SECTION VI

Pathology and Biological Markers of Invasive Breast Cancer

CHAPTER 24

Genomic Events in Breast Cancer Progression

Rodrigo Goncalves, Burcu Cakar, Ron Bose,
Cynthia X. Ma, and Matthew J. Ellis

CHAPTER CONTENTS

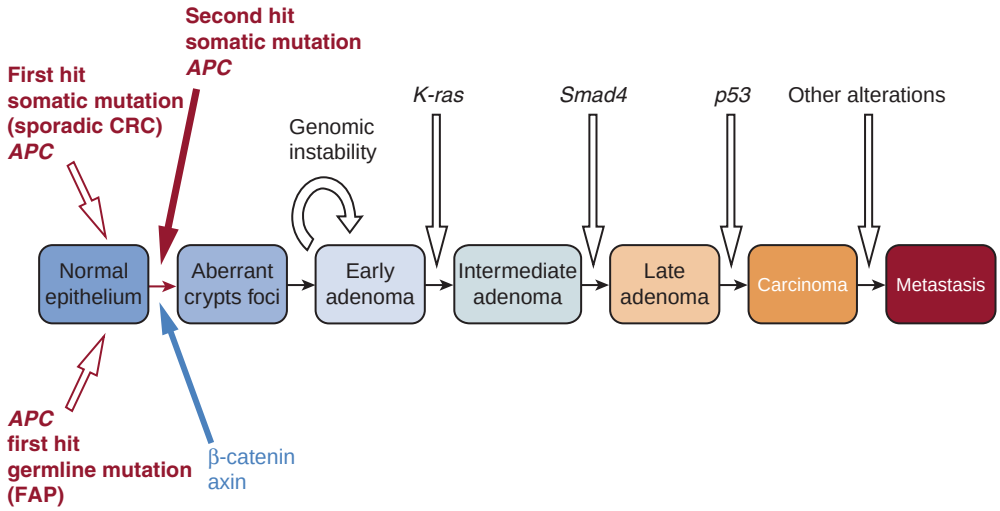
INTRODUCTION

Breast cancers are thought usually to develop from regions of cellular atypia into clinically evident preinvasive or invasive lesions with subsequent evolution of lethal features such as metastatic spead and therapeutic resistance. Biological and statistical models that guide our thinking about breast cancer genomic progression events that underlie this process include linear, stepwise models, such as those proposed by Vogelstein and coworkers for colon cancer (Fig. 24-1A) and branched, Darwinian evolutionary models, such as that proposed by Nowell, where there is no fixed order of events or steps (Fig. 24-1B) (1,2). The recent application of next-generation sequencing technology has uncovered immense genomic complexity but has mostly focused on a single time point—the breast cancer genome at diagnosis. Longitudinal studies of individual cancer genomes over time will ultimately be required to completely characterize the genomics of breast cancer progression and are now possible as massively parallel sequencing platforms become more accessible. In this chapter, we will describe the theoretical basis for breast cancer evolution, from the earliest stages to advanced disease. We will review what is known about the dynamic structural changes in the genome that underlie the disease.

NEXT-GENERATION DNA SEQUENCING

The revolution in DNA sequencing technology, with the development of next-generation sequencing instruments, has provided a wealth of new data on the genomic evolution of cancer, and it is worthwhile beginning our discussion with an overview of this technology as many of the discussions in this chapter rely on data derived from these "massively parallel sequencing" (MPS) approaches. The development and commercialization of next-generation DNA sequencing instruments began around 2006 and has made DNA sequencing thousands of times faster and considerably cheaper. With this technological advance, projects to sequence large numbers of cancer genomes became feasible. Here, we will mostly focus on an MPS process called "sequencing-by-synthesis," as most data sets have used Illumina-based technology. The steps in this process involve generating a DNA library from the sample of interest (Fig. 24-2A) and attaching individual DNA molecules to a glass slide called a flow cell. The individual sequences are then amplified into "clusters" to increase signal intensity (Fig. 24-2B). A sequencing reaction is then performed whereby a different colored fluorophor is activated when each of the four different nucleotides are added to the DNA polymer (Fig. 24-2C) (3,4). These sequential light reactions are captured by a sensitive light detector and the sequences entered into programs that align the sequences to the reference human genome. The process is remarkably efficient, and sequencing throughput is advancing rapidly. Currently more than 100 billion base pairs (Gigabases, Gb) can be generated per instrument run. Other methodologies and companies for next-generation DNA sequencing include the SOLiD system developed by Applied Biosystems, and single-molecule DNA sequencers, which are still under development (3).

A key advantage of the MPS approach is that the analysis begins with an individual DNA molecule. This is fundamentally different than the original Sanger DNA sequencing method, developed over 35 years ago, which averages sequences across millions of DNA molecules and, as a



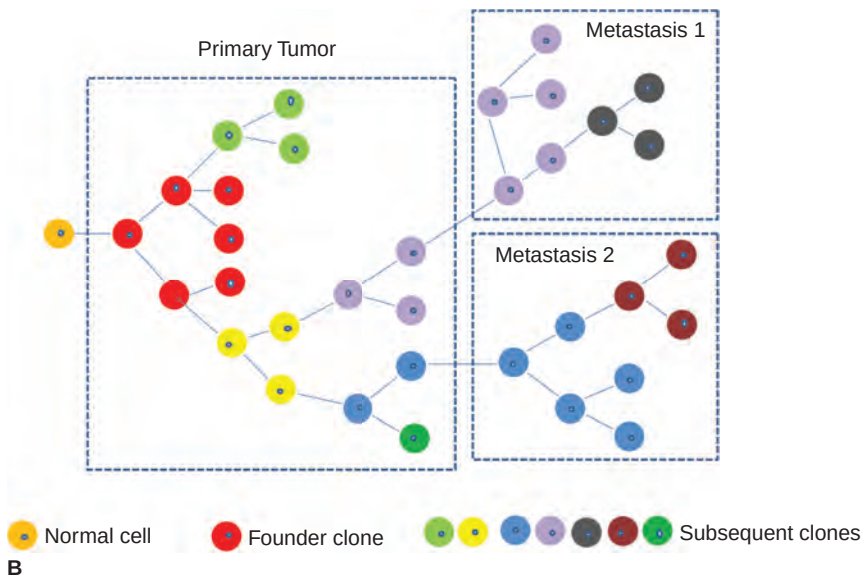


FIGURE 24-1 **(A)** The development of cancer through sequential steps. This model proposes that colon cancers develop from aberrant foci (atypia) and adenomas in a stepwise process. (From Pinto D, Clevers H. Wnt, stem cells and cancer in the intestine. *Biol Cell* 2005;97:185–196.) **(B)** Evolutionary models of cancer with the development of subclones.

result, has limited ability to distinguish variations in DNA sequences. Because MPS provides data on the frequency of a DNA mutation within a population, tumor clonality or heterogenity can be inferred from the variant allele frequency, and this provides new means for studying the clonal progression of cancer. Rare alleles can be detected down to a frequency of between 0.1% and 1% depending on the depth of the sequencing instrument and the fidelity of the enzymes used to generate the original clusters on the flow cell.

Much of the sequencing funded by the National Cancer Institute has focused on the initial diagnostic sample from invasive cancers through The Cancer Genome Atlas Project, with the goal to catalogue all the somatic mutations and structual abnoramlities in breast cancer (5). The application of this approach in the study of breast cancer is still in its infancy. Our current understanding of the genomic alterations that promote preinvasive to invasive breast cancer is still largely based on comparative genomic hybridization (CGH) techniques, loss of heterozygosity (LOH) analysis, gene expression profiling, and selective gene sequencing studies that have been applied to synchronous preinvasive and invasive breast cancers.

GENOMIC MODELS OF BREAST CANCER PROGRESSION

To understand breast cancer progression, a description of the anatomy of the breast and the histology of preinvasive versus invasive breast cancer is required; the reader is guided to Chapters 1, 9, 21, and 25 which deal with these issues in depth. In brief, several models have been proposed to describe the development of breast cancer that focus on the relationship between preinvasive and invasive breast cancers. The most

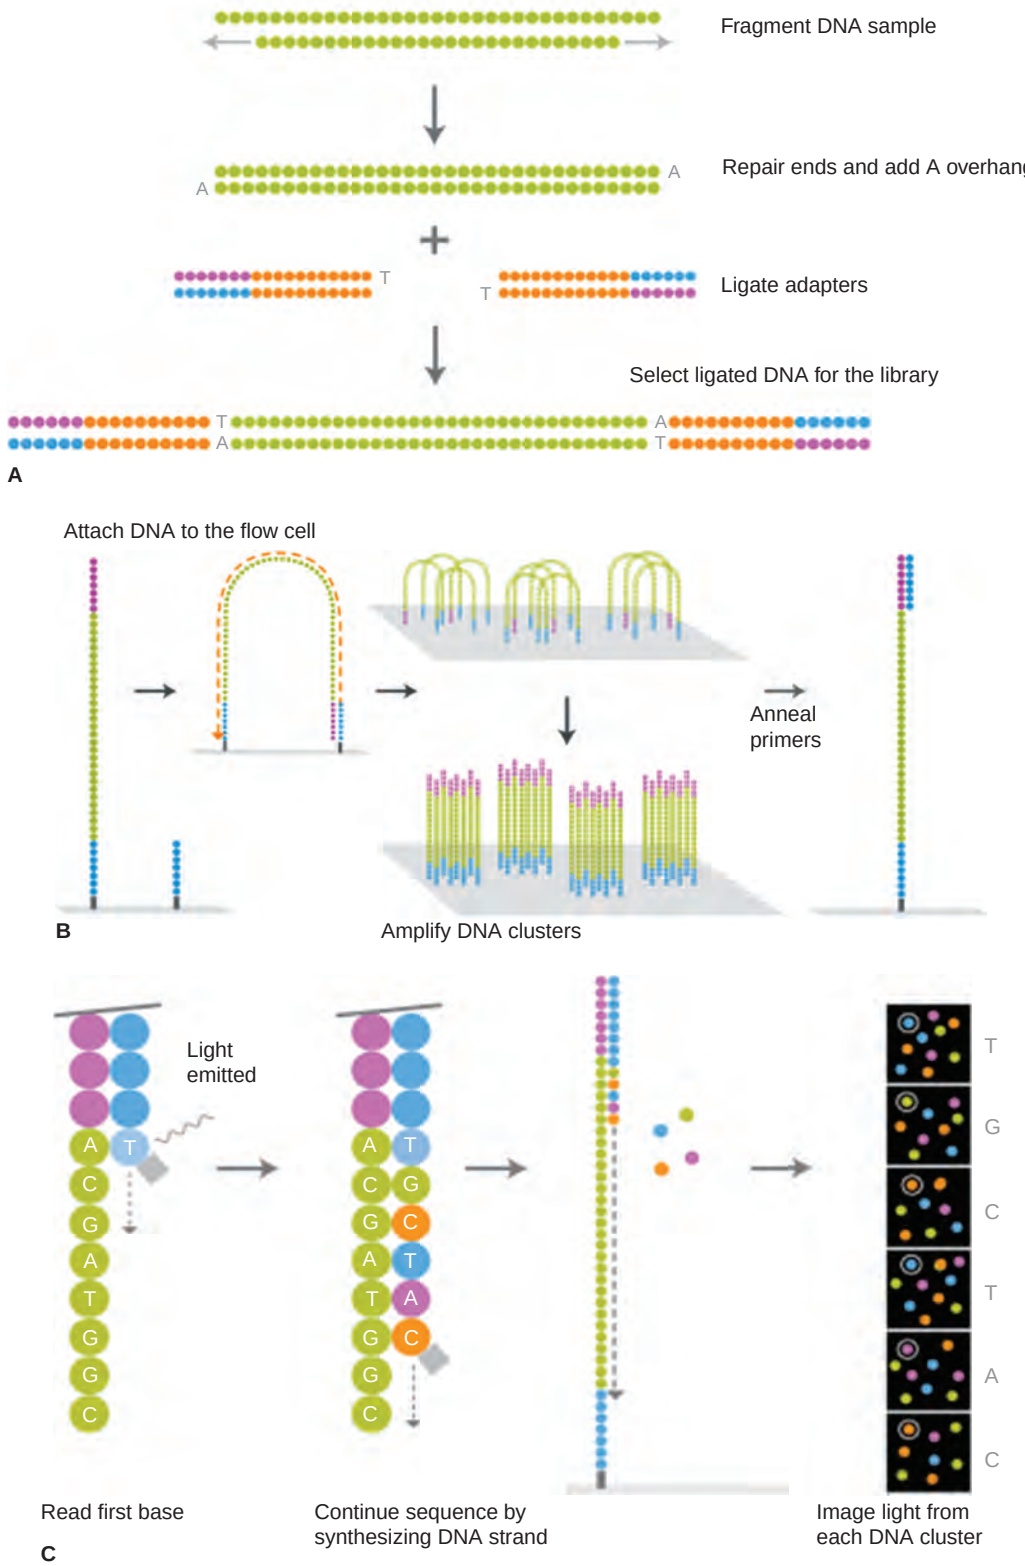

FIGURE 24-2 Next-generation DNA sequencing on the Illumina sequencing instruments. **(A)** DNA Sample preparation to create the library for sequencing. **(B)** Attaching the DNA to the surface of the flow cell and generating clusters of identical DNA molecules for sequencing. **(C)** Sequencing by synthesis. Each round attaches a DNA nucleotide to the DNA molecule and releases light, which is detected by a very sensitive camera. (From Ansourge WJ. Next-generation DNA sequencing techniques. *New Biotechnol* 2009;25(4):195–203.)

widely accepted "linear" multistep model suggests a transition from normal epithelium to invasive breast cancer via non-atypical and atypical hyperplasia and *in situ* carcinoma through accumulation of genetic mutations (6). In this classic Wellings model, premalignant breast lesions arise from terminal ductal lobular units (TDLUs) and give rise to flat epithelial ayplasia (FEA), atypical ductal hyperplasia (ADH), and ductal carcinoma in situ (DCIS), which subsequently progresses, over a long period of time, to invasive ductal carcinoma (IDC), whereas atypical lobular hyperplasia (ALH) and lobular carcinoma in situ (LCIS) progress to invasive lobular cancer (ILC) (Fig. 24-3) (7). This theory was originally based on the histologic observation of the gradual histologic continuity, but it also has been supported by analyses of genetic alterations that compared preinvasive and invasive breast cancers, especially when they occur in the same breast (8–11). Subsequent findings introduced the concept of usual ductal hyperplasia (UDH), in which cells pile up to fill the terminal duct (TD) and acini compared to the single or minimally pseudostratified layer of cells in FEA that distends the TDLU, as the direct precursor to ADH (12,13). However, UDH as the precursor for ADH has not been supported by recent immunohistochemical and molecular evidence. The LOH pattern observed in UDH is notably different from that associated with ADH and DCIS (8,14–18). This linear model of breast cancer progression provided the rationale for detection methods such as mammography in the hope of diagnosing and treating breast cancer at earlier and preinvasive stages before lethal features of the disease have developed (19). However, the occurrence of a preinvasive lesion is probably not an obligatory event in the development of invasive breast cancer. Although many premalignant lesions progress through the lifespan of some

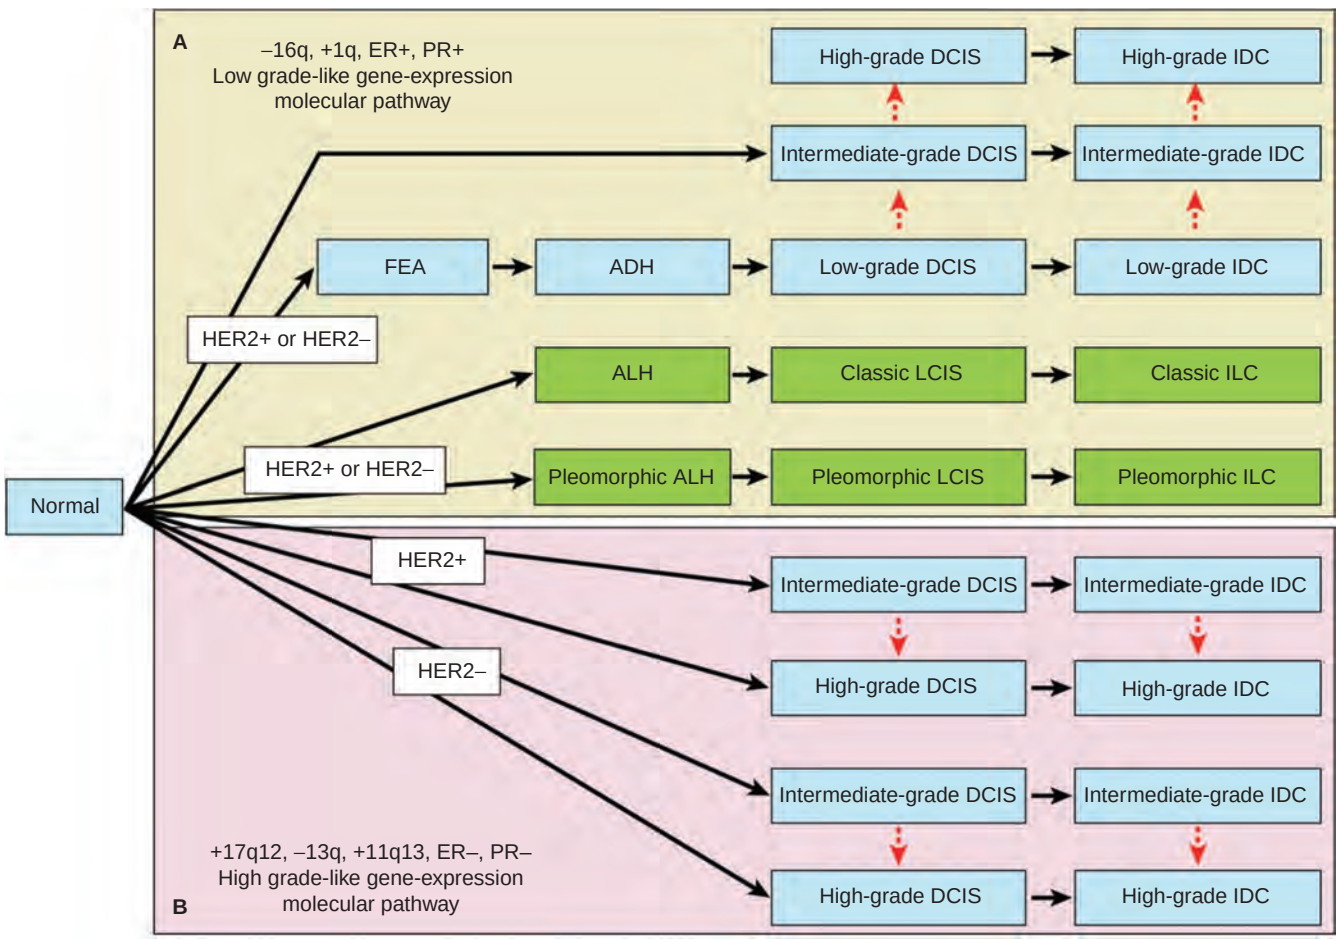

FIGURE 24-3 Multistep human breast cancer progression model. The low grade–like gene-expression molecular pathway is characterized by chromosome 16q loss, predominant ER and PR expression, and a low-grade gene expression profile populated with genes associated with ER positivity. **(A)** This low-grade pathway is observed in preinvasive lesions of both ductal and lobular subtype. **(B)** The high grade–like gene-expression molecular pathway is characterized by loss of chromosome 13q; gain of 11q13 and/or amplification of 17q12; infrequent expression of ER and PR; and a high-grade gene expression signature populated with genes associated with cell cycle, centrosomal function, and DNA repair. Pleomorphic atypical ductal hyperplasia (ALH), pleomorphic lobular carcinoma in situ (LCIS), and pleomorphic invasive lobular carcinoma (ILC) phenotypically resemble high-grade tumors, and immunohistochemical (ER positivity) and genetic data (16q loss and 1q gain) support an evolutionary association with the low grade–like gene expression molecular pathway. (From Sgroi DC. Preinvasive breast cancer. *Annu Rev Pathol* 2010;5:193–221.)

patients, others might stay stable throughout their lives; it remains unclear which lesions have the capacity to progress to invasive cancer. The "nonlinear" or "branched" model builds upon the "linear" model in that it agrees that DCIS is the precurser for IDC, but hypothesizes that different grades of DCIS progress to corresponding grades of IDC. In contrast, the "parallel" model hypothesizes that DCIS and IDC are parallel and independent developments from a common progenitor cell through different grades (20). This is supported by the investigation of gene copy number changes in synchronous DCIS and IDC lesions, which demonstrated changes that are specific to DCIS or IDC (21).

GENOMIC ALTERATIONS SUPPORTING PREINVASIVE LESIONS AS PRECURSORS OF INVASIVE BREAST CANCER

The molecular differences among the preinvasive and invasive breast cancers are largely unknown but have been an area of great research interest with the hope to identify the key events that drive the development and progression of invasive breast cancer. The pathological heterogeneity and the microscopic size of the preinvasive lesions have posed a practical challenge in isolating sufficient material that is devoid of contaminating tissues. The availability of laser capture microdissection (LCM) and genome-wide analysis tools provide a new opportunity to discover genetic events specifically activated or inactivated in the course of breast cancer development.

LOH and CGH Studies

Multiple studies indicate that genetic alterations that confer the potential for invasive growth already exist in the earliest phenotypically recognized preinvasive stages. Initial studies of the genetic evolution of breast cancer progression used relatively insensitive loss of heterozygosity (LOH)/comparative genomic hybridization (CGH) techniques (8,10,22,23). For example, O'Connell et al. studied 399 microdissected preinvasive lesions (211 UDH, 51 ADH, 81 noncomedo DCIS, and 56 comedo DCIS) for LOH at 15 polymorphic genetic loci known to exhibit high rates of loss in invasive breast cancer (IBC) and assessed the sharing of LOH between synchronous preinvasive and invasive cancers. For breast samples without DCIS and IBC, 37% of UDH and 42% of ADH lesions showed LOH in at least one locus, although loss at any given locus was uncommon (range, 0%–15%), suggesting that the development of hyperplasias can involve many different genes. In breast samples without IBC, LOH was common in DCIS, with 70% of noncomedo lesions and 79% of comedo lesions showing at least one loss with up to 37% of samples harboring LOH on chromosomes 16q, 17p, and 17q. When DCIS lesions from breasts with or without IBC were compared, substantially more LOH was observed in the breast with IBC at a few loci (on chromosomes 2p, 11p, and 17q), suggesting that genetic alterations in these regions may be important in the progression of DCIS to invasive disease. Among specimens harvested from breasts with IBC, 37% of concurrent UDH, 45% of ADH, 77% of noncomedo DCIS, and 80% of comedo DCIS lesions shared LOH with synchronous cancers at one locus or more. Similarly, in another CGH study performed on a panel of breast tumors that included 10 DCIS, 18 IBC, and two lymph node metastasis, there was an overall trend toward an increase in the number of genetic gains and losses in the IBC (24). In a study of 41 cases of sporadic breast cancer that focused on LOH of chromosome 11q13, LOH on chromosome 11q13 was present in 24 of 36 (67%) of the informative invasive breast cancer cases. The identical allelic loss was shared in the microdissected DCIS and the corresponding invasive breast cancer in 71% (15 of 21) of the available cases (23). Moelans et al. analyzed 21 genes including transcription factors and thyrosine kinases in DCIS and adjacent IDC (25) and found that there were no copy number differences between them. These studies provided molecular genetic support for the notion that invasive breast cancer arises from preinvasive lesions and that DCIS is genetically as advanced as IDC and the driving genetic events already occurred at the preinvasive stage. This conclusion is thus somewhat paradoxical because DCIS is a benign disorder and invasive disease is not. We therefore still do not have a clear idea of the genomic determinants of the DCIS to invasive transition, which is a clear impetus for more detailed studies using MPS.

Expression Profiling

The molecular similarity between preinvasive lesions and invasive breast cancer has also been observed at the level of gene expression. Using LCM, T-7 based RNA amplification and DNA microarrays analysis, Ma et al. compared the gene expression profile of normal TDLU epithelium and synchronous ADH, DCIS, or IDC in a study of 36 breast cancer specimens (26). Compared to patient-matched normal epithelial cells, significant alterations in global gene expression occurred at ADH, which persisted in the later stages of DCIS and IDC. There were extensive similarities at the transcriptome level among the paired ADH, DCIS, and IDC without any consistent gene expression unique to each of the three identities. These observations were consistent with an earlier study of global gene expression profiles using serial analysis of gene expression (SAGE), although performed on a limited cohort of normal mammary epithelial cells, DCIS, IDC, and metastatic disease (27).

Similar to IBC, DCIS exhibits significant histologic and biological diversity between different cases. Under microarray gene expression analysis, intrinsic subtypes originally described for IBC have also been observed in DCIS (28–30). In a recent immunohistochemistry (IHC) analysis of a tissue microarray composed with 188 cases of pure DCIS (31), a frequency of 38.3% for Luminal A (ER+/PR+/HER2–), 6.9% Luminal B (ER+ and PR– and/or HER 2+), 14.9% HER2 (ER–/PR–/HER2+), 7.5% TN (ER–/PR–/HER2–) and 4.2% basal-like (ER–/PR–/HER2–/CK5/6 and/or EGFR+) was observed according to IHC criteria of intrinsic subtypes (32). These studies indicated that the molecular heterogeneity of IBC is reflected at the stage of DCIS, and DCIS may be classified in a manner similar to invasive breast cancer.

GENETIC ALTERATIONS INDICATING DISTINCT GENOMIC PATHWAYS ASSOCIATED WITH LOW- AND HIGH-GRADE BREAST CANCERS

In gene expression profiling studies of synchronous DCIS and IDC lesions, the greatest alterations were among the different histological grades of DCIS and IDC (26). Notably, the grade I and grade III tumors demonstrated reciprocal gene expression patterns, whereas grade II tumors exhibited a hybrid pattern of grade I and grade III signatures. ADH samples demonstrated a grade I gene expression signature and clustered with the low-grade DCIS and IDC. Similarly, several comparative genomic hybridization studies revealed that the low-grade and high-grade DCIS have distinct gains and losses of genetic material. In the CGH study by Buerger et al. on 38 DCIS and 6 associated invasive breast cancers,

TABLE 24-1

Chromosomal Aberrations of DCIS and IDC

Low-grade DCIS	Intermediate-grade DCIS	High-grade DCIS
16 q loss	1 q gain 11 q loss	8p,11q,13q,14q loss 1q,5p,8q,17q gain 17q12 and 11q13 amplification

Low-grade IDC	High-grade IDC
16 q loss 1q,16p,8q gain	8p,11q,13q,1p and 8q loss 1q,8q,17q,20q and 16p gain 17q12 and 11q13 amplification

Intermediate-grade DCIS lesions have common features with low- and high-grade IDC.

losses of 16q were exclusively seen in well- and intermediately-differentiated DCIS. A higher frequency of gains of 1q and losses of 11q was observed in intermediately-differentiated DCIS. The poorly-differentiated DCIS displayed complex genomic alterations, including loss of 8p, 11q, 13q, and 14q and gains of 1p, 8q, and 17q. This was characterized by a higher frequency of amplifications of 17q12 and 11q13. Analysis of paired IBC revealed a CGH pattern similar to the DCIS counterpart (33). This data provided further evidence that DCIS are precursor lesions of IBC, but progression from low- and high-grade DCIS to IBC are likely from different genetic pathways (34) (Table 24-1).

In addition, FEA and ADH has morphological overlap with low-grade carcinomas, and ADH is accepted as a precursor lesion for low-grade/noncomedo DCIS. Molecularly, FEA has a genetic profile that overlaps with those of synchronous low-grade DCIS and low-grade invasive carcinomas and has a high rate of LOH at 16q, supporting its precursor role in the evolution to low-grade cancers (11). In another study, FEA exhibited recurrent chromosomal copy number gains and losses (gains on 15p, 16p, and 19; losses on 16q, 17p, and X), which overlap with those observed in both ADH and low-grade DCIS (9).

However, the precursor lesion of high-grade/comedo DCIS is not clear. High-grade DCIS lesions are associated with more complex genetic alterations and overexpression of genes related to mitotic activity and cell cycle processes (35). In a comparison of copy number changes of 21 breast cancer–related genes between laser-microdissected DCIS and adjacent IDC lesions (25), no significant differences existed between DCIS and adjacent IDC. However, low/intermediate-grade DCIS showed on average 6 gains/amplifications versus 8 in high-grade DCIS. Furthermore, alterations of *AURKA* (aurora kinase A) and *CCNE1* (cyclin E1) were exclusively found in high-grade DCIS, and *HER2*, *PRDM14* (PR domain containing 14), and *EMSY* amplification was more frequent in high-grade DCIS than in low/intermediate-grade DCIS. These data indicate that DCIS is genetically as advanced as IBC and support a model in which different histological grades of DCIS are associated with distinct genomic changes that progress to IDC in different routes.

