber

Diets high in fiber have been hypothesized to protect against breast cancer, perhaps due to inhibition of the intestinal reabsorption of estrogens excreted via the biliary system. A high-fiber diet was associated with reduced incidence of mammary cancer in animals (386). Dietary fiber includes crude fiber that is excreted unchanged, and various soluble fiber fractions that may have different biologic effects. In a meta-analysis of 10 case-control studies with estimates of dietary fiber intake, a statistically significant RR of 0.85 for a 20-g/day increase in dietary fiber was observed (352). In a recent meta-analysis of 16 cohort studies, a significantly lower risk of breast cancer among women with the highest compared to lowest intakes was seen in only one study (433). However, a weak, statistically significant inverse association was seen in the combined analysis; the RR for highest versus lowest intake of total dietary fiber was 0.93 (95% CI, 0.89–0.98). When examined separately, no significant association was seen for intakes of fiber from fruits, vegetables, or cereals.

Micronutrients

Vitamin A

Vitamin A consists of preformed vitamin A (retinol, retinyl esters, and related compounds) from animal sources and certain carotenoids found primarily in fruits and vegetables that are partially converted to retinol in the intestinal epithelium (carotenoid vitamin A). Many carotenoids are potent antioxidants and thus may provide a cellular defense against reactive oxygen species, which damage DNA. Vitamin A is also a regulator of cell differentiation and may prevent the emergence of cells with a malignant phenotype. Retinol inhibits the growth of human breast carcinoma cells *in vitro* (434), and retinyl acetate reduces breast cancer incidence in some rodent models (435).

In the earliest large case-control study of total vitamin A intake (retinol plus carotenoids vitamin A) (351), a significant

inverse trend was seen (RR of 0.8 for highest vs. lowest quartile of vitamin A intake). In a meta-analysis of nine other case-control studies with data on vitamin A intake (352), a significant inverse association between total vitamin A and breast cancer was reported. However, when preformed vitamin A and carotenoids were examined separately, the data from these case-control studies are more strongly supportive of a protective association for carotenoid vitamin A than for preformed vitamin A. In more recent case-control studies, inverse associations were observed between dietary intakes of β-carotene and lutein/zeaxanthin and risk of breast cancer in premenopausal women (436).

Prospective data have supported a modest inverse relation between carotenoids and breast cancer. In a cohort of Canadian women (519 cases) (437), a marginally significant protective association between total vitamin A intake and breast cancer was seen, with both preformed vitamin A and β-carotene contributing to the inverse association. With 14 years of follow-up in the Nurses' Health Study (2,697 cases), an inverse association with total vitamin A was seen only among premenopausal women (438). This inverse association was primarily accounted for by carotenoid sources of vitamin A; when specific carotenoids were examined, intakes of β-carotene and lutein/zeaxanthin were associated with reduced risk, but intake of lycopene was not. In a recent pooled analysis including 18 cohort studies and over 33,000 incident cases of breast cancer, higher intakes of β-carotene, α-carotene, and lutein/zeaxanthin were inversely associated with risk of estrogen receptor-negative breast cancer (439). For the highest versus lowest quintile of β-carotene, the relative risk was 0.84 (95% CI, 0.77–0.93). No association was seen for estrogen receptor-positive tumors.

An alternative to the dietary assessment of vitamin A intake and carotenoids is the measurement of vitamin A-related compounds in blood. Studies of blood retinol are minimally informative about vitamin A intake in well-nourished populations because the liver maintains relatively constant blood retinol concentrations. However, blood levels of β-carotene do reflect β-carotene intake. In a meta-analysis, blood levels of β-carotene were more strongly and consistently associated with lower risk of breast cancer than was dietary intake of β-carotene (440). In a recent pooled analysis of primary data from prospective cohort studies, including 3,055 cases of breast cancer, inverse associations were seen with blood levels of α-carotene, β-carotene, lutein/zeaxanthin, and total carotenoids (441). The association with β-carotene was stronger for estrogen-receptor-negative tumors (for highest vs. lowest quintile, RR = 0.52; 95% CI, 0.36–0.77) than for estrogen receptor positive tumors (RR = 0.83; 95% CI, 0.66–1.04; test for heterogeneity by receptor status = 0.01). Recent progress in genomics has identified variants in the β-carotene monooxygenase genes, which convert β-carotene to two molecules of retinol, and thus influences plasma β-carotene intake independent of dietary intakes. Following the concept of "Mendelian randomization," evidence that these genetic variants are related to risk of breast cancer would provide strong support for the role of β-carotene (or its precursors). In an analysis examining these genetic variants in relation to risk of breast cancer, no association was seen (442). However, the confidence intervals were too wide to exclude the effect predicted by published associations between blood carotenoids and incidence of breast cancer; very large sample sizes are needed for such analyses.

Thus, available data are suggestive of a modest protective effect of vitamin A intake on breast cancer, although the evidence is stronger for benefits of carotenoid sources of vitamin A. Also, evidence of benefit for β-carotene is stronger for ER- tumors. However, it is possible that other anticarcinogens in vegetables and fruits, including carotenoids such as lutein, are responsible for the apparent benefits. Ideally, the effect of vitamin A supplements, in the form of either preformed vitamin A or carotenoids, should be evaluated in randomized trials. In a randomized trial of fenretinide, a powerful synthetic retinoid, in the prevention of contralateral breast cancer among women already diagnosed with a first breast cancer, no overall effort was seen (443), although a significant benefit was seen in premenopausal women. The Women's Health Study of 40,000 female health professionals was a randomized trial designed to test whether β-carotene or vitamin E supplements reduce breast cancer risk. However, the β-carotene arm was terminated in 1996 after reports from trials in Finland and the United States that β-carotene supplements appeared to increase risk of lung cancer among smoking men. Thus, data from randomized trials on specific carotenoids and breast cancer risk, particularly among premenopausal women, may never be available.

Vitamin E

Vitamin E is also an antioxidant and has inhibited mammary tumors in rodents in some, but not all, experiments (444). Although relatively few studies have assessed the association between dietary vitamin E (α-tocopherol) intake and breast cancer, evidence of benefit has not been seen in prospective studies (437,438,445,446), including with high doses of supplement use for long durations. In a 10-year randomized trial using 600 IU of vitamin E on alternate days, there was no effect on breast cancer incidence (447).

Vitamin C

Vitamin C (ascorbic acid) is also an antioxidant that can block the formation of carcinogenic nitrosamines. Few animal studies have assessed the effect of vitamin C on mammary cancer; in a study in rats, there was no effect of ascorbic acid on the growth of either transplanted or dimethyl benzanthracene–induced mammary tumors (448).

In a meta-analysis of nine case-control studies with data on vitamin C (352), a significant inverse association (RR = 0.7 for each 300-mg/day increase in vitamin C) was observed. However, in prospective studies, intake of vitamin C has not been associated with risk of breast cancer (437,438,445,446,449,450). In the 14-year follow-up of the Nurses' Health Study, no evidence of any reduction in risk was seen with long-term use of vitamin C supplements (438). Thus, the available prospective data do not support benefits of high vitamin C intake for reducing breast cancer risk.

Vitamin D

Vitamin D and its metabolites can reduce cell proliferation, enhance apoptosis, and inhibit tumor progression in animal models (451). Epidemiologic studies provide some support for reduced risk of breast cancer with higher intake, particularly in premenopausal women (452–454). However, vitamin D is unique among nutrients in that the dominant source is obtained by the action of sunlight on a precursor molecule in the skin, rather than by diet. Plasma levels of 25-OH vitamin D (25(OH)D) provide an integrated biomarker of vitamin D from all sources that can be used in epidemiologic studies. Although many studies have shown an inverse relation between plasma 25-OH vitamin D levels and risk of colon cancer (455), the epidemiologic evidence is less clear for breast cancer (456). Eleven nested case-control and retrospective studies have been conducted, and in only two was a significant inverse association observed (457). In

a meta-analysis of these 11 studies, a modest and marginally significant inverse relation was seen (summary relative risk comparing the highest with the lowest category = 0.86 (95% CI, 0.75–1.00) (457). A second meta-analysis restricted to nine prospective studies found a nonlinear inverse association among postmenopausal women, whereby between the range of 27-<35 ng/mL, a 5 ng/mL increase in 25(OH)D was associated with a 12% lower risk of breast cancer (RR = 0.88 per 5 ng/mL; 95% CI, 0.79–0.97) (458). In contrast, no association was found among premenopausal women. In addition to possibly reducing incidence of breast cancer, higher intakes or blood levels after diagnosis could potentially improve prognosis. However, in several studies utilizing blood samples collected after diagnosis, no relation with recurrence was seen (456). Because 25-OH vitamin D levels can be readily increased by supplements, resolution of the relationship between vitamin D and risk of breast cancer should be a high priority.

Selenium

Selenium, an important component of the antioxidant enzyme glutathione peroxidase, inhibits cell proliferation and in animal studies protects against a variety of cancers, although usually at high levels of intake (459). Ecologic studies have shown strong inverse associations between county-specific (in the United States) and national measures of selenium exposure and breast cancer rates (460). Selenium intake cannot be measured accurately by means of dietary assessment in geographically dispersed populations because of the high variability in the selenium content of individual foods, depending on the geographic area in which the foods were grown. However, selenium levels in tissues such as blood and toenails do reflect selenium intake (461) and thus provide an informative measure of diet.

Several studies using these biomarkers of selenium intake have been performed. In most prospective studies (462–464), no association between toenail selenium and risk of breast cancer has been observed. Of the prospective studies, only that of Knekt et al. (465) from Finland showed any evidence of an increased risk among women in the lowest category of selenium. Because Finland at that time had extremely low selenium intakes, this observation is consistent with the possibility that a threshold exists below which low selenium intake does increase breast cancer risk. In a small randomized trial, breast cancer was the only malignancy that occurred more often among those receiving selenium supplements (466). Taken together, these data suggest that increases in selenium intake are unlikely to reduce risk of breast cancer in countries with existing moderate or high levels of selenium intake.

Other Dietary Constituents

Alcohol

Substantial evidence now supports the existence of a positive association between alcohol consumption and breast cancer risk (393). In a pooled analysis of the six largest cohort studies with data on alcohol and dietary factors (467), the risk of breast cancer increased monotonically with increasing intake of alcohol (Fig. 18-13) with no statistical evidence of heterogeneity among studies. For a 10-g/day increase in alcohol, breast cancer risk increased by 9% (95% CI, 4–13%, and in the Million Women's Study a small but statistically significant excess was seen beginning at one drink per day (468). In an update of the Nurses' Health Study with 28 years of follow-up and repeated measures of alcohol consumption, a 15% increase in risk was seen even with 2 to 6 drinks per week (469). Alcohol consumption both before and after age 40 independently contributed to risk. In these analyses, adjustment for known breast cancer risk factors and dietary variables hypothesized to be related to breast cancer had little impact on the association with alcohol. In the collective literature, beer, wine, and liquor all contribute to the positive association (393,467,469-471), strongly suggesting that alcohol *per se* is responsible for the increased risk.

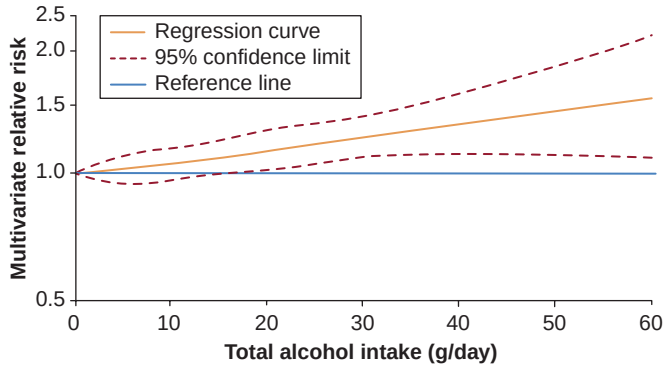

FIGURE 18-13 Nonparametric regression for the relationship between total alcohol intake and breast cancer. One drink of beer, wine, or liquor equals 10 to 15 g of alcohol. (From Smith-Warner SA, Spiegelman D, Yaun S-S, et al. Alcohol and breast cancer in women: a pooled analysis of cohort studies. *JAMA* 1998;279:535–540, with permission.)

Whether reducing alcohol consumption in middle life will decrease risk of breast cancer is an important practical issue. In one early report (472), women who drank before age 30 years and later stopped experienced a similar elevation in risk compared to those who continued to drink. However, in a large study designed to address this issue (473), recent consumption of three or more drinks per day was associated with an RR of 2.2, whereas the RR was 0.9 for consumption of three or more drinks per day from aged 16 to 29 years. This suggests that recent adult drinking may be more important than drinking patterns earlier in life and that reductions in consumption in midlife should reduce risks of breast cancer.

In short-term intervention studies, consumption of approximately two alcoholic drinks per day increased total and bioavailable estrogen levels in premenopausal women (474), and single doses of alcohol acutely increased plasma estradiol levels in postmenopausal women (475), suggesting a mechanism by which alcohol may increase breast cancer risk. In a cross-sectional study, alcohol intake was associated with elevated plasma levels of estrone sulfate, a long-term indicator of estrogen status (419), which in turn has been associated with future risk of breast cancer (124). In several large prospective studies, high intake of folic acid appeared to mitigate the excess risk of breast cancer due to alcohol, although the findings have not been consistent (470,476–479). This relationship was confirmed using plasma folic acid levels (480). Because alcohol inactivates folic acid metabolites and low folate levels are associated with increased misincorporation of uracil into DNA, this finding suggests another possible mechanism for the adverse effects of alcohol.

Of all the associations between dietary factors and breast cancer risk, the relation with alcohol is by far the most consistent. This association has been observed in many diverse

populations, and rigorous attempts to account for this relation by other variables have been unsuccessful. Moreover, the effect of alcohol on endogenous estrogen levels provides a plausible mechanism. Together, this body of data provides strong evidence for a causal relationship between alcohol consumption and breast cancer risk. However, the public health implications of this knowledge are complicated by the fact that consumption of one to two alcoholic beverages per day is almost certainly protective against cardiovascular disease. Because cardiovascular disease is the leading cause of death among women, moderate drinking is associated overall with a modest reduction in total mortality among groups with appreciable risk of coronary heart disease (481). This would not apply to young adults or those with very low levels of risk factors. Although still complex, reduction of daily alcohol consumption appears to be one of relatively few methods for actively reducing breast cancer risk, whereas many methods exist to reduce risk of cardiovascular disease. For women choosing to consume alcohol regularly, use of a multivitamin to assure adequate folic acid intake appears prudent.

Coffee and Tea

Considerable speculation that caffeine may be a risk factor for breast cancer followed a report that women with benign breast disease experienced relief from symptoms after eliminating caffeine from their diet. In prospective studies, no increase in breast cancer risk has been seen with intakes of caffeine or its main sources, coffee or tea (449,482–484), and in one (485) a weak, but significant, inverse association between coffee and caffeine consumption and breast cancer risk was observed. Similarly, no evidence for an association between tea consumption and risk of breast cancer has been seen in epidemiologic studies (486). Thus, the epidemiologic evidence is not compatible with any substantial increase in breast cancer risk associated with drinking coffee or tea.

Phytoestrogens

Phytoestrogens in soy products have attracted scientific and popular attention, in part because they are highly consumed in Asian countries, such as Japan and China, which have low rates of cancer (487). These compounds, which include daidzen and genistein, can bind ERs but are much less potent than estradiol. Thus, these substances may act like tamoxifen by blocking the action of endogenous estrogens to reduce breast cancer risk. Dietary supplementation with a large amount of soy protein slightly lengthened menstrual cycle (488), which would be predicted to decrease breast cancer risk only minimally. Also, soy protein consumption is not the primary explanation for low rates breast cancer in Japan and China because rates are similarly low in other parts of China, elsewhere in Asia, and in many developing countries where soy and related foods are not regularly used. In case-control studies in Singapore (489) and China (490), and in Asian Americans (491), intake of soy products, particularly during adolescence, was associated with lower risk of breast cancer. However, in two other case-control studies in China (492,493) and in a prospective study from Japan (494), little relation was seen. However, in the large prospective Shanghai Women's Study (495), women who consumed a higher amount of soy during adolescence or early adulthood had a lower risk of premenopausal, but not postmenopausal, breast cancer. Thus, the overall evidence suggests that high consumption of soy products during adolescence or young adulthood, when endogenous estrogens are high, may reduce risk of breast cancer, but intakes later in life have little or no effect (495–497).

Another group of compounds formed from glucosinolates found in cruciferous vegetables (such as broccoli, cauliflower, and cabbage) are hypothesized to alter the balance of estrogen metabolism toward less potent forms, but data on humans have not been supportive (498). The possibility that phytochemicals that block the estrogen function or modulate estrogen metabolism may provide a nontoxic means of altering breast cancer risk has obtained some support from studies of soy consumption in Asia. Further data on the effect of amounts and ages when a benefit is possible would be valuable.

Specific Foods

Foods contain an extremely complex mix of essential nutrients and other compounds that could individually or collectively influence breast cancer risk in ways that may not be detected by the study of individual nutrients. Thus, an examination of foods and food groups in relation to risk of breast cancer could be informative. However, because the foods examined in most studies are too numerous to be reported individually, published results are likely to reflect a bias toward reporting findings that are statistically significant or that fit preexisting hypotheses.

Inverse associations between intakes of fruits and vegetables and breast cancer risk have been reported in a many case-control studies (471). These associations have been more consistent for vegetables than for fruits and for green vegetables in particular. However, in the pooled analysis of eight large prospective studies (7,377 cases among 351,825 women), only weak and nonsignificant associations were seen with increasing consumption of fruit and vegetables (498). Comparing highest to lowest quartiles, RRs were 0.93 (95% CI, 0.86–1.00) for total fruits, 0.96 (95% CI, 0.89–1.04) for total vegetables, and 0.93 (95% CI, 0.86–1.00) for total fruits plus vegetables. A thorough search among specific fruits and vegetables and botanical groups did not reveal any significant associations. A similar lack of association was seen in a large multicentered cohort study in Europe (499). In a meta-analysis of prospective studies that included over 16,000 cases of breast cancer, similar weak inverse associations to the earlier pooled analysis were seen, but the associations for total fruits and vegetables were statistically significant (500). For a 200-gram per day increment (about 2 servings per day), the RRs were 0.96 (95 % CI, 0.93–1.00) for total fruits and vegetables and 0.94 (95 % CI, 0.89–1.00) for fruits. Recent findings suggest that a reduction in risk of breast cancer with higher intakes of fruits and vegetables may be specific for estrogen receptor negative tumors (501); the relative risk comparing highest with lowest quintiles of vegetables intake was 0.68 (95% CI, 0.51–0.91) for ER- cancers but no association was seen with ER+ cancers. This specificity has been confirmed in the Black Women's Health Study (502) and the EPIC Study (503), and it is also consistent with the findings noted above for intake and blood levels of carotenoids.

Associations between red meat consumption and risk of breast cancer have been reported sporadically (504). However, in the pooled analysis of large cohort studies (7,379 cases) (505), no association was seen with consumption of red meat, white meat, or dairy products. In an analysis that retrospectively assessed degree of cooking (506), consumption of well-done red meat was associated with breast cancer incidence. This will require evaluation in prospective analyses. In a prospective study among premenopausal women, intake of red meat was associated with a two-fold increase in risk of breast cancers that were positive for estrogen and progesterone receptors (373). Fat *per se* was not associated with breast cancer risk, suggesting that

other constituents of red meat consumed early in adult life may increase breast cancer risk. Approximately half of this cohort also completed a detailed questionnaire about their diet during high school; consumption of red meat during this period was also associated with risk of premenopausal breast cancer (375). This finding is consistent with a greater susceptibility of breast tissue to carcinogens during this period of life but needs replication; unfortunately, few such studies exist.

Although a protective effect of fish consumption has been suggested in a few studies, the overall evidence from case-control and cohort studies suggests little relationship (505). Intake of nuts and legumes has received limited attention in reports on diet and breast cancer, but in general, no relation has been seen (471,486).

Dietary Patterns

Overall dietary patterns have been examined in relation to breast cancer incidence. In the Nurses' Health Study, the Alternative Healthy Eating Index and a Mediterranean dietary pattern were associated with a lower risk of ER- but not ER+ breast cancer (501); this association was mainly due to higher intake of fruits and vegetables. Notably, the Healthy Eating Index, reflecting the 2000 U.S. dietary guidelines, was not associated with risk of either lower risk of either ER+ or ER- breast cancer. Similar findings for a Mediterranean dietary score were seen in the EPIC study (for high compared to low score, the relative risk of ER+/PR- tumors was HR 0.80; 95% CI, 0.65-0.99, p for trend = 0.04) (503).

Diet and Breast Cancer Survival

Regardless of whether diet is related to the occurrence of breast cancer, if postdiagnosis diet were related to risk of recurrence or survival, then dietary modifications might assist in breast cancer treatment. In one study of diet after diagnosis (albeit in the 1 to 5 months immediately after the diagnosis), no association was seen between dietary fat intake and survival (507). Among premenopausal women, higher consumption of butter, margarine, and lard after diagnosis was associated with greater likelihood of reoccurrence (508). In a larger study, diet was assessed before and after breast cancer diagnosis (509). Greater fat intake after diagnosis was associated with a nonsignificantly worse survival outcome. However, higher protein consumption, mainly from poultry, fish, and dairy sources, was related to a better prognosis, even after controlling for protein consumption prior to diagnosis. Although overall dietary patterns after diagnosis were not associated with breast cancer mortality in this cohort, a prudent dietary pattern was associated with lower mortality, and Western pattern with higher mortality, from causes other than breast cancer (510). Similarly, higher intake of trans fat and saturated fat after diagnosis of breast cancer was associated with higher overall mortality, although not breast-cancer-specific mortality (511). This is important because with early diagnosis and good treatment, the large majority of women will survive their breast cancer, but they remain at risk for diseases of women in general.

In a recent pooled analysis, alcohol consumption after diagnosis of breast cancer has overall not been associated with survival (512), although a marginally significant increase in recurrence was seen in postmenopausal women. Also in a pooled analysis, higher soy consumption after diagnosis was associated with a nonsignificantly lower risk of breast-cancer-specific mortality, and a significantly lower risk of breast cancer recurrence (513). Also, regular use of supplements of vitamin E and vitamin C was associated with lower risk of breast cancer recurrence (514).

Several randomized trials have been conducted among women with early-stage breast cancer to determine the effects of dietary change on recurrence or mortality. In one trial, 2,437 women with breast cancer were randomized to a low fat diet or their usual diet and followed for an average of 5 years (515). Dietary fat intake was reduced to 33 grams per day in the intervention group compared to 51 grams per day in the control group, and weight was also six pounds lower in the intervention group. In a preliminary report, 9.8% of women in the intervention group experienced a relapse compared to 12.4% of women in the control group (RR = 0.76; 95% CI, 0.60–0.98, p = .077 for stratified log rank test and p = .034 for adjusted Cox model analysis). These results were suggestive of a possible benefit of the intervention, but not conclusive, and it is not possible to know whether any benefit is due to reduction of fat intake or lower weight gain (potentially due to the intense intervention because the overall evidence does not support a specific benefit of fat reduction on body weight).

In another trial among 3,088 women, one group was assigned to a diet high in fruits, vegetables, and fiber and low in fat (516). During an average of 7.3 years of follow-up, 256 women in the intervention group (16.7%) versus 262 in the comparison group (16.9%) developed an invasive breast cancer event (RR = 0.96; 95% CI, 0.80–1.14; p = .63), and 155 intervention women in the intervention group (10.1%) versus 160 women in the control group (10.3%) died (RR = 0.91; 95% CI, 0.72–1.15; p = .43). The increase in fruit and vegetable consumption was large, and documented by a 50% increase in blood carotenoid level, but the reported difference in fat intake was small (-15%), so this study primarily tested the benefit of increasing fruit and vegetable intake.

Summary of Diet and Breast Cancer

The role of specific dietary factors in breast cancer causation is not completely resolved. Enthusiasm for the hypothesis that dietary fat intake was responsible for the high rates of breast cancer rates in Western countries was based largely on the weakest form of epidemiologic evidence—ecologic correlation studies. Results from prospective studies and randomized trials do not support the concept that fat intake in middle or later life has a major relation to breast cancer risk. Excess energy intake in relation to physical activity during adulthood, which accelerates growth and the onset of menstruation during childhood, leads to weight gain in middle life and thus can contribute substantially to breast cancer risk. These effects of energy balance clearly account for an important part of international differences in breast cancer rates. Some evidence suggests that carotenoids or other compounds in carotenoid-rich foods may reduce breast cancer risk modestly, but these findings are not conclusive and deserve further consideration. Alcohol intake, even at very low levels, is a well-established risk factor for breast cancer, and studies demonstrating that even moderate alcohol intake increases endogenous estrogen levels provide a potential mechanism, thus supporting a causal interpretation. Diet during childhood has been relatively unstudied, but recent evidence suggests that higher intake of soy products and lower intake of red meat during this period may reduce risk of breast cancer. Other recent findings suggest that characterization of breast cancers by hormone receptor status, and potentially other features, may be important in studies of diet. A Mediterranean dietary pattern, higher intakes of vegetables and fruits, and lower intake of carbohydrates and glycemic load appear to be related specifically

to risk of ER- breast cancer. Because of the importance of ER- breast cancer and limited progress in the identification of preventive strategies, these findings are promising and need to be pursued further.

Although our understanding of diet and breast cancer is incomplete, evidence can be considered conclusive that breast cancer risk can be reduced by avoiding weight gain during adult years and by limiting alcohol consumption. Although less conclusive, some evidence suggests that breast cancer risk can be modestly reduced by limiting intake of red meat during early adult life, by replacing saturated fat with monounsaturated fat, and by consuming more fruits, vegetables, and whole grains (which characterizes the Mediterranean dietary pattern). Even with some uncertainty regarding their relationships with breast cancer, these dietary behaviors can be strongly recommended because they will substantially reduce risks of coronary heart disease (354) and diabetes (517).

PHYSICAL ACTIVITY

Regular physical activity has been hypothesized to prevent breast cancer and in 2002 the International Agency on Cancer Research concluded that there was "convincing" evidence that physical activity reduces the risk of breast cancer (518). A number of potential mechanisms have been proposed including changes in menstrual cycle characteristics, lowering sex hormones and insulin-like growth factors, and/or improving immune function (519,520). A recent review of potential mechanisms concluded that BMI and estrogens were the most likely links between physical activity and breast cancer risk (521). The mechanisms by which physical activity reduces exposure to hormones vary by period of life. Young girls participating in strenuous athletic training such as running and ballet dancing have delayed menarche (522–524), which is known to reduce risk of breast cancer, and even moderate-intensity physical activity may delay menstruation (398). This effect of activity at young ages may be reflected in lower body weight and body fat, both of which are determinants of delayed menstruation (399,522). A later menarche is associated with a later onset of regular ovulatory cycles and lower serum estrogen concentrations during adolescence (525). Once menstruation has been established, anovulatory and irregular menstrual cycles may be more common among moderately and strenuously active women than among inactive women (396,524,526), although there is disagreement regarding the degree to which the intensity of physical activity influences menstrual abnormalities (527). Further, a substantial degree of ovarian dysfunction may occur even among physically active women who appear to have normal menstrual cycles (528). Among older women, levels of past and current physical activity influence fat stores (522,523,528–531), which after the menopause are primary sites of conversion of androstenedione to estrogen (532,533).

A number of epidemiologic studies have reported an inverse association between physical activity and postmenopausal breast cancer, although the evidence is less consistent for premenopausal breast cancer (519,520,534–537). However, there are a number of aspects regarding this association that remain unclear. Methodologic differences in physical activity assessment are likely to have contributed to inconsistencies in study results. Studies have differed in the ages at which physical activity was assessed, methods for measuring intensity, frequency, and duration of physical activity, definition and categorization of physical activity levels (including consideration of only recreational, or recreational and occupational, activity), and age at breast cancer diagnosis. However, results have varied even among studies that have tried to assess physical activity at similar times in life using similar tools.

One of the strongest reductions in breast cancer risk associated with increased physical activity was reported in a population-based case-control study of women younger than 40 years (538). The RR was 0.42 (95% CI, 0.27–0.64) comparing women with a lifetime average of 3.8 hours or more of physical activity per week to those with an average of 0 hours per week. This was the first study explicitly devoted to the relationship between physical activity and breast cancer, and it was also the first to use a detailed physical activity assessment instrument to quantify the average number of hours per week of recreational physical activity over the reproductive life span, beginning at menarche. Activities such as housework, gardening, and easy walking not for the explicit purpose of physical exercise were not counted in the measure of physical activity. These researchers concluded from their various analyses that lifelong physical activity is the critical exposure of interest with regard to breast cancer risk.

Since publication of this study, many other studies (537,539–554) have assessed the relationship between lifetime physical activity and breast cancer risk. In one of these studies (547), results support those reported above, with reduced risk of breast cancer in premenopausal women with higher lifetime physical activity. The RR for average lifetime total activity was 0.77 (95% CI, 0.64–0.93) comparing the equivalent of 3.25 hours or more of running/jogging per week to those with less activity. In contrast, another study found no association between activity in earlier periods of life and postmenopausal breast cancer (548).

Types of activity are widely varied across individuals, as well as across studies. Broad categories of recreational, household, and/or occupational activity have been assessed in many studies. In one study among postmenopausal women, recreational physical activity was not associated with breast cancer risk, whereas household and occupational physical activity was inversely associated with risk (odds ratio [OR] = 0.57, 95% CI, 0.41–0.79; and OR = 0.59, 95% CI, 0.44–0.81), comparing highest to lowest quartiles of household and occupational activity, respectively. The findings of inverse associations with household and occupational physical activity, but not with recreational activity, suggest that residual confounding by sociodemographic and reproductive factors are at least partly responsible for the observed inverse relationships. Among types of recreational activities, some studies have observed stronger associations for more moderate or vigorous activities, compared with less intense activities (555). However, even brisk walking appears to be beneficial, as was reported in one study (556).

A case-control study conducted among premenopausal and postmenopausal women in urban Shanghai (544) found significant inverse dose–response relationships between years of (recreational) exercise participation and breast cancer risk, as well as between lifetime occupational activity and breast cancer risk. In contrast, a case-control study nested within the Women's Health Study (543), which also assessed lifetime physical activity (recreational only), found no association between physical activity (lifetime or at any specific time in life) and breast cancer risk.

It has been hypothesized that high levels of physical activity during adolescence are particularly important with respect to influencing breast cancer risk. A retrospective cohort study of college alumnae (557) found that women who had been former college athletes had a 40% lower risk

of breast cancer later in life than their nonathletic peers (OR = 0.61, 95% CI, 0.44–0.84). However, other studies that have examined the association between physical activity during adolescence and breast cancer risk have found little evidence for a protective effect. Indeed, some studies have observed stronger associations with more recent, or later in life, physical activity.

In contrast to the detailed measurement of lifetime physical activity employed by some of the studies mentioned earlier, a relatively simple measure of physical activity was used in a prospective cohort study of Norwegian women aged 20 to 54 years at baseline (558). Over a period of 3 to 5 years, women were administered two surveys about their current patterns of physical activity during leisure hours; they were asked to rank themselves on a four-point scale with respect to activity level. The RR was 0.63 (95% CI, 0.42–0.95) for consistently active women compared to consistently sedentary women, which is one of the strongest RRs reported in the literature.

Several recent studies have examined physical activity by tumor type and survival. The association with invasive breast cancer appears consistent across several studies, while an association with in situ disease has been observed in some studies but not others (559,560). Although a few studies have observed differences in the association by hormone receptor status, the differences are not consistent, with some studies finding stronger associations with ER+ disease and others finding stronger associations with ER- disease (550,559,561). However, there are several studies that have investigated ER and/or ER/PR status and have found the reduced risk with physical activity to be apparent with both hormone receptor positive and negative tumors (547,548,556,562,563). A large pooled analysis of physical activity after breast cancer diagnosis reported reduced breast cancer mortality with at least 2.5 hours of moderate intensity physical activity per week, compared to those with lower activity (RR = 0.75; 95% CI, 0.65–0.85) (564). Risk of recurrence, however, was not reduced among those more physically active.

There would be obvious public health significance to an association between a modifiable lifestyle risk factor such as physical activity and breast cancer. There are already more than 70 observational epidemiologic studies of this issue, a number of them published in the last five years (547–550,552,556,559–561,563,565–573). Despite the wealth of data on the subject, it is difficult to come to a clear conclusion on the topic given numerous methodologic issues. These issues include the resolution of whether a critical lifetime period exists during which increased physical activity exerts its strongest effect on breast cancer risk, or whether lifetime physical activity is the critical exposure of interest for most women. It is also unclear if the effects of physical activity on breast cancer differ in particular subgroups of women. For example, studies have suggested the association is modified by family history of breast cancer (539,540,545,561), menopausal status (535,570), menopausal hormone therapy (561), or BMI (545,561,570,574). A second important issue relates to the quantification of physical activity and how information on frequency, intensity, duration, and time span of activity can and should be combined into a single measure or a small number of measures that can be readily modeled. A third issue pertains to the validity of women's reports of past physical activity. In case-control studies, random error in recall of past activity levels that is not dependent on disease status would be expected, on average, to dilute any inverse association that might truly exist. If errors are differential by disease status, however, findings may be biased in either direction away from their true point estimates. A fourth issue concerns the need to consider recreational, occupational, and household physical activity together. In studies of physical activity, the potential exists for confounding by reproductive characteristics for several reasons. Women in physically active jobs are more likely to be of lower socioeconomic status and thus may be more likely to have a lower risk reproductive profile. Women with higher levels of household activity may be more likely to be homemakers with children, and thus, again, to have a lower risk reproductive profile. Women with higher levels of recreational physical activity may be more likely to have lower levels of occupational and household activity; they may be more likely to be of higher socioeconomic status than women with lower levels of recreational activity and thus to have a higher risk reproductive profile. It is difficult in observational studies to control thoroughly for such potential confounding. Finally, although a hormonal mechanism linking physical activity and breast cancer risk has been postulated, there are few data relating physical activity over sustained periods to lower endogenous ovarian hormone levels. Available studies have been very short term, based on small numbers of women, and often limited to comparisons between young women who engage in high levels of activity and inactive young women.

Although numerous studies have examined the association between physical activity and risk of breast cancer, a number of issues remain unsettled. While the association appears somewhat weaker in cohort compared with case-control studies, taken together, the weight of the evidence suggests that regular physical activity modestly protects against breast cancer (518), and this is most evident for postmenopausal breast cancer. Evidence relating higher physical activity to risk of postmenopausal breast cancer is strong because of the important role of activity in controlling weight gain, an important cause of postmenopausal breast cancer. This, in addition to many other benefits of staying lean and fit, provides sufficient justification for including regular physical activity in daily life.

IONIZING RADIATION

More is probably known about radiation-induced breast cancer than about any other radiation-induced malignancy, with the possible exception of radiation-induced leukemia. The knowledge that ionizing radiation to the chest in cumulative moderate to high doses (e.g., 1 to 3 Gy) at young ages substantially increases breast cancer risk comes from several lines of evidence, including atomic bomb survivor studies, studies of diagnostic/therapeutic uses of radiation, and occupational studies.

Among survivors of the atomic bombing of Hiroshima and Nagasaki (575), breast cancer risk was strongly associated with estimated breast tissue dose of radiation. Further, the RR of breast cancer associated with each radiation dose depended heavily on the age at the time of the bombing, being highest for women exposed before age 10 years. For women exposed after age 40 years, there was no significant elevation in subsequent breast cancer risk.

Studies of diagnostic radiation have revealed a similar pattern of excess risk of breast cancer associated both with higher doses and with younger ages at exposure. In a study of women who received substantial radiation to the chest as a result of repeated fluoroscopic examinations for tuberculosis (576), the maximum excess risk was among women with first exposure between the ages of 10 and 14 years, whereas women first exposed at age 35 years or later had virtually no excess risk. Girls examined frequently for scoliosis with full

spinal x-rays also faced an increased risk of breast cancer later in life (577).

Studies of therapeutic radiation for nonmalignant and malignant disease have revealed the same pattern. In a study of women exposed to radiation therapy to the chest as treatment for Hodgkin's disease (578), the excess risk of breast cancer again was dependent on dose and age at irradiation. In a study of radiation treatment of breast cancer and development of second breast cancers (579), risk of second cases was significantly elevated (above its already high level) among women who underwent radiation at younger than 45 years. Women who are heterozygous for the ATM gene are hypothesized to be at increased risk of breast cancer and at increased risk of radiation-induced breast cancer (580). One report (581), however, found no ATM mutations in women with contralateral breast cancer and failed to support the hypothesis that ATM carriers account for a significant fraction of breast cancer cases that arose in women after radiation therapy. Studies of women who have developed subsequent breast cancer after radiation therapy for Hodgkin's disease also reported no association with ATM heterozygosity (582).

Studies of radionuclide therapy have shown that women treated with such regimens have an increased risk of breast cancer later in life. A German study of young persons injected with radium-224 for bone diseases in 1945 to 1955 showed subsequent high rates of bone cancer, and there was an increased risk of breast cancer observed in both women and men in the cohort (583).

Occupational studies provide a final set of evidence about radiation-induced breast cancer. Increased breast cancer incidence was observed among some groups of women who in the early part of the twentieth century painted watch dials and gauges with radium-226 (584); such increased risk has also been observed among women in China who pioneered in the fields of radiology and medical x-ray work (585). Some of this excess may have been due to higher breast cancer risk profiles of the women in such occupations, that is, a higher proportion of them tended to be nulliparous in comparison to the general population of women. The slightly increased risk of breast cancer observed among women who worked during World War II as x-ray technologists might have been due to nulliparity; there were a disproportionate number of Catholic nuns in these cohorts (586). Studies of women employed in subsequent times as x-ray technologists have not found this increased risk of breast cancer (587,588).

The risk associated with infrequent low-dose radiation exposure to the chest has been difficult to quantify, because the expected excess of breast cancers is small relative to the background risk (576). Thus, the risk of breast cancer associated with low-dose radiation, such as mammography, has been estimated by extrapolating the dose–response relationship from studies of women exposed to higher doses of radiation (589). In this way, <1% of all cases of breast cancer have been estimated to result from diagnostic radiography (589).

Genetic variation in DNA repair genes may modify the risk of breast cancer associated with low to moderate exposures of ionizing radiation (590). Initial studies among women with *BRCA1* and *BRCA2* mutations genes involved in the repair of double-strand breaks have reported inconsistent finding on the effect of exposure to mammography and chest x-rays on breast cancer risk among mutation carriers (591–593).

Additional studies of genetic variation and low-dose exposure to radiation may yield useful information about which women face an identifiably higher risk of radiation-induced breast cancer from mammographic surveillance.

ENVIRONMENTAL POLLUTION

Evidence of geographic variation in incidence and mortality rates of breast cancer within the United States, the steady increase in incidence over time, and the identification of suspected breast cancer clusters have stimulated interest in the possibility that industrial chemicals or electromagnetic fields may be environmental risk factors for breast cancer. The experimental and epidemiologic evidence for associations of certain specific synthetic chemicals with breast cancer are considered in the following sections and have been comprehensively reviewed with detailed citations elsewhere (594–597).

Organochlorines

Epidemiologic studies of breast cancer and environmental exposures to synthetic chemicals have concentrated on biologically persistent organochlorines. This class of compounds includes pesticides, such as 2,2-bis(*p*-chlorophenyl)-1,1,1-trichloromethane (DDT), chlordane, hexachlorocyclohexane (HCH, lindane), hexachlorobenzene (HCB), kepone, and mirex; industrial chemicals, such as polychlorinated biphenyls (PCBs) and polybrominated biphenyls (PBBs); and dioxins (polychlorinated dibenzofurans [PCDFs] and polychlorinated dibenzodioxin [PCDDs]), produced as combustion byproducts of PCBs or contaminants of pesticides. Many of these chemicals are weak estrogens and are, therefore, hypothesized to increase breast cancer risk by mimicking endogenous estradiol. Furthermore, they are excreted in breast milk, suggesting that ductal and other cells in the breast are directly exposed. Other compounds, specifically the dioxins and some PCB congeners, exhibit antiestrogenic activity; therefore, despite the established carcinogenicity of dioxin at other anatomic sites in animal tests, they might be protective against breast cancer.

The organochlorines are highly lipophilic and resistant to metabolism. Thus, many of these compounds bioaccumulate in the food chain and persist in the body. These chemicals can be measured in breast milk, adipose tissue, and blood. Most of the epidemiologic literature on organochlorines focuses on DDT, DDE (1,1-dichloro-2,2,-bis (*p*-dichlorophenyl)ethylene, the main metabolite of DDT), and PCBs because they are among the most persistent in humans. The general population was thought to be exposed to these compounds predominantly through ingestion of fish, dairy products, and meat. Almost everyone in the United States has had some measurable exposure; however, the average body burden of some of these chemicals (e.g., DDT) has been decreasing with time since the cessation of their production in this country (1972 for DDT and 1977 for PCBs).

In a study of PCB-contaminated fatty fish from the Baltic Sea, breast cancer rates among fishermen's wives from the contaminated east coast were higher than rates among fishermen's wives from the noncontaminated west coast (RR = 1.35; 95% CI, 0.98–1.86) (598). However, there was no control for other known breast cancer risk factors. In a study of consumption of sports fish in the U.S. Great Lakes region (sports fish in this region have been shown to be a source of exposure to PCBs and organochorine residues), no association was observed across all women studied (n = 1,481 cases), however, a positive association was observed among premenopausal women (n = 386, RR = 1.70; 95% CI, 1.16–2.50) (599). An accidental explosion in 1976 in a chemical plant near Seveso, Italy, provided the opportunity to evaluate exposure to high levels of dioxin. Breast cancer incidence during the decade after the accident in the areas closest to the accident was slightly but not significantly lower than expected (600).

The results of small case-control studies of organochlorine levels and breast cancer risk have been inconsistent. In a large European case-control study (265 cases), a significantly inverse trend between levels of adipose DDE and risk of breast cancer was observed after controlling for known breast cancer risk factors; the authors did not evaluate PCBs (601). In a case-control study in Buffalo, New York, lipid-adjusted serum levels of DDE, HCB, mirex, and total PCBs were evaluated among 154 incident breast cancer cases and 192 community controls. There was no evidence of a positive association between any of these compounds and breast cancer risk with the possible exception of less chlorinated PCBs (602). Lopez-Carrillo et al. (603) analyzed serum DDE levels in a case-control study in Mexico, where the pesticide is still in use. Serum DDE levels were not associated with risk of breast cancer. However, in one small study, contrary to expectation, the levels of octachlorinated dibenzo-*p*-dioxin (OCDD) were slightly elevated in the cases (604), although no differences were observed for six other polychlorinated dibenzo-*p*-dioxin isomers. In a large case-control study conducted on Long Island, New York, no association with breast cancer risk was seen for blood levels of DDE, chlordane, dieldrin, or common PCB congeners (605). African American women have been shown in some studies to have higher levels of exposure to these chemicals; however, in a case-control study of 355 breast cancer cases, no elevation in risk was seen for those with the highest serum levels of a PCBs or organochlorine pesticide residues (606).

Several prospective studies have used stored blood samples collected prior to diagnosis to evaluate the relationship between DDE and total PCBs with breast cancer (607–609). In a cohort in New York City of 14,290 women, a strong association between serum DDE levels and risk of breast cancer was initially reported (609), but no relation was seen with longer follow-up (610). No association with PCB levels was observed in this cohort. In a prospective study of 57,040 San Francisco Bay area women who had provided blood in the late 1960s, when DDT and PCBs were still in production (608), 50 white, 50 African American, and 50 Asian breast cancer cases occurring after blood draw and prior to 1991 were selected and compared with 150 age- and ethnicity-matched control women. Risk of breast cancer was not associated with either DDE or PCB level when all ethnic groups were combined, although nonsignificant elevated risks were observed for DDE for African Americans and whites. Among 236 breast cancer cases and their matched controls in the Nurses' Health Study, there was no evidence of a positive association of breast cancer with either DDE or PCBs (607). The multivariate RRs for women in the highest quintile compared to women in the lowest were 0.72 (95% CI, 0.4–1.4) for DDE and 0.66 (95% CI, 0.32–1.37) for PCBs. For women in the highest quintiles of both DDE and PCBs, the RR was 0.43 (95% CI, 0.13–1.44) for joint exposure. In further follow-up in this cohort, adding an additional 143 postmenopausal cases, results were similar (611). A pooled study reanalyzing data from the five large studies in the Northeast has also found no association between PCBs and DDE levels and breast cancer risk when comparing the highest and lowest quintiles (595). In a large nested case-control study from Denmark, concentrations of 14 pesticides and 18 PCBs measured in adipose tissue samples collected at baseline, no association was seen for any of these chemicals with breast cancer risk among 409 postmenopausal cases; a lower risk of estrogen-receptor negative cancer was seen in the highest category of exposure for several of the PCBs and organochlorines (612). However, in a recent nested case-control study of 129 cases who were diagnosed an average of 17 years after they had blood drawn shortly after childbirth at an average age of 26 years, a positive association was observed for serum DDT levels and early life breast cancer risk (613).

In summary, recent large studies have not found evidence of increased breast cancer risk among postmenopausal women associated with blood levels of DDE or total PCBs; however, a small effect will always be difficult to exclude, as will hypotheses relating to specific subgroups such as premenopausal women. All available studies address exposure to organochlorines in the decade or two prior to enrollment; it will be very difficult to obtain data to address the hypothesis that childhood or even *in utero* exposure is associated with breast cancer risk 50 or more years afterward. Nonetheless, organochlorines appear unlikely to be an important breast cancer risk factors or an explanation for secular changes in breast cancer rates.

Electromagnetic Fields

Electromagnetic fields (EMFs) have been proposed to alter breast cancer risk, perhaps by altering melatonin secretion by the pineal gland. Although animal evidence is suggestive, few data address the relation of melatonin levels to human breast cancer risk. Exposure to light at night suppresses melatonin secretion, and in some studies, breast cancer risk has been lower among blind women (614,615). Gathering high-quality epidemiologic data on EMF and nocturnal light exposure is challenging, and these hypotheses are unlikely to be resolved definitively anytime soon. Evidence of an elevated risk of male breast cancer associated with presumed occupational EMF exposure based on job title has been observed in some studies, but these results are based on small numbers of cases. No evidence of an increased risk of breast cancer was observed in the studies that also included female employees. In case-control studies designed specifically to study occupational exposure to EMF and breast cancer in women, small increases in risk have been inconsistently observed. However, in those studies misclassification of exposure is a major concern. Because classifications are based on subjects' "usual" occupation, often obtained from death certificates, duration of exposure and personal work tasks could not be accounted for in most of the studies and adjustment for known breast cancer risk factors was limited or entirely absent.

The general population is exposed to EMF primarily from power lines, transformer substations, and electrical appliance use. In an initial 1987 study of mortality from all cancer subtypes and residential wiring configurations, a statistically significant elevation in female breast cancer incidence was associated with magnitude of exposure at the current residence (616). However, other studies in Britain, the Netherlands, and Taiwan did not observe an association between female breast cancer deaths and residence in the vicinity of electricity transmission facilities. Again, these studies are limited by the indirect methods used to assess EMF exposure.

Use of electric blankets (produced before 1990) throughout the night approximately doubles an individual's average exposure to EMFs, because the blanket is placed close to the body. In one case–control study, the use of electric blankets continuously throughout the night was associated with marginally significant increases for postmenopausal breast cancer (OR = 1.46; 95% CI, 0.96–2.20) (617) and for premenopausal breast cancer (OR = 1.43; 95% CI, 0.94–2.17) (618). However, in a recent large case-control study of breast cancer in women younger than 55 years, no association was seen (619), and no association was seen in retrospective or prospective analyses within the large Nurses' Health Study cohort (620), or in the large Long Island case-control study based on 1,354 cases (621).

In 2001, IARC conducted a formal review of the available evidence and concluded that the evidence at that time was inadequate to assess the effects of magnetic fields and breast cancer. Since that report, five additional studies of occupational exposure and four of residential exposure have been conducted (622). At present the biological plausibility and most recent epidemiologic studies do not support an important relation between EMF exposure and breast cancer risk (622).

Active and Passive Smoking

The relation between active cigarette smoking and risk of breast cancer has been extensively evaluated in both case-control and cohort studies; collectively, the data provide strong evidence against any major overall relationship. It has been hypothesized that initiation of smoking early in adolescence, when breast tissue may be maximally sensitive to carcinogenic influences, may increase risk of breast cancer, although study results have been inconsistent (596,623,624). Among large, prospective cohort studies, there is suggestive evidence of a positive association with long-term smoking prior to the first birth (625–629). In the Norwegian-Swedish Women's Lifestyle and Health Cohort Study of over 100,000 participants, women who initiated smoking during their teenage years and continued to smoke for 20+ years were at an increased risk of breast cancer (comparing women who initiated smoking before age 15 to never smokers RR = 1.48; 95% CI, 1.03–2.13) (626). This increased risk of breast cancer was not observed among women who smoked for 20+ years, but started smoking after their first birth. These results are consistent with the hypothesis that breast tissue is particularly susceptible to carcinogens between early puberty and the first full-term pregnancy (66).

Passive smoking has been suggested to be an important risk for breast cancer in part because sidestream smoke contains more carcinogenic activity per milligram than mainstream smoke. In several case-control studies, increases in risk of breast cancer have been seen, but usually without evidence of a dose response. Despite these positive associations, it is difficult to reconcile the absence of an effect of heavy smoking for decades with an effect of exposure to much lower amounts of environmental smoke. A likely explanation for the positive association seen in case-control studies is methodologic bias related to the selection of controls or the retrospective recall of exposure to passive smoke. In the Nurses' Health Study, passive smoking in childhood or adulthood was not associated with breast cancer risk (628). In general, results from the Women's Health Initiative Observational Study are consistent with no association with passive smoking, although they did report that women that were exposed to extensive long-term exposure to passive smoking (e.g., ≥10 years during childhood and ≥20 years adult at home and ≥10 years adult at work) were the only group at an increased risk (629).

Silicone Breast Implants

Most studies examining the relation of silicone breast implants with breast cancer risk have actually reported lower rates of breast cancer among women with implants (630–635); thus, a direct association between silicone breast implants and the occurrence of breast cancer is unlikely.

Early anecdotal reports (636–639) of breast cancer among women whose breasts had been augmented with silicone raised concerns about a causal link with the disease. Since then, a number of observational studies, both case control and cohort, have been conducted. Most of these studies have found *reduced* breast cancer risk among women with implants compared to either the general population or women without implants. Reported reductions in risk in some of these studies have been large (on the order of 50% or 60%). A large retrospective cohort study (640) 10,778 women who had breast implants before 1989 and 3,214 comparison women who had had plastic surgery not involving silicone during the same time responded to a medical questionnaire. In analyses based on external and internal comparisons, the women who had had breast implants were not at elevated risk of breast cancer. The overall SIR comparing breast cancer incidence among the breast implant cohort to the Atlanta SEER incidence rates was 0.89 (95% CI, 0.8–1.1). The RR of breast cancer comparing the implant cohort to the comparison group of other patients who had undergone plastic surgery was 0.79 (95% CI, 0.6–1.1). There was no statistically significant heterogeneity in risk according to age or calendar year in which implants were received (in part, this calendar-year variable was a surrogate for the type of implant), and there was no variation in risk of breast cancer by preimplantation chest or cup size. There was indication of a slight decrease in risk of breast cancer in both the external and the internal comparisons during the initial 10-year period following breast implantation. This likely reflects a preimplantation screening/selection bias. The authors note that characteristics of patients who had breast implants could predispose to the discovery of a lower risk of breast cancer among such women; these characteristics include small breasts and thinness. In a follow-up of 2,763 women who underwent cosmetic breast implant surgery in Denmark on average about 15 years previously, breast cancer incidence was nonsignificantly reduced compared to a series of 1,736 who had other forms of plastic surgery (635). In a large series of 24,588 women who underwent bilateral augmentation mammoplasty in Quebec or Ontario, breast cancer rates were actually significantly lower after a median of about 15 years, than among women who had other forms of plastic surgery (632). In both these studies, results were similar when restricted to women who received silicone implants.

In summary, there is strong epidemiologic evidence that breast implants do not lead to increased risk of breast cancer (641). Further, findings of significantly decreased risks in some studies probably reflect a combination of short duration of follow-up after implantation (i.e., bias due to preimplantation screening and selection for women who do not have breast abnormalities) and favorable breast cancer risk profiles of women who tend to seek breast augmentation.

Summary of Evidence on Environmental Pollution and Breast Cancer Risk

In general, current evidence does not support any substantial relationship between exposure to human made chemicals or electrical fields in the environment and breast cancer risk. The best recent evidence in prospective analyses does not support an association between exposure to organochlorines and breast cancer risk. Although occupational studies of EMF exposure have been inconclusive, residential studies imply that there is no risk associated with overhead power lines. Overall increases in breast cancer incidence due to active or passive smoking are not supported by prospective data, but modest increases due to smoking at early ages cannot be excluded.

Although other environmental exposures that have not been identified may warrant evaluation, with the exception of ionizing radiation, no environmental exposure can be confidently labeled as a cause of breast cancer based on current evidence.

OCCUPATION

A review of 115 studies published between 1971 and 1994 (642) found little support for an association between specific occupations and breast cancer risk. Limited evidence suggested that cosmetologists, beauticians, and pharmaceutical manufacturing workers had a modestly elevated risk of breast cancer, but conclusions were not possible because of lack of adequate exposure data. Although ionizing radiation is a recognized risk factor for breast cancer and studies conducted in the early part of the century confirmed this, none of the more recent studies of radiation workers, including x-ray technicians, workers at uranium fuel plants, and atomic energy plants found an elevation of breast cancer risk among women in these occupations. The few studies carried out on specific occupational agents have not provided any evidence of association. In particular, although organic solvents may increase risk of various cancers in animals, women who worked in dry cleaning, shoe manufacturing, or who were exposed to trichloroethylene did not have an elevated risk of breast cancer (642).

Despite the large literature on occupation as a risk factor, most studies have simply examined associations between occupational title and breast cancer risk; specific information on exposure to potential carcinogens was collected in only a few studies. Although some studies collected detailed information on lifetime occupational history, often broad occupational groupings representing only the most recent occupation were used in analyses. Further, most studies have not controlled adequately for known breast cancer risk factors, in particular, reproductive factors, that are likely confounders of any observed association with occupation (643). Employment outside the home, and in a specific occupation, is likely to be highly correlated with educational attainment and socioeconomic status, and thus with reproductive characteristics. In the few studies that have controlled for sociodemographic and reproductive risk, breast cancer risk did not vary across occupational groups. In contrast, a consistent finding across studies that were unable to control for important confounders has been an increased breast cancer risk among more highly educated women, rather than a consistently observed association for any specific occupation. Thus, further analyses of occupational titles without consideration of known breast cancer risk factors or actual workplace exposures are unlikely to be informative.