EVOLUTION FROM LOWER TO HIGHER GRADE LESIONS

The significant intratumoral histological and biological diversity within cases of DCIS argues for an evolution of DCIS from lower grade to higher grade (28). In an analysis of 120 consecutive cases of pure DCIS, 45.8% of cases showed areas of diversity in nuclear grades, including 30% with grades I and II, 6.6% with grades II and III, and 9.2% with grades I, II, and III. In addition, about one-third of the cases showing histologic diversity also showed biologic diversity for one or more biomarkers that included ER, GATA3, HER2, CK5/6, CK18, and p53 by immunohistochemistry staining. Similarly, in studies assessing the LOH, DCIS contained many of the same specific genetic defects regardless of histologic differentiation, although the absolute number of defects was found to be higher in higher grade lesions (8). Furthermore, a significant subset of genes expressed at higher levels in grade III DCIS compared to grade I DCIS were further elevated in IDC. In addition, the link between tumor grade and transition from DCIS to IDC is consistent with the clinical observation that grade III DCIS is more likely to be associated with occult invasive disease than grade I DCIS (36).

MOLECULAR MARKERS OF DCIS THAT PREDICT RECURRENCE AND INVASIVE PROGRESSION

The evolution of genetic events that drives the process of breast tumorigenesis is poorly understood. As demonstrated in previous studies, many genetic alterations present in the invasive breast cancer already exist in the earliest phenotypically identifiable lesions such as ADH. However, gene expression profiling, CGH, and candidate gene approach, which are the main technologies used in these studies, are limited in their capacity for detailed genomic interrogation. A comprehensive genomic sequencing study of synchronous preinvasive and invasive cancer in comparison to the normal breast epithelial cells is needed but has not been reported. In this section, we will focus on available data investigating molecular markers that may predict the prognosis of DCIS and potential candidate drivers in cancer progression.

Prognostic Markers

Low ER or PR expression or HER2 amplification is associated with higher grades of DCIS and recurrence (37–41). A molecular signature of lack of ER and PR, HER2 overexpression, accumulation of p53, and high Ki67 expression was proposed to predict recurrence (42). COX-2 and p16 have also been associated with progression or recurrence. In a retrospective study, DCIS lesions that were positive for p16, COX-2, and Ki67 expression were significantly associated with risk of subsequent invasive cancer, whereas DCIS lesions that either lacked ER but were positive for HER2 and Ki67 or that lacked COX2 but were positive for p16 and Ki67 were associated with recurrence of DCIS (43). However, with the exception of ER/PR, none of these molecular markers are routinely assessed in the clinic due to the lack of sufficient evidence or established interventions.

Several other molecular markers, including cell cycle regulation and apoptotic markers (cyclin D1, cyclin A, cyclin E, p21, p27, p53, Bcl-2, Bax, Survivin, c-myc, and Rb), angiogenesis-related proteins (VEGF and heparanase-1), and extracellular matrix-related proteins (CD10, secreted protein acidic and rich in cysteine), have been investigated in molecular epidemiology studies; however, the data have not been conclusive (44).

Candidate Drivers of Invasive Progression

ER is commonly expressed in preinvasive lesions, 95% and 75% in ADH/LCIS and DCIS lesions, respectively (10). Binding

of estrogen to ER stimulates the growth and differentiation of breast epithelium; therefore, prolonged estrogen exposure in preinvasive disease might have a role in the development of breast cancer. Consistent with the important role of estrogen in breast cancer progression, tamoxifen has been shown to be an effective drug for prevention of breast cancer in high risk patients as well as an effective adjuvant hormonal therapy for patients with resected ER+ DCIS.

HER2 overexpression occurs commonly in high-grade lesions (60%) compared to low-grade lesions (10%). In addition, HER2 is not overexpressed in TDLUs, very rarely in ADH, and about 2% in LCIS. The absence of HER2 overexpression in the earliest phase of preinvasive disease and its association with higher grade DCIS and more aggressive clinic behavior suggest HER2 overexpression is a driving event in cancer progression (45). A randomized phase III trial of adjuvant radiotherapy with or without trastuzumab in patients with HER2+ DCIS resected by lumpectomy is ongoing to evaluate the effect of HER2-targeting in ipsilateral breast cancer recurrence (NCT00769379).

As mentioned above, the precise genetic event(s) triggered during the transition from DCIS to IDC is a critical unknown in the study of breast cancer. A few limited studies that compared the IDC with the adjacent DCIS suggested that *c-Myc* or *FGFR1* amplification may be involved in this process because these genetic events occurred more frequently in the IDC compared to the adjacent DCIS lesions (46–48), while *PIK3CA, AKT1,* and *TP53* mutations are early events that appeared to already exist at the DCIS stage (Table 24-2). Knudson et al. confirmed in their study that DCIS present in concert with IBC harbors gene expression profiles similar to IBC; however, when IBC and pure DCIS were compared, the expression differences became clearer (49). Genes associated with epithelial-to-mesenchymal transition and myoepithelial specific genes were enriched in IBC relative to DCIS, particularly in the stromal component. There have been few *in vivo* studies addressing the function of genes in the progression of DCIS to IDC. Using a "mammary intraductal DCIS" xenograft model, Lee et al. studied the progression of DCIS to invasive breast cancer *in vivo* by introducing specific genes in the human DCIS cell line. Four genes, including a protease inhibitor (*CSTA*) and three genes involved in cell adhesion and signaling (*FAT1*, *DST*, and *TMEM45A*), which were usually elevated in clinical samples of DCIS, were found to suppress the progression of DCIS to invasive cancer (50).

THE ROLE OF THE TUMOR MICROENVIRONMENT

The morphogenesis and functional differentiation of mammary epithelium are known to depend on signals from systemic hormones and on cues from the local tissue microenvironment, and epithelial-mesenchymal interactions are important for breast cancer tumorigenesis (51). Multiple lines of evidence point to the potential importance of tumor microenvironment, which is composed of fibroblasts, myoepithelial cells, endothelial cells, and various immune cells or leukocytes during the transition from invasive to metastatic breast cancer (52–54) and from DCIS to IDC (55,56). To analyze the contribution of tumor microenvironment, several groups have performed unbiased high-throughput genomic and transcriptomic analysis on different tissue/cellular compartments of preinvasive and invasive breast cancer. Using cell-type specific antibodies, Allinen et al. isolated different cell types including epithelial cells, myoepithelial cells, myofibroblasts, leukocytes, and endothelial cells from normal breast, DCIS, or invasive breast cancer specimens and performed comprehensive gene expression profile and aCGH analysis of each cell type (55). While genetic changes by CGH were restricted to tumor epithelial cells of DCIS and IDC, gene expression changes are present

TABLE 24-2

Genetic Alterations in the Invasive Breast Cancer Compared to the Adjacent DCIS

Genes	*Method*	*Patient Features*	*Results*
c-Myc(45)	CGH and FISH	n = 12 IBC with large *in situ* component	*c-Myc* is amplified in IBC but not paired DCIS
c-Myc amplification *CDH1* loss(46)	FISH probe panel consisting of oncogenes and tumor suppresor genes, single-cell genetic analyses	n = 13 synchronous DCIS and IDC	*c-Myc* gain and *CDH1* loss were the most frequent changes between DCIS and IDC
FGFR1(47)	FISH performed on selected gene on tissue microarray	n = 179 pure DCIS, n = 438 invasive carcinoma, n = 216 with DCIS component	*FGFR1* amplification is more frequent in invasive carcinoma, associated with decreased overall survival (OS)
PIK3CA(48)	LCM, PCR sequencing for exon 9 and exon 20	n = 125 DCIS, n = 108 IBC	Similar in DCIS and IDC
AKT/PIK3CA(49)	LCM and PCR mutation analysis	n = 81 invasive + *in situ* carcinoma	12/81 *PIK3CA* mutation, 3/78 *AKT* mutation, no difference in DCIS and IBC
TP53(50)	LCM, PCR mutation analyses	n = 32 DCIS, n = 38 IBC, n = 48 mixture	No significant difference in *TP53* mutations in DCIS and IBC

CGH, comparative genomic hybridization; DCIS, ductal carcinoma in situ; FISH, fluorescence in situ hybridization; *FGFR1,* fibroblast growth factor receptor 1; IDC, invasive ductal carcinoma; LCM, laser capture microdissection; PCR, polymerase chain reaction; *PIK3CA,* phosphatidylinositol-4,5-bisphosphate 3-kinase; *TP53,* tumor protein 53.

in all cell types. The most consistent and dramatic gene expression changes occurred in myoepithelial cells from normal breast and those from DCIS samples. Interestingly, a significant fraction of these genes were secreted or cell-surface proteins, including CXCL12 and CXCL14 chemokines, suggesting paracrine interactions between myoepithelial and other cell types. Similarly, in an oligonucleotide microarray study performed on 14 patient-matched normal epithelium, normal stroma, tumor epithelium, and tumor-associated stroma from DCIS and invasive cancer, the transition from DCIS to invasive carcinoma was accompanied by significant increases in the expression of genes encoding extracellular matrix proteins and matrix metalloproteases (MMP2, MMP11, and MMP14) and cell cycle-related genes, in the stroma compartment (56). In contrast, the epithelial compartment demonstrates no or rare gene expression changes during the DCIS to IDC transition. These findings support the notion that stroma-produced MMPs may be key players driving the DCIS-to-IDC transition. Studies indicate the presence of distinct epigenetic changes in tumor-associated stroma cells (57,58). Future studies investigating the mechanisms of epigenetic changes may shed new light on the control of gene expression during breast tumorigenesis and tumor progression.

CLONAL EVOLUTION DURING INVASIVE PROGRESSION

Single-cell genetic analysis and next-generation sequencing studies support the hypothesis that IBC is the result of clonal evolution driven by a combination of an increased mutation rate and selection pressure on cells within the evolving malignant focus. Using a 4-FISH probe panel that targets 8 candidate genes, including oncogenes *COX2, c-Myc, HER2, CCND1,* and *ZNF217* and tumor suppressor genes *DBC2, CDH1,* and *TP53* and 2 centromere probes, single-cell analysis of copy number changes of the 8 genes was performed on 13 cases of synchronous DCIS and IDC (47). Signal patterns were counted in 76 to 220 nuclei per sample. A high degree of chromosomal instability, defined as variability in the signal patterns from one cell to another in a tumor population (Fig. 24-4), was observed in both DCIS and IDC samples. Despite enormous intercellular heterogeneity in DCIS and IDC, nonrandom distribution of genomic imbalances was observed. The progression from DCIS to IDC was commonly accompanied by loss of *CDH1* and gain of *MYC (c-Myc).* Four of 13 DCIS showed identical clonal imbalances in the IBC (see Fig. 24-4, Category I). Six cases revealed a switch, four of which acquired a gain of *MYC* in IDC (see Fig. 24-4, Category II). In one case, the major clone in the IDC was one of several clones in the DCIS (see Fig. 24-4, Category IV), and in another case, the major clone in the DCIS became one of the two major clones in the IDC (see Fig. 24-4, Category III). This data suggest that transition from DCIS to IBC is driven by a selection of clone(s) with a specific repertoire of genetic alterations. This hypothesis was further supported by another study of 13 matched DCIS and IDC pairs by a CGH and Sequenom MassARRAY (59). Although the genomic profiles of matched DCIS and IDCs were similar, amplification of distinct loci (i.e., 1q41, 2q24.2, 6q22.31, 7q11.21, 8q21.2, and 9p13.3) was either restricted to, or more prevalent in, one of the components in 3 pairs. *PIK3CA* mutations were restricted to the DCIS component in two cases, and reduced from 49% in the DCIS to 25% in the IDC component in the third case. Similarly, it is well known that some DCIS harboring *HER2* gene amplification are associated with HER2-negative invasive carcinomas (60,61).

Using newly developed bioinformatic algorithms (62), Nik-Zainal et al. reconstructed the genomic evolution and a model of breast cancer development over molecular time (Fig. 24-5A) based on analysis of NGS data obtained for 21 breast cancers that included ER+ (n = 5), HER2+ (n = 4), triple negative breast cancer (TNBC) (n = 3), *BRCA1* mutant (n = 5), and *BRCA2* mutant (n = 4) cases. An example of the phylogenetic tree constructed for PD4120, which was sequenced to 188-fold depth is shown in Figure 24–5B. The chronological orders of copy number gains in 16 informative breast cancer genomes are shown in Figure 24-5C. A key milestone in this evolutionary process is the appearance of the "most-recent common ancestor"—the cell with the full range of somatic mutations found in all tumor cells, which demarcates the point when divergent subclones branch out from the initial clone (see Fig. 24-5A,B) (63,64). Strikingly, many oncogenic events, including several driver mutations such as mutations in *PIK3CA* and *TP53*, amplifications of *ERBB2, MYC,* and *CCND1,* and somatic loss of the *BRCA1* and *BRCA2* alleles, accumulated before the emergence of the most-recent common ancestor and were identified in all tumor cells among the 21 breast cancers studied. Another important finding from the study was that all of the tumors contained a dominant subclonal lineage, accounting for more than 50% of cancer cells in the sample and carrying many hundreds or thousands of point mutations. Using PD4120a as an example, 26,762 of the 70,690 somatic substitutions genome-wide were present in all tumor cells, and 4 major subclones were present by statistical modeling of the distribution of clonal and sublonal mutations, with the dominant clone composed of an estimated 70% of the cells in the tumor sample (35% of sequencing reads reported this variant) (Fig. 24-5D). Chromosomal instability was found to be common throughout the history of the cancer although not usually the earliest genomic event. This results in the clonal acquisition of many recurrent abnormalities, such as gains of 1q and 8q and losses of 17p, and considerable divergence among subclones. Similarly, other mutations accumulate during the tumor's development. Once again, it is not clear what triggers the development of the dominant clone. One theory is that this involves an event referred to as chromotripsis (Greek; *chromos* for *chromosome, tripsis* for *shattered into pieces*). Chromotripsis describes a cataclysmic event in which tens to hundreds of genomic rearrangements interspersed with widespread losses of sequence fragments occur in a one-off cellular crisis (65). This is accompanied occasionally by the formation of small circular DNA molecules (double-minute chromosomes), which could become amplified with oncogenes. Strikingly, this genomic rearrangement has been found to be limited to one or a few chromosomes, with affected regions criss-crossing back and forth and showing the characteristic pattern of copy number oscillations between two copy number states. This phenomenon was recently discovered amidst a flood of information from the NGS, in which both ends of 50 to 100 million genomic DNA fragments per sample are sequenced and aligned to a reference genome. In the initial analysis of 10 chronic lymphocytic leukemia (CLL) cases, chromotripsis was detected in one sample (Fig. 24-6) (65). Chromotripsis was identified in 18 of 746 (2.4%; 95% CI, 1.5%–3.9%) cancer cell lines subsequently analyzed using the high-resolution single nucleotide polymorphism (SNP) array data (65). The affected cell lines were across many different tumor types including melanoma; small-cell lung cancer; glioma; non-small–cell lung cancer; synovial sarcoma; and esophageal, colorectal, renal, and thyroid cancers. Additionally, a similar proportion of cases demonstrated evidence of chromotripsis in the analysis of SNP array data from 2,792 cancer specimens that composed 80% of primary tumors. This phenomenon

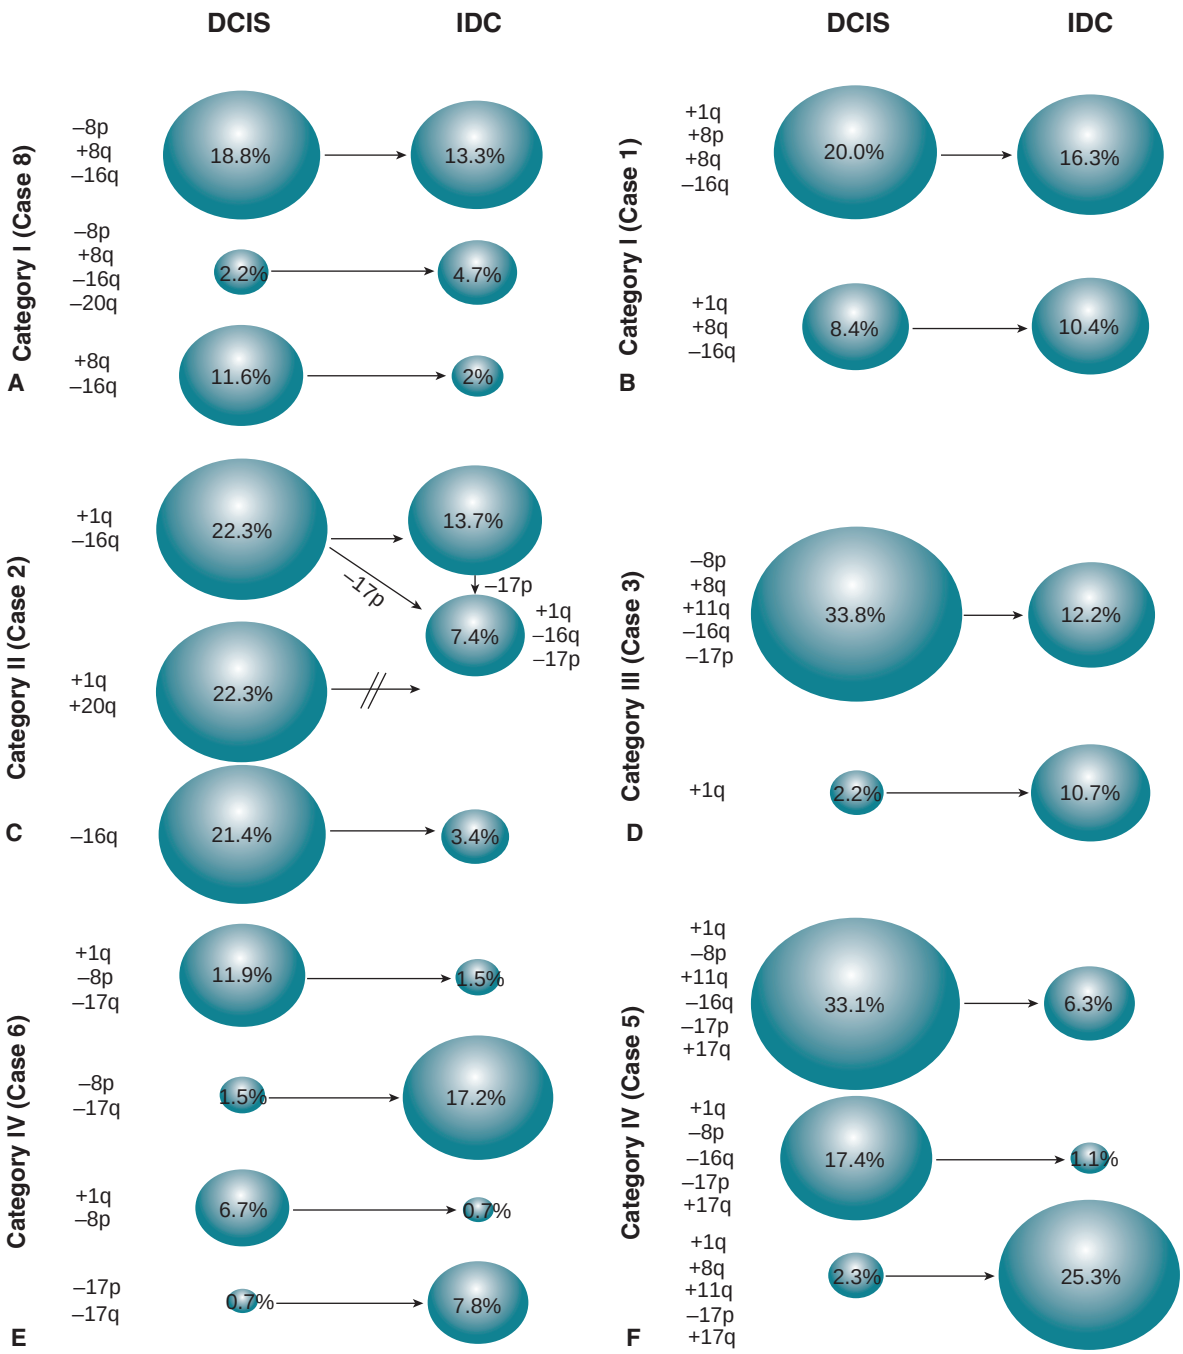

FIGURE 24-4 Schematic presentation of examples of clonal evolution in categories I **(A and B)**, II **(C)**, III **(D)**, and IV **(E and F)** based on the presence of imbalance clones. In case 8 (A) the major clone in DCIS [an 18.8% gain of *MYC* (+8q), losses of *DBC2* (–8p) and *CDH1* (–16q)] was also the major clone in IDC (13.3%). A rare clone in the DCIS (a gain of *MYC*, losses of *DBC2, CDH1,* and *ZNF217*) expanded to become the second largest clone, whereas the second largest clone in DCIS (a gain of *MYC*, a loss of *CDH1*) became rare in the IDC. The text on the left of each panel denotes whether specific chromosome arms are gained (+) or lost (–). The sizes of the circles reflect the frequency with which a clone occurred, which is specified by the percentages in the circles as well. In (C), the clone that occurred in 7.4% of the IDC could have emerged by losses of 17p from either the major clone in the DCIS (+1q, –16q) or the IDC clone present in 13.7% of the cells. Note that one of the major clones in the DCIS (+1q, +20q) vanished in the IDC. (From Heselmeyer-Haddad K, et al. Single-cell genetic analysis of ductal carcinoma in situ and invasive breast cancer reveals enormous tumor heterogeneity yet conserved genomic imbalances and gain of MYC during progression. *Am J Pathol* 2012;181:1807–1822.)

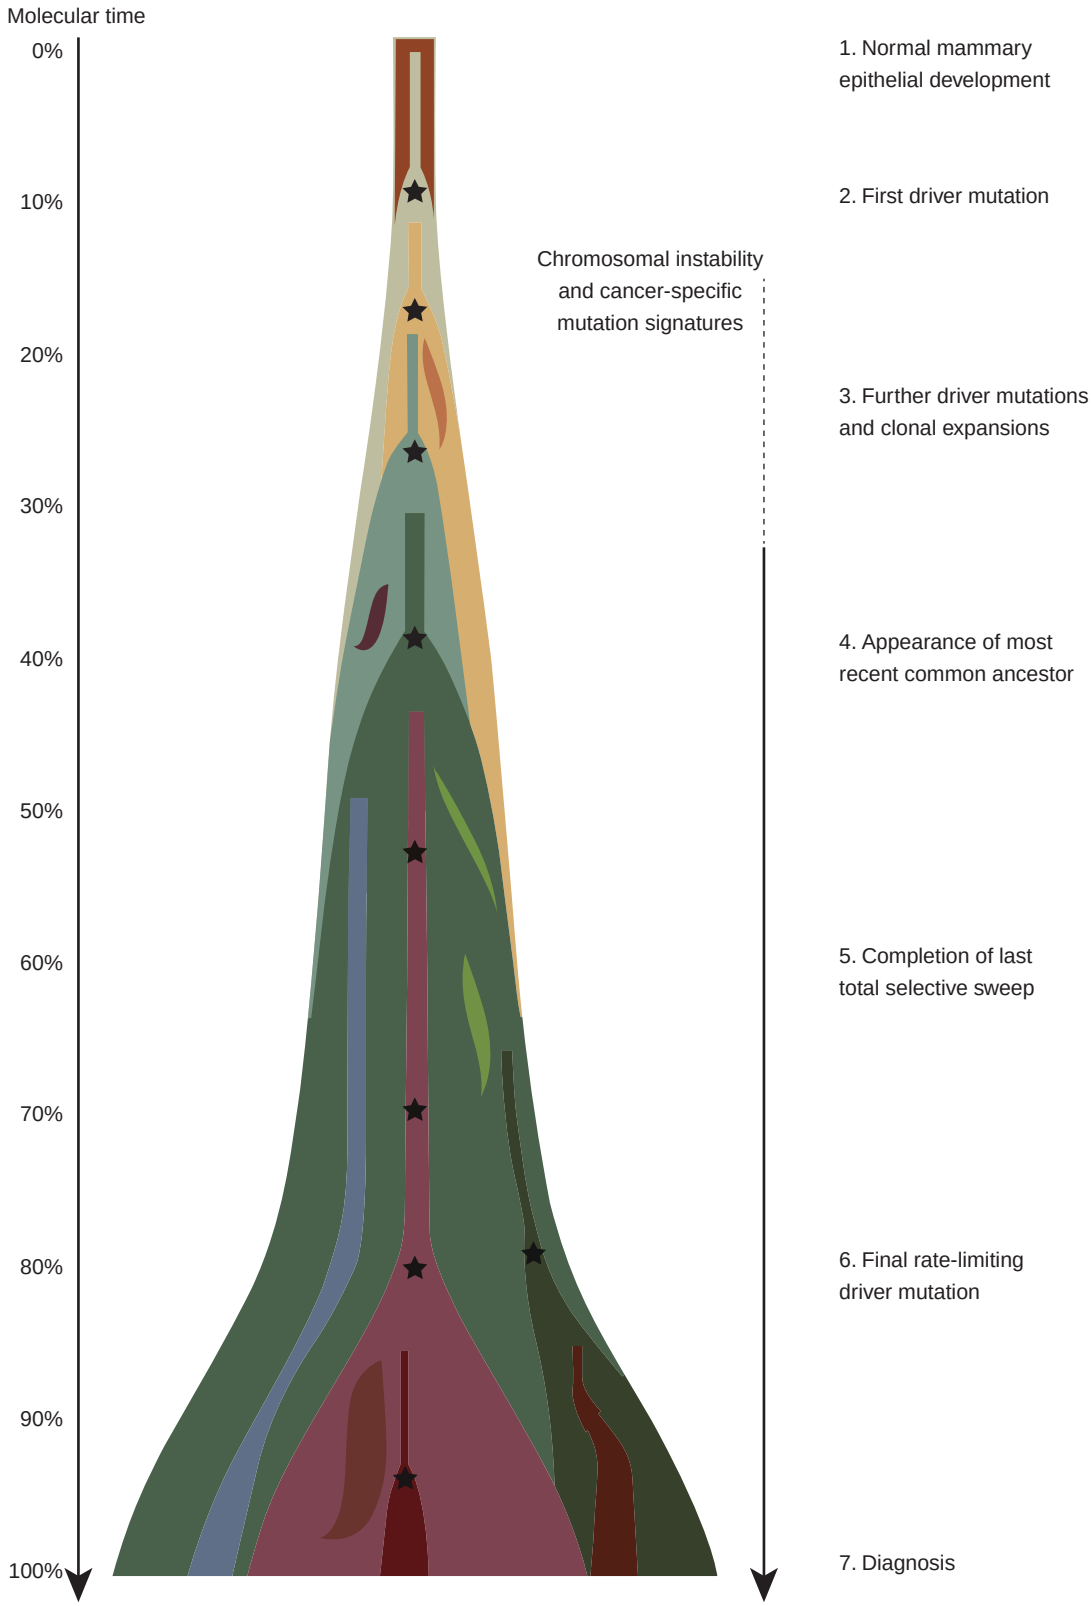

FIGURE 24-5 **(A)** A model for breast cancer development over molecular time. The cancer evolves through acquisitions of driver mutations (*black stars*), which produce clonal expansions. These driver mutations occur only infrequently in long-lived lineages of cells, which passively accumulate many mutations without expansion.

has been found to be particularly common in bone cancers (9 or 20 tumors identified). The argument that the chromotriptic changes are a result of a single catastrophic event was based on the observation of the coordinated gene arragement, with the restriction of two copy number and preservation of LOH of involved regions and was supported by a statistical analysis using Monte Carlo simulations of the progressive model of gradual accumulation of random alterations (65). The mechanisms underlying chromotripsis are unknown. One hypothesis is that chromosomes can be "pulverized" or undergo premature chromosome compaction (66), a phenomon observed during cell-fusion experiments, in which incompletely replicated chromosomes from the S phase nucleus shatter when induced to undergo chromosomal condensation by signals from the host cell in mitosis (67,68). But how this process involves only one or two chromosomes or a single chromosome arm remains to be explained. A lack of sequence homology between joined segments of the regions affected argues that the nonhomologous end-joining DNA repair system is involved after the massive DNA fragmentation. The end results of chromotripsis are the survival advantage that could be offered when tumor suppressors are lost and the generation of new fusion genes in the disrupted chromosome, as well as amplified oncogenes occurring on the derivative chromosomes. Examples include the identification of a normal copy of chromosome 8 as well as a large number of double-minute chromosomes that are composed of 15 distinct segments of chromosome 8, leading to amplification of the *MYC* oncogene in a small-cell lung cancer cell line and the identification of simultaneous loss of several tumor suppressor genes including *CDKN2A, WRN,* and *FBXW7* in a chordoma sample (65).

SEQUENCING OF A BREAST CANCER PRIMARY AND METASTASIS

In 2009, Shah et al. described the mutational evolution of a lobular breast carcinoma (69). The DNA sequence of a metastatic, lobular breast carcinoma was obtained using next-generation DNA sequencing and comparison was made to the patient's original primary breast cancer, which was resected 9 years previously. The metastasis contained 32 somatic, protein-coding mutations. Of these, five mutations were prevalent in the primary cancer, six were present at lower frequency in the primary cancer (between 1% and 13%) and were more prevalent in the metastasis, and nineteen mutations could not be detected at all in the primary. Another study, conducted by Ding et al., investigated the genomic differences between DNA derived from a primary

FIGURE 24-5 *(Continued)* **(C)** Timing of copy number gains in 16 informative breast cancer genomes from the ploidy of mutations. The point estimates of timing for specific copy number gains are shown as arrows colored by the type of chromosomal aberration, with 95% confidence intervals generated by bootstrapping shown as horizontal lines. Molecular time is shown as an *arrow*, with the timing estimated as a fraction of point mutation time.

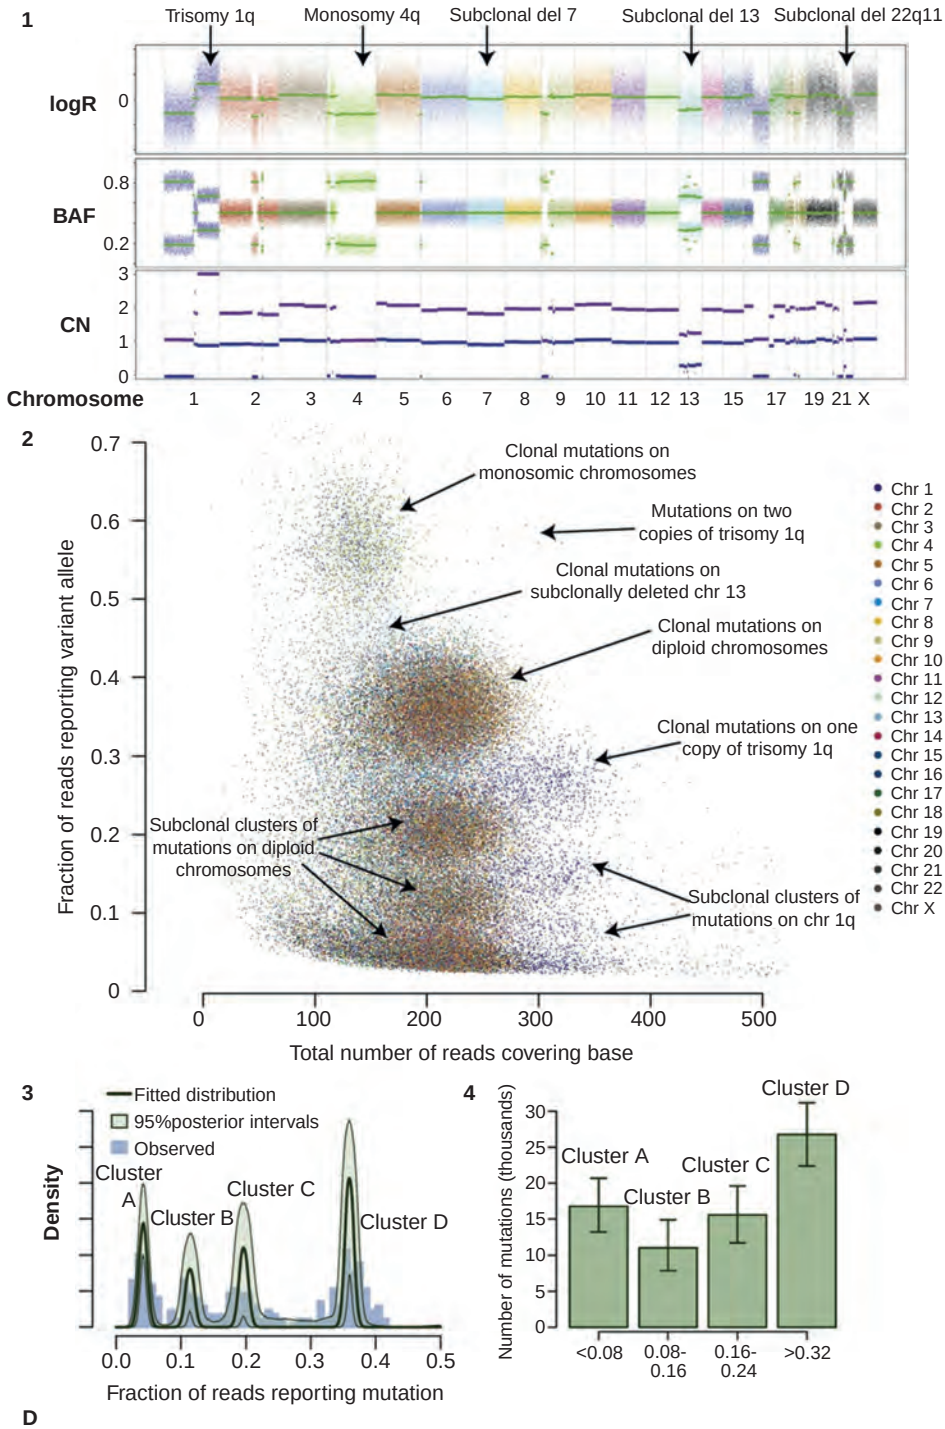

FIGURE 24-5 *(Continued)* **(D)** Genomic architecture of PD4120a, a breast cancer genome sequenced to 188-fold coverage: (1) Copy number profile of the sample, with the upper panel showing the logR of intensity, and the middle panel showing the B allele fraction (BAF) of germline heterozygous SNPs. Genomic segments of constant logR and BAF value were identified by the ASCAT algorithm (*green lines*). These were interpreted to give estimated overall copy number (*purple lines*) and copy number of the minor allele (*blue lines*) across the genome (*lower panel*). (2) Distribution of 70,690 somatically acquired base substitutions according to the total number of reads across that base (x-axis) and the fraction of those reads reporting the variant (y-axis). Points are colored according to the chromosome the mutation derives from. (3) Statistical modeling of the distribution of clonal and subclonal mutations by a Bayesian Dirichlet process. The empiric histogram of mutations is shown in pale blue, with the fitted distribution as a dark green line. Also shown are the 95% posterior confidence intervals for the fitted distribution (*pale green area*). Four separate clusters of mutations, named A–D, are identified. (4) Estimated number of mutations found in clusters A–D, with the error bars representing the 95% posterior confidence intervals. (From Nik-Zainal S, Alexandrov LB, Wedge DC, et al. The life history of 21 breast cancers. *Cell* 2012;149:994–1007.)

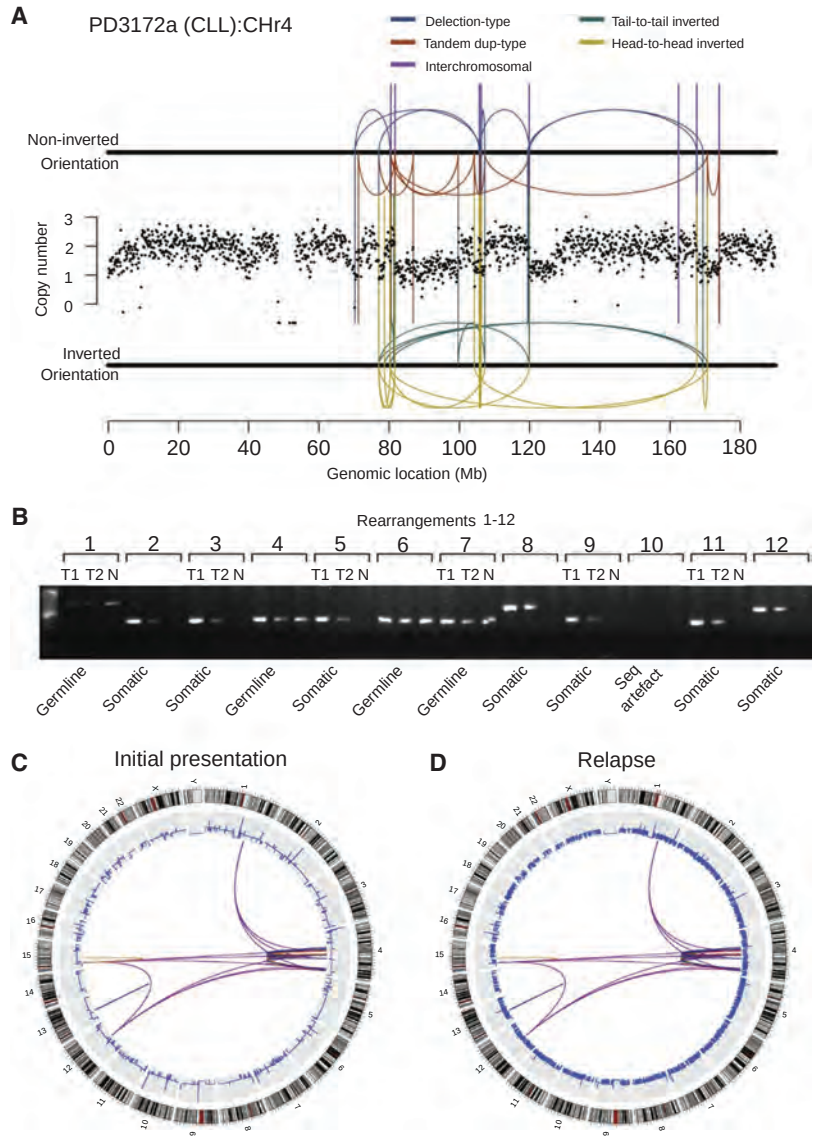

FIGURE 24-6 Clustered rearrangements on chromosome 4q in a patient with chronic lymphocytic leukemia. **(A)** Copy number between 70 Mb and 170 Mb of the chromosome oscillates between a copy number of 1 and 2, demarcated by back-and-forth intrachromosomal rearrangements of all four possible orientations, as well as several interchromosomal rearrangements. **(B)** PCR gel of 12 putative genomic rearrangements identified by sequencing. PCR across the breakpoint is performed for each rearrangement on tumor DNA for samples taken at initial presentation (T1) and relapse (T2) as well as germline DNA (N). **(C)** Genome-wide profile of rearrangements in a sample taken before chemotherapy. Chromosomes range around the outside of the circle, copy number changes are shown by the blue line in the inner ring, and somatically acquired genomic rearrangements are shown as arcs linking the two relevant genomic points. **(D)** Genome-wide profile of rearrangements from the same patient 31 months later, at relapse after therapy, which showed all rearrangements present at initial presentation were present at relapse, and the striking copy number profile persisted. There were no new genomic rearrangements, suggesting that the process generating this complex regional remodeling had resolved before the patient was first diagnosed. (From Stephens PJ, Greenman CD, Fu B, et al. Massive genomic rearrangement acquired in a single catastrophic event during cancer development. *Cell* 2011;144:27–40.)

tumor, a metastasis, and a xenograft sample from the same patient (70). The samples were obtained from a 44-year-old African American woman with triple-negative breast cancer resistant to initial chemotherapy. The primary breast cancer contained 48 somatic, protein-coding mutations, which had a wide range of variant allele frequencies. The metastasis contained all 48 of these mutations, but about half of these mutations showed higher variant allele frequency in the metastasis, indicating enrichment or clonal selection in the metastasis. This enrichment was also seen in the xenograft that was derived from the primary cancer, and, because the sample to establish the xenograft was obtained prior to any cancer treatment, this argues that this enrichment or clonal selection is an intrinsic property of the cancer and not due to the effects of treatment. Further, two new mutations and one large DNA deletion were present in the metastasis but not in the primary cancer, indicating that there was some degree of genomic evolution in the cells making up the metastasis.

Studies of other cancer types also provide guidance about the type of genomic progression that can occur in breast cancer. Sequencing of a renal cell cancer that had metastasized to the lung and chest wall showed substantial intratumor genomic heterogenity (71). The researchers sampled 9 different areas within the primary tumor and 3 metastases (1 from the perinephric fat metastasis; 2 from the chest wall metastasis) and found that only 31% to 37% of the mutations were common to all samples. They constructed a phylogenetic tree based on these results (Fig. 24-7) and proposed that the shared mutations are found in the trunk of this tree (ubiquitous mutations, indicated in blue) whereas the remainder of mutations (63% to 69%) are located in the branches of the tree (indicated in yellow, green, or red). Based on these cases, a schema of clonal evolution in both the primary tumor and metastasis can be proposed (Fig. 24-8) (72). Because of genomic instability in the cancer cells, heterogenity and different subclones develop within the primary tumor. Metastases can develop either early or late in the cancer and are an opportunity for one or several subclones to grow at a distant site. The metastasis can derive from a dominant clone or a minor clone of the primary cancer, which will influence how similar the metastasis and primary cancer are in mutation pattern or even in response to treatment. The ability to sequence individual cancer cells (73) is providing further information about this clonal evolution process and will likely lead to future advances in this area.

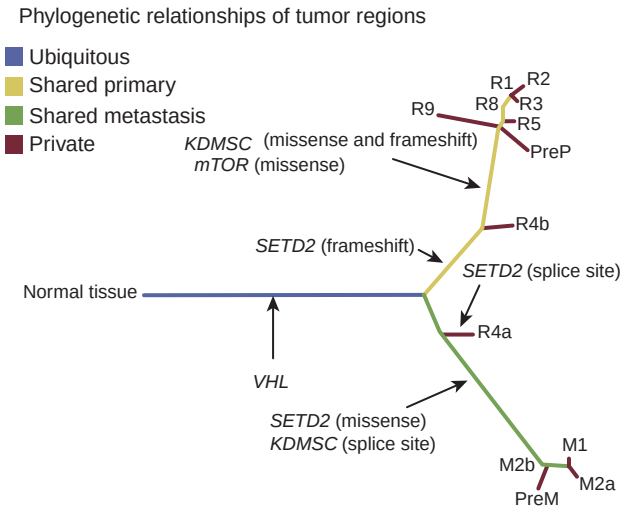

FIGURE 24-7 Phylogenetic relationships of the different renal cell cancer regions and metastases. A single renal cell cancer was subdivided into 9 regions (labeled R1–R9). Additionally, a perrinephric metastasis (M1) and a chest wall metastasis (subdivided into two halves, M2a and M2b) were sequenced. R4a and R4b are the subclones detected in R4. A question mark indicates that the detected SETD2 splice-site mutation probably resides in R4a, whereas R4b most likely shares the SETD2 frameshift mutation also found in other primary-tumor regions. Branch lengths are proportional to the number of nonsilent mutations separating the branching points. Potential driver mutations were acquired by the indicated genes in the branch (arrows). (From Gerlinger M, Rowan AJ, Horswell S, et al. Intratumor heterogeneity and branched evolution revealed by multiregion sequencing. *N Engl J Med* 2012;366:883–892.)

COMPARISON OF THE CLONAL EVOLUTION MODEL AND THE CANCER STEM CELL MODEL

In addition to the clonal evolution model discussed extensively up to this point, the cancer stem cell model also offers an explanation for tumor heterogeneity and cancer progression. The cancer stem cell hypothesis proposes that there is a subpopulation of cells within the tumor that are capable of self-renewal and multi-lineage differentiation (74,75). These cells can be isolated based on low expression of the heat stable antigen (CD24), high level expression of the hyaluronic acid receptor (CD44), and expression of aldehyde dehydrogenase (ALDH1) (76–78). In the cancer stem cell model, only mutations in these cells are propagated, and the clonal evolution in them gives rise to the genomic heterogenity in the cancer (Fig. 24-9). Data to support this concept come from Nik-Zainal et al., where 21 primary breast cancer samples were sequenced and their clonal evolution was analyzed with bioinformatic algorithms as described earlier (63). They observed that all tumors contained a dominant subclone that accounted for more than 50% of cancer cells in the sample. They postulated that this expansion of a dominant clone is the final step in the development of a tumor that is responsible for triggering diagnosis, due to the emergence of a palpable mass. As there is minimal evidence of clonal expansion before the accumulation of all mutations in the dominant subclone, they suggest that the dominant clone becomes a cancer-initiating population, which is conceptually similar to a cancer stem cell (79). Similarly, Shah et al. performed deep sequencing, to a depth of 20,000X, on 104 triple-negative breast cancers (80). They observed that groups of mutations within individual cases have different clonal frequencies, indicative of distinct clonal genotypes. These triple-negative breast cancers had a wide range of clonal frequencies in the mutations sequenced, with some cases showing only one or two clonal populations (indicating a smaller number of clonal genotypes), whereas other tumours exhibited more extensive clonal evolution. The findings that many breast cancers have a dominant clone could be the result of this clone having a competitive advantage and taking over the tumor (the clonal evolution model) or could result from one or a few clones in the cancer stem cells, which then propagate and fill the tumor with their progeny.

The cancer stem cell model has also been proposed to explain the existence of the intrinsic molecular subtypes of breast cancer defined by gene expression (Fig. 24-10) (81,82). With the comprehensive genomic sequencing analysis of hundreds and thousands of invasive breast cancers in recent years, it is well established that the profound difference in the gene expression patterns among the various molecular subtypes is accompanied by subtype-specific genetic alterations (Table 24-3) (80,83–90). This suggests that the molecular subtypes are mechanistically different and perhaps derived from progenitor cells (or stem cells) at different stages of differentiation (81,91,92). Lim et al. isolated and funtionally characterized the 4 populations of breast cells by fluorescence-activated cell sorting (FACS) analysis of EpCAM and CD49f (81). Using transplation assays in immunocompromised mice, the $CD49f^{hi}EpCAM^{-}$ subpopulation was enriched with bipotent (ability to derive luminal and myoepithelial progenitors) mammary stem cell progenitors (MaSC), the $CD49f^{+}EpCAM^{+}$ subpopulation was enriched for luminal progenitor, the $CD49f^{-}EpCAM^{+}$ subpopulation were committed luminal cells, and the $CD49f^{-}EpCAM^{-}$ subpopulation were stromal cells. The data comparing the gene expression profiles of these different subpopulations of cells and that of invasive breast cancers suggest that Luminal A, Luminal B, and HER2-enriched breast cancers are likely derived from the more mature luminal cells, while basal-like tumors are derived from the less differentiated "luminal restricted progenitor" cells, and the claudin-low tumors are derived from the pluripotent or bipotent stem cell population (see Fig. 24-10) (81,82,91–93).

EFFECTS OF TREATMENT ON CLONAL EVOLUTION

The development of endocrine therapy resistance or chemotherapy resistance in advanced breast cancers contributes significantly to patient mortality. Cancer treatment imposes a selective pressure on a tumor that can create an evolutionary bottleneck (Fig. 24-11). Drug resistant clones, which already existed as a minor population within the cancer, can be selected for and expand after cancer treatment (72,94). Genomic studies investigating the effects of treatment on breast cancer cells are still in progress, but evidence for this phenonemon comes from other cancer types. *BRCA2* mutant ovarian cancers are sensitive to cisplatin and PARP inhibitors, but secondary mutations in the *BRCA2* gene have been identified which give rise to resistance to these drugs (95,96). Similarly, resistance to imatinib in chronic myelogenous leukemia (CML) arises from secondary mutations in the BCR-ABL fusion protein (97). Chemotherapy or radiation therapy can itself induce mutations through DNA damage. Temozolomide treatment of glioblastoma multiforme

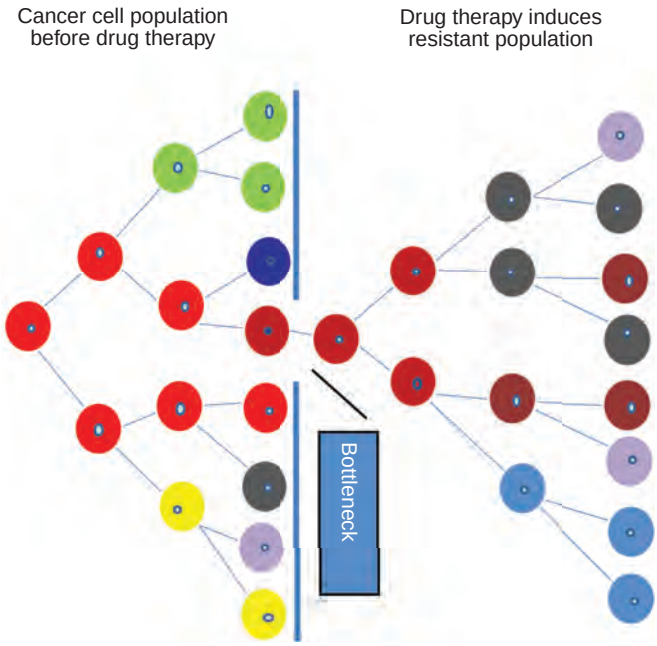

FIGURE 24-11 Tumor heterogeneity during progression and treatment.

produces a statistically significant increase in patient survival, but subsequent recurrence and drug resistance in the cancer is frequently seen. Hunter et al. sequenced two recurrent glioma that had been treated with temozolomide and identified large numbers of somatic mutations in a pattern that was consistent with alkylating agent–induced mutations (98). They identified inactivating somatic mutations of the mismatch repair gene MSH6 in both of these cancers, and they proposed that these MSH6 mutations both conferred resistance to alkylating agents and triggered accelerated mutagenesis in the resistant clones. Accelerating mutagenesis will result in more clonal heterogenity in the cancer and has the potential to give rise to cancers that more difficult to treat. In 1976, Nowell proposed that more research should be directed toward understanding and controlling the evolutionary process in tumors (2). Next-generation DNA sequencing provides a higher volume of data to understand this process, but the ability to control or reduce clonal evolution in cancer is still beyond our current capabilities.

CONCLUSIONS

Despite recent advances, it remains clear that insufficient effort has been placed on acquiring samples from patients with a range of premalignant lesions in order to determine the molecular landscape of precursor lesions. Similarly, at the other end of the scale, we still do not have a comprehensive catalog of the genomic landscape of advanced breast cancer. A comprehensive effort should be made to longitudinally sample the disease so that we can understand the genome dynamics of disease progression. It does appear that the process cannot be described as linear with a series of checkpoints, as Vogelstein imagined; this process is much more chaotic and complex than that, with any one tumor containing a spectrum of dominant and subdominant clones that constantly evolve in response to environmental and therapeutic stresses. Despite this, breast cancer is a curable illness in the majority of cases, which means that heterogenity can be successfully overcome with the right treatment. However, for many patients who are not cured, genomic heterogenity and Darwinian evolution at the cellular level is the root cause of their incurability.

CHAPTER 25

Pathology of Invasive Breast Cancer

Deborah Dillon, Anthony J. Guidi, and Stuart J. Schnitt

CHAPTER CONTENTS

Invasive breast cancers constitute a heterogeneous group of lesions that differ with regard to their clinical presentation, radiographic characteristics, histopathologic and molecular features, and biological potential. The most widely used classification of invasive breast cancers, and that used in this chapter (with minor modifications), is that of the World Health Organization (1). This classification scheme is based on the growth pattern and cytologic features of the invasive tumor cells and does not imply histogenesis or site of origin within the mammary duct system. For example, although the classification system recognizes invasive carcinomas designated "ductal" and "lobular," this is not meant to indicate that the former originates in extralobular ducts and the latter in lobules. In fact, subgross whole organ sectioning has demonstrated that most invasive breast cancers arise in the terminal duct lobular unit, regardless of histologic type (2).

The most common histologic type of invasive breast cancer by far is invasive (infiltrating) ductal carcinoma. In fact, the diagnosis of invasive ductal carcinoma is a diagnosis by default, since this tumor type is defined as a type of cancer not classified into any of the other categories of invasive mammary carcinoma (1). To further emphasize this point, and to distinguish these tumors from invasive breast cancers with specific or special histological features (such as invasive lobular, tubular, mucinous, papillary, and other rare types), some authorities prefer the term *invasive* or *infiltrating ductal carcinoma, not otherwise specified (NOS)* or of *no special type (NST)*. In this chapter, the terms *invasive ductal carcinoma, infiltrating ductal carcinoma,* and *infiltrating or invasive carcinoma of no special type* are used interchangeably.

The distribution of histologic types of invasive breast cancer has varied among published series (Table 25-1). These differences may be related to a number of factors including the nature of the patient population and variability in the confines of definition for the different histological types. In general, special type cancers comprise approximately 20% to 30% of invasive carcinomas, and at least 90% of a tumor should demonstrate the defining histological characteristics of a special type cancer to be designated as that histological type (6).

The widespread use of screening mammography has had a dramatic impact on the nature of invasive breast cancers encountered in clinical practice. The value of mammography in detecting more cases of ductal carcinoma *in situ*, smaller invasive breast cancers, and fewer cancers with axillary lymph node involvement is well recognized. However, mammography has also resulted in a change in the distribution of the histological features of the invasive breast cancers detected. In particular, special type cancers (particularly tubular carcinomas) and cancers of lower histological grade are more frequently observed in mammographically screened populations than in patients who present with a palpable mass, particularly in the prevalent round of screening.

Most invasive breast cancers have an associated component of *in situ* carcinoma, although the extent of the *in situ* component varies considerably. The prevailing view has long been that the invasive carcinomas derive from the *in situ* component. This is based not only on the frequent coexistence of the two lesions, but on the histological similarities between the invasive and *in situ* components within the same lesion. For example, a number of studies have

TABLE 25-1

Histologic Types of Invasive Breast Cancer in Four Large Series before the Widespread Use of Mammographic Screening

		Histologic Type (%)

[a]In some series, designated "not otherwise specified" (NOS) or "no special type" (NST).

clearly documented that low-grade invasive cancers are most often associated with low-grade ductal carcinoma *in situ*, and high-grade invasive cancers with high-grade *in situ* lesions (7). In addition, studies evaluating profiles of biological markers and genetic abnormalities have shown that coexisting invasive and *in situ* carcinomas often share the same immunophenotype and genetic alterations. Gene expression profiling studies have confirmed this observation (8).

The routine pathologic examination of invasive breast cancers has extended beyond simply determining and reporting the histologic type of the tumor. Although histologic typing provides important prognostic information in and of itself, other morphologic features that are evaluable on routine histologic sections are also of prognostic value. In this chapter, the various histologic types of invasive breast cancer will be discussed as will pathologic features important in the assessment of prognosis (prognostic factors) and response to therapy (predictive factors). Characteristic molecular and immunophenotypic features will also be noted where appropriate.

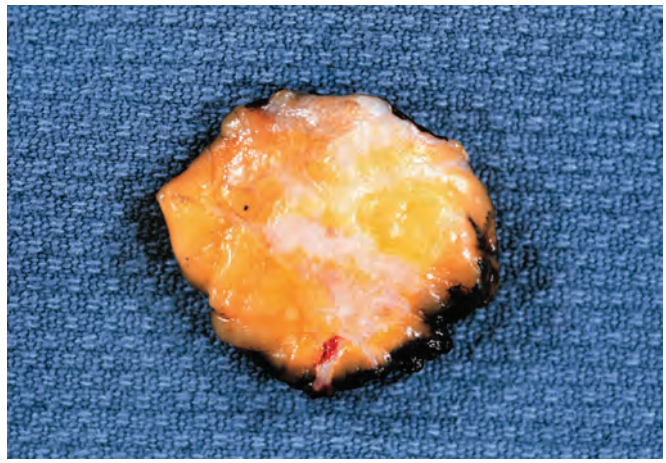

FIGURE 25-1 **Cut surface of an excision specimen containing an invasive ductal carcinoma.** The tumor appears as an irregular area of whitish tissue.

INVASIVE (INFILTRATING) DUCTAL CARCINOMA

Invasive ductal carcinomas represent the single largest group of invasive breast cancers. Although these tumors are most commonly encountered in pure form, a substantial minority exhibit admixed foci of other histologic types. The classification of tumors composed primarily of invasive ductal carcinoma with a minor component consisting of one or more other histological types is problematic. Some authorities categorize such lesions as invasive ductal carcinomas (or invasive carcinomas of no special type) and simply note the presence of the other types, whereas others classify them as "mixed."

Clinical Presentation

Invasive ductal carcinomas most often present as a palpable mass and/or mammographic abnormality. There are no clinical or mammographic characteristics that distinguish invasive ductal carcinomas from other histologic types of invasive cancer. Rarely, these lesions present with Paget disease of the nipple.

Gross Pathology

The classic macroscopic appearance of invasive ductal carcinoma is that of a scirrhous carcinoma, characterized by a firm, sometimes rock-hard, mass that on cut section has a gray-white gritty surface (Fig. 25-1). This consistency and appearance is due to the desmoplastic tumor stroma and not the neoplastic cells themselves. Some invasive ductal carcinomas are composed primarily of tumor cells with little desmoplastic stromal reaction, and such lesions are grossly tan and soft. Although most invasive ductal cancers have a stellate or spiculated contour with irregular peripheral margins, some lesions have rounded, pushing margins, and still others are grossly well circumscribed.