PERSONAL FACTORS AND MEDICAL CONDITIONS

Mammographic density and benign breast diseases are two factors that have been studied as intermediate markers of breast cancer risk. In general, they are believed to be generalized markers of increased risk of breast cancer. In addition, a variety of diseases and medications are known or suspected to cause or to be associated with modifications of hormones and/or growth factors and thus may influence breast cancer risk (644).

Mammographic Density

Percent mammographic density (PMD) is one of the strongest risk factors for breast cancer and is predictive of breast cancer risk for at least 10 years in the future. Women with the highest mammographic density are at a four- to six-fold greater risk of breast cancer than women with the lowest density (645–647). Because of this strong association, mammographic density has been suggested as a surrogate marker of breast cancer risk (648) that may be used as an endpoint in intervention trials (648–652). The radiographic appearance of the breast on a mammogram varies depending on the composition of the breast. Fat is radiolucent and appears dark. In contrast, epithelial cells and connective tissue are radiodense; they appear light on a mammogram and are considered to be "mammographically dense." Thus, both epithelial and stromal cells are responsible for the appearance of dense tissue on a mammogram (653). The biologic mechanism underlying the strong association with breast cancer risk is unclear; however, it has been hypothesized that it may represent a cumulative exposure to estrogens, mitogens, and/or mutagens (654), or the number of breast cells at risk (655).

The PMD measure used in the clinic today is the breast-imaging reporting and data system (BI-RADS) density measure proposed by the American College of Radiology, which is visually assessed by the radiologist (656). However, the motivation for assessing BI-RADS is to alert radiologists because sensitivity of mammography is lower in women with dense breasts; the intention was not for risk assessment. Extensive data support the association between BI-RADS classifications and Wolfe's parenchymal patterns, another mammographic density measure, and breast cancer risk (645,657–662). The standard measurement of PMD in the research setting is based on an operator-assisted thresholding method that provides a more reliable quantitative assessment of percent mammographic density; these methods have also found a remarkably consistent positive association between PMD and breast cancer risk (645,663). While both qualitative and quantitative assessments of mammographic density predict breast cancer risk, they are subject to reader differences and measurement error, which will bias study results toward the null (664). Future work to develop reliable, automated measures of breast density is needed.

Benign Breast Disease

Benign breast disease (BBD) is a heterogeneous group of component histologic subtypes. Considered as a single entity, benign breast disease has been associated with breast cancer in most (665–668), but not all studies (669,670). As early as 1945, certain lesions have been implicated in conferring a greater increased risk of breast cancer more than others (671). Foote and Stewart (671) reported atypical epithelial hyperplasia and duct papillomatosis of atypical structure to be more common in breasts with cancer than in normal breasts. Subsequent retrospective investigations, with systematic review and reclassification of histopathology slides, have confirmed an association between proliferative lesions, especially those with atypia, and breast cancer (672–679), but not all have supported such a relation (680-682). In prospective studies, where investigators have examined the risk associated with histologic subtypes of benign breast disease, the proliferative—and, in particular, atypical—lesions were associated with the highest risk (683–685).

In a large follow-up study, Page and collaborators systematically reviewed and reclassified 10,366 consecutive breast biopsies from three Nashville hospitals. They reported results of 17 years median follow-up on 3,303 patients from this group in two initial publications (683,686). All proliferative lesions were associated with an increased risk of subsequent breast cancer (RR = 1.9), while those with nonproliferative lesions were not at increased risk (RR = 0.9). In this study, proliferative lesions were found in approximately 27% of biopsies. Page et al. found the proliferative lesions of highest risk to be atypical lobular hyperplasia (RR = 4.5) and atypical ductal hyperplasia (RR = 4.1). They defined these lesions as having some, but not all, features of carcinoma

in situ, which is associated with an 11- to 12-fold increase in invasive breast cancer risk.

Data from the Nurses' Health Study are consistent with study from Dupont and Page; they reported an intermediate risk among women with previous proliferative disease without atypia (RR = 1.5; 95% CI, 1.2–2.0) and the highest risk of breast cancer among women with atypical hyperplasia (RR = 4.1; 95% CI, 2.9–5.8). In this study, proliferative lesions accounted for approximately 57% of all benign breast diseases. However, the magnitude of the breast cancer risk differed according to histologic type of atypical hyperplasia (AH). The OR for the subsequent development of breast cancer was higher among women with atypical lobular hyperplasia (ALH) (OR 5.5, 95% CI, 3.3–9.2) than for those with atypical ductal hyperplasia (ADH) (OR = 3.1; 95% CI, 2.0–4.8). Overall, 58.9% of invasive breast cancers that developed in women with AH were in the ipsilateral breast. While the risk of ipsilateral breast cancer was somewhat higher among women with ALH than those with ADH (61.3% vs. 55.9%), this difference was not statistically significant (p = .66) (687).

The biologic meaning of atypical lobular and atypical ductal lesions is controversial, primarily because their natural history is unclear (688). A central issue is whether these atypical lesions are markers of general breast cancer risk, precursor lesions, or perhaps both. Most studies that have examined the laterality of benign and subsequent malignant lesions have found that only about half of the invasive breast cancers are in the same breast in which the atypical hyperplasia was previously diagnosed, suggesting that these lesions are markers of generalized risk (689). However, data are limited on laterality with regard to the type of atypical lesion. Although data are limited, two independent studies report that atypical lobular and ductal hyperplasias may also be different, in that atypical lobular hyperplasia may in fact increase the risk of breast cancer in the same breast as the benign lesion (687,690).

Diabetes

Type 2 diabetes has been suggested to increase risk of breast cancer. Hyperinsulinemia, as occurs in adult-onset diabetes, may promote breast cancer because insulin may be a growth factor for human breast cancer cells (691). Further, insulin levels are inversely related to levels of SHBG, and thus are positively related to available estrogens and androgens (644). Many studies have lacked information about the type and severity of diabetes, making the interpretation of the various findings difficult (644). A meta-analysis of 39 independent studies reported that women with diabetes had a 27% (95% CI, 1.16–1.39) increased risk of breast cancer that was limited to postmenopausal women (692). When limited to studies that adjusted for BMI, the risk estimate was attenuated (RR = 1.16; 95% CI, 1.08–1.24). Recently, there has been interest in the potential protective effects of metformin, an insulin-lowering agent used to treat diabetes, on cancer risk (693). A meta-analysis of seven studies reported a 17% reduced risk of breast cancer comparing diabetics treated with metformin to women with diabetes treated with other therapies (694). In the Women's Health Initiative, compared to women without diabetes, women with diabetes treated with metformin were at a 25% lower risk of breast cancer (RR = 0.75; 95% CI, 0.57–0.99), while those with diabetes not treated with metformin were at a nonsignificant increased risk of breast cancer (RR = 1.16; 95% CI, 0.93–1.45) (695). The exact mechanism by which metformin may reduce cancer risk is unclear; however, it is hypothesized that it may be through activation of the AMP-activated protein kinase (AMPK) pathway and inhibition of cell growth. A better understanding of the pathway involved and studies that can tease apart the effects of changes in BMI, metabolic profiles, and sex hormones will be necessary for determining if these associations are causally related to metformin. There are also suggestive studies that metformin use may improve breast cancer prognosis, although studies to date have been relatively small.

Thyroid Cancer

There have been reports that women with a diagnosis of thyroid cancer are more likely to develop breast cancer than women without such a diagnosis; this association was first noted in 1966 (696). A study published in 2001 (697) sought to overcome the problem of small sample size that plagued many of the previous studies by using SEER registry data from 1973 to 1994. In this analysis, premenopausal white women who had thyroid carcinoma were more likely to develop breast cancer 5 to 20 years later than women without a diagnosis of thyroid carcinoma (RR = 1.41; 95% CI, 1.18–1.68). There was no evidence of such increased risk among postmenopausal white women. Point estimates of RR were elevated in both premenopausal and postmenopausal black women (RR = 1.54; 95% CI, 0.66–3.03 and RR = 1.29; 95% CI, 0.52–2.67, respectively), but statistical power was poor due to low numbers. There was no increased risk of subsequent thyroid cancer following an initial diagnosis of breast cancer, suggesting that a woman's susceptibility to breast cancer after thyroid cancer may be related to treatment of the thyroid cancer rather than to genetic or environmental susceptibility to these two cancers simultaneously.

Anti-inflammatory Drugs

Strong evidence suggests that nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, inhibit colon carcinogenesis in humans (698,699), thereby providing a rationale to investigate an inhibitory role of NSAIDs in breast carcinogenesis. However, evidence on the association between NSAID use and breast cancer is conflicting. In a large case-control study (700), women who had used an NSAID three or more times per week for at least 1 year were at decreased risk of breast cancer compared to nonusers (OR = 0.66). Similarly, the observational study of the Women's Health Initiative found that regular NSAIDs users (2+ tablets/week) had a 21% decreased risk of breast cancer (RR, 0.79; 95% CI, 0.60–1.04) (701). In contrast, a large prospective study (702), found no relationship with regular or heavy use of aspirin compared to nonusers. The California Teachers Study also observed no overall association between regular NSAID use and incidence of breast cancer (703). The Nurses' Health Study found a nonsignificant 9% (HR = 0.91; 95% CI, 0.81–1.01) reduced risk of breast cancer with regular aspirin use for more than 20 years (704). In addition, this study did not find any differences by hormone receptor status or cyclo-oxygenase (COX2) expression. Unanswered questions remain regarding the effect of regular NSAID use for long durations, the effect of different doses, and the effects of different nonaspirin NSAIDs on breast cancer incidence (705). In contrast, prospective cohort and randomized control data support a protective effect on breast cancer recurrence and survival (706).

Statins

A growing body of literature suggests that statins have antitumor activity by interrupting cell-cycle progression and inducing apoptosis. Statins are a class of lipid-lowering drugs prescribed for the prevention of cardiovascular disease. A meta-analysis of randomized trials (707) and two large prospective studies (708,709) suggest that statins as a group are

not associated with breast cancer incidence. However, one study reported that the lipophilic class of statins (e.g., simvastatin and lovastatin) was associated with an 18% (HR = 0.82; 95% CI, 0.70–0.97) reduction in breast cancer incidence (708). However, this association with lipophilic statins has not been confirmed in other large population-based studies (710–712). Further evaluation of specific classes of statins and long-term use are necessary.

Pregnancy-related Conditions

A history of eclampsia, preeclampsia, or pregnancy-induced hypertension has been associated with a reduced risk of breast cancer in parous women in at least three case–control studies (713–715) and one cohort study (716). Further, women born to mothers who had preeclamptic pregnancies also appear to have reduced risk of breast cancer (717). Explanations for these findings have focused on hormone-related factors: Women who develop preeclampsia have been found to have relatively low estrogen levels during pregnancy, and the lower exposure to estrogens *in utero* may confer a benefit to the female fetus in terms of lifetime breast cancer risk reduction (717). High levels of α-fetoprotein, a glycoprotein with antiestrogenic properties, are associated with preeclampsia and thus may mediate the association between preeclampsia and reduced breast cancer risk in female offspring (717). Nonspecific cellular immune responses may be involved as well (718,719).

Epstein-Barr Virus

Epstein-Barr virus (EBV) is the most ubiquitous viral (herpes) infection among humans, with >90% of the adult population worldwide affected by it. In the vast majority of individuals, the persistent infection remains asymptomatic, but a small minority of individuals develop EBV-associated tumors, including Burkitt's lymphoma and Hodgkin's lymphoma. Based on several lines of evidence, it has been hypothesized (720–722) that breast carcinoma is also an EBV-associated tumor. However, the limited data on the relationship between EBV and breast cancer are conflicting (723–729). For instance, Bonnet et al. (723) detected the EBV genome by polymerase chain reaction (PCR) in 51% of 100 primary invasive breast carcinomas, whereas the virus was detected in only 10% of a sample of healthy tissues adjacent to the tumors. Further, the virus was more frequently associated with the most aggressive tumors. Other studies have found no molecular or immunohistochemical evidence for an association between EBV and the development of breast carcinoma (724,726,727,730,731). Results of at least one study (732) suggest that EBV DNA detected in breast carcinoma tissues is likely related to the presence of EBV-infected lymphocytes in the tumor stroma and does not indicate infection of the tumor cells with the virus; thus, that breast carcinoma is not an EBV-associated tumor.

Selective Serotonin Reuptake Inhibitors (SSRIs)

At least two studies reported that selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants promote mammary tumors in rodents (733,734). Epidemiologic studies in humans have produced inconsistent results. One study conducted before SSRIs were widely available found an increased breast cancer risk among tricyclic antidepressant users (735). A more recent study also found such an increased risk (736). One study found a decreased risk of breast cancer among tricyclic antidepressant users (737), although some studies have found no association (738,739). Research findings are similarly inconsistent for SSRIs. Two studies that employed prescription databases to assess exposure found no association between SSRI use and breast cancer risk (738,740), although a study that relied on self-report of medication usage found an elevated risk of breast cancer among recent SSRI users (739). Future epidemiologic studies of this topic must control adequately for possibly strong confounders such as alcohol use and obesity, which may be associated with use of antidepressants, and should rely on an objective assessment of medication usage, because cancer cases may be more likely to recall medication use than noncases. Further, the indication for antidepressant use may itself be associated with increased cancer risk, and depression may be an early symptom of occult cancer.

Cytotoxic drugs, used in the treatment of cancer, may exert their own carcinogenic effects. One category of cytotoxic drugs, alkylating agents, may lead to an increased risk of solid tumors, including breast cancer, although evidence for this hypothesis is weak (741).

ETIOLOGIC SUMMARY

Much is known about the behavioral factors that influence breast cancer risk, and more recently the links between these factors and the pathophysiology of the disease have become clearer. Known and suspected risk factors are described in Table 18-2, grouped by reproductive, hormonal, nutritional, and other variables. Approximate strengths of association are also given for specific comparisons. These comparisons are somewhat arbitrary because many of these risk factors are continuous variables and the RRs will depend on the levels chosen for comparison. For example, we have compared ages at menarche of 15 years with 11 years, but the RR would be stronger if age 17 years were contrasted with age 11 years. Although most of these risk factors are established with a high degree of certainty, some such as low consumption of monounsaturated fat will require further research for confirmation.

Mechanisms linking known and suspected risk factors to the development of breast cancer are known with varying levels of certainty. Early events involve mutations of breast stem cells. These mutations can be inherited (e.g., mutations in *BRCA1, BRCA2*, or *p53*) or acquired, such as by exposure to ionizing radiation. At present there is little evidence that classic chemical carcinogens play an important role in human breast cancer by causing early mutations; oxidative damage from endogenous metabolism is hypothesized to contribute to DNA damage (742), but the importance of this mechanism is difficult to quantify. To the extent that oxidative damage is important, dietary carotenoids and other antioxidants in fruits and vegetables might reduce risk and higher intake of monounsaturated fat will result in cell structures that are less easily oxidized. Low availability of folic acid, which is exacerbated by high alcohol intake, leads to the incorporation of uracil rather than thymine into DNA and can be a cause of DNA damage. Pregnancy appears to render the breast substantially less susceptible to somatic mutations, although the exact mechanisms are unclear; thus, earlier first pregnancies will minimize the period of susceptibility. Vitamin A also plays a role in maintaining cell differentiation, but it may be that only quite low intakes are related to increased risk.

High endogenous estrogen levels are well established as an important cause of breast cancer, and many known risk factors operate through this pathway. The additional contribution of cyclic estrogen exposure (as opposed to

TABLE 18-2

Risk Factors for Breast Cancer and Approximate Strength of Association

Reproductive Factors	*Hormonal Factors*	*Nutritional/Lifestyle Factors*	*Other Factors*
Early age at first period +	OC use (current vs. none) +	Obesity (>30 BMI vs. <25) Premenopausal – Postmenopausal +	Family history (mother and sister)[a] +++
Age at first birth (>35 vs. <20) ++	Estrogen replacement (10+ yr vs. none) +	Adult weight gain (postmenopausal) ++	Family history (first-degree relative)[b] ++
No. of births (0 vs. 1 child) +	Estrogen plus progesterone replacement (>5 yr vs. none) ++	Alcohol (1 or more drink/day vs. none) +	Jewish heritage (yes vs. no) +
Age at menopause (5-yr increment)	High blood estrogens or androgens (postmenopause) +++	Height (>5 feet 7 inches) +	Ionizing radiation (yes vs. no) +
Breast-feeding (>1 yr vs. none) –	High blood prolactin ++	Physical activity (>3 hr/wk) –	Benign breast diseased (MD diagnosed)[d] ++
		Monounsaturated fat[c] – (vs. saturated fat)	Mammographic density (highest category vs. lowest) +++
		Low intake of fruits and vegetables[c] (specifically for ER- breast cancer) +

[a]Two first-degree relatives who have a history of breast cancer before age 65 years versus no relative.
[b]First-degree relative who has a history of breast cancer before age 65 years versus no relative.
[c]Upper quartile (top 25%) versus lower quartile (lowest 25%).
[d]Clinically recognized chronic cystic, fibrocystic, or other benign breast disease versus none.

continuously high levels) is less clear, but much available evidence indicates that progestins add to breast cancer risk. Factors that increase lifetime exposure to estrogens and progestins include early age at menarche, regular ovulation, and late menopause. Lactation and overweight during young adult life result in anovulation and this probably accounts for some of their protective effects. Extreme underweight also causes anovulation and would be expected to reduce risk, but direct evidence is lacking. Alcohol consumption increases endogenous estrogen levels and may, at least in part, account for the observed increase in risk among regular drinkers. The increase in risk of breast cancer among current or recent users of oral contraceptives is also presumably due to their estrogenic (and probable progestational) effects. After menopause, the major determinants of estrogen exposure are the amount of body fat and use of postmenopausal hormones; these are both important risk factors for breast cancer. Increases in physical activity can delay the onset of menarche and can reduce risk of breast cancer by helping to control weight gain and decrease endogenous estrogen exposure.

Estrogens, by their mitotic effect on breast cells, appear to accelerate the development of breast cancer at many points along the progression from early mutation to metastasis and death. By increasing cell multiplication, estrogens may also increase the probability that DNA lesions become mutations. Although earlier exposure to high estrogen levels during adolescence increases risk decades later, reduction in levels late in life abruptly reduces risk, whether this be by castration, cessation of postmenopausal hormones, or the administration of antiestrogens. Other growth factors in addition to estrogens, particularly IGF-I and prolactin, also appear to contribute to risk of breast cancer, but these relationships are less firmly established.

Although this broad outline of breast carcinogenesis is unlikely to change substantially with further research, many details are incomplete and other contributing factors will probably be documented. For example, genetic polymorphisms yet to be identified may contribute to variation in endogenous levels of, or responsiveness to, estrogens, IGF-I, and prolactin. Dietary and other behavioral determinants of these factors are incompletely defined. Also, other molecular mechanisms such as DNA repair and apoptosis are thought to be important in carcinogenesis in general, but the extent to which exogenous factors influence these processes in the context of human breast cancer is not known.

ATTRIBUTABLE RISK: THE QUANTITATIVE CONTRIBUTION OF KNOWN RISK FACTORS

As noted early in this chapter, the search for specific breast cancer risk factors has been stimulated by the large differences in rates of breast cancer among countries and by changes in rates among migrating populations and within countries over time. The extent to which known risk factors account for these differences in rates is, therefore, of considerable interest. An often-quoted estimate is that only 30% of breast cancer cases are explained by known risk factors (743,744). This has been widely used to suggest that other major risk factors remain to be discovered, in part fueling the search for environmental pollutants that may be responsible. However, a study of population attributable risks in a nationwide survey estimated that at least 45% to 55% of breast cancer cases in the United States may be explained by later age at first birth, nulliparity, family

history of breast cancer, higher socioeconomic status, earlier age at menarche, and prior benign breast disease (745). In another analysis, parity and age at menarche, first birth, and menopause appeared to explain more than half of the difference between breast cancer rates in China and in the United States (98). The rapid decline in age at menarche in Korea since World War II (746), a drop in parity to very low levels, and the rise in premenopausal breast cancer incidence to rates comparable to Western countries (747), further attests to the power of these reproductive patterns to account for variation in incidence. Among postmenopausal women, just the combination of weight gain after age 18 years and use of postmenopausal hormones accounted for approximately one-third of breast cancer incidence (283). Among women who do not use postmenopausal hormones, weight gain from age 18 accounts for 24.2% of postmenopausal breast cancer (748). Combined with the reproductive variables, this would clearly account for a large majority of the international differences.

A precise determination of the degree to which changes in the prevalence of known breast cancer risk factors account for the increases in breast cancer rates over time is difficult. Changes in age at first birth do not appear to account for appreciable increases in overall U.S. breast cancer rates through 1990, although more delayed childbearing by women born after 1950 should ultimately contribute to an approximately 9% increase in rates (749). However, since the 1940s, adiposity, use of postmenopausal hormones, and alcohol consumption by women have increased dramatically. Although further work is needed to quantify these contributions to the secular trends, novel risk factors are not required to account for substantial increases in breast cancer rates.

COMMUNICATING RISK TO PATIENTS

Women and their healthcare providers are increasingly exposed to information on epidemiologic risk factors for breast cancer, benefits of prevention strategies, and treatment options. The Gail et al. model of breast cancer risk prediction (750) is increasingly used by clinicians to assess breast cancer risk for women with differing risk factor profiles. This model has been validated but identifies as high risk only a minority of women who will go on to develop breast cancer (751). However, evidence suggests that the understanding of personal risk by women is poor. For example, in a sample of women with a family history of breast cancer, more than two-thirds of women overestimated their lifetime risk of breast cancer, even after participating in a counseling session (752). The overestimation of risk was substantial and perhaps could lead to inappropriate behaviors, such as overscreening, excessive breast self-exam, or inappropriate decisions regarding prophylactic mastectomy or other strategies.

Factors that appear to influence perception of risk include numeracy (753). Women with higher numeracy scores had significantly higher accuracy in gauging the benefits of mammography. Lower education, obesity, having three or more comorbidities, and current cigarette smoking were related to unrealistic pessimism about breast cancer in a nationally representative sample of women (754). Importantly, when discussing risk and risk reduction, research indicates that both absolute risk and RR must be included in the message to maximize the accuracy of risk perception. A presentation must be capable of presenting probabilities about a variety of possible outcomes in a comprehensible manner. It must also attempt to counter "side effect aversion" (755,756). Furthermore, any tool that aids the presentation of risks and benefits must address potential misperceptions about the magnitudes of breast cancer risks, and it must not overwhelm people with the complexity of reducing risk with, for example, a selective estrogen receptor modulator (SERM) (752,757,758). While more effective formats for presentation of risk and benefits are required, the evidence supports discussion of "risk in 1,000 women exactly like you," as well as the magnitude of risk reduction, perhaps as a percentage.

PREVENTION OF BREAST CANCER

Approaches for primary prevention of breast cancer according to period of life are discussed here briefly and are considered in more detail elsewhere (759). Although many reasons for the high rates of breast cancer in affluent Western populations are known, this knowledge does not necessarily translate easily into strategies for breast cancer prevention. Some risk factors (such as age at menarche) are well established but difficult to modify; some (such as postmenopausal hormone use) are well established but carry benefits as well as risks; and others (such as replacing saturated fat with monounsaturated fat) are unproven but have other strong benefits that justify the strategy, with reduction in breast cancer being a possible additional benefit. Also, known risk factors for breast cancer are modest in magnitude; RRs are usually in the range of 1.3 to 1.8 for attainable changes. Although these RRs are far less dramatic than that between smoking and lung cancer, they should still be considered important. To provide perspective, the RR of death from breast cancer for women who do not have mammography compared to those who receive regular mammograms is about 1.3. As we give great importance and resources to the provision of mammography, the avoidance of a risk factor with a similar magnitude of effect should have even higher priority because this prevents both the occurrence and the need for treatment of breast cancer as well as death. When considering primary prevention, it is important to remember that even small changes at the individual level can produce substantial changes in the population rates of disease (760).

Some strategies for prevention can be implemented by individuals themselves, but the health system and governments and society as a whole can take actions that will influence rates of breast cancer importantly. In Table 18-3 possible prevention strategies are listed, along with actions that can be taken at these different levels to reduce rates of breast cancer.

Early onset of menarche in the United States and other affluent countries is largely the result of rapid growth and weight gain of children related to an abundant food supply, excellent sanitation, and low levels of physical activity (including sitting in school). Much of this is desirable for many reasons, and there is no reasonable expectation that we could or would want to increase the average age at menarche to 17 years, as has been typical in rural China. Yet, generally desirable increases in physical activity, such as greater recreational activities, have been associated with modest delays in age at menarche (398,761) and should thus contribute to reductions in breast cancer, and we now have more direct evidence that higher levels of activity during this period of life are associated with lower risk. Society, through the provision of daily physical activity in schools and safe environments for recreational activity, must play a major role in these efforts.

Early age at first birth will substantially reduce breast cancer, but the societal trends are in the opposite direction because of delay of childbirth until after educational

TABLE 18-3

Possible Strategies and Levels of Action for Primary Prevention of Breast Cancer

Strategy	*Individual*	*Health System*	*Society/Government*
Delay menarche	Provide parental support for recreational activity and limit television watching	Encourage regular activity	Provide daily physical activity in schools and safe play environment
Breast-feed	Breast-feed at least 6 mo/ pregnancy	Encourage lactation	Provide infant child care at work and/or long maternal leaves
Limit alcohol	Limit intake to several drinks per week	Provide education	Develop social norms for low alcohol intake by women
Avoid long-term estrogen therapy, especially if combined with progestagens	Limit use to treatment of symptoms	Educate patients on risks and benefits	
Avoid adult weight gain	Engage in regular physical activity, moderately restrain total calorie intake	Counsel patients on the importance of avoiding weight gain	Provide safe environment for pedestrians and bicycle riding; provide work-site and community recreational facilities
Eat five servings of fruit and vegetables per day; limit red meat consumption; and replace saturated fat with olive, canola, and other oils high in monounsaturated fat	Make healthy dietary choices	Encourage healthy diets	Provide healthy choices in work site and schools, and provide best current information on diet and health

programs are completed and careers are established. Further, unplanned early pregnancies and more than an average of two completed pregnancies per woman have undesirable social and ecologic consequences. Nevertheless, a social norm that encouraged carefully planned first pregnancies at the beginning of advanced education and career development would reduce breast cancer rates. This would require major behavioral changes and social supports, such as for childcare, to be practical on a widespread basis. Because of the complex social changes needed for this to be a practical strategy for breast cancer prevention and potential undesirable consequences, we have not included it in Table 18-3.

At least 6 months of breast-feeding is recommended for optimal infant health (762) and evidence suggests this will modestly reduce risk of breast cancer, particularly among premenopausal women. Improved physician counseling (763) can encourage this practice, but changes at workplaces to allow breast-feeding and longer maternity leaves will also be needed for many women to adopt this practice.

Alcohol consumption has a complex mix of desirable and adverse health effects, one being an increase in breast cancer. Among adolescents and young adult women, the increases in breast cancer will not be counterbalanced by a reduction in heart disease, as risk of this is extremely low. Individuals should make decisions considering all the risks and benefits, but for a middle-aged woman who drinks alcohol on a daily basis, reducing intake is one of relatively few behavioral changes that is likely to reduce risk of breast cancer. Taking a multiple vitamin containing folic acid greatly reduces risks of neural tube defects and may prevent coronary heart disease (764) and colon cancer (765), and some evidence suggests this may mitigate the excess risk of breast cancer due to alcohol (480). Thus, taking a multiple vitamin appears sensible for women who do elect to drink regularly.

Postmenopausal hormone use, like alcohol consumption, involves a complex trade-off of benefits and risks. From the standpoint of breast cancer risk, the optimal strategy would be to use estrogens not at all or for less than 10 years to relieve menopausal symptoms. Most importantly, combined use of estrogen plus progestin for more than 1 year should be avoided. The range of options, however, is increasing with the demonstration that tamoxifen and raloxifene, two selective estrogen receptor modulators, can be effective in the primary prevention of breast cancer. Physicians will need to play a key role in advising women in this rapidly evolving field.

Avoiding weight gain during adult life can importantly reduce risk of postmenopausal breast cancer, as well as cardiovascular disease and many other conditions. Individual women can reduce weight gain by exercising regularly and moderately restraining caloric intake, which is facilitated by overall quality of diet (766). Healthcare providers play an important role in counseling patients throughout adult life about the importance of weight control. However, the incorporation of greater physical activity into daily life will be difficult for many persons unless governments provide a safer and more accessible environment for pedestrians and bicycle riders. The provision of work-site and community exercise facilities can also contribute importantly.

Few specific aspects of diet that influence risk of breast cancer are well established, but recent evidence based on multiple prospective studies of dietary intake and measurements of blood carotenoid levels strongly suggest that an abundant consumption of fruits and vegetables will reduce risks of estrogen receptor negative breast cancer. Other

evidence suggests that limiting red meat (particularly in childhood and early adult life) and replacing saturated and trans-fat with monounsaturated fat may also reduce risk. These strategies are consistent with an overall Mediterranean-type dietary pattern, which is reasonable to adopt because this will reduce risk of cardiovascular and other diseases, and modestly lower risk of breast cancer may be an added benefit. Physicians can assess dietary habits and provide guidance, and governmental policies influence diets in many ways. Providing the best current information on diet and health is one such role.

With demonstration that tamoxifen and probably other selective ER modulators can be effective in the primary prevention of breast cancer (117,119), chemoprevention has become an option for women at elevated risk. Many other pharmacologic agents are being evaluated and are likely to increase the alternatives. The availability of effective chemopreventive agents raises many questions about the optimal criteria for use of these drugs. Evaluation of an individual woman's risk of breast cancer has become much more important because this risk can now be modified. Until recently, risk has been primarily based on an evaluation of family and reproductive history and history of benign breast disease. New information on risk based on genotype, detailed histologic characteristics of benign breast disease (767), and serum hormone levels (124) now allows a much more powerful prediction of risk for an individual woman. Screening for elevated estrogen levels in postmenopausal women to help identify those who would most benefit from an estrogen antagonist, as is done for serum cholesterol, may become part of medical practice. Physicians will play a key role in keeping abreast of this rapidly developing area and counseling patients appropriately.

In summary, available evidence provides a basis for strategies that can reduce risk of breast cancer, although some of these represent complex decision making. Attainable objectives can make an important impact on individual risk of breast cancer. However, even the collective implementation of all lifestyle strategies will not reduce population rates of breast cancer to the very low levels of traditional agrarian societies because the magnitude of the necessary changes is unrealistic or undesirable. Thus, a role will exist for hormonal and other chemopreventive interventions that may be appropriate for women at particularly high risk and, potentially, for wide segments of the population because few women can be considered to have very low risk. Together, the modification of nutritional and lifestyle risk factors and the judicious use of chemopreventive agents can have a major impact on incidence of this important disease.

CHAPTER 19

Management of Other High Risk Patients

Seema A. Khan

CHAPTER CONTENTS

INTRODUCTION

Breast cancer risk can be attributed to three major sources: increasing age, lifetime estrogen exposure (endogenous and exogenous), and genetic susceptibility. These major factors play a critical role in breast epithelial transformation and appear to converge in the phenotypic expression of proliferative precursor lesions of the breast epithelium, as observed in the unaffected breasts of women who are genetically susceptible (e.g., BRCA mutation carriers) as well as women at risk for the so-called "sporadic" breast cancer. This chapter will focus on the identification and management of women at higher than average risk for sporadic breast cancer; management of women who are genetically susceptible and those with lobular carcinoma *in situ* is covered in Chapters 12 and 16. The following discussions of breast cancer "risk" will apply to women who do not carry mutations of known breast cancer susceptibility genes. Additionally, a full discussion of the epidemiology of sporadic breast cancer can be found in Chapter 18, along with pertinent references; these risk factors are reviewed here only from the perspective of identification and management of individuals (rather than populations) at risk for breast cancer.

The management of women at increased risk for breast cancer includes: a) identification of high risk women (or risk estimation); b) recommendations for life-style modifications that may reduce risk; c) a plan for breast surveillance; d) discussion of pharmacologic prevention; and e) discussion of prophylactic mastectomy (if appropriate and sought by the patient).

IDENTIFICATION OF HIGH RISK WOMEN

Age: The relation of age to breast cancer risk is discussed fully in Chapter 18 but it is worthwhile noting here that breast cancer risk estimation for individuals is heavily influenced by age. Incidence rates rise sharply with age, starting in the mid-to-late 30s, and all currently used statistical risk estimation models relate the known relative risk (RR) for a particular risk factor to the age-specific breast cancer frequency in that population. This is important to recognize in terms of breast cancer risk management, as a 5-year risk estimate of 1.7% using the Gail model-2 (National Cancer Institute (NCI) Breast Cancer Risk Assessment Tool) has been widely used as a benchmark measure of breast cancer risk. The 5-year breast cancer Gail model probability for an average 45-year-old woman is 1%, while the similar estimate for an average 65-year-old woman is 2%. Thus a 45-year-old woman who has a 5-year breast cancer probability of 1.7% is at higher lifetime risk than her 65-year-old counterpart. However, as the same 45-year-old woman ages, if she does not acquire any new risk factors and does not develop breast cancer, her estimated risk declines and approaches the average risk for her age group. Thus longer-term risk estimates (e.g., 10-or 20-year estimates) may be a more useful framework for risk counseling, and life-time risk estimates (calculated to age 85 or 90) have become a commonly used benchmark for comparison of risk groups, most useful for younger women.

Risk Factors Related to Reproductive Hormones: A wide array of established risk factors for breast cancer relates to endogenous life-time estrogen exposure. These include young age at menarche, late age at first full-term pregnancy,

no exposure to lactation, and late age at menopause. Among postmenopausal women, higher serum estradiol levels are robustly linked to breast cancer risk, and among premenopausal women there is a suggestion of higher levels of the androgenic estradiol precursors in breast cancer cases but these differences are not sufficient to utilize serum hormone levels for risk estimation in clinical practice. Although the risk associated with reproductive variables has been generally attributed to estrogen exposure, the hormones progesterone and prolactin also deserve consideration. Thus, the number of ovulatory cycles during a woman's reproductive life-span (with their luteal phase progesterone surge) is a stronger determinant of breast cancer risk than the length of time from menarche to menopause, and the short-term increase in breast cancer risk following pregnancy is at least partially attributed to the high progesterone exposure of pregnancy. Furthermore, exogenous progestin exposure in the form of combination postmenopausal hormone therapy (CMHT) carries a larger breast cancer risk than therapy with estrogen alone. In premenopausal women, current oral contraceptive use has long been associated with a modest increase in breast cancer risk, but recent data on the use of depo-medroxyprogesterone acetate (DMPA) shows a twofold increase in breast cancer risk, with a trend toward higher grade and triple negative tumors (1). Prolactin exposure, too, is now clearly implicated in breast cancer causation, and the protective effect of pregnancy is mediated, at least partially, through a long-term lowering of serum prolactin. Epidemiological studies have shown that breast cancer cases demonstrate higher serum prolactin levels than controls, prior to the onset of breast cancer.

Other well-established risk factors also appear to operate through the endocrine axis: postmenopausal obesity is associated with increased aromatization of androgenic precursors in adipose tissue, lower sex hormone-binding globulin, and higher free estradiol. Physical activity in adolescence delays menarche and the onset of ovulatory cycles; later in life, it protects against obesity and may operate through other mechanisms as well. Moderate to heavy alcohol consumption is associated with higher circulating sex steroid levels and may retard the hepatic metabolism of hormones.

In general, the contribution of these individual risk factors to overall risk is modest, and relative risk estimates for each of these factors from most studies are in the range of 1.5–2.0. It is therefore difficult to apply this information to individual risk estimation unless it is incorporated into multifactorial statistical models, the prototype of which is the Gail model (2), validated in the Breast Cancer Prevention Trial (3). More recently developed models (Tyrer-Cusick) do include additional endocrine risk factors (age at menarche, use of postmenopausal hormone therapy, height, weight) and family history (4). Breast cancer risk estimation is discussed more fully below.

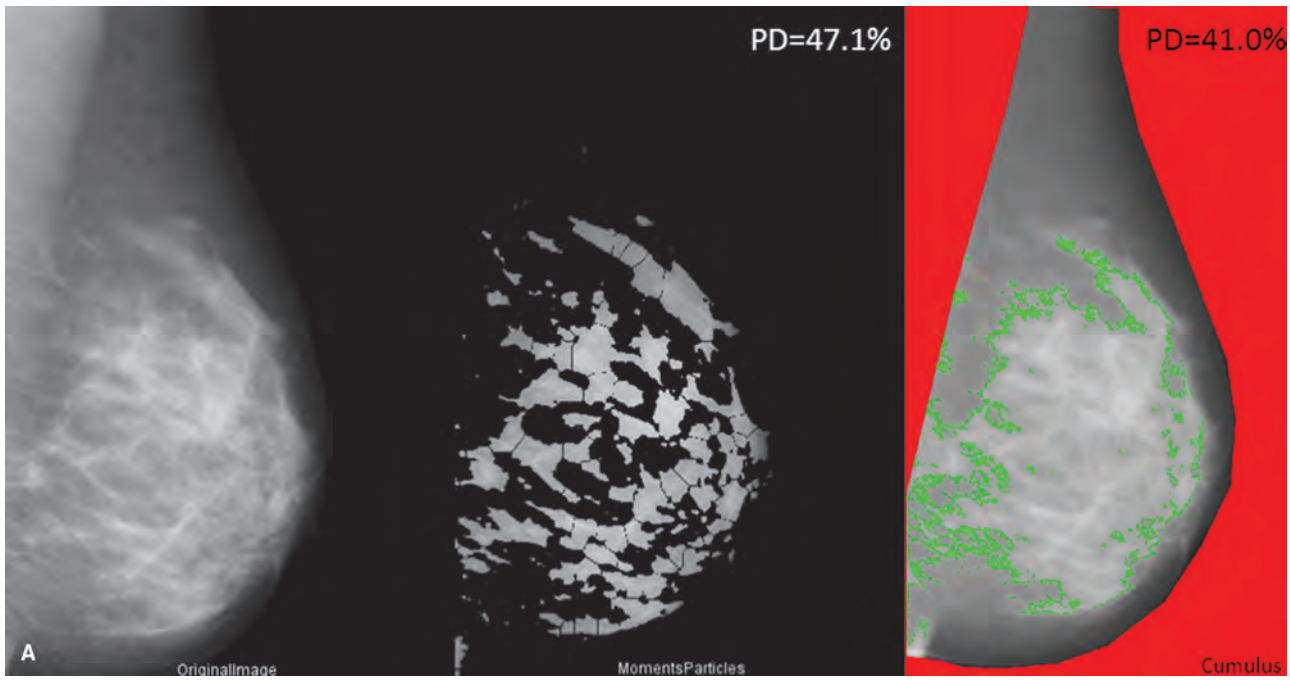
Mammographic Density

The radiographic appearance of the breast varies according to differences in the relative distributions of fat and fibroglandular tissues, where fat appears dark and radiographically dense areas appear light. It is reported on mammography reports using the standard reporting lexicon as BIRADS 1 through 4 (mostly fatty, scattered densities, heterogeneously dense, or very dense). These categories are intended to correspond to the percent dense area (<25%, 25%–50%, 51%–75%, and >75%) measured by application of a computer algorithm to digitized film screen images. Much of the published literature is based on a semiautomated algorithm (the CUMULUS software, developed by Byng et al.) but additional algorithms based on publically available software are being developed as shown in Figure 19-1. Volumetric, three-dimensional measurements are also being tested and may be more closely related to breast cancer risk. Mammographic density is at least partially genetically determined and a recent genome-wide association study has shown that polymorphisms associated with mammographic density are also associated with breast cancer risk (5).

There is now a substantial body of evidence showing that extensive mammographic density is strongly associated with an increased risk of breast cancer. The relative risk for the highest category of breast density (>75% of breast area is dense) has been reproducible across several large studies, and, on meta-analysis of these, the RR for the highest density category ranges from 3.25 to 6.49 (6). Additionally, a combined analysis of three nested case-control studies which included 1,112 participants of breast cancer screening programs (7) showed that women with mammographic density of more than 75% had a breast cancer RR of 4.7 (95% CI 3.0,7.4) compared to women with mammographic density less than 10%. In particular, women with the highest density category had a very high risk of being diagnosed with breast cancer within 12 months of the screening mammogram (RR = 17), suggesting that high mammographic density might mask the cancer. Among postmenopausal women, the association of percent dense area with breast cancer risk is stronger for those using hormone therapy; other data suggest an interaction between alcohol use of more than 1 drink daily and mammographic density. Based on these results, it is important to identify women with high percent density to counsel them about modifiable risk factors. Research on alternative imaging techniques for earlier detection is also needed.

The importance of mammographic density as a strong and independent risk factor for breast cancer is amplified by its high prevalence, with about one-third of the general population of women displaying dense areas of 50% or greater on mammography. Because of this prevalence, the fraction of breast cancer cases attributable to high mammographic density is in the range of 16% to 32% and higher in premenopausal women (7). Thus, the impact of breast density on cancer risk is far stronger than any of the known endocrine-related risk factors and in the same range as the risk associated with atypical proliferative lesions of the breast.

Studies examining the correlation between serum sex-steroid levels and mammographic density have not shown any consistent associations, with one large study by Verheus et al. in 2007 showing no relationship between circulating sex steroid levels and mammographic density but a more recent examination of hormonal variation in premenopausal women showing a positive association with mean estrogen level through the menstrual cycle. It would be of interest to determine if local breast estradiol levels (e.g., those in nipple aspiration fluid) are related more closely to breast density than circulating levels; these studies are ongoing. On the other hand, mammographic density and serum sex steroids (estradiol and testosterone) may have independent and additive effects on breast cancer risk as suggested by a recently reported case-control study nested within the Harvard Nurses' Health Study. Other hints that mammographic density is modulated by the endocrine environment come from the significant correlation between mammographic density and serum insulin-like growth factor-1 (IGF-1) that has been observed in premenopausal women (8). Prolactin is a potentially important hormone in breast carcinogenesis—higher levels in the serum are associated with increased breast cancer risk in both pre- and postmenopausal women—and several studies now suggest an association between serum prolactin levels and mammographic density.



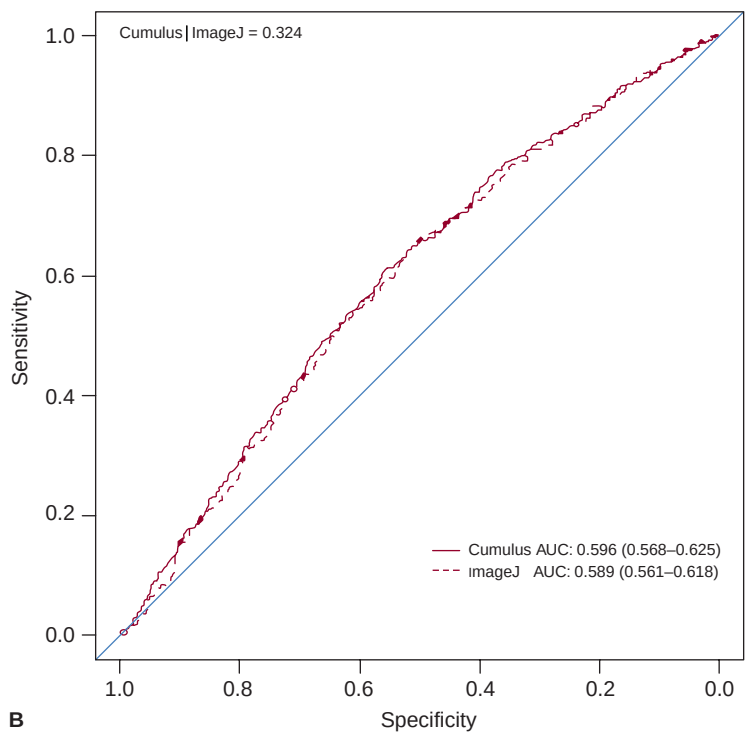


FIGURE 19-1 Mammographic density measurement. Examples of processed images. **(A)** An example of a digitized mammogram before and after thresholding and application of the watershed algorithm (one image, one particular thresholding algorithm, Moments), and the same image thresholded by using Cumulus **(B).** Discriminatory powers of Cumulus and ImageJ for predicting breast cancer risk, as measured by area under curve (AUC). Legend on the top-left corner summarizes *P* values for the Delong test between two receiver operating characteristic (ROC) curves. Legend on the bottom-right corner summarizes the AUC for each model with corresponding 95% confidence intervals. There were 3,593 participants with eligible film mammograms (1,784 cases and 1,809 controls). (From Li et al. High-throughput mammographic-density measurement: a tool for risk prediction of breast cancer. *Breast Cancer Res* 2012;14(4):R114.)

Studies relating breast density to histological findings have shown that high mammographic density is associated with an increased risk for atypical hyperplasia. However, in breast epithelial samples obtained from high risk women using random fine needle aspiration, no correlation was seen between cytologic atypia or cell proliferation (measured by Ki-67 labeling) and mammographic density. Quantitative microscopy of the autopsied breast shows relationships between mammographic density and total nuclear area, epithelial and nonepithelial nuclear area, glandular structures, and amount of collagen. Similarly, in reduction mammoplasty samples, the epithelial cell volume was concentrated in areas of high density connective tissue, and was significantly related to the mammographic density. This increased epithelial and stromal area in dense tissue does not translate into increased cell proliferation or steroid receptor expression in epithelial cells. Thus, there is no clear biological explanation for the association of breast density with cancer risk, and much remains to be done in order to incorporate the measurement and modulation of mammographic density into algorithms for breast cancer risk assessment.

An important, and potentially the most useful, aspect of breast density is the possibility that it is modifiable. This is most evident by the fact that the use of combination

postmenopausal hormone therapy (PMHT) increases percent breast density whereas tamoxifen therapy not only reduces it, but a decrease in mammographic density appears to predict preventive benefit. In a post-hoc sub-study of the International Breast Cancer Intervention Study (IBIS) trial, women who demonstrated a 10% or greater reduction in density following 12 months of tamoxifen use demonstrated a two-thirds reduction in breast cancer risk, whereas no significant risk reduction was seen in women whose mammographic density did not change (9). Small studies of ovarian suppression with a gonadotrophin-releasing hormone agonist in premenopausal women, and in BRCA1 mutation carriers, suggest another avenue of breast density reduction. Other data are more mixed; a meta-analysis of physical activity and mammographic density showed no significant effect, and vitamin D supplementation in the Women's Health Initiative similarly had a null effect. Aspirin use, which appears to reduce breast cancer risk, shows no relationship to breast density. Therefore, although modification of breast density is possible, not all pathways of breast cancer risk reduction are reflected as reductions in breast density.

Breast Epithelial Hyperplasia and Involution

The present paradigm for the development of breast cancer suggests that in the breast, as in other epithelial organs, the etiologic pathways of malignancy converge in the occurrence of breast epithelial hyperplasia or intraepithelial neoplasia (IEN). This concept is supported by data going back several decades, relating benign breast disease (specifically epithelial proliferation) to an increased risk of subsequent breast cancer; several studies have shown that the breast cancer risk of women with hyperplasia without atypia is roughly twofold greater than women without; and the risk associated with atypical hyperplasia is increased approximately fourfold (10,11). The specific lesions included in the category of hyperplasia without atypia consist of moderate or florid duct hyperplasia, intraductal papilloma, sclerosing adenosis, and radial scar. The lesions usually included in the category of atypical proliferation include atypical duct hyperplasia (ADH), atypical lobular hyperplasia (ALH), atypical papilloma, and flat epithelial atypia (see Chapter 9 for more detail). Although data from the large retrospective cohort from Nashville, TN, showed a strong interaction between atypical hyperplasia and a positive family history for breast cancer (the risk associated with a history of first degree relative with breast cancer and atypical hyperplasia was increased almost 10-fold), two recent studies do not substantiate these findings and show no added increase in risk for women with atypical hyperplasia and a positive family history (11,12). Although there was a suggestion of a more marked risk increase with ALH than ADH in the Nashville and Nurses cohorts, recent results from the Mayo Clinic cohort do not show a difference in risk between ALH and ADH. However, an increasing number of atypical foci, the presence of calcifications in the histological material, and the combination of ADH and ALH, all raise risk significantly over that observed in the absence of these findings (Fig. 19-2).

Despite the consistently increased risk seen with typical and atypical epithelial proliferation in the breast, most women with these findings do not, in fact, develop breast cancer (e.g., 80% of the 330 women with atypical hyperplasia in the Mayo cohort remained free of breast cancer over a mean follow-up period of almost 14 years). A number of authors have attempted to identify molecular factors which might improve the specificity of risk assessment, so that preventive interventions can be targeted to a more purified high risk group. Despite a number of potential risk biomarkers, there has been little progress in prospective validation of these. The more obvious immunohistochemical markers estrogen receptor, p53, and HER-2/neu demonstrate risk increases of two- to threefold but have not been validated and are not in clinical use. Expression of cyclooxygenase-2 (COX-2) has been examined in atypical lesions from women in the Mayo cohort, with an observed increase in breast cancer risk with increasing COX-2 expression. Thus, if expression was weak or absent, RR was 2.63 (95% CI 3.0,7.4); with

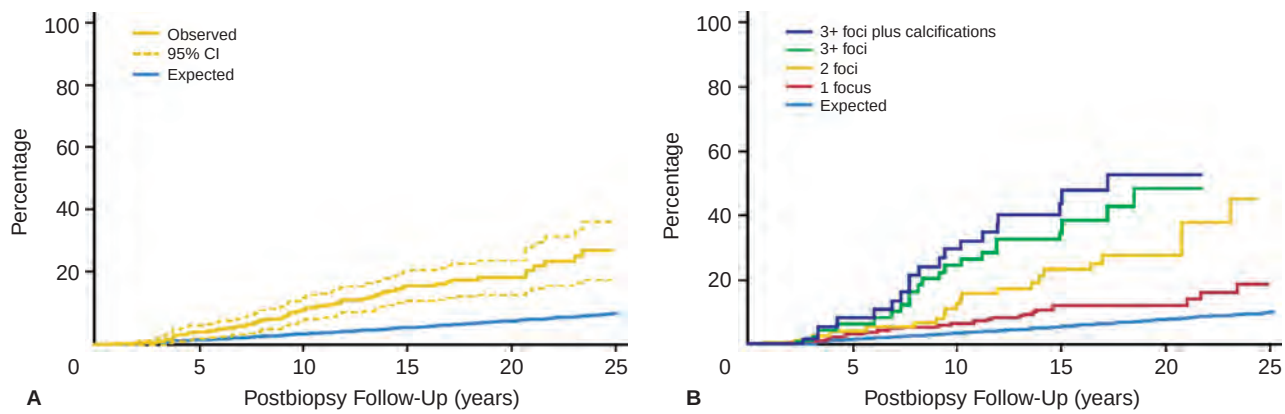

FIGURE 19-2 **(A)** Cumulative risk of breast cancer over time. Observed cumulative breast cancer incidence among women with atypical hyperplasia, with 95% represented by stippled lines. Expected breast cancer events were calculated by applying age- and calendar period-stratified person-years of observation to corresponding lows Surveillance, Epidemiology, and End Results breast cancer incidence rates. Observed and expected events cumulated after accounting for death as a competing. **(B)** Observed and expected cumulative breast cancer incidence among women with atypical hyperplasia, stratified by number of foci of atypia and histologic presence of calcifications. (From Degnim AC, Visscher DW, Berman HK, et al., Stratification of breast cancer risk in women with atypia: a Mayo cohort. *J Clin Oncol* 2007;1;25(19):2671–2677. Epub 2007Jun 11. (A is Fig 2; B is Fig 3, both on page 2675.))

moderate COX-2 expression, RR was 3.56 (95% CI, 1.94, 5.97) and with strong expression, RR was 5.66 (95% CI, 2.59, 10.75). Although these findings have not been replicated, the fact that COX-2 expression is also a marker of increased recurrence risk in DCIS lesions strengthens the possibility that the findings are biologically significant. Nevertheless, at the moment there are no validated risk biomarkers in breast epithelial lesions, and the morphologic diagnosis of atypical hyperplasia and lobular carcinoma *in situ* remains the strongest tissue-based marker of breast cancer risk.

An additional aspect of breast histology that has been investigated recently by Hartmann and colleagues in the Mayo Clinic cohort is the appearance of age-related lobular involution, described as physiological atrophy of the breast, with a decrease in the number and size of acini per lobule. These investigators hypothesized that absence of involution may be a risk factor for breast cancer, and classified benign biopsy sections into three categories: no involution where 0% lobules were involuted, partial involution with 1% to 74% lobules involuted, or complete involution with ≥75% lobules involuted. Involuted terminal duct lobular units (TDLUs) contain only a few to several small acini and flattened, inconspicuous acinar epithelium with fibrosis or fatty replacement of specialized intralobular stroma. They found a significant increase in relative risk in women displaying complete absence of involution. On further analysis, in a study that included mammographic density data, it appears that lobular involution is inversely associated with breast density (61% of women with extremely dense breasts displayed no involution); it remains independently associated with breast cancer risk following adjustment for mammographic density. Thus, the highest risk was observed in women with no involution and dense breasts (adjusted HR = 4.08, 95% CI = 1.72–9.68) (13). The mechanism of increased risk related to failure of lobular involution remains to be defined, but it is clearly plausible that involution is related to attrition of cytokine and hormonal signals that both maintain parenchymal volume, and support tumorigenesis in breast epithelium.

BREAST EPITHELIAL SAMPLING IN ASYMPTOMATIC, HIGH RISK WOMEN

Until recently, atypical hyperplasia has been identified only in women who developed breast lumps or mammographic findings that required biopsy. In such populations, the prevalence of atypical hyperplasia in an older series of open surgical biopsies was 3.5% (10) but more recent estimates in series of core needle biopsies of image-detected lesions range up to 9%. Autopsy studies suggest that the prevalence of occult atypical IEN could be as high 26%, depending on the detail of the sampling. There is good evidence, therefore, that the prevalence of occult breast IEN is significantly higher than that suggested by surgical biopsy data.

The recent interest in techniques for the sampling of epithelium from clinically normal breasts is motivated by the expectation that an improved ability to identify occult IEN would lead to improvements in our ability to assess individual risk. Noninvasive methods of breast epithelial sampling have another important application: the potential for the development of surrogate endpoints for the occurrence of malignancy, which are notably lacking in the field of breast cancer prevention at the moment. Although there has been significant progress in this area over the last decade or so, breast epithelial sampling of asymptomatic women remains a research tool, with no specific application in the clinical management of high risk women; available methods are briefly summarized below.

Methods of Non-Invasive, Minimal Sampling of the Healthy High Risk Breast

The techniques available include two, which obtain fluid and cells from ductal lumina (nipple aspiration fluid and ductal lavage) and two, which obtain epithelial and stromal cells via random fine or core needle biopsy.

Nipple Aspiration Fluid (NAF): Nipple fluid contains cells that are exfoliated into the ductal lumen and can be collected at the duct orifice by suction-aspiration. It is well tolerated, inexpensive, and produces samples that are paucicellular (or acellular) but rich in proteins, hormones, and possibly nucleic acids. It was first evaluated by Papanicolaou in the 1950s, with the goal of breast cancer detection, and was subsequently furthered by Sartorius, who developed a breast pump device designed to improve nipple fluid yield from asymptomatic women. The method in use today involves breast massage, dekeratinization of the nipple, and suction-aspiration with commercially available devices (Atossa Genetics, Halo Healthcare). Analyses of cells or protein in NAF samples obtained with these devices are also commercially available. However, the validation of protein assays is lacking, and reproducibility of cytologic analyses has long been a problem. A significant limitation of NAF as a biosample is the great variability in the fraction of women who yield of nipple fluid in various studies; a recent report from the Netherlands by van Diest and colleagues describes the successful use of oxytocin nasal spray to induce NAF production but the absence of a comparison group, or a within-person comparison before and after oxytocin use renders it difficult to interpret these results. Oxytocin nasal spray currently has no FDA approved uses in the United States, is difficult to obtain, and expensive. An added concern in the interpretation of studies of NAF-based biomarkers is the inability to extend these to women who do not yield NAF, and recent data suggest that non-yielders of NAF have significantly lower serum prolactin levels than yielders (Khan et al., manuscript under review).

Ductal Lavage (DL): DL is an extension of NAF, designed to overcome the problems of scant cellularity in NAF samples, and to sample the entire length of the ductal tree (14). The procedure involves application of a topical anesthetic or periareolar infiltration with lidocaine; the elicitation of nipple fluid as described above, cannulation of each fluid-yielding duct (non-fluid yielding ducts can also be cannulated) with a single lumen catheter and lavage with normal saline. The lavage effluent is fixed, centrifuged to recover a cell pellet, and cytological smears prepared. Ductal lavage was introduced with the expectation that it would perform better than NAF in the identification of occult IEN. When compared to NAF, DL samples consistently provide a higher cell yield, but at significantly greater cost in supplies, time, and patient discomfort. Although some investigations continue, this technique has not proven useful for early diagnosis of breast cancer, risk evaluation, or for monitoring of biomarkers in prevention trials (15).

Random Fine-Needle Aspiration (rFNA): The rRNA method is performed in the clinically and radiologically normal breast in healthy, high risk women. It is based on the concept of field change in the high risk breast and does not provide site-specific sampling. First tested by Marshall in Utah in the late 1980s, major work in this area has subsequently been reported from University of Kansas by Fabian and colleagues, who have modified the original technique (16). After local anesthesia with buffered lidocaine with

epinephrine, eight to ten passes are made per breast with a 21 gauge needle introduced at two locations (periareolar, upper outer and upper inner quadrants). Samples from both breasts are pooled. With the prophylactic use of Vitamin K, use of buffered lidocaine, post-procedure cold packs, and tight-fitting sports bras, hematomas are rare, and the procedure is generally well tolerated.

Random Core Needle Biopsy (rCNB): With the availability of spring-loaded core needle biopsy devices, rCNB has become a possible approach to breast epithelial sampling. Some data exist in terms of the utility of this approach for tissue acquisition for biomarker studies (17), but there is no published information as to its use in risk assessment. In one biomarker study, up to seven cores were obtained from each subject, through the same skin incision. On average, 3 of the 6–7 cores per subject contained epithelium, the rest being fatty. The investigators were able to count 3,000 cells per case after Ki-67 labeling, by combining a mean of 11 core-cut sections per subject. They did not find any significant difference in pre- and posttreatment Ki-67 labeling indices (17).

OCCULT IEN AND BREAST CANCER RISK

The concept of epithelial sampling to define breast cancer risk was pioneered by Petrakis and colleagues, who published a series of reports through the 1970s to the present, characterizing nipple fluid yield and cytologic findings in healthy women. In two cohorts studied by this group, NAF yield varied considerably (85% for the first cohort and 40% for the second) (18). In the first cohort, women who produced NAF and had cytological evidence of hyperplasia developed breast cancer at a 2.5-fold higher rate (95% CI, 1.1–5.5), which increased to 4.9-fold (95% CI, 1.7–13.9) when cytologic atypia was present (Fig. 19-3). Women who did not produce NAF were the reference group. In the second cohort, accrued between 1981 and 1991, the relative risk was 2.0 (95% CI, 1.3–3.3) for the hyperplasia and atypical hyperplasia groups combined, as no cancers occurred in the 22 women with atypical hyperplasia. There are no long-term follow-up studies of women who have undergone ductal lavage.

The notion that occult IEN exists in high risk women and can be identified through random needle sampling techniques was substantiated by findings from a study of rFNA performed by Fabian et al., in 486 high risk women (median 5-year Gail model estimate of 4%), followed for a median of 45 months after rFNA, showed that evidence of hyperplasia with atypia on random FNA equates with an increased short-term risk of breast cancer (see Fig. 19-3). Hyperplasia with atypia was present in the initial FNA in 21% of women, and was predictive of the probability of developing breast cancer independent of a 10-year Gail risk. Good separation of cumulative 3-year breast cancer incidence rates was achieved by using a combination of Gail risk and rFNA atypia: women with both an above-median Gail risk and hyperplasia with atypia on rFNA had an incidence rate of 15%, those with only an above-median Gail risk had a 3-year incidence of 4%, and those with a below-median Gail risk had no cancers detected in the first 3 years of follow-up. These findings have yet to be validated in a multi-institutional setting.

Practical Utility of Identifying IEN

The identification of occult IEN remains, for the moment, in the realm of clinical research, as both of the long-term studies demonstrating the value of occult IEN for breast cancer risk prediction (NAF and rFNA) came from single institutions and have not been replicated. Further, these institutions have the benefit of highly developed cytological expertise, an important issue because the reproducibility of cytological assessment of these minimal samples is problematic. For women whose risk estimate would be changed by a finding of occult atypia, data regarding the decision-making value of this information are beginning to appear. Although several studies have reported that a low fraction of risk-eligible women accept tamoxifen therapy, an analysis of accrual patterns to the Breast Cancer Prevention Trial and the STAR trial (Study of Tamoxifen and Raloxifene) show that 36% of women with a history of atypical IEN were willing to participate, compared to 21% of those without a history of breast IEN. Data from Northwestern University shows a similar trend for acceptance of prophylactic tamoxifen, in that the acceptance rate in 68 high risk women who were offered tamoxifen because of a history of atypical IEN was 53%, compared to 29% of 65 women who were high risk for other reasons. (p = .008). Furthermore, among 99 high risk women who underwent rFNA, 50% of those with atypical findings accepted tamoxifen therapy (19).

BIOMARKER EVALUATION IN BREAST EPITHELIAL SAMPLES

Biomarker assessment in breast epithelial samples can potentially add precision to risk estimation as discussed-earlier; however, the validation of potential risk biomarkers has proved challenging. Molecular markers of risk that have been evaluated in rFNA studies range from immunocytochemistry of proteins (such as EGFR, ER, p53), to methylation of promoter regions of tumor suppressor genes. Although these biomarkers are significantly related to features such as epithelial atypia and obesity, there is no validated biomarker panel that can be used to improve precision of risk estimation beyond what is achieved with the identification of IEN.

The reversibility of biomarkers in short-term Phase 2/3 studies of chemopreventive intervention has not been demonstrated so far, although attempts have been made, using surrogate endpoints related to cell morphology and biomarker expression in rFNA samples (16). In single arm studies with letrozole as the intervention in postmenopausal women, and flaxseed isoflavones in premenopausal women, Ki-67 labeling did decrease significantly in the posttreatment samples, but the lack of an untreated control arm renders interpretation difficult (20). Nevertheless, Ki-67 labeling is a promising intermediate endpoint based on its validation in neoadjuvant breast cancer therapy trials, where posttreatment Ki-67 is a strong independent predictor of clinical outcomes.

ESTIMATION OF RISK FOR SPORADIC BREAST CANCER

Breast cancer risk estimation has acquired a practical importance with the availability of proven methods of surveillance and risk reduction, which are logically targeted to high risk women. As discussed earlier, epidemiological investigations over the past half-century defined a number of breast cancer risk factors, and numerical estimation of group or individual breast cancer risk has become possible through the development of statistical models which incorporate these risk factors. The first of these was developed by Gail and colleagues, who used data collected during the Breast Cancer Detection and Demonstration Project, and combined several known risk factors: age at menarche, age at first full-term pregnancy, number of first degree relatives with breast cancer, number of surgical breast biopsies, and whether or not the biopsy showed atypical hyperplasia. Specific probability estimates were then calculated using age- and race-specific frequencies of breast cancer in the population, recognizing that uncertainty was greater in non-European women because baseline data were not as robust. This model (available at http://www.cancer.gov/bcrisktool/) has been validated prospectively (21), and risk assessment using statistical models has been adopted as a standard clinical tool.

Although use of the Gail model has led to precise prediction of rates of breast cancer occurrence in groups of women (3) (i.e., it is well calibrated for populations), the ability to identify individual women who will develop breast cancer (i.e., its discriminatory ability) remains poor. The discriminatory ability of a model is measured by the concordance statistic, which is equivalent to the area under the curve (AUC) in a receiver-operator curve (ROC) analysis, and examines the sensitivity and specificity of a given test at different thresholds. Thus, the concordance statistic, or AUC, measures the overall accuracy of the model, and for a perfect model should approach 1.0, whereas for a useful model should be 0.8 or greater. A concordance statistic of 0.5 would imply a model that predicts as well as chance (e.g., flipping a coin). The concordance statistic for the Gail model in the Nurses Health Study was 0.58 (95% CI, 0.56–0.60). Only 3.3% of women who developed breast cancer in the Nurses cohort had a risk above the threshold recommended for preventive intervention with tamoxifen (22). In addition, the model overestimates risk in young, unscreened women and underestimates risk in women over 59 years of age. Well established sources of risk, such as mammographic density, body mass index, and use of hormone replacement therapy are not included. Finally, it is a model that is well calibrated for sporadic breast cancer risk but does not address important attributes of family history associated with inherited susceptibility syndromes, (age at onset, bilaterality of cancer, affected second degree relatives, and history of ovarian cancer).

More recently, several other models have been developed that attempt to incorporate features of breast cancer risk applicable to both the genetic and the environmental/endocrine components. The Tyrer-Cusick model (4) incorporates a number of endocrine risk factors including age at menopause and use of hormones for postmenopausal women, height, weight, and a family history that includes information on extended family, age at onset, and ovarian cancer information (available at http://www.ems-trials.org/riskevaluator/). The model calculates personal risk over 10 years and life-time (presented in comparison to population risk); and computes the probability of BRCA 1 and 2 mutations. In the IBIS-I trial, the number of observed cancers did not differ significantly from the number predicted (23); and in a separate high risk cohort studied by Amir et al. in Manchester, the model had a discriminatory accuracy of 0.762, compared to 0.735 for the Gail model. Prospective validation is expected from the IBIS-II trial, where high risk postmenopausal women are being randomized to anastrozole or placebo, but existing data suggest that the model performs better than the Gail in populations with strong familial risk, where the IBIS model showed better discrimination (AUC = 69.5%, CI = 63.8%–75.2%) than did the Gail model (AUC = 63.2%, CI = 57.6%–68.9%) (24). However, among women with atypical hyperplasia or lobular carcinoma *in situ*, the IBIS model performs poorly, with significant overestimation of breast cancer risk (25).

Adding Mammographic Density

Given the strong impact of mammographic density on breast cancer risk, efforts are under way to incorporate this important risk factor into predictive models. Gail et al. have incorporated mammographic density data on 7,500 women from the national cancer detection demonstration project (NCDDP) into the GAIL-2 model, and have found that their new model remains well calibrated in a set of 1,744 white women, with a modest increase in discriminatory power. The average age-specific concordance was 0.643 for the new model, in comparison with 0.596, for Gail model 2 (26). A second model including mammographic density has been developed by Barlow and colleagues using data from the Breast Cancer Surveillance Consortium. For premenopausal women, significant risk factors included age, breast density, a positive family history of breast cancer, and a prior breast procedure. The fitted model had a concordance statistic of 0.631 (95% CI = 0.618–0.644), compared to 0.607 (95% CI = 0.592–0.621) when breast density was excluded. For postmenopausal women, the c statistic for the overall model was 0.624 (95% CI = 0.619–0.630). When breast density was

excluded, the c statistic decreased to 0.605 (95% CI = 0.600–0.611). Mammographic density has also been added to the Gail model in a post-hoc analysis of the Study of Tamoxifen and Raloxifene (STAR) and resulted in minimal improvement in prediction accuracy (27). The addition of mammographic density, therefore, seems to improve risk estimation modestly at best, suggesting that mammographic density has substantial overlap with risk factors that are largely already included in the Gail model.

Risk Estimation for African American Women

The Gail model/NCI risk assessment tool underestimates risk in women of African ancestry. A modification of the Gail model has been developed by Gail et al. using 1,600 AA case-control pairs from the Women's Contraceptive and Reproductive Experiences (CARE) Study (28). Five-year breast cancer risk estimates from the CARE model and the NCI Breast Cancer Risk Assessment Tool show good agreement in younger women, but estimates for older women (over 45 years) are higher with the CARE model. The calibration of the CARE model was tested in the 14,059 African American women who entered womens' health initiative (WHI) without a prior history of breast cancer, 350 of whom developed invasive breast cancer over a mean 7-year follow-up period. The number of women predicted to develop breast cancer with the CARE model (323) was not significantly different from the number observed, with an observed-to-predicted ratio of O/E = 1.08 (95% CI = 0.97–1.20). This held up for most categories, with the exception of women with a prior history of benign breast biopsy, where the O/E was significantly lower than observed, indicating underestimation of the breast cancer risk. For women who had one benign breast biopsy and for those who had two or more biopsy examinations the rates were 1.51 (95% CI =1.20–1.92) and 1.65 (95% CI = 1.16–2.35), respectively. Among screenees for the STAR trial, the models agreed for 83% of the AA women screened, but 14.5% of women were risk eligible for the trial when screened with the NCI Breast Cancer Risk Assessment Tool, compared to 30.3% with the CARE model.

Estimation of Risk by Hormone Receptor Status

For the implementation of targeted risk reduction with selective estrogen receptor modulators (SERMs) such as tamoxifen, which are effective only in the prevention of estrogen receptor (ER) positive breast cancer, the identification of women specifically at risk for ER positive disease is highly desirable. For women with a prior history of breast cancer, the hormone receptor status of the first primary tumor may predict that of a future second primary, as evidenced in a pooled analysis of contralateral breast cancers observed in national surgical breast & bowel project (NSABP) treatment trials (29). Among women who had not received tamoxifen, there was strong concordance between the ER status of the first and second primary cancers: 89% of those with an ER positive primary cancer had an ER positive contralateral breast cancer and 70% with an ER negative primary breast cancer had an ER-negative contralateral breast cancer (or, for the association between primary and contralateral ER status = 14.8, 95% CI 3.8–74.3). In a subsequent study by Arpino and colleagues from the Baylor College of Medicine, the ER concordance between first and second primaries was 88% when the first primary was ER positive; but when the first primary was ER negative, only 25% of women developed an ER negative second primary. Among patients who received tamoxifen, both studies showed that the ER status of the second primary was not predicted by that of the first primary. A subsequent study based on surveillance, epidemiology and end-Results (SEER) data provides further confirmation of the similarity in hormone receptor status of first and second breast primary tumors, which is particularly strong among young women with ER negative index primaries, possibly reflecting the inclusion of women with BRCA1 mutations (30).

Among unaffected women, there are modest positive associations between the risk for ER positive disease and European ancestry, postmenopausal obesity, and post menopausal hormone therapy. High serum hormone levels have also been associated with the risk of ER positive breast cancer in several studies, but in a nested case-control study within the EPIC (European Prospective Investigation into Cancer and Nutrition) cohort, sex steroid hormones were associated with increased risks of hormone receptor positive and hormone receptor negative breast cancer. The risk of ER+PR+ breast cancer was significantly increased by about threefold for highest versus lowest tertile of estradiol and twofold for similar categories of testosterone. The risk of ER-PR- breast cancer was similarly significantly increased, twofold for both estradiol and testosterone (31). In the Women's Health Initiative cohort the discriminatory accuracy of the Gail model was 0.58 overall (95% CI, 0.56–0.60), but was slightly better for women who developed ER positive breast cancer (0.60, 95% CI, 0.58–0.62). For the prediction of ER negative breast cancer, the model performed no better than chance (32). The AUC for the Gail model in the WHI is seen in Figure 19-4. Thus, with the possible exception of an ER positive first primary tumor, there is no indicator of risk for ER positive breast cancer that is specific enough to select women for endocrine prevention strategies on this basis.

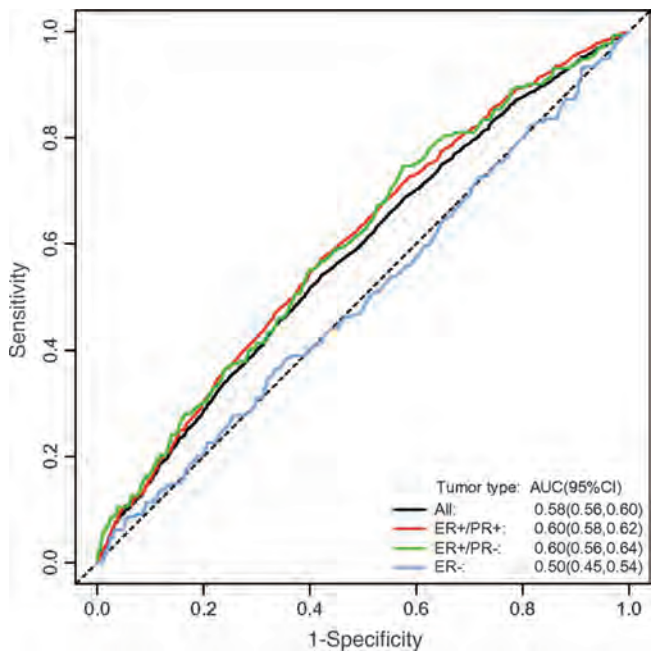

FIGURE 19-4 Receiver operating characteristic analysis and corresponding area under the curve (AUC) statistics for Gail model of prediction of invasive breast cancer risk by receptor status evaluated on the Women's Health Initiative clinical trial cohort. ER, estrogen receptor; PR, progesterone receptor; CI, confidence interval. (From Chlebowski RT, Anderson GL, Lane DS, et al. Predicting risk of breast cancer in postmenopausal women by hormone receptor status. *J Natl Cancer Inst* 2007;99(22):1695–1705, Oxford University Press.)

MANAGEMENT OF WOMEN AT HIGHER THAN AVERAGE RISK

Once a woman has been determined to be at high risk but is not a mutation carrier, the management issues to be considered include counseling regarding life-style factors that may modify risk, surveillance for early detection of breast cancer, and pharmacologic interventions to reduce risk. The discussion of prophylactic mastectomy in the non-mutation carrier should be undertaken with women who wish to explore this option, but this is best initiated by the patient rather than the physician.

Surveillance

Physical examination is the most basic form of breast cancer surveillance and remains an important part of the surveillance plan. It is generally recommended twice or thrice a year in high risk women, and can be shared between her various physicians (e.g., gynecologist, breast surgeon, internist) or may be performed by the same practitioner. In many offices, experienced physician extenders can provide this service with a high level of competence. Self examination should be encouraged, although it is of uncertain utility in the early detection of breast cancer. However, women should be encouraged to learn the topography of their own breasts so that a change is easily noted.

Annual mammography remains the mainstay of breast surveillance, although its relatively poor performance in young, high risk women has led to the evaluation of other imaging modalities: whole breast ultrasound (WBUS) and magnetic resonance imaging (MRI). The evidence for WBUS utility in surveillance of women with dense breasts is accumulating, and several studies have shown that screening with WBUS increases cancer yield by 3–4 per 1,000 screens in women with dense breasts. The American College of Radiology Imaging Network (ACRIN) 6666 protocol randomized 2,659 women with dense breasts and at least one other risk factor to either WBUS first or mammogram first, performed by different study radiologists who were blinded to the results of the other test. WBUS detected 4.3 cancers per 1,000 screens that were not seen on mammogram, 80% of which were invasive. Among incidence screens in years two and three, the sensitivity of mammography plus ultrasound was 0.76 (95% CI, 0.65–0.85), significantly higher than for mammography alone (0.52; 95% CI, 0.40–0.64), but with significantly lower specificity (0.84; versus 0.91) (33).

The addition of breast MRI to mammography and US in the surveillance of high risk women has been evaluated in several studies and there is good consensus that it adds to the effectiveness of breast surveillance for women with BRCA mutations and those with a high probability of being mutation carriers (see Chapters 13 and 17). In 2007, the American Cancer Society published guidelines for the incorporation of breast MRI in the surveillance regimen of women at increased risk of breast cancer *based on family history* (34), recommending surveillance MRI for women who have a life-time breast cancer risk of 20% to 25% as estimated with BRCAPRO or other models that largely utilize family history (i.e., *not* the Gail model). In a study of 687 women with high risk family history (1/3 mutation carriers and 2/3 with BRCAPRO lifetime risk of >20%) Kuhl et al. have compared the yield of MRI, mammography, and ultrasound. They document a cancer yield of about 15 per 1,000 screens for MRI, compared to 5 to 6 for mammography alone and ultrasonography alone (35). Of note, there were no interval cancers in the 2.5 years of follow-up, and MRI alone performed as well as MRI in combination with other modalities, raising the question of whether other screening tests can be dropped when MRI is used in this population.

However, the addition of MRI to the surveillance regimen of women at risk for sporadic breast cancer is still controversial. The expense of MRI and the burden of multiple repeat imaging examinations and biopsies generated needs to be considered along with the lack of evidence that MRI utilization in these populations improves survival or other cancer-related outcomes. The American Cancer Society and the national comprehensive cancer network (NCCN) guidelines are in agreement that there is not sufficient evidence to recommend use of MRI in women with high risk epithelial lesions.

RISK REDUCING INTERVENTIONS

Modifiable Breast Cancer Risk Factors

Despite the vast amount of information available on features that may increase the risk of developing breast cancer, few of these are modifiable, and, therefore, most cannot be exploited for breast cancer risk reduction. Of those that are modifiable, high life-time physical activity is associated with a lower risk of breast cancer; during adolescence, physical activity is associated with delayed menarche and delay in the establishment of regular ovulatory cycles. Later in life, a beneficial effect of physical activity has been observed in several recent studies. Postmenopausal obesity, too, should be modifiable, and high risk women who are obese should be directed toward weight control, as the combination of increased physical activity and caloric restriction are likely to have salutary effects not only on breast cancer risk, but on overall health. Among the reproductive risk factors, lactation appears to be protective against breast cancer. Women who accumulate a life-time exposure to lactation of at least 15 months have a lower risk for breast cancer after adjusting for other risk factors. Every 12-month period of lactation decreases risk by 4.3%, as estimated in a meta-analysis of over 50,000 breast cancer cases and 100,000 controls from 30 countries. The relative benefit of lactation was homogeneous across countries. Women of child-bearing age should, therefore, be encouraged to nurse their children for as long a period as feasible.

Alcohol use is clearly modifiable, although there does not appear to be any difference in risk according to timing of alcohol consumption during early, middle or late adulthood, and there is no clear evidence that a decrease in alcohol use later in life will reduce breast cancer risk. Nevertheless, as in recommendations for diet, weight control, and physical activity, advice regarding moderation of alcohol use is generally well placed. There is evidence for an interaction between menopausal hormone use and alcohol use, so that women who consume two or more drinks daily and also use hormones are at higher risk than those exposed to either factor alone (36). Thus, women on postmenopausal hormones should be particularly cautioned against regular alcohol use.

It is not clear whether mammographic density is modifiable through life-style changes. There is clearly a large genetic component to the determinants of mammographic density, as discussed previously. In contrast, the impact of dietary restriction or physical activity has been difficult to demonstrate conclusively. In a study of a low fat dietary intervention, no change in breast density was observed (37), and there are no specific dietary patterns associated with high density. A recent systemic review of 20 studies did not identify a significant association between physical activity and mammographic density (38). However, breast density decrease with pharmacologic intervention (tamoxifen) was

associated with tamoxifen benefit in the IBIS trial (9), suggesting that with some preventive interventions, this may be a useful surrogate endpoint of benefit.

Current users of combination postmenopausal hormone therapy clearly experience an increased risk of breast cancer (39). The risk elevation appears to dissipate once hormone use is discontinued, and, therefore, high risk women should be advised to abstain from use of combination hormone therapy except for the control of menopausal symptoms, and then to use these in the lowest effective dose for the shortest possible time. In addition, it is reasonable to target hormone replacement to specific symptoms: for example, for vaginal dryness, low dose vaginal estrogen replacement results in a far lower systemic exposure than oral therapy. Data from the WHI suggest that use of estradiol alone in hysterectomized women does not increase risk (40); this hypothesis needs further testing and is somewhat at odds with the results of cohort studies which showed a lower risk for estradiol alone than combination therapy, but risk was still higher than among non-users of postmenopausal hormones. Therefore, symptomatic postmenopausal women may use estradiol alone if they have undergone hysterectomy, but use in the absence of symptoms should still be discouraged.

Pharmacological Intervention

The clinical trials of breast cancer prevention are discussed fully, and referenced, in Chapter 20; the following discussion focuses on selection criteria that may guide use of specific medications based on risk profile and patient characteristics. Strong Level I evidence now supports the use of SERMs, and aromatase inhibitors (AIs) for primary prevention in healthy, high risk women. The landmark Breast Cancer Prevention Trial (BCPT) of the NSABP study led to the establishment of tamoxifen, the prototypic SERM, as a method to reduce risk of breast cancer in women, a finding confirmed by the IBIS-I trial. The equivalence of tamoxifen to the second generation SERM raloxifene (in postmenopausal women only) was established in the STAR (P-2) trial of the NSABP. The third generation of breast cancer prevention trials in postmenopausal women has demonstrated that two newer SERMs (lasofoxifene and arzoxifene) offer similar breast cancer risk reduction in postmenopausal women, with beneficial effects on bone, and for arzoxifene, similar thromboembolic risk (see Chapter 20 for full discussion). Finally, aromatase inhibitors have entered the primary prevention arena, with publication of early results of exemestane therapy in the MAP.3 trial. Recruitment to the IBIS-II trial (testing anastrozole against placebo) is now closed, and follow-up is ongoing.

SERMs

Tamoxifen remains the standard of care for premenopausal women who are risk eligible for pharmacologic prevention, with a low risk of significant adverse effects. It should also be considered in hysterectomized postmenopausal women because of the slightly greater efficacy seen in the 8-year follow-up publication of the STAR trial (41). The benefits of tamoxifen, therefore, include a one-half to one-third reduction in the risk of invasive breast cancer; a similar reduction in the risk of non-invasive breast cancer; a one-third reduction in the risk of new benign breast biopsies; a reduction in mammographic density; and a reduction in osteoporotic fractures (seen in the BCPT only with a significant 32% reduction in osteoporotic fractures) (41). Women who are high risk because of a history of atypical hyperplasia appear to derive a larger benefit from tamoxifen therapy, with a risk reduction of 46% (41). These women also seem to be more willing to accept recommendations for preventive medication; therefore, this discussion should be included in the management plan for all women with a biopsy diagnosis of atypical hyperplasia. At-risk women can also be reassured that the benefit of tamoxifen is long-lived, judging from the overview data reported by the Early Breast Cancer Trialists' Group, where incidence rates remain lower in women who used five years of tamoxifen therapy, going out to 15 years and confirmed by the long-term results of the IBIS-I trial, where the reduction in breast cancer incidence in the tamoxifen arm is maintained to the same degree or better in the second five-year period following cessation of tamoxifen therapy (42).

The possibility that the standard 20 mg dose of tamoxifen is not required for therapeutic efficacy has been considered by Decensi and colleagues in a series of studies (43) designed to examine the effect of dose reductions of tamoxifen. In a pre-surgical study of women with ER positive invasive breast cancer, a daily dose of 20 mg was compared to doses of 5 mg and 1 mg. There was equivalent reduction in tumor cell proliferation in all three groups, and serum biomarkers such as sex hormone binding globulin, fibrinogen, anti-thrombin III, and decreases in insulin-like growth factor showed a significant dose-response relationship, suggesting potentially lower for toxicity at lower doses. A Phase III trial in healthy postmenopausal women has completed accrual.

Post-menopausal women with an intact uterus should be offered raloxifene because the uterine toxicity of tamoxifen seen in the BCPT has not been observed with raloxifene. An apparently lower protective benefit against DCIS in the initial publication was less evident on longer follow-up (44). For the hysterectomized postmenopausal woman, the decision between tamoxifen and raloxifene would be a trade-off between the generally better tolerability of raloxifene and the somewhat better efficacy of tamoxifen.

Although it would be desirable to select women who are specifically at high risk for ER positive breast cancer for SERM therapy, at this time there is no basis for denying a woman tamoxifen therapy because of a predicted risk of ER negative disease, with the possible exception of breast cancer survivors with ER negative index primaries. Data from a subset analysis of the multiple outcomes for raloxifene (MORE) trial suggested that women with the highest quartile of serum estradiol levels were at highest risk and also derived the greatest benefit from raloxifene therapy (45). But a similar subset analysis by NSABP investigators showed no difference in breast cancer risk of BCPT participants by estradiol levels, and no differential benefit of tamoxifen therapy (46).

Toxicity of SERMS: The uptake of tamoxifen therapy among high risk women has been highly variable, with concerns about toxicity being widely discussed and publicized. Because tamoxifen is now being mainly used in premenopausal women, it should be noted that the risk of tamoxifen-induced uterine neoplasia increases with age, with prior use of postmenopausal hormone therapy, with BMI, and with increasing duration of tamoxifen use (particularly over 5 years). In the BCPT, women aged 49 years or younger experienced a non-significant excess of uterine cancer (RR = 1.42, 95% CI = 0.55–3.81); uterine safety is, therefore, a relatively minor concern in this age group. In contrast, there was a substantially higher frequency of uterine malignancy in older women (RR = 5.33, 95% CI = 2.47–13.17). Annual uterine surveillance with Papanicolaou smears and pelvic examination is, therefore, recommended for women with intact uteri who are using tamoxifen, with additional testing (transvaginal ultrasound, uterine biopsies) reserved for those with symptoms such as uterine bleeding or abnormalities on clinical surveillance.

The risk of thromboembolic disease (TED) associated with tamoxifen is increased approximately twofold, but, again, was observed mainly in older women (IBIS-I, NSABP P-1). With raloxifene, the risk of deep vein thrombosis and pulmonary embolism may be lower than with tamoxifen but the risk of stroke and transient ischemic attacks is similar. Subgroups of women who should not be offered SERM therapy include obese women, those with recent surgery, fracture, or immobilization who are at increased risk of thrombotic events. Data on the added risk associated with Factor V Leiden or prothrombin G20210→A (PT20210) mutations are mixed (47). Notably, thromboembolic events occur early in the course of treatment, and these predict a continued higher risk. Thus, increased risk of TED needs to be factored into the SERM therapy decision by women who have risk factors for it (i.e., overweight, smokers, wheelchair-confined), and it seems reasonable to advise women on tamoxifen therapy to discontinue use approximately two weeks prior to major surgery, but screening women who are SERM candidates for factor V Leiden or thrombin mutations is not warranted.

The risk-benefit balance of SERM therapy in postmenopausal women has been nicely synthesized by Freedman and colleagues in an analysis of pooled data from the BCPT, the STAR trial, and the Women's Health Initiative; this is presented in Figure 19-5. It is worth emphasizing that the toxicity of tamoxifen in women under 50 is low: the risk of uterine malignancy is essentially unchanged, and the risk of deep vein thrombosis is increased about twofold, but normalizes rapidly once the drug is discontinued (48).

The quality of life side effects such as hot flashes and vaginal symptoms as well as the perceived association of tamoxifen use with weight gain and depressive symptoms has resulted in low rates of tamoxifen acceptance by both pre- and postmenopausal women who are risk-eligible for tamoxifen. Discussion of the management options for these at the time when SERM use is recommended is helpful and can increase uptake of therapy. The use of low dose vaginal estradiol supplements (either estradiol coated rings, or low dose estradiol tablets) for vaginal symptoms has not been formally evaluated in relation to breast cancer risk, but is reasonable in women with vaginal symptoms as the systemic estrogen exposure with these preparations is extremely low and unlike estrogen-containing vaginal creams, serum estradiol levels are not affected. The alleviation of hot flashes with selective serotonin uptake inhibitors is helpful for many women on tamoxifen therapy but recent data regarding the deleterious effects of some of these compounds on CYP2D6 activity and, therefore, the formation of the active tamoxifen metabolites endoxifen and 4-hydoxytamoxifen suggest that selective serotonin reuptake inhibitors (SSRI) agents should be selected based on lack of CYP2D6 antagonism. Gabapentin is an alternative agent in women with severe hot flashes. The concomitant use of postmenopausal hormone therapy does not appear to alleviate hot flashes and data from the Italian and Marsden trials where hormone therapy was allowed, suggests that this interferes with the benefit of tamoxifen therapy. Additionally (although there are no specific data to this effect) one would worry that the uterine and thromboembolic toxicity of SERMs would increase if SERMS were combined with estrogen with or without progestins.

Aromatase Inhibitors

Aromatase inhibitors are the second group of breast cancer prevention agents, with data from therapy trials suggesting an improved benefit over tamoxifen in risk reduction for contralateral breast cancer, and early results from the MAP3 trial showing efficacy of exemestane for primary prevention of breast cancer in high risk postmenopausal women. Results from the IBIS II trial (testing anastrozole) should be available in the next several years, and additional data regarding the impact of anastrozole on contralateral breast events in women with DCIS is anticipated from the NSABP B-35 and IBIS II trials. For postmenopausal women with an intact uterus, or those with a history of (or risk factors for) thromboembolic disease, aromatase inhibitors are clearly an option. Although they are generally well tolerated, the musculoskeletal morbidity can be significant, and SERM therapy may be a better choice for women with musculoskeletal pain syndromes or osteopenia/osteoporosis. Longer follow-up of MAP.3 and maturation of IBIS II data will provide better information regarding the risk-benefit balance of these agents in healthy women (particularly the frequency of arthralgias, bone loss, fractures, loss of libido, vaginal dryness, and cardiovascular safety). At present, the use of AIs for primary prevention should be restricted to those women who are at significant risk (e.g., those with a history of LCIS) and have a contraindication to SERM therapy (e.g., a history of deep vein thrombosis). AIs may also be considered for primary prevention in women who have completed SERM therapy for breast cancer prophylaxi but continue to develop new atypical lesions of the breast.

Risk-Reducing Mastectomy

For selected women at high risk for breast cancer who are either not good candidates for pharmacologic risk reduction, or are highly motivated to reduce risk to the lowest level possible, prophylactic mastectomy may be a reasonable consideration. Indications for risk-reducing mastectomy have been outlined by the Society of Surgical Oncology (49), and include i) mutations in BRCA 1 and 2 or other genetic susceptibility genes; ii) strong family history with no demonstrable mutation; iii) histological risk factors; and iv) difficult surveillance. In the setting of a strong family history, genetic evaluation should be strongly encouraged; the identification of a cancer-causing mutation in the family will mean that individuals who test negative can be reassured that they are population risk. If a mutation cannot be identified following testing of the appropriate affected individuals in the family, mutations in as yet unidentified genes may be responsible and, after appropriate counseling, prophylactic mastectomy can be undertaken. The family history pattern in this setting would be similar to BRCA mutation families (early age of onset, at least two generations involved). Women with histological risk factors (atypical hyperplasia, LCIS) should first be given a full explanation of the risks and benefits of SERM therapy for chemoprevention as this subset derives a particularly large benefit from it. Prophylactic mastectomy in this setting should be reserved for women who have contraindications to SERM therapy, or are unwilling to take it and yet seek a substantial reduction in breast cancer risk. With the advent of MRI and ultrasound imaging, difficult surveillance should be an unusual indication for prophylactic mastectomy.

The option of risk-reducing mastectomy with nipple preservation has received attention recently, with several reported series showing that the procedure is feasible, with survival of the nipple-areolar complex in about 95% of women. However, the long-term safety of this procedure is not fully established, and bearing in mind the known possibility of new primary breast cancer following subcutaneous mastectomy (50), meticulous attention needs to be paid to complete resection of breast tissue (including the axillary tail) if this procedure is undertaken for risk reduction.

Blue: strong evidence of benefits outweighing risks **Yellow: moderate evidence of benefits outweighing risks**
Grey: benefits do not outweigh risks

FIGURE 19-5 Benefit/risk indices for tamoxifen and raloxifene chemoprevention by level of 5-year projected risk for invasive breast cancer (IBC) by age group. The upper panels show estimates for white, non-Hispanic women (**A:** uterus intact and **B:** without uterus); the lower panels show estimates for African American women (**C:** uterus intact, **D:** without uterus). Based on a woman's risk factors (age, ethnicity, breast cancer risk, and whether she has a uterus), one can calculate her probability of having a health event in 5 years in the absence or presence of preventive therapy. To summarize risks and benefits in a single index, Vogel et al. assigned weights of 1.0 for life-threatening events (IBC, hip fracture, endometrial cancer, stroke, and pulmonary embolism) and 0.5 for severe events (*in situ* breast cancer and deep vein thrombosis). The net benefit index is the expected number of life-threatening equivalent events in 5 years without SERM therapy in 10,000 such women minus the expected number of life-threatening equivalent events if SERM therapy is used. (A severe event is regarded as equivalent to half a life-threatening event). For example, in Panel A, among 10,000 non-Hispanic, white women with a uterus, age 50 to 59 years, and with a 5-year IBC risk of 3.5%, one expects that 108 life-threatening equivalent events would be prevented in 5 years by taking raloxifene instead of placebo, and there is strong evidence (*P* .9; blue) that the benefits of taking raloxifene outweigh the risks. If tamoxifen were used instead, we estimate chemoprevention would result in 25 excess life-threatening events (*P* .6, gray). BCPT, Breast Cancer Prevention Trial; WHI, Women's Health Initiative; RR, relative risk; STAR, Study of Tamoxifen and Raloxifene.

MANAGEMENT SUMMARY

- Women at risk for sporadic breast cancer are a heterogeneous population and include those with endocrine and life-style risk factors, proliferative breast disease, and lesser degrees of family history.
- Breast cancer risk can be quantitated using a variety of statistical models, which perform well in general for groups of women but lack discriminatory power for individuals.
- The degree of improved precision resulting from the addition of mammographic density measurements to existing models is modest.
- Minimally invasive techniques to sample breast epithelium and identify occult epithelial atypia remain investigational at present.
- Women at increased risk should be counseled about modifiable risk factors: long-term lactation by women in child-bearing age, regular physical activity, the avoidance of more than light alcohol use, avoidance of postmenopausal weight gain, the limitation of postmenopausal hormone use to the alleviation of symptoms with lowest possible dose for the shortest possible time.
- Surveillance for this group of patients includes annual mammography, directed ultrasound, and magnetic resonance imaging for those with lifetime risk of 20% or greater, calculated using models based on family history (after a full discussion of risks and benefits, including the likely need for additional imaging and biopsies). Data regarding potential benefits of MRI surveillance for women with mammographically dense breasts and atypical epithelial lesions is being accumulated in ongoing trials.
- Pharmacologic intervention to reduce breast cancer risk consists of tamoxifen for premenopausal women, and raloxifene or exemestane for postmenopausal women. Hysterectomized, postmenopausal women, particularly those with musculoskeletal concerns, should be given the option of tamoxifen therapy, with a discussion of the marginally better preventive efficacy of tamoxifen compared to raloxifene.
- Prophylactic mastectomy should be reserved for those at markedly increased life-time risk (e.g., 30% or greater) who are unable or unwilling to take risk-reducing medication, and seek prophylactic mastectomy as a way to manage their risk.

CHAPTER 20

Chemoprevention

Michelle I. Savage and Powel H. Brown

CHAPTER CONTENTS

INTRODUCTION

Breast cancers represent the highest proportion of noncutaneous cancer in women in the United States. Current estimates predict more than 226,000 diagnoses of breast cancer in these women, resulting in 39,000 deaths in 2012 alone (1). Critical insights have been and continue to be established in breast carcinogenesis, resulting in strategies enabling more effective screening, risk assessment, risk reduction, and intervention.

Screening methods, such as digital mammography and breast MRI scans, are now routine, with standard practice including annual mammographic screening for all women beginning at age 40 (2) and annual MRI scans gaining in use for women at very high risk. Other tests not yet routine but gaining in use include breast ultrasound and tomography analyses.

Effective prevention of breast cancer is critically dependent upon the identification of high-risk patients and has been more thoroughly developed than other cancers. Classification of individuals at high risk based upon known risk factors and biomarkers specific for breast cancer (e.g., obesity, alcohol consumption, *BRCA1/2, TP53, PTEN*, mammographic breast density, family history, and endocrine-related risks, such as lack of children and early menarche) facilitates the identification of women most likely to benefit from early intervention. This enables targeted chemoprevention specifically within higher risk populations, maximizing the potential for effective prevention. To this end, models aimed at assessing risk have been developed and continue to be the focus of studies seeking to further improve their effectiveness at predicting breast cancer risk. These include the Gail, Tyrer-Cuzick ("IBIS"), Berry-Parmigiani-Aguilar (*BRCA*-Pro), Claus, and Couch models as well as the Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm (BOADICEA) (3,4). Each of these models was developed to facilitate stratification of the population into categories of predictable risk, defining individuals at low, average, moderate, high and very high risk, thereby enabling the identification of those most likely to benefit from preventive therapies.

In addition to screening and risk assessment, recent advances in breast carcinogenesis research have led to more effective strategies for risk reduction. Prophylactic bilateral mastectomies, which have demonstrated a 90% reduction of breast cancer risk, are currently used as an aggressive strategy for primary breast cancer prevention among extremely high-risk women (e.g., *BRCA1/2* carriers) (5). However, breast cancer prevention incorporates both less aggressive strategies designed for the general population (e.g., behavioral approaches reducing exposure to carcinogens such as medical radiation, limiting alcohol consumption, and maintaining a healthy weight) as well as the more aggressive risk-based approaches (e.g., preventive therapeutics, bilateral mastectomy, and possibly vaccines). Today, primary breast cancer prevention efforts integrate these strategies, centering on reducing exposure to known carcinogens and exogenous estrogen in combination with behavioral strategies to reduce risk. The remaining prevention strategies are used in high-risk groups, including preventive therapies approved by the FDA (e.g., tamoxifen and raloxifene), surgical strategies (bilateral mastectomies), and additional interventions, such as novel drugs and vaccines currently being tested in clinical trials.

Chemoprevention provides the means to reduce breast cancer incidence and is the current focus of a broad range of studies investigating the therapeutic potential of natural and synthetic agents for the prevention of breast cancer. However, as breast cancer encompasses both estrogen receptor (ER)-positive and ER-negative subtypes, distinct chemopreventive strategies may be required for effective intervention. This requires the evaluation of both short- and long-term toxicities of preventive agents to establish the individualized risk–benefit ratios.

In this chapter, we will outline the results of landmark clinical studies testing the selective estrogen receptor modulators (SERMs) tamoxifen and raloxifene that demonstrated the effectiveness of chemoprevention in breast cancer. We will also review additional studies targeting the ER for breast cancer prevention as well as strategies focused

on decreasing risk of ER-negative breast cancer. Finally, we will summarize current recommendations for management of women at increased risk of both ER-positive and ER-negative breast cancer. Strategies incorporating multiple aspects of prevention carry the highest potential for effective reduction of breast cancer incidence and mortality. Furthermore, those strategies addressing the individual patient as a whole, combining risk assessment, screening, and preventive strategies, will lay the foundation for breast cancer prevention in the future.

BREAST CANCER CHEMOPREVENTION

Antiestrogen drugs are highly effective for the treatment of breast cancer and have been shown to reduce the incidence of second primary breast cancers in women with early stage breast cancer (6,7). These results led to testing selective estrogen receptor modulators (SERMs), as well as other hormonal agents, for primary prevention of breast cancer in high-risk women.

Selective Estrogen Receptor Modulators (SERMs)

Five antiestrogen SERMs have been tested in clinical trials over the past two decades, including tamoxifen, raloxifene, idoxifene, arzoxifene, and lasofoxifene. The first-generation SERM, tamoxifen, was the first FDA-approved endocrine preventive therapy in high-risk women; the four large Phase III cancer prevention trials testing tamoxifen are outlined in Table 20-1. In addition, three Phase III studies have been conducted to determine the preventive effects of the second generation SERM, raloxifene, on breast cancer, followed by a fourth study comparing treatment with raloxifene versus tamoxifen. More recently, two Phase III studies have tested the third generation SERMs lasofoxifene and arzoxifene.

Tamoxifen

Endocrine treatment has been shown to reduce recurrence and mortality rates of ER-positive breast cancer and is able to do so in a manner independent of chemotherapy (6). The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) recently reported an updated meta-analyses for women in trials that examined the 10- to 15-year follow-up effects of 5 years of adjuvant tamoxifen (6,7). This report demonstrated that second primary breast cancers were reduced by 50% in women using tamoxifen. These studies laid the foundation for investigations focused on the development of breast cancer preventive drugs and resulted in a series of Phase III tamoxifen prevention trials in moderate-to-high-risk women with no diagnosis of breast cancer (Table 20-1). These four Phase III studies follow in chronological order and form the initial timeline for SERM-based therapeutic breast cancer prevention.

Royal Marsden Trial: Recruitment for the Royal Marsden Tamoxifen Breast Cancer Prevention Trial extended from 1986 to 1996 (8). Initially designed as a pilot trial, the primary goal was to determine the preventive effects of tamoxifen in 2,494 high-risk undiagnosed women. 20-year follow-up results identified a non-statistically significant decrease in overall (hazard ratio [HR] = 0.84, CI 0.64–1.10, p = .2) and invasive (HR = 0.78, CI 0.58–1.04, p = .005) breast cancer incidence following tamoxifen treatment (8). In addition, this study demonstrated a significant effect of tamoxifen on ER-positive (HR = 0.61, CI 0.43–0.864) but not ER-negative breast cancers.

NSABP P-1 (BCPT) Trial: The largest of the SERM breast cancer prevention trials, the National Surgical Adjuvant Breast and Bowel Project (NSABP) Breast Cancer Prevention Trial (BCPT) P-1, recruited 13,388 women from 1992–1996 (9). The effect of 5 years of tamoxifen treatment (20 mg/day, n = 6,681) on the incidence of invasive breast cancer was investigated in pre- and postmenopausal women at increased risk of breast cancer. A 49% decrease in invasive breast cancer was seen with tamoxifen versus placebo (relative risk [RR] = 0.51, CI 0.39–0.66). These initial results were reported in 1998 and led to early termination of the trial, followed by FDA approval of tamoxifen for treatment of women at high risk of breast cancer. The 7-year follow-up results confirmed the initial study findings, demonstrating reductions in invasive (RR = 0.57, CI 0.46–0.70), noninvasive (RR = 0.63, CI 0.45–0.89), ER-positive (RR = 0.38, CI 0.28–0.50), and ductal carcinoma *in situ* (DCIS) (HR = 0.54, CI 0.36–0.80) breast cancers, but no decrease in ER-negative tumor incidence (9). Although the NSABP P-1 trial also identified toxicity associated with tamoxifen, including increased hot flushes, vaginal discharge, and increased risk of endometrial cancer and thromboembolic events, the study established tamoxifen as the most effective treatment strategy for the prevention of breast cancer, particularly, ER-positive breast cancer.

Italian Tamoxifen Prevention Study: The Italian Randomized Tamoxifen Prevention Trial recruited 5,408 women at normal risk of breast cancer (10). However, to avoid the undesired side effect of increased incidence of endometrial cancer, the Italian trial limited the study population to healthy women who had previously undergone a hysterectomy. Importantly, many of these women took postmenopausal hormones after their hysterectomy. An unanticipated high subject dropout rate (26%) resulted in early termination of recruitment, but follow-up was continued with the previously enrolled subjects. While no statistically significant reduction in breast cancer incidence was initially observed, the 11-year follow-up report demonstrated a 76% reduction in hormone receptor (HR)-positive breast cancers in high-risk patients previously treated with a bilateral oophorectomy (RR = 0.24, CI 0.10–0.59), suggesting a preventive effect associated with tamoxifen (10).

IBIS-I Trial: Recruitment for the International Breast Cancer Intervention Study I breast cancer prevention trial spanned from 1992 to 2001 and resulted in the accrual of 7,154 women at high risk for breast cancer (11). With the primary objective of identifying whether the risk–benefit ratio associated with tamoxifen treatment was sufficient to support its use for the prevention of breast cancer, this study measured breast cancer incidence following 5 years of treatment with tamoxifen (20 mg/day, n = 3,578) versus placebo (n = 3,566). The 96-month follow-up report demonstrated a reduction of risk in subjects not receiving hormone replacement therapy (HRT) while on treatment that was limited to all (RR = 0.62, CI 0.46–0.83), ER-positive (RR = 0.49, CI 0.32–0.74), and DCIS (HR = 0.52, CI 0.27–0.99) breast cancer, although a non-statistically significant decrease in ER-negative breast cancer was reported. In addition, 5 years of tamoxifen treatment was associated with an improved long-term risk–benefit ratio characterized by a cancer preventive benefit persisting for 10 years and a reduction in toxicity after stopping treatment (11).

Adverse Events Associated with Tamoxifen Treatment: Across the four large-scale Phase III tamoxifen cancer prevention trials (all treating with 20 mg/day for 5 years, except the Royal Marsden Trial, which included 8 years of treatment), endometrial/uterine cancer and thromboembolic

TABLE 20-1

Selective Estrogen-Receptor Modulator (SERM) Breast Cancer Prevention Studies

	Trial	*Participants*	*Study Design*	*Reduction in Incidence*	*RR/HR (95%CI)*
TAMOXIFEN	Royal Marsden[1,2] (Recruitment: 1986–1996)	• 2,494 high-risk women • 30–70 y of age	1,238 tamoxifen (20 mg/d) and 1,233 placebo Treatment time: for 8 y	All breast cancers: 16% Invasive breast cancer: 22% Invasive ER-positive breast cancer: 39%	HR 0.84 (0.64–1.10) HR 0.78 (0.58–1.04) HR 0.61 (0.43–0.86)
	NOTE: No difference initially; longer follow-up showed reductions in invasive and ER-positive breast cancer incidence, but no significant change in ER-negative or overall breast cancer incidence				
	NSABP-P1(BCPT)[3,4] (Recruitment: 1992–1997)	• 13,388 high-risk women • >35 y of age	6,681 tamoxifen (20 mg/d) and 6,707 placebo Treatment time: 5 y Follow-up: 7 y	Invasive breast cancer: 43% Invasive ER-positive breast cancer: 62% Noninvasive DCIS/LCIS breast cancer: 37%	RR 0.57 (0.46–0.70) RR 0.38 (0.28–0.50) RR 0.63 (0.45–0.89)
	Italian[5,6] (Recruitment: 1992–1997)	• 5,408 normal-risk women with a hysterectomy • 35–70 y of age	2,700 tamoxifen (20 mg/d) and 2,708 placebo Treatment time: 5 y Follow-up: 11 y	All breast cancers: 16% Invasive breast cancer: 20% Invasive ER-positive breast cancer: –10% Noninvasive breast cancer: –50%	RR 0.84 (0.60–1.17) RR 0.80 (0.56–1.15) RR 1.10 (0.59–2.05) RR 1.50 (0.53–4.20)
	IBIS-I[7,8] (Recruitment: 1992–2001)	• 7,154 high-risk women • 35–70 y of age	3,579 tamoxifen (20 mg/d) and 3,575 placebo Treatment time: 5 y Follow-up: 96-mo	All breast cancers: 27% Invasive breast cancer: 26% Invasive ER-positive breast cancer: 34% Noninvasive DCIS breast cancer: 37%	RR 0.73 (0.58–0.91) RR 0.74 (0.58–0.94) RR 0.66 (0.50–0.87) RR 0.63 (0.32–1.20)
RALOXIFENE	MORE[9] (Recruitment: 1994–1998)	• 7,705 postmenopausal women with low BMD • <80 y of age	2,557 raloxifene (60 mg/d), 2,572 raloxifene (120 mg/d) and 2,576 placebo Treatment time: 4 y Follow-up: 40 mos avg.	All breast cancers: 65% Invasive breast cancer: 76% Invasive ER-positive breast cancer: 90%	RR 0.35 (0.21–0.58) RR 0.24 (0.13–0.44) RR 0.10 (0.04–0.24)
	CORE[10] (Recruitment: 1998–2002)	• 5,213 postmenopausal women with low BMD (reconsented from MORE trial) • <80 y of age	3,510 raloxifene (60 mg/d) and 1,703 placebo Treatment time: an additional 4 years after 4 y of raloxifene on MORE trial	All breast cancers: 50% Invasive breast cancer: 59% Invasive ER-positive breast cancer: 66% Noninvasive breast cancer: –78%	HR 0.50 (0.30–0.82) HR 0.41 (0.24–0.71) HR 0.34 (0.18–0.66) HR 1.78 (0.37–8.61)
	RUTH[11] (Recruitment: 1998–2000)	• 10,101 postmenopausal women with CHD • >35 y of age	5,044 raloxifene (60 mg/d) and 5,057 placebo Treatment time: median 5.6 y	All breast cancers: 33% Invasive breast cancer: 44% Invasive ER-positive breast cancer: 55% Noninvasive breast cancer: –117% Reduction in invasive ER-positive tumors	HR 0.67 (0.47–0.96) HR 0.56 (0.38–0.83) HR 0.45 (0.28–0.72) HR 2.17 (0.75–6.24)

TAM VS RALOX	NSABP-P2[12,13] (STAR) (Recruitment: 1999–2004)	• 19,490 high-risk, post-menopausal women • >35 y of age	9,736 tamoxifen (20 mg/d) and 9,754 raloxifene (60 mg/d) Treatment time: 5 y Follow-up: median 81-mo	*Raloxifene vs. tamoxifen:* Invasive breast cancer: –24% Noninvasive DCIS breast cancer: –22% Noninvasive DCIS/LCIS breast cancer: –2%	 RR 1.24 (1.05–1.47) RR 1.22 (0.88–1.69) RR 1.02 (0.61–1.70)

and cardiovascular events constituted the most common adverse events (8–11). Other negative side effects most consistently reported within these studies included cerebrovascular events, vaginal symptoms, and hot flushes or cold/night sweats (Table 20-2). In addition, an increase in risk of cataracts was observed in subjects receiving tamoxifen versus placebo in the NSABP P-1 (21%) and IBIS-I (0.4%, not statistically significant) trials. Most negative effects related to tamoxifen treatment did not persist beyond the active treatment period, and while long-term follow-up reports demonstrate no significant increase in total or cause-specific death, neither do they demonstrate a significant improvement in survival among subjects taking tamoxifen versus placebo (Tables 20-2 and 20-3).