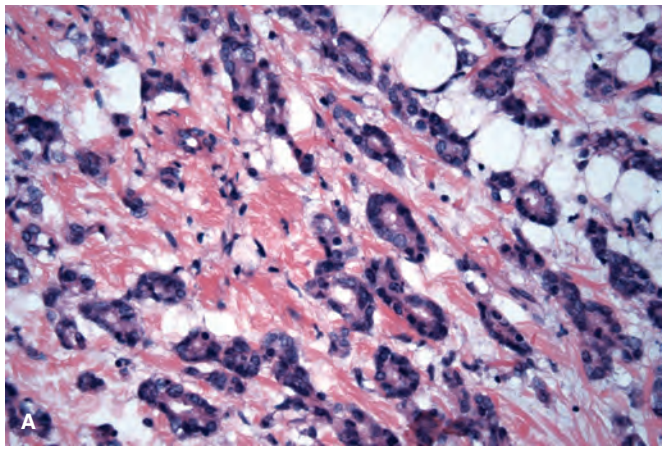
Histopathology

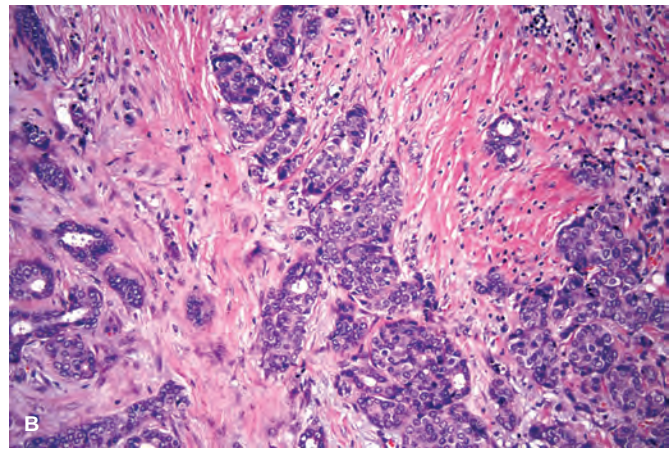
The microscopic appearance of invasive ductal carcinomas is highly heterogeneous with regard to growth pattern, cytologic features, mitotic activity, stromal desmoplasia, extent of the associated ductal carcinoma *in situ* (DCIS) component, and contour. Variability in histologic features may even be seen within a single case. The tumor cells may be arranged as glandular structures; as nests, cords, or trabeculae of various sizes; or as solid sheets. Foci of necrosis are evident in some cases and may be extensive. Cytologically, the tumor cells range from those that show little deviation from normal breast epithelial cells to those exhibiting marked cellular pleomorphism and nuclear atypia. Mitotic activity can range from imperceptible to marked. Stromal desmoplasia is inapparent to minimal in some cases. At the other end of the spectrum, some tumors show such prominent stromal desmoplasia that the tumor cells constitute only a minor component of the lesion. Similarly, some invasive ductal carcinomas have no identifiable component of DCIS, whereas in others, the *in situ* carcinoma is the predominant component of the tumor. An associated lymphocytic or lymphoplasmacytic infiltrate may or may not be present. Finally, the microscopic margins of the cancer may be infiltrating, pushing, circumscribed, or mixed.

Recognizing that invasive ductal carcinomas are a histologically diverse group of lesions, many investigators have attempted to stratify them based upon certain microscopic features. The most common method to subclassify invasive ductal carcinomas is grading, which may be based solely on nuclear features (nuclear grading) or on a combination of architectural and nuclear characteristics (histologic grading). Histologic grading is the method of grading most often used in current practice. The histologic grading system currently in most widespread use is that of Elston and Ellis (reviewed in detail in reference 9). This system is a modification of the grading system proposed by Bloom and Richardson in 1957, but provides strictly defined criteria that are lacking in the original description. Tubule formation, nuclear pleomorphism, and mitotic activity are each scored on a 1 to 3 scale. The sum of the scores for these three parameters provides the overall histologic grade, such that tumors in which the sum of the scores is 3 to 5 are designated grade 1 (well differentiated), those with score sums of 6 and 7 are designated grade 2 (moderately differentiated), and those with score sums of 8 and 9 are designated grade 3 (poorly differentiated) (Fig. 25-2; Table 25-2). The prognostic significance of histologic grading is discussed below (see section on prognostic factors).

Biomarkers

The expression of biologic markers, such as estrogen and progesterone receptors, growth factors, oncogene and tumor suppressor gene products, and other markers is





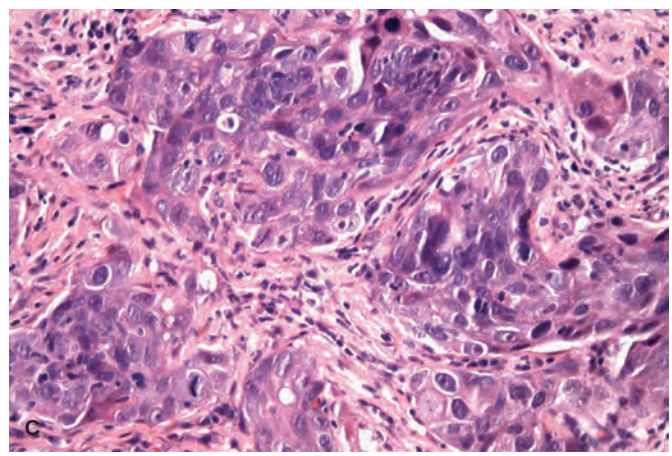


FIGURE 25-2 **Invasive ductal carcinoma. (A)** Histologic grade 1. **(B)** Histologic grade 2. **(C)** Histologic grade 3.

TABLE 25-2

Histologic Grading System for Invasive Breast Cancers (Elston and Ellis Modification of Bloom and Richardson Grading System)

Components of Grade	*Score*
Tubules	
>75% of tumor composed of tubules	1 point
10%–75% of tumor composed of tubules	2 points
<10% of tumor composed of tubules	3 points
Nuclear grade	
Nuclei small and uniform	1 point
Moderate variation in nuclear size and shape	2 points
Marked nuclear pleomorphism	3 points
Mitotic rate	
Dependent on microscope field area	1–3 points
Histologic Grade	**Total points**
1 (well differentiated)	3–5
2 (moderately differentiated)	6–7
3 (poorly differentiated)	8–9

highly variable in invasive ductal carcinomas as might be anticipated from their histologic heterogeneity. Although a large number of biomarkers have been studied in invasive ductal carcinomas, only estrogen receptor, progesterone receptor, and HER2 are reported in routine clinical practice at this time. Overall, 70% to 80% of invasive ductal carcinomas are estrogen receptor positive and approximately 15% are HER2 amplified and overexpressed.

Invasive ductal carcinomas also display a wide variety of genetic and genomic alterations. In gene expression profiling studies, invasive ductal carcinomas may be found within all major molecular subtypes (24).

Clinical Course and Prognosis

The prognosis of invasive ductal cancer varies according to tumor size, histologic grade, lymph node status, and presence of lymphovascular invasion as well as expression of hormone receptors and HER2 (see section on prognostic factors). However, even within this group prognostically favorable specialized tumor types can be identified, as discussed below.

INVASIVE (INFILTRATING) LOBULAR CARCINOMA

Invasive lobular carcinomas constitute the second most frequent type of invasive breast cancer, in most series accounting for approximately 5% to 15% of cases. Although some of this variability may be related to differences in patient populations, much of it appears to be due to differences in diagnostic

criteria. In particular, since the "classical" form of invasive lobular carcinoma was first described by Foote and Stewart (11), a variety of authors have described invasive breast cancers that they consider variants of invasive lobular carcinoma, thereby expanding the spectrum of this histologic type and accounting for a higher incidence of invasive lobular carcinoma in more recent series than in the past. In addition, recent studies have suggested that the increase in the frequency of infiltrating lobular carcinoma may be in part related to the use of postmenopausal hormone replacement therapy (14).

Invasive lobular carcinomas are characterized by multifocality in the ipsilateral breast and appear to be more often bilateral than other types of invasive breast cancer. Lobular carcinoma *in situ* coexists with invasive lobular carcinoma in the majority of cases, with 70% to 80% of cases of invasive lobular carcinoma associated with foci of lobular carcinoma *in situ*.

Clinical Presentation

Invasive lobular carcinoma may present as a palpable mass or a mammographic abnormality with characteristics similar to those of invasive ductal carcinomas (i.e., discrete, firm mass on palpation; spiculated mass on mammogram). However, both the findings on physical examination and the mammographic appearance of invasive lobular carcinomas may be quite subtle. On physical examination, there may be only a vague area of thickening or induration, without definable margins. Mammographic findings may be equally subtle, with many invasive lobular carcinomas appearing as poorly defined areas of asymmetric density with architectural distortion and others revealing no mammographic abnormalities, even in the presence of a palpable mass. In fact, the extent of the tumor may be substantially underestimated by both physical examination and mammography.

Gross Pathology

Some invasive lobular carcinomas appear as firm, gritty, gray-white masses, indistinguishable from invasive ductal carcinomas. However, in other cases, no mass is grossly evident and the breast tissue may have only a rubbery consistency. In still other cases, no abnormality is evident on visual inspection or upon palpation of the involved breast tissue and the presence of carcinoma is revealed only upon microscopic examination.

Histopathology

Invasive lobular carcinomas as a group show distinctive cytologic features and patterns of tumor cell infiltration of the stroma. The *classical form* is characterized by small, relatively uniform neoplastic cells that invade the stroma singly and in a single-file pattern which results in the formation of linear strands (Fig. 25-3). These cells frequently encircle mammary ducts in a targetoid manner. Furthermore, the tumor cells may infiltrate the breast stroma and adipose tissue in an insidious fashion, invoking little or no desmoplastic stromal reaction. This feature accounts for the difficulty in detecting some invasive lobular carcinomas on physical examination, mammography and gross pathologic examination. The nuclei of the neoplastic cells are usually small, show little variation in size, and are often eccentric. Mitotic figures are infrequent. The cells may contain intracytoplasmic lumina which, in some, may be large enough to impart a signet ring cell appearance. However, in the classical form of invasive lobular carcinoma, cells with a signet ring configuration comprise only a small proportion of the tumor cell population.

Many examples of invasive lobular carcinoma (as well as lobular carcinoma *in situ*) are characterized histologically by tumor cells that are loosely cohesive. This phenotype may be, at least in part, related to the fact that both *in situ* and invasive lobular carcinomas typically show loss of expression of the adhesion molecule E-cadherin. This is associated, in many cases, with mutations in the gene encoding this protein (17) or to loss of heterozygosity on chromosome 16q22.1, the region of the E-cadherin gene (18). Although loss of E-cadherin expression characterizes lobular carcinomas and distinguishes them from ductal-type carcinomas, a subset of lobular carcinomas are reported to be E-cadherin positive (19). Thus, membrane expression of E-cadherin in an invasive carcinoma with morphologic characteristics of invasive lobular carcinoma is not, by itself, sufficient for classification as invasive ductal carcinoma.

Variant forms of invasive lobular carcinoma differ from the classical form with regard to architectural and/or cytologic features. In the solid and alveolar variants, the cells comprising the tumor have features characteristic of the classical form of invasive lobular carcinoma, but differ from the classical form with regard to the growth pattern of the tumor cells (10). In the *solid form*, the neoplastic cells grow in large confluent sheets with little intervening

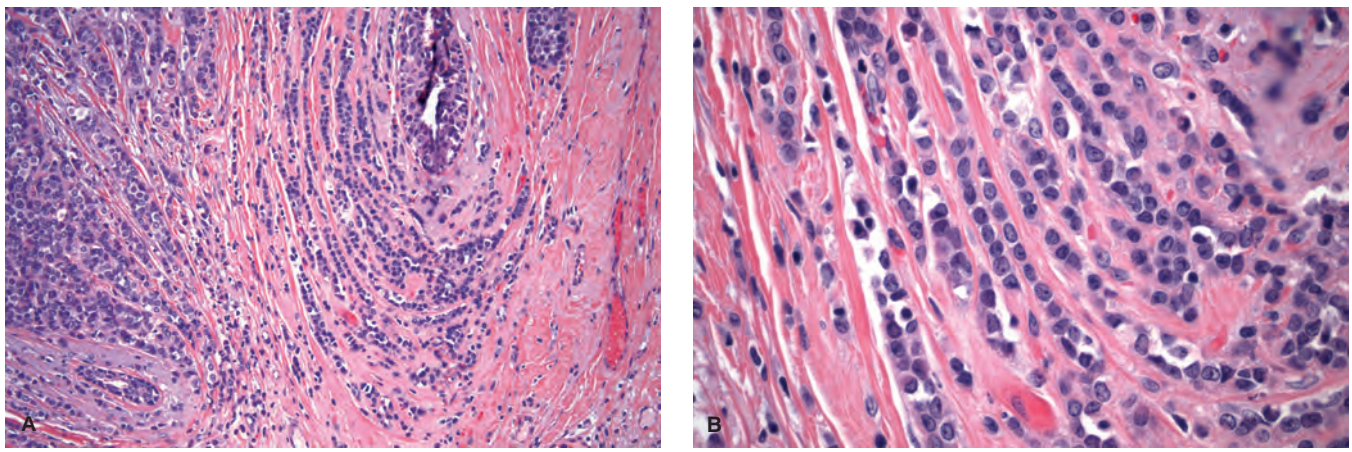

FIGURE 25-3 **Invasive lobular carcinoma, classic type. (A)** Linear strands of tumor cells infiltrate the stroma. **(B)** Higher-power view to demonstrate cytologic detail. The tumor cells have small, relatively uniform nuclei.

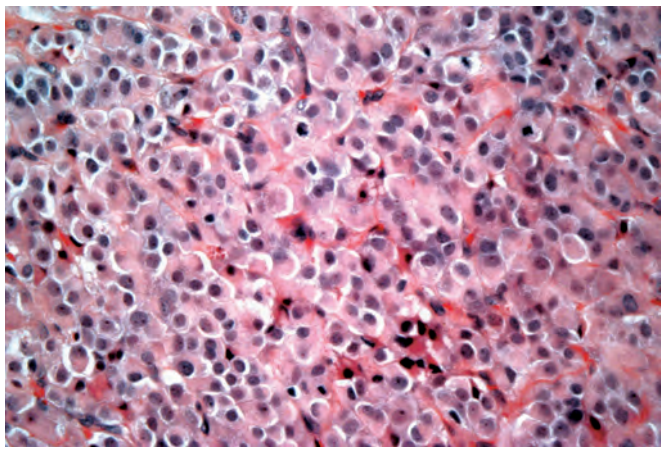

FIGURE 25-4 **Invasive lobular carcinoma, solid type.** The tumor cells grow in a confluent sheet with little intervening stroma.

stroma (Fig. 25-4). The *alveolar form* is characterized by tumor cells that grow in groups of 20 or more cells. These cellular aggregates are separated from one another by a delicate fibrovascular stroma (Fig. 25-5). Although a *trabecular variant* has also been described (10), there is considerable overlap between this pattern and that seen in the classical form of invasive lobular carcinoma. In the *pleomorphic variant,* the neoplastic cells are larger, exhibit more nuclear variation than that seen in the classical form, and may show apocrine features (13) (Fig. 25-6). Although signet ring cells can be seen in the classical type of invasive lobular carcinoma as well as in some examples of invasive ductal carcinoma, tumors that are composed of a prominent component of signet ring cells that otherwise have the characteristic features of invasive lobular carcinoma are considered to represent the *signet ring cell variant* of invasive lobular carcinoma (12). *Histiocytoid carcinoma* is an apocrine variant of invasive lobular carcinoma in which the tumor cells have a histiocyte-like appearance with abundant foamy pale eosinophilic cytoplasm and mild nuclear atypia (20). Some authors have recognized a "mixed" category of invasive lobular carcinoma. This term is generally used to designate lesions in which no single pattern comprises more than 80% to 85% of the lesion (21).

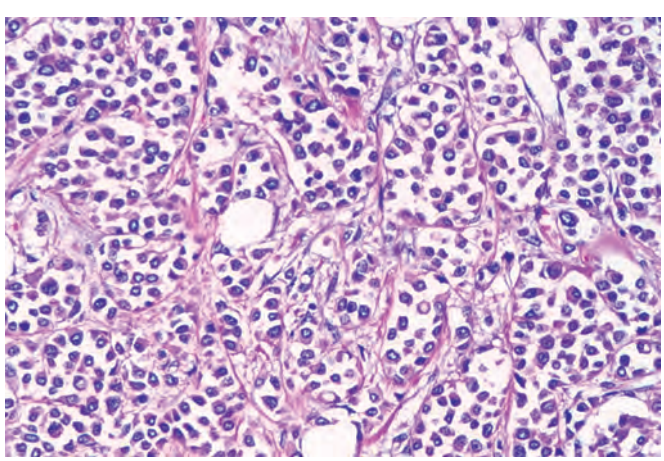

FIGURE 25-5 **Invasive lobular carcinoma, alveolar type.** Loosely cohesive tumor cell aggregates are separated by delicate fibrous septa.

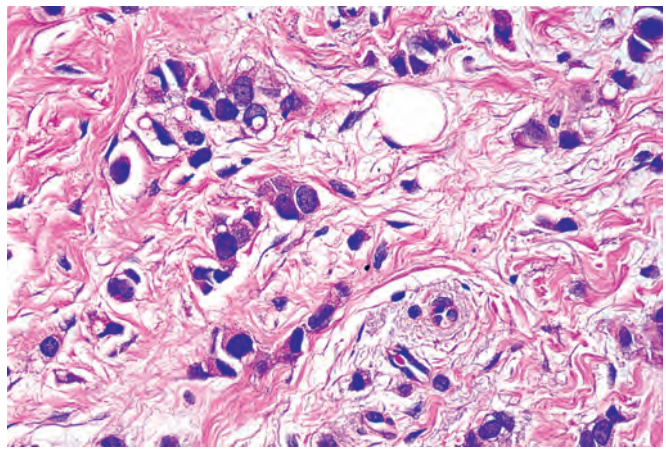

FIGURE 25-6 **Invasive lobular carcinoma, pleomorphic type.** The tumor cells infiltrate the stroma in linear strands, similar to those seen in the classic type of invasive lobular carcinoma. However, the cells in this lobular variant show considerable nuclear pleomorphism, in contrast to the small, monomorphic nuclei characteristic of the classic type of invasive lobular carcinoma (compare with Fig. 25-3B).

The relative frequency of the various lobular subtypes is difficult to discern since not all subtypes have been recognized in all series. In addition, patient selection criteria have varied among these studies. In the series of Dixon et al., among 103 invasive lobular carcinomas, 30% were of the classical type, 22% were solid, 19% were alveolar, and 29% were mixed lesions (15). In the experience of Ellis et al., 40% of invasive lobular carcinomas were of the classical type, 10% were solid type, 4% were alveolar, and 40% were mixed (6). In contrast, in a study from Memorial Sloan-Kettering Cancer Center, 176 of 230 invasive lobular carcinomas (77%) were of the classical type and the remainder were variants: 4% solid, 6% alveolar, and 13% mixed (16) (Table 25-3).

Biomarkers

Classical invasive lobular carcinomas typically show expression of estrogen and progesterone receptors and rarely show HER2 overexpression or amplification. Although pleomorphic lobular carcinomas are also frequently estrogen receptor and progesterone receptor positive, they may also show overexpression and amplification of HER2 (23). Gross cystic disease fluid protein 15 is seen in about one-third of all invasive lobular carcinomas, but is present in the vast majority of lesions that show prominent signet ring cell features (22).

In gene expression profiling studies, most invasive lobular carcinomas are classified as luminal A subtype; however, some cases fall within the luminal B, HER2 and basal-like groups (24). Chromosomal analysis shows characteristic loss of 16q and gain of material on 1q and 16p (18).

Clinical Course and Prognosis

There are several aspects of the clinical course of invasive lobular carcinomas that merit consideration. First, a number of studies have noted differences in the pattern of metastatic spread between invasive lobular and invasive ductal carcinomas. In particular, metastases to the lungs, liver, and brain parenchyma appear to be less common in patients with lobular than ductal cancers (25,26). In contrast, lobular carcinomas have a greater propensity to metastasize to the

TABLE 25-3

Frequency of Invasive Lobular Carcinoma Subtypes in Series with More Than 100 Patients

DiCostanzo et al. (16)	230	77	4	6	Not included	13

leptomeninges, peritoneal surfaces, retroperitoneum, gastrointestinal tract, and reproductive organs and bone (25). In fact, the majority of cases of carcinomatous meningitis in patients with metastatic breast cancer occur in patients with lobular cancers (98,26). Peritoneal metastases may appear as numerous small nodules studding the peritoneal surfaces in a manner similar to that seen in ovarian carcinoma (25,26). Metastases to the stomach can produce an appearance that simulates an infiltrative (linitis plastica) type of primary gastric carcinoma (27). Involvement of the uterus may result in vaginal bleeding (28), whereas metastatic tumor in the ovary may produce ovarian enlargement and the appearance of a Krukenberg tumor.

Whether or not invasive lobular carcinomas differ in overall prognosis from invasive ductal carcinomas is difficult to determine due in large part to variations in the application of histologic criteria for the diagnosis of invasive lobular carcinoma. However, the prognosis of patients with invasive lobular carcinoma as a group has not consistently been shown to differ from that of patients with invasive ductal carcinoma. Several studies have suggested that the prognosis for the classical form of invasive lobular carcinoma is better than variant types and than invasive ductal carcinomas (6,15,16). Available evidence suggests that the pleomorphic variant and the signet ring cell variant (when defined as lesions in which greater than 10% of the neoplastic cells are of the signet ring cell type) appear to be associated with a particularly poor clinical outcome (13).

Numerous clinical follow-up studies have indicated that patients with invasive lobular carcinoma can be adequately treated with conservative surgery and radiation therapy following complete gross excision of the tumor, with local recurrence rates comparable to those seen in patients with invasive ductal carcinoma (reviewed in reference 29).

INVASIVE CARCINOMAS WITH DUCTAL AND LOBULAR FEATURES

A small proportion of invasive breast cancers, up to 5% in most studies, are not readily classifiable as either ductal or lobular (6). Invasive cancers may be difficult to classify definitively as either ductal or lobular either because they show distinct features of both or have features that are indeterminate. Cancers that show distinct areas of invasive ductal carcinoma and invasive lobular carcinoma are best classified as mixed invasive ductal and invasive lobular carcinoma. *Tubulolobular carcinoma* is a distinctive type of low-grade invasive breast cancer that is E-cadherin positive but shows both ductal and lobular morphologic features. In this variant, some of the tumor cells invade the stroma in linear strands characteristic of the classical form of invasive lobular carcinoma whereas others form small tubules with round to ovoid contours. These tubules are smaller and less angulated than those seen in tubular carcinoma (see below). Some invasive cancers have both cytologic and architectural features that are intermediate between those of invasive ductal and invasive lobular carcinomas. Immunohistochemical staining for E-cadherin and cytokeratin 8 has been proposed as a useful adjunct in making the distinction between ductal and lobular carcinomas in histologically problematic or indeterminate cases (30). The fact that it may be difficult for the pathologist to categorize a given lesion as ductal or lobular in some cases should not be surprising in view of reports suggesting that some invasive ductal carcinomas exhibit cytogenetic alterations that are similar to those seen in invasive lobular carcinomas (18).

Given the heterogeneous nature of the lesions included in this group, data on clinical features and outcome of patients with invasive carcinomas with ductal and lobular features are difficult to interpret. However, these lesions do not appear to be distinctive in their rate of local recurrence or distant failure when compared with patients with invasive ductal or invasive lobular carcinomas.

TUBULAR CARCINOMA

Tubular carcinoma is a special type cancer that is associated with limited metastatic potential and an excellent prognosis. Prior to the widespread use of screening mammography, tubular carcinomas accounted for less than 4% of all breast cancers (31). However, these tumors account for a much higher proportion of cancers detected in mammographically screened populations.

Clinical Presentation

The mean age at presentation for patients with tubular carcinoma is in the early sixth decade (31,32). Historically, the majority of tubular carcinomas were detected as palpable lesions; however, the majority (60% to 70%) now present as nonpalpable mammographic abnormalities. Not infrequently, tubular carcinomas are discovered incidentally in biopsies performed for unrelated reasons. Rare examples of tubular carcinoma have been reported in men.

Mammographic abnormalities, in the absence of a palpable mass, have been reported in the majority (80%) of patients with tubular carcinomas; however, mammographically occult tubular carcinomas are not infrequent. When a mammographic abnormality is present, it is usually a mass lesion, occasionally associated with microcalcifications. The mass may be irregular, round, oval, or lobulated. The majority of tubular carcinomas have spiculated margins, and cannot be distinguished radiologically from infiltrating ductal carcinomas.

Gross Pathology

Tubular carcinomas are typically small, with an average diameter less than 1.0 cm in most series (32). Tubular carcinomas detected by screening mammography are typically smaller than palpable lesions. Grossly tubular carcinomas are firm, spiculated lesions that are indistinguishable from infiltrating ductal carcinomas.

Histopathology

Tubular carcinomas are characterized by a proliferation of well-formed glands or tubules formed by a single layer of epithelial cells without surrounding myoepithelial cells. These tubules tend to be ovoid in shape and have sharply angular contours with tapering ends, and open lumens. The cells comprising these tubules are characterized by low-grade nuclear features and are usually polarized toward the lumen, often exhibiting apical cytoplasmic "snouts" (Fig. 25-7). The stroma of tubular carcinomas usually has desmoplastic features, and prominent elastosis may be present. There is now general agreement that more than 90% of the tumor should exhibit this characteristic morphology to be categorized as a "pure" tubular carcinoma (1); however, the proportion required for this diagnosis in published studies has varied from 75% to 100%.

The majority of tubular carcinomas have an associated intraductal component. The DCIS seen in association with tubular carcinoma is usually of low nuclear grade, with cribriform and micropapillary patterns, and does not typically comprise a large proportion of the tumor mass. In addition, flat epithelial atypia may be found in the vicinity of tubular carcinomas (36). Lobular carcinoma *in situ* may also be observed in association with tubular carcinoma. The frequency of multifocality and multicentricity in tubular carcinoma is difficult to determine due to varying definitions and methods of specimen sampling employed by different investigators. In one report in which 17 mastectomy specimens with tubular carcinomas were examined using the Egan serial subgross method (37), Lagios et al. (33) found a 56% incidence of multicentricity, defined in that study as carcinoma of any type present 5 cm from the index lesion. This incidence was significantly greater than a control group comprised of mastectomy specimens containing breast cancers of other types (33).

Because these lesions are extremely well differentiated, several benign entities such as sclerosing adenosis, radial scars, complex sclerosing lesions, and microglandular adenosis may enter into the differential diagnosis. In such cases, the use of immunohistochemical stains may be necessary in order to arrive at the correct diagnosis.

Biomarkers

The expression of various biologic markers in tubular carcinomas generally reflects the well-differentiated nature and favorable prognosis associated with these lesions. Tubular carcinomas are strongly positive for estrogen receptor and usually positive for progesterone receptor. In addition, these lesions are almost always diploid, have a low proliferative rate and no HER2 overexpression or amplification (38). When compared to invasive carcinomas of no special type, tubular carcinomas exhibit fewer overall chromosomal changes, more often show losses of 16q and less often show losses of 17p (39). On gene expression profiling studies, tubular carcinomas fall into the luminal A category (24).

Clinical Course and Prognosis

The reported incidence of axillary lymph node metastases in patients with tubular carcinomas is up to 29% (31,32); however, there is considerable variation in the histologic definitions employed in these studies. A number of studies have shown an inverse relationship between the degree of tubular differentiation and the incidence of lymph node metastases (34). Nevertheless, even patients with "pure" tubular carcinomas (over 90% tubules) have nodal metastases in up to 15% of cases (35). However, as with other types of breast cancer, the size of the tumor strongly influences the likelihood of axillary metastases. Winchester reported that 67% of tubular carcinomas associated with nodal metastases were greater than the median size of 1.0 cm (35). The relative infrequency of nodal disease in patients with small tubular carcinomas has led some investigators to advocate abandoning axillary lymph node dissection in these patients.