Endometrial/Uterine Cancer Increased risk of endometrial cancer following treatment with tamoxifen was reported in the Royal Marsden, NSABP P-1, and IBIS-1 Trials. The first published evidence of this was in the 1998 interim analysis of the Royal Marsden study that, by the 20-year follow-up, identified a 2.5-fold increase in endometrial cancer for subjects who had received tamoxifen versus placebo (8). The NSABP P-1 and IBIS-1 Trials have also reported a 1.5- to 3.4-fold elevated risk of endometrial cancer associated with tamoxifen therapy in participants ≥50 years of age (9). The majority of all endometrial cancer cases (53 in the tamoxifen arm, 17 in the placebo arm) were classified as International Federation of Gynecology and Obstetrics (FIGO) (12) stage I.

Thromboembolic and Cardiovascular Events Primary incidences of thromboembolic and cardiovascular events consistently reported in the four trials were in increased rates of stroke and venous thromboembolic events. Strokes were 25% lower for subjects in the tamoxifen arm of the Royal Marsden Trial (8); however, the NSABP P-1 (9), IBIS-I (11), and Italian (10) trials reported non-statistically significant increased rates of stroke/cerebrovascular accidents in the tamoxifen study arm. Increased incidence of deep vein thrombosis and overall thromboembolic events was reported in the tamoxifen arms of the Royal Marsden (8), IBIS-I (11), and NSABP P-1 (9) trials.

Risk vs. Benefit: In an analysis of the risks and benefits associated with tamoxifen treatment for the prevention of breast cancer, Gail and coworkers concluded that these are dependent on the age, race, and breast cancer risk level of the individual (13). They described the increased risk for deep vein thrombosis, endometrial cancer, pulmonary embolism, and stroke, predicting 15, 16, 15, and 13, respectively, additional cases per 1,000 women following 5 years of tamoxifen treatment. In addition, differential efficacy of tamoxifen was age and race dependent, with the overall benefit defined as 97, 53, and 1 fewer cases for invasive breast cancer, *in situ* breast cancer, and hip fractures, respectively, per 1,000 women treated with tamoxifen for 5 years.

Due to the variation in risk–benefit effects and ratios for African American women versus white women, the Gail model, originally developed to predict risk in white women using the NCI's Breast Cancer Risk Assessment Tool (www.cancer.gov/bcrisktool), has been updated specifically for African American women. This risk assessment model, known as the Women's Contraceptive and Reproductive Experiences (CARE) model, more accurately predicts risk of breast cancer within this population. Finally, while tamoxifen has been shown to significantly reduce risk of invasive breast cancer by 49%, a greatly increased benefit is seen in women with prior atypical ductal hyperplasia (ADH) and lobular carcinoma *in situ* (LCIS) lesions, which exhibit relative reductions of 86% and 56%, respectively (14).

Preventive Therapy is Now Standard of Care: Collectively, the results of the tamoxifen trials, particularly the dramatic results of the NSABP P-1 breast cancer prevention trial, led to FDA approval of the SERM tamoxifen as a viable therapeutic strategy for breast cancer risk reduction. This decision, representing the first approval of a preventive agent for breast cancer risk reduction by the FDA, has led to the acceptance of tamoxifen as the standard premenopausal endocrine therapy for the prevention of breast cancer, especially ER-positive breast cancer.

In 1999, based upon the collective results of these four Phase III randomized clinical trials investigating the effects of tamoxifen in the prevention of breast cancer, the American Society of Clinical Oncology (ASCO) published a review of the data with recommendations for its use as a cancer preventive therapy (15). The most recent ASCO guidelines include tamoxifen therapy (20 mg/d for 5 years) as a treatment option for long-term (≥10 years) risk reduction of invasive ER-positive breast cancer in premenopausal women ≥35 years of age with LCIS or a 5-year projected absolute risk of breast cancer ≥1.66% (16). However, tamoxifen should not be used in women with a history or at high risk of deep venous thrombosis, pulmonary embolism, or cerebral vascular accidents. In addition, ASCO guidelines recommend avoiding tamoxifen use in individuals who are immobilized, pregnant, nursing, or receiving HRT. Despite FDA approval and consensus recommendations by ASCO and other professional organizations, tamoxifen is very rarely used for breast cancer prevention due to patient concerns about side effects and a lack of demonstrated survival benefit from tamoxifen use in this setting.

Raloxifene

Raloxifene was initially developed as a potential therapeutic agent for osteoporosis for the prevention of bone fractures. Three large-scale Phase III raloxifene clinical trials have since investigated the effects of the drug versus placebo as a preventive therapy for breast cancer, bone fractures, and heart disease (the Multiple Outcomes of Raloxifene Evaluation [MORE], Continuing Outcomes Relevant to Evista [CORE], and Raloxifene Use for the Heart [RUTH] trials) (Table 20-1). In addition, the NSABP Study of Tamoxifen and Raloxifene (STAR) P-2 Trial compared raloxifene to tamoxifen. The consecutive nature of the information provided by the MORE/CORE trials has enabled the comparison of incidence rates among women treated for 4 years (duration of treatment in the MORE trial) versus 8 years (duration of treatment in both the MORE and CORE trials).

Multiple Outcomes of Raloxifene Evaluation: In the 1990s, the MORE trial was conducted to determine the effectiveness of raloxifene in reducing bone fractures in 7,705 postmenopausal women 80 years of age or younger with osteoporosis, but also investigated the secondary endpoints of breast cancer and heart disease (17). Participants were treated for 3 years with low-dose raloxifene (60 mg/day), high-dose raloxifene (120 mg/day), or placebo, and all participants received both calcium and Vitamin D (cholecalciferol) supplements. This trial demonstrated that postmenopausal raloxifene treatment was associated with a dose-dependent reduction in vertebral bone fractures (60 mg/d: RR = 0.7, CI 0.5–0.8; 120 mg/d: RR = 0.5, CI 0.4–0.7) (17). In addition, dose-independent reductions were observed in all (RR = 0.35, CI 0.21–0.58) and invasive breast cancers (RR = 0.24, CI 0.13–0.44). However, as with tamoxifen, the study results demonstrated a decrease in risk of ER-positive (RR = 0.10, CI 0.04–0.24), but not ER-negative breast cancer.

Continuing outcomes relevant to evista trial: The CORE Trial was designed to enable an additional 4 years of raloxifene therapy in participants of the MORE trial to better ascertain the preventive efficacy of raloxifene in reduction of bone fracture incidence, with a secondary endpoint of ER-positive breast cancer incidence (18). Participants from the placebo arm of the MORE Trial were treated with placebo in the CORE Trial (n = 1,703), while subjects from either treatment arm received raloxifene (60 mg/day, n = 3,510) for an additional 4 years. While both the 4-year CORE results and 8-year MORE/CORE results demonstrated reduced incidence of invasive and ER-positive breast cancers, extended treatment resulted in increased levels of prevention. Incidence rates after 4-years versus 8-years of raloxifene therapy identified decreases in invasive breast cancer incidence of 31% (HR = 0.69, CI 0.23–2.01) and 59% (HR = 0.41, CI 0.21–0.81), respectively (18). These results suggest persistence of the preventive effects of raloxifene following discontinuation of therapy as well as increased prevention with 8 years of treatment. Decreased incidence of ER-positive breast cancer also improved with extended treatment, rising from 66% (HR = 0.34, CI 0.18–0.66) to 76% (HR = 0.24, CI 0.15–0.40); however, no significant decrease in ER-negative breast cancer was observed with either treatment regimen (17,18).

Raloxifene Use for the Heart (RUTH) Trial: The Raloxifene Use for the Heart (RUTH) Trial investigated the incidence of both invasive breast cancer and coronary events associated with 5 years of raloxifene treatment (60 mg/day) (19). Between 1998 and 2000, a total of 10,101 women were randomized to the study (raloxifene: n = 5,044; placebo: n = 5,057). Reductions of 44% in invasive (HR = 0.56, CI 0.38–0.83) and 55% in ER-positive (HR = 0.45, CI 0.28–0.72) breast cancer incidence were identified in subjects receiving raloxifene treatment for a median of 5.6 years, while no significant reductions were found in ER-negative or noninvasive breast cancers. This confirmed the results of the MORE and CORE trials (19).

Other Beneficial Effects: The MORE and CORE trials studied the effects of raloxifene in women with osteoporosis. Consequently, data included vertebral and nonvertebral fractures as well as changes in bone mineral density and bone turnover. 36 months of raloxifene treatment resulted in a 30% to 50% reduction in vertebral fractures (low-dose arm: RR = 0.7, CI 0.5–0.8; high-dose arm: RR = 0.5, CI 0.4–0.7) and a 2% to 3% increase in bone mineral density of both the spine and hip ($p < .001$) compared to the placebo (17). Statistically significant reductions of nonvertebral fractures were limited to ankle fractures, which decreased by 40% in the pooled raloxifene arms (RR = 0.6, CI 0.4–1.0). These results demonstrate that raloxifene treatment of postmenopausal women with osteoporosis leads to preservation of bone density and reductions of both bone turnover and risk of vertebral fractures. The RUTH trial confirmed this, reporting 35% fewer vertebral fractures in raloxifene patients (HR = 0.65, CI 0.47–0.89) (19).

Adverse Events Associated With Raloxifene Treatment: Raloxifene therapy has been shown to result in adverse thromboembolic/cardiovascular events as well as other negative side effects, including hot flushes, leg cramps, hypertension, peripheral edema, and vaginal discharge and bleeding.

Endometrial/Uterine Cancer No significant difference was observed in incidence of endometrial cancer in the raloxifene or placebo arms of the MORE or CORE trials (17). Likewise, the RUTH study found no significant change in risk of endometrial cancer between treatment arms (19). Collectively, these results demonstrate that treatment with raloxifene, unlike tamoxifen, does not increase risk of endometrial cancer.

Thromboembolic and Cardiovascular Events 36 to 40 months of raloxifene therapy produced increased risk of venous thromboembolic events in the MORE trial (17). These events, including deep vein thrombophlebitis and pulmonary embolism, were significant for both low- and high-dose treatment groups compared to placebo (pooled treatment arms: RR = 3.1, CI 1.5–6.2). The RUTH trial confirmed this, reporting a 44% increase in venous thromboembolic events in participants of the raloxifene arm (HR = 1.44, CI 1.06–1.95) (19). In addition, the RUTH trial reported a 49% increased risk of fatal cerebrovascular stroke following raloxifene treatment (HR = 1.49, CI 1.00–2.24).

Coronary Heart Disease The RUTH trial was designed specifically to determine whether treatment with raloxifene affected coronary heart disease (CHD). However, results from the RUTH trial identified no effect on the risk of CHD associated with raloxifene treatment in women with CHD or at increased risk for CHD (19).

Study of Tamoxifen and Raloxifene (Star) / NSABP P-2 Trial: Following the initial report of the NSABP P-1 (BCPT) and the other tamoxifen and raloxifene prevention trials (17,18), the NSABP STAR P-2 Trial was developed (Table 20-1) (20). The primary objective of this study was to compare the effects, beneficial and toxicity-related, of the two SERMs tamoxifen and raloxifene. This two-arm trial investigated the effects of 5 years of treatment with tamoxifen (20 mg/day) versus raloxifene (60 mg/day). While the initial results showed equal efficacy of tamoxifen and raloxifene in reduction of breast cancer risk, the 81-month follow-up results demonstrated that raloxifene was 76% as effective as tamoxifen in preventing invasive breast cancer (RR = 1.24, CI 1.05–1.47), and 78% as effective as tamoxifen in preventing both noninvasive breast cancer (RR = 1.22, CI 0.95–1.59) and DCIS (RR = 1.22, CI 0.88–1.69) (Fig. 20-1) (20). Furthermore, after stopping treatment, persistence of the cancer-preventive effect of tamoxifen was observed, while that of raloxifene began to diminish (Fig. 20-1). Conversely, decreased toxicity was observed with raloxifene, with subjects characterized by significantly fewer invasive endometrial/uterine cancers (RR = 0.55, CI 0.36–0.83), uterine hyperplasia (RR = 0.19, CI 0.12–0.29), thromboembolic events (RR = 0.75, CI 0.60–0.93), and cataracts developed during follow-up (RR = 0.80, CI 0.72–0.89). No differences in the frequency of ischemic heart disease events or strokes or in the number of deaths were observed (Fig. 20-2) (20).

Ultimately, this study demonstrated the effectiveness of both tamoxifen and raloxifene in reducing risk of breast cancer in high-risk postmenopausal women. More specifically, the NSABP P-2 results identify both subject- and SERM-specific risk–benefit ratios associated with treatment (21). These findings support either agent for breast cancer prevention in high-risk postmenopausal women. Raloxifene preventive therapy may be particularly effective for a high-risk postmenopausal woman who has an intact uterus and is concerned about risk of hot flushes and thromboembolic side effects, while tamoxifen preventive therapy may be preferred in a high-risk postmenopausal woman without a uterus (21).

Recommendations for the Use of Raloxifene for Breast Cancer Risk Reduction: In 2007, following the MORE, CORE, and RUTH clinical trials, the FDA approved raloxifene hydrochloride as a preventive therapy for postmenopausal women with

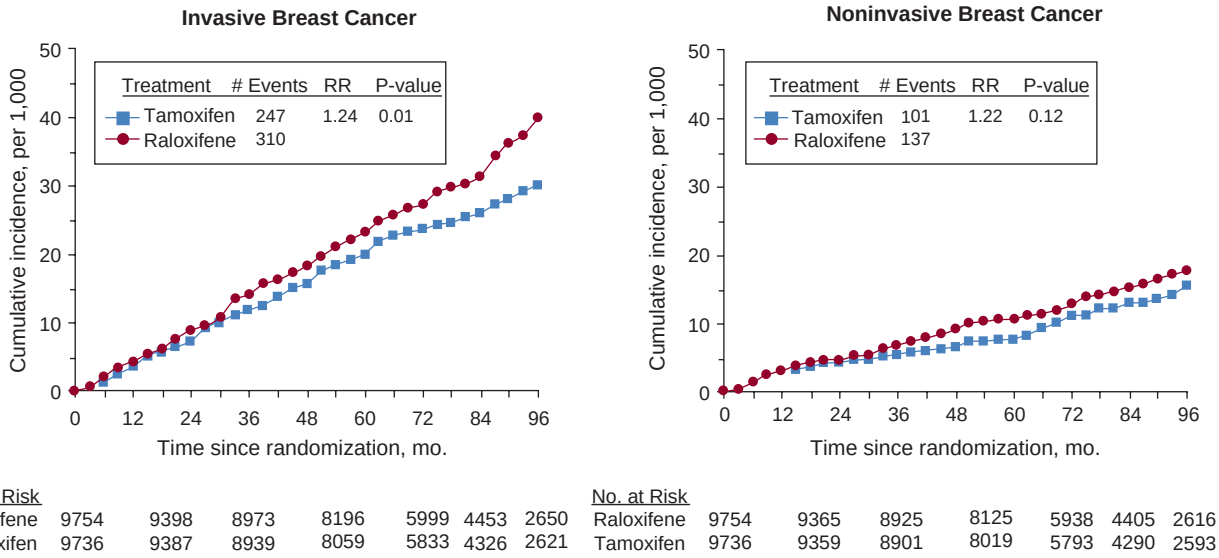

FIGURE 20-1 **NSABP STAR P-2 Trial: Updated results.** 81-month follow-up incidence rates for invasive and noninvasive breast cancer following treatment with tamoxifen or raloxifene. (From Vogel V, et al. Update of the National Surgical Adjuvant Breast and Bowel Project Study of Tamoxifen and Raloxifene (STAR) P-2 Trial: preventing breast cancer. *Cancer Prev Res* 2010;3(6):696–706, with permission.)

osteoporosis or at high risk for invasive breast cancer. In 2009, ASCO published its first clinical practice recommendation of raloxifene (20 mg/day for 5 years) for the prevention of ER-positive breast cancer in postmenopausal women without a history or at risk of thromboembolic events, a recommendation retained in the 2013 update (16).

Other SERMs

While no SERMs aside from tamoxifen and raloxifene have been approved by the FDA, several have been and continue to be the focus of recent/current clinical trials. Among these are the third-generation SERMs lasofoxifene and arzoxifene.

Lasofoxifene

Several studies have investigated the third-generation SERM lasofoxifene in postmenopausal women, including the Postmenopausal Evaluation and Risk Reduction with Lasofoxifene (PEARL) (22) and Comparison of Raloxifene and Lasofoxifene (CORAL) (23) trials. The PEARL trial, a 5-year Phase III study investigating lasofoxifene versus placebo, demonstrated a 79% decrease in breast cancer following treatment with lasofoxifene (0.5 mg/day) (Table 20-1) and was associated with fewer adverse events (including major coronary events, vertebral and nonvertebral fractures, and stroke) than previously studied SERMs (22). The 2-year Phase III CORAL trial compared the effects of raloxifene, lasofoxifene, and placebo on bone mineral density; it identified similar adverse effect profiles associated with both SERMs, but a more profound decrease in low-density lipoprotein cholesterol levels and improved bone mineral density of the lumbar spine in subjects treated with lasofoxifene (23).

Arzoxifene

Another third-generation SERM, arzoxifene, was the focus of the GENERATIONS trial, which accrued a total of 9,354 postmenopausal women with osteoporosis or low bone mass (osteopenia) (Table 20-1) (2). The objective of the study was to determine the effects of 60 months of arzoxifene (20 mg/day; n = 4,676) or placebo (n = 4,678) on vertebral fracture in osteoporotic women and to evaluate its ability to prevent

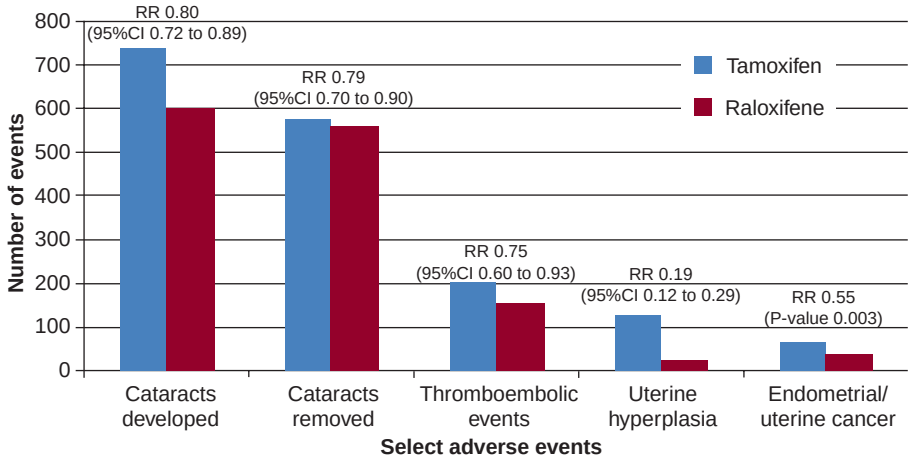

FIGURE 20-2 **NSABP STAR P-2 Trial: Updated results.** Comparison of select adverse events following treatment with tamoxifen versus raloxifene. (Adapted from Vogel V, et al. Update of the National Surgical Adjuvant Breast and Bowel Project Study of Tamoxifen and Raloxifene (STAR) P-2 Trial: Preventing Breast Cancer. *Cancer Prev Res* 2010;3(6):696–706.)

invasive breast cancer in all subjects. The 48-month follow-up reported reduced risk of both invasive (HR = 0.30, CI 0.08–1.09) and ER-positive (HR = 0.30, CI 0.14–0.63) breast cancer in arzoxifene subjects (2). In addition, subjects with osteoporosis had a 41% reduction in risk of vertebral fractures (RR = 0.58, 95% CI 0.45–0.77). Non-statistically significant increases in incidence of endometrial cancer and endometrial hyperplasia occurred in participants treated with arzoxifene. Arzoxifene was also associated with increased risk of venous thromboembolic events (63 of the 90 events, 95% CI 1.5–3.7), and other side effects, including vaginal symptoms, hot flushes, and muscle cramps.

Next-Generation SERMs

To improve upon the risk–benefit profiles of tamoxifen and raloxifene, other SERMs developed and investigated include toremifene, acolbifene, idoxifene, droloxifene, levomeloxifene, bazedoxifene, and ospemifene. Although tamoxifen and raloxifene are FDA approved as drugs for breast cancer risk reduction, newer SERMs have demonstrated potential as preventive alternatives with high tolerability for postmenopausal osteoporotic women. Dr. Jack Cuzick and collaborators recently published an updated meta-analysis comparing the effects of SERMs reported in 9 large-scale prevention trials (Fig. 20-3) (24). As demonstrated within the individual trials, treatment with SERMs decreases incidence of overall and ER-positive breast cancer, but not ER-negative breast cancer. Furthermore, all SERMs, with the singular exception of raloxifene, reduce incidence of DCIS; the next-generation SERMs, particularly lasofoxifene (0.5 mg/d), reduce incidence of vertebral fractures but increase incidence of venous thromboembolic events. Continued development of third-generation SERMs for cancer preventive indications is needed and will require substantial support from pharmaceutical companies. However, these companies have become increasingly reluctant to develop preventive agents due to liability concerns focused on rare toxicities of drugs given to cancer-free women.

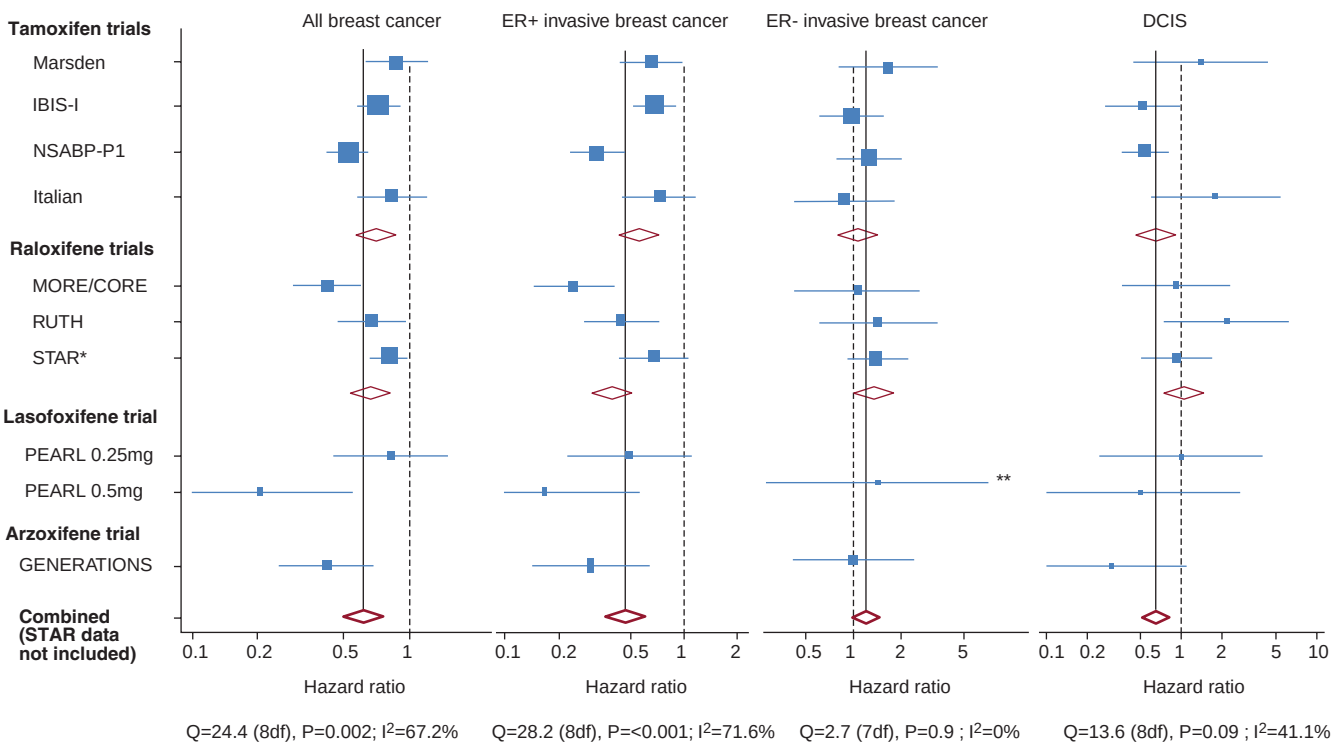
SERMs as Standard of Care for Breast Cancer Prevention

Due to the lack of long-term evaluation of the next generation SERMs in large-scale Phase III prevention trials, tamoxifen and raloxifene remain the only SERMs currently used for the clinical prevention of breast cancer. Of three drugs recommended by ASCO for the prevention of breast cancer, these two SERMs are the only FDA-approved drugs for breast cancer risk reduction (16).

Aromatase Inhibitors (AIs)

Effect of AIs on Second Primary Tumors from Treatment Trials

Multiple clinical studies have investigated aromatase inhibitors (AIs), which inhibit the conversion of peripheral androgens to estrogens, for the treatment of women with hormone receptor positive breast cancer. AIs tested include the reversible, nonsteroidal inhibitors anastrozole and letrozole as well as the irreversible steroidal inhibitor exemestane. The cancer preventive potential of AIs was discovered by investigating the development of second primary contralateral tumors in women with early breast cancer



*Adjusted by overall tamoxifen effect to give raloxifene vs. placebo comparison, STAR data not included in overall effect ** Pooled data

FIGURE 20-3 **Preventive impact of SERMs.** (From Cuzick J, et al. Selective oestrogen receptor modulators in prevention of breast cancer: an updated meta-analysis of individual participant data. *Lancet* 2013;381(9880):1827–1834, with permission.)

who were treated with AIs as adjuvant therapy. These trials have demonstrated significant reductions in both contralateral and ER-positive breast cancer following treatment with anastrozole (25–28) as well as lower incidence of uterine cancers, hot flushes, and venous thromboembolic events but higher incidence of bone fractures (25). In addition, the effectiveness of the AIs letrozole (29,30) and exemestane (8,31–33) versus tamoxifen for the treatment of early breast cancer have demonstrated reduced risk of both recurrence and contralateral breast cancers associated with AI versus tamoxifen therapy (8,32). These findings have stimulated the development of several prevention trials testing AIs in women with DCIS or at high risk of breast cancer.

Prevention Trials

Trials of AIs in Women with DCIS Breast Cancer: Two Phase III trials are currently comparing the cancer preventive effect of anastrozole versus tamoxifen in women with DCIS. These studies, the NSABP B-35 and IBIS-II (DCIS) trials, are discussed in Chapter 23 (DCIS and Microinvasion), and summarized in Table 20-4. Results from these two studies, collectively encompassing over 7,000 women with DCIS (target accrual), are anticipated within the upcoming years and will help define incidence of breast cancer (DCIS recurrence, invasive and contralateral breast cancer) following 5 years of treatment with anastrozole (1 mg/day) versus tamoxifen (20 mg/day).

Trials of AIs in Women at High Risk of Breast Cancer: Two other Phase III breast cancer prevention trials have or are testing AIs in postmenopausal women at high risk of breast cancer, the NCIC-MAP.3 trial testing exemestane (34) and the second component of the IBIS-II trial, known as the IBIS-II Prevention trial, testing anastrozole (35) (Table 20-4). Initial results of the NCIC-MAP.3 trial (34) were recently reported and demonstrate that exemestane reduces the incidence of invasive breast cancer by 65% (HR = 0.35; 95% CI 0.18–0.70) and ER-positive breast cancer by 73% (HR = 0.27; 95% CI 0.12–0.60) (34) (Fig. 20-4). Furthermore, these results showed a favorable risk-to-benefit ratio supported by no significant change in quality of life or serious toxicities (Table 20-5). Adverse events reported include arthritis and hot flushes, but do not include osteoporosis or the endometrial cancers and thromboembolic events associated with tamoxifen. In a recent review by DeCensi et al. (36), the significant improvement in breast cancer preventive efficacy of exemestane as compared to SERMs was noted; however, the question of whether serious exemestane-induced toxicities occur, particularly bone-related toxicities, will depend upon extended follow-up results of the MAP.3 trial.

AIs as Standard of Care for Breast Cancer Prevention

Based upon the NCIC-MAP.3 trial results, the most recent ASCO consensus statement includes the recommendation to include exemestane (25 mg/d for 5 years) as a therapeutic alternative to tamoxifen and/or raloxifene in postmenopausal women ≥35 years of age with atypical hyperplasia, LCIS, or ER-positive breast cancer (16). While exemestane has not yet received approval by the FDA beyond use as an adjuvant treatment for breast cancer, ASCO's updated guidelines represent the first instance of a non-SERM drug being recommended for the prevention of breast cancer. The IBIS-II anastrozole trial results are anticipated in the near future and should clarify whether anastrozole will also be useful for breast cancer prevention.

PREVENTION OF ER-NEGATIVE BREAST CANCER

While Phase III clinical trials demonstrate the effectiveness of SERMs and AIs in preventing ER-positive breast cancer, there is a clear need for drugs that can prevent ER-negative breast cancer (Fig. 20-5) (37). Promising approaches include preventive therapy with retinoids, inhibitors of the HER2 family of receptor kinases, COX-2 inhibitors, PARP inhibitors, and metformin as well as vaccine approaches.

HER2/EGFR-*Tyrosine Kinase Inhibitors*

Overexpression of members of the *ErbB* family of growth factor receptors, particularly *ErbB2* (HER2, *neu*) (overexpressed in 20% to 25% of human breast cancers), can induce breast cell transformation (38). HER2 inhibitors, such as trastuzumab (Herceptin), pertuzumab, and lapatinib (an oral dual kinase inhibitor of HER2 and *EGFR*), are useful drugs for the treatment of HER2-positive breast cancer (38). Given the activity of these drugs in the treatment setting, they are now being tested in pre-clinical and early clinical trials as breast cancer preventive drugs (Table 20-6). Clinical trials testing trastuzumab for the treatment of HER2-positive DCIS include the Phase II trial reported by Kuerer et al. (39) and the ongoing Phase III NSABP B-43 trial. In the Phase II trial, an immunologic response (increased antibody-dependent cell mediated cytotoxicity), but no pathologic response or antiproliferative activity was noted following a single dose preoperative trastuzumab treatment (39). In the Phase III NSABP B-43 trial, women who have already had excisional surgery are being treated with radiation or radiation plus two doses of trastuzumab. The primary endpoint of this study is the cumulative incidence of ipsilateral invasive breast cancer, ipsilateral skin cancer recurrence, and ipsilateral DCIS.

Several pre-clinical and clinical studies of oral HER2 and *EGFR* receptor tyrosine kinase inhibitors have also been conducted, including studies of the *EGFR* inhibitor gefitinib and the dual *EGFR*/HER2 kinase inhibitor lapatinib. These studies have demonstrated a significant delay in time-to-tumor development of ER-negative, HER2-positive mammary tumors in *ErbB2*/HER2-transgenic mice with 9 months of treatment (40,41) and have provided the rationale to test lapatinib in early cancer prevention clinical trials (Table 20-6). Two Phase II trials have been developed testing the effects of lapatinib therapy prior to tumor excision on Ki67 immunohistochemical staining in DCIS cells in women with HER2-positive DCIS. In the DeCensi study, recent results identify that treatment with lapatinib (1,500 mg/day) reduces cell proliferation in breast cancer tissue, adjacent ductal intraepithelial neoplasia, and distant ductal hyperplasias (42). These results indicate an antiproliferative effect of lapatinib on both cancer and pre-cancerous cells. The second Phase II trial testing a lower dose of lapatinib (1,000 mg/day) is ongoing.

Other Cancer Prevention Agents

Retinoids: Derivatives of vitamin A, retinoids, regulate development, differentiation, and homeostasis in most cells by binding retinoic acid receptors (RARs) (43) and include the naturally occurring RAR ligands, such as all-trans retinoic acid (ATRA), alitretinoin (9-*cis*-RA), and isotretinoin (13-*cis*-RA). These agents have been shown to affect a number of mechanisms, including the down-regulation of expression of COX-2 and cyclin D1 (44), inhibition of AP-1 transcription factor activity (45), induction of cell cycle arrest at G1 (46), and overexpression of IGF binding proteins (IGF-BPs) 3 and 6 (45), RAR-beta (45), and TGF-beta (47). In addition, various

animal models have established the cancer preventive effects of 13-*cis*- and 9-*cis*-RA in mammary tumorigenesis in mice and rats (48,49), and second primary head and neck tumors in humans (50). However, toxicities associated with these retinoids have prevented either agent from being used as standard of care in the clinical setting (49,50).

In 2006, Veronesi and colleagues presented the 15-year results of a multicenter Phase III clinical trial investigating the effects of the synthetic retinoid fenretinide on the prevention of contralateral or second ipsilateral breast cancer (Table 20-7) (51). This study identified a reduction in risk of second primary breast tumors in premenopausal women. Furthermore, the preventive efficacy of fenretinide persisted for several years following cessation of treatment and was associated with minimal adverse events. This agent remains a promising prevention strategy, although formulation and drug supply have presented challenges to its further development.

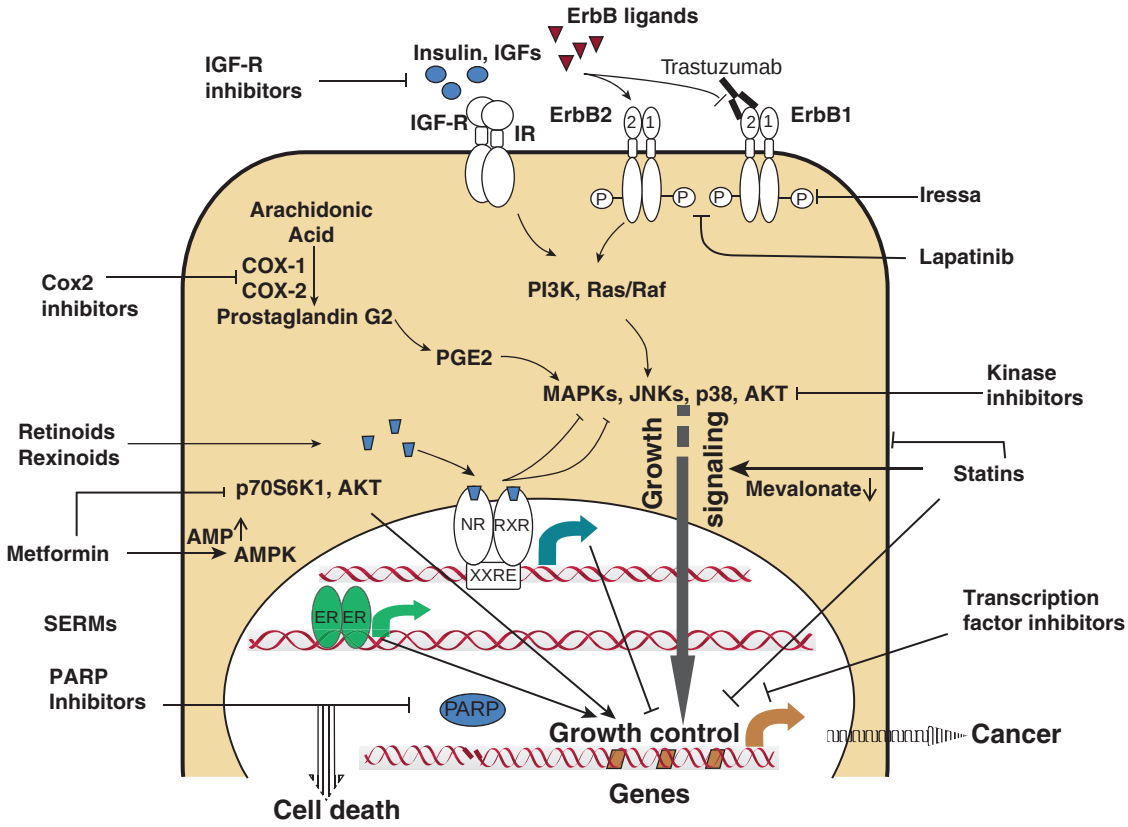

FIGURE 20-5 **Oncogenic pathways in the cell.** (Adapted from Uray I, Brown P. Chemoprevention of hormone receptor-negative breast cancer: new approaches needed; recent results. *Cancer Res* 2011;188:147–162.)

While retinoids bind RARs, rexinoids preferentially activate retinoid X receptors (RXRs), which are dimeric partners of RARs. Rexinoids, including bexarotene (LG1069) and the newer third-generation rexinoid LG100268, bind RXRs and activate the RAR:RXR dimeric transcription factor. A number of animal studies have already shown increased preventive efficacy as well as decreased toxicity following treatment with rexinoids versus retinoids (52–54). Results from studies in transgenic mice demonstrate prevention of ER-negative mammary tumorigenesis with either bexarotene or LG100268 (Fig. 20-6) (41,55), while combined LG100268-tamoxifen treatment has been shown to be more effective at suppressing mammary tumorigenesis than either drug alone (56). Moreover, toxicity resulting from treatment with LG100268 is significantly lower than that associated with bexarotene or naturally occurring retinoids. While results from a recently conducted Phase II clinical trial demonstrate that rexinoid treatment is associated with significant down-regulation of cyclin D1 and decreased cellular proliferation in breast tissue of postmenopausal women at high risk of breast cancer (57), it also caused toxicity (elevated serum triglycerides and subclinical hypothyroidism) and thus may be limited in use to high-risk women willing to tolerate moderate toxicity. The future of retinoids and rexinoids as cancer preventive agents depends upon upcoming results from pre-clinical and clinical studies currently testing the efficacy and toxicity of these agents in the preventive setting.

COX-2 Inhibitors: In 1988, Kune et al. demonstrated that prevention of colorectal cancer was possible through the use of nonsteroidal anti-inflammatory drugs (NSAIDs), which inhibit the eicosanoid pathway (58). Aspirin and other NSAIDs have been shown to inhibit cyclooxygenase (COX), for which two isoforms, COX-1 and COX-2, have been described. COX-1 is constitutively expressed in most cells, while inducible COX-2 expression is limited by location, state of inflammation, and/or mitogenic stimulation. The COX-2 inhibitor celecoxib has received FDA approval for use in reducing colonic polyps in individuals with familial adenomatous polyposis (FAP) (59).

Numerous epidemiological (60–64) studies have identified reduced cancer risk (e.g., lung, colon, breast) associated with long-term use of the irreversible COX-1 and COX-2 inhibitor, aspirin (63,64), and ongoing studies with extended follow-up periods will help to further establish the long-term prophylactic benefit of aspirin use (64). In addition, the preventive effects of NSAIDs and selective COX-2 inhibitors have been the focus of a variety of pre-clinical studies. Among these, dietary treatment with celecoxib has been shown to significantly reduce mammary tumors in MMTV-erbB2 transgenic mice (65) as well as breast tumor incidence (68%), multiplicity (86%), and volume (81%) in Sprague Dawley rats (66).

The preventive activity of NSAIDs and COX-2 inhibitors has also been the focus of a number of clinical studies; five such studies investigating the COX-2 inhibitor celecoxib on breast cancer are listed in Table 20-8. However, cardiovascular toxicities associated with COX-2 inhibitors discovered in large Phase III colon polyp prevention trials (67–71) have halted the development of celecoxib for chemoprevention, with several Phase II breast cancer prevention trials having been stopped due to concerns about rare but serious toxicities. Given the importance of COX-2 in carcinogenesis,

TABLE 20-7

Phase III Clinical Breast Cancer Prevention Trial Results of Fenretinide in the Prevention of Second Primary Tumors in Women (30–70 years of age)

Event	*Treatment arm (fenretinide, n = 872)*	*Control arm (n = 867)*	*HR (95% CI)*
All Breast Cancer (contra- and ipsilateral)			
Premenopausal	83	126	0.62 (0.46–0.83)
Postmenopausal	85	64	1.23 (0.63–2.40)
Total	168	190	0.83 (0.67–1.03)
Contralateral Breast Cancer			
Premenopausal	26	43	0.63 (0.38–1.04)
Postmenopausal	45	34	1.23 (0.41–3.71)
Total	71	77	0.90 (0.65–1.26)
Ipsilateral Breast Cancer			
Premenopausal	57	83	0.61 (0.43–0.87)
Postmenopausal	40	32	1.16 (0.49–2.74)
Total	97	115	0.77 (0.58–1.02)

Both HR and CI were adjusted for menopausal status at time of randomization, type of primary tumor surgery, tumor size, and histology. As some subjects had both contra- and ipsilateral tumors as first recurrence events, these figures do not necessarily add up. CI, confidence interval; HR, hazard ratio. Data adapted from Veronesi, et al. Fifteen-year results of a randomized phase III trial of fenretinide to prevent second breast cancer. *Annals Oncol* 2006;17(7):1065–1071, with permission.

current research is focused on identifying alternative targetable molecules within this pathway, enabling safer, more effective preventive interventions.

Metformin: Metformin activates AMP-activated protein kinase (AMPK) and has become the first-line therapy of choice for type 2 diabetes mellitus as well as a treatment strategy for polycystic ovary syndrome (PCOS). A review of epidemiologic studies by Xue and Michels identified an association between type 2 diabetes and breast cancer risk, particularly apparent in postmenopausal women (72). In addition, treatment with metformin has been shown to inhibit breast cancer cell growth (73) and mammary tumor growth in *HER-2/neu* transgenic mice (74). Likewise, epidemiological studies investigating risk of breast cancer in patients being treated with metformin for diabetes have recently demonstrated significant reductions in risk of breast cancer following treatment with metformin versus other antidiabetic therapies (75–82). Following these studies, several early phase clinical trials showed reduced proliferation of breast cancer cells following metformin treatment (Table 20-9) (83).

Several additional clinical trials studying metformin are currently in progress or have yet to release results (Table 20-9), including the Phase III NCIC-MA.32 trial, in which women with early stage breast cancer are being treated with metformin. This trial will examine the effect of metformin on invasive disease-free survival, overall survival, and contralateral breast cancer incidence. Although study results are not expected for several years, the results of a window of opportunity study have been recently published, demonstrating decreased Ki67 staining and increased TUNEL staining (markers for proliferation and apoptosis, respectively), following treatment with metformin (83).

Statins: Statins inhibit the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, which leads to reduced cellular biosynthesis of cholesterol, improved endothelial function, and modulation of the membrane microdomain (84). Epidemiologic studies of individuals taking lipid-lowering drugs (e.g., atorvastatin, cerivastatin, fluvastatin, lovastatin, simvastatin, pravastatin) have shown reduced risk of breast, prostate, and colorectal cancers (85–88). Furthermore, statins cause inhibition of proliferation in ER-negative breast cancer cell lines (89) and in ER-negative mouse models (90). However, epidemiological studies have produced mixed results: a meta-analysis of breast cancer studies failed to report a significant decrease in risk of breast cancer (91), while other studies have demonstrated reductions in risk approaching 50% (92). Furthermore, treatment with lipophilic statins has been shown to influence tumor phenotype (e.g., fewer ER/PR-negative tumors, lower tumor grade/stage), with increased effects from ≥1 year treatment before diagnosis of cancer (92).

A number of Phase II prevention trials investigating the biologic impact of statins in breast cancer prevention are currently in progress. Garwood et al. have reported increased apoptosis and reduced proliferation with short-term fluvastatin treatment (3 weeks of 20 or 80 mg/day) in subjects with high-grade breast cancer (93). In addition, positive results from other statin studies evaluating simvastatin as a preventive strategy for women at increased risk of breast cancer (a biomarker modulation study) (94) and for risk of recurrence (a large population-based cohort study) (95) have been reported recently. Overall, despite the somewhat controversial nature of the efficacy of statins, current findings support further investigation of these agents as potential breast cancer chemopreventive alternatives.

PARP Inhibitors: Inhibition of poly (ADP-ribose) polymerase (PARP), particularly of PARP-1 and -2, provides yet another approach for targeted prevention of breast cancer (96). In PARP1-deficient cells, which are associated with loss-of-function *BRCA* mutations, homologous recombination is impaired through inhibition of single-strand break recombination, resulting in cellular lethality (97). Because PARP inhibitors require *BRCA1/2* mutations in order to be effective, they provide a novel synthetic lethal preventive strategy that is highly and preferentially toxic to *BCRA1/2* mutant tumor cells versus normal cells (37). Pre-clinical studies investigating the efficacy and tolerability of PARP inhibitors (e.g., iniparib, olaparib, rucaparib, velparib) have led to Phase I and II clinical trials of these drugs alone and in combination with cisplatin and gemcitabine, two chemotherapeutic agents that induce DNA-damage (98–100). However, while PARP inhibitors such as olaparib have shown high efficacy and tolerability with few negative side effects (98,101),

Data from: [1]Hadad S, et al. *Breast Cancer Res Treat* 2011;128(3):783–794; [2]Bonanni B, et al. *J Clin Oncol* 2012;30(21):2593–2600; [3]Niraula S, et al. *Breast Cancer Res Treat* 2012;135(3): 821–830; [4]Goodwin PJ, et al. *Breast Cancer Res Treat* 2011;126(1):215–220.

additional clinical data further defining their effectiveness and tolerability as chemopreventive agents for *BRCA1/2* carriers will determine their place in the future of breast cancer prevention.

Natural Products: In addition to pharmacologic approaches, current advances in the understanding of the association between diet and tumorigenesis have led to a wide range of natural products becoming the focus of breast and other cancer prevention studies, particularly as cancer is considered by many to be a disease that is largely preventable. These alternative strategies include specific diets, dietary and medicinal botanicals, and biologically active food components (BFCs) that have been found to both prevent disease and promote health. While over a hundred natural compounds are currently in clinical use (102), among those that have been shown to be inversely associated with an increased risk of breast cancer in pre-clinical, early clinical, and population-based studies are catechins (e.g., epigallocatechin gallate [EGCG], green tea extract); curcumin (yellow pigment in the spice turmeric of the ginger family); the flavonoids deguelin (a rotenoid in several plant species), luteolin (in vegetables including broccoli and cabbage), and those in pomegranate juice (cyanidin, delphinidin, and petunidin); indole-3-carbinol (I3C; in cruciferous vegetables); lycopene (red pigment of tomatoes, guava, pink grapefruit, and watermelon) and other carotenoids; omega-3-fatty acids (in marine and plant oils); resveratrol (antioxidant in the skins of red grapes, mulberries, and other plants); soy isoflavones (genistein, daidzein, and glycitein); and vitamin D.

Mechanistic analyses have demonstrated numerous, and in many cases multiple, signal transduction pathways targeted by these agents, including the activator protein-1 (AP-1), angiogenesis, antiviral, cytokine (e.g., osteoprotegerin), DNA methylation, growth factor (CSF, EGF, FGF, IGF, PDGF, and TGF), immunologic, nuclear factor-kappaB (NF-kappaB), p53, phase I and II enzymatic, and signal transducers and activators of transcription (STAT), ubiquitin-proteosome, pathways (103). While further clinical studies are needed, natural products offer promising alternative strategies for the prevention of breast cancer in the future.

Vaccine Approaches: Vaccination strategies targeting breast cancer include preventive treatments and therapeutic interventions for metastatic breast cancer. However, vaccine strategies in healthy individuals without cancer could enable the immune system to detect precancerous lesions otherwise undetectable by the immune system. For this reason, immunologic interventions are felt to be a particularly promising prevention strategy. Analysis of sera from breast cancer patients has been shown to contain serum antibodies against oncogenic proteins (e.g., carcinoembryonic antigen (CEA), cyclin B1, HER2*/neu,* and *p53*) at the time of treatment (104, 105). Furthermore, all but CEA antibody are present at diagnosis, and HER2 and *p53* antibodies are in prediagnostic sera (104). Peptide vaccines incorporate an immunoadjuvant into the treatment to stimulate the immune response of the subject (106). GP2, AE37, and E75 are three HER2*/neu* peptide vaccines currently in Phase I, II, or III clinical breast cancer trials. Both GP2 and E75 are major histocompatibility complex (MHC) class I peptides and stimulate tumor cell-destroying CD8-positive T cells (107), thereby limiting their effectivity to human leucocyte antigen A2-positive (HLA-$A2^+$) and HLA-$A3^+$patients (106). Conversely, AE37 is an MHC class II peptide and stimulates CD4-positive T cells (107), enabling induction of higher antitumor responses and encompassing a larger number of HLA types (106).

A successful Phase I dose escalation trial of the GP2 vaccine (108), has led to a Phase II prevention trial studying recurrence in node-positive or high-risk node-negative breast cancer patients, currently in progress. Likewise, potency of the AE37 vaccine in the absence of an immunoadjuvant has been demonstrated in a Phase Ib trial (109), which has resulted in an ongoing Phase II trial comparing the efficacy and tolerance of the GP2 and AE37 vaccines. This study has already demonstrated AE37 vaccination-mediated reductions in risk of 49% for all subjects and 68% for patients with low HER2 expression and patients with triple-negative breast cancer (109). However, E75 is the most studied of the HER2-derived cytotoxic T-lymphocyte peptide vaccines and the focus of a number of clinical trials. Phase I and II studies of E75 induced immunity in HLA-$A2^+$ and HLA-$A3^+$ disease-free, node-positive breast cancer patients have identified peptide-specific immune responses *in vivo* and improved disease-free survival (DFS) that persists over time, with highest clinical benefit in low-HER2/*neu* expressing patients (110). A booster program to prevent decreased immunity over time has now been initiated. In addition, recruitment is underway for the first Phase III clinical trial of a breast cancer vaccine, the Prevention of Recurrence in Early-Stage, Node-Positive Breast Cancer with Low to Intermediate HER2 Expression with NeuVax Treatment (PRESENT) study, which is investigating the effects of the E75 vaccination on 3-year DFS in 700 early-stage node-positive breast cancer patients. Positive trial results could lay the foundation necessary for the translation of the E75 vaccine into the clinical prevention setting.

Other Promising Agents

Other agents being tested in pre-clinical studies include insulin-like growth factor receptor (IGF1R) inhibitors, mammalian target of rapamycin (mTOR) inhibitors, phosphatidylinositol 3-kinase (PI3K) inhibitors, and synthetic oleanane triterpenoids, including 2-cyano-3,12-dioxooleana-1,9(11)-dien-28-oic acid (CDDO), CDDO-methyl ester (CDDO-Me), and CDDO-imidazolide (CDDO-Im).

Inhibitors of the IGF-1 pathway, which has been shown to be critical in mammary gland differentiation and development, provide one such option. These inhibitors, including agents such as cixutumumab, figitumumab, pasireotide, and R1507, have the potential of being useful for the prevention of both ER-positive and ER-negative breast cancer (111).

Likewise, mTOR inhibitors (e.g., rapamycin and the rapalogs deforolimus, everolimus, sirolimus, and temsirolimus) may be useful as cancer prevention agents. PI3K/AKT/mTOR signaling is critical for tumorigenesis and angiogenesis (112). mTOR functions as a downstream effector of the PI3K/AKT signaling pathway, participates in the phosphorylation of multiple kinases (e.g., 40S ribosomal S6 kinase [S6K], a marker associated with aging) (113) and interacts with growth factors in regulating cell cycle progression, among other things (114). While clinical results for these agents have been encouraging and demonstrate acceptable toxicity, further research is needed to assess the cancer preventive potential of these agents.

Finally, CDDO, CDDO-Im and CDDO-Me, which target the Nrf2 transcription factor, have been shown to delay mammary tumor formation and to synergistically enhance the effects of LG100268 in the suppression of ER-negative tumors (52,115). Based upon epidemiological, pre-clinical, and clinical results, alternative strategies, including IGF, mTOR, and PI3K inhibitors, as well as CDDO esters, may provide promising strategies for breast cancer prevention in the future.

SELECTION OF WHOM TO TREAT

Clinical trials have demonstrated that several drugs, including antiestrogen SERMs and aromatase inhibitors, can effectively prevent many breast cancers in women, especially ER-positive breast cancers. The current ASCO recommendations for reducing risk of breast cancer are outlined in Table 20-10 (16). Two drugs, tamoxifen and raloxifene, are currently FDA approved to treat women at increased risk of breast cancer. Of these, tamoxifen remains the only FDA-approved preventive therapy for high-risk premenopausal women, while both tamoxifen and raloxifene can be used in high-risk post-menopausal women. In addition, the aromatase inhibitor exemestane has recently been added to the ASCO clinical practice guidelines as an alternative preventive intervention for ER-positive breast cancers in post-menopausal women (16). However, the selection of which SERM or AI use in these post-menopausal women should be based on the individual's risk–benefit ratio. For example, for a high-risk post-menopausal woman without a uterus, the risk of tamoxifen is lessened; such a woman may thus prefer tamoxifen. On the other hand, a high-risk woman with an intact uterus and concerns about hot flushes and thromboembolic risks may be best treated with raloxifene (which does not increase the risk of uterine cancer and induces less hot flushing and thromboembolic events) or potentially with exemestane (which does not increase the risk of thromboembolic events). Conversely, for a high-risk postmenopausal women with a history of a deep venous thrombosis and normal bone mineral density, it is possible that exemestane could be used, pending FDA approval for breast cancer risk reduction. Finally, for women with atypical ductal hyperplasia premalignant lesions, tamoxifen preventive therapy should be considered, since tamoxifen reduced breast cancer risk in such women by 90% in the NSABP P-1 clinical trial (116). Other agents such as trastuzumab, lapatinib, retinoids, and vaccines are being investigated in clinical trials but are not yet being used clinically. Through the application of currently available drugs, it is now possible to significantly reduce the risk of ER-positive breast cancer in high-risk women. It is anticipated that ultimately, pre-clinical and clinical research will produce and/or identify drug-based preventive therapies capable of greatly reducing the incidence of ER-positive, HER2-positive, and ER-negative breast cancer.