With regard to survival, patients with tubular carcinoma have an excellent prognosis, equivalent in some series to age-matched women without breast cancer (40). In the randomized prospective NSABP-B06 trial, 1090 node-negative and 651 node-positive patients were classified with regard to histologic type, and the "favorable" category included 120 patients with tubular carcinoma (43). Both node-negative and node-positive patients in the "favorable" category

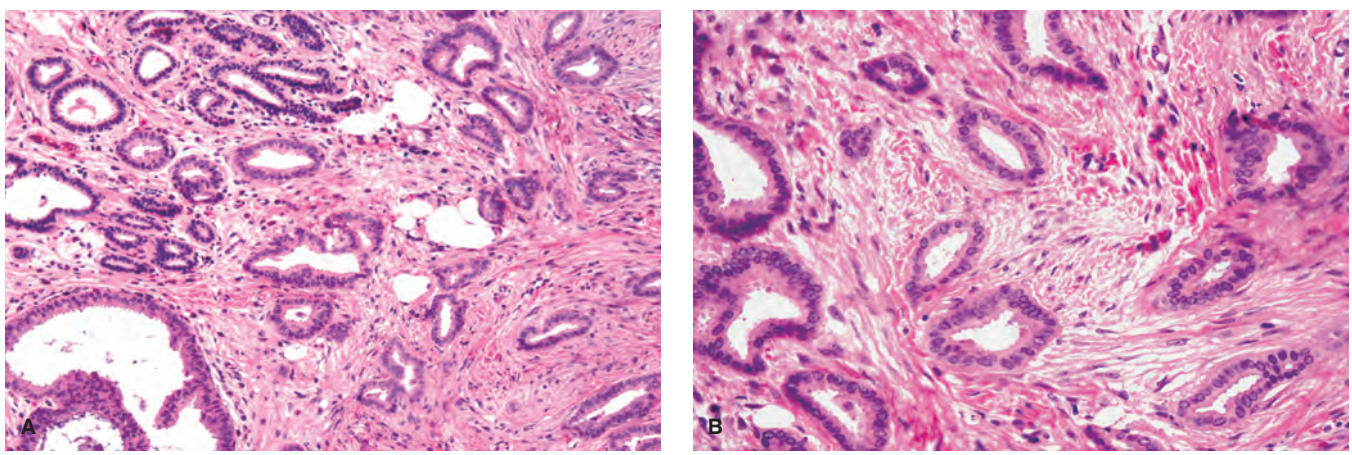

FIGURE 25-7 **Tubular carcinoma. (A)** This tumor is composed of well-formed glandular structures in a desmoplastic stroma. **(B)** The glands, or tubules, are elongated, and some have tapering ends. Numerous cytoplasmic "snouts" are evident at the luminal aspect of the tumor cells.

experienced significantly greater overall survival at 10 years compared to other patients in a univariate analysis, and "favorable" histology proved to be an independent predictor of survival in node-negative patients by multivariate analysis (43). Similar improved survival rates in patients with tubular carcinoma were reported in a series of 1,621 patients, although these patients were not stratified by node status (6). In this latter study, even patients with "tubular mixed" tumors (which were defined as stellate cancers composed of cells typical of invasive ductal carcinoma but with central tubules identical to tubular carcinoma) experienced significantly better overall survival compared to patients with invasive ductal carcinoma (6). In addition, two series, one examining node-negative early stage breast cancer patients treated with mastectomy, and the other examining early stage patients treated with breast-conserving therapy, both reported that patients with tubular carcinoma had significantly lower rates of distant recurrences compared to patients with invasive ductal carcinoma (41,42).

Other investigators have suggested that even patients with node-positive tubular carcinomas have a good prognosis. When tubular carcinoma does metastasize to axillary lymph nodes, usually one and seldom more than three nodes are involved. Several investigators have concluded that the presence of nodal disease in patients with tubular carcinoma does not affect disease-free or overall survival in these patients (35).

Reports examining the use of conservative surgery and radiation therapy in patients with tubular carcinoma show no significant differences in local recurrence rates when patients with tubular carcinomas are compared to patients with invasive ductal carcinoma (42). Although it is tempting to speculate that at least some patients with tubular carcinoma may be adequately treated with local excision alone (i.e., without radiation therapy), there are currently insufficient data to consider this a standard treatment option.

MUCINOUS CARCINOMA

Mucinous carcinoma (also known as colloid carcinoma) is another special type cancer that is associated with a relatively favorable prognosis. The reported incidence of mucinous carcinoma varies depending on the histologic criteria. Most studies have indicated that less than 5% of invasive breast carcinomas have a mucinous component and of these, less than half represent pure mucinous carcinomas (44).

Clinical Presentation

The mean age at presentation for patients with mucinous carcinoma is in the seventh or early eighth decade in most studies, and is greater than that for patients with breast cancers of no special type. Many patients with mucinous carcinoma present with palpable tumors. However, with widespread screening mammography, a substantial proportion (30% to 70%) present with nonpalpable mammographic abnormalities, most often poorly defined or lobulated mass lesions that are rarely associated with calcification (46). Wilson and coworkers reported that pure mucinous carcinomas were more often associated with a circumscribed, lobulated contour than the irregular borders characteristic of tumors with a mixture of mucinous and nonmucinous components (mixed mucinous tumors) (46). In addition, mammographically occult mucinous carcinomas are not infrequent.

Gross Pathology

Mucinous carcinomas average approximately 3 cm in size, with a wide range reported in the literature (47). Mucinous carcinomas have a distinctive gross appearance. These lesions are typically circumscribed and have a variably soft, gelatinous consistency, and a glistening cut surface. However, lesions with a greater amount of fibrous stroma may have a firmer consistency.

Histopathology

The hallmark of mucinous carcinomas is extracellular mucin production. However, the extent of extracellular mucin varies from tumor to tumor. Typically, tumor cells in small clusters are dispersed within pools of extracellular mucin (Fig. 25-8). This characteristic histology should comprise at least 90% of the tumor (or 100% according to some) (6) to qualify for the diagnosis of mucinous carcinoma. The cells comprising mucinous carcinomas are usually of low or intermediate nuclear grade. Mucinous neoplasms intermixed with other non-mucinous histologic features are classified as "mixed" mucinous tumors. The cellularity of mucinous carcinomas is variable, with some tumors being highly cellular (type B) and others relatively paucicellular (type A). For paucicellular type A mucinous carcinomas, the differential diagnosis may

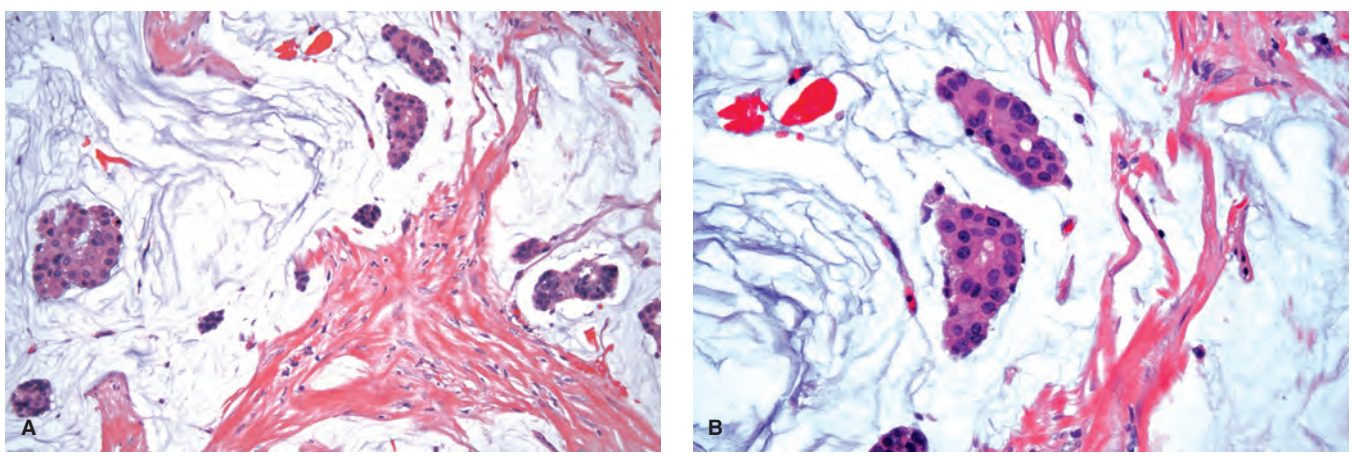

FIGURE 25-8 **Mucinous carcinoma. (A)** The tumor is composed of clusters of neoplastic cells dispersed in mucous pools. **(B)** In this specimen, the neoplastic cells have intermediate-grade nuclei.

include mucocele-like lesions, benign lesions characterized by cystically dilated ducts associated with rupture and extravasation of mucin into the stroma. Type B mucinous carcinomas may show endocrine differentiation, including immunoreactivity for chromogranin or synaptophysin (48). Mucinous carcinomas are often accompanied by a DCIS component which may have a papillary, micropapillary, cribriform, or solid pattern. In some cases, the DCIS may also exhibit prominent extracellular mucin production (47).

Biomarkers

The expression of various biological markers in mucinous carcinomas reflects the good prognosis associated with these lesions. Mucinous carcinomas are generally estrogen receptor positive. The majority of cases (about 70%) are also progesterone receptor positive. In addition, mucinous carcinomas usually do not overexpress the HER2 protein or show HER2 amplification (38). Mucinous carcinomas show relatively little genomic instability, with substantially fewer chromosomal gains and losses than invasive carcinomas of no special type (49). In gene expression studies, mucinous carcinomas generally cluster within the luminal A subtype. Type B mucinous carcinomas are distinct from type A mucinous carcinomas and cluster with other breast carcinomas showing neuroendocrine differentiation (50).

Clinical Course and Prognosis

Only 12% of patients presented with axillary lymph node metastasis in the SEER database review of over 11,000 patients with pure mucinous carcinoma (45). This is significantly less than the incidence of node positivity seen in mixed mucinous tumors or invasive breast cancers of no special type. Lymph node involvement is related to tumor size and is extremely rare in mucinous carcinomas measuring less than 1 cm (38).

With regard to survival, 38 patients with mucinous carcinoma were enrolled in the NSABP-B06 trial, and they experienced the same significantly increased survival as patients with tubular carcinoma, particularly in the node-negative group (43). Similar results were reported by Ellis and coworkers in their retrospective series; however, these patients were not stratified by nodal status (6). A report utilizing the SEER database compared 20-year survival data from 11,422 patients with mucinous carcinoma and patients with invasive ductal carcinoma diagnosed between 1973 and 2002 (45). Similar to the studies cited above, this report indicated that the patients with mucinous carcinoma present most often with localized disease (86%), with only 12% having regional lymph node involvement and 2% with distant metastases at the time of diagnosis. Although there were no significant differences in overall survival, survival at 10, 15, and 20 years for mucinous carcinoma was 89%, 85%, and 81%, respectively, compared with 72%, 66%, and 62% for invasive ductal carcinoma. The most significant prognostic factors in multivariate analyses were nodal status, then age, tumor size, progesterone receptor status, and nuclear grade (45). In addition, two series, one examining node-negative early stage breast cancer patients treated with mastectomy (with 20-year follow-up), and the other examining early stage patients treated with breast-conserving therapy (with 10-year follow-up), both reported that patients with mucinous carcinoma had significantly lower rates of distant recurrences compared to patients with invasive ductal carcinoma (41,42). Several studies have noted that a significant number of late recurrences are seen in patients with mucinous carcinoma, with one report documenting a recurrence 30 years after initial treatment (51).

Several studies have examined the use of conservative surgery and radiation therapy in patients with mucinous carcinoma, and report no significant differences in local recurrence rates compared to patients with invasive ductal carcinoma (42). Given the relatively good prognosis in patients with mucinous carcinoma, some authors have raised the question of whether radiation therapy can be safely omitted after breast-conserving surgery in patients with this tumor type; however, at this time, there are insufficient data on which to base such a recommendation.

Mucinous carcinomas have rarely been associated with unusual metastatic manifestations, including mucin embolism resulting in fatal cerebral infarcts and pseudomyxoma peritonei (52,53).

CARCINOMAS WITH MEDULLARY FEATURES

Classic medullary carcinomas are rare, accounting for less than 1% of all invasive breast cancers. Initial reports indicated that this type of breast cancer had a favorable prognosis despite its aggressive histologic appearance (54,55). However, there is considerable controversy regarding the appropriate histologic definition of medullary carcinoma, as well as the reproducibility of this diagnosis among pathologists. Carcinomas with some but not all of the features of medullary carcinoma have been called “atypical medullary carcinomas,” “invasive carcinomas with medullary features,” and “invasive ductal carcinomas with medullary features.” Given the difficulties in applying the criteria for medullary carcinoma reproducibly, the current WHO classification combines medullary carcinomas, atypical medullary carcinomas and invasive ductal carcinomas with medullary features into a single group designated “carcinomas with medullary features” (1).

Clinical Presentation

Patients with carcinomas with medullary features usually present at a younger age than patients with other breast cancers, owing, at least in part, to the inclusion in this group of patients with inherited *BRCA1* mutations. The majority of patients present with a palpable mass. Of interest, some patients with this tumor type exhibit axillary lymphadenopathy at the time of presentation with histologic examination of the lymph nodes showing only benign reactive changes (59). Rare examples of carcinoma with medullary features have been reported in males.

Most carcinomas with medullary features are associated with a moderately well-defined mass without calcifications (59); however, a significant proportion are associated with an ill-defined margin. Moreover, the majority of mammographically well-circumscribed cancers are infiltrating ductal carcinomas rather than medullary carcinomas (60). On ultrasound examination, medullary carcinomas are generally well-circumscribed, frequently lobulated, and hypoechoic (60).

Gross Pathology

The mean size of medullary carcinomas is similar to that of breast cancers of no special type (47). Grossly, these lesions are well circumscribed, soft, tan-brown to gray tumors that bulge above the cut surface of the specimen. A multinodular appearance may be appreciated in some cases. Areas of hemorrhage, necrosis, or cystic degeneration may be present in tumors of any size, but prominent necrosis is often seen in larger tumors.

Histopathology

Several similar but distinct classification systems for the histologic diagnosis of medullary carcinomas have been proposed (56–58). All three classification schemes recognize the following attributes, but the relative importance and the mandatory nature of each are stressed to a different degree: (i) syncytial growth pattern of the tumor cells in more than 75% of the tumor, (ii) admixed lymphoplasmacytic infiltrate, (iii) microscopic circumscription,(iv) grade 2 or 3 nuclei, and (v) absence of glandular differentiation (Fig. 25-9). Tumors that lack a variable number of these characteristics (depending on the system used) have been classified either as "atypical medullary carcinoma," or invasive ductal carcinoma.

Carcinomas with medullary features may show hemorrhage, tumor necrosis, cystic degeneration, and various types of metaplasia of the tumor cells, most often squamous metaplasia (47). Some tumors exhibit bizarre cytologic features with marked nuclear atypia and multinucleated tumor giant cells. There is usually little or no associated *in situ* carcinoma.

Biomarkers

Carcinomas with medullary features are typically estrogen receptor negative, progesterone receptor negative, and lack HER2 overexpression/amplification ("triple negative") and show a high proliferation rate. They often show a basal-like phenotype, with expression of basal cytokeratins (CK5/6, 14, and 17) and epidermal growth factor receptor (EGFR) and may have *TP53* mutations. Genomic instability is a characteristic feature of these lesions. Most breast cancers in women with germline *BRCA1* mutations show medullary features; however, only about 13% of cancers with medullary features are associated with germline *BRCA1* mutations (61). Many of the sporadic carcinomas show inactivation of *BRCA1* by somatic mutation or promoter hypermethylation (62).

Gene expression profiling studies have compared patterns of gene expression in 22 cancers diagnosed as medullary carcinoma with 44 high-grade invasive ductal carcinomas. Results of these studies showed that 95% of medullary carcinomas displayed a basal-like profile, similar to that seen in the basal group of invasive ductal carcinomas. Compared with the basal group of invasive ductal carcinomas, however, medullary carcinomas showed lower expression of genes involved in smooth muscle differentiation and greater expression of genes on 12p13 and 6p21, regions known to contain genes involved in pluripotency. Together, these findings suggest that carcinomas with medullary features represent a subset of basal-like breast cancers (63). Studies using array comparative genomic hybridization (CGH) have further clarified the similarities and differences between cancers diagnosed as medullary and other basal-like carcinomas. In one study, medullary carcinomas and other basal-like carcinomas were both characterized by 1q and 8q gains and X losses, with medullary carcinomas typically showing greater chromosomal instability and a wider spectrum of chromosomal gains and losses (64).

Clinical Course and Prognosis

Although studies have differed in the histologic criteria employed, most studies indicate that the incidence of axillary lymph node metastases is lower in patients with medullary carcinomas (19% to 46%) than in those with atypical medullary carcinomas (30% to 52%) or invasive ductal carcinomas with medullary features (29% to 65%) (56,57).

Data regarding survival rates in patients with medullary carcinoma and carcinomas with medullary features are difficult to interpret given the different classification systems employed and general lack of reproducibility. Although a number of earlier studies reported a more favorable prognosis for medullary carcinomas, this finding has not been confirmed in all studies. In addition, a number of studies have also questioned the practical applicability of the diagnostic criteria. Thus, although there may be patients with medullary carcinoma who have improved survival compared to patients with breast cancers of no special type, the ability of pathologists to reliably and reproducibly identify this subset of patients is limited at the current time. It is essential that clinicians be aware of these limitations when confronted with a pathology report suggesting the diagnosis of medullary carcinoma or carcinoma with medullary features. Recently, some studies have suggested that features of the associated inflammatory infiltrate may be important in the prognosis of both high-grade medullary-like and non-medullary-like carcinomas (65,66).

The results of the use of breast-conserving therapy in patients with medullary carcinoma have been reported in several studies (42) with no significant differences in local recurrence rates among patients with medullary carcinoma compared to patients with invasive ductal carcinoma. Thus,

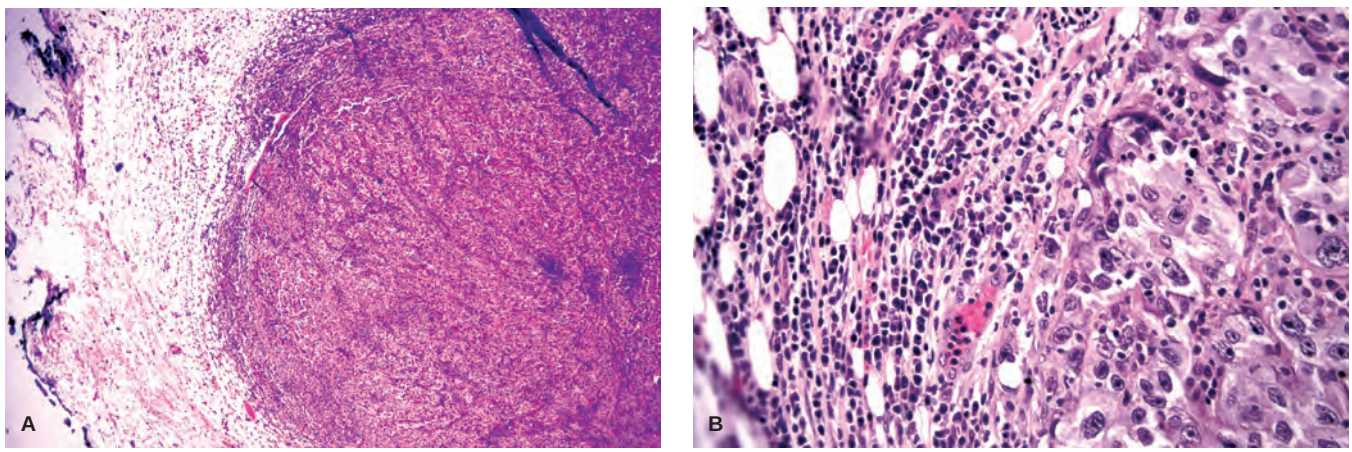

FIGURE 25-9 **Medullary carcinoma. (A)** Low-power photomicrograph demonstrating the well-circumscribed border of the tumor. **(B)** The tumor cells show high-grade nuclear features, and a prominent admixture of lymphocytes and plasma cells is seen.

the available data suggest that conservative surgery and radiation therapy is appropriate local treatment for patients with medullary carcinoma and carcinoma with medullary features.

INVASIVE CRIBRIFORM CARCINOMA

Invasive cribriform carcinoma is a well-differentiated cancer that shares some morphologic features with tubular carcinoma, and is also associated with a favorable prognosis. Invasive cribriform carcinoma accounts for 1% to 4% of invasive breast cancers (67).

Clinical Presentation

The majority of patients with invasive cribriform carcinoma present in the sixth decade (range 19 to 86 years) (67). Tumors may present as a palpable mass, but are often clinically occult and detected by mammography as spiculated masses with or without associated calcifications.

Gross Pathology

No distinctive gross features of invasive cribriform carcinoma have been described.

Histopathology

Invasive cribriform carcinomas are characterized by low- to intermediate-grade tumor cells that invade the stroma in a cribriform or fenestrated growth pattern similar to that seen in the cribriform pattern of DCIS (Fig. 25-10). These tumors often show admixtures of other histologic patterns of invasive breast cancer, particularly tubular carcinoma, which is seen in approximately 20% of cases. The "classic" variant of invasive cribriform carcinoma, described by Page et al. (67), is defined as a tumor composed of an exclusively invasive cribriform pattern, or a tumor with more than 50% invasive cribriform features in which the remainder of the tumor exhibits features of tubular carcinoma. Tumors with any component of nontubular carcinoma were described as "mixed" in that study. Most invasive cribriform carcinomas are associated with DCIS, usually of the cribriform type. The average size of these tumors is relatively large, 3.1 cm (range 1 to 14 cm) for the classical variant of cribriform carcinoma, to 4.2 cm (range 2 to 9 cm) for tumors of mixed histology (67).

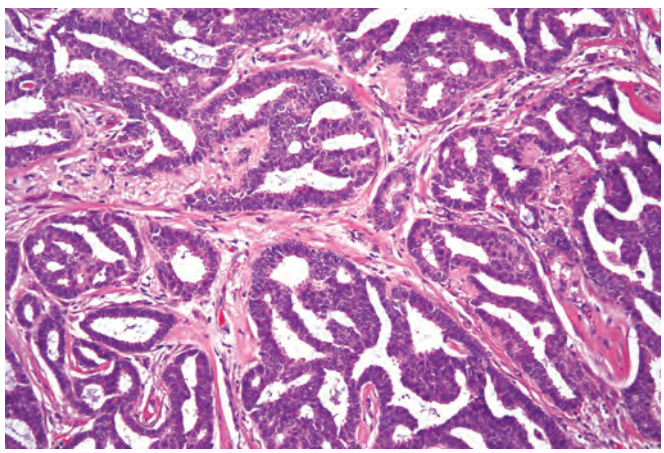

FIGURE 25-10 **Invasive cribriform carcinoma.** The tumor cells invade the stroma in nests that have a fenestrated growth pattern, similar to that seen in the cribriform pattern of ductal carcinoma *in situ*.

The main lesion to distinguish from invasive cribriform carcinoma is the cribriform pattern of DCIS. Invasive cribriform carcinoma ignores normal breast architecture and infiltrates between ducts and lobules, whereas DCIS maintains the normal ductal and lobular architecture. In contrast to cribriform DCIS, where the involved spaces have smooth, rounded contours, the infiltrating glands of invasive cribriform carcinoma often show irregular, sharp, and angulated borders. The stroma in invasive cribriform carcinoma tends to be desmoplastic compared to that associated with cribriform DCIS. Last, the main distinguishing feature is the lack of myoepithelial cells surrounding the glandular islands of invasive cribriform carcinoma, in contrast to their presence in cribriform DCIS. Immunohistochemistry for myoepithelial markers may be useful in distinguishing the two and in determining an accurate size for the invasive component. Also in the differential diagnosis is adenoid cystic carcinoma. Immunohistochemistry for myoepithelial markers can be helpful in documenting the dual epithelial/myoepithelial cell population characteristic of adenoid cystic carcinoma not present in invasive cribriform carcinoma.

Biomarkers

Invasive cribriform carcinomas are positive for estrogen receptor and most are also positive for progesterone receptor. These cancers typically show no overexpression or amplification of HER2. On gene expression profiling studies, invasive cribriform carcinomas fall into the luminal A subtype (24).

Clinical Course and Prognosis

In the series of Page et al. (67), none of the 35 lesions categorized as the classic variant of invasive cribriform carcinoma exhibited lymphatic/vascular space invasion, compared to 3 of 16 (19%) tumors with mixed histology. In that study, axillary lymph node metastases were seen in 14% of patients with classic cribriform carcinoma and 16% of patients with tumors of mixed histology (67). With a median follow-up interval of 14.5 years, Page et al. reported no deaths related to invasive cribriform carcinoma in patients with the classic variant (although one patient recurred in axillary and supraclavicular lymph nodes), but 38% (6 of 16) patients with tumors of mixed histology died of their disease (67). In general, patients with pure invasive cribriform carcinoma have a more favorable prognosis than do patients whose tumors show mixed histologic types (24,67). The excellent prognosis in invasive cribriform carcinoma was confirmed by Ellis and coworkers (6), who reported a 10-year survival of 91% in 13 patients, compared to a 47% 10-year survival for patients with invasive carcinoma of no special type.

INVASIVE PAPILLARY CARCINOMA

Invasive papillary carcinomas are extremely rare. Most published literature concerning papillary carcinomas of the breast includes both invasive and *in situ* papillary lesions. Although published series suggest that these tumors comprise from less than 1% to 2% of invasive breast cancers (68,69), in our experience true invasive papillary carcinomas are even more infrequent than this.

Clinical Presentation

Invasive papillary carcinomas are diagnosed predominantly in postmenopausal patients. Similar to medullary carcinomas, Fisher et al. noted that a significant proportion of patients with invasive papillary carcinoma exhibit axillary

lymphadenopathy suggestive of metastatic disease, but which on pathologic examination is due to benign reactive changes (68).

Mammographically, invasive papillary carcinoma is reportedly characterized by nodular densities which may be multiple, and are frequently lobulated (69,70). These reports should be interpreted with caution, however, as one study noted the difficulty in distinguishing between intracystic papillary carcinoma, intracystic papillary carcinoma with invasion, and invasive papillary carcinoma on imaging (70).

Gross Pathology

Fisher et al. reported that invasive papillary carcinoma is grossly circumscribed in two-thirds of cases (68). Other invasive papillary carcinomas are grossly indistinguishable from invasive breast cancers of no special type.

Histopathology

Of the 1,603 breast cancers reviewed in the NSABP-B04 study, 38 had papillary features, and all but 3 of these were "pure," without an admixture of other invasive histologic types. Microscopically, invasive papillary carcinomas are characteristically circumscribed, show delicate or blunt papillae, and show focal solid areas of tumor growth (Fig. 25-11). The cells typically show amphophilic cytoplasm, but may have apocrine features, and also may exhibit apical "snouting." The nuclei of tumor cells are typically intermediate grade and most tumors are histologic grade 2 (68). Tumor stroma is not abundant in most cases, and occasional cases show prominent extracellular mucin production. DCIS is present in more than 75% of cases, and usually, but not exclusively, has a papillary pattern and may be associated with microcalcifications.

In some lesions in which both the invasive and *in situ* components have papillary features, it may be difficult to determine the relative proportion of each without myoepithelial stains. Many encapsulated papillary carcinomas (also called intracystic papillary carcinomas) have been shown to have absent myoepithelium around the periphery. This finding raises the possibility that these are indolent invasive carcinomas with an expansile growth pattern. However, given their excellent outcome with local therapy alone, the current WHO classification recommends that encapsulated papillary carcinomas be staged and managed as *in situ* lesions (Tis), unless there are areas of frank invasion (1). Areas of invasive ductal carcinoma of no special type may be seen in association with encapsulated papillary carcinoma, solid papillary carcinoma or papillary DCIS. These invasive cancers should be classified according to their individual features and not as invasive papillary carcinoma.

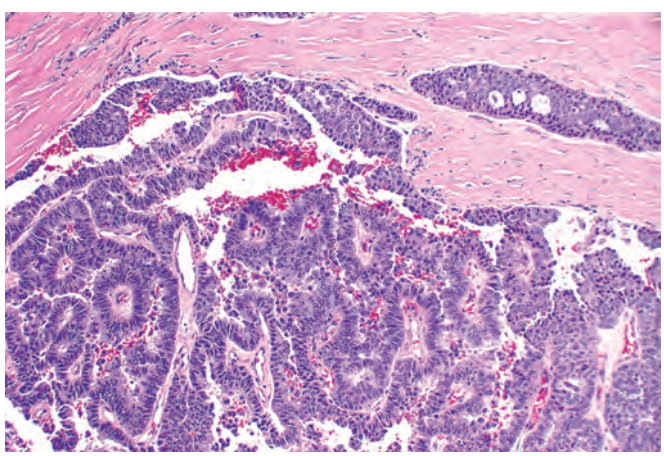

FIGURE 25-11 **Invasive papillary carcinoma.** The tumor cells are organized around fibrovascular cores.

Biomarkers

There is little information on expression of hormone receptors and HER2 in invasive papillary carcinoma; however, the small number of reported cases have been hormone receptor positive and HER2 negative. Based on the rarity of this tumor, metastasis from other sites, including ovary and lung, might be considered in the differential diagnosis, especially for lesions without an *in situ* component.