MANAGEMENT SUMMARY

- Tamoxifen and raloxifene are now FDA-approved for breast cancer risk reduction in high-risk women. While raloxifene is slightly less effective at preventing breast cancer than tamoxifen, it is associated with fewer adverse events.
  - Tamoxifen (20mg/day for 5 years) can be used for pre- and postmenopausal women 35 years of age or older if they have been diagnosed with LCIS or have a 1.66% or higher 5-year projected risk of breast cancer according to the Gail risk model (http://www.cancer.gov/bcrisktool), and is expected to reduce risk of invasive ER-positive breast cancer by approximately 50%.
  - Raloxifene (60 mg/day for 5 years) can be used for postmenopausal women 35 years of age or older if they have been diagnosed with LCIS or have a 1.66% or higher 5-year projected risk of breast cancer according to the Gail risk model (http://www.cancer.gov/bcrisktool), and is expected to reduce risk of invasive ER-positive breast cancer by approximately 39%.
- Women with ADH premalignant lesions exhibit 85% reduction in breast cancer risk following treatment with tamoxifen.
- The most effective risk-benefit ratios for tamoxifen treatment are observed in premenopausal women at increased risk of breast cancer. This is due to the reduced risk of thromboembolic events and uterine cancer.
- Older, postmenopausal women have an age-related increased risk of deep-vein thrombosis and pulmonary embolisms and should be evaluated carefully prior to being offered tamoxifen as a preventive strategy for breast cancer.
- Neither tamoxifen nor raloxifene are recommended for breast cancer risk reduction in women: 1) with a history of deep vein thrombosis, pulmonary embolus, stroke, or transient ischemic attack; 2) currently nursing or likely to become pregnant; or 3) currently being treated with hormone therapy.
- Women with osteoporosis may receive increased benefit with more than 5 years of treatment with raloxifene.
- Exemestane (25mg/day for 5 years) is a potential therapeutic alternative to tamoxifen or raloxifene for breast cancer risk reduction in postmenopausal women if they have been diagnosed with ADH or LCIS or have a 1.66% or higher 5-year projected risk of breast cancer according to the Gail model. Treatment with exemestane is expected to reduce the risk of invasive ER-positive breast cancer by 65% in postmenopausal, high-risk women. Exemestane has not yet received FDA approval as a preventive treatment for breast cancer.
- Tamoxifen, raloxifene, and exemestane have not yet been approved by the European Medicines Authority for breast cancer prevention. However, guidelines from the National Institute for Health and Clinical Excellence (NICE) released in June of 2013 recommend offering high-risk (≥30% lifetime risk from age 20 or >8% risk between ages 40 and 50, determined by BOADICEA and/or the new Manchester scoring system), premenopausal women with no history of thromboembolic disease or endometrial cancer 5 years of tamoxifen treatment. NICE guidelines also recommend that high-risk, postmenopausal women with a uterus be offered tamoxifen or raloxifene, while high-risk, postmenopausal women without a uterus be offered tamoxifen for breast cancer prevention if they have no history of thromboembolic disease or endometrial cancer.

SECTION V

In Situ Carcinoma

CHAPTER 21

Ductal Carcinoma *In Situ* and Other Intraductal Lesions: Pathology, Immunohistochemistry, and Molecular Alterations

Adriana D. Corben and Edi Brogi

CHAPTER CONTENTS

Intraductal proliferative lesions are epithelial proliferations confined to the mammary ductal-lobular system. Based on architectural and cytologic features we classify these lesions as usual ductal hyperplasia (UDH), flat epithelial atypia (FEA), atypical ductal hyperplasia (ADH), and ductal carcinoma *in situ* (DCIS). DCIS, ADH, and FEA are established non-obligate morphologic precursors of breast carcinoma, albeit of very different biologic potential, whereas UDH is a benign proliferation that enters in the differential diagnosis of DCIS and ADH.

NORMAL BREAST

The mammary lobule is the milk-producing unit of the breast. It consists of a grape-like aggregate of acini surrounded by specialized mammary stroma. The acini drain into a terminal ductule, part of which is intralobular, and part extralobular. Few lobules and the terminal ductule that drains them form together the terminal duct lobular unit (TDLU) (Fig. 21-1A). Subgross pathology studies have shown that most of the epithelial changes occurring in the breast, including DCIS, originate in the TDLU (1).

The cellular lining of the mammary lobules and ducts consists of an inner (luminal) epithelial layer and an outer myoepithelial cell (MEC) layer. The luminal epithelium lining the glandular lumen has a polarized morphology, with the nucleus at one pole of the cell and an apical cytoplasmic compartment at the other end. Normal luminal epithelial cells show continuous linear membranous positivity for E-cadherin, a transmembrane adhesion molecule encoded by the *CDH1* gene, which is located at 16q22.1. Monostratified normal luminal cells usually are negative for CK5/6. A continuous layer of MECs surrounds the luminal epithelium. The morphology of MECs ranges from inconspicuous, with compressed nuclei and scant cytoplasm, to epithelioid with abundant clear cytoplasm. MECs can be readily demonstrated with immunohistochemical stains for cytoplasmic contractile proteins (i.e., calponin, smooth muscle actin, and smooth muscle myosin heavy chain) or p63—a p53 homologue that decorates the nucleus. E-cadherin reactivity in MECs has membranous linear distribution with a characteristic granular quality.

Estrogen and progesterone play a central role in regulating the growth and differentiation of normal breast tissue. Nuclear expression of estrogen receptor (ER)-α is present in normal ductal and lobular luminal cells, but it is limited to a small and sparse percentage of the cells, and varies with the phases of the menstrual cycle. ER-β is expressed more diffusely in normal breast tissue and is present in the epithelial cells of ducts and lobules, in MECs, endothelium, and stromal cells. The expression of ER-β does not vary during the menstrual cycle but is reduced in UDH, ADH, and DCIS. Some investigators have speculated that the

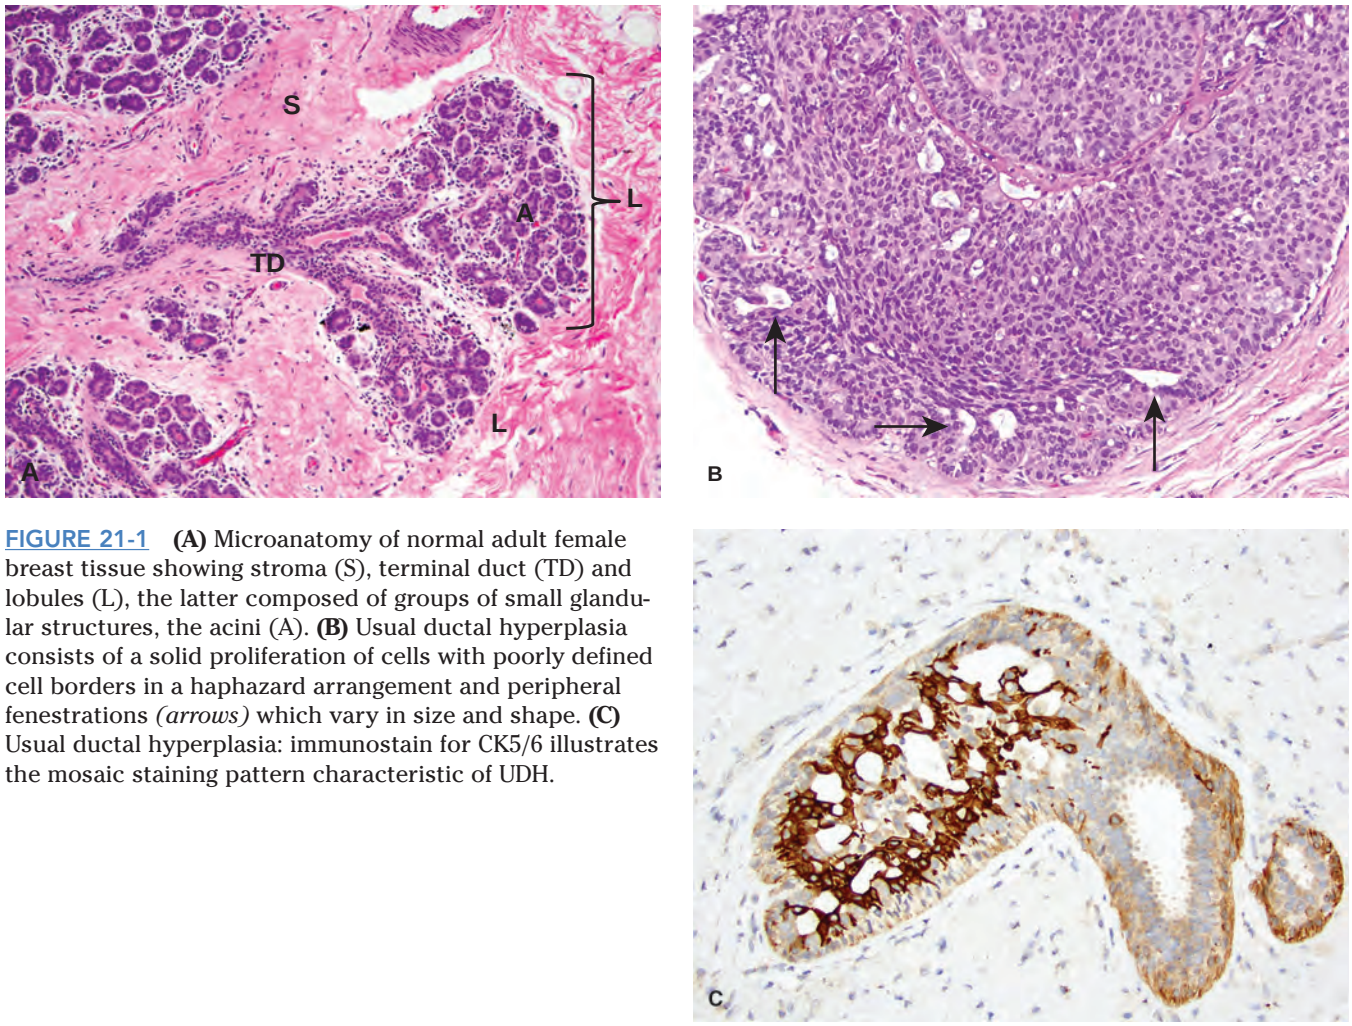

FIGURE 21-1 **(A)** Microanatomy of normal adult female breast tissue showing stroma (S), terminal duct (TD) and lobules (L), the latter composed of groups of small glandular structures, the acini (A). **(B)** Usual ductal hyperplasia consists of a solid proliferation of cells with poorly defined cell borders in a haphazard arrangement and peripheral fenestrations *(arrows)* which vary in size and shape. **(C)** Usual ductal hyperplasia: immunostain for CK5/6 illustrates the mosaic staining pattern characteristic of UDH.

relative levels of ER-β and ER-α may be important in determining the risk of breast cancer development and higher levels of ER-β relative to ER-α are protective against neoplastic progression. The expression of progesterone receptor (PR) in the ductal and lobular epithelium does not seem to vary with the menstrual cycle.

Carcinomas and its precursors are composed of transformed epithelial cells. Whether all breast epithelium has the potential to transform or this capability is limited to epithelial stem cells or progenitor cells is a topic of research and debate. Few authors have documented silent chromosomal alterations in morphologically normal epithelial cells, and suggested that they may predispose to premalignant or malignant transformation (2). However, these changes have low frequency and are more often seen in morphologically normal cells adjacent to carcinoma than away from it (2). Alterations affecting the p16 tumor suppressor gene increased epithelial proliferation and elevated expression of cyclooxygenase-2 (COX-2) have been documented in morphologically normal mammary epithelium, especially in women at high risk of breast carcinoma (3).

Usual Ductal Hyperplasia

The term *UDH* refers to a non-neoplastic epithelial proliferation. It can range from mild, consisting of just two to four cell layers, to florid, when it entirely fills and distends the ducts. UDH arising in a radial scar or in a papilloma can show focal necrosis, raising the differential diagnosis of DCIS. The cells comprising UDH are cytologically benign, vary in size, shape and orientation, have poorly defined borders, and are haphazardly arranged (Fig. 21-1B). Fenestrations lined by non-polarized cells are usually present within UDH, and often have circumferential distribution along the periphery of a duct.

Low and heterogenous expression of ER occurs in 30% to 40% of UDH cells, mainly at the periphery of the lesion. The proliferation rate is low (2%–5%). UDH shows a mosaic staining pattern for the basal keratins CK5/6 (see Fig. 21-1C) and 34BE12 (4). The pattern of immunoreactivity helps distinguish UDH from ADH and focal DCIS, as the latter two lesions are usually negative for these antigens with very few exceptions. Although some high-grade DCIS is CK5/6-positive, as discussed later in this chapter, nuclear atypia and pleomorphism distinguish it from UDH. UDH is associated with a 1.5- to 2-folds increase in the risk of breast cancer, which may occur in either breast. The risk is slightly higher in women with UDH who also have a first-degree relative with breast carcinoma (5).

Few and inconsistent genetic alterations have been documented in UDH, but no substantial shared genetic abnormalities with ADH, DCIS, or invasive breast cancer have been

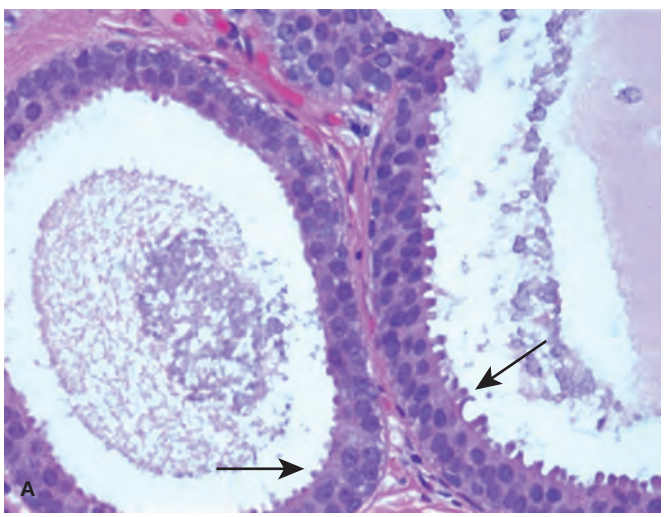
identified (6). Studies have shown that chromosomal loss of heterozygosity (LOH) is lower in UDH (4.5%–13%) than in ADH and low-grade DCIS (7). Comparative genomic hybridization (CGH) has identified few unbalanced chromosomal aberrations in UDH in some studies (8), but not in others (9). Some of the studies reporting chromosomal alterations in UDH used whole genome amplification methods (8) which may be more susceptible to artifacts. Overall, the chromosomal aberrations found in most UDH lesions are not similar to those observed in invasive carcinoma, effectively ruling out the possibility that UDH might represent a morphologic precursor of breast carcinoma (6).

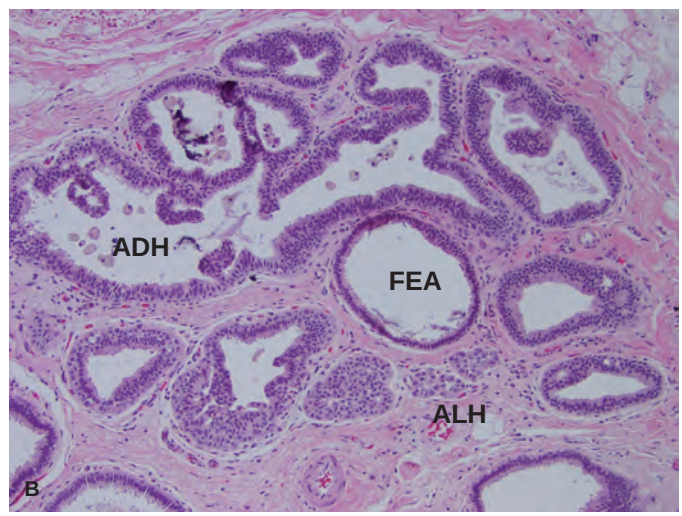
Flat Epithelial Atypia

FEA consists of enlarged TDLUs in which the native epithelial cells are replaced by "one to several layers of a single cell type showing low-grade (monomorphic) cytologic atypia" (10) (see Fig. 21-2A). The involved TDLUs have variably dilated acini with rounded contour. The nuclei of FEA cells are monomorphic, round to ovoid, and resemble those of ADH and low-grade DCIS. The proliferation is architecturally "flat" and devoid of any complex pattern (i.e., micropapillae, focal rigid bridges, bars and arcades, or sieve-like fenestrations) seen in ADH and low-grade DCIS. Lesions currently classified as FEA have been previously referred to by a wide range of terms, most notably "clinging carcinoma of the monomorphic type" and "columnar cell change with atypia." Columnar cell change, columnar cell hyperplasia, and FEA often coexist in adjacent lobules and even within the same TDLU. These diagnoses are not mutually exclusive, but only FEA has cytologic atypia.

The cells of FEA are positive for low-molecular-weight CKs, such as CK8, CK18, and CK19 (9). Even though FEA cells lack expression of high-molecular-weight CKs, such as CK5/6 (9,11), immunohistochemical stains for CK5/6 do not help to differentiate FEA from monostratified normal ductal epithelium, as the latter is also CK5/6 negative. In FEA strong positivity for ER is present in about 85% of the cells (9,12) and for PR in about 50% (9,12). The cells are characterized by strong cytoplasmic expression of bcl-2, and show minimal to no apoptosis (12). The proliferation index of FEA is significantly higher than in morphologically normal TDLUs (6% vs. 2%, respectively) (12).

FEA commonly coexists with ADH (see Fig. 21-2B), low-grade DCIS and tubular carcinoma, and shares close cytologic and immunophenotypic similarities with these lesions (1,13,14). Few investigators have also noted an association between columnar cell lesions/FEA and lobular carcinoma *in situ* (LCIS) and atypical lobular hyperplasia (ALH) (see Fig. 21-2B-C) (13,15).





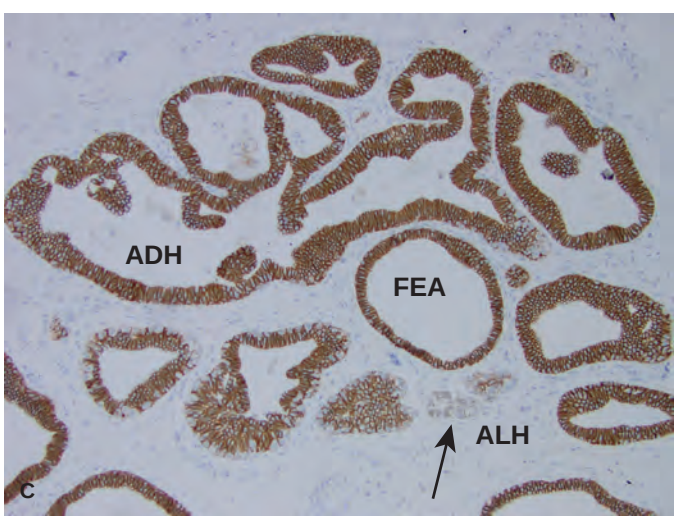


FIGURE 21-2 **(A)** Flat epithelial atypia (FEA): the lining epithelial cells have prominent apical cytoplasmic snouts *(arrows)* and round to oval nuclei, relatively uniform in appearance. Low-grade, monomorphic-type cytologic atypia characterizes FEA. **(B)** FEA, atypical ductal hyperplasia (ADH) and atypical lobular hyperplasia (ALH). Some of the spaces in this TDLU show the characteristic features of FEA. One space shows a rigid bridge and cellular tufts composed by cells cytologically identical to those of FEA, however, because of the more complex architecture in this space, a diagnosis of ADH is warranted. ALH frequently coexists with FEA and ADH. **(C)** E-cadherin staining of the same area shown in **(B)**. Loss of membranous E-cadherin is appreciated in ALH *(arrow)*, whereas the epithelial cells of the normal TDLU, FEA, and ADH show strong membtranous positivity.

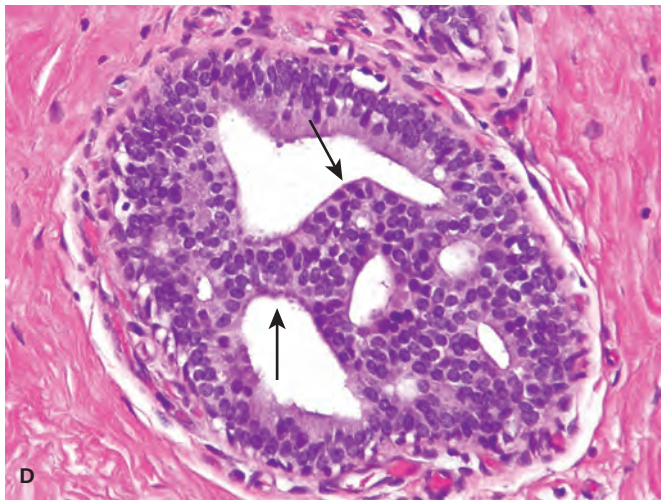

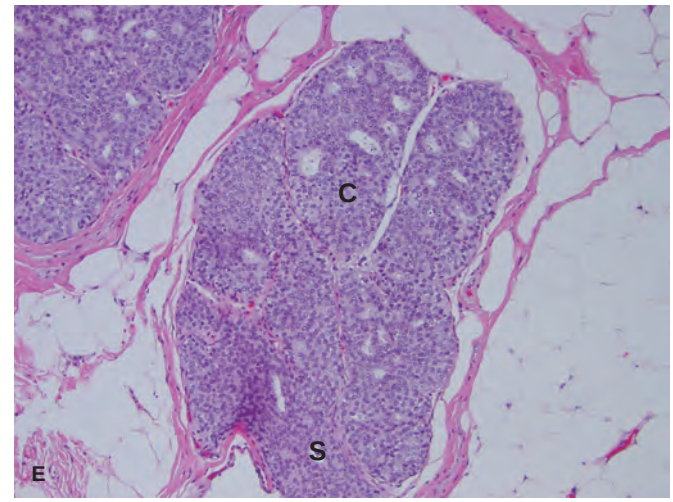

FIGURE 21-2 *(Continued)* **(D)** ADH comprising of uniform atypical cells in cellular rigid bridges *(arrows)*. The qualitative features of this lesion approach those of low-grade DCIS, but the lesion is limited in extent. **(E)** Low-grade DCIS with a solid (S) and cribriform (C) architectural pattern. The nuclei are small and uniform in appearance.

Molecular analysis shows that FEA has recurrent chromosomal alterations consistent with a clonal population (9,16). Recurrent copy number alterations include loss of 16q and gains of 15q, 16p, 17q, and 19q. Allelic imbalances are most frequently seen at 3p, 9q, 10q, 11q, 16q, 17p, and 17q (16).

Based on these findings FEA is part of the spectrum of low-grade mammary epithelial lesions (Fig. 21-3A), which include ADH, low-grade DCIS, tubular and tubulolobular carcinoma, invasive cribriform carcinoma, low-grade invasive ductal carcinoma, ALH, classic LCIS and invasive lobular carcinoma, classic type. It has been proposed that FEA represents the first morphologically recognizable precursor of low-grade mammary neoplasia (9,14). The risk of subsequent carcinoma associated with FEA has not been fully determined, but it is believed to be lower than for ADH (10). At present, no additional treatment or special screening modalities are recommended for patients with only FEA (10).

Atypical Ductal Hyperplasia

ADH is a very focal neoplastic epithelial proliferation confined to the mammary ductal-lobular system. The cells composing ADH are relatively small and monomorphic, with round to avoid nuclei, fine chromatin and inconspicuous nucleoli. They tend to be evenly spaced, show well-defined cell borders and focally form rigid arches and bridges (see Fig. 21-2D), trabecular bars of uniform thickness, or club-shaped micropapillae. They can also display solid foci or focal incomplete cribriform pattern, which results from the orderly arrangement of polarized cells around a neoformed glandular lumen. These cells are morphologically similar to those composing low-grade DCIS, but they are not as homogeneous. Extent of the lesion is an important criterion in differentiating ADH from low-grade DCIS, although there is no universally accepted size cutoff to distinguish between the two. Usually DCIS is diagnosed when the neoplastic proliferation involves at least two separate ducts or spans at least 2 mm, and any smaller lesion is classified as ADH. The diagnosis of ADH applies only to lesions for which the differential diagnosis of low-grade DCIS is considered, but that do not show the full range of diagnostic features. Despite undeniable limitations, the use of size criteria fosters interobserver reproducibility in the interpretation of small borderline ductal lesions.

The cells comprising ADH typically have strong and nearly uniform (90%–100%) positivity for ER and PR, but no cytoplasmic reactivity for CK5/6 (11) and 34BE12 (4). The use of these markers is of no practical value in the differential diagnosis with low-grade DCIS, but can be useful in the differential diagnosis with UDH, that is positive with a checkerboard pattern (see Fig. 21-1C). ADH has a low proliferative rate (4%–5%).

Recurrent chromosomal alterations including losses at 16q and 17p and gains at 1q (9) have been identified in ADH, similar to the changes found in low-grade DCIS as well as in the lesions part of the low-grade mammary epithelial neoplasia family (see Fig. 21-3A).

ADH is associated with a four to five-fold increase in the risk of subsequent breast cancer, with approximately equal frequency in both breasts.

Apocrine Lesions

The normal breast often shows apocrine metaplasia. Apocrine metaplastic cells are enlarged, have abundant finely granular, and eosinophilic cytoplasm, large round vesicular nuclei, prominent eosinophilic nucleoli and intracytoplasmic vacuoles (17). The degree of nuclear enlargement and prominence of the nucleoli can be worrisome and misleading, unless the apocrine nature of the process is recognized. Usually apocrine metaplasia is an incidental finding and coexists with benign or malignant lesions.

Apocrine atypical cells are characterized by enlarged nuclei with at least three-fold variation in size (17). The distinction between atypical apocrine adenosis and apocrine DCIS can be challenging, especially when the apocrine proliferation involves sclerosing adenosis or a sclerosing lesion. In equivocal cases a conservative diagnosis of atypical apocrine adenosis is usually preferable. Atypical apocrine adenosis in a core needle biopsy mandates excision.

When atypical apocrine epithelium is present in sclerosing adenosis, the combination of epithelial cells with enlarged nuclei and prominent nucleoli and glandular

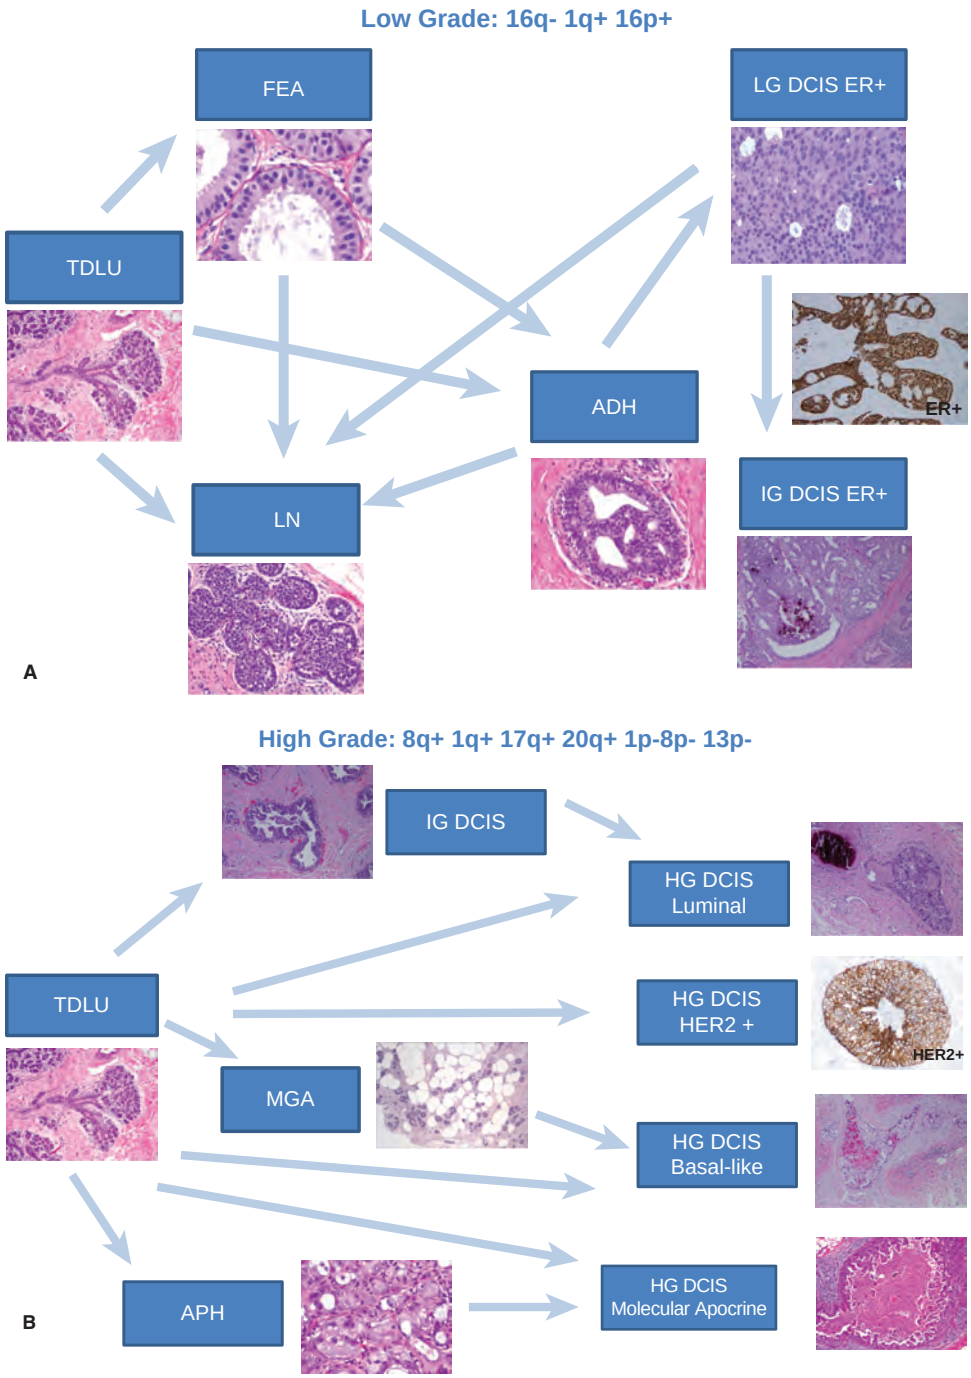

FIGURE 21-3 **(A)** "Low-grade breast neoplasia family." Similar genomic aberrations have been identified in FEA, ADH, low-grade DCIS, and lobular neoplasia (ALH/LCIS). FEA is the earliest morphologically recognizable precursor of this group of lesions. **(B)** High-grade (HG) DCIS. This heterogenous group of lesions lacks ER, PR and expresses HER2. A basal-type of DCIS is also present. The high-grade DCIS harbor numerous genomic chromosomal alterations. Connectors drawn with discontinuous lines (microglandular adenosis and atypical apocrine hyperplasia) represent hypothetical links yet to be demonstrated modified from diagram of Lopez-Garcia et al. (6).

distortion produces a pattern that can mimic invasive apocrine carcinoma. Immunostains for MEC markers are useful in the differential diagnosis with invasive carcinoma.

Intraductal apocrine lesions are typically androgen receptor (AR) positive and frequently lack ER and PR expression. HER2 expression has not been reported in benign apocrine lesions, but it has been described in up to 50% of *in situ* and invasive apocrine carcinomas (18).

Genetic studies of apocrine metaplasia have shown that at least a proportion carries genetic changes, suggesting that some lesions are clonal and may represent non-obligate morphologic precursors of carcinoma (19,20). Selim et al. (20) assessed LOH in 41 cases of benign apocrine lesions with different degrees of architectural complexity and found that 20% of cases showed allelic alterations in at least one chromosomal locus. Jones et al. (19) used CGH to compare 10 cases of apocrine micropapillary hyperplasia, 10 apocrine DCIS, and 4 invasive apocrine carcinomas, and found that the number of unbalanced genetic aberrations was directly related to the complexity and atypia of the lesion. In particular, the mean number of chromosomal alterations in apocrine hyperplasia was 4.1 compared to 10.2 in apocrine DCIS and 14.8 in invasive apocrine carcinoma. The most common alterations in apocrine hyperplasia included

gains of 2q, 13q, and 1p, and losses of 1p, 17q, 22q, 2p, 10q, and 16q (19). Apocrine *in situ* and invasive carcinomas most commonly showed gains of 1q, 2q, and 1p, and losses of 1p, 22q, 17q, 12q, and 16q (19).

The breast cancer risk associated with apocrine adenosis and atypical apocrine adenosis has not been well defined. In one study, none of 47 patients with atypical apocrine adenosis developed cancer at a mean follow-up of 35 months (21). A study of 37 patients with mean follow-up of almost 9 years documented a relative risk of 5.5 (17), but the authors acknowledged that some of their index cases may have represented apocrine DCIS involving sclerosing adenosis rather than atypical apocrine adenosis. A recent study (22) of 37 patients with atypical apocrine adenosis and average follow-up of 14 years identified 3 out of 37 women (8.1%) who developed breast carcinoma. In one patient DCIS was diagnosed in the contralateral breast after a 12 year follow-up. Two patients developed ipsilateral invasive carcinoma after 4 and 18 years. No apocrine atypia was present in the background breast parenchyma and the tumors showed no evidence of apocrine differentiation. Despite the limited number of study patients, the authors concluded that atypical apocrine adenosis does not appear to be an aggressive lesion and it should not be regarded as a direct precursor of breast carcinoma (22).

DUCTAL CARCINOMA *IN SITU*

The term *DCIS* is defined by the World Health Organization (WHO) as "a neoplastic proliferation of epithelial cells confined to the mammary ductal-lobular system and characterized by subtle to marked cytologic atypia and an inherent but not necessarily obligate tendency to progression to invasive breast cancer" (10). DCIS encompasses a heterogeneous group of lesions that differ significantly with regard to clinical presentation, morphologic features, biomarker profile, genetic abnormalities and biologic potential.

At present, DCIS accounts for about 20% to 25% of all newly diagnosed breast cancers, compared to less than 5% in the pre-screening mammography era. Overall, the incidence of DCIS rose from 1.87 cases per 100,000 women in 1973–1975 to 32.5 cases per 100,000 women in 1999–2004. Much of this increase is attributable to the widespread adoption of screening mammography and better detection of lower grade lesions. In general, the rate of noncomedo DCIS has increased across all age groups, whereas the rate of comedo DCIS has been constant or decreased.

In current clinical practice, 80% to 85% of cases with DCIS are detected because of associated mammographic calcifications (Ca^{2+}), which are usually rod shaped or linear branching in high-grade DCIS or granular and segmental in low-grade DCIS. Up to 20%–30% of DCIS may present as a soft tissue density with or without associated Ca^{2+} or as an area of architectural distortion. Rarely DCIS presents as a palpable mass, nipple discharge, Paget's disease of the nipple, or constitutes an incidental microscopic finding in breast tissue removed for another abnormality.

In most (98.8%) cases DCIS is unicentric and has segmental distribution, as elegantly demonstrated by Holland et al. (23). Multicentric DCIS, defined as foci of DCIS in two different quadrants separated by morphologically normal intervening breast parenchyma, is relatively uncommon (23). Discontinuous growth within ducts has been reported in 70% of low-grade DCIS, 55% of intermediate-grade DCIS, and 10% of high-grade DCIS (24), but the discontinuity could result from incomplete visualization of a complex branching three-dimensional structure in a two-dimensional plane. The designation of extensive ductal component applies whenever DCIS admixed with invasive carcinoma constitutes 25% or more of the tumor mass and/or extends away from it.

The diagnosis of DCIS with either high or intermediate nuclear grade is independent from the extent of the lesion, whereas size greater than 2 mm or involvement of at least two ducts is required for the diagnosis of DCIS with low nuclear grade. In core biopsy (CBX) material, it may be difficult to differentiate ADH (see Fig. 21-2D) and focal low-grade DCIS (see Fig. 21-2E) and a conservative approach is usually recommended. Ideally, the final interpretation of a small atypical borderline ductal lesion diagnosed at CBX would involve re-evaluation of the CBX material together with the surgical excision specimen, but this practice is not always possible. Fine needle aspiration (FNA) of DCIS shows large aggregates of neoplastic cells, admixed with single cells and rare small stromal fragments. In general, the FNA material obtained from DCIS contains fewer single cells and fewer stromal fragments than the FNA material obtained from an invasive carcinoma. These morphologic features, however, are variable and their interpretation is also operator dependent. Therefore, the positive predictive value and interobserver reproducibility of FNA in the diagnosis of DCIS versus invasive carcinoma are relatively low. Although combination of the cytology findings with clinical and radiologic features often allows to "best guess" whether the lesion represents DCIS or invasive carcinoma. CBX has become the preferred method of preoperative diagnosis, as it provides more definitive, consistent and reproducible information, as well as tissue suitable for ancillary studies.

DCIS is a non-obligate morphologic precursor of breast carcinoma, but its rate of progression varies greatly depending on the intrinsic biology of the lesion. Recurrence is also dependent on its complete removal and adjuvant treatment.

Gross Examination

At present, most cases of DCIS do not display overt macroscopic findings at gross examination. DCIS with high nuclear grade and extensive necrosis sometimes forms a mass lesion because of substantial periductal fibrosis. Specks of pasty material consisting of necrotic debris extruding from the ducts may be noted on the cut surface of a specimen containing high-grade DCIS with extensive necrosis. Mass-forming lesions regarded in the past as intracystic papillary DCIS are now re-classified as encapsulated papillary carcinoma, a recently recognized special variant of low-grade invasive carcinoma with extremely indolent behavior (10). Despite morphologic reclassification as an invasive process in the absence of an overt invasive carcinoma, the management of these tumors remains unchanged.

If a surgical excision was obtained to remove an area of DCIS with associated Ca^{2+} the specimen radiograph obtained to document removal of the calcified target is used by the pathologist to localize the area of interest in the corresponding gross specimen. At present, a preoperative diagnosis of DCIS obtained by CBX is available for most cases, and histologic evaluation of the CBX site needs to be documented in the report to ensure that the radiologic target was removed and examined histologically.

Because of the paucity of gross findings in most cases of DCIS, extensive histologic sampling of the resection specimen is required for optimal evaluation of the lesion, to assess the extent of DCIS, exclude the possibility of (micro)invasion, and accurately evaluate margin status. As recommended by the College of American Pathologists (CAP) (25), the surgical excision specimen is measured in all three dimensions, and

serially sliced in 0.3 to 0.4 cm thick sections perpendicular to the major axis. In some laboratories, radiographic images of the tissue slices are obtained to identify all Ca^{2+} and ensure that they are examined histologically. A surgical specimen obtained following CBX diagnosis of DCIS is usually entirely and sequentially submitted for histologic examination. Practically speaking, surgical excision specimens larger than 6 cm are often sampled selectively by submitting a wide area of tissue (radius of about 2.5 to 3 cm) centered around the biopsy site, any area of gross abnormalities, and representatively sections of the grossly unremarkable breast parenchyma away from the biopsy site. The remaining tissue is saved and can be submitted at a later time, if the pathologist deems it necessary.

At present, there is no universally accepted classification system for DCIS. The pathology report should include information about the morphologic features of DCIS that have been shown to correlate with clinical behavior and outcome. These parameters were first agreed upon by the panelists of a consensus conference on DCIS in 1997 and have been further detailed and expanded in the protocol for examination of breast specimens with DCIS released by the CAP in 2009 (25).

Size

The size of DCIS correlates with the likelihood of residual disease after re-excision, close or positive margins, local recurrence, and the possibility that undetected areas of invasion might exist. However, if wide margins are obtained, the extent of DCIS is not as important for predicting local recurrence. The following methods are used to assess the size of DCIS (Fig. 21-4A–E).

a) If DCIS is present in only one tissue block, its size is measured microscopically as the largest span between the two ducts involved by DCIS that are further away from one another. This situation is rare, as such small lesions are uncommon (see Fig. 21-4A).
b) If the surgical specimen is entirely and sequentially submitted, and DCIS is present in few consecutive tissue blocks, the size of DCIS is estimated by multiplying the number of blocks involved by DCIS by the thickness of the tissue in each block (approximately 0.4 cm) (see Fig. 21-4B).
c) If only representative blocks of the surgical specimen are submitted, account should be kept of the intervening sections not submitted for histologic examination. The extent of DCIS is estimated by adding the number of the blocks microscopically proven to contain DCIS and the number of the intervening blocks and multiplying the sum by the estimated thickness of each block (see Fig. 21-4C).
d) If DCIS involves opposing margins of a specimen, the span of DCIS is as great as the distance between the two margins (see Fig. 21-4D).
e) When high-grade DCIS forms a mass lesion, the size of the mass is measured grossly and confirmed microscopically (see Fig. 21-4E).

The largest estimate obtained using any of the above methods is the estimated extent of DCIS in the specimen. Gaps in ductal involvement suggestive of multifocality may occur, particularly in cases of low-grade DCIS.

In the current practice of breast-conserving surgery, DCIS may be incompletely excised by the first surgical procedure and is present in either multiple specimens from the same surgical procedure or in multiple specimens from subsequent procedures. In these cases, the span of DCIS present in different specimens cannot be added and the pathologic size is the largest span of DCIS in any of the specimens. Close correlation with imaging studies is recommended. The mean or median size of DCIS reported by few investigators ranges from 1.4 to 2.7 cm.

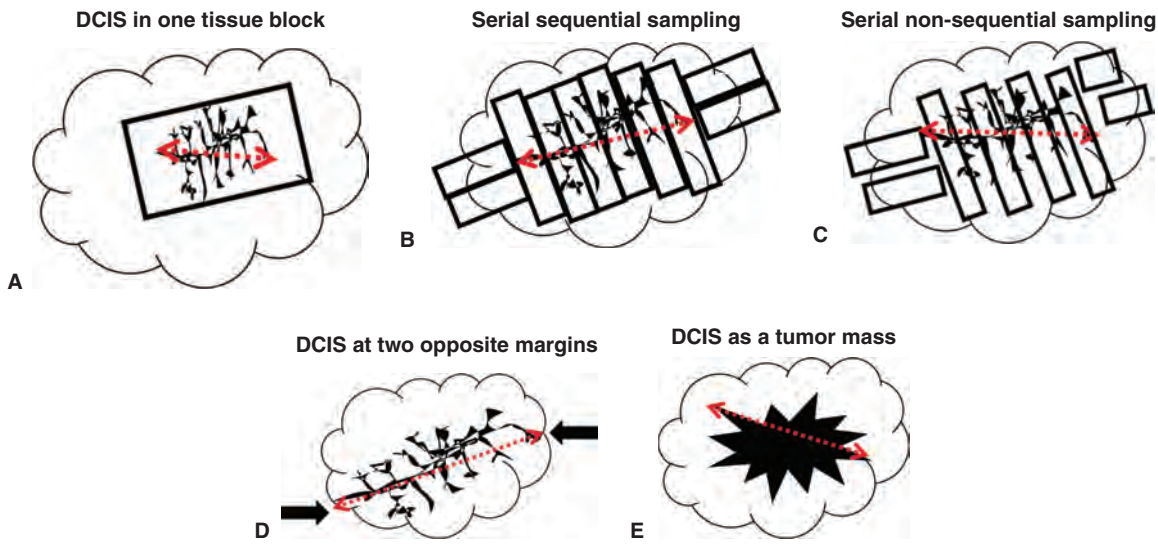

FIGURE 21-4 **(A)** If DCIS is present only in one tissue block, the size of DCIS is measured on the H&E slide as the largest distance between two ducts involved by DCIS. **(B)** If the specimen is entirely and sequentially submitted, the size of DCIS is estimated based on the number of the involved tissue blocks: i.e., 6 consecutive blocks × 0.4 cm = DCIS spans 2.4 cm. **(C)** If the specimen is not entirely submitted, the size of DCIS is estimated as in B) by adding the number of un-sampled intervening slices: i.e., (4 blocks + 3 intervening sections) × 0.4 cm = DCIS spans 2.8 cm. **(D)** If DCIS involves two opposite margins, the size of DCIS corresponds to the distance between the two margins. **(E)** If the DCIS forms a tumor mass, the size of DCIS is measured grossly modified from diagram of Lester et al. (25).

Nuclear Grade

DCIS is stratified primarily by nuclear grade. Low-grade nuclei are slightly enlarged (1.5×–2× the size of a red blood cell [RBC]) and uniform, have a regular nuclear membrane, fine and homogeneous chromatin and rare inconspicuous nucleoli. High-grade nuclei are large (size greater than 2.5× RBC), have marked variation in size and shape, coarse chromatin and prominent, sometimes multiple nucleoli. Mitoses are frequent. Intermediate-grade nuclei are less pleomorphic than high-grade nuclei, but lack the uniformity characteristic of low-grade nuclei. Nuclear grade within a given DCIS lesion tends to be relatively uniform in 84% of cases, but it is heterogeneous in the remaining 16% (26).

Architectural Patterns

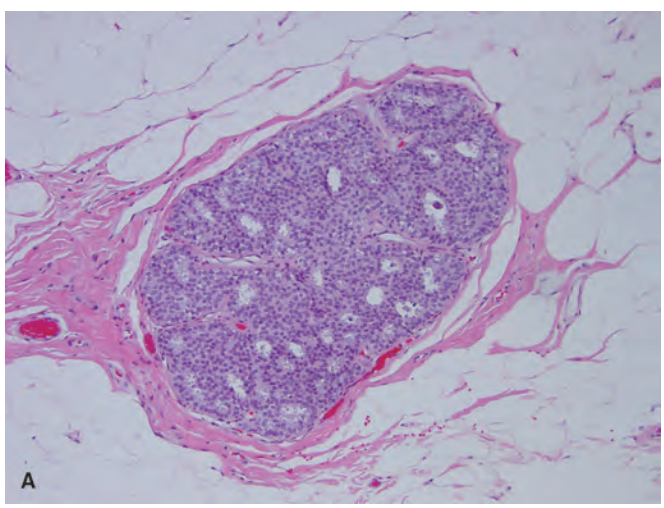
DCIS can show few different patterns (Fig. 21-5A–E) including cribriform, micropapillary, papillary, solid and clinging/flat. The comedo type is characterized by extensive central zonal necrosis. DCIS with mixed architectural patterns constitutes the majority of cases (62%), followed by solid DCIS (31%) (26). This classification has only minimal clinical or prognostic significance, although it shows some correlation with extent of disease. Bellamy et al. (27) found that involvement of more than one quadrant occurred in 71% of cases of micropapillary DCIS, irrespective of nuclear grade or necrosis, whereas comedo, solid and cribriform DCIS involved more than one quadrant only in 8%, 17%, and 25% of cases, respectively. When completeness of local excision was related to architectural pattern, solid DCIS (including solid DCIS with necrosis) was significantly more often completely excised (72%) than DCIS with any other architectural pattern (30%) (p <.01) (27).

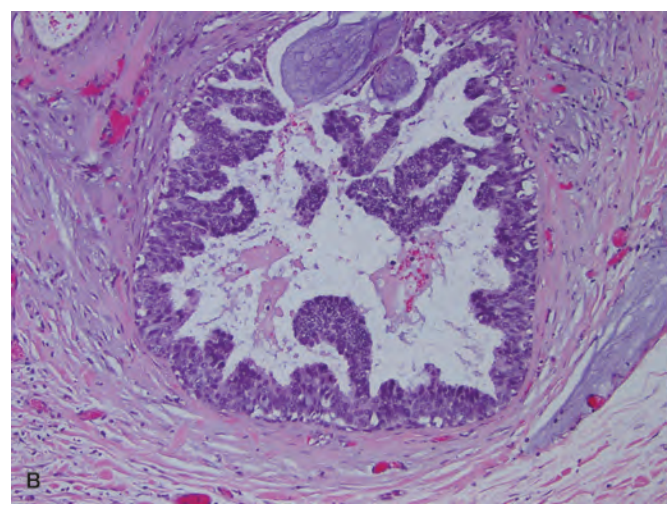
Necrosis

A number of studies have shown that the presence of necrosis in DCIS modifies the risk associated with nuclear grade. Necrosis is defined as the presence of ghost cells and karyorrhectic debris and can involve the central zone of a duct (comedo necrosis) or be punctate and non-zonal. Zonal necrosis usually occurs in DCIS with high nuclear grade and often contains coarse Ca^{2+}. *Comedo DCIS* is a descriptive term which refers to the gross finding of pasty material extruding from the ducts that may be in cases of DCIS with extensive necrosis, but it is not specific for a certain nuclear grade, architectural pattern, or extent of necrosis.

Margin Assessment

There is no standard method of margin evaluation for breast specimens with DCIS (or with invasive carcinoma). Furthermore, the definition of a positive margin (tumor at ink) is agreed upon, but there is no full agreement on what constitutes a "negative" margin. Margin status can be evaluated using different methods, but two are the most commonly used.





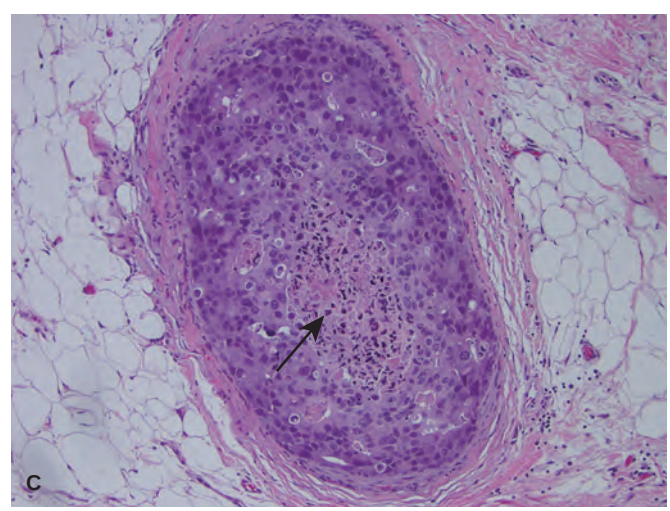


FIGURE 21-5 Nuclear grading and architectural patterns of DCIS: **(A)** low-grade, cribriform, **(B)** intermediate-grade, micropapillary, **(C)** high-grade, solid with central necrosis *(arrow)*,

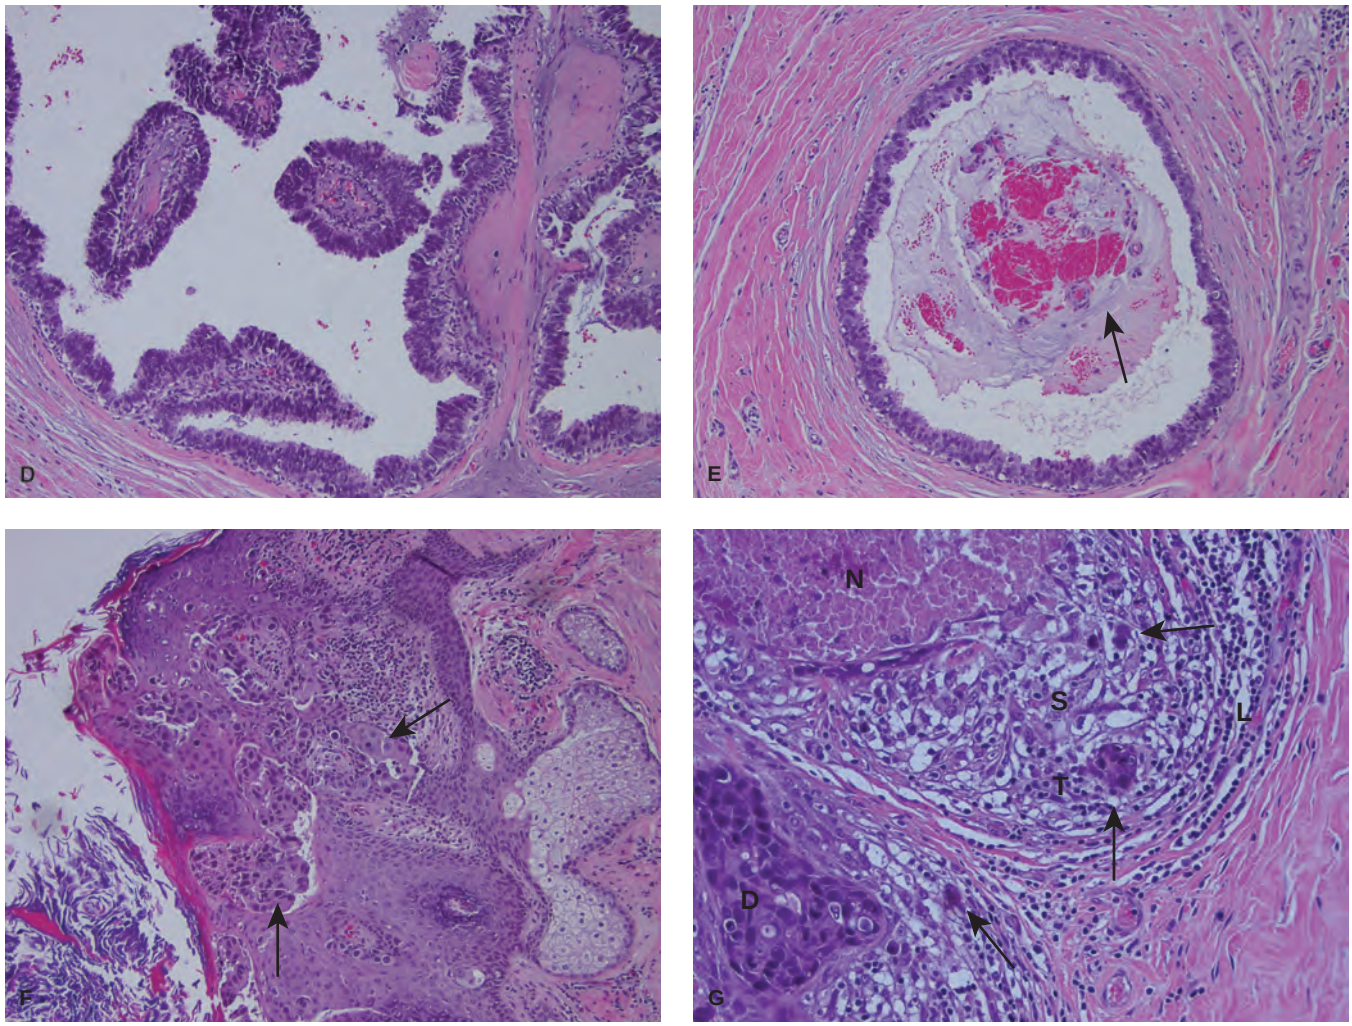

FIGURE 21-5 *(Continued)* **(D)** intermediate-grade, papillary, and **(E)** intermediate-grade, flat with mucin production *(arrow)*. **(F)** Paget's disease: scattered malignant glandular epithelial cells *(arrows)* are present in the epidermis. The cells have large nuclei with prominent nucleoli and pale, amphophilic cytoplasm. **(G)** Microinvasive ductal carcinoma: the foci of high-grade solid DCIS (D) are associated with Necrosis (N) and are surrounded by Stromal desmoplasia (S) and dense Lymphocytic infiltrate (L). Admixed within the lymphocyte-rich stroma are few Tumor cells (T, *arrows*), singly and in small nests.

a) *Radial (perpendicular) margin.* The specimen is oriented with at least two of the margins (usually superior and lateral margins) marked with metal clips or sutures. The six margins of the specimen are inked by the surgeon or by the prosector using different colors. The specimen is sectioned, and perpendicular sections of the inked margins are submitted for microscopic examination. This technique allows measuring the exact microscopic distance between DCIS and the closest inked margin present in the same tissue section.

b) *All margins of the lumpectomy cavity are separately submitted by the surgeon.* The surgeon resects the index lesion and then removes separate margins from the superior, inferior, lateral, medial, and posterior wall of the surgical cavity. An anterior margin specimen may or may not be submitted. The surgeon designates with a suture or clip the surface of each additional margin specimen that corresponds to the final surgical margin. This surface is inked by the prosector, and the specimen is sectioned with cuts perpendicular to the inked surface. The distance between DCIS and the closest linked margin is assessed. The main excision specimen containing the target lesion is usually not oriented and does not necessarily need to be inked. This method allows precise margin designation, accurate measurement of margin width, and avoids disruption of the tissue secondary to compression at the time of specimen radiography. A study has reported a reduced rate of re-excision for excisions that used this method (28).

Calcifications

Most cases of DCIS are diagnosed following biopsy of microcalcifications detected on screening mammograms. The radiologist usually qualifies the calcifications (Ca^{2+}) as "suspicious" or "pleomorphic" to indicate high level of concern for DCIS. At the time of the CBX the radiologist separates the core containing Ca^{2+} from those without. The cores with Ca^{2+} and the additional tissue cores without Ca^{2+} kept separate and placed in formalin-filled specimen container and submitted to pathology. The prosector submits the tissue in separate cassettes indicating whether the tissue contains Ca^{2+} or not. Core needle

biopsies performed for mammographic Ca^{2+} are also received with the specimen x-ray. When reviewing the hematoxylin and eosin (H&E) slides of a case, the pathologist examines the accompanying specimen x-ray to determine if the amount of Ca^{2+} present in the slides accounts for the amount, size and type of Ca^{2+} seen in the specimen x-ray. If insufficient Ca^{2+} are present in the H&E slides, the tissue blocks are x-rayed to verify which block(s) contain Ca^{2+} and how deep they are into the tissue block. Deeper sections are cut until the target Ca^{2+} are identified.

For proper correlation with the mammographic findings, the pathologist needs to detail whether Ca^{2+} are present in the surgical excision specimen and if they are associated with DCIS and/or present in benign breast parenchyma. The identification of residual Ca^{2+} in a post-excision mammogram is a strong predictor of residual DCIS and constitutes an indication for re-excision, even if the margin of the prior excision specimen was reported as negative.

Subtypes

Based on these above features, DCIS is subdivided into three large groups, generally referred to as high-grade, low-grade, and intermediate-grade DCIS.

High-Grade DCIS usually has high nuclear grade, solid or micropapillary architecture with central zonal (comedo) necrosis (see Fig. 21-5). The neoplastic cells show little to no polarization. Coarse pleomorphic Ca^{2+} are typically associated with necrotic debris. The periductal stroma often displays a cellular fibroblastic proliferation with collagen deposition (desmoplasia), chronic inflammation, and angiogenesis. The stromal response may be very prominent and result in a palpable breast abnormality. Paget's disease of the nipple is almost invariably associated with high-grade DCIS (see Fig. 21-5).

Low-Grade DCIS is a relatively monotonous proliferation of polarized cells with round and uniform nuclei. The neoplastic cells are orderly assembled into club-shaped micropapillae and/or cribriform spaces; a purely solid architecture is less common (see Fig. 21-5). The associated Ca^{2+} are often small and psammomatous. Albeit very uncommon, the presence of foci of punctate necrosis does not preclude the diagnosis of low-grade DCIS if the neoplastic cells show the characteristic cytologic features.

Intermediate-Grade DCIS typically has solid or cribriform architecture and most of the cells are polarized. The nuclei have features intermediate between low and high grade, and necrosis and mitotic activity can vary (see Fig. 21-5).

Unusual Morphologic Variants

A minority of DCIS lesions show unusual morphology. Variants of DCIS have signet ring, apocrine, spindled or even squamous morphology. There is no consensus or uniform approach to the grading of these unusual variants, although some believe that nuclear features and necrosis are most informative of the biology of the lesion. One of the most common variants is *DCIS with apocrine morphology* (see Fig. 21-3B). It usually has solid, micropapillary or cribriform architecture. The cells have abundant and somewhat granular eosinophilic cytoplasm and large nuclei with prominent nucleoli. Nuclear atypia is usually moderate to severe, but low-grade apocrine DCIS can also occur. Central necrosis is often present in high-grade apocrine DCIS, raising the differential diagnosis with high-grade non-apocrine DCIS. Calcifications may be seen in the involved ducts. A diagnosis of high-grade apocrine DCIS is usually straightforward because these lesions are characterized by marked cytologic atypia and frequently comedo necrosis. At the other end of the spectrum, it may be difficult to distinguish low-grade apocrine DCIS from apocrine metaplasia because they share similar features, such as round shape and single prominent nucleoli. An apocrine intraductal proliferative lesion composed of cells with only minimal cytoplasmic atypia should be categorized as DCIS only if it has fully developed architectural features of DCIS. Apocrine DCIS can extend into lobules and into areas of sclerosing adenosis, in a pattern that simulates invasive carcinoma. Immunostains for myoepithelial cells are valuable in resolving this differentiated diagnosis. Sometimes, it may be difficult to distinguish apocrine DCIS involving sclerosing adenosis from atypical apocrine adenosis, particularly when cytologic atypia is low or moderate.

Cystic hypersecretory DCIS is another uncommon, but extremely characteristic variant of DCIS. It is characterized macroscopically and microscopically by cysts filled with viscid and homogenous eosinophilic material that closely resembles thyroid colloid. Invasive carcinoma associated with cystic hypersecretory DCIS is usually high grade and has no specific morphology.

Post Treatment

Even if invasive carcinoma shows pathologic complete response in patients treated with neoadjuvant chemotherapy DCIS may persist. In such cases, DCIS usually shows chemotherapy effect, including bizarre cytomorphology and large coarse intraductal Ca^{2+}. The full spectrum of these alterations, probably dependent on different treatment agents, has not been fully characterized. Conversely, adjuvant radiotherapy greatly alters the normal ductal epithelium and some of the early changes induced by radiotherapy can mimic residual/recurrent DCIS. In particular, tissue biopsies obtained within the first few months since completion of radiotherapy need to be examined carefully, and the findings should be compared with those in the untreated DCIS, to avoid overdiagnosis.

Immunoprofile

Generally speaking, low-grade DCIS is characterized by diffuse and strong expression of ER-α in 90% to 100% of cells (see Fig. 21-3A). PR is also positive in most cells. The proliferation rate of low-grade DCIS tends to be low (around 5% to 6%) and does not differ significantly from that of FEA and ADH. HER2 is rarely expressed in low-grade DCIS, but may be detected in up to 10% of the cells. In contrast, high-grade DCIS is ER-positive in 30% to 90% of the cases, show variable positivity for PR, and has a higher proliferation rate (Ki-67 staining in up to 30% to 40% of the cells). HER2 protein expression and gene amplification is detected in about 70% of intermediate- and high-grade DCIS, and usually characterizes biologically aggressive DCIS (see Fig. 21-3B). The use of HER2 targeted therapy for DCIS is currently explored in clinical trials. Nuclear p53 protein and p53 gene mutations are seen in about half of high-grade DCIS cases (29). Intermediate DCIS lesions are more heterogenous with regard to the expression of the above biomarkers. AR is also expressed in some forms of DCIS. In one study (30), AR was detected in 89.3% of ER-positive DCIS, in 87.9% of PR-positive DCIS and in 80% of HER2-positive DCIS.

The benefit of tamoxifen treatment in patients with DCIS managed by surgical excision and radiotherapy correlates with ER-positivity (31). Status of ER in DCIS is assessed routinely using immunochemistry. In clinical practice, ER- or PR-positivity result is defined as nuclear staining in at least 1% of the cells.

All types of DCIS have strong and continuous linear membranous positivity for the adhesion molecule E-cadherin.

Following the identification of molecular subtypes of invasive breast carcinoma (i.e., Luminal A and B, HER2-rich, and basal subtypes) (32) and of surrogate molecular immunoprofiles based on reactivity for ER, PR, HER2, and basal markers CK5/6 and epidermal growth factor receptor (EGFR), investigators have documented similar molecular subtypes in DCIS. In particular, a basal subtype of DCIS (i.e., ER-, PR-, and HER-negative and CK5/6- and/or EGFR-positive) has been identified (33). Basal DCIS constitutes about 6% to 8% of all DCIS. It has intermediate to high-grade morphology (34) (see Fig. 21-3B), but the morphologic features of basal DCIS are not sufficiently characteristic to recognize it without the use of immunohistochemical markers. Cytoplasmic positivity for CK5/6 and/or EGFR in basal DCIS is focal and heterogeneous, and not too different from that observed in UDH, but nuclear atypia is high. Basal DCIS was identified in 32/392 (8.2%) women with DCIS. In one study (34) the nuclear grade was high in 20 (62.5%) cases, intermediate in 11 (34.4%) and low in one (3.1%) case. Twenty-six women underwent breast-conserving surgery and 10 received postoperative radiotherapy. Six women were treated by mastectomy. At median follow-up of 122 months (range 3–130), basal-like DCIS showed higher risk for local recurrence, invasive recurrence and systemic recurrence than non-basal DCIS, but the results were not statistically significant. These differences were not attributable to triple negative phenotype (34). At present, basal DCIS does not constitute a specific diagnostic entity and it is not commented upon in a pathology report.

Differential Diagnosis

The differential diagnoses of FEA versus clinging DCIS, UDH versus DCIS, and ADH versus DCIS are mentioned in prior paragraphs. Three other important differential diagnoses are discussed below.

DCIS versus LCIS

The distinction between solid DCIS versus LCIS has significant implications with regard to assessment of margin status and the extent of surgical excision and need for adjuvant radiotherapy. Some solid DCIS has morphologic features that overlap with those of LCIS, including classic LCIS (composed of small dyshesive cells with monotonous nuclei), LCIS with comedo necrosis (characterized by massive acinar expansion, central necrosis, Ca^{2+}, and low grade atypia), and pleomorphic LCIS (defined by nuclear pleomorphism, central necrosis, and Ca^{2+}). Cell dyshesion and intracytoplasmic vacuoles favor a diagnosis of LCIS (see Fig. 21-3A), whereas cohesive growth, lack of intracytoplasmic vacuoles, polarization of cells, and focal formation of microacini favor DCIS. In problematic cases the differential diagnosis is usually resolved with an immunohistochemical staining for E-cadherin, as LCIS is typically E-cadherin-negative, whereas the cells of DCIS have continuous linear membranous positivity for this marker.

DCIS versus Invasive Carcinoma

Some invasive carcinomas exhibit patterns that simulate DCIS (such as invasive cribriform carcinoma and adenoid cystic carcinoma). Conversely, DCIS involving lobules, sclerosing adenosis or a radial sclerosing lesion can closely resemble stromal invasion. Immunostains for myoepithelial markers are of great value in these situations. The presence of a peripheral MEC layer around nests of neoplastic cells supports a diagnosis of DCIS, whereas its absence supports a diagnosis of invasive carcinoma (35). The only exception to this rule is microglandular adenosis (MGA), a rare "benign" lesion composed of monostratified and cytologically bland glands devoid of myoepithelium, but surrounded by basement membrane. MGA has a haphazard infiltrative pattern and DCIS and invasive carcinoma often arise in association with it. MGA and MGA-associated carcinomas have triple-negative phenotype (see Fig. 21-3B) (36). Two studies have provided genetic evidence that MGA is a non-obligate morphologic precursor of MGA-associated invasive carcinoma (37,38).

Microinvasive Carcinoma (MIC)

MIC is defined as invasion spanning no more than 1 mm in greatest diameter (see Fig. 21-5G). MIC often occurs in a background of high-grade DCIS and is very unusual in the context of low-grade DCIS (or LCIS). Stains for MECs and keratin are helpful to demonstrate the presence of tumor cells in the stroma. ER (and PR) status of MIC is usually reported. Information on HER2 status of MIC is of debatable utility. If MIC is not present on the deeper sections used for these biomarker studies, the ER immunoprofile of the adjacent DCIS is usually reported.

Molecular Profile

Low- and high-grade DCIS are fundamentally different diseases and each is genetically related to its invasive counterpart (39).

Expression profiling analysis of matched *in situ* and invasive carcinoma has shown that lesions of similar histologic grade cluster together, indicating a close relationship within low-grade and high-grade DCIS and corresponding invasive carcinomas, but not across low- and high-grade lesions (39). Breast cancers also segregate into two groups based on the expression of ER and ER-regulated genes, confirming that ER-dependent pathways are fundamental in the development and progression of ER-positive carcinoma (32).

The current model of breast cancer (6), based on morphological, immunophenotypical, molecular features, identifies two main and fairly distinct groups of lesions.

The low-grade group, which encompasses the low-grade breast neoplasia family, includes FEA, ADH, DCIS, lobular neoplasia, and their invasive counterparts. This group of lesions is characterized by expression of ER and PR related genes, and lacks HER2 overexpression and expression of basal genes. It roughly corresponds to the Luminal A lesions. The cells have diploid/near-diploid karyotype and are characterized by recurrent chromosomal alterations, namely deletion of 16q (in over 80% of cases) and gains of 1q (in over 75% of cases) and 16p (in over 50% of cases) (40) (Fig. 21-3A).

The high-grade group is characterized by greater diversity and contains DCIS corresponding to the Luminal B, HER2-overexpressing and basal type carcinomas, and also includes apocrine carcinomas (6,41). The immunoprofile and patterns of genetic aberrations of high-grade DCIS are more heterogenous than in low-grade-DCIS. High-grade DCIS is characterized by aneuploidy, complex karyotypes and numerous unbalanced genomic changes mapping to several chromosomal arms, including recurrent losses at 8q, 9p, 11q, 13q, 17q, and 22q, and gains at 1q (in over 60% of cases), 8q (in over 75% of cases) and 17q (40). Studies have also described gains of 5p, 17q, 20q, and losses of 11q, 13q, and 14q. Recent molecular and genetic evidence suggests that progression from low-grade DCIS to high-grade DCIS may occur in some cases, but the pathways that lead to the development of low- and high-grade lesions are for the most part distinct and separate (6,42,43). Consistent with these data is the observation that only

TABLE 21-1

	Usual Ductal Hyperplasia (UDH)	*Flat Epithelial Atypia (FEA)*	*Atypical Ductal Hyperplasia (ADH)*	*Ductal Carcinoma In Situ (DCIS)*
Definition (as in WHO, 2012 (10))	• Solid or fenestrated proliferation of epithelial cells that often show streaming growth particularly in the center of involved spaces	• Neoplastic alteration of TDLUs characterized by replacement of native epithelial cells by one to several layers of a single epithelial cell type showing low-grade (monomorphic) cytologic atypia	• Proliferation of monomorphic, evenly placed epithelial cells involving TDLUs	• Neoplastic proliferation of epithelial cells confined to mammary ductal-lobular system and characterized by subtle to marked cytological atypia and an inherent but not necessarily obligate tendency for progression to invasive breast cancer
Clinical and Radiologic Features	• Incidental finding, no specific clinical or radiologic features	• Clinically asymptomatic • Often identified as (clustered) indeterminate mammographic calcifications	• Clinically asymptomatic • Usually identified mammographically as calcifications • Can be incidental finding	• Rare cases present clinically as mass, Paget's disease of the nipple or nipple discharge • Mammographic calcifications
Prognosis	• 1.5×–2× risk of breast cancer in either breast	• No established risk (risk probably higher than UDH, but lower than ADH)	• 4×–5× risk of breast cancer	• Can recur locally as DCIS or invasive carcinoma • Distant metastases are rare
Treatment	• Mammographic surveillance	• Diagnosis of FEA at core biopsy mandates surgical excision • No other treatment recommendations	• Diagnosis of ADH at core biopsy mandates surgical excision • Mammographic surveillance • Chemoprevention	• Surgical excision with negative margins + radiation therapy or mastectomy • Chemoprevention
Gross Findings	• Not specific	• Not specific	• Not specific	• Rarely evident as speckled ill-defined area or mass
Microscopic Findings	• Haphazard proliferation of three or more layers of epithelium with irregular slit-like lumina connected in 3-D	• One to several layers of ductal cells with cytologic atypia but no architectural complexity • Often coexists with ADH, low-grade DCIS, ALH/LCIS, and tubular carcinoma	• Uniform cell population with low-grade cytologic atypia and incomplete architectural features of low-grade DCIS • Focal (<2 mm or <2 ducts)	• Complex architecture (cribriform spaces, micropapillae, solid, papillary) • Nuclear atypia (low, intermediate or high) • Necrosis can be present • Mitoses • Discontinuous growth pattern within ducts in 70% low-grade DCIS, 55% intermediate-DCIS, and 10% high-grade DCIS • Variable size

Immunohistochemical Features	• Heterogeneous staining positive for CK5/6 and ER	• CK5/6-negative and ER-positive	• CK5/6-negative and ER-positive	• Usually CK5/6-negative (except basal DCIS) and ER-positive (90–100% low-grade DCIS; 30–90% high-grade DCIS) • HER2-positive in 70% of intermediate- and high-grade DCIS • Low-grade DCIS is rarely HER2-positive • Apocrine DCIS is AR-positive and ER-negative • Basal DCIS is ER-, PR-, HER2-negative, and CK5/6- and/or EGFR-positive
Differential Diagnosis	• ADH • DCIS	• Apocrine lesions • Cystic hypersecretory lesions • Flat/clinging intermediate-grade DCIS	• Low-grade DCIS • UDH	• LCIS (E-cadherin negative) • (Micro)invasive carcinoma (especially when DCIS involves a sclerosing lesion)
Molecular Findings	• Few and inconsistent chromosomal alterations that are different from those of invasive carcinoma	• Chromosomal alterations consistent with clonal population • Loss at 16q • Gains at 15q, 16p, 17q, and 19q	• Chromosomal alterations consistent with clonal population • Losses at 16q and 17p • Gain at 1q	• Chromosomal alterations consistent with clonal population • Low-grade DCIS: diploid/near diploid karyotype; deletion of 16q • High-grade DCIS: numerous, heterogenous, complex and unbalanced genomic alterations (see Fig. 21-3)

less than 30% of high-grade carcinomas show deletion of 16q, suggesting that only a small group of high-grade carcinomas are derived from low-grade DCIS, whereas the majority of high-grade DCIS either develops *de novo* or originates from a (still unidentified) putative precursor other than ADH/low-grade DCIS (6). Morphologic precursor lesions of most high-grade DCIS have not yet being identified, except for two, namely MGA for some basal-like DCIS (44) and apocrine atypia for apocrine DCIS (45) (see Fig. 21-3B).

Heselmeyer-Haddad et al. (46) used FISH probes for the oncogenes COX-2 (1q), MYC (8q), CCND1 (11q), HER2 (17q), and ZNF217 (20q), and the tumor suppressor genes DBC2 (8p), CDH1 (16q), and TP53 (17p) to determine nonrandom chromosomal gains and losses, to assess the degree of intratumor heterogeneity, and to reconstruct clonal relationships between synchronous DCIS and invasive ductal carcinoma by single cell analysis of 13 selected cases. They found that DCIS had a lower degree of chromosomal instability than the corresponding invasive ductal carcinoma. Gains of COX-2 and MYC, together with losses of DBC2, CDH1, and TP53 occurred most commonly during the progression of DCIS to invasive carcinoma (46), and in particular MYC gains and CDH1 losses were more frequent in invasive carcinomas.

Hernandez et al. (47) performed a comprehensive profiling of mutations of known cancer-related genes in matched DCIS and adjacent invasive ductal carcinomas. The authors confirmed that activating phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit alpha (PIK3CA) mutations are frequent in DCIS (48), and more prevalent than in the adjacent invasive carcinoma. These results suggest that PIK3CA mutations play an important role in DCIS initiation rather than in its progression to invasive ductal carcinoma (48). Other studies have found no substantial genetic differences between matched DCIS and invasive carcinoma. A large constellation of genetic and/or epigenetic aberrations, some of which are mediated by the microenvironment (49), may be at play in the progression from DCIS to invasive disease.

Lee et al. (50) carried out comprehensive expression profiling of 53 DCIS and 51 invasive breast carcinomas, including separate samples of tumor epithelium and adjacent stroma prepared by laser-capture microdissection, and found increased expression of a total of 470 genes. Elevated expression of genes involved in the synthesis and organization of extracellular matrix was particularly prominent in invasive carcinoma compared to DCIS (50). The investigators analyzed *in vivo* the progression of DCIS to invasive carcinoma using three DCIS-like human breast epithelial cell lines DCIS.COM, SUM225, and h.DCIS.01, engineered to express specific genes into a "mammary intraductal DCIS (MIND)" xenograft model. In the xenografts the progression to invasive breast carcinoma was dramatically increased by suppression of four specific genes, namely Cystatin-A (CSTA), a protease inhibitor, DST, FAT1 and TMEM45A (50), involved in cell adhesion and signaling. On the contrary, the expression of these genes was elevated in cases of DCIS with no invasion. These results suggest that these genes are involved in suppressing the progression of DCIS to invasive carcinoma.

Summary

In summary, intraductal proliferative lesions are cytologically and architecturally diverse.

DCIS is a heterogeneous group of neoplastic intraductal lesions characterized by increased epithelial proliferation with different architectural patterns and cytological atypia ranging from mild to severe.

Molecular data suggest that DCIS is as heterogeneous as invasive carcinoma. Based on morphological, immunophenotypical and molecular features DCIS can be classified into two groups (see Fig. 21-3A and B). The low-grade breast neoplasia family includes FEA, ADH, low-grade DCIS, lobular neoplasia, and their invasive counterparts. These lesions are ER positive, HER2 negative and lack of expression basal markers. They are characterized by deletion of 16q. The high-grade DCIS lesions are more heterogenous. Most lack ER, some express HER2 and some are ER, PR, and HER2 negative but express basal markers. Numerous and complex unbalanced genomic alterations are found in high-grade DCIS.

Table 21-1 Highlights key features of the ductal lesions discussed in the chapter.

Margin status, nuclear grade, and necrosis are the most predictive parameters of clinical outcome, which is also significantly influenced by adjuvant radiation and hormonal treatment.

CHAPTER 22

Lobular Carcinoma *In Situ*: Biology and Management

Tari A. King and Jorge S. Reis-Filho

CHAPTER CONTENTS

Lobular carcinoma *in situ* (LCIS) and atypical lobular hyperplasia (ALH) are relatively uncommon breast lesions, which are typically discovered in breast biopsies taken for other reasons. The first description of LCIS was reported by Ewing in 1919, who depicted this lesion as an "atypical proliferation of acinar cells" of the breast (1). The main characteristics of this lesion, however, were not thoroughly documented until 1941 in the seminal study by Foote and Stewart, in which the term *LCIS* was coined to refer to a spectrum of "noninfiltrative lesions of a definitely cancerous cytology" that would constitute precursors of invasive breast cancer, and be composed of a monomorphic population of dyshesive cells that expand the terminal duct–lobular units (2). A less-prominent *in situ* proliferation composed of cells cytologically identical to those of LCIS, and associated with a lower risk of breast cancer development, was subsequently identified and named ALH (3). In a review of 211 cases of LCIS not associated with other forms of breast cancer, Haagensen et al. (4) observed the difficulties in differentiating between LCIS and ALH, and suggested that the term *LCIS* not associated with invasive cancer would constitute a misnomer, given that the available evidence at that time supported the contention that these lesions would in fact constitute a "benign, non-infiltrating, special microscopic form of lobular proliferation of the mammary epithelium" (4). The term *lobular neoplasia (LN)* was subsequently put forward to refer to the entire spectrum of these *in situ* lesions, including ALH and LCIS (4). Although surgeons, oncologists, and pathologists are familiar with the concept of LCIS, the terminology and classification for these lesions, their biological significance (risk indicator vs. precursor for invasive cancer), and the best course of management following diagnosis remain controversial. This chapter will discuss the clinicopathological and molecular characteristics of LN, and the impact of recent developments on the management of these lesions.

Several of the concepts initially put forth by Foote and Stewart (2) on the biology of LCIS remain valid today. The term *LCIS* was chosen to emphasize the histologic similarities between the cells of LCIS and those of frankly invasive lobular carcinoma (ILC), and, importantly, was not meant to infer that the cell of origin resided in the lobules; in fact, it was acknowledged that LCIS would originate in the terminal duct–lobular unit and small ducts (2). In addition, LCIS was reported to be frequently multicentric and bilateral, and not readily identifiable on gross examination. Microscopically, the cells that constitute LCIS were thought to disseminate through the ductal system in a way akin to that of Paget's disease; however, LCIS was almost never seen in association with true Paget's disease of the nipple (2). Based on the frequent identification of LCIS in association with ILC and following the analogy of ductal carcinoma *in situ* (DCIS) and invasive ductal carcinoma (IDC), Foote and Stewart (2) hypothesized that the neoplastic cells of LCIS would still be contained within a basement membrane, and that this lesion would constitute a "hazard" (i.e., risk factor) of breast cancer development and a step along the pathway to the development of invasive cancer. Hence, based on the evidence available, simple mastectomy was suggested as the standard form of treatment (2).

Emerging data throughout the 1970s from Haagensen et al. (4) and others (5) demonstrating that the risk of breast cancer development following a diagnosis of LCIS was lower than expected for a direct precursor lesion (approximately 1% per year) and was conferred equally to both breasts generated controversy regarding the significance of these lesions and led to disparate recommendations for management, ranging from observation only to bilateral mastectomy. In current practice, a diagnosis of ALH or LCIS is typically perceived as a risk indicator rather than a precursor of subsequent carcinoma and, as such, radical treatment has fallen out of favor. Yet, observational evidence to suggest that the

risk of breast cancer development following a diagnosis of LN is higher in the ipsilateral than in the contralateral breast and compelling molecular data that demonstrate that ALH and LCIS are clonal neoplastic proliferations that commonly harbor the same genetic aberrations as those found in adjacent invasive cancers (6–10) have reinstated the notion that ALH and LCIS are both non-obligate precursors *and* risk indicators of invasive breast cancer. Questions regarding the biology and optimal management of these lesions have returned to the forefront of breast cancer research and practice.

EPIDEMIOLOGY AND CLINICAL FEATURES

LCIS is most frequently diagnosed in women aged 40 to 55 years (4,11). The true prevalence of LCIS in the general population, however, is difficult to estimate and likely exceeds the incidence, given that it does not present as a mass lesion nor does it have a specific radiographic appearance. Lesions diagnosed in the pre-mammography screening era were typically incidental microscopic findings in biopsies and excision specimens obtained for other reasons (2,4). The reported incidence of LCIS in otherwise benign breast biopsy specimens ranges from 0.5% to 3.8% (4,11), whereas population-based data reported to Surveillance, Epidemiology, and End Results (SEER) from 1978 to 1998 demonstrate an incidence of 3.19 per 100,000 women (12). It is noteworthy, however, that during this time period there was an observed four-fold increase in the number of LCIS cases reported among women over 40 years of age, with the highest incidence rate (11.47 per 100,000 person-years) in 1998 among women 50 to 59 years of age. While this trend may reflect the increasing use of mammography and image-guided biopsies during this time period (12,13), the impact of other factors, such as the use of postmenopausal hormone replacement and more accurate pathologic diagnosis of LN based on ancillary immunohistochemical markers (see below) remains a matter of speculation. LCIS is often multifocal, with more than 50% of patients diagnosed with LCIS showing multiple foci in the ipsilateral breast. Furthermore, bilateral lesions are reported in approximately one-third of patients (14,15). Such multifocality in a clinically non-detectable lesion is one of the reasons why planning subsequent management has proven problematic and contentious. More recent imaging series suggest that LCIS may be associated with microcalcifications (16), and LCIS has been reported to enhance on MRI (17); however, imaging criteria to differentiate LCIS from overt malignancy are lacking, and, as such, women with LCIS are frequently subject to multiple biopsies demonstrating otherwise benign findings.

The clinical characteristics of LCIS, including its multifocal and bilateral distribution, and evidence of familial clustering (18,19) have led to the hypothesis that these lesions could be underpinned by germline genetic abnormalities. Although a hereditary form of diffuse gastric cancer and breast lobular carcinoma caused by *CDH1* germline mutations (20) has been described, the potential genes involved and the pattern of inheritance of familial LCIS outside of this context remain unclear (see below).

The clinical characteristics of LCIS that support its role as a risk factor for the subsequent development of breast cancer include the cumulative long-term risk of breast cancer development that is generally conferred to both breasts, averaging 1% to 2% per year, and the observation that not all breast cancers developing after a diagnosis of LCIS are of lobular histology (reviewed in reference (21). The incidence of invasive breast cancer following a diagnosis of LCIS is steady over time (22), with a similar number of invasive lesions being reported within and after 5 years of follow-up (23). Others have also demonstrated the cumulative long-term risk, with one study reporting that over 50% of patients developed beast cancer between 15 and 30 years of follow-up (5). ALH is also associated with an increased risk of subsequent breast cancer; however, this is of a lower magnitude than that conferred by LCIS. Patients diagnosed with ALH have a four- to five-fold higher risk than the general population (i.e., women of comparable age who have had a breast biopsy performed with no atypical proliferative disease diagnosed), whereas a relative risk of 8 to 10 times is conferred by a diagnosis of LCIS (11,24,25). Hence, these observations suggest that the term *LN,* albeit helpful to describe this group of lesions collectively, may not suffice to guide the management of patients with lobular lesions, and specific classification of LN into ALH and LCIS may still be justified. It should be noted, however, that the distinctions between ALH and LCIS are subjective and, for some experts, the differences between these two categories of LN are more easily expressed in words than in actual practice (23).

The risk of breast cancer development following a diagnosis of ALH or LCIS is bilateral (14,22,26), which is consistent with the notion that these lesions are risk indicators; however, some have reported a higher rate of breast cancer in the ipsilateral breast (9,21,27), supporting a precursor role for LCIS. The histological type of breast cancer following a diagnosis of LN also differs among these reports. In studies that suggest the risk is conferred equally to both breasts, there are, similarly, an equal number of subsequent IDCs and ILCs reported to occur after a diagnosis of LCIS (22), which is consistent with the notion that LCIS would not constitute a true precursor lesion. On the other hand, in most studies that report a higher incidence of ipsilateral cancer development, the majority of the cancers are of lobular histology (8,21,23). This clinical observation, in parallel with SEER data demonstrating an increasing incidence of both LCIS and ILC from the late-1980s to the mid-1990s among women 50 years of age and older (12,28), have led to renewed interest the debate over the clinical significance of LCIS.

Taken together, the current epidemiological, observational, and clinical data support the contention that LN is not only a risk indicator, but also a non-obligate precursor of invasive breast cancer. This notion is lent further credence by the striking morphologic similarities between cells of ALH or LCIS and ILC, and molecular data demonstrating the clonality between LN and synchronous invasive breast cancer (see below); in particular, the presence of concordant gene copy number and allelic abnormalities (6,29), mitochondrial DNA mutations (7), and identical *CDH1* gene mutations in matched LCIS and ILC from the same patients (10).

HISTOLOGICAL FEATURES AND CLASSIFICATION

Despite the controversies surrounding the clinical implications of ALH and LCIS, their histologic features have been well characterized. The latest World Health Organization (WHO) classification of breast tumors defines LN as “a spectrum of atypical epithelial lesions originating in the terminal duct-lobular unit and characterized by a proliferation of generally small, non-cohesive cells, with or without pagetoid involvement of the terminal ducts” (30). At scanning magnification, these lesions are characterized by a variable enlargement of the acini, which are filled up and, at least in part, are expanded by a proliferation of monomorphic population of dyshesive

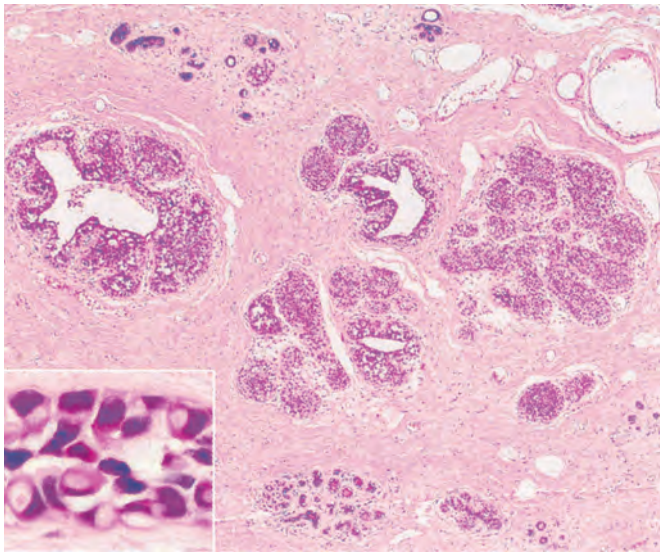

FIGURE 22-1 **Low-power (scanning electron microscopic) appearance of classic lobular carcinoma *in situ*, showing filling and distension of lobules.** Normal lobules are seen at the top and bottom center of the picture for comparison. Inset shows typical cytologic detail of the cells with prominent intracytoplasmic lumina and a magenta body.

small, round, or polygonal cells, with inconspicuous cytoplasm (Fig. 22-1). In fact, the main histological characteristic of LN is that its cells are loosely cohesive, regularly spaced, and fill and distend the acini, with an overall maintenance of the lobular architecture (Fig. 22-2). Intracytoplasmic vacuoles, sometimes containing a central eosinophilic dot (known as magenta body), are usually found (2,4,21,30). Despite the apparent monomorphism of the classic variant of LN, some variability in the cytomorphology between different cases, and frequently within the same case, is easily appreciated, and two cytologic subtypes have been recognized (Table 22-1). Type A cells are small, dyshesive cells with scant cytoplasm and nuclei approximately 1.5 times the size of that of a lymphocyte, whereas type B cells have more abundant, often clear cytoplasm nuclei that are approximately

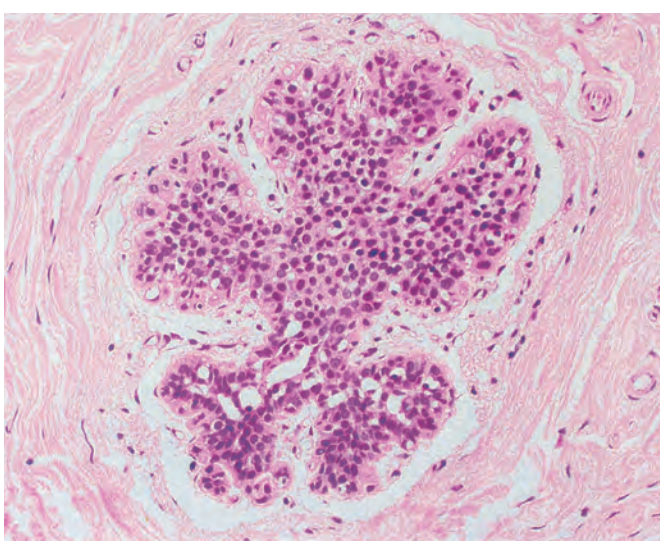

FIGURE 22-2 Typical appearance of a lobular unit distended by lobular carcinoma *in situ*.

two times bigger than a lymphocyte nucleus, mild-to-moderate nuclear atypia (nuclear pleomorphism 1 or 2), and indistinct or absent nucleoli (21,31). It should be noted, however, that this cytological classification scheme has not been shown to be of clinical utility and does not have a direct correlation with the risk of invasive breast cancer development. Other than an academic exercise, this classification system is only a reminder that some degree of cytologic variation can be observed in *bona fide* cases of classic LN. In the classic form of LN, mitoses and necrosis are uncommon. Pagetoid spread within the affected terminal duct–lobular unit, whereby the neoplastic cells extend along adjacent ducts between intact overlying epithelium and underlying basement membrane, is frequently observed (Fig. 22-3). The presence of glandular lumina is not seen in fully developed cases; it should be noted, however, that in lobules partially affected by LN, residual glandular structures can be found.

The sub-classification of LN into ALH and LCIS is quantitative rather than qualitative (30). While for a diagnosis of LCIS more than half the acini in an involved lobular unit must be filled and distended by the characteristic cells, leaving no central lumina, ALH is defined as a less well-developed and less-extensive lesion, where the characteristic cells only partly fill the acini, with only minimal or no distention of the lobule (Fig. 22-4), and glandular lumina can still be found (9,24,30,32). In an attempt to standardize the diagnosis of ALH and LCIS, it has been proposed that lobular distention should be defined as eight or more cells present in the cross-sectional diameter of an acinus, and that the number of acini involved in cases of ALH should account for less than half of the whole terminal duct–lobular unit (9,24,30,32). Although the use of this sub-classification would be justified on the basis of the lower risk conferred by ALH than by LCIS, the differentiation between ALH and LCIS based on the criteria described above is not only arbitrary, but also subjective, prone to interobserver and intraobserver variability, and dependent on the extent of sampling of a given lesion. Therefore, the use of the term *LN* to encompass the whole range of changes, and remove this variability, is preferable for diagnostic purposes, particularly in core needle biopsy specimens (21,33). In fact, in the context of diagnostic core biopsies, the term *LN,* with no attempt to distinguish ALH and LCIS, is recommended in the guidelines of breast cancer screening programs (e.g., the United Kingdom National Health Service Breast Screening Programme [NHS BSP]) (33).

Arguably, a more relevant distinction is between the classic form of LN and the pleomorphic variant of LCIS (PLCIS), which was first identified as a distinct entity by Eusebi et al. in 1992 (34). This variant is characterized by pleomorphic cells that are substantially bigger than those of classic LN (31,34), and by more abundant, pink, and often finely granular cytoplasm. Features of apocrine differentiation are frequently found (34,35). As compared to the nuclei of classic LN, PLCIS nuclei are bigger (four times the size of lymphocyte nucleus), more pleomorphic, and atypical nuclei, often containing conspicuous nucleoli (Fig. 22-5). PLCIS not uncommonly presents with central, comedo–type necrosis and microcalcifications; yet, necrosis is not required for the diagnosis. Recognition of the pleomorphic subtype is important because the combination of cellular features, necrosis, and calcification can lead to difficulty in differentiation from DCIS, and potentially overtreatment, although data regarding the natural history of PLCIS are very limited. Until additional data regarding the natural history of PLCIS are available, this distinction has important implications for treatment. Whereas some advocate for a more aggressive approach to PLCIS, with treatment recommendation akin to those for DCIS, it should be noted that this approach is supported

TABLE 22-1

Cytological and Histopathological Features of Classic and Pleomorphic Lobular Carcinomas

Type of Carcinoma	*Nuclear Size*[a]	*Nuclear Pleomorphism*[b]	*Nucleoli*	*Cytoplasm*	*Dyshesion*	*Central Necrosis*	*Calcifications*	*Apocrine Differentiation*
LCIS Type A	1.5×	1, rarely 2	Inconspicuous	Scant	Present, but inconspicuous	Absent	Occasional	Absent
LCIS Type B	2×	1 or 2	Inconspicuous to small	Moderate	Yes	Absent	Occasional	Absent
PLCIS	≥4	Usually 3	Present, often small	Moderate to abundant	Yes	Frequent	Frequent	Focal
Apocrine PLCIS	≥4	3	Present, prominent	Abundant	Yes	Frequent	Frequent	Defining feature

LCIS, lobular carcinoma *in situ*; PLCIS, pleomorphic LCIS.

only by molecular data demonstrating that PLCIS shares many similarities with pleomorphic ILC, not by long-term outcomes data.

Additional variants of LN have been reported, including apocrine, histiocytoid, rhabdoid, endocrine, amphicrine, and the apocrine PLCIS variant (21,30). The biological and clinical significance of these lesions also remains to be determined.

A further system for classification of LN has been proposed using the terminology *lobular intraepithelial neoplasia (LIN)*, with subdivision, based on morphologic criteria and clinical outcome, into three grades (LIN 1, LIN 2, LIN 3), with LIN 3 representing the PLCIS end of the spectrum (36,37). This system pre-supposes that the risk of invasive carcinoma development would be related to increasing grade of LIN. This classification system, albeit interesting and potentially sparing women from a diagnosis of "carcinoma" in the case of LCIS, is supported by limited evidence and has not been endorsed in the latest edition of the WHO classification (30).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of LN includes artifacts, benign breast lesions, and other forms of breast cancer precursors. Prolonged periods of warm ischemia and poor tissue fixation, not uncommonly seen in mastectomy specimens, can result in an artifactual discohesion of cells within a lobular unit, which can mimic ALH and LCIS (21). Benign lesions that may superficially resemble LN include foci of lactational change, where the cells harbor intracytoplasmic lipid droplets, and clear-cell metaplasia (21). More troublesome is the histologic appearance of LN colonizing other benign breast lesions, including fibroadenoma, sclerosing adenosis, and radial scar, which, clinically and radiologically, can present as a mass. Particularly well-known but rather remarkably problematic examples of LN in sclerosing adenosis may resemble IDC to the unwary, due to the distorted appearance of the residual ductal and lobular structures lined by LN cells and immersed in a sclerotic stroma (21,30). In this context, immunohistochemical markers to demonstrate the presence

FIGURE 22-3 Pagetoid spread. Lobular carcinoma *in situ* cells (*arrowheads*) are seen growing beneath, and displacing inward, the luminal epithelium of a duct.

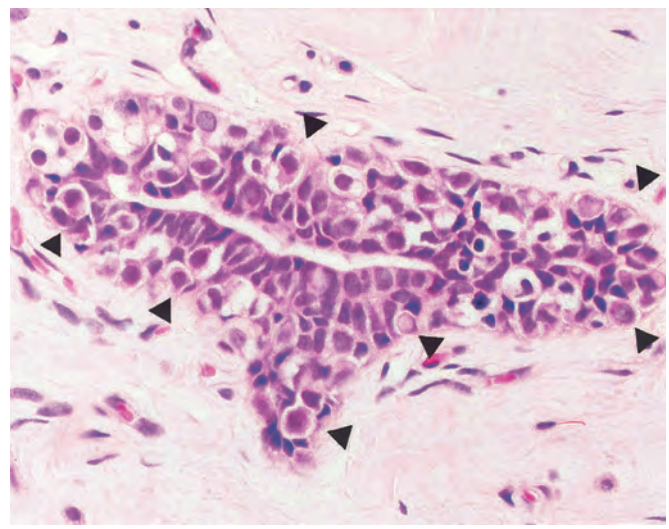

FIGURE 22-4 **Atypical lobular hyperplasia.** A lobular unit is focally and partially filled by characteristic cells with intracytoplasmic lumina (*arrowheads*).

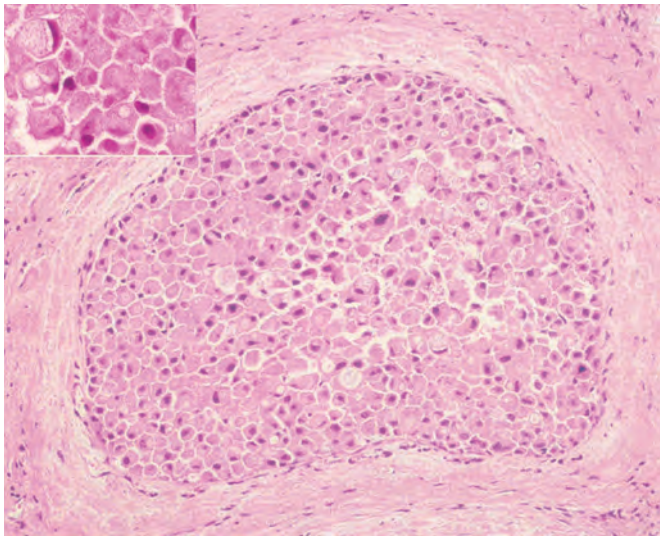

FIGURE 22-5 **Pleomorphic lobular carcinoma *in situ*.** The duct is filled with large, discohesive cells showing apocrine features, intracytoplasmic lumina, and occasional signet ring cells (detailed in insert).

of a myoepithelial cell layer, including nuclear (e.g., p63) and cytoplasmic (e.g., smooth muscle myosin heavy chain or calponin) myoepithelial markers, and markers to ascertain the LN nature of the neoplastic cells (e.g., E-cadherin, β-catenin, and/or p120 catenin) are useful in making the distinction.

Differentiating low-grade, solid DCIS from LN is challenging, even in surgical excisional samples. In cases of low-grade *in situ* proliferations with indeterminate features, the identification of some histologic features can be of help; the presence of a mosaic growth pattern with prominent intracytoplasmic vacuoles is suggestive of LN, whereas the presence of microacinar-like structures favors a diagnosis of solid low-grade DCIS. In this context, E–cadherin and p120 catenin are particularly helpful (see below) (38,39). It should be noted, however, that for some lesions, the distinction between LN and solid low-grade DCIS in limited core biopsy specimens may be impossible. In addition, mixed lesions composed of *bona fide* LN and low-grade DCIS have been reported. Another important differential diagnosis, particularly in core biopsies, is cancerization of the lobules by DCIS. In cases with equivocal histologic features, immunohistochemistry with anti–E–cadherin and p120 catenin antibodies is helpful, given that lack of membranous E–cadherin and p120 catenin cytoplasmic staining would be consistent with a diagnosis of LN rather than cancerization of the lobules by DCIS.

The differentiation of PLCIS from high-grade DCIS can be challenging, given that both are composed of pleomorphic cells with marked cytological atypia, both often display comedo-type necrosis, and both express similar patterns of ER, progesterone receptor (PR), and HER2 expression, including lack of or reduction in ER and PR expression, and overexpression of HER2 (35,40). Importantly, however, the neoplastic cells of PLCIS display the characteristic dyshesiveness, and these lesions consistently lack E-cadherin and β-catenin, and express cytoplasmic p120 catenin (see below).

MOLECULAR PATHOLOGY

The advent of laser capture microdissection and high-throughput genomic and transcriptomic methods have allowed for the study of pre-invasive lesions of the breast. In the last decade, molecular genetic studies have provided a wealth of increasingly more coherent data on the pathways of breast cancer evolution and how these findings correlate with morphological features (8,30). It is currently accepted that ER-positive and ER-negative breast cancers are fundamentally different diseases, with distinct patterns of gene expression changes (41) and repertoires of genetic aberrations (42).

ER-positive breast cancers are characterized by recurrent deletions of 16q, gains of 1q and 16p; additional genetic aberrations including *CCND1* and *FGFR1* amplification, gain of 8q, and losses of 11q, 13q, and 17q are observed in high-grade lesions. ER-negative breast cancers, on the other hand, are characterized by a more complex pattern of gene copy number aberrations, with multiple low-level gains and deletions affecting multiple chromosomal arms; deletions of 16q, however, are remarkably rare in these cancers (8,30). The repertoires of mutations in ER-positive and ER-negative disease are also different. For instance, while ER-positive cancers are characterized by recurrent *PIK3CA, PTEN, AKT1, GATA3, CDH1, MAP3K1, MAP2K4,* and *CDKN1B* mutations, ER-negative cancers often harbor *TP53* mutations (42).

Molecular studies of LN have been instrumental in highlighting the role of E-cadherin inactivation in the development of lobular lesions and in providing evidence to demonstrate that ALH and LCIS are in fact non-obligate precursors of invasive cancer rather than being simply risk indicators of subsequent breast cancer development.

Immunophenotype

All subtypes of LCIS are associated with strong expression of ER-alpha (ERα), ER-beta (ERβ), and PR in the majority of neoplastic cells (Table 22-2). Classic forms of LN usually display an immunohistochemical profile consistent with that of ER-positive breast cancer with a less-aggressive clinical behavior (i.e., luminal A), including lack of HER2 and *p53* expression, and exhibit low proliferation indices, as defined by Ki67. PLCIS, on the other hand, may express no or low levels of ER and PR expression, and frequently harbors HER2 gene amplification and positivity, and its Ki67 labeling indices are usually higher than those of classic LCIS. These features, however, are reported to be predominantly found in the apocrine subtype of PLCIS which also often express GCDFP-15 (gross cystic disease fluid protein-15), a marker of apocrine differentiation (21,30,35); however, the criteria to differentiate between PLCIS and apocrine PLCIS remain a matter of controversy.

Although the high molecular weight cytokeratins identified by the clone 34βE12 (i.e., cytokeratins 1, 5, 10, and 14) were reported to be consistently expressed in LN, and that this antibody would constitute a useful marker to differentiate between LN and low-grade solid DCIS, there is direct evidence to demonstrate that LN cells do not express cytokeratins 1, 5, 10, and 14, and that 34βE12 expression in LN may be an artifact of antigen retrieval. Hence, caution should be exercised when using the 34βE12 for a diagnosis of LN (21,30).

E-Cadherin and Related Proteins in Lobular Neoplasia

LN, including its pleomorphic variant, and ILC are characterized by a dysfunctional E-cadherin-catenin adhesion complex. E-cadherin is a transmembrane adhesion molecule found in adherens junctions and mediates homophilic-homotypic adhesion in epithelial cells; its intracytoplasmic domain is bound to p120 catenin and β-catenin. In breast epithelial cells, loss of E-cadherin results in cytoplasmic,

TABLE 22-2

Summary of Immunohistochemical Marker Status

	LN (ALH/ LCIS)	*ILC*	*Low-Grade DCIS*	*Low-Grade IDC*	*PLCIS*	*Pleomorphic ILC*	*High-Grade ER+ DCIS*	*High-Grade ER+ IDC*

[a]Abnormal patterns can occasionally be seen in the form of discontinuous or fragmented staining or cytoplasmic "dots."
[b]Up to 15% of cases display E-cadherin membranous expression.
[c]Despite the lack of β-catenin membranous expression, nuclear expression is vanishingly rare in LN and PLCIS.
[d]Approximately 10% of cases may lack membranous E-cadherin expression (87).
ALH, atypical lobular hyperplasia; IDC, invasive ductal carcinoma; ILC, invasive lobular carcinoma; LCIS, lobular carcinoma *in situ*; DCIS, ductal carcinoma *in situ*; PLCIS, pleomorphic LCIS; ER, estrogen receptor; PgR, progesterone receptor; GCDFP-15, gross cystic disease fluid protein-15; LN, lobular neoplasia; –/+, often negative though sometimes positive; +/–, often positive though sometimes negative.

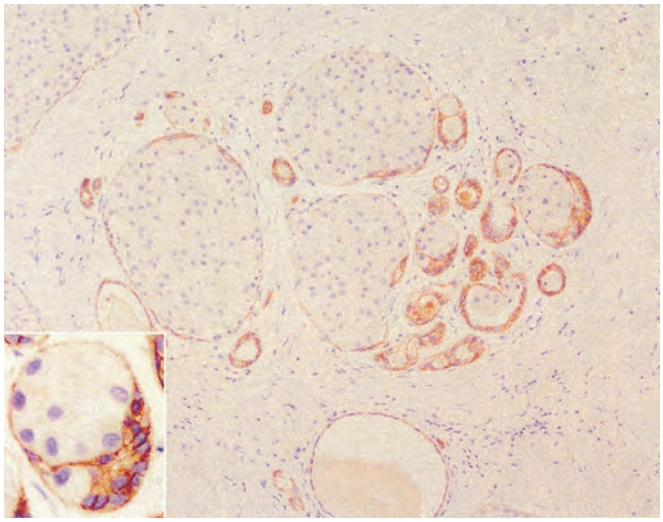

FIGURE 22-6 **E-cadherin immunohistochemical staining in lobular carcinoma *in situ*.** The outer rim of myoepithelial cells show strong membrane staining, whereas the lobular carcinoma *in situ* cells filling the lumen are uniformly negative.

and occasionally nuclear, accumulation of p120 catenin, and loss of β-catenin membranous expression, but without nuclear accumulation of β-catenin or activation of the canonical Wnt pathway (39,43).

Lack or marked down-regulation of E-cadherin expression (Fig. 22-6) is observed in over 95% of ALH, LCIS, PLCIS, ILCs, and metastatic deposits of ILCs, and is believed to be the cause of the characteristic dyshesiveness of LN and PLCIS cells (8,21,30,35,38,44). The study of other components of the E-cadherin-catenin complex in LN, PLCIS, and ILCs has revealed that these lesions are also characterized by lack of β-catenin membranous expression and cytoplasmic expression of p120 catenin. The use of E-cadherin as an ancillary marker to differentiate LCIS and DCIS, particularly in cases of solid *in situ* proliferations with indeterminate features, has been advocated. In this context, lesions with positive E-cadherin staining should be considered as DCIS, whereas those lacking E-cadherin expression should be classified as LCIS (8,21,38). In lesions where a mixed pattern of positively and negatively stained cells are observed, they should be classified as a mixed. The existence of mixed cases should not be surprising, given the molecular similarities between LN and low-grade DCIS (6,8) (see below).

The indiscriminate use of E-cadherin in diagnostic breast pathology has led to misunderstandings in regard to the actual diagnostic value of this marker, particularly when a detailed inspection of staining is not performed. LN not uncommonly displays "aberrant" expression of E-cadherin in the form of fragmented, focal, or beaded patterns (21,30,45). Furthermore, membranous expression of E-cadherin does not preclude the diagnosis of LN in a lesion with clear-cut histologic features of LN, given that approximately 10% to 16% of ILCs may be E-cadherin-positive (21,30,45). Although the actual prevalence of E-cadherin-positive classic LN is yet to be established, anecdotal cases of classic LN with strong and continuous E-cadherin expression have been reported (46), and in these cases, β-catenin and p120 catenin may provide additional evidence to differentiate between LN and DCIS.

An accurate differentiation between LN and DCIS is of paramount importance, in particular when these lesions are found at the surgical margins. Some validation for using E-cadherin in classification comes from clinical-pathological studies of patients having pure LCIS in core needle biopsy, where E-cadherin positive LCIS was associated with a higher risk for development of invasive carcinoma compared to E-cadherin negative LCIS.

Molecular Aspects of E-Cadherin Inactivation

One the most frequent genetic aberrations in ER-positive breast lesions, in particular, those of low histological grade, is 16q loss, which occurs in a high proportion of cases as an early event in the neoplastic development of LN and low-grade DCIS (6,8,10,21,30). While the target gene of 16q deletions in ductal lesions remains to be identified, in lobular lesions, the *CDH1* gene, which encodes E-cadherin, has been shown to be the target (8,10,21,30). The mechanisms resulting in *CDH1* gene silencing include a combination of genetic, epigenetic, and transcriptional mechanisms. In fact, loss of 16q is usually accompanied by *CDH1* inactivating mutations, *CDH1* homozygous deletions, and *CDH1* gene promoter methylation leading to biallelic silencing of the gene and loss of protein expression (8,21,30).

The study of *CDH1* gene mutations in ALH, LCIS, and synchronous ILC has provided direct evidence to suggest that some LN and ILCs are clonally related, given the presence of identical *CDH1* gene mutations in the LN and ILC components (8,10,21,30). Consistent with the lack of E-cadherin expression in ALH and LCIS, *CDH1* gene mutations have been documented in these lesions; however, some have suggested that these mutations would be less frequent in ALH (47). One potential explanation for the apparent lower frequency of *CDH1* mutations in ALH lies in the challenges posed by the extraction of DNA from samples with small numbers of ALH cells, which are intimately admixed with residual luminal and myoepithelial cells.

In addition to the genetic mechanisms reported to result in *CDH1* gene inactivation, there is evidence that E-cadherin expression can be transcriptionally regulated via a number of different transcription factors. Activation of the transforming growth factor β (TGF-β) pathway, and up-regulation of Snail, Slug, and *ZEB1* have been reported to result in down-regulation of E-cadherin in lobular lesions (30,45,48). In addition, transcriptomic and immunohistochemical analyses of members of the E-cadherin-catenin complex TWIST and SNAIL revealed that there is a stepwise decrease of the mRNA and proteins of the E-cadherin and catenin families from LCIS to ILC concurrent with up-regulation of TWIST and SNAIL (44).