Clinical Course and Prognosis

There are limited data on the prognostic significance of invasive papillary carcinoma (43,68,71). Among 35 patients with this tumor in the NSABP-B04 trial, after 5 years median follow-up, there were only 3 treatment failures, including 1 patient who died from metastatic papillary carcinoma. These survival data were similar to those reported for patients with pure tubular and mucinous carcinomas in this study (68). A later publication updating the NSABP-B04 results at 15 years revealed that patients with "favorable" histology tumors (including invasive papillary carcinomas) still had significantly better survival in univariate analysis, but tumor histology was not an independent predictor of survival in multivariate analysis (71). However, node-negative patients with invasive papillary carcinomas enrolled in the NSABP-B06 trial experienced improved survival after 10 years follow-up compared to patients with carcinomas of no special type, and tumor histology was an independent predictor of survival in multivariate analysis (43).

INVASIVE MICROPAPILLARY CARCINOMA

Pure invasive micropapillary carcinoma comprises up to 2% of invasive carcinomas of the breast; however, foci of micropapillary carcinoma are more commonly seen mixed with other histologic types, most often invasive ductal carcinoma of no special type. Patients with invasive micropapillary carcinoma often present with axillary lymph node metastases and have a relatively poor prognosis (72–75).

Clinical Presentation

The mean age at presentation for patients with invasive micropapillary carcinoma is 54 to 62 years (72–75). Patients may present with a palpable mass or a mammographically detected lesion, similar to carcinomas of no special type.

Gross Pathology

No distinguishing gross features have been described. The median size was reported as 1.5 cm in one study (range 0.8 to 3 cm), and 4.9 cm in a second study (72,73). A more recent study of 80 cases reported a mean size of 2 cm (range 0.1 to 10 cm) (74). These sizes are significantly larger than invasive carcinomas of no special type (73).

Histopathology

These tumors are characterized by clusters of cells in a micropapillary or tubular-alveolar arrangement that appear to be suspended in a clear space. These micropapillary clusters, unlike true papillary lesions, lack fibrovascular cores (Fig. 25-12). The cell clusters characteristically

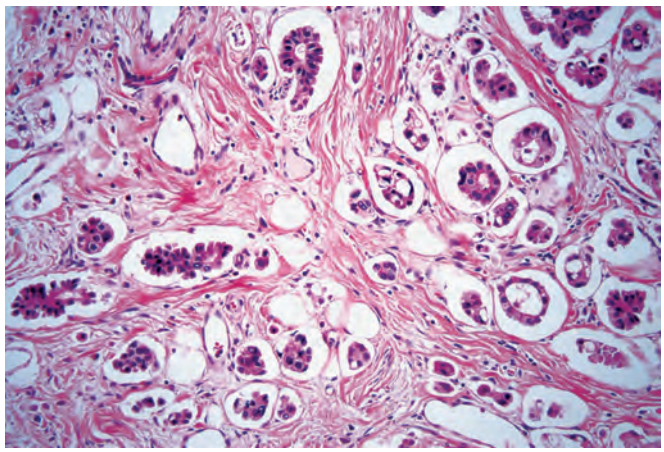

FIGURE 25-12 **Invasive micropapillary carcinoma.** Clusters of neoplastic cells, some forming glands, are present in clear spaces separated by fibrovascular tissue.

have an "inside-out" arrangement, with the apical surface polarized to the outside. This reverse polarity can be demonstrated using immunohistochemistry for epithelial membrane antigen (EMA). The overall appearance of invasive micropapillary carcinoma may mimic serous papillary carcinomas of the ovary, or may simulate lymphatic/vascular space invasion (72). True lymphatic/vascular space invasion has been reported in 33% to 67% of cases, and may be extensive (72–74). Cytologically, the cells comprising the invasive micropapillary carcinoma usually have low to intermediate grade nuclei. The majority of tumors (67% to 70%) are associated with a DCIS component with micropapillary and cribriform patterns (72,73). A minority of cases (33%) have shown calcifications histologically (72).

An invasive micropapillary component is found in approximately 6% of all breast carcinomas (75). However, this component usually makes up a small proportion of the overall tumor, involving less than 20% of the tumor mass in one study (75). In most reported cases, invasive micropapillary carcinomas have been admixed to a variable degree with invasive carcinomas of no special type or, in a minority of cases, with mucinous carcinoma. However, unlike other special type carcinomas, the prognostic implications appear to be the same whether the micropapillary component is present focally or diffusely within the tumor (73,75).

Biomarkers

The majority of invasive micropapillary carcinomas are estrogen receptor positive (72% to 75%), and about half are positive for progesterone receptor. HER2 protein overexpression is reported in up to a third of cases (76,77), with amplification being somewhat less frequent (10% to 30% of cases) (24,78). Immunohistochemical positivity with Wilm's Tumor Antigen 1 (WT-1) and PAX8 are rarely seen in breast cancer and can be useful in distinguishing metastatic micropapillary carcinoma of breast from papillary serous adenocarcinoma of the gynecologic tract in difficult cases.

Array CGH studies have shown recurrent gains of 8q, 17q, and 20q and deletions of 6q and 13q in both pure and mixed micropapillary carcinomas (79). Of interest, similar alterations have been found in both the micropapillary and nonmicropapillary areas in mixed micropapillary carcinomas (78,79). In gene expression profiling studies, invasive micropapillary carcinomas are usually classified as luminal A or luminal B subtype (24).

Clinical Course and Prognosis

In a study of 27 patients with pure invasive micropapillary carcinoma, axillary lymph node metastases were seen in all 27 patients, compared to 66% of patients with invasive carcinoma of no special type (73). Furthermore, four or more lymph nodes were involved in 82% of cases, and on average, nine lymph nodes were positive for metastatic carcinoma. Follow-up information was available for 12 patients, and of these, 6 died an average of 22 months after their initial treatment (73). In a different study of 80 cases of invasive micropapillary carcinoma, 47 (72%) of 65 cases with axillary lymph node dissections had positive lymph nodes (74). Another study that analyzed both pure and mixed invasive micropapillary carcinoma found axillary lymph node metastases present in 77% of cases. The metastases were typically multiple, with 51% of cases having 3 or more positive nodes (75). Importantly, these authors found no significant difference in lymph node status, ER status, tumor size, tumor grade, or lymphatic vascular invasion between tumors with predominant versus focal invasive micropapillary components. Interestingly, the clinical outcome of tumors with invasive micropapillary histology did not differ from infiltrating ductal carcinomas of similar stage and nodal status (75). These findings suggest that while carcinomas with an invasive micropapillary component typically present with higher-stage disease than patients with invasive carcinoma of no special type, when adjusted for stage, the prognosis of these two groups is similar.

METAPLASTIC CARCINOMA

Metaplastic carcinomas represent a morphologically heterogeneous group of invasive breast cancers in which a variable portion of the glandular epithelial cells comprising the tumor have undergone transformation into an alternate cell type—either a nonglandular epithelial cell type (e.g., squamous cell), a mesenchymal cell type (e.g., spindle cell, chondroid, osseous, or myoid), or both. There are numerous published reports describing various aspects of metaplastic carcinomas, and numerous appellations have been applied to the various tumors comprising this group. However, there is no uniformly agreed-upon classification scheme for these tumors. Metaplastic carcinomas are uncommon lesions, representing less than 5% of all breast cancers. The prognostic implications of metaplastic carcinomas are difficult to define, and may relate to some degree to the type of metaplasia present, as discussed below.

Clinical Presentation

Patients with metaplastic carcinoma are similar to patients with invasive carcinoma of no special type with regard to their age at presentation, the manner in which their tumors are detected, and the location within the breast in which these tumors arise (81,82). Most patients present with a single palpable lesion that not infrequently is associated with rapid growth of short duration (82). Skin fixation has been noted in 35% of patients and fixation to deep tissues in 23% of patients in one study (81).

The mammographic appearance of metaplastic carcinoma is not specific. Most are fairly circumscribed, noncalcified lesions, which in many cases appear benign (83). Some show both a circumscribed portion and a spiculated portion, which in one study correlated with the metaplastic and invasive epithelial components, respectively (83,84). Foci of osseous metaplasia may be detected mammographically in a subset of cases.

Gross Pathology

The gross appearance of metaplastic carcinomas is not distinctive, and these tumors can either be well circumscribed or show an indistinct or irregular border. Cystic degenerative changes are not infrequent, particularly in lesions with squamous differentiation. In general, metaplastic carcinomas tend to be relatively large tumors, compared to invasive carcinomas of no special type.

Histopathology

Microscopically, metaplastic carcinomas are highly distinctive, but vary in the types and extent of metaplastic changes. Although there is no universally accepted classification system, current WHO classification (1) includes five subtypes: metaplastic carcinoma with mesenchymal differentiation, spindle cell carcinoma, low-grade adenosquamous carcinoma, fibromatosis-like metaplastic carcinoma, and squamous cell carcinoma.

Metaplastic carcinoma with mesenchymal differentiation most commonly shows chondroid and osseous heterologous elements (Figs. 25-13 and 25-14). In these tumors, the cartilage and bone may appear histologically benign or frankly malignant, resembling chondrosarcoma and osteosarcoma, respectively. If the heterologous metaplastic component of a particular tumor predominates, the differential diagnosis will include a malignant phyllodes tumor with heterologous elements and stromal overgrowth, as well as a pure sarcoma, either primary or metastatic. The correct diagnosis in such cases may require extensive tissue sampling in order to demonstrate epithelial elements. In some cases, immunohistochemical staining for epithelial markers, such as cytokeratin, may be required for proper diagnosis. A panel of cytokeratin antibodies may be necessary, including broad-spectrum and high-molecular weight/basal cytokeratin antibodies, as keratin immunoreactivity may be only focal.

Spindle cell carcinomas may occur as purely spindle cell lesions or mixed with glandular, squamous or heterologous elements (Fig. 25-15). The spindle cells can vary from bland to highly pleomorphic and can show fascicular, fasciitis-like, storiform or haphazard growth patterns. The borders are typically infiltrating, with entrapped normal ducts and lobules. High-grade lesions may completely obliterate normal breast architecture. In areas, spindle cells may merge with areas that have a more epithelioid appearance. In mixed lesions, areas of invasive breast carcinoma not otherwise specified or DCIS can provide evidence of the epithelial nature of the lesion. However, in pure spindle cell tumors, immunohistochemical stains for keratin and other markers may be required for the correct diagnosis. Immunoreactivity for keratins may be only focal and use of a panel of cytokeratin antibodies may be necessary, including broad-spectrum and high-molecular weight/basal cytokeratin antibodies. Spindle cell carcinomas also commonly express markers associated with myoepithelial cells, including p63 and actins.

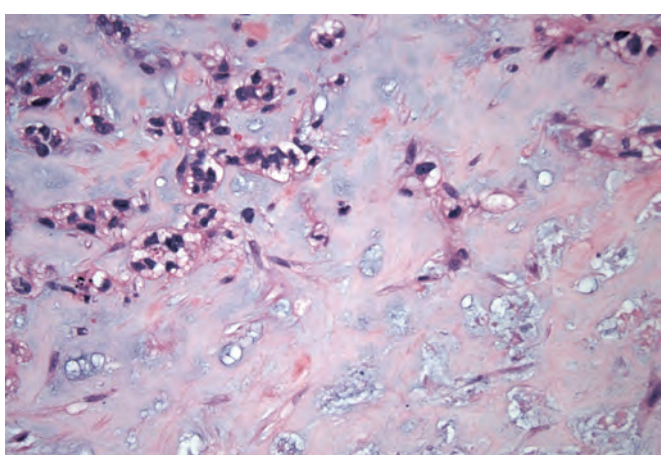

FIGURE 25-13 **Metaplastic carcinoma with chondroid metaplasia.** A small area of conventional invasive ductal carcinoma is present at the left side of this photomicrograph. The major portion of this tumor, however, is composed of neoplastic cells in a chondroid matrix.

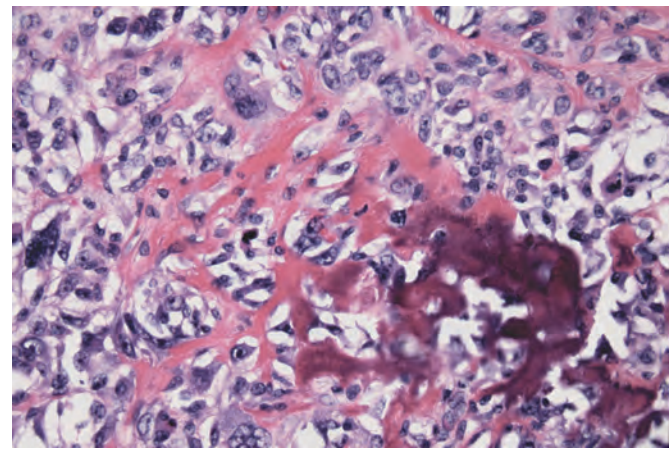

FIGURE 25-14 **Metaplastic carcinoma with osseous metaplasia.** Although some of this neoplasm shows features of invasive ductal carcinoma (left), foci of osteoid formation are evident.

Pure *squamous cell carcinoma* of the breast is rare; however, foci of squamous differentiation may be seen in invasive carcinomas of no special type and are commonly seen in carcinomas with medullary features. Pure squamous cell carcinoma of the breast often shows prominent cystic degeneration and may range from well to poorly differentiated. In well-differentiated cases, parts of the tumor may be composed of squamous epithelial-lined cysts resembling benign epidermal inclusion cysts. Spindle cell differentiation is commonly seen in association with squamous differentiation. In pure squamous cell lesions, the differential diagnosis should include spread from a squamous cell carcinoma at another site.

Low-grade adenosquamous carcinoma is an unusual subtype of metaplastic carcinoma that appears to represent a distinct clinicopathologic entity (86,87) (Fig. 25-16). These tumors may sometimes arise in association with a preexisting benign sclerosing process, such as a complex sclerosing lesion, sclerosing papilloma or adenomyoepithelioma (87). Low-grade adenosquamous carcinomas are typically smaller than other metaplastic carcinomas, with a median size between 2.0 and 2.8 cm (range 0.5 to 8.6 cm) (86,87). They exhibit a firm, yellow cut surface with irregular borders. Histologically, these tumors are well differentiated, show epidermoid differentiation, and often have a peculiar collagenized, lamellated stroma. Areas of squamous differentiation are present in most tumors, and are admixed with areas of glandular differentiation (Fig. 25-16). The glands often show elongated, compressed lumens, which may suggest syringomatous differentiation. Microcysts filled with

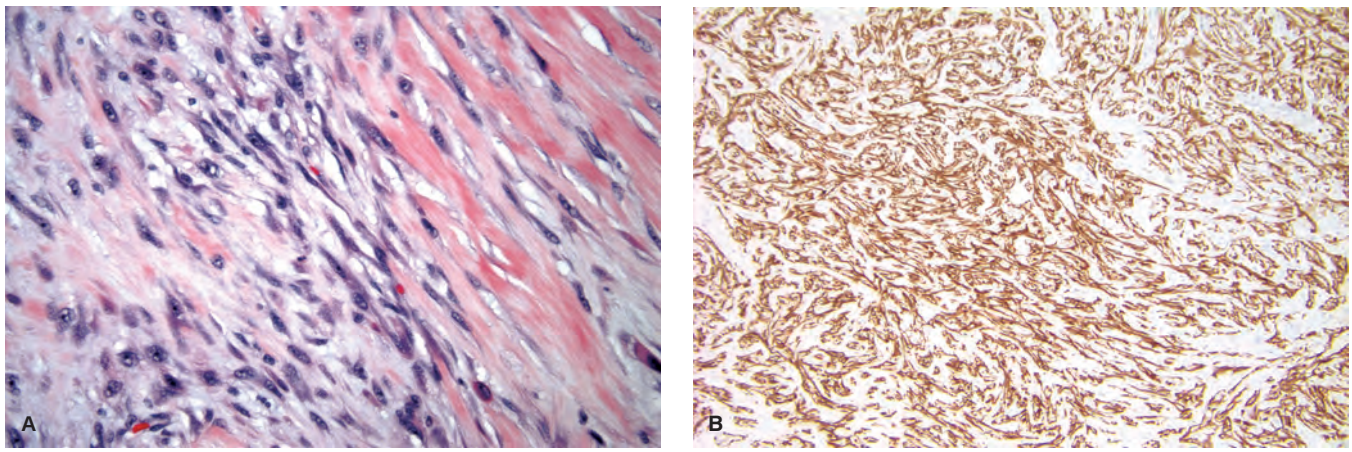

FIGURE 25-15 **Metaplastic carcinoma, spindle cell type. (A)** Hematoxylin and eosin-stained sections reveal interlacing fascicles of spindle cells without evidence of epithelial differentiation. **(B)** Immunoperoxidase stain for keratin reveals that most of the tumor cells show immunoreactivity for this protein, characteristic of cells with an epithelial phenotype.

keratinaceous material may be present. DCIS is usually not seen. Clusters of stromal lymphocytes may be present at the periphery of the lesion.

The differential diagnosis of low-grade adenosquamous carcinoma includes syringomatous adenoma of the nipple, reactive squamous metaplasia, and tubular carcinoma. These lesions may be locally aggressive, but have a relatively good prognosis when compared with other metaplastic carcinomas (86,87).

Fibromatosis-like metaplastic carcinoma is a low-grade metaplastic breast tumor composed of bland spindle cells that resemble those seen in fibromatosis (88). Unlike fibromatosis, the spindle cells in this lesion show expression of cytokeratin at least focally. Small foci of squamous differentiation or epithelioid cell clusters may also be present. These tumors may sometimes arise in association with a preexisting benign sclerosing process (87). This rare tumor is associated with a high rate of local recurrence (80). Regional and distant metastases have also been reported (88).

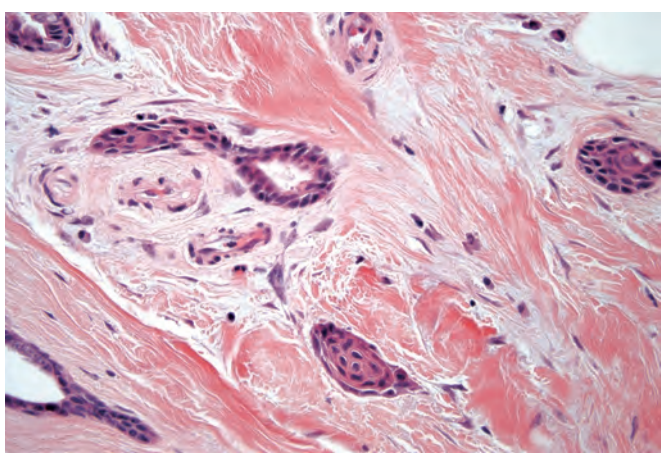

FIGURE 25-16 **Low-grade adenosquamous carcinoma.** The tumor shows foci of glandular and squamous differentiation. The neoplastic cells have low-grade nuclear features.

Biomarkers

Metaplastic carcinomas are typically negative for estrogen receptor, progesterone receptor, and HER2, regardless of the histologic subtype examined. Many show at least focal expression of basal cytokeratins (CK5/6, 14, and 17), EGFR, and p63. Some metaplastic carcinomas express myoepithelial markers, blurring the distinction between metaplastic carcinomas and myoepithelial carcinomas (see below). In gene expression studies, some metaplastic carcinomas cluster in the basal-like group and others in the claudin-low group (24).

Clonality in metaplastic carcinomas has been assessed using microdissection techniques and evaluation of loss of heterozygosity at multiple chromosomal loci (85). In one study, all six cases of metaplastic carcinoma demonstrated identical clonality of the epithelial and mesenchymal components, and the same clone was also identified in nearby DCIS in one case. The authors concluded that the mesenchymal component of these lesions arose from mutation of the epithelial component (85).

Clinical Course and Prognosis

The reported frequency of axillary lymph node metastases in patients with metaplastic carcinoma is lower than for patients with invasive carcinomas of no special type of equivalent size and grade (1). As with other triple-negative breast cancers, distant metastases, especially to lung and brain, may be seen even in the absence of axillary lymph node metastases. Metastatic lesions may either demonstrate an epithelial phenotype, the metaplastic phenotype, or both.

Survival data reported in various studies are difficult to compare due to the relatively small numbers of patients included in the studies, differences in tumor types, differences in treatment and follow-up intervals and the paucity of studies that stratify patients by stage. However, as a group, patients with metaplastic carcinomas appear to have a lower rate of response to chemotherapy and a poorer outcome than patients with other triple-negative breast carcinomas (89). At the present time, it is difficult to determine the prognostic significance of the presence or absence of specific metaplastic components. However, low-grade

adenosquamous carcinoma and low-grade fibromatosis-like metaplastic carcinoma both appear to have a relatively favorable prognosis (87,90).

CARCINOMAS WITH NEUROENDOCRINE FEATURES

Some invasive breast cancers show evidence of neuroendocrine differentiation at the morphologic level, histochemical level, immunohistochemical level, or some combination of these. In addition, in rare instances, breast carcinomas can secrete hormonal products that cause clinical symptoms.

Clinical Presentation

With the exception of the very rare functioning neuroendocrine tumor which results in clinical manifestations due to hormone production and secretion, carcinomas with neuroendocrine differentiation do not demonstrate unique clinical manifestations. In most studies, the median age of patients and the location in which these tumors arise in the breast are similar to those seen in invasive cancers of no special type. Distinctive mammographic or ultrasound characteristics of invasive carcinomas with neuroendocrine differentiation have not been reported.

Gross Pathology

Invasive carcinomas with neuroendocrine differentiation are not associated with distinctive gross characteristics and the reported mean size in most studies is similar to invasive cancers of no special type.

Histopathology

Carcinomas with neuroendocrine differentiation represent a heterogeneous group of neoplasms. This is related to the fact that "neuroendocrine differentiation" is defined differently in various studies. Many invasive carcinomas of no special type and some mucinous and solid papillary tumors show neuroendocrine differentiation by histochemical or immunohistochemical studies. Most reports refer to "argyrophilic" carcinomas, lesions that demonstrate distinctive granular material in the cytoplasm of tumor cells (argyrophilic granules) when stained with histochemical stains such as the Grimelius stain. Argyrophilic granules have been reported in up to half of all breast carcinomas, depending on methodology, interpretation and, possibly differences in patient selection (91). Argyrophilic carcinomas can be associated with a variety of histologic appearances, including tumors with no overt morphologic evidence of endocrine differentiation. Tumors with typical endocrine morphology may fail to demonstrate histochemical evidence of argyrophilia. Most tumors with morphologic evidence of neuroendocrine differentiation also demonstrate immunoreactivity for one or more specific neuroendocrine markers such as chromogranin or synaptophysin; however, many "argyrophilic" tumors are negative for these markers by immunohistochemistry (92). Therefore, argyrophilic carcinomas clearly represent a heterogeneous group of tumors, only some of which should be considered as showing true neuroendocrine differentiation.

In a study of neuroendocrine differentiation in a series of breast carcinomas using immunohistochemistry for neuron-specific enolase, chromogranin A and synaptophysin 11% of cases were positive for more than one endocrine marker (94). However, none of the tumors showed more than 50% tumor cells positive for the neuroendocrine markers and many cases had fewer than 5% of tumor cells positive. There was no significant association between neuroendocrine differentiation and tumor size, grade, or stage. In addition, overall or disease-free survival did not differ among patients with tumors with or without neuroendocrine differentiation (94).

Of tumors showing morphologic evidence of neuroendocrine differentiation by routine light microscopy, distinct morphologic subtypes have been recognized. Primary tumors that are morphologically indistinguishable from carcinoid tumors occurring elsewhere in the body comprise less than 1% of all breast cancers (Fig. 25-17) and are classified as neuroendocrine carcinoma, well differentiated, in the most recent WHO classification (1). These tumors must be distinguished from metastatic carcinoids, which occasionally involve the breast and may even initially present as breast masses (95). In some cases, the presence of DCIS in the region of the tumor can assist with this differential diagnosis. In equivocal cases, a clinical evaluation to rule out an alternate primary site may be required.

At the other end of the neuroendocrine spectrum are primary breast carcinomas which are indistinguishable from small-cell (oat-cell) carcinomas (neuroendocrine carcinoma, poorly differentiated/small-cell carcinoma in the most recent WHO classification 1) or large-cell neuroendocrine carcinomas in other sites (96). Again, these tumors must be distinguished from metastatic small cell or large cell neuroendocrine carcinoma involving the breast, and a clinical evaluation to rule out an alternate primary site, such as the lung, may be required (97).

Biomarkers

There is only limited information regarding the expression of biomarkers in invasive carcinomas with neuroendocrine differentiation. Small studies suggest that most tumors are positive for estrogen receptor and progesterone receptor (96) and negative for HER2 amplification or membrane overexpression (96). In gene expression profiling studies, ER-positive carcinomas with neuroendocrine differentiation cluster together with mucinous carcinomas in the luminal subtype (24).

Clinical Course and Prognosis

There appears to be no significant difference in the incidence of axillary lymph node metastases in patients with invasive carcinoma with neuroendocrine differentiation compared

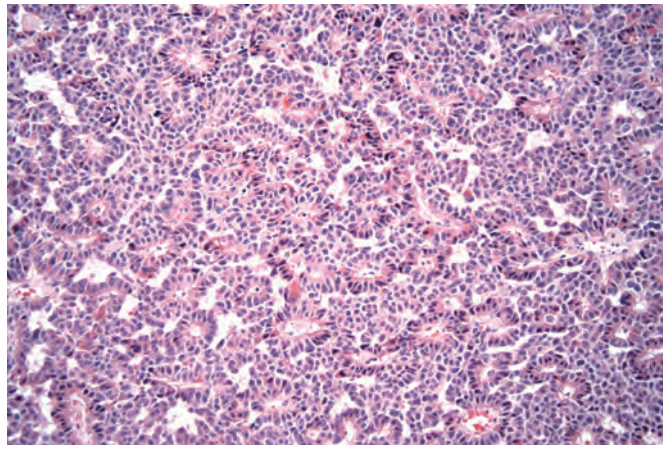

FIGURE 25-17 **Carcinoid tumor.** This tumor is composed of nests of cells that focally form acinar structures. The nuclei are small and uniform, and the cytoplasm is eosinophilic and granular. This histologic appearance is identical to that seen in carcinoid tumors in other sites.

with patients with invasive carcinoma of no special type. With regard to survival data, some of the retrospective reports provide limited follow-up data, but it is difficult to reach firm conclusions regarding the prognostic implications of endocrine differentiation in invasive breast cancer due to the relatively small numbers of patients included in the studies, differences in inclusion criteria, differences in treatment and follow-up intervals, the lack of appropriately matched control groups, and the lack of studies which stratify patients by stage. Nevertheless, with regard to patients with argyrophilic tumors and carcinoid tumors, the available data do not point to any difference in prognosis from that of patients with invasive cancers of no special type. On the other hand, as may be expected based on the behavior of small-cell carcinoma arising from other sites, most but not all reports indicate an aggressive clinical course in patients with primary small-cell carcinoma of the breast (95,96).

Small studies have examined the use of breast-conserving treatment for patients with neuroendocrine carcinomas. Three patients with node-negative carcinoid tumors were treated by excision alone and followed for 15 months to 7 years (93), and no recurrences were observed. In a recent study of 9 patients with small-cell carcinoma, 3 underwent mastectomy and 6 had breast-conserving therapy (lumpectomy) (96). Two of 9 patients developed metastases; all patients were alive at 3 to 35 months of follow-up. Firm conclusions cannot be drawn from these anecdotal data. Patients with invasive breast cancers with neuroendocrine differentiation should be treated in a manner appropriate to the size and stage of the lesion.

ADENOID CYSTIC CARCINOMA

Adenoid cystic carcinoma is a rare and morphologically distinct form of invasive carcinoma. These tumors comprise less than 0.1% of all breast cancers (1) and are associated with an excellent prognosis.

Clinical Presentation

The median age of patients with adenoid cystic carcinoma varies among studies, but is usually in the sixth or early seventh decade, with a wide age range reported. These tumors present as a palpable mass with the majority of lesions discovered in the subareolar or central region of the breast (98,99). These lesions are rarely multicentric and the incidence of contralateral breast cancers does not appear increased. Rarely, this tumor has been reported in males (99).

Mammographically, these tumors can appear as well-defined lobulated masses, ill-defined masses, or spiculated lesions (60). Some adenoid cystic carcinomas present with mammographic microcalcifications, whereas others are mammographically occult.

Gross Pathology

The reported size range of adenoid cystic carcinomas is broad. Grossly, these tumors are usually circumscribed and nodular; however, the microscopic extent of the lesion may be appreciably greater than the grossly evident lesion in 50% to 65% of cases (99).