The strong circumstantial evidence suggesting that *CDH1* gene inactivation is a driver of the lobular phenotype has been corroborated by direct evidence from a conditional mouse model, where *CDH1* gene mutations and *p53* knockout were targeted in an epithelium-specific manner (49). This study revealed that E-cadherin inactivation leads to the genesis of invasive tumors that display the cardinal features of human invasive lobular carcinomas, being composed of dyshesive cells, which infiltrate the mammary gland stroma as single cells and single cell-files, and metastasize to anatomical sites usually affected by ILC, including the gastrointestinal tract, serosal surfaces, and bone (49). It should be noted, however, that lesions consistent with LN were not documented in this animal model and that the pleomorphism exhibited by the cells from the tumors of this animal model, the presence of p53 inactivation, and lack of ER-expression would be consistent with the features of pleomorphic ILC rather than those of the classic variant (50).

Despite the familial predisposition reported for LN, the genes involved in this predisposition remain unclear.

CDH1 germline gene mutations account for approximately 30% of cases of hereditary diffuse gastric carcinoma, which have similar growth features to lobular carcinomas (20,30). Notwithstanding the clear pathogenetic role of somatic *CDH1* gene mutations in LN and ILC, germline mutations of *CDH1* have been shown to play a limited role in familial LN and ILC. In fact, although ILCs have been reported in the context of hereditary diffuse gastric cancer syndrome, patients with *CDH1* germline gene mutations presenting solely with LN and/or ILCs are vanishingly rare (30,51). Cancer predisposition genes, including *BRCA1, BRCA2, MLH1,* and *MSH2,* have been reported not to be significantly involved in the pathogenesis of familial lobular neoplasms (30). Intriguingly, an association between *CHEK2* U157T mutation and familial predisposition to lobular carcinomas has been reported (52).

Genomics of Lobular Neoplasia

Genome-wide genetic analyses of gene copy number aberrations and allelic changes, as defined by comparative genomic hybridization (CGH) and single nucleotide polymorphism (SNP) arrays of LN have revealed that these lesions are clonal and neoplastic, that their most frequent copy number changes include 16p, 16q, 17p, and 22q, and gain of material from 6q (6,8,29,30,35,53). In one study, pure ALH harbored a surprisingly high level of genetic instability compared to pure LCIS and lobular lesions from other studies (54). This was interpreted as a mechanism by which most pure ALH develop high-level genetic change and die off, rather than acquire select genetic changes allowing progression to LCIS and ILC; alternative explanations may stem from the limited amount of input DNA from ALH cells employed in the study. SNP array analyses have recently demonstrated that classic LCIS and a substantial proportion of adjacent synchronous lesions, including ER-positive DCIS, invasive lobular carcinoma, and ER-positive invasive ductal carcinoma, are often clonally related (6). This notion has been further corroborated by CGH studies of matched LCIS and ILC (29), and by the analysis of mitochondrial DNA heteroplasmy and mitochondrial gene mutations (7), which revealed clonal patterns in three out of five ILCs following a diagnosis of LCIS.

PLCIS and pleomorphic ILC are genetically related entities (35,37,55,56), highlighting the potential precursor role of PLCIS in the development pleomorphic ILC akin to the relationship between LCIS and ILC. *In situ* and invasive pleomorphic lobular lesions have similar genomic profiles to classic LN and ILC, including loss of 16q, and gain of 1q and 16p; however, they do have more complex genomes (35,37,55,56) and amplification of genomic loci involving oncogenes associated with an aggressive phenotype, such as *MYC* (8q24) and HER2 (17q12) (35,55,56). One study in which PLCIS was sub-classified into those with and without apocrine features suggested that only apocrine, but not conventional PLCIS, would have more gene copy number aberrations than classic LCIS (35); further studies employing an objective definition of this subtype of PLCIS are required to confirm these molecular observations and to determine the clinical significance of these lesions. Importantly, there is evidence, although limited, to suggest that PLCIS and matched invasive pleomorphic ILC are clonally related, based on the similarities of the gene copy number changes they harbor (55).

CLINICAL MANAGEMENT

In current practice, the management of LCIS continues to be a challenge. Although largely accepted as a risk factor for the subsequent development of breast cancer, the long-term cumulative risk and our inability to predict which women will develop breast cancer generates considerable uncertainty among providers, and management options in 2013 remain disparate, ranging from observation to bilateral risk-reducing surgery. Differences in individual patient responses to varying levels of risk also contribute to the wide variations seen in clinical practice (57).

Surgical Considerations

The advent of widespread breast cancer screening programs and image-guided core biopsy procedures has likely contributed to the increasing incidence of LCIS (12), and the presence of ALH and LCIS in core needle biopsy specimens of screen-detected lesions has changed the perception regarding the radiologic appearance of these lesions. Historically, LCIS was thought to lack a radiographic correlate; however, recent studies report calcifications in up to 67% of mammographically screen-detected classic LCIS lesions and in nearly all reported cases of screen-detected PLCIS (12,13,31,35,40). The current National Comprehensive Cancer Network (NCCN) guidelines recommend surgical excision following a core biopsy diagnosis of LCIS to rule out an adjacent malignancy (58). These guidelines, however, are largely based on limited data from retrospective series that report the upgrade rate at surgical excision for a core biopsy diagnosis of LCIS to range from 0% to 50% (57,59–63). Limitations of these series include the fact that many of them are small single-institution reports and that not all patients with LCIS underwent surgical excision, raising the possibility of an inherent selection bias for excision in certain cases, such as those with radiographic-pathologic discordance, and increasing the likelihood of finding an associated malignancy. Hussain and Cunnick illustrated these issues in a pooled analysis of studies published from 1999 to 2008. The authors identified 1,229 reported cases of LN on core biopsy, of which only 789 (64%) underwent surgical excision. Among these, 241 (31%) cases were further classified as LCIS. Following surgical excision, 32% of LCIS cases were upstaged to either DCIS or invasive cancer as compared to 19% and 29% of cases defined as either ALH (280 cases) and or unspecified LN (246 cases), respectively (16).

More recently, two single-institution series have demonstrated that, with careful exclusion of cases with other high-risk lesions on core biopsy (i.e., ADH, papilloma, radial scar) and with exclusion of cases with radiographic-pathologic discordance, the actual rate of upstaging to DCIS or invasive cancer is quite low (64,65). Rendi et al. reported an upgrade rate of 4% following surgical excision of 68 cases of LN on core biopsy, and similarly, Murray et al. (66) reported an upgrade rate of 3% following surgical excision of 72 cases of LN on core biopsy. In both of these series, the cancers identified were small, low-grade malignancies. Although both of these series are also retrospective and potentially subject to selection bias, they represent the most careful reviews of this clinical scenario to date and suggest that, in the context of multidisciplinary review, routine excision is not warranted for all cases of LCIS on core biopsy. Additional reports focusing on upgrade rates following a core biopsy diagnosis of pure ALH also support observation for select cases (67,68). In cases of ALH or LCIS that are not surgically excised, short-term mammographic follow-up is recommended.

Widespread use of core needle biopsies to evaluate screening abnormalities, in combination with advances in immunohistochemistry and molecular biology, have also resulted in a greater appreciation of the phenotypic and genotypic diversity within the spectrum of LN and to the diagnosis of so called *variants* of LCIS as described above. Although there is considerable speculation that PLCIS

TABLE 22-3

Upgrade Rates Following Surgical Excision for a Core Biopsy Diagnosis of PLCIS

		PLCIS		
Series		#	# *Excised*	% *CA*
Georgian-Smith and Lawton (59)	1999–2000	NA	5	40%
Pacelli et al. (63)	NA	5	5	60%

Sullivan et al.[c] (90)	2001–2009	LCIS-N = 11	11	45%
		LCIS-P = 17	17	29%

[a]2 of 10 cases possible "microinvasive carcinoma" on core biopsy.
[b]One-third of cancer cases presented as a "mass" on imaging.
[c]Includes 9 cases identified on E-cadherin staining of DCIS core biopsy cases.
PLCIS, pleomorphic LCIS; CA, carcinoma; NA, not applicable; LCIS, lobular carcinoma *in situ*; LCIS-N, LCIS with necrosis; LCIS-P, pleomorphic LCIS.

represents a more aggressive subtype, data regarding the natural history of this lesion are limited to two small retrospective reports describing recurrences of PLCIS after excision (31,69). Available data do, however, support routine excision when PLCIS is diagnosed on core biopsy with upgrade rates consistently exceeding 25% (Table 22-3). It should be noted that the small number of cases identified over the span of several years in all of these series suggest that the true incidence of PLCIS is likely quite low.

A diagnosis of classic LCIS or ALH made by surgical excision does not require further surgical intervention, and there is no indication to document margin status in a specimen that contains only LN (21). Similarly, the finding of classic LCIS or ALH in the surrounding breast parenchyma of a lumpectomy specimen containing DCIS or invasive carcinoma does not alter surgical management of the breast primary and does not increase the rate of local recurrence in patients undergoing breast conservation (58,70,71). In a review of 2,894 patients treated with breast-conserving therapy from 1980 to 2007, 290 (10%) of whom had LCIS in the lumpectomy specimen, there were no differences in the 5-year actuarial rates of local recurrence for patients with and without LCIS (2% for both groups). Among the 290 patients in the LCIS group, 84 were documented to have LCIS at the margin. The 5-year actuarial rate of local recurrence for patients with LCIS at the margin was 6% as compared to 1% for those with LCIS in the specimen but away from the margin (p = NS). On univariate analysis, the presence of LCIS in the specimen or at the margin did not predict for local recurrence, whereas patient age, menopausal status, use of adjuvant therapy, and the presence of an extensive intraductal component were significant predictors. On multivariate analysis, adjusting for differences between the LCIS and no-LCIS cohorts, the presence of LCIS in the specimen (HR, 1.66; 95% CI, 0.86–3.18) or at the margin (HR, 1.52; 95% CI, 0.48–4.83) was not significantly associated with local recurrence.

The importance of clear margins following excision of PLCIS is largely unknown as the available data are limited to one series reporting margin status and follow-up after excision with or without radiation in 26 cases of PLCIS (69). At a mean follow-up of 46 months (range 4 to108 months), one of six patients whose original excision showed PLCIS at the margin developed recurrent PLCIS. There were no other events reported. Until additional data are available, it is reasonable to pursue margin-negative excision for PLCIS, yet one should remember this is based on pragmatism rather than strong scientific evidence. Further, there are no data on the efficacy of radiation therapy following excision of PLCIS, and rather than assuming that its clinical behavior is known and recommending aggressive surgical treatment and/or radiation therapy, prospective efforts to document clinical outcomes and define the true magnitude of risk imparted by this lesion should be actively pursued.

Management of the High-Risk Patient

Once a concurrent malignancy has been excluded, women with LCIS should be counseled regarding their increased risk of breast cancer. Compared to the general population, women with LCIS have an eight-fold to 10-fold increased risk of breast cancer (11). In the series with the longest follow-up, the probability of developing carcinoma *in situ* or invasive cancer was 13% in the first 10 years after diagnosis, 26% after 20 years, and 35% by 35 years, or roughly 1% per year (72). When counseling women about their risk, it is important to stress that the risk remains steady over their lifetimes and that, therefore, the absolute risk of breast cancer for an individual is impacted by their age at LCIS diagnosis. Importantly, however, most women with LCIS will not develop invasive breast cancer.

Surveillance

The NCCN Breast Cancer Screening and Diagnosis Clinical Practice Guidelines for women with LCIS include annual mammography and clinical breast exam (CBE) every 6 to 12 months with consideration of annual MRI (73). Although enhanced breast cancer surveillance strategies that include screening with breast MRI are commonly recommended for women at high risk, the American Cancer Society (ACS) guidelines do not support routine use of MRI in this setting, stating that there is not enough evidence to recommend for or against MRI screening in women at increased risk from LCIS, making the NCCN guideline somewhat difficult to interpret (74). The ACS guidelines are based on the increased sensitivity of MRI

in women at high risk due to an inherited predisposition or strong family history of breast cancer; however, the biology of the breast cancers that develop in women with LCIS differs from those that develop in women at risk on the basis of BRCA mutations, and the optimal screening strategy for women with LCIS remains uncertain.

Until recently, data directly addressing the role of MRI in women with LCIS were limited to two retrospective radiology reports demonstrating that MRI finds mammographically occult cancers in approximately 4% of women with a prior history of LCIS (75,76) and a study from the Memorial Sloan-Kettering Cancer Center (MSKCC) Surveillance program by Port et al. In that study, 252 women with LCIS were included, 135 (54%) of whom were participating in MRI screening (77). The MSKCC experience has now been updated to include 776 patients with LCIS, 59% of whom have been participating in MRI screening, with longitudinal follow-up from 1996 to 2009 (78). This large, well-annotated dataset now includes 98 cancer diagnoses and continues to demonstrate no difference in the crude cancer detection rate among women having conventional screening or conventional screening plus MRI. Taking into account other breast cancer risk factors, length of follow-up, number of MRIs, and the time dependency of breast cancer development, using Landmark Analyses, King et al. further demonstrated that routine use of MRI screening does not result in increased rates of cancer detection in any of the first 3 years following LCIS diagnosis, nor does it result in earlier stage at diagnosis. Not surprisingly, women in the MRI-screened group were significantly more likely to undergo one or more benign biopsies during the surveillance period (36% vs. 13%, $p < .0001$), reflecting the low specificity of this imaging modality; a problem that translates to increased patient anxiety and increased health care costs.

Importantly, in this large, modern cohort of women with LCIS followed longitudinally, King et al. also noted that the subsequent invasive cancers that developed were equally divided between those of the ductal and lobular phenotype, and of the 26 lobular cancers that were diagnosed, 10 were diagnosed by MRI imaging, 10 by conventional imaging, and 6 by CBE, reiterating the importance of CBE in this high-risk population. Another pervasive misconception is the propensity of lobular cancers to be bilateral, leading to a strong consideration for contralateral prophylactic mastectomy among women diagnosed with unilateral invasive lobular cancer. Among the 6 LCIS patients in this cohort who developed bilateral breast cancer, none were bilateral lobular cancers. Data from SEER also clearly document that an initial diagnosis of lobular cancer does not increase the risk of a metachronous contralateral cancer compared to patients with ductal disease (79). Finally, this dataset demonstrates that women with classic LCIS, which displays an immunohistochemical profile consistent with that of ER-positive breast cancer, overwhelmingly develop ER-positive breast cancers, which are likely to be detected at small size during routine screening.

Until information on the natural history of PLCIS is available, minimal surveillance strategies for this lesion should include biannual CBE and annual mammography. The decision to incorporate MRI screening should be made on an individual basis following a full discussion of the potential risks and benefits of this approach.

Chemoprevention

Prospective randomized data from the National Surgical Adjuvant Breast and Bowel Project (NSABP) Breast Cancer Prevention Trial (BCPT, P-1) demonstrated that among high-risk women, tamoxifen decreased the risk of developing invasive breast cancer by 49% (80). Similarly, the NSABP Study of Tamoxifen and Raloxifene (STAR, P-2) demonstrated that raloxifene was just as effective as tamoxifen in reducing the risk of breast cancer in high-risk postmenopausal women (81). Women with LCIS were well represented in both of these studies, comprising 6.2% of 13,338 participants in the P-1 trial and 9.2% of 19,747 participants in the STAR trial. In both subsets, chemoprevention reduced the risk of developing breast cancer by more than 50%. Collectively, these data led to a statement from the American Society of Clinical Oncology (ASCO) recommending 5 years of tamoxifen for high-risk premenopausal women to reduce the risk of ER-positive invasive breast cancer and raloxifene to reduce risk for postmenopausal women. Although there are no data to directly address the use of chemoprevention in PLCIS, the fact that the vast majority of these lesions are ER positive supports a potential role for chemoprevention in patients with this diagnosis.

More recently, the MAP.3 trial demonstrated that compared to placebo, exemestane reduced the risk of invasive breast cancer by 65% in postmenopausal women and appeared to be beneficial in women with a history of ADH, ALH, and/or LCIS (82), and in a large observational study of 2,459 women diagnosed with atypical breast lesions, including LCIS, Coopey et al. reported a significant decrease in breast cancer risk with chemoprevention for all types of atypia ($p < .001$), with estimates ranging from a risk reduction of 50% at 5 years to 65% at 10 years. Findings from the MSKCC surveillance program also validate the benefit of chemoprevention in women with LCIS in the clinical setting. Among 998 women, 163 (16%) of whom reported chemoprevention use of at least 6 months, there was a significant reduction in the incidence of breast cancer with chemoprevention, 14.5% versus 3.6% ($p < .0001$), at a median follow-up of 84 months (57).

Despite these findings, neither tamoxifen nor raloxifene has been widely embraced, and studies addressing patient and physician attitudes toward chemoprevention are limited. Port et al. found that among 43 high-risk patients offered tamoxifen, 41 declined due to perceived risks (83). Tchou el al. (84) reported a higher acceptance rate of 42% among 137 high-risk women offered tamoxifen, and specifically noted that older age and a history of atypical hyperplasia or LCIS were significant predictors of patient acceptance of tamoxifen at their institution. Collectively, these findings strongly support the need to improve our efforts to educate both high-risk patients and their health care providers about the benefits of chemoprevention in decreasing breast cancer risk.

Risk-Reducing Surgery

When LCIS was first described, it was treated as a malignancy necessitating mastectomy like all breast carcinomas at the time, and this remained the standard approach until studies demonstrated that the actual risk of breast cancer was lower than expected and that women with LCIS were equally likely to be diagnosed with ipsilateral or contralateral breast cancers; thus bilateral total mastectomy would be the only logical operation to truly reduce risk. In parallel with the trend toward more conservative therapy for the treatment of invasive breast cancer, aggressive surgical therapy for LCIS fell out of favor and, in the modern MSKCC experience, only a minority of women with LCIS (5%) pursue bilateral prophylactic mastectomy (57). Nevertheless, bilateral prophylactic mastectomy (BPM) may be a reasonable option for a subset of women with LCIS and other risk factors, such as a strong family history or extremely dense breasts.

Historically, BPM was reported to result in an approximately 90% risk reduction for the development of subsequent cancer (85). This figure was based on a retrospective analysis of 639 women with a family history of breast cancer undergoing bilateral prophylactic mastectomies between

1960 and 1993. While it is important to educate patients that prophylactic mastectomy *does not* completely eliminate cancer risk, many women in this series underwent subcutaneous mastectomy, an operation which has fallen out of favor due to the amount of breast tissue frequently left behind, and a more recent retrospective case-cohort study evaluating the efficacy of BPM in a community practice setting reported a 95% risk reduction (86). The current standard of care for prophylactic mastectomy is total mastectomy (with or without reconstruction) with the goal of removing the entire mammary gland as would be performed during therapeutic mastectomy. The desire for nipple preservation in this setting and others is becoming increasingly common, and while this may result in improved cosmesis and patient satisfaction, prospective data supporting this contention and/or the long-term oncologic safety of this approach are not yet available.

Patients considering surgery for risk reduction need to be fully aware of all the risks and benefits of this approach, and should be encouraged to consider the impact that prophylactic surgery may have on their quality of life with respect to body image and sexual functioning. If reconstruction is to be pursued, they should also have a reasonable expectation for the most likely cosmetic outcome. The decision to undergo BPM is highly individualized and should not be undertaken without ample time to consider all of the available options for risk management.

MANAGEMENT SUMMARY

- LCIS and ALH are uncommon pathologic findings, representing part of a spectrum of epithelial proliferations referred to as LN. They are typically incidental findings, identified in up to 4% of otherwise benign breast biopsies, yet, given that they have no distinctive clinical presentation or imaging features, the prevalence of LCIS likely exceeds its incidence.
- A diagnosis of LCIS confers a long-term cumulative risk of subsequent breast cancer that averages 1% to 2% per year and remains steady over time, resulting in relative risk of breast cancer that is eight-fold to 10-fold greater than the general population risk. ALH is associated with a relative risk of breast cancer four-fold to five-fold greater than the general population.
- Routine surgical excision following a core biopsy diagnosis of LN is supported by NCCN guidelines; however, emerging data support observation in cases in which there are no other indications for excision, and radiographic-pathologic concordance has been confirmed by multidisciplinary review. A core biopsy diagnosis of PLCIS should be followed by surgical excision due to the high rates of associated cancer in reported series.
- A diagnosis of LN made by surgical excision does not require further surgical intervention; there is no indication to document margin status in specimens that contain only LN. The presence of LN in a lumpectomy specimen or at the margin is not a contraindication to breast conservation and does not require re-excision.
- Given the available data, it is reasonable to attempt complete excision to a negative margin for cases of PLCIS. However, there are no data to support the efficacy of radiation therapy for this diagnosis.
- Patients with LN should be informed of their increased risk of breast cancer, and counseled regarding both medical and surgical risk-reducing options. Chemoprevention significantly decreases the risk of breast cancer in patients with LN by at least 50%, and bilateral prophylactic mastectomy reduces the risk of breast cancer by 90% to 95%.

CHAPTER 23

Ductal Carcinoma *In Situ* and Microinvasive Carcinoma

Kimberly J. Van Zee, Julia White, Monica Morrow, and Jay R. Harris

CHAPTER CONTENTS

INTRODUCTION

Ductal carcinoma *in situ* (DCIS), also known as intraductal carcinoma, is a noninvasive carcinoma. Historically, DCIS was an uncommon lesion that was routinely treated by mastectomy, and little attention was given to defining its natural history or exploring alternative local treatments. The widespread use of screening mammography has resulted in a significant increase in the rate of detection of DCIS (1) (Fig. 23-1). Although no prospective randomized trial has ever compared mastectomy with breast-conserving surgery for DCIS, the acceptance of breast-conserving therapy for the treatment of invasive carcinoma lead to its acceptance for the treatment of DCIS. Furthermore, four prospective randomized studies of radiation after breast-conserving surgery for DCIS have shown that breast cancer specific survival is excellent, with or without radiation (2–5). Therefore, there is a debate as to whether all DCIS should be regarded as early stage carcinoma and treated with either mastectomy or lumpectomy and irradiation, or whether excision alone can be used to treat some DCIS.

PRESENTATION

In 90% of cases, DCIS presents as an abnormal screening mammogram in an asymptomatic woman. Prior to widespread screening with mammography, DCIS presented with clinical symptoms and was an uncommon entity. In 1983, before screening was widely used, only 4,901 women were diagnosed with DCIS in the United States, accounting for 3.8% of all breast cancer (6). By 2013, approximately 64,640 new DCIS diagnoses will be made, representing approximately 20% to 25% of all new breast cancers (7). The SEER database has documented that the incidence of DCIS rose from 5.83 per 100,000 women in 1975 to 37.25 per 100,000 in 2009 (8). The increased incidence was observed in all age categories, with the greatest rise among women over 50 years of age (Fig. 23-1). The incidence of DCIS, like invasive breast cancer, is strongly related to age. DCIS is extremely uncommon before age 35 to 39; with incidences of less than 11 cases per 100,000. After that, the incidence rises steadily to a peak of 102 per 100,000 at ages 65 to 69. In contrast, invasive breast cancer incidence peaks at a later age (75–79 years) with incidence of 433.1 per 100,000 women (8,9).

The increase in DCIS diagnosis has not been uniform across histological types (Fig. 23-2). An earlier analysis of the SEER database from 1980 to 2001 demonstrated that comedo histology rose in incidence from 1980 through 1995 but then stabilized or decreased slightly thereafter, while non-comedo histology continued to rise thorough the end of the study period (10). The age-adjusted incidence of DCIS was the highest among Caucasian women, followed by African-American and Asian-Pacific Islander women (11).

Microcalcifications are the predominant finding on screening mammography leading to a diagnosis of DCIS. As an example, in a study of 217 women 50 to 69 years of age with DCIS detected by mammography while participating in the Breast Cancer Screening program in Norway from 1995 through 2007, calcifications were present for 93%. On pathology review, calcifications were associated with grade 1 DCIS in 15%, grade 2 in 11%, and grade 3 in 74% (12). Calcification morphology on mammography was most frequently described as “fine pleomorphic.” In comparison, in a large surgical series from France of 909 cases of DCIS diagnosed from 1980 to 1999, 76.2% were detected by mammography without clinical symptoms, 12% had a palpable mass, and 12% presented with nipple discharge (13). Of

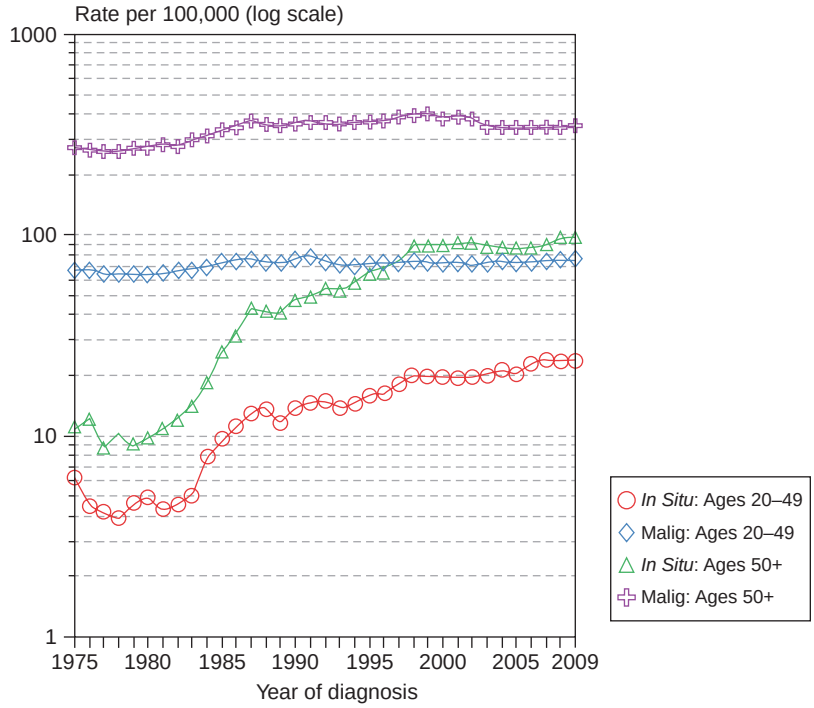

FIGURE 23-1 SEER Incidence rates 1975 to 2009 for *in situ* versus invasive breast cancer by age, all races. (From Howlader N, Noone AM, Krapcho M, et al., eds. SEER Cancer Statistics Review, 1975–2010, National Cancer Institute. Bethesda, MD, http://seer.cancer.gov/csr/1975_2010/, based on November 2012 SEER data submission, posted to the SEER web site, April 2013.)

those with a palpable mass, 47.1% also had mammographic abnormalities. Microcalcification was the most common finding in 75.5%, with fine pleomorphic calcifications being the most frequently seen (40.4%), followed by amorphous or indistinct calcifications (35.9%). Fine pleomorphic and fine-linear branching calcifications were significantly associated with the presence of grade 3 DCIS and necrosis (13).

DCIS that is diagnosed with a palpable mass or nipple discharge is more likely to be extensive disease. Examination of 50 mastectomy specimens in a population of DCIS patients, of whom 58% were detected with mammography and 42% with clinical mass or nipple symptoms, revealed that presentation with a palpable mass, nipple discharge, or as Paget's disease was accompanied by a greater incidence of multicentricity and/or microinvasion than was DCIS detected by mammography (14). In addition, patients with comedo necrosis or micropapillary architecture were more likely to be multicentric than other histologic subtypes. More recent studies suggest that, in most cases, true multicentricity in DCIS is rare. Holland and Hendricks studied 119 mastectomy specimens containing DCIS by a subgross pathologic-mammographic technique (15). In all but one case, the tumor was confined to a single "segment" of the breast. Clear-cut multicentric distribution (defined in this study as foci of DCIS separated by 4 cm or more of uninvolved breast tissue) was seen in only one patient. Faverly et al., using stereomicroscopic three-dimensional analysis to define the growth pattern of DCIS in the mammary duct system, studied 60 mastectomy specimens containing DCIS (16). There was continuous growth pattern in the ducts for 50% and a discontinuous pattern in 50%, characterized by uninvolved breast tissue "gaps" between foci of DCIS. In most instances, these gaps were small (< 5 mm in 82% of cases). The likelihood of finding such gaps was related to the DCIS

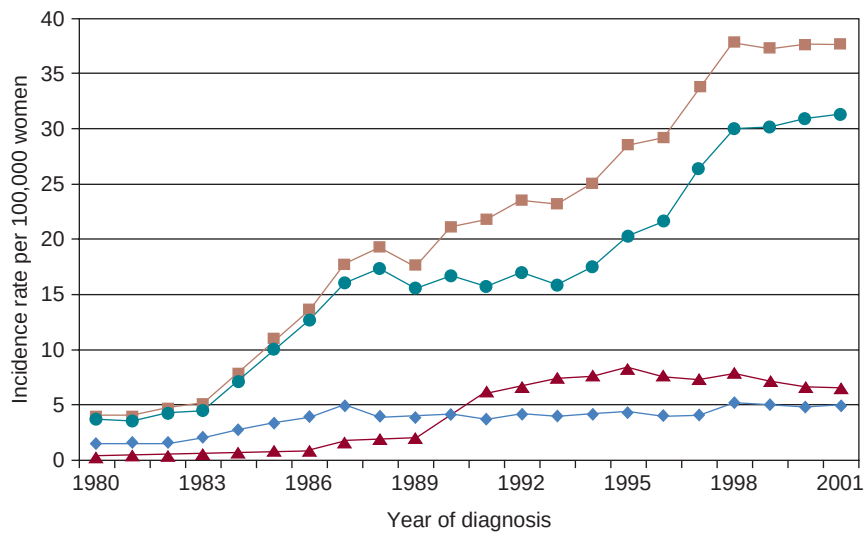

FIGURE 23-2 Incidence of *in situ* carcinoma (per 100,000 women) by different histological types among women ages ≥ 30 years, 1980 to 2001. (■ DCIS overall, ● non-comedo DCIS, ▲ comedo DCIS, ◆ LCIS. From Li CI, Daling JR, Malone KE, et al. Age-Specific Incidence Rates of *In situ* Breast Carcinomas by Histologic Type, 1980 to 2001. *Cancer Epidemiol Biomarkers Prev*. American Association for Cancer Research, 2005).

differentiation: 90% of poorly differentiated cases grew in a continuous manner without gaps, while 45% and only 30% of intermediate and well-differentiated lesions, respectively, were continuous. The findings in these two studies indicate that, in most cases, DCIS involves the breast in a segmental distribution, and truly multicentric disease is uncommon.

Mammography is the established method for detection and evaluation of extent of disease, but MRI is being increasingly studied for its clinical utility in DCIS diagnosis (17). Historically, MRI was considered a poor imaging tool to assess DCIS. The adoption of higher spatial resolution techniques and diagnostic criteria that are different than those used for invasive cancer has led to improved detection of DCIS by MRI. In the International Breast MRI Consortium study of patients with suspicious mammographic or clinical findings, the sensitivity of MRI for the detection of DCIS was 73%; significantly lower than the 91% observed for invasive cancer (18). The American College of Radiology Imaging Network (ACRIN) compared the diagnostic accuracy of mammography, clinical examination, US, and MRI prospectively in the preoperative assessment of 171 malignant foci, 38 of which were DCIS, in 121 breasts from 111 women. MR imaging identified 34 of 38 (89%) DCIS foci, which was significantly more than was detected with either US ($p < .001$) or mammography ($p < .01$) (19). These results were further supported by Kuhl et al. (20), who reported on 167 cases of DCIS that had, at some point during their workup, undergone both mammography and MRI. All imaging was re-read centrally and MRI studies were read blinded to the mammogram findings. MRI detected 92% of cases as compared to 56% by mammography ($p < .0001$). Of the 89 cases of high-grade DCIS, 48% were diagnosed by MRI but missed by mammography. Other studies have similarly demonstrated a 70% to 90% MRI sensitivity for DCIS detection (21). Additional investigation to clarify the clinical role of MRI for diagnosing DCIS and its prognostic implication are needed.

NATURAL HISTORY

There is significant evidence based on epidemiology, clinical observation, and growing numbers of genetic, molecular, and epigenetic studies that DCIS is a precursor lesion for invasive cancer. However, predicting which individual DCIS case will progress to invasive breast cancer if left untreated remains indefinable.

Epidemiologic studies that examine risk factors for DCIS show that they are remarkably similar to those for invasive breast cancer, including a family history of breast cancer, nulliparity, older age at first childbirth, and breast density (9). Clinical observation of DCIS progression to invasive cancer is limited as surgical resection is done once a diagnosis of DCIS is made. However, clinical follow-up from benign breast biopsies that received no additional intervention but on re-review many years later were diagnosed as DCIS offers some insight regarding clinical progression. Sanders et al. (22) identified 28 cases of small, low-grade, non-comedo DCIS during a review of 11,760 consecutive breast biopsies performed from 1950 through 1968. With a median follow-up of 28 years, 11 of 28 women (39%) developed ipsilateral invasive breast carcinoma, all in the same quadrant from which the original biopsy was taken. Seven (64%) of the 11 recurrences developed within 10 years, and 5 (45%) of the 11 (18% of all 28 cases) died of metastatic disease. Eusebi et al. reported on 80 cases of DCIS retrospectively diagnosed out of 9,446 breast biopsies done between 1964 and 1976, and with a median follow-up of 17.5 years. Pure "clinging carcinoma" (CC) was diagnosed in 41; 9 with pleomorphic nuclei (consistent with DCIS) and 32 with monomorphic nuclei which is currently considered flat epithelial atypia. Five (12%) developed an ipsilateral breast cancer: 2 of the 9 with pleomorphic nuclei developed ipsilateral invasive carcinoma, and 2 of the 32 with monomorphic nuclei developed DCIS. Of the 30 cases of CC associated with cribriform DCIS, LCIS, or both, 5 (17%) had an ipsilateral invasive recurrence. Two of 7 cases with cribriform DCIS developed an ipsilateral DCIS recurrence, and 2 of 2 cases with comedo DCIS developed an invasive recurrence (23). In a similar study, Rosen et al. (24), described 30 women with untreated DCIS; complete follow-up was available only for 15. Ipsilateral invasive breast cancers occurred in 7 of the 15 (53%) at a mean of 9.7 years after the diagnosis of DCIS. More recently, Collins et al. (25), found 13 cases of DCIS (0.7%) out of 1,877 breast biopsies performed from 1973 through 1991 on the Nurses' Health Study. Nuclear grading of the 13 cases revealed 6 to be intermediate, and 3 were high nuclear grade. A total of 10 cases recurred (77%); 6 (46%) developed invasive breast cancer at a mean of 9 years, and 4 (31%) developed DCIS at a mean of 3.75 years after the initial biopsy was performed.

The clear limitation of these studies is that the completeness of excision by the original biopsy is unknown; however, as a whole, they demonstrate that a significant portion of both low- and high-grade DCIS can progress to invasive breast cancer, supporting its role as a precursor.

Another source of indirect clinical evidence of DCIS as a precursor comes from autopsy studies. Alpers and Wellings (26) assessed a series of 185 randomly selected breasts from 101 women examined by a subgross sampling technique. One or more foci of DCIS were found in only 11 cases (6%). The lowest prevalence was noted in the oldest women: 3 of 56 (5%) in women younger than age 49; 7 of 70 women (10%) in women ages 50 through 69; and in 1 of 59 women (2%) older than 70 years were found. In a study with similar methodology, Bartow et al. (27), performed pathologic examination of the breast on 519 autopsied women 14 years of age or older without clinical evidence of breast cancer. Only one case of DCIS was identified in a 40 year old; five occult invasive carcinomas were found in women ages 45 to 87. These findings suggest that DCIS progresses to clinically evident breast cancer given its very low prevalence at autopsy, particularly in the oldest cohort of women.

There has been considerable research over the last several years in understanding the gene expression changes that occur in DCIS relative to what is known in invasive breast cancer. Over the past decade, the successful combination of highly specific tissue microdissection technologies with advanced high-throughput genomic, gene-expression, and proteomic technologies has enabled a better understanding of the pre-invasive stages of breast cancer progression (28). It is now acknowledged that significant genomic and gene expression parallels exist between the pre-invasive and invasive stages of breast cancer.

Several studies have examined genetic changes in DCIS, i.e., loss of heterozygosity (LOH), at genetic loci (typically considered to be approximate locations of inactivated tumor suppressor genes) known to exhibit high rates of loss in invasive breast cancer. These showed that the frequency of chromosomal losses, specifically regions 16q and 17p, in ADH is similar to that observed in DCIS and invasive carcinoma (28). O'Connell and colleagues examined 399 pre-malignant breast lesions, studying 15 genetic loci known to show high rates of LOH in invasive breast cancer (29). In breasts without invasive breast cancer, they found at least one locus of LOH in 42% of ADH, 70% of non-comedo DCIS, and 79% of comedo DCIS. Among specimens harvested from cancerous breasts, LOH was shared with the synchronous cancer in at least one locus in 45% of ADH, 77% of non-comedo

DCIS, and 80% of comedo DCIS lesions. This observation that the majority of both comedo and non-comedo DCIS share their LOH phenotypes with synchronous invasive breast cancer supports the concept that DCIS is a direct precursor of invasive breast cancer.

Ma and associates used laser capture microdissection and DNA microarrays to generate *in situ* gene expression profiles in 36 breast tissue specimens that exhibited one or more lesions of ADH, DCIS, and invasive carcinoma (30). No consistent gene expression alterations unique to ADH, DCIS or invasive carcinoma were found; instead, the greatest alterations in gene expression were seen by histological grades. Similar to what has been observed with invasive breast cancer, distinct gene-expression signatures are present in low- and high-grade DCIS lesions, and are consistent with genetic alterations and phenotypes seen in comparable grade invasive cancer. These data suggest that low-grade DCIS progresses to low-grade invasive and high-grade DCIS to high-grade invasive, with intermediate-grade DCIS representing intermediary behaviors.

There has been increasing focus on the DCIS microenvironment for identification of promoters of tumor progression. Recent gene-expression and epigenetic data strongly suggest that the stromal and myoepithelial microenvironment of pre-invasive breast cancer actively participates in the transition from pre-invasive to invasive disease (28). Allinen et al. (31) developed a purification procedure that allows the isolation of pure cell populations from normal breast tissue, DCIS, and invasive carcinoma. They demonstrated that genes coding for *CXCL14* and *CXCL12* chemokines were overexpressed in DCIS myoepithelial cells and myofibroblasts, respectively, compared to normal breast tissue. These chemokines can bind to receptors on adjacent epithelial cells and enhance their proliferation, migration, and invasion. Thus, chemokines may have a part in the transition from DCIS to invasive breast cancer by acting as paracrine factors. This illustrates how signaling from the DCIS stromal and myoepithelial microenvironment may play an important role in tumorigenesis.

These genetic and molecular studies give further evidence that ductal pre-invasive stages (ADH and DCIS) are non-obligate precursors to invasive disease with variable clinical behavior.

TREATMENT

The uncertainty regarding the natural history of DCIS has resulted in a wide range of local treatment practices, from excision alone to mastectomy. There is now a significant body of mature data from prospective, randomized trials in well-characterized populations of women with DCIS that provides information about the risks of local recurrence and death after treatment with lumpectomy alone, and lumpectomy and radiation therapy (RT). Clinical trials have also evaluated the benefit of endocrine therapy in patients with DCIS. There are no prospective studies evaluating mastectomy or comparing it to breast-conserving surgery.

Mastectomy

Theoretically, mastectomy should be 100% curative for pure DCIS. While no prospective studies of mastectomy for DCIS exist, large (at least 100 women) retrospective series, with at least 5 years of follow-up, report actual local recurrence rates in the 1% to 3% range (Table 23-1). A meta-analysis of 1,574 mastectomies reported a recurrence rate of 1.4% (95% confidence interval [CI], 0.7–2.1) at an average follow-up of 80 months (32). Recurrence after mastectomy is usually invasive carcinoma and may present as either local recurrence or distant metastases without evidence of local recurrence. Breast cancer-specific survival rates at 10 years after mastectomy for DCIS are ≥ 98% (33,34).

Skin-sparing mastectomy allows preservation of the native skin envelope, resulting in improved cosmesis with immediate reconstruction. At a mean follow-up of 82 months, local recurrence occurred in 3.1% of 223 consecutive patients undergoing skin-sparing mastectomy for DCIS (35). Others have reported local recurrence rates from 0% to 4% at 3.5 to 10 years of follow-up (35).

In an effort to further reduce the psychological and cosmetic impact of mastectomy, nipple-sparing mastectomy has been recently explored. To date, limited local recurrence data are available. In 158 patients undergoing mastectomy with intraoperative radiation of the nipple-areola complex for ductal intraepithelial neoplasia, Petit et al. reported a 5-year local recurrence rate of 5%, with a nipple-areolar complex recurrence rate of 2.9% (36). A prospective series of 33 women undergoing 54 nipple-sparing mastectomies from the University of Texas MD Anderson Cancer Center (MDACC) reported a 30% complication rate in the nipple-areola complex, 11% in the skin flaps, and the need to remove the nipple-areolar complex due to DCIS involvement in 12% (37). Cosmetic outcome was acceptable (as judged by plastic surgeons) in 73% of breasts and 56% of nipple-areolar complexes, with most (67%) being laterally displaced.

Treatment failure after mastectomy for DCIS may be due to unsampled or unrecognized invasive carcinoma that results in local recurrence or distant metastases, or it may be due to incomplete removal of breast tissue. Residual breast tissue may harbor DCIS; it also has the potential for development of a new carcinoma that would be manifested as a "local recurrence."

Mastectomy is a highly effective treatment for DCIS, but it is a radical approach to a lesion that may not progress to invasive carcinoma during the patient's lifetime. It seems somewhat paradoxical that a woman with a palpable invasive carcinoma should be able to preserve her breast, whereas the "reward" for screening and early detection of DCIS is a mastectomy. The acceptance of breast-conserving therapy for the treatment of invasive carcinoma led to its use as a treatment for DCIS. However, no randomized trial has ever compared the treatment of DCIS by mastectomy with treatment by breast-conserving approaches, and no such trial is likely to occur. In some cases, the assumption has been made that because these two treatments result in equivalent survival for patients with invasive carcinoma, the same is true for patients with DCIS. This assumption is flawed because of the fundamental difference in the risk of metastatic disease for patients with invasive carcinoma and those with DCIS. In DCIS, unlike invasive cancer, the risk of metastases at diagnosis is negligible, while an invasive local recurrence carries with it the potential risk of breast cancer mortality. Therefore, the incidence of invasive recurrence and the results of salvage therapy should determine the suitability of breast-conserving approaches as a treatment for DCIS.

Breast-Conserving Surgery and Radiation Therapy

Five randomized control trials have evaluated the extent of benefit from breast radiotherapy in reducing cancer recurrence following complete excision for DCIS (Table 23-2). The first of these was the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-17 clinical trial that, from 1985 through 1990, enrolled 818 women who had undergone lumpectomy for DCIS with microscopically clear margins and were randomized to observation post excision versus whole breast radiotherapy. The characteristics of the DCIS population accrued are seen in (Table 23-3). At 42 months median follow-up, a 59%

average annual reduction in ipsilateral breast cancer events was demonstrated with the addition of radiotherapy after lumpectomy (38) that persisted at 8 (39)and 12 years median follow-up (40). The most recent analysis done after 17.25 years median follow-up demonstrates a sustained benefit of breast radiotherapy with a 52% relative reduction in the risk of invasive ipsilateral breast cancer recurrence (hazard ratio [HR], 0.48; 95% CI, 0.33–0.69; $p < .001$) and a 47% reduction in the risk of DCIS ipsilateral in-breast recurrence (HR, 0.53; 95% CI, 0.35–0.8; $p < .001$) compared to those randomized to lumpectomy alone. The same percentage of women developed contralateral breast cancer in the lumpectomy-alone group (10.3%) and in the group that received radiotherapy (10.2%). Likewise, overall and breast cancer mortality did not differ for the lumpectomy-alone versus the breast radiotherapy group (2).

The European Organization for Research and Treatment of Cancer (EORTC) conducted a similarly designed randomized clinical trial investigating the role of radiotherapy after lumpectomy for DCIS ≤ 5 cm in size (3,41). It enrolled 1,010 women between 1986 and 1996. Microscopically clear resection margins were not stipulated for eligibility in this trial. In comparison to NSABP B-17 (Table 23-3), this population had less screen-detected DCIS (71%) and fewer excisions with negative surgical margins (78%). The first results reported at a median of 4.25 years demonstrated a 43% relative reduction in cancer recurrence in the treated breast with the addition of radiotherapy; 16% for observation versus 9% with treatment ($p = .005$) (41). Ten-year outcomes from the EORTC 10853 trial demonstrated a sustained 47% relative reduction in ipsilateral local recurrence (3). An approximately equal reduction in DCIS and invasive cancer recurrences was seen. There was no difference at 10 years by treatment group in the rate of contralateral breast cancer, distant metastases, breast cancer deaths, and overall survival.

The Swedish Breast Cancer group, from 1987–1999, enrolled 1,067 women who had undergone lumpectomy for DCIS occupying a quadrant or less of the breast into the SweDCIS trial. Women were randomized to observation versus postoperative whole breast radiotherapy. Microscopically clear surgical margins were not required. In 97%, specimen radiography was done at the time of lumpectomy. The patient population was similar to that enrolled on the EORTC 10853 clinical trial (Table 23-3). At 5 years a 67% relative reduction in local recurrence in the treated breast was seen: 22% in the observation group versus 7% in the radiotherapy group ($p < .0001$) (42). At a mean of 8 years of follow-up, a sustained 60% reduction in local recurrence (corresponding RR of 0.40 (95% CI, 0.30–0.54) was seen with the addition of radiotherapy. There were similar reductions in risk for ipsilateral invasive and DCIS recurrences (Table 23-2) (5).

The United Kingdom, Australia, and New Zealand (UK/ANZ) DCIS Trial accrued 1,701 women with DCIS detected in the National Breast Screening Program who had undergone lumpectomy with cancer-free surgical margins between 1990 and 1998 (4,43). The trial used a 2×2 factorial design to assess radiotherapy, tamoxifen, or both in patients with completely excised DCIS. Patients could elect to either enter into the four-way randomization or one of two separate two-way randomizations. Among the various randomization schemes, 1,030 patients were randomized to radiotherapy or observation after lumpectomy. This population reflects its origins from the screening program, so most (91%) are 50 years or older, and given the trial design, 54% received tamoxifen (Table 23-3). At a median follow-up of 5.25 years, radiotherapy was associated with a 64% relative and 8.9% absolute reduction in risk for all ipsilateral events (13.7% in the control group and 4.8% in the irradiated group, $p < .0001$) (43). A durable effect of radiotherapy is seen at 12.7 years median follow-up with a 68% relative and 12.3% absolute reduction in ipsilateral cancer recurrences (from 19.4% in the control versus 7.1% with irradiation; HR, 0.32; 95% CI, 0.22–0.47; $p < .0001$) (Table 23-2) (4).

A meta-analysis by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) provides a concise overview of radiotherapy effect following lumpectomy for DCIS (44). A total of 3,729 women were eligible for analysis from the NSABP B-17, EORTC 10953, SweDCIS, and UK/ANZ trials, with a median follow-up of 8.9 years. Radiotherapy approximately halved the rate of ipsilateral breast events (rate ratio 0.46; standard error [SE], 0.05; 2 $p < .00001$) with no evidence of heterogeneity between the trials in the proportional reduction. At 5 years after randomization, the absolute reduction in risk was 10.5% (SE 1.2%, 7.6% vs. 18.1%) and at 10 years after, it was 15.2% (SE 1.6%, 12.9% vs. 28.1%). Radiotherapy was effective in reducing ipsilateral breast events regardless of whether the woman was younger or older than 50 years at diagnosis, local excision or sector resection had been performed, and tamoxifen or not was given (tamoxifen only given on the UK/ANZ trial). Furthermore, radiotherapy was effective in reducing ipsilateral breast events regardless of the mode of detection, surgical margin status, focality, histologic or nuclear grade, or the presence of comedo necrosis or comedo/solid architecture. Radiotherapy resulted in a larger proportional reduction in the rate of ipsilateral breast recurrence for women older than 50 years of age than for younger women (rate ratios: age < 50 years 0.69, SE 0.12; ≥ 50 years 0.38, SE 0.06; $2p = 0.0004$ for the difference between these proportional reductions). The proportional reduction did not differ significantly according to any other factor. There was no significant difference in the meta-analysis for breast cancer or overall mortality between treatment arms. The 10-year cumulative risk of breast cancer mortality was 4.1% for the radiotherapy groups and 3.7% for observation post lumpectomy (44). Importantly, there was no significant difference in heart disease deaths in those irradiated versus observed.

Within the EBCTCG analysis a "low-risk" group was sought in which the absolute risk of ipsilateral breast events was so low that the addition of radiotherapy would provide little absolute gain. There were 297 such cases of DCIS identified that were low-grade, less than 20 mm in size, and had negative surgical margins. Among them, the 10-year risk of an ipsilateral event in those allocated to lumpectomy alone was substantial at 30.1%, and even with this relatively small number of women, the effect of radiotherapy was highly significant (rate ratio 0.48; SE 0.17; $2p = 0.002$), with a 10-year absolute gain of 18.0% (SE, 5.5%) (44).

Recently, the Radiation Therapy Oncology Group (RTOG) reported the results from its RTOG 9804 clinical trial for "Good Risk" DCIS post lumpectomy, randomizing patients to observation versus breast radiotherapy (45). The results from prior randomized trials likely reflect the inclusion of DCIS cases with higher risk features: high histologic and/or nuclear grade, involved surgical margins in some cases, larger tumor sizes, and limited tamoxifen use. RTOG 9804 sought to identify and determine radiotherapy benefit after lumpectomy for DCIS patients who were expected to have a low risk of ipsilateral breast recurrence. The study opened in 1999 and was targeted to accrue 1,790 women, but closed because of poor accrual in 2006 having randomized 636 patients. RTOG 9804 enrolled women with smaller lesions, all of which were low- or intermediate-grade DCIS. The study had a much higher rate of adjuvant tamoxifen use (62%) (Table 23-3). After a median follow-up of 7.2 years there have been 19 in-breast recurrences (42% invasive, 58% DCIS) in the observation arm (7-year rate, 6.7%) and 2 (50% invasive, 50% DCIS) in the radiotherapy group (7-year rate, 0.9%) for a hazard ratio of 0.11 (95% CI, 0.03–0.47; $p = .0003$)

(45). The eligibility criteria for RTOG 9804 are similar to the low/intermediate-grade stratum of the Eastern Cooperative Oncology Group (ECOG) single arm registration-observation study for DCIS post lumpectomy discussed elsewhere (46). For the low/intermediate-grade stratum on ECOG 5194, the 7-year rate of ipsilateral breast recurrence is 10.5% (46). This discrepancy in 7-year rates of ipsilateral breast recurrence between the two trials may be influenced by the tamoxifen use that was double in the RTOG 9804 (62%) population compared to the ECOG 5194 low/intermediate-grade stratum (31%). Additional follow-up of RTOG 9804 is needed to ensure endurance of the results given its incomplete accrual and the longer time to failure that has been reported for lower-grade DCIS; however, it appears that, based on standard clinical-pathologic criteria, a cohort of DCIS could be identified with a low rate of in-breast recurrence at 7 years without radiotherapy (but with tamoxifen in most). However, even in this low-risk group, the addition of radiotherapy reduced the in-breast recurrence rate by a relative 89% and an absolute 5.8%.

In addition to the randomized control trials, there have been numerous institutional experiences with lumpectomy and RT for DCIS demonstrating similar in-breast cancer event rates, acceptable toxicity, good cosmetic results, and excellent breast cancer-specific survival (Table 23-4).

Radiation Therapy Methods

The radiotherapy delivered post lumpectomy was fairly consistent across the 5 randomized trials, and in all cases the entire breast was irradiated (Table 23-5). The most common radiotherapy regimen was to deliver 50 Gy to the whole breast over 25 treatments or fractions of 2 Gy daily over a treatment period of 5 weeks. Boost or additional dose to the lumpectomy cavity vicinity was not recommended. Given that radiotherapy after lumpectomy for DCIS does not give a survival benefit, there has been understandable concern regarding the known excess risk for cardiovascular mortality associated with breast radiotherapy in the past (47). Methods of breast radiotherapy post lumpectomy that avoid/minimize cardiac irradiation for left-sided DCIS cases are imperative. One of the important findings of the EBCTCG meta-analysis is that there was no statistically significant excess heart disease mortality for those given breast radiotherapy after lumpectomy (44). There were 26/1878 (1.38%) heart disease deaths for those allocated to post lumpectomy radiotherapy versus 29/1851 (1.57%) for lumpectomy alone with 8.9 years median follow-up.

Shortened whole breast irradiation (WBI) treatment courses that are achieved with hypofractionation, or the delivery of larger daily radiation doses of 2.67 Gy to a total of 40 or 42.67 Gy with 15 or 16 treatments over approximately 3 weeks time, are being increasingly used after excision for DCIS. New

York University reported a Phase I/II single arm prospective trial in 59 patients using hypofractionated WBI of 42 Gy in 15 fractions of 2.8 Gy for treatment of DCIS (48). At a median follow-up of 36 months, there were no grade 3 radiation toxicities early or late, 91% of women reported a good-excellent cosmetic outcome, and no in-breast recurrences were reported. The University of Toronto reported their retrospective analysis of 266 women with DCIS who received either standard fractionated (104 cases) or hypofractionated (162 cases) WBI post lumpectomy. With a median follow-up of 3.76 years, the actuarial risk of ipsilateral breast recurrence at 4 years was 7% with hypofractionated WBI and 6% with the conventional schedule (p = .9) (49). The American Society for Radiation Oncology (ASTRO) evidence-based guideline on Fractionation for Whole Breast Irradiation concluded that data were insufficient so far to recommend for or against hypofractionated WBI post lumpectomy for women with DCIS (50).