Histopathology

Histologically, these tumors are similar to adenoid cystic carcinomas that arise in the salivary glands and are composed of epithelial cells with variable degrees of glandular, squamous, and sebaceous differentiation, myoepithelial/basaloid cells, and characteristic collections of acellular basement membrane material (Fig. 25-18). The epithelial component can assume variable architectural patterns including solid, cribriform, tubular, and trabecular configurations. A solid variant of adenoid cystic carcinoma in which the cells display prominent basaloid features has been described (100). Some of these patterns may raise the differential diagnosis of *in situ* or invasive cribriform carcinoma, or benign conditions such as collagenous spherulosis. Immunohistochemical studies have documented the presence of two cell populations. Cytokeratin 7-positive epithelial cells line true lumens with intact polarity in the glandular component. In addition, pseudolumens, containing myxoid or eosinophilic basement membrane material, are surrounded by cells positive for myoepithelial markers, such as p63, smooth muscle myosin heavy chain, calponin, and basal cytokeratins. Associated DCIS is seen in a minority of cases. Perineural invasion is also seen in some cases and may be prominent. Lymphatic vessel invasion is only rarely identified.

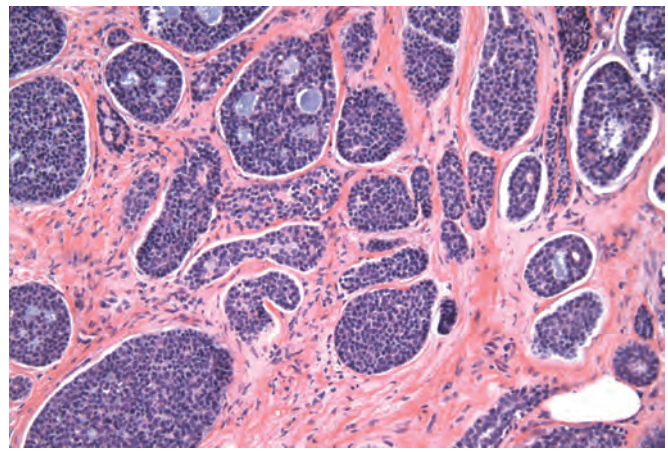

FIGURE 25-18 **Adenoid cystic carcinoma.** In this specimen, the invasive tumor cells grow in a cribriform pattern. Intraluminal aggregates of basement membrane material are present.

Biomarkers

Adenoid cystic carcinomas are usually estrogen and progesterone receptor negative and lack HER2 overexpression/amplification. Expression of KIT protein is characteristic, but not specific for, adenoid cystic carcinomas. Similar to salivary gland adenoid cystic carcinomas, these tumors are also characterized by a recurrent t(6;9) translocation (q22-23; p23-24) that results in the MYB-NFIB fusion transcript (101). These cancers cluster in the basal-like group on gene expression profiling studies (24).

Clinical Course and Prognosis

Patients with adenoid cystic carcinoma have an excellent prognosis. Only rare instances of axillary lymph node metastases have been reported (98). Based on a small number of cases, there is some evidence to suggest that the solid variant of adenoid cystic carcinoma with basaloid features may have a greater incidence of lymph node metastases (100). Distant metastases are also infrequent (98,100), and death due to adenoid cystic carcinoma is exceedingly rare (98). Some investigators have proposed using the histologic grading system employed for adenoid cystic carcinomas of salivary glands and have reported that the grading

system provided prognostically useful information (98). The prognostic utility of this grading system, however, has been disputed (99).

There are only sporadic reports of breast-conserving treatment for patients with adenoid cystic carcinoma. While local recurrences following excision alone have been described (98,99), details regarding microscopic margin status are rarely provided. At the present time treatment of patients with adenoid cystic carcinoma should follow the same guidelines as those of other invasive breast cancers.

CARCINOMAS WITH APOCRINE DIFFERENTIATION

Although many invasive breast cancers of various types show some evidence of apocrine differentiation, extensive apocrine differentiation throughout the tumor is less frequent, reported in up to 4% of invasive breast carcinomas (1). While the morphologic features of these tumors are distinctive, available evidence suggests that patients with these tumors have the same prognosis as patients with invasive breast cancers of no special type.

Clinical Presentation

Patients with apocrine carcinomas are similar in age and mode of presentation to patients with invasive carcinoma of no special type, with the exception of one report in which 7 of 34 patients (21%) demonstrated skin involvement by tumor (102). Only rare examples of apocrine carcinoma have been reported in males. There is a low reported incidence of multifocal lesions and contralateral tumors.

The mammographic characteristics of apocrine carcinomas are not distinctive (60). Most tumors present as masses with ill-defined margins, and microcalcifications are infrequent. In addition, the ultrasound findings associated with these tumors are nonspecific (60).

Gross Pathology

No distinctive gross findings are associated with apocrine carcinoma, and the size distribution is similar to invasive carcinomas of no special type.

Histopathology

In contrast, the histologic features of apocrine carcinoma are highly distinctive. The invasive patterns are usually those seen in invasive ductal carcinoma, but in some cases, lesions with apocrine cytology can exhibit a pattern of invasion more characteristic of invasive lobular carcinomas. One variant with a distinctive discohesive and diffusely infiltrative pattern has been designated as having "myoblastoid" or "histiocytoid" features (20), and in some cases this lesion may mimic a granular cell tumor. Cytologically, the tumor cells have cytoplasm that is abundant and eosinophilic, with obvious granularity in some cases. The nuclei vary in grade, but typically show prominent nucleoli (Fig. 25-19). There is frequently associated DCIS that may have apocrine features.

Biomarkers

Apocrine carcinomas are typically estrogen receptor negative and progesterone receptor negative. They characteristically show immunoreactivity for gross cystic disease fluid protein 15 (22) and androgen receptor (103). HER2 overexpression and amplification are also commonly seen. In one recent study, 88% of HER2-positive tumors showed apocrine features (104). In gene expression profiling studies, about half of these cancers show a "molecular apocrine" signature, with the remainder of cases clustering with the luminal or HER2 subtypes (24). These data support the notion that carcinomas with apocrine differentiation do not represent a distinct entity (1).

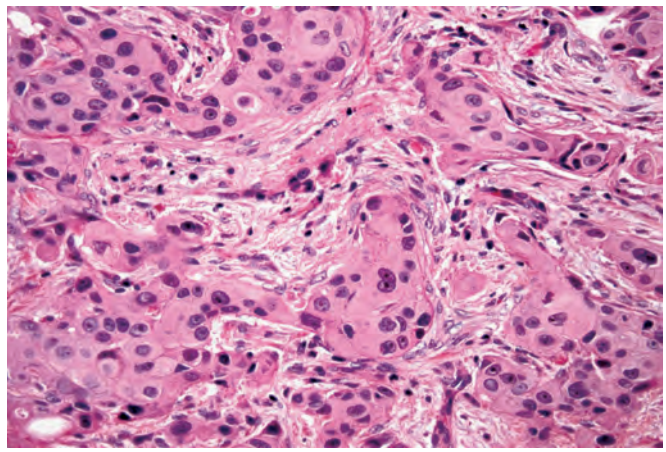

FIGURE 25-19 **Apocrine carcinoma.** The tumor cells show abundant eosinophilic granular cytoplasm.

Clinical Course and Prognosis

Patients with apocrine carcinoma do not appear to have a significantly different incidence of axillary lymph node involvement at presentation compared with patients with invasive carcinoma of no special type. Furthermore, a number of studies have compared patients with apocrine carcinoma with control patients with invasive carcinomas of no special type, matched for stage, and no appreciable differences in disease-free or overall survival have been observed (102). These observations have led some to conclude that apocrine carcinomas are more a morphologic curiosity than a distinct clinicopathologic entity. On the other hand, the presence of androgen receptor in many of these cases suggests an alternate therapeutic strategy for at least some of these cancers (103).

SECRETORY CARCINOMA

Secretory carcinoma is a rare low-grade invasive breast carcinoma that accounts for less than 0.1% of all breast cancers (1). Although secretory carcinomas occur over a wide age range, they account for a substantial number of primary breast cancers diagnosed in childhood, and thus have also been referred to as "juvenile breast carcinoma." In most cases, secretory carcinomas are associated with an indolent clinical course.

Clinical Presentation

Secretory carcinomas present over a wide age range (3 to 73 years) with a median age in the third decade (1). The majority of reported cases have been in females, but rare cases have occurred in males including several examples in association with gynecomastia. Most lesions are detected as palpable masses. These can arise anywhere in the breast but are most commonly subareolar. No association has been documented with underlying medical conditions or hormonal abnormalities. In addition, no increased incidence of a positive family history of breast cancer has been reported

in patients with secretory carcinoma. Only rare cases have been reported to be multicentric, and there does not appear to be an increased incidence of contralateral breast cancer in these patients.

Mammographic abnormalities associated with secretory carcinoma in adults have not been described in detail. On ultrasound examination, these lesions sometimes appear as hypoechoic lesions with heterogeneous internal echo texture and posterior acoustic enhancement, similar to a fibroadenoma (60).

Gross Pathology

Secretory carcinomas are typically grossly well circumscribed. A broad size range has been reported, with a median size of 3 cm noted in one relatively large series (105).

Histopathology

Histologically, these lesions are characterized by a proliferation of relatively low-grade tumor cells that form glandular structures and microcystic spaces filled with a vacuolated, lightly eosinophilic secretion that is periodic acid Schiff-positive, diastase-resistant (Fig. 25-20). The tumor cells have abundant eosinophilic or clear cytoplasm. Nuclei typically show little pleomorphism and few mitoses. DCIS is frequently present in association with the invasive component, and can be of the solid, cribriform, or papillary patterns, most often with low-grade nuclear features. The tumor border is typically well circumscribed, but may be infiltrative.

Biomarkers

Of the small number of cases that have been evaluated, most appear to be estrogen receptor, progesterone receptor, and HER2 negative (106). Secretory carcinomas are characterized by a balanced translocation t(12;15), creating a *ETV6-NTRK3* gene fusion encoding a chimeric tyrosine kinase (107). In gene profiling studies, secretory carcinomas cluster with the basal-like subtype (24).

Clinical Course and Prognosis

The majority of patients with secretory carcinoma have stage I disease and an indolent clinical course. Nevertheless, approximately one-quarter to one-third of the reported cases of secretory carcinomas have been associated with axillary lymph node metastases, and this ratio holds true in both younger and older age groups (105). The vast majority of axillary metastases involve three lymph nodes or fewer.

Limited clinical follow-up data are available, but the prognosis for secretory carcinomas appears favorable, particularly in children and young adults (1). However, late recurrences in the breast (105) and chest wall (108) have been reported in older patients.

Distant metastases are rare, but do occur in patients with secretory carcinoma and have resulted in patient deaths in rare instances (105). Neither the efficacy of conservative surgery and radiation therapy nor the role of adjuvant chemotherapy in patients with secretory carcinoma has been defined.

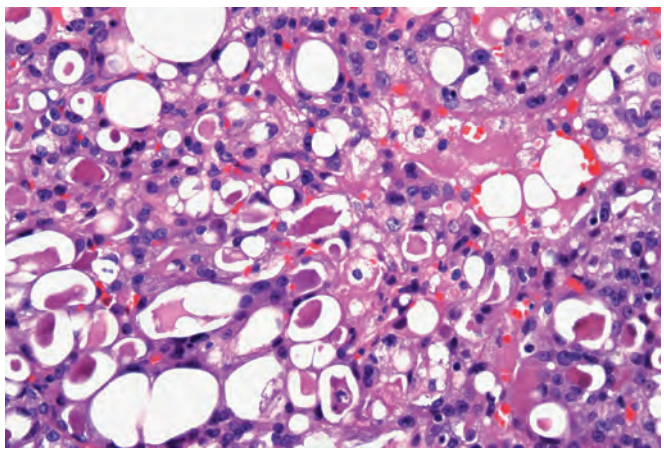

FIGURE 25-20 **Secretory carcinoma.** The tumor cells form glandular spaces, many of which contain eosinophilic secretions.

MISCELLANEOUS RARE INVASIVE BREAST CANCERS

Invasive Carcinoma with Osteoclast-Like Giant Cells

Invasive carcinoma with osteoclast-like giant cells is characterized by an invasive epithelial component with admixed giant cells that morphologically resemble osteoclasts and have the phenotypic features of histiocytes on immunohistochemical and ultrastructural analysis. The clinical features of patients with these tumors and their location within the breast are similar to patients with invasive carcinomas of no special type. Invasive carcinoma with osteoclast-like giant cells is associated with a benign appearance both mammographically (109) and grossly, due to the presence of circumscribed borders. On macroscopic examination, these lesions are typically circumscribed, fleshy, and brown in color due to recent and remote hemorrhage and benign vascular proliferation. Hemorrhage and hemosiderin deposition are characteristic features. The epithelial component of the tumor is usually moderately to poorly differentiated invasive ductal carcinoma (Fig. 25-21), but osteoclast-like giant cells have also been reported in invasive lobular carcinomas and most other special type cancers (110). The giant-cell component can be, but is not invariably present in metastatic lesions (110). Although the prognostic significance of the giant-cell component is not know with certainty, available evidence

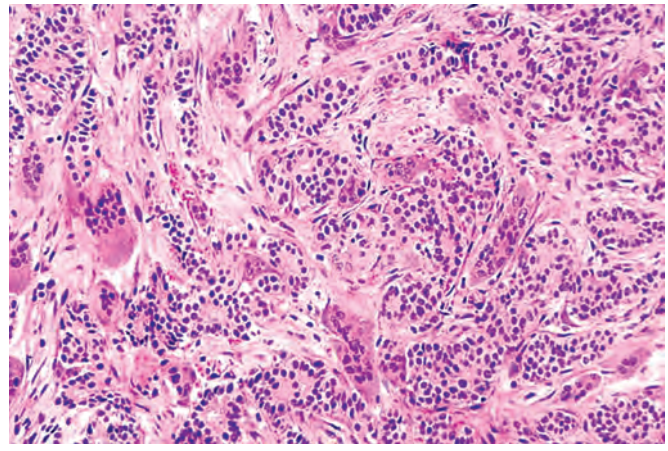

FIGURE 25-21 **Invasive carcinoma with osteoclast-like giant cells.** The epithelial component of this tumor forms solid nests and glands and has low-grade nuclear features. Numerous multinucleated giant cells resembling osteoclasts are admixed with the neoplastic epithelial cells.

suggests that these tumors do not appear to be any more or less aggressive than breast cancers of no special type and that the prognosis is related to the characteristics of the associated carcinoma.

Invasive Carcinoma with Choriocarcinomatous Features

Invasive carcinoma with choriocarcinomatous features is an exceedingly rare form of breast cancer. Only two reports have described the presence of choriocarcinomatous elements (i.e., trophoblastic differentiation) admixed with conventional breast carcinomas (111,112). The choriocarcinomatous component was associated with invasive ductal carcinoma in one case (111) and metastatic mucinous carcinoma in the second (112). The choriocarcinomatous elements in these tumors produce human chorionic gonadotropin (111). If choriocarcinomatous features are encountered in a breast tumor, the differential diagnosis should include choriocarcinoma metastatic to the breast, as several such cases have been reported.

Lipid-Rich and Glycogen-Rich Carcinomas

Variable amounts of lipid and/or glycogen are commonly present in the cytoplasm of breast cancer cells. However, a small proportion of breast carcinomas are characterized by tumor cells that contain abundant lipid or abundant glycogen within their cytoplasm. These lesions have been termed *lipid-rich carcinomas* and *glycogen-rich carcinomas*, respectively. On routine light microscopy the tumor cells comprising these lesions show vacuolated, clear cell cytoplasmic features, due to the fact that the lipid and glycogen are dissolved during tissue processing. However, neither lipid-rich nor glycogen-rich carcinomas appear to be distinct clinicopathologic entities and the importance of recognizing these lesions lies in the fact that they may mimic other forms of malignancy, particularly metastatic renal-cell carcinoma (1).

Mucinous Cystadenocarcinoma

Mucinous cystadenocarcinoma is a rare variant of invasive breast carcinoma that is morphologically indistinguishable from mucinous cystadenocarcinoma of the ovary or pancreas (113). Although these tumors may be associated with the extravasation of mucin, they are otherwise morphologically distinct from conventional mucinous carcinoma of the breast. The importance of recognizing these tumors is that they must be distinguished from metastatic lesions in the breast, particularly those of ovarian origin. The prognostic significance of primary mucinous cystadenocarcinoma of the breast is currently unknown.

Carcinoma of the Male Breast

Carcinoma of the breast in men arises at a later age than in women and is approximately 100 times less frequent than carcinoma of the female breast. It is more common in certain parts of the world such as Egypt, where it is related to chronic liver disease secondary to schistosomiasis. Hormonal factors play a less important role than in breast cancer in women, with radiation exposure and genetic factors being more important (114). An association has also been noted with Klinefelter syndrome (118) and prostate cancer. The association with prostate cancer is difficult to evaluate because of both the use of estrogens to treat prostate cancer (119) and the likelihood of prostate cancer to metastasize to the breast, where it may be confused with primary breast cancer (120).

A significant proportion of men with breast cancer have a positive family history, many being associated with germline mutations in *BRCA2* and a smaller number with germline mutations in *BRCA1* (115). In a recent study of 382 male breast cancers using immunohistochemical profiles four molecular subtypes were represented, luminal A being the most common (68%), luminal B (27%), triple negative (4%), and HER2-positive (2%) (116).

Breast cancer in men tends to present at higher stage than in women. Ulceration of the overlying skin is common. Infiltrating ductal carcinoma is the most common histologic type followed by papillary carcinoma; however, all histologic types of carcinoma have been reported. Although the prognosis of male breast cancer is reported to be poorer than that of breast cancer in females, this appears largely related to more advanced disease stage at presentation. When adjusted for tumor grade and stage, prognosis appears to be similar for males and females (117). Male breast cancers are usually estrogen and progesterone receptor positive and most are also positive for androgen receptor. HER2-positive cancers have been reported in men, but appear to be less common than in women. Treatment in most reported series has been radical mastectomy with adjuvant radiotherapy and chemotherapy.

EXTRAMAMMARY MALIGNANCIES METASTATIC TO THE BREAST

There are numerous reports of metastatic tumors involving the breast. Secondary tumor deposits in the breast may emanate from the contralateral breast or from virtually any nonmammary site. In one series, metastases to the breast from nonmammary malignancies comprised 1.2% of all malignancies diagnosed in the breast (97). Because many nonmammary malignancies can mimic the features of usual or unusual types of primary breast tumors, it can be very difficult to distinguish between the two in a subset of cases, particularly when there is no history of a prior nonmammary malignancy. Nevertheless, this distinction is critical for appropriate patient management.

Metastatic lesions involving the breast almost never occur in the absence of metastases to other sites, even when the breast metastasis is the first clinically detected site. When metastases are detected in the breast, a solitary unilateral lesion is present in 85% of cases; multiple lesions are present in 10% of cases, and diffuse involvement of the breast occurs in 5% of cases (121). The presence of tumor in ipsilateral axillary lymph nodes does not necessarily imply that the malignancy is a primary breast tumor, as metastatic deposits simultaneously involving the breast and axillary lymph nodes are not infrequent (121).

Although metastatic lesions in the breast can mimic the mammographic appearance of primary breast cancers, they are more likely to be multiple, bilateral, and exhibit well-defined margins without evidence of spiculation (60,121). Mammographic microcalcifications associated with metastatic lesions are rare, but have been reported in association with metastatic ovarian tumors. On ultrasound examination, metastatic tumors involving the breast are usually round or ovoid masses with some degree of lobulation, and variable internal echoes (60).

Metastatic tumors to the breast have a variable gross appearance, depending on the type of metastasis. In general, however, these lesions may be single or multiple, and are generally well demarcated from the surrounding breast parenchyma. The histologic and cytologic appearance of these neoplasms is related to the site of origin of the primary

tumor. Metastatic lesions most frequently described in the breast include malignant melanoma (97,121), lung carcinoma (97,121), carcinoid tumors from a variety of primary sites (95), and prostate carcinoma in men (120). Less frequent metastases to the breast include ovarian carcinoma, gastric carcinoma, renal cell carcinoma, thyroid carcinoma, various malignant tumors from the head and neck, various types of sarcoma, colorectal carcinoma, medulloblastoma, neuroblastoma, malignant mesothelioma, carcinoma of the urinary bladder, endometrial carcinoma, cervical carcinoma, chloroma, and choriocarcinoma (1).

To a variable degree, the histologic features of many of the aforementioned tumors may mimic a primary breast carcinoma. Therefore it is important that the pathologist consider the possibility of metastasis in cases with unusual clinical, mammographic, or pathologic features. It is also imperative that any relevant information (such as a history of prior malignancy or simultaneous unexplained masses occurring elsewhere) is conveyed to the pathologist. If a tumor displays unusual histologic findings that raise the possibility of a metastasis, the pathologist may opt to additionally sample the tumor to look for areas more typical of primary breast carcinoma and for foci of associated DCIS. In addition, immunohistochemical stains for a variety of markers may be helpful in defining a tumor as being of mammary or nonmammary origin. The markers chosen will depend on the differential diagnosis in any given case. Expression of estrogen receptor, CK7, GCDFP15, and/or mammaglobin may support a primary carcinoma of breast in an appropriate clinical setting.

MOLECULAR TUMOR CLASSIFICATION

Gene expression profiling studies have identified at least four major breast cancer subtypes: luminal A, luminal B, HER2, and basal-like (122). These subtypes differ with regard to their patterns of gene expression, clinical features, response to treatment, and outcome. Luminal A and luminal B cancers in general have a good prognosis and show high expression of hormone receptors and associated genes. Together these two subtypes account for approximately 70% of all breast cancers. The luminal B cancers tend to be higher grade than the luminal A cancers and some may overexpress HER2. Both luminal A and luminal B cancers tend to respond to endocrine therapy, with luminal A cancers showing the best response. Response of the luminal cancers to chemotherapy is variable, with the luminal B cancers generally showing better response.

The HER2 cancers show high expression of HER2 and low expression of estrogen receptor and associated genes. They account for approximately 15% of all breast cancers and are generally ER/PR negative. HER2 cancers are more likely to be high grade and lymph node positive. These cancers show the best response to trastuzumab and to anthracycline-based chemotherapy, but overall have a poor prognosis.

One of the most interesting findings of these studies is the elucidation of basal-like breast cancers that are associated with a particularly poor prognosis. The basal-like breast cancers show high expression of basal epithelial genes and basal cytokeratins, low expression of estrogen receptor and ER-associated genes, as well as low expression of HER2. They constitute approximately 15% of all breast cancers and are often referred to as "triple-negative" cancers, as they are invariably ER, PR, and HER2 negative. The basal-like tumor phenotype is especially common in African American women and is also the characteristic phenotype of *BRCA1*-associated breast cancers. Basal-like cancers have a poor prognosis and are not amenable to treatment with either endocrine therapy or trastuzumab since they are hormone receptor negative and do not show HER2 overexpression or amplification.

Breast cancers are not routinely classified for clinical purposes using gene expression profiling. However, the molecular subtype of a given tumor may be approximated using immunohistochemistry for ER, PR, HER2, CK5/6, EGFR, and Ki67. In general, luminal A cancers are ER/PR positive, HER2 negative with a low proliferative rate (e.g., Ki-67 less than 14%). Luminal B cancers are ER/PR positive, HER2 negative with a high proliferation rate (e.g., Ki67 over 14%), or HER2 positive. HER2 subtype cancers are ER/PR negative and HER2 positive, and basal-like cancers are ER/PR negative and HER2 negative (so called "triple negative"). It should be noted, however, that while basal-like cancers are triple negative, not all triple-negative cancers are basal-like. The use of additional immunostains (particularly cytokeratin 5/6 and epidermal growth factor receptor) may be used to further refine the categorization of basal-like cancers.

In addition to its important role in the classification of breast cancers, expression profiling has also been used to grade invasive breast cancers ("genomic grade index"). Using the genomic grade index, histologic grade 3 invasive breast cancers and histologic grade 1 invasive breast cancers have distinct gene expression patterns. In contrast, no distinct expression signature is seen for histologic grade 2 tumors. The genomic grade index allows further stratification of patients with histologic grade 2 tumors into good and poor prognosis groups (123).

HISTOPATHOLOGIC FEATURES OF HEREDITARY BREAST CANCER

Up to 10% of breast cancers are associated with mutations in high-penetrance susceptibility genes (reviewed in reference 117). Of these, breast cancers that develop in women with a genetic predisposition as a result of inherited mutations in *BRCA1* and *BRCA2* have been the most extensively characterized. Recognition of histologic features that may indicate a genetic predisposition might be useful for providing insight into the function of these genes and as an aid to identify patients in whom screening for these genetic abnormalities might provide a high yield.

There is general agreement that *BRCA1*-related cancers are more frequently carcinomas with medullary features and other basal-like carcinomas than are cancers in patients without this genetic alteration. Cancers associated with *BRCA1* mutations typically have high histologic grade, high mitotic rate, geographic necrosis, pushing margins, and an associated lymphocytic infiltrate. In addition, *BRCA1*-related cancers are usually ER, PR, and HER2 negative (triple negative), express basal cytokeratins, and have *TP53* mutations. These cancers cluster with the basal-like group on gene expression profiling studies (24). None of these features, singly or in combination, uniquely identifies a cancer as being related to *BRCA1* mutation. Similar features can be seen in sporadic basal-like breast cancers, many of which show somatic inactivation of *BRCA1*.

The histologic features reported in *BRCA2*-related breast cancers have been less consistent. Some studies have noted a higher proportion of tubular-lobular group cancers (including tubular, lobular, tubulolobular, and pleomorphic lobular) in *BRCA2* mutation carriers than in other patients. However, this has not been confirmed in larger studies. Some investigators have reported that *BRCA2*-related cancers tend to be of high histologic grade, whereas others have not noted a significant difference in histologic grade when

BRCA2-related cancers are compared with controls. In the largest study to date, Bane et al. studied 64 *BRCA2*-associated breast cancers and 185 *BRCA* mutation negative age and ethnicity matched controls (124). In this series, the majority of *BRCA2*-associated cancers were invasive ductal carcinomas, with lobular carcinomas showing similar frequency in the two groups. *BRCA2*-associated tumors were less likely to be grade I/III (6% vs. 19% in controls) and more likely to be grade III/III (60% vs. 39% in controls) and, in general, showed pushing rather than infiltrative margins. Controlling for tumor grade, *BRCA2*-associated cancers were more often positive for estrogen receptor and less likely to express basal cytokeratins or overexpress HER2. *BRCA2*-associated tumors and controls overall showed no difference in expression of TP53, BCL2, Ki67 or CCND1(cyclin D1) (124).

HISTOPATHOLOGIC PROGNOSTIC FACTORS

There is much interest in identifying biological, molecular and genetic markers that may be useful to help assess the prognosis of patients with invasive breast cancer. This is discussed in other chapters. However, a considerable amount of useful prognostic information can still be obtained from routine histopathologic examination of specimens with breast cancer. Clinical follow-up studies have repeatedly demonstrated that features such as axillary lymph node status, tumor size, histologic type, histologic grade, and lymphatic vessel invasion represent powerful and independent prognostic indicators. In fact, these traditional prognostic factors should be considered the standard against which any new prognostic factors are measured.

Axillary Lymph Node Status

There is uniform agreement that the status of the axillary lymph nodes is the single most important prognostic factor for patients with breast cancer and that disease-free and overall survival decrease as the number of positive lymph nodes increases. Current AJCC staging classifies lymph node metastases as macrometastases (over 2 mm), micrometastases (over 0.2 mm up to 2 mm) or isolated tumor cells (ITCs) (up to 0.2 mm or less than 200 cells) (125). Although the adverse clinical impact of axillary macrometastases on outcome is well established, the significance of axillary micrometastases and ITCs has been controversial, particularly those identified exclusively by the use of immunohistochemistry. Two recent clinical trials have looked specifically at this question. In the NSABP B32 trial, 5-year survival was 95.8% for patients without occult metastases and 94.6% for those with occult metastases (126). The authors concluded that although the difference (1.2%) was statistically significant, it was not clinically important. The ACOSOG Z0010 trial showed a 5-year survival of 95.7% for patients without occult metastases and 95.1% for those with occult metastases (not statistically significant) (127). These data do not support the routine use of immunohistochemistry in the evaluation of axillary lymph nodes for the purpose of identifying occult micrometastases or ITCs.