The potential benefit of adding a boost, or supplemental radiation dose focused on the lumpectomy cavity vicinity only following WBI, remains an area of controversy for radiation management of DCIS. Boost was not part of protocol therapy in any of the 5 randomized clinical trials (Table 23-5). In the treatment of invasive breast cancer with breast-conserving therapy, the EORTC 22881-10882 clinical trial demonstrated that the use of a boost dose to the lumpectomy cavity vicinity after WBI resulted in a 41% relative and 4% absolute reduction in local recurrence at 10 years (p = .0001) (51). Given these data for invasive disease, the practice of adding a boost has been adopted following WBI for DCIS. This is evident in the 1,003 pooled cases from 10 institutions treated with breast radiotherapy post lumpectomy between 1973 and 1995, where a boost was delivered in 72% (52). In that study, there was not a significant difference in local recurrence for those that received less than 60 Gy (9%) versus those who received more (11%) (p = .91) at a median of 8.9 years follow-up. The use of a boost for DCIS is supported by a retrospective pooled analysis by the Rare Cancer Network that studied 373 young women (age < 45 years) with DCIS across 18 institutions who all underwent lumpectomy and then were either observed or received WBI with or without a boost (53). After a median follow-up of 6 years, the 10-year local recurrence rate reported for no radiotherapy was 34%; 28% for WBI without boost; and 14% for WBI with boost (p < .0001). However, another retrospective analysis from the British Columbia Cancer Agency database found no benefit of boost in 995 cases of DCIS treated with breast-conserving therapy with a 9.3 year median follow-up. In this analysis, the rate of local recurrence at 10 years was 13% in 475 cases without radiotherapy, 6% in 378 cases with WBI without boost, and 9% in 144 cases of WBI with boost (p = .065) (54). A secondary unplanned analysis examining the benefit of the "boost" was done on the NSABP B-24 clinical trial that examined tamoxifen effect after lumpectomy and WBI for DCIS (55). In this sub-analysis of 1,569 women enrolled on NSABP B24 with a 14.1-year median follow-up, it was documented that the 692 women who received a boost after WBI (38%) were more likely to have had involved margins and the presence of comedo necrosis than the 877 who were not boosted. The use of a boost did not result in a reduction in the rate of ipsilateral breast recurrence: 14.3% without boost and 13.8% with boost (55). The use of boost in the EORTC 22881-10882 clinical trial was accompanied by a significant increase in severe fibrosis and worsening of the cosmetic outcome (51). In the setting of DCIS, it is important to weigh the local control benefit of using a boost against the potential for adverse toxicity and cosmetic outcomes. These unanswered questions regarding radiotherapy fractionation and boost for DCIS are being addressed in a phase III randomized trial (NCT00470236) by the Trans-Tasman Radiation Oncology Group (TROG), "Radiation Doses and Fractionation Schedules in Non-low Risk Ductal Carcinoma in Situ (DCIS) of the Breast." This trial opened in 2007 and is targeted to accrue 1,600 women.

Early reports of accelerated partial breast irradiation (APBI) that focuses a short course (5–10 treatments over 5–8 days) of post excision radiotherapy solely to the vicinity of the lumpectomy cavity for treatment of DCIS have been favorable. Twelve institutions participated in a phase II clinical study using the MammoSite® brachytherapy for APBI for DCIS post lumpectomy, enrolling 133 patients from 2003–2006 (56). With a mean follow-up period of 9.5 months, there were 2 DCIS failures in the ipsilateral breast. William Beaumont Hospital reported retrospectively on 99 cases of DCIS treated with post lumpectomy APBI (57), and with a mean follow-up of 3 years, there has been 1 ipsilateral breast recurrence for a reported 5-year rate of 1.4%. There are 194 cases of DCIS in the American Society of Breast Surgeons registry of 1,449 cases from 97 institutions of early-stage breast cancer treated with APBI using the MammoSite® brachytherapy device (58). The most recent update after a median follow-up of 4.5 years reported 6 patients (3.1%) who had an ipsilateral breast recurrence, for a 5-year actuarial local recurrence rate of 3.39%. Acknowledging that these early results in DCIS are promising, but that the overall experience so far is limited and without prospective data, the ASTRO consensus statement regarding the patient selection criteria and best practices for the use of APBI outside the context of a clinical trial categorized DCIS as a "Cautionary" group (59). The NSABP B-39/RTOG 0413 phase III clinical trial comparing ABPI versus standard WBI for early-stage breast cancer post excision accrued 4,216 women between 2005 and 2013, and 24.4%, or 1,028, are DCIS. The pending outcome from this trial will clarify which DCIS patients are best suited to APBI post lumpectomy.

Tamoxifen

Tamoxifen use for DCIS developed from its observed benefit in reducing ipsilateral recurrent and new contralateral breast events in the management of invasive breast cancer treated with breast-conserving therapy (60). While radiotherapy post lumpectomy for DCIS results in a relative 50% to 60% reduction in ipsilateral breast recurrence, the residual absolute recurrence rates of between 9% and 20% or higher in some cohorts at 10 to 15 years follow-up (Table 23-2) have left opportunity for improvement. Two clinical trials have tested the impact of tamoxifen after lumpectomy with or without WBI for further reducing breast cancer events for DCIS: NSABP B-24 (2,61) and UK/ANZ (4,43). The NSABP B-24 clinical trial tested the hypothesis that in patients with DCIS treatment with lumpectomy, postoperative WBI and tamoxifen would be more effective than lumpectomy with WBI alone in prevention of invasive and non-invasive cancers in the ipsilateral and contralateral breast (61). This double-blind, randomized controlled trial enrolled 1,804 patients between 1991 and 1994 who all received lumpectomy and ipsilateral breast radiotherapy and then were randomly assigned to receive either placebo (n = 902) or tamoxifen (n = 902). Tamoxifen dose was 10 mg twice daily. Thirty-one percent of patients who started therapy discontinued treatment before 5 years. The patient population in this study included 33.5% who were less than 50 years of age, 83% whose DCIS was detected by mammography, 84% that had a lesion size less than 1 cm, and 25% who had positive or unknown surgical margins. At a median follow-up of 6.2 years, there were 37% fewer breast

cancer events in the tamoxifen group than the placebo group (p = .0009). A lower rate of ipsilateral-breast recurrences in the tamoxifen group was apparent only for invasive tumors (44% reduction). The rate of ipsilateral DCIS recurrences was not significantly lower in the tamoxifen group (p = ·43), but the reduction in contralateral breast DCIS was 13 versus 3, a 78% reduction (p = .02). Long-term outcomes of NSABP B-24 reporting at a median follow-up of 13.6 years (2) demonstrate a sustained 32% reduction in the risk of invasive ipsilateral recurrence in the tamoxifen compared with the placebo group (HR, 0.68; 95% CI, 0.49–0.95; p = .025). Regarding ipsilateral DCIS recurrences, the addition of tamoxifen resulted in a non-statistically significant risk reduction of 16% compared with placebo (HR, 0.84; 95% CI, 0.60–1.19; p = .33). There was a 32% reduction in contralateral breast cancer for patients who received tamoxifen versus placebo (HR, 0.68; 95% CI, 0.48–0.95; p = .023).

A combined analysis of outcomes from NSABP B-24 and B-17 that looks across trials demonstrates that radiotherapy and tamoxifen together resulted in a 70% relative risk reduction of invasive ipsilateral breast recurrence compared to lumpectomy alone (2). RT decreased the cumulative incidence of invasive ipsilateral recurrence at 15 years from 19.4% in the lumpectomy-only to 8.9% in the B-17 Lumpectomy-RT group, and to 10% in the B-24 lumpectomy-RT + placebo group. The cumulative incidence of ipsilateral invasive cancer recurrence was lower in the lumpectomy-WBI-tamoxifen group: 8.5% at 15 years.

In NSABP B-24, the addition of tamoxifen did not result in a statistically significant reduction in breast cancer mortality risk (HR, 0.86; 95% CI, 0.66–1.11) compared with lumpectomy and radiotherapy alone. However, across the B-24 and B-17 trials, women who developed an invasive ipsilateral breast recurrence, relative to those who did not, had a greater risk of all-cause death (HR, 1.75; 95% CI, 1.24–2.45), and the effect was larger (HR, 7.06; 95% CI, 4.14–12.03) if only breast cancer–related deaths were considered (2). In contrast, there was no statistically significant increase in overall mortality risk (HR, 0.81; 95% CI, 0.51–1.27) or breast cancer mortality risk (HR, 1.49; 95% CI, 0.71–3.15) for those who had DCIS recurrence. Of note, women who developed an invasive contralateral breast cancer had an increase in mortality risk (HR, 2.62; 95% CI, 1.82–3.77) similar to those who developed an ipsilateral invasive breast cancer recurrence.

The estrogen receptor (ER) status was unknown for the DCIS cases enrolled in NSABP B-24. Retrospectively, ER and/or progesterone receptor (PR) status has been attained in 732 cases, either from tissue blocks (449 patients) or from the laboratories (283 patients) used by enrolling institutions (62). The ER and PR were positive in 76% and 66% of patients, respectively. Patients with ER positive DCIS who received adjuvant tamoxifen versus placebo showed significant reductions in any breast cancer event (HR, 0.58; p = .0015), any invasive breast cancer (HR, 0.53; p = .005), and any contralateral breast cancer (HR, 0.50; p = .02). No significant benefit of tamoxifen in addition to lumpectomy and radiotherapy was seen with ER negative DCIS.

The benefit of tamoxifen after lumpectomy alone or with breast radiotherapy was also evaluated in the UK/ANZ trial in which 1,576 patients were randomly allocated to receive tamoxifen dosed at 20 mg per day (n = 794) or not given tamoxifen (n = 782). Of these, 912 were randomized in a 2×2 design to radiotherapy and tamoxifen, while 664 chose no radiotherapy and were only randomized to tamoxifen. Eleven percent stopped taking the drug before 5 years. Sixty-seven percent did not receive breast radiotherapy after lumpectomy (n = 1,053), and 33% underwent WBI post lumpectomy (n = 523). At a median follow-up of 4.4 years, tamoxifen did not significantly reduce the overall event rate nor the ipsilateral breast recurrence rate (13% with tamoxifen versus 15% without, p = .42) (43). In contrast, by median follow-up of 12.7 years, the use of tamoxifen did reduce the overall breast cancer event rate (ipsilateral + contralateral) (18.1% with tamoxifen vs. 24.6% without, p = .002) and the ipsilateral breast cancer event rate (15.7% with tamoxifen and 19.6% without, p = .04) (4). There was a significantly reduced rate of recurrent ipsilateral DCIS (8.6% with tamoxifen vs. 12.1% without, respectively, p = .03), but not ipsilateral invasive disease (6.8% with and 6.9% without tamoxifen, p = .79). Women who were randomly assigned to tamoxifen but were not treated with radiotherapy (n = 1,053) also had a significant overall reduction in new breast events (13.2% with tamoxifen and 17% without, p = .04). However, this benefit was confined to a reduction in DCIS events (7.4% with tamoxifen vs. 10.4% without, p = .04); no difference in invasive recurrences was seen (5.5% with tamoxifen versus 6% without, p = .6). There was no apparent benefit from receipt of tamoxifen among those who had lumpectomy *with* radiotherapy (n = 532; ipsilateral event rate with tamoxifen 2.4% vs. 2.6% without, p = .8) (4). There was a significant reduction in all contralateral events in those randomly assigned to tamoxifen (1.9% vs. 4.2%, p = .005).

The apparent discordance in the results from NSABP B-24 and UK/ANZ, especially in regard to tamoxifen benefit in the irradiated patients, may reflect the differences in patient populations enrolled in these respective trials. Thirty percent of patients enrolled in NSABP B-24 were less than 50 years of age compared to only 9% in the UK/ANZ trial. This disparity in younger women who have a higher likelihood of in-breast recurrence and proportionally smaller benefit from radiotherapy compared to women older than 50 (44) may explain the greater tamoxifen impact in irradiated patients in the NSABP B-24 trial.

Aromatase Inhibitors and Trastuzumab

The success of tamoxifen in lowering all rates of recurrence encourages the search for more effective and/or less toxic agents to reduce recurrent and new breast cancer events following lumpectomy for DCIS. Aromatase inhibitors have been documented to prevent invasive breast cancer in postmenopausal women (63) and reduce new contralateral breast cancer to a greater extent than tamoxifen after treatment of endocrine-sensitive invasive breast cancer (64). The outcomes from two randomized clinical trials that have completed accrual and that test the relative benefit of anastrozole in comparison to tamoxifen for reducing breast cancer events after lumpectomy for DCIS are awaited. Between 2003 and 2007, NSABP B-35 randomized 3,000 postmenopausal women diagnosed with DCIS treated with lumpectomy and breast radiotherapy in double-blind fashion to 5 years of tamoxifen 20 mg daily (and an anastrozole appearing placebo) versus anastrozole 1mg daily (and a tamoxifen appearing placebo). The International Breast Cancer Intervention Study II (IBIS II) similarly randomized 2,980 women over age 40 who had undergone lumpectomy for DCIS to either 5 years of tamoxifen or anastrozole between 2003 and 2011.

Trastuzumab has been demonstrated to be effective and safe in the treatment of HER2 overexpressing invasive breast cancer. HER2 overexpression in DCIS can range from 30% to 50% (65) and has been associated with higher rates of subsequent ipsilateral breast cancer recurrence (66). NSABP B-43 is actively accruing women with HER2 overexpressing DCIS treated with lumpectomy to be randomized to standard WBI versus 2 doses of trastuzumab every 3 weeks during

radiotherapy to determine whether trastuzumab given concurrently with radiotherapy is beneficial in preventing subsequent breast cancer events. The targeted accrual is 2,000, and as of the close of 2012, over 1,000 patients have been randomized.

Breast-Conserving Surgery Alone

The four published prospective, randomized trials (2–5) have demonstrated that the addition of RT to excision significantly decreases ipsilateral breast tumor recurrence (IBTR) but does not improve overall or disease-specific survival. It is possible that with larger populations and follow-up that some difference would emerge, but with randomization of approximately 4,000 women and median follow-up of 8 to 17 years, no hint of such a trend exists. Because radiation has not improved survival, and because there are rare but potentially serious risks associated with radiation, including secondary malignancies and cardiac disease (47,67), there has been persistent interest in treating some subsets of women with DCIS by excision alone. In fact, most academic radiation oncologists surveyed would not recommend radiation to all women with DCIS (68). Numerous risk factors for local recurrence have been identified, leading to the belief that at least some subset of DCIS may have a recurrence risk low enough to not justify radiation. A number of retrospective studies, usually including a highly select group of patients with small mammographically detected tumors of low histologic grade, have suggested that DCIS can be treated with excision alone with a high rate of local control. A number of these studies are shown in Table 23-6.

There have been two prospective studies of wide excision alone for DCIS (Table 23-7). The Dana-Farber/Harvard Cancer Center conducted a single-arm, prospective trial of wide excision alone from 1995 to 2002 (80,136). Entry criteria included DCIS of predominant grade 1 or 2 with a mammographic extent of no greater than 2.5 cm and final margin width of at least 1 cm. Tamoxifen was not permitted. The accrual goal was 200 patients; in July 2002 the study closed to further accrual at 158 patients because the number of local recurrences (n = 13) met the stopping rules. The median patient age was 51 years, and 94% had mammographically detected DCIS. Re-excision was performed in 133 (84%) of which no residual disease was identified in 92%. The median follow-up was 3.6 years (range, 0 to 6.9 years). Thirteen patients had local recurrence as the first site of failure between 0.6 and 5.2 years, resulting in a rate of ipsilateral local recurrence of 2.4% per patient-year (95% CI, 1.3%–4.1%), corresponding to a 5-year rate of 12%. Ten recurrences were in the same quadrant as the initial DCIS and three were elsewhere in the ipsilateral breast. Four (31%) recurred with invasive disease, all under 1 cm in size, and none with nodal metastases. No patient developed distant metastasis. A recent update with median follow-up of 11 years reported an annual local recurrence rate of 1.9% per patient-year and a 10-year local recurrence rate of 15.6% (136).

Another prospective, single-arm study examining the role of excision alone in the treatment of DCIS was reported by the Eastern Cooperative Oncology Group and North Central Cancer Treatment Group (46) (Table 23-7). Eligibility criteria for this study included DCIS at least 3 mm in size, excised with a margin width of 3 mm or more as determined by sequential sectioning and complete embedding. The study was open to patients with low- or intermediate-grade DCIS 2.5 cm or less in size, and high-grade DCIS (defined as nuclear grade 3 with necrosis) up to 1 cm in size. A postexcision mammogram was required for all participants. At a median follow-up of 6.7 years, the 7-year IBTR rate was 18% (95% CI, 10.2%–25.9%) for patients with high-grade DCIS, while IBTR occurred in 10.5% (95% CI, 7.5%–13.6%) of those with low- or intermediate-grade DCIS. In the high-grade group, 35% of IBTR were invasive; in the low/intermediate-grade stratum, 53% were invasive. The 7-year rate of contralateral breast cancer in the high- and low-grade groups was 7.4% and 4.8%, respectively. Comparison of 5- and 7-year results suggests a plateauing of recurrences in the high-grade but not in the low-grade stratum. This observation is further supported by a recent update for a subset of the population (91). Previous studies of patients treated with

excision and RT have shown that while early IBTR is more common in high-grade DCIS, after 10 years of follow-up, IBTR rates do not differ on the basis of grade (81).

The RTOG 98-04 included low-risk patients similar to those in the ECOG low-intermediate grade stratum, although the proportion taking tamoxifen in the RTOG study (62%) was double that in the ECOG study (31%). Patients were randomized to RT or observation. The reported 7-year IBTR rate is 6.7% with excision alone as compared to 0.9% with radiation (45).

The prospective data from these studies suggest that while careful selection can identify patients who can be treated with excision alone and achieve IBTR rates similar to those that received radiation in the randomized trials, there remains a substantial local recurrence rate despite margins of 1 cm or more. These results support the findings of the randomized trials that no subset of patients has been identified for which radiation does not reduce IBTR rate.

RISK FACTORS FOR LOCAL RECURRENCE

A number of studies have addressed prognostic factors for local recurrence in patients treated for DCIS by either excision alone or excision and RT.

Margin Status

Margin status is seen in almost all studies to be associated with local recurrence, although the categorization schemes used to report margin status are variable. Whether outcomes are analyzed with close and positive margin status combined, or with strictly positive margins (tumor on ink), almost all studies show significantly higher rates of local recurrence in patients with close or positive margins as compared to those with margins reported as negative (Tables 23-8 and 23-9).

The question of optimal margin width remains controversial. Because of the variability in specimen processing and grouping of margin widths, comparisons between studies are difficult. Silverstein reported a strong association between margin status and local recurrence in retrospective reviews of patients treated with excision alone and with RT. In a report of 469 patients, with a mean follow-up of 81 months, the 8-year incidence of local recurrence after excision alone was 58%, 20%, and 3% for margins less than 1 mm, 1 to 9 mm, and at least 10 mm, respectively, as compared to 30%, 12%, and 4%, respectively, for women treated with excision and RT (82). These data led the authors to conclude that RT is not justified if the margin width is large. In a more recent report, 12-year rates of local recurrence for women with margins at least 10 mm were 14% for excision alone and 2.5% for excision and RT (74), consistent with the idea that radiation does reduce the rate of local recurrence in all subsets. In the prospective ECOG study of excision alone, comparison of those with at least 10 mm margins to those with between 3 and 10 mm margins showed no difference in 5-year local recurrence rates in either high- or low/intermediate-grade strata (46).

One reason for the inconsistent association between margin status and local recurrence may be the variability in methods of assessing margin status and the sampling error inherent in the examination of a three-dimensional irregular specimen to determine completeness of excision. Supporting the concept that margin determination has significant sampling error are series that have found an

association between volume of breast tissue excised (83,84) or volume of disease near the margin (84,85) and local recurrence rates. In a series of 294 women with 11 years of follow-up, Rudloff et al. showed an association between greater volume of disease near the margin and greater reduction in risk of local recurrence with radiation (85).

A meta-analysis of 22 studies of the impact of margin width on local failure of DCIS included 4,660 patients treated with excision and RT (86). The relative risk of IBTR for those with negative margins was 0.36 (95% CI, 0.27–0.47; $p < .0001$) compared to those with positive margins. For those with negative versus close margins (defined by each study, ranging from <1 to >5 mm), the relative risk of IBTR was 0.59 (95% CI, 0.42–0.83; $p < .001$). Furthermore, the relative risk of IBTR for a 2 mm or greater margin was 0.53 (95% CI, 0.26–0.96; $p < .05$) compared to a lesser margin. When compared to margin widths of at least 5 mm, those with margin width of 1 mm had a relative risk of 2.89 (95% CI, 1.2–8.1; $p < .05$), and those with margin width of 2 mm had a relative risk of 1.51 (95% CI, 0.51–5.0; $p > .05$) (86). The 2 mm vs. 5 mm margin width comparison may be underpowered due to limited number of patients in these groups.

Taken together, these studies demonstrate that margin status is associated with risk of IBTR. The rate of local recurrence is lower with negative margins compared with close, positive, or uncertain margins. To date, there is no convincing evidence that a margin width larger than 2 mm lowers recurrence rates for women receiving RT. However, the optimal margin width for those receiving and not receiving RT remains uncertain.

Age

Young age has consistently been associated with higher rates of ipsilateral breast cancer recurrence following lumpectomy for DCIS with or without radiotherapy in the randomized control trials as well as single institution and multi-institution experiences (3–5,39,52,71,87) (Table 23-10). In the SweDCIS trial and UK/ANZ trials, young age was not associated with worse local recurrence after lumpectomy alone; however, older women in these trials had a proportionally greater benefit from the addition of breast radiotherapy compared to younger women (4,5). This is further reflected in the EBCTCG meta-analysis where radiotherapy resulted in a larger proportional reduction in the rate of ipsilateral breast recurrence for women older than 50 years of age than for younger women (44). When the meta-analysis was subdivided into five groups according to age (<40, 40–49, 50–59, 60–69, ≥70), the trend in the proportional reduction in ipsilateral breast recurrence with increasing age was significant ($p = .02$). The difference between the proportional reductions in younger and older women did not appear to be accounted for by differences in histological grade or comedo necrosis, or by differences in nuclear grade or architecture. Other investigators have proposed that worse local control rates in younger women with DCIS are explained by the greater prevalence of poor prognostic features. Younger women are more likely to present with clinical symptoms and have higher nuclear grade lesions, each of which has been associated with increased risk of ipsilateral breast recurrence (3,87).

Method of Detection

DCIS that is detected by clinical symptoms instead of mammographic screening carries a higher risk of ipsilateral breast recurrence following lumpectomy with or without breast radiotherapy (2,85,87–89). In a SEER-based cohort study of 1,026 women with DCIS in the San Francisco Bay Area, ipsilateral invasive cancer recurrence was more likely in women whose initial DCIS lesions were detected by palpation than in women whose initial DCIS lesions were detected by mammography (OR, 4.9; 95% CI, 1.7–14.2) (89). The 10-year risk of breast cancer mortality in this study was greatest for women who were age 40 years at diagnosis with DCIS detected by palpation (2.5%; 95% CI, 2.4%–2.5%) or with a high nuclear grade (2.5%, 95% CI, 2.1%–3.0%) (89). The poorer prognosis associated with clinical detection may be confounded by young age. Women age 40 to 50 are less likely to receive regular mammogram screening than their older counterparts. Investigators from MDACC found in their large, single institutional series of 2,037 patients with DCIS, 56.1% of those under 40 presented with clinical rather than radiologic signs of breast cancer, compared with 14% over age 40 ($p = .001$) (87). However, another series found clinical detection to be associated with a higher local recurrence risk even on multivariable analysis that controlled for age (HR, 2.3; 95% CI, 1.2–4.5) (85).

Pathologic Features

The presence of comedo necrosis, high nuclear grade, and larger lesion size are frequently but not consistently associated with increased rates of in-breast recurrence following lumpectomy with or without breast radiotherapy. This may be related to the acknowledged inter-pathologist variability in the description/grading of DCIS, the existence of different DCIS pathology grading systems, and treatment bias inherent in retrospective datasets examining this issue. Therefore, data from prospective trials with central pathology reviewed represent a good opportunity to examine the influence of pathology features.

In the EORTC 10853 clinical trial, the 10-year risk of a subsequent breast event was associated both with poor or intermediate-grade histology and comedo-solid architecture (3). DCIS with poor or intermediate differentiation had a 26% or 27% rate of a subsequent breast cancer event versus 14% for well differentiated lesions ($p < .001$). Similarly, the recurrence rate was 27% for a solid/comedo histology, 26% for cribriform and 9% for clinging/micropapillary ($p = .001$) (3).

A central review of pathology slides was performed on 623 patients, or 77% of the entire NSABP B-17 cohort: 303 treated by lumpectomy only, and 320 by lumpectomy and WBI at a median follow-up of 8 years (146). Nine pathologic features were examined for association with in-breast recurrence: comedo necrosis, histologic type, margins, lymphoid infiltrate, nuclear grade, focality, cancerization, stroma, and tumor size. When all nine pathologic features were examined jointly for prognostic significance, only comedo necrosis remained as a significant predictor for in-breast cancer recurrence.

A total of 72% of 1,694 cases entered into the UK/ANZ DCIS trial had full pathological review, and many pathology features were assessed for their association with ipsilateral recurrence (90). All reviewed cases were graded according to several recognized classifications of DCIS, including cyto-nuclear features (National Pathology Coordinating Group, 2005), traditional/historical nomenclature, Van Nuys grade, Nottingham grade, differentiation (Holland), main architecture, and necrosis. At a median follow-up of 4.4 years, all of the grading systems applied showed a significant increase in ipsilateral breast recurrence rates with higher grade, comedo type necrosis, and predominant growth pattern/architecture of the disease. Specifically, patients with a solid morphology as the main architectural pattern of DCIS had a 15.2% recurrence rate compared with 14.3% of those with micropapillary DCIS, and only 7.3% of those with predominantly cribriform DCIS.

These findings are corroborated by the SEER/San Francisco Bay Area study of lumpectomy only for DCIS, in which the 5-year risk of ipsilateral invasive cancer recurrence was greater with high nuclear-grade lesions (11.8%; 95% CI, 9.9%–14.1%) than for those with low nuclear-grade lesions (4.8%; 95% CI, 3.7%–6.8%) (89). In contrast, in a review of 287 cases of DCIS from 10 institutions with a 10.3-year median follow-up, investigators reported that comedo

histology and nuclear grade 3 combined did not predict higher rates of in-breast recurrence, but instead predicted a shorter interval to recurrence. The median interval to local recurrence was 3.1 years (mean, 4.4; range, 1.6 to 13) for patients with the combination of comedo plus nuclear grade 3 features; the median interval to local recurrence was 6.5 years (mean, 7.0; range, 1.9 to 16.8) for patients without this combination (81).

The similarity in local recurrence between high-grade and low/intermediate-grade DCIS was also found with later follow-up in the ECOG study, where 10-year IBTR rates were 19.0% and 14.6%, respectively (91). Taken together, these data suggest that high nuclear grade lesions have a higher rate of local recurrence initially, but with longer follow-up, the low-grade lesions eventually "catch up" to the rate of IBTR seen in the high-grade group, suggesting that the recurrences of low-grade DCIS are ultimately of similar frequency but are slower to manifest themselves.

Size of the DCIS lesion has been associated with a greater risk of in-breast recurrence in some series (87,89,90) but not in others (146). In a study from MDACC, the 5-year recurrence risk of 5.6% was seen for lesions ≥ 1.5 cm versus 2.2% for those under 1.5 cm in size, a difference that persisted on multivariate analysis (p = .013) (87).

Biomarkers

For women undergoing lumpectomy for DCIS, the ability to consistently stratify patients, using known clinical and histologic features to differentiate those whose risk of recurrence in the breast warrants adjuvant therapies, has remained elusive. The development of biomarkers may help better discriminate which patients' prognoses following lumpectomy warrant adjuvant radiotherapy and/or tamoxifen, and help prevent both under- and overtreatment that exists currently.

The utility of biomarkers in DCIS management has already been shown in the case of ER and PR receptors. In the NSABP B-24, only those DCIS cases with hormone receptor-positivity derived the benefit of reduced breast cancer events from tamoxifen use (62). A small study from the University of Toronto performed immunohistochemistry (IHC) staining for nine markers: ER, PR, Ki-67, p53, p21, cyclinD1, HER2/neu, calgranulin, and psoriasin on the specimens of 213 patients with DCIS treated with either lumpectomy alone (n = 141) or with breast radiotherapy (n = 72) (66). The rate of recurrence at 10 years (median follow-up, 7.7–8.7 years) was 36% for patients treated with lumpectomy alone and 18% for women who received adjuvant breast radiotherapy. HER2/neu overexpression was the only molecular marker associated with an increased risk of any local recurrence on univariate analysis (HR, 2.11; 95% CI, 1.21–3.68; p = .01). Ki-67 did not predict for local recurrence on univariate analysis; however, after adjustment for age and use of RT, individuals with HER2 positive/Ki-67 positive DCIS had a higher likelihood of developing local recurrence at 10 years: 39% (20/51) versus 18.5% (30/162) for cases without this profile (p = .0024) (66). Similarly, in the SEER/San Francisco Bay Area cohort of 1,162 DCIS cases treated with lumpectomy alone, IHC for ER, PR, Ki-67 antigen, p53, p16, epidermal growth factor receptor-2 (ERBB2, HER2/neu oncoprotein), and cyclooxygenase-2 (COX-2) was done. In a multivariable model, DCIS lesions that were p16 positive, COX-2 positive, Ki-67 positive or those detected by palpation were significantly more likely to develop subsequent ipsilateral invasive cancer recurrence (92).

Gene expression has been correlated with DCIS prognosis post lumpectomy and represents an important area of future investigation. ECOG investigators presented a "DCIS Score" subset of the 21 Gene Oncotype DX Recurrence Score for hormone receptor-invasive cancer. The DCIS Score, consisting of 12 genes, was able to stratify cases by risk of ipsilateral invasive recurrence on a subset of 327 cases or 49% of those enrolled in the ECOG 5194 single-arm observation post lumpectomy trial (91). Similarly, loss of retinoblastoma (RB) and phosphate and tensin homolog (PTEN) suppressor genes was strongly associated with ipsilateral invasive breast cancer recurrence in 236 patients with DCIS treated with lumpectomy alone (93).

There are numerous areas of promising investigation toward biomarker development for DCIS; however, so far, hormone receptor status is the only one validated for clinical practice.

Treatment Era

Variability in the outcome of DCIS can be seen by era of treatment, with improvement noted for those patients treated more recently. An analysis of a SEER database of 7,072 women at least 40 years of age with DCIS who were treated from 1978 to 1989 and had an 8.25-year median follow-up, revealed that among those diagnosed from 1978–1983, 1.5% died of breast cancer within 5 years and 3.4% within 10 years. In comparison, women diagnosed from 1984–1989 were less likely to die of breast cancer: 0.7% and 1.9% within 5 and 10 years, respectively (94). Results were similar for women 40 to 49 years of age, and those 50 years of age and older. Using a Cox proportional hazard model adjusted for age and race, the relative risk of death from breast cancer for women diagnosed with DCIS in the latter treatment era was 0.6 (95% CI, 0.4 to .0.8) compared with that for women diagnosed between 1978–1983. Women diagnosed from 1984 to 1989, but not those diagnosed earlier, were also less likely than women in the general population to die of all causes (10-year standardized mortality ratio, 0.8; 95% CI, 0.7–0.8).

The Cancer Research Network consortium of 14 health maintenance organizations demonstrated the effect of treatment era on ipsilateral breast recurrence in 2,995 women with DCIS treated between 1990 and 2001 (95). In this population, the treatment was lumpectomy alone in 42.5%, lumpectomy with breast radiotherapy in 42.4%, lumpectomy with tamoxifen in 4.4%, and lumpectomy with radiotherapy and tamoxifen in 11%. The 5-year risk of any breast cancer event (ipsilateral, contralateral, or regional/distant disease) decreased from 18.5% (95% CI, 13.6–23.5) for patients diagnosed in 1990–1991, to 11.0% (95% CI, 8.4–13.6) for patients diagnosed in 1998–1999. Among patients treated with lumpectomy alone (no radiotherapy or tamoxifen), the five-year risk of any second breast cancer was 20.8% (95% CI, 14.7–26.9) in 1990–1991, and 15.2% (95% CI, 10.0–20.4) in 1998–1999; and for the lumpectomy and radiotherapy cohort, it was 15.4% (95% CI, 6.1–24.7) and 11.2% (95% CI, 7.4–15.0), respectively, for the earlier and later time periods. Trends in the pathology features by treatment era were also seen. The proportion of patients with high nuclear-grade tumors decreased; in calendar years 1990–1991, 1995–1996, and 2000–2001, it was 46%, 28%, and 32%, respectively (p = .03). The proportion with involved surgical margins decreased over the years 1990–1991, 1995–1996, and 2000–2001 were 15%, 10%, and 0%, respectively (p = .03) (95). In a series from Memorial Sloan-Kettering Cancer Center, a multivariate analysis of 1,681 women treated from 1991 to 2006 with breast-conserving surgery, with or without radiation, showed that the time period of surgery was highly correlated with risk of IBTR, with the later years being associated with a 43% reduction in IBTR risk after controlling for 9 clinical, pathologic, and treatment factors (76). The observed improvements in outcomes over time are likely due to improvements in detection with mammographic screening, pathologic evaluation including discernment of margins for completeness of excision, and treatment.

ESTIMATING RISK OF LOCAL RECURRENCE

There are numerous factors associated with risk of local recurrence for a woman with DCIS undergoing breast conservation. The risk associated with a factor is generally expressed as a risk ratio, rather than as an absolute risk, making it difficult to estimate the absolute risk of local recurrence for an individual. Furthermore, because there are many factors that are associated with IBTR, it is difficult to combine several to arrive at an overall risk estimate for local recurrence for an individual patient. Therefore, there has been interest in combining them to allow such estimation. An individualized risk estimate can assist patients and clinicians in decision making regarding the various treatment options available.

Silverstein et al. (96) combined four factors into the Van Nuys Prognostic Index (VNPI). The risk factors included were high nuclear grade, narrow margins, necrosis, and larger size of lesion, based on the work of Lagios. Lagios had reported on 79 patients with mostly small (< 2.5 cm), mammographically detected DCIS treated by excision alone (72). Specimens were sequentially embedded in their entirety, with extent determined by three-dimensional reconstruction. The mean tumor size was 6.8 mm. After a mean follow-up of 135 months, the 15-year actuarial local recurrence rate was 22%. Silverstein developed the VNPI using retrospective data from 254 patients and was validated using Lagios's series of 79 patients (72). The populations were then combined for the published report, which showed no benefit for radiation in the low-risk subgroup, where the 8-year actuarial local failure rate was 3%, regardless of treatment with radiation (96).

A potential source of bias in the VNPI is that it was applied to the same population of patients in whom it was derived. Furthermore, these patients were treated over a long period of time, from 1972 to 1995, and those treated before 1989 generally received radiation, while those treated after 1989 generally did not receive radiation (86). As discussed above, IBTR rates are generally higher in earlier years as compared to later treatment eras, raising the possibility that other factors played a role in the low rate of recurrence seen in patients without radiation (97,98). In addition, the applicability of the classification system depends on the reproducibility of the individual components. Because the tissue processing performed by Silverstein et al. is not routinely used, comparable DCIS size and margin width measurements are not generally available.

Application of the VNPI to independent populations has validated its ability to separate patients into risk groups, but has not confirmed the finding that among the lowest risk group, the incidence of IBTR is extremely low (2% in Silverstein's report) (96,99).

The VNPI has subsequently been modified to include patient age (100). In a retrospective analysis of 538 patients treated with breast-conserving therapy, those with the lowest VNPI scores were not found to benefit from breast irradiation (100).

Silverstein et al. (82) has also suggested that any DCIS lesion, regardless of size or grade, that could be excised with a margin of 1 cm in all directions did not require RT or tamoxifen. This approach eliminates the problems of consistent size measurement and histologic grade that are inherent in the VNPI. In a retrospective review of 469 patients, Silverstein et al. (82) found no statistically significant decrease in 8-year local failure with the use of RT in patients whose tumors were excised to a margin width of 10 mm or greater (4% with RT, 3% without RT, $p = .92$).

Updated results of widely excised DCIS (>1 cm margins) are available from Macdonald et al. (74). Among 212 patients treated with excision alone, the 12-year probability of any breast recurrence was 14%, and the 12-year probability of an invasive recurrence was 3.4%. Among the 60 patients treated with excision and RT, there was only one recurrence (12-year local recurrence = 2.5%), and it was an invasive recurrence.

Boland et al. (101) applied the original VNPI (96) to a population of 237 patients who had undergone breast conservation with a median follow-up of 47 months. Sixteen percent received RT. They found that the VNPI stratified patients into low, intermediate, and high risk for IBTR ($p < .001$), but that the practical application of the VNPI was limited by the fact that most patients (78%) were categorized as intermediate risk. MacAusland et al. (102) retrospectively analyzed 222 patients treated with excision alone using the original VNPI classification (96), the age modified VNPI (100), and margin width of 1 cm or greater (82). With a median follow-up of 4.6 years, the crude rate of IBTR was 8.6%. At 5 years, IBTR rates were not statistically different for the low-, intermediate-, or high-risk groups using any of the three Van Nuys models. However, Di Saverio et al. (103) retrospectively applied the age-modified VNPI to 259 patients with a mean follow-up of 130 months, treated from 1976 to 2006. Most did not receive RT. Among the 186 patients who underwent surgery alone, the 10-year risk of local recurrence was lower for those with low VNPI (6%) as compared to those with intermediate or high VNPI (17%; $p < .05$).

In summary, the VNPI provides a method of risk stratification for women with DCIS treated with breast-conserving surgery. However, others have not been able to validate its ability to identify a subgroup at extremely low risk of IBTR who do not benefit from RT.

In an attempt to better provide individualized risk estimates for women with DCIS, Rudloff et al. (76) combined 10 clinical, pathologic, and treatment factors from 1,681 patients into a nomogram that estimates risk of IBTR at 5 and 10 years after breast-conserving surgery. Median follow-up was 5.6 years, with 294 women followed for at least 10 years. Internal validation with bootstrap resampling was performed (C-index, 0.704; bootstrap validated, 0.688). The model separated the population into octiles of 10-year local recurrence risk ranging from ~5% to ~35%. The model is available as an online tool, where the user can enter the values of all variables, and the result is given as a probability of local recurrence at 5 or 10 years. (http://nomograms.mskcc.org/Breast/DuctalCarcinomaInSituRecurrencePage.aspx)

Yi et al. applied this nomogram to an independent population of 734 women with median follow-up of 7.1 years, with 206 women followed for at least 10 years (104). They also divided their smaller population into octiles of risk and found that the observed 10-year local recurrence rates were well-approximated by the nomogram risk estimates. Discrimination, as assessed by the C-index, was 0.654. Using a case-control analysis, Collins et al. reported that application of the nomogram to their large population-based cohort of DCIS resulted in highly accurate prediction of 5-year risk (105). Recently, Sweldens et al. applied the DCIS nomogram to a Belgian population of 467 women with a median follow-up of 7.2 years. Nearly all received radiation. Calibration was accurate, and the C-index was 0.67 for cases with complete data (106). Together, these studies show that the DCIS nomogram can risk stratify for local recurrence of DCIS in diverse patient populations.

Many investigators have sought molecular markers that would allow risk stratification for DCIS, both for local recurrence and for prediction of progression to invasion. Recently, Solin et al. reported the development of a multi-gene assay that estimates 10-year risk of local recurrence after excision alone (91). This assay was applied to 327 patients with DCIS treated with excision alone from the ECOG E5194 study (46), and it was able to stratify women into three 10-year local

recurrence risk groups: low (12%; 95% CI, 8–18%), intermediate (25%; 95% CI, 14–41%) and high risk (27%; 95% CI, 15–46%). Unfortunately, this assay was unable to identify a group of women with very low (< 9%) risk of IBTR, even within this especially favorable population, and the risk of IBTR was virtually identical between the intermediate- and high-risk groups. Furthermore, there is no evidence to date that this assay is predictive of benefit from RT; i.e., that it is able to identify those who would or would not benefit from use of RT.

These methods of risk estimation hold promise in assisting patients in the decision making regarding various treatment options for DCIS. Prediction of invasive recurrence and development of a molecular marker predictive of benefit from radiation remain future goals of the research community.

TREATMENT SELECTION IN DUCTAL CARCINOMA *IN SITU*

The available information on DCIS suggests that many are candidates for treatment with excision and irradiation, and a smaller group may be appropriately treated with excision alone. Mastectomy is indicated for extensive DCIS not amenable to a conservative approach. The initial step in treatment selection is to determine, on the basis of the history and physical examination, imaging, and pathologic findings, whether the patient is a candidate for a breast-conserving approach. If so, the risks and benefits, and what is entailed in breast-conserving surgery with or without radiation as well as mastectomy (including reconstruction), should be described in detail. The risk of local recurrence, particularly an invasive recurrence, is a major focus of this discussion because regardless of the type of local therapy selected, the risk of breast cancer–specific mortality is extremely low. Guidelines for the selection of local therapy in DCIS have been developed by a joint committee of the American College of Surgeons, American College of Radiology, and the College of American Pathologists (107).

Absolute indications for mastectomy include multicentric DCIS or diffuse, malignant-appearing microcalcifications covering an area too large to encompass with a cosmetic resection. The persistence of tumor at resection margins after a reasonable number of surgical attempts is also an indication for mastectomy. Although DCIS lesions are generally not clinically detectable, they may be quite extensive.

Most patients who require mastectomy can be identified before surgery with a careful imaging evaluation to determine the extent of the lesion. Holland et al. (108) have reported that the extent of poorly differentiated DCIS assessed by microscopy correlated well with the extent of the lesion evaluated radiologically, but the mammographic appearance of well-differentiated DCIS substantially underestimated the microscopic extent. However, the routine use of magnification views as part of the mammographic evaluation allowed the detection of additional calcifications that reduced the discrepancy between the pathologically and mammographically determined extent of well-differentiated DCIS.

While magnetic resonance imaging (MRI) has been increasingly used in the patient with DCIS, its benefit has yet to be defined. While some studies have found that MRI is more sensitive in the detection of DCIS than is mammography (19,20), improved outcomes have not been demonstrated, and increases in additional biopsies and mastectomy rates have been found in retrospective studies (109–111).

A retrospective study evaluated preoperative MRI in 352 women whose DCIS was diagnosed by core needle biopsy from 2008 to 2010 (109). All cases had preoperative mammogram, and 217 underwent MRI. Women who underwent MRI were younger, and more likely to be pre/perimenopausal, have dense breasts, present with a clinical abnormality, have microinvasion or suspicion for microinvasion on core biopsy, and undergo sentinel lymph node biopsy. The rate of additional biopsy was significantly higher in the MRI group; 38.3% underwent a second biopsy, and 18% underwent three or more additional biopsies, compared with 6.7% and 2.2%, respectively ($p < .0001$), in the mammography group. Overall, mastectomy was more common in the MRI group (37%) as compared to the mammography group (28%) ($p = .06$). No multivariate analysis was reported, and interpretation of retrospective studies such as this are limited by the inherent differences in the MRI and no-MRI groups. Other retrospective studies that suffer from the same potential confounding have also reported higher mastectomy rates for DCIS when preoperative MRI was used (110,111). In contrast to these studies, Allen et al. retrospectively examined 98 patients with DCIS, 63 of whom underwent MRI after diagnosis with core needle biopsy (112). Patients in the MRI group had mastectomy rates similar to the patients in the no-MRI group (20.3% vs. 25.7%; $p = .62$).

Two prospective randomized studies of the addition of MRI to preoperative screening failed to show a decrease in re-excision rates in women with DCIS and invasive carcinoma (113,114). In the COMICE trial, the re-excision rate of 19% was identical with or without MRI (113). In the MONET trial, the re-excision rate in the preoperative MRI arm was 34%, paradoxically higher than that in the control arm (114). Of the 23 additional surgeries required in the MRI group, most (n = 14) were in patients with DCIS. This suggests that especially among women with DCIS, MRI underestimated extent of disease.

Most importantly, there is no evidence of decreased recurrence rates in patients undergoing breast-conserving therapy and perioperative MRI. In a retrospective study of the utility of MRI, 136 women with DCIS were treated with breast-conserving surgery and RT, and the incidence of local recurrence was compared (115). In the subset of 31 women with DCIS who had an MRI, the 8-year incidence of local recurrence was 6%, identical to that of the 105 women with DCIS who did not undergo MRI. Pilewskie et al. (116) examined the association of MRI with local recurrence in a population of 2,255 women with DCIS treated with breast-conserving surgery with or without RT. On multivariate analysis controlling for 8 clinical and pathologic characteristics, the use of MRI did not affect the rate of IBTR at 8 years ($p = .48$), even in the subset that did not receive RT ($p = .32$). Therefore, at present, MRI cannot be considered part of the routine preoperative evaluation of the woman with DCIS.

Radiologic localization should be used to guide the surgical excision; if the calcifications are extensive, bracketing is useful to aid in complete excision. Specimen mammography is essential to confirm the excision of calcifications. Postexcision mammogram is useful to document the removal of all suspicious calcifications. Even when the margins of excision are negative, postexcision mammography can demonstrate residual calcifications indicative of the need for further resection. In most patients, a postexcision mammogram can be obtained within 2 to 4 weeks after surgery.

For the woman who appears to have mammographically localized DCIS and is a candidate for breast conservation, a decision regarding the magnitude of benefit that will be obtained from RT cannot be made until the lesion has been excised and a pathology report is available. To facilitate decision making, a detailed pathologic evaluation is necessary. The evaluation should include inking of the specimen and measurement of both specimen and tumor size (if there is a gross lesion) before sectioning. Because accurate measurement of microscopic DCIS is often difficult, reporting the

number of blocks in which DCIS is present and the number of blocks examined, as well as its largest single extent in any one slide, is often useful. The correlation of microcalcifications with DCIS (i.e., whether calcifications are present in the DCIS or in adjacent breast tissue) as well as the margin status should be noted. If margins are involved, the extent of involvement should be stated; when margins are negative, proximity of the lesion to the margin should be noted. The nomogram discussed previously is available online to easily calculate individualized risk estimates to assist in decision making (76).

The authors approach patients before surgery with the assumption that breast irradiation will be a part of their treatment if they choose breast-conserving therapy. Contraindications to RT, as for invasive cancer, include prior therapeutic irradiation to the ipsilateral breast, diagnosis early in pregnancy, and active scleroderma or systemic lupus erythematous. Large areas of DCIS that cannot be excised to clearly negative margins with an acceptable cosmetic outcome should prompt a discussion of mastectomy. An adequate excision is of particular concern in patients younger than 40 years of age with high-grade, ER negative DCIS because of their higher baseline risk of recurrence. In patients who are candidates for breast irradiation, the final decision about the risks and benefits of RT and tamoxifen in an individual case is made when the final pathology report is available. Although it is clear that there are some patients who receive a small absolute benefit from either irradiation or tamoxifen, the final decision regarding the use of RT and tamoxifen is heavily influenced by the patient's perception of what level of benefit is meaningful to her. The ability to treat local recurrence with further breast preservation using re-excision and RT is one of the potential benefits of initial treatment with excision alone. However, local recurrence is psychologically traumatic, and only 44% of patients who had recurrence after initial treatment by excision alone in the NSABP B-17 trial chose breast-conserving surgery again (39). Furthermore, approximately 50% of recurrences are invasive and carry a risk of distant metastasis (2). To date, no clinical or molecular characteristics have been identified that reliably predict a minimal benefit from RT.

The use of sentinel node biopsy is reserved for patients undergoing mastectomy. If a pre-surgical diagnosis of DCIS is made by percutaneous core needle biopsy, invasive carcinoma is found in approximately 20% of cases at the time of surgical excision (117). Invasion is more frequent in large areas of DCIS, and the performance of a mastectomy precludes subsequent sentinel node biopsy. In patients undergoing breast conservation, sentinel node biopsy can be selectively applied to the subset of women found to have invasive carcinoma after surgical excision.

In summary, the term DCIS encompasses a heterogeneous group of lesions of varying malignant potential. In the future, advances in research may allow researchers to reliably identify those lesions that have the propensity to recur locally as invasive cancer and those that will display the metastatic phenotype. Until this goal is reached, therapy must be directed toward minimizing the risk of local recurrence while maintaining quality of life. The appropriate therapeutic strategy will vary based on both patient and disease characteristics, as well as patient preferences.

MICROINVASIVE BREAST CANCER

The widespread adoption of breast cancer screening with mammogram has increased the detection rate of microinvasive breast cancer as well as DCIS. Microinvasive breast carcinoma is defined as invasive carcinoma of the breast with no single invasive focus (multiple foci may be present) measuring more than 1 mm (118). It is almost always encountered in the setting of ductal carcinoma *in situ* (DCIS); and much less commonly with LCIS. A frequently encountered problem in examination of histological specimens is identifying a small focus or foci of invasive carcinoma, or microinvasion (119). Microinvasion can be overdiagnosed because of misinterpretation of the pattern of DCIS or the presence of artifacts. Examples of pathology entities that can make interpreting microinvasion challenging include: DCIS involving lobules (lobular cancerization) or benign complex sclerosing lesions, such as a radial scar; associated chronic inflammatory reaction that obscures involved ducts and acini; branching of ducts; fibrosis from prior needle biopsy distorting ducts; crush artifacts; and cautery effects (119). Similarly, microinvasion can be underdiagnosed as a result of tissue sampling.

The presence of myoepithelial cells around nests of carcinoma cells defines the process as being *in situ*. IHC for myoepithelial cells has been used to help determine whether a process represents *in situ* carcinoma or stromal invasion. A variety of markers have been used to detect myoepithelial cells; the most commonly used antibodies are smooth-muscle myosin heavy chain (SMM-HC) and calponin. Optimal specificity and sensitivity for detection of myoepithelial cells can be achieved when the SMM-HC marker is used in conjunction with the more sensitive but less specific marker, calponin (120). Serial sectioning of the specimen supported by IHC staining for the presence of myoepithelial cells provides the best method for diagnosis of microinvasion.

Different definitions of microinvasion have existed in the past contributing to inconsistent reporting of its incidence. The diagnostic dilemma that arises from an inconsistent definition of microinvasion is illustrated in the study by

Padmore et al. of 59 cases of microinvasion diagnosed from 1982 to 1992 at Fox Chase Cancer Center that underwent secondary pathology review. On re-review, the microinvasion was reclassified as pure DCIS in 16 cases, equivocal microinvasion in 7, microinvasive in 11, and T1a-c (i.e., invasive cancer > 1 mm in size) in 25. The fifth edition of the American Joint Committee on Cancer (AJCC) Cancer Staging Manual, published in 1997, is the first one that recognized a specific T category for microinvasive breast cancer, defined as "the extension of cancer cells beyond the basement membrane into the adjacent tissues with no focus more than 0.1 cm in greatest dimension" and formally classified it as pT1mic. With this definition, the estimated overall incidence is less than 1% (119,121,122). Microinvasion has been noted to be more frequently associated with DCIS that is more than 2.1 to 2.5 cm in size (122,123), or high grade (123–125), and with the presence of comedo necrosis (123,126). The likelihood of hormone receptor positivity and HER2 overexpression is mostly unknown for microinvasive breast cancer, as the information is often incomplete in the studies reporting and/or there was insufficient material for analysis (126,127,144). However, a higher frequency of HER2 overexpression in microinvasive breast cancer has been reported in one study (128).

As illustrated in Table 23-11, the rate of sentinel node involvement can be as high as 13% for cases with microinvasion on core biopsy. However, the rate of macrometastases is low in this population: 0% to 5%. Micrometastases and isolated tumor cells (ITC) are found with similar frequency. When microinvasion is present with DCIS on core biopsy, there is a general agreement that due to the significant rate of sentinel node findings and the absence of final histologic analysis from complete surgical resection, that sentinel lymph node biopsy is a recommended procedure.

The favorable prognosis of microinvasive breast cancer as defined by the AJCC is seen in Table 23-12. In these studies, at 3 to 9 years median follow-up after treatment, there were 0% to 8.3% local recurrences, 0% to 2.7% distant metastases, and 95.7% to 100% overall survival. For patients treated with breast-conservation therapy, cumulative incidences of local recurrence at 5 and 10 years of 4.2% and 8.3%, respectively, have been reported (126,127). Margalit et al. from the Harvard Oncology program reported that close/positive DCIS margins (compared to negative margins) with both breast-conserving therapy and mastectomy were significantly associated with an increased risk of local recurrence (hazard ratio [HR], 8.8; 95% CI, 1.6–48.8; $p = .003$) (126). Yale University investigators retrospectively compared the outcome in 373 DCIS to 72 microinvasive cases treated during the same time period and found similar 10-year local recurrence rates: 6.8% with DCIS and 8.3% with microinvasion experienced a local relapse, for a 10-year local recurrence-free survival rate of 89.0% and 90.7%, respectively (127). Overall, this supports the belief that the prognosis for microinvasive breast cancer is intermediate—better than that of small invasive breast cancer and approaching what is seen with DCIS.

MANAGEMENT SUMMARY

- DCIS is a heterogeneous disease with varying potential for progression to invasive cancer.
- Pathologic or molecular factors that reliably predict for an individual woman's risk of progression to invasive cancer after excision of DCIS have not been identified.
- Appropriate treatment options for DCIS are primarily determined by the extent of disease in the breast relative to the size of the breast.
- A detailed mammographic evaluation of the extent of DCIS is essential for treatment planning. The role of MRI is uncertain.
- Total mastectomy results in excellent local control with local failures of approximately 1% to 2% and breast cancer-specific survival of ≥ 98% for patients with DCIS.
- Patients with localized DCIS are candidates for treatment with excision.
- RT reduces the rate of local recurrence by approximately 50%. Subsets of DCIS patients for whom RT does not reduce the local recurrence rate have not been reproducibly identified.
- Excision and RT in suitable candidates results in 10-year local failure rates of 7% to 13% when treated in the more modern screening era with careful mammographic and pathologic evaluation.

- In highly selected patients with favorable or lower-risk features, excision alone for DCIS results in local recurrence rates of 10% to 15% at 7 to 8 years, which may be an acceptable outcome to a patient depending on her individual and clinical circumstances.
- Breast cancer-specific survival after excision with or without RT is ≥ 96%, numerically similar to what is reported from mastectomy series.
- Negative margins are associated with a lower risk of local recurrence than positive margins (ink on DCIS). "Close" margins have been variably defined, but are associated with higher risk of local recurrence than "negative" margins on meta-analysis. For women undergoing RT, evidence is lacking to show a lower local recurrence rate is associated with margin widths larger than 2 mm. However, a specific margin width that optimizes local control for those who do or do not receive RT has not been identified.
- Local recurrence rates after excision with or without RT have decreased over time, probably due to improvements in imaging and pathologic analysis.
- Patients should be included in the treatment decision making to learn what magnitude of risk reduction is meaningful to them; particularly for DCIS with clinical and pathologic features associated with a small absolute benefit from adjuvant radiotherapy or tamoxifen postexcision.
- Biomarkers, in addition to hormone receptors, for both prognosis and prediction of adjuvant treatment response are under investigation, but none are yet ready for routine clinical use.
- Tamoxifen benefits ER positive DCIS. The combination of tamoxifen and RT maximizes local control in ER positive DCIS post lumpectomy and reduces the number of new contralateral breast cancers.
- Sentinel lymph node biopsy is not routinely indicated in DCIS. In women undergoing mastectomy for extensive DCIS, a sentinel lymph node biopsy obviates the need for axillary dissection if invasion is found and is recommended.
- Nodal metastases are present in 4% to 7% of patients with microinvasive carcinoma, and sentinel lymph node biopsy is indicated when the results will influence subsequent treatment.
- A detailed discussion of the pros and cons of the various treatment options is needed to allow each woman with DCIS to make an informed treatment choice.