Tumor Size

Numerous studies have demonstrated that the size of an invasive breast cancer is one of the most powerful prognostic factors for both axillary lymph node involvement and clinical outcome. In a study of almost 25,000 breast cancer cases, Carter et al. demonstrated a linear relationship between tumor size and axillary nodal involvement as well as between tumor size and survival (129). The prognostic significance of tumor size is independent of axillary lymph node status and is a particularly valuable prognostic indicator in women with node-negative disease (Tables 25-4 and 25-5). A number of studies have suggested that even among patients with breast cancers 2 cm and smaller (T1), assessment of tumor size permits further stratification of patients with regard to the likelihood of axillary lymph node involvement and outcome. In a study of 644 patients with T1 breast cancer from Memorial Sloan-Kettering Cancer Center, the likelihood of axillary nodal involvement was 11% for tumors 0.1 to 0.5 cm, 15% for lesions 0.6 to 1.0 cm, 25% for tumors 1.1 to 1.3 cm, 34% for tumors 1.4 to 1.6 cm, and 43% for cancers that were 1.7 to 2.0 cm (130). Furthermore, among node-negative patients treated by mastectomy without adjuvant systemic therapy, those with cancers 1cm or smaller had a 20-year recurrence-free survival rate of 88%, significantly higher than the 72% recurrence-free survival rate observed for patients with tumors 1.1 to 2.0 cm in size (41). However, there is substantial variation in the reported rates of axillary node involvement and clinical outcome for patients with small tumors, particularly tumors that are 1 cm and smaller and not all investigators have observed that patients with tumors 1cm and smaller have significantly lower rates of axillary node involvement and disease recurrence than those with tumors between 1 and 2 cm. Nonetheless, most studies have reported a very favorable clinical outcome for node-negative patients with tumors 1 cm and smaller, with 5- to 10-year disease-free survival rates of 90% or greater.

TABLE 25-4

Five-Year Survival Rates (in Percentage) according to Tumor Size and Axillary Lymph Node Status

	Lymph Node Status		
Tumor Size (cm)	*Negative*	*1–3 Positive*	*≥4 Positive*
<2	96.3	87.4	66.0
2–5	89.4	79.9	58.7
>5	82.2	73.0	45.5

Adapted from Carter CL, Allen C, Henson DE. Relation of tumor size, lymph node status and survival in 24,740 breast cancer cases. *Cancer* 1989;63(1):181–187.

TABLE 25-5

Five-Year Survival Rates according to Tumor Size in Patients with Axillary Node–Negative Breast Cancer

Tumor Size (cm)	*No. Patients*	*5-Year Survival (%)*
<0.5	269	99.2
0.5–0.9	791	98.3
1.0–1.9	4,668	92.3
2.0–2.9	4,010	90.6
3.0–3.9	2,072	86.2
4.0–4.9	845	84.6
>5.0	809	82.2

Adapted from Carter CL, Allen C, Henson DE. Relation of tumor size, lymph node status and survival in 24,740 breast cancer cases. *Cancer* 1989;63(1):181–187.

Several studies have suggested that the prognostic significance of size may be related to the method of detection of the cancer. For example, Silverstein et al. (133) reported that for every substage among the T1 tumors and among T2 tumors, nonpalpable lesions were less likely to have axillary node involvement than palpable lesions. In that study, positive axillary lymph nodes were seen in 2 of 51 (4%) nonpalpable T1a lesions (≤0.5 cm) and in 3 of 50 (6%) palpable T1a tumors. Among T1b lesions (0.51 to 1.0cm), the frequency of positive nodes was 7% among the 92 nonpalpable lesions compared with 23% among the 143 palpable cancers. In patients with T1c lesions (1.1 to 2.0 cm) the frequency of positive lymph nodes was 16% for nonpalpable lesions compared with 31% for palpable tumors. Among patients with T2 tumors (2.1 to 5.0 cm), axillary nodes were involved in 23% of patients with nonpalpable lesions and in 48% of those with palpable tumors. Arnesson et al. also reported that mode of detection had an impact on axillary lymph node involvement in breast cancers 1 cm or smaller (134). In that series, lymph nodes were involved in 9% of the 221 T1a and T1b tumors detected by mammographic screening compared with 20% of the 89 clinically detected lesions ($p < .03$). Patients with screen-detected invasive cancers also have more favorable long-term survival. In a recent study of almost 2,000 cases in Finland, 22% of cancers were screen-detected and 88% were detected by other means. In this study, 15-year survival was 86% for patients with screen-detected cancers and 66% for patients with cancers detected by other methods (128).

Accurate measurement of breast cancer size is essential to provide the most clinically meaningful information. However, studies of the significance of tumor size in breast cancer have used various methods to determine size including clinical measurement, mammographic assessment, gross measurement, microscopic measurement of the entire lesion, and microscopic measurement of only the invasive component. In some studies, the method used to measure the tumor is not stated. This may at least partially explain differences in rates of axillary node involvement and clinical outcome in various studies. The most clinically significant measure of tumor size is the size of the invasive component of the lesion as determined from microscopic evaluation. The AJCC Cancer Staging Manual notes that the pT stage should be based on the measurement of the invasive component only (125). This approach appears to be justified since several studies have indicated that in many cases there are substantial differences in the size of the lesion as determined from gross pathologic examination and the size determined from microscopic measurement of the invasive component, particularly for small lesions. For example, in one series of 118 patients in whom the gross tumor size was measured as 2 cm or smaller, the gross tumor size was smaller than the microscopic size in 31% of cases, larger in 46%, and the same in only 22% (131). In 35% of these cases, the gross and microscopic tumor sizes differed by more than 3 mm. Similar discrepancies between gross and microscopic size were seen when the analysis was limited to those lesions in which the gross tumor size was measured as smaller than 1 cm. Of greatest importance, however, is the observation that the microscopic size of the invasive component of the tumor is the one that is most closely correlated with prognosis (131).

One important, but unresolved, issue for both pathologists and clinicians is how to assess and report the tumor size in lesions that have more than one focus of invasive cancer, since it is not known if the prognosis is related to the largest single focus or to the cumulative volume of invasive cancer. There is some evidence to suggest that invasive carcinomas with multiple foci of invasion have higher rates of axillary lymph node involvement than those lesions characterized by a single focus of invasion (135). Additional studies are needed to determine with certainty if the number of lymph node metastases might be predicted best by the aggregate size of the invasive foci. For staging purposes, the size of the largest single focus of invasion is used; however, it seems most prudent for the pathologist to measure microscopically the size of each focus of invasive cancer and report the individual sizes in the pathology report.

Histologic Type

Some histologic types of breast cancer are associated with a particularly favorable clinical outcome (6,41). Special type tumors that have consistently been shown to have an excellent prognosis include tubular, invasive cribriform, mucinous, and adenoid cystic carcinomas. Some authors also place tubulolobular carcinomas and papillary carcinomas in this group. Moreover, Rosen et al. have shown that the 20-year recurrence-free survival of special type tumors 1.1 to 3.0 cm in size is similar to that of invasive ductal carcinomas 1 cm and smaller (87% and 86%, respectively) (41). However, strict diagnostic criteria must be employed in order to observe the favorable outcome reported for these lesions.

Histologic Grade

The importance of tumor grading as a prognostic factor in patients with breast cancer has been clearly demonstrated in numerous clinical outcome studies. In fact, tumor grading has been shown to be of prognostic value even in patients with breast cancers 1cm and smaller. Although a variety of methods of nuclear and histologic grading have been used in these studies, the grading method in most widespread clinical use at the present time is the Nottingham combined histologic grading system of Elston and Ellis (137). These authors advocate the use of histologic grading for all types of invasive breast cancer, acknowledging, however, that histologic grade partially defines some of these histologic types (for example, tubular carcinomas are by definition grade 1 and medullary-type carcinomas are grade 3 lesions). In the Nottingham grading system, 1 to 3 points are assigned for each of three features: tubule formation, nuclear grade, and mitotic rate. The scores are then added, with a total score of 3 to 5 categorized as grade 1 (well differentiated), 6 and 7 as grade 2 (moderately differentiated), and 8 and 9 as grade 3 (poorly differentiated). Long-term follow-up studies have repeatedly shown higher rates of distant metastasis and poorer survival in patients with higher-grade tumors, independent of lymph node status and tumor size.

The results of a study of 1,081 invasive breast cancers from patients treated with conservative surgery and radiation therapy at the Joint Center for Radiation Therapy in Boston illustrate the value of this histologic grading system and also illustrate some important caveats in the interpretation of grading data. In that study, time to distant recurrence was greatest for grade 1 cancers and least for grade 3 tumors (Fig. 25-22). Furthermore, in a polychotomous logistic regression analysis, increasing tumor grade was associated with a significantly increased risk of distant metastasis at 10 years (138). However, the hazard ratios for distant failure among the three grades were not constant over time. In particular, the risk of distant metastasis was highest for grade 3 tumors only within the first 3 years of follow-up. Beyond that time, the risk of metastasis associated with grade 2 tumors was actually greater than the risk associated with grade 3 cancers (Fig. 25-23). These observations emphasize that in interpreting data relating histologic grade

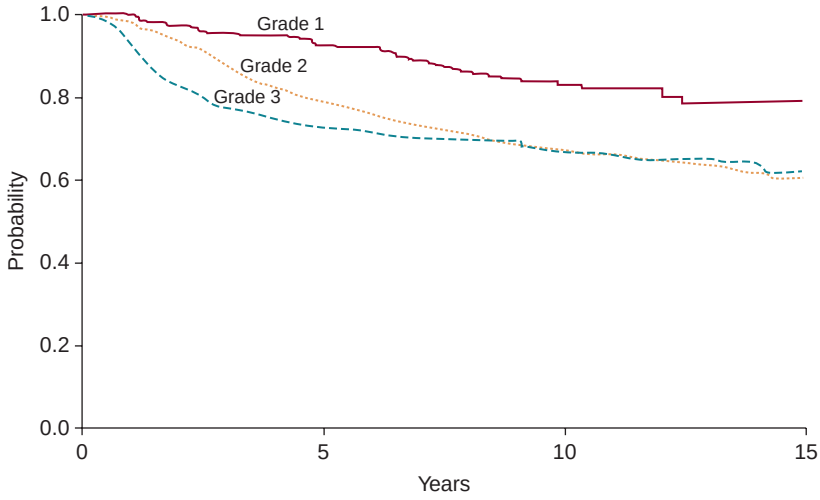

FIGURE 25-22 Kaplan-Meier curves indicating time to distant failure for 1,081 patients with invasive breast cancer according to histologic grade.

to clinical outcome, the length of follow-up must be taken into consideration. They further suggest that grade may be best viewed as an indicator of time to recurrence rather than absolute rate of recurrence.

Histologic grade also provides useful information with regard to response to chemotherapy and is, therefore, a predictive factor as well as a prognostic indicator. The results of several studies have suggested that the presence of high histologic grade is associated with a better response to chemotherapy than low histologic grade (139). For example, although basal-like carcinomas are associated with shorter relapse-free and overall survival, they are also associated with high response rates to neoadjuvant chemotherapy (140).

A frequent criticism of the use of histologic grading is that this assessment is subjective and, as a consequence, prone to considerable interobserver variability. Most of the studies that have suggested this have used grading systems that lack precisely defined criteria and/or did not attempt to educate the participating pathologists in the use of the system evaluated. Recent studies have indicated that the use of strict criteria and guidelines for histologic grading can result in acceptable levels of interobserver agreement and also identify areas that might benefit from refinement. In one of these studies, six pathologists each graded 75 invasive ductal carcinomas using the Elston and Ellis grading system (141). Moderate to substantial agreement was found for the overall histologic grade. There was substantial agreement with regard to tubule formation, moderate agreement for mitotic count, and near moderate agreement for nuclear pleomorphism as determined by generalized kappa statistics. These authors concluded that this grading system is suitable for use in clinical practice and suggested that efforts to improve agreement on nuclear grading would be of value in further fostering agreement in histologic grading.

Lymphovascular Invasion

The presence of tumor emboli in lymphovascular spaces has been shown in numerous studies to be an important and independent prognostic factor (Fig. 25-24). Its major clinical value is in identifying node-negative patients at increased risk for axillary lymph node involvement and adverse outcome. The identification of lymphatic vessel invasion may be of particular importance in patients with T1, node-negative breast cancers, since this finding may permit the identification of a subset of patients at increased risk for axillary lymph node involvement and distant metastasis in

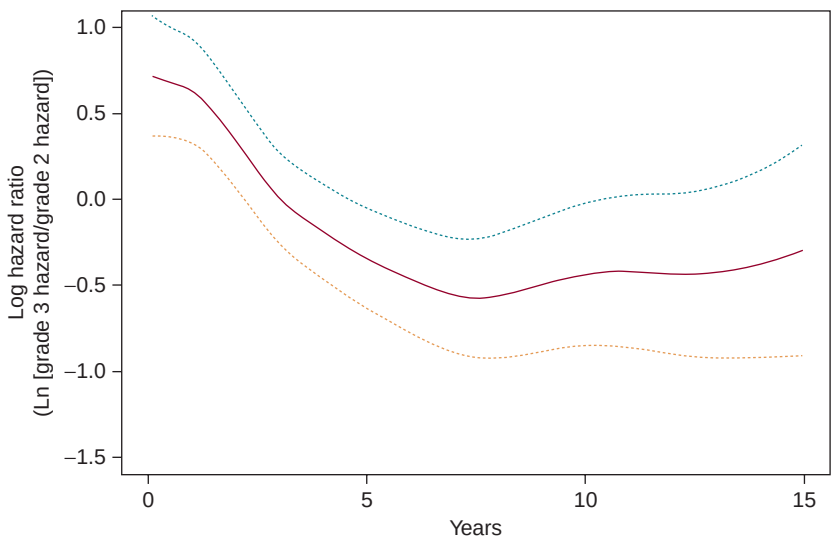

FIGURE 25-23 **Hazard ratio for distant recurrence for patients with histologic grade 3 tumors compared with those with grade 2 tumors.** Distant recurrence is greater for patients with grade 3 tumors than for those with grade 2 tumors when the curve is above zero, and less for those with grade 3 than for those with grade 2 when the curve is below zero (*dotted lines* represent 95% confidence limits).

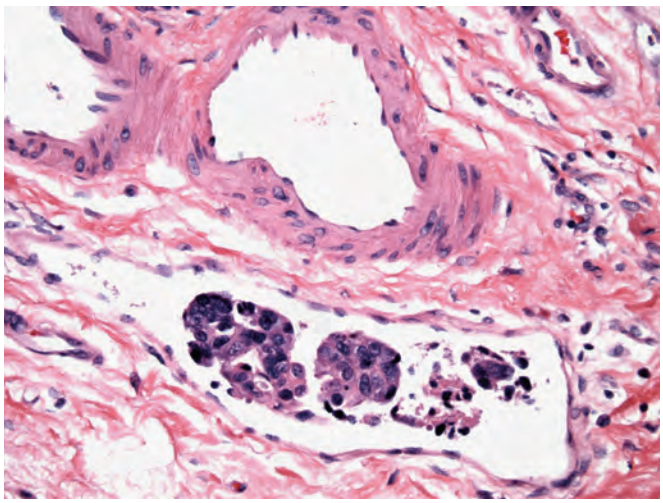

FIGURE 25-24 **Lymphatic vessel invasion.** A tumor embolus is present in a thin-walled, endothelial-lined space.

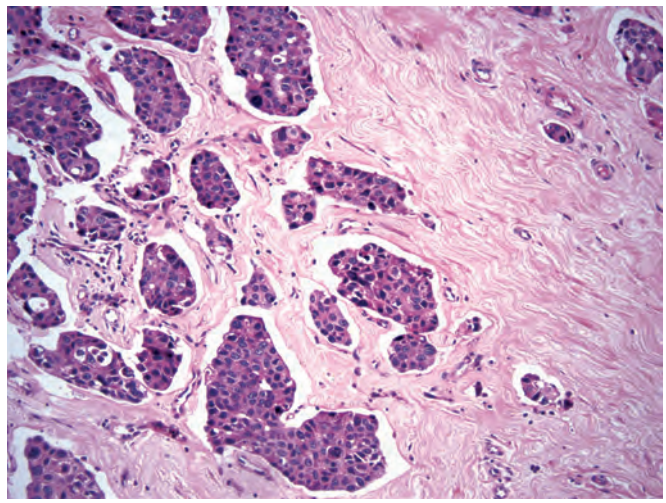

FIGURE 25-25 **Retraction artifact.** Tumor cells are present in artifactual tissue spaces, created by retraction of the surrounding stroma. These spaces lack an endothelial lining.

this otherwise favorable group. For example, in one recent study, lymphatic vessel invasion was the only clinical or pathologic factor associated with lymph node metastasis in patients with tumors 1 cm and smaller. In that study, lymph node involvement was present in four of seven patients whose tumors showed lymphatic vessel invasion (57%) compared with only 1 of 100 patients without lymphatic vessel invasion (132). In another study of 461 patients with T1, node-negative breast cancer, patients with tumors lacking lymphatic vessel invasion had a 20-year survival rate of 81% compared with 64% for those whose tumors exhibited lymphatic vessel invasion (41). Similar findings have been reported by others, even when the analysis is restricted to the subset of T1 breast cancers that are 1 cm and smaller.

As with histologic grade, the ability of pathologists to reproducibly identify lymphatic vessel invasion has been challenged. The use of strict criteria for the identification of lymphatic vessel invasion is, therefore, imperative. In particular, retraction of the stroma is not uncommonly seen around nests of invasive cancer cells, and care should be taken not to interpret this erroneously as lymphatic vessel invasion (Fig. 25-25). For this reason, assessment for lymphovascular invasion is best performed outside the area of the invasive carcinoma.

A number of investigators have evaluated the use of immunohistochemical stains for endothelial cells (including stains for factor VIII–related antigen, CD34, Ulex europaeus agglutinin I, and blood group isoantigens) and basement membrane components as an aid in the identification of lymphatic vessel invasion. However, these stains have been of limited value due both to staining of other elements in the tissue as well as false negative staining. The monoclonal antibody D2-40 recognizes lymphatic endothelium and appears to be the most useful for the detection of lymphatic vessel invasion in routinely processed tissue sections. Otherwise, lymphatic vessel invasion is best assessed on routine hematoxylin and eosin-stained sections using strict diagnostic criteria.

Other Factors

A number of other histologic factors have been reported to have prognostic value in patients with invasive breast cancer. The presence of *blood vessel invasion* (i.e., invasion of veins and arteries) has been reported to have an adverse effect on clinical outcome. In the long-term follow-up study from Memorial Sloan-Kettering Cancer Center, blood vessel invasion was identified in 14% of patients with T1N0 cancers and in 22% with T1N1 lesions using elastic tissue stains (136). A significantly worse outcome was seen for patients with than those without blood vessel invasion in both groups in that study. However, there is a broad range in the reported incidence of blood vessel invasion, ranging from under 5% to almost 50% (1). This is due to a variety of factors including the nature of the patient population, the criteria and methodology used to determine the presence of blood vessel invasion, and the occasional difficulty in distinguishing blood vessels from mammary ducts. Some studies use the term *blood vessel invasion* to denote those vascular structures that possess a muscular or elastic tissue component in their wall, whereas others include in addition thin-walled vessels of capillary caliber, many of which probably represent lymphatic spaces. Furthermore, some studies have based the evaluation for blood vessel invasion on examination of hematoxylin and eosin stained sections whereas others have employed elastic tissue stains. In our experience, invasion of arterial and venous caliber vascular structures is uncommon.

The relationship between clinical outcome and the extent of *mononuclear inflammatory cell infiltrate* in association with invasive breast cancers has also been investigated. The presence of a prominent mononuclear cell infiltrate has been correlated in some studies with high histologic grade (138). However, the prognostic significance of this finding is controversial with some studies noting an adverse effect of a prominent mononuclear cell infiltrate on clinical outcome and others observing either no significant effect or a beneficial effect (142).

The presence of *perineural invasion* is sometimes observed in invasive breast cancers. This phenomenon is often seen in association with lymphatic vessel invasion but it has not been shown to be an independent prognostic factor.

The *extent of ductal carcinoma in situ* associated with invasive cancers has also been studied as a potential prognostic factor. Numerous investigators have shown that the presence of an extensive intraductal component is

a prognostic factor for local recurrence in the breast in patients treated with conservative surgery and radiation therapy when the status of the excision margins is unknown. However, this factor is not an independent predictor of local recurrence following conservative surgery and radiation therapy when the microscopic margin status is taken into consideration (reviewed in reference 29). Silverberg and Chitale reported an inverse relationship between the amount of ductal carcinoma *in situ* and both the risk of axillary lymph node metastasis and the 5-year survival rate in a series of patients with invasive ductal carcinoma treated by mastectomy (143). However, in another series of 573 patients with invasive ductal carcinoma treated by mastectomy, there was no significant relationship between the extent of intraductal involvement and either recurrence or survival (144). Similarly, among 533 patients with invasive carcinoma treated with conservative surgery and radiation therapy, the presence of an extensive intraductal component was not associated with the risk of distant metastasis in a multiple logistic regression analysis (145). Therefore, while the extent of associated ductal carcinoma *in situ* is a consideration in the local management of patients treated with breast-conserving therapy, it does not appear to be a significant prognostic factor with regard to distant metastasis or survival.

Combining Prognostic Factors

Although a variety of prognostic factors have been reported for patients with invasive breast cancer, how best to integrate these factors to assess patient outcome and formulate therapeutic decisions is an ongoing challenge. Several authors have developed prognostic indices for this purpose, which take into account various combinations of factors. The Nottingham Prognostic Index, for instance, takes into consideration tumor size, lymph node status and histologic grade. This index has been used to stratify patients with breast cancer into good, moderate and poor prognostic groups with annual mortality rates of 3%, 7%, and 30%, respectively (146). Another group of investigators has proposed a prognostic index which combines tumor size, lymph node status and mitotic index (morphometric prognostic index) (147). This index has been shown to be a useful prognostic discriminator for premenopausal patients with both node-negative and node-positive disease. Although prognostic indices such as these have not yet been widely accepted into clinical practice, they represent important attempts to refine prognostication in patients with invasive breast cancer.

CONTENTS OF THE FINAL SURGICAL PATHOLOGY REPORT

The final surgical pathology report for specimens containing invasive breast cancer should include, in addition to the diagnosis, information needed for staging and therapeutic decision making. The information used by clinicians in determining treatment options varies among different institutions. However, at a minimum, every surgical pathology report for specimens containing an invasive breast cancer should include the type of specimen submitted, laterality, specimen size, tumor size, histologic type, histologic grade, presence or absence of lymphatic vessel invasion, presence and extent of DCIS, the status of the microscopic margins, and lymph node status (if applicable) (148). In addition, for specimens removed because of the presence of mammographically detected microcalcifications, it is important to note the location of the calcifications (i.e., in association with invasive cancer, carcinoma *in situ*, benign breast ducts and lobules, stroma or blood vessels). If ancillary studies are in progress (e.g., hormone receptor assays, HER2, other prognostic markers, etc.), this should also be documented in the final report. The use of standardized, synoptic-type reports, either in addition to or in place of a narrative report, is encouraged. A protocol and checklist for the reporting of invasive breast cancer is available from the College of American Pathologists (www.cap.org).

CHAPTER 26

Estrogen and Progesterone Receptor Testing for Prognosis and Prediction

Mitchell Dowsett and William Miller

CHAPTER CONTENTS

BACKGROUND

The major actions of steroid hormones are mediated through specific receptors that bind hormones with high affinity and thereby generate effective signaling. Some but not all breast cancers retain the hormonal sensitivity of the target organ in which they have developed such that their growth and development appear to depend on estrogen and, possibly, progesterone. As a consequence, treatments targeted at hormones and their signaling pathways have been used both to prevent and treat breast cancer. The hormonal sensitivity and therapeutic effects appear to be mediated through estrogen receptors (ERs) and progesterone receptors (PgRs). Consequently, measurement of these steroid receptors in breast cancers is used for estimating patient prognosis, particularly the likelihood of tumor response to and patient benefit from endocrine therapy.

Thus, the objectives of this chapter are to describe (a) the different forms of ER and PgR and their biology; (b) the methodology used to measure steroid receptors; (c) the utility of ER and PgR in determining clinical outcome of patients with breast cancer; and (d) the current status of the receptors in predicting the likelihood of response to treatment and therefore the selection of specific therapies in individual patients.

BIOLOGY OF ESTROGEN RECEPTORS (ERs) AND PROGESTERONE RECEPTORS (PgRs)

Structure and Function

ER and PgR belong to a family of nuclear hormone receptors that function as transcription factors when bound to their respective ligands.

Two separate ER isoforms have substantial homology, ERα and ERβ, and are encoded by two separate genes, ESR1 and ESR2, respectively (Fig. 26-1). The precise cell-specific physiologic and pathophysiologic roles of ERβ in breast cancer are currently unclear. Also few definitive data support any clinical role for ERβ at present, and routine evaluation of ERβ is rarely performed. Therefore, in the absence of qualification, the term ER refers to the product of ESR1 (ERα) throughout this review. PgR also exists in two separate but highly homologous isoforms (PgR A and B), which have been shown to have different regulatory effects but so far have not been shown to have significantly different predictive value.

Human ERα, ERβ, and PgR share common structural and functional organization with a central DNA binding domain (DBD) and a carboxyl-terminal hormone binding domain

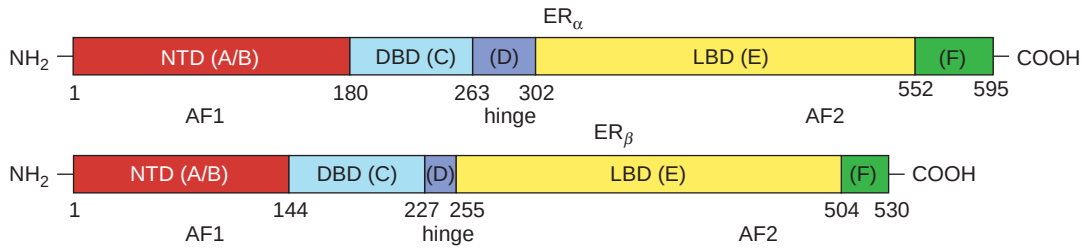

FIGURE 26-1 Linear organizational structure of ERα and ERβ. NTD: amino terminal domain; DBD: DNA binding domain; LBD: ligand binding domain; amino acid numbering for the extent of each domain is shown below the structure. (From Kumar R, Zakharov MN, Khan SH, et al. The dynamic structure of the estrogen receptor. *J Amino Acids* 2011;2011: 812540. Published online July 26, 2011.)

(HBD) (Fig. 26-1). Binding the hormone to its specific receptors activates the receptors and facilitates binding to response elements present in the promoter of responsive genes. Coregulatory proteins coordinately act to influence transcription of responsive genes and influence the nature of response.

Regulation

Mechanisms regulating ERα and β function include differential usage of upstream untranslated exons, the splicing of their messenger RNA (mRNA), and post-translational modifications (1). At least seven different promoters have been identified for ER (1). Alternative RNA splicing is relatively common in breast cancers, but there is little evidence that these result in equivalent protein variants that are detectable in clinical specimens, and none are recommended for use as prognostic or predictive tumor markers.

Post-Translational Modifications

Numerous post-translational modifications of ER and PgR have been reported, most notably through phosphorylation, ubiquination, and acetylation.

Phosphorylation of receptor protein is particularly influential. Several kinases can phosphorylate ERα, including p38 mitogen-activated protein kinase (*MAPK*), cyclin A-CDK2, CDK7, c-Src, and $pp90^{rsk1}$ (2). Other important signaling molecules, such as AKT, and extracellular regulated kinase (ERK1/2) MAPK can also differentially phosphorylate ERα. Phosphorylation of ERα can occur at several sites and may alter response to ligands (2); for example, phosphorylation of ERα serine (S) 167 by AKT and S118 by ERK1/2 can produce ligand-independent activation of ERα (and thereby confer apparent hormone resistance) (3). ERα phosphorylation can also occur at S118, producing complex effects, and be decreased by endocrine therapy. Phosphorylation events are complex and interdependent and, for example, phosphorylation at ERα S305 can regulate the subsequent phosphorylation of S118 (4). Receptor phosphorylation also affects events such as receptor turnover, cellular localization, and transcriptional activity; however, the clinical utility of measuring ERα phosphorylation has not yet been demonstrated. Both PgR-A and B isoforms are phosphorylated at multiple serine residues (5), but how PgR serine phosphorylation regulates its function is not well defined.

Ubiquitination can regulate ERα protein levels and response to estrogen (6) by mediating proteasomal degradation (6) or influencing transcriptional activity. Acetylation can occur on several lysine residues within the ER protein and thereby change DNA binding and ligand-dependent activation.

Estrogen Receptor Gene Alterations

Only a few mutations have been reported in the ERα gene. The (K303R *ERα*) mutation that causes a single amino acid change in the ERα hinge domain leads to hypersensitivity to the growth effects of estrogen. One group has reported this to be present in about one-third of premalignant lesions and in one-half of invasive breast tumors (7). However, the literature is not consistent, and other studies employing different methodologies have failed to detect the mutation in invasive cancers (8), reported it in only 6% of breast cancers (9), or associated the mutation to a family history of breast cancer (10). Clearly, more definitive research needs to be performed.

Whether the ER gene locus (*ESR1*) is a target for increased gene copy number (amplification) is controversial and not as frequent as originally thought. However, amplifications between primary and metastatic tumors appear to be concordant, and tumors with *ESR1* gene amplification also express higher levels of ERα by immunohistochemistry (11). Although some preliminary results suggest that *ESR1* amplification may predict resistance to adjuvant tamoxifen in postmenopausal women with ER positive breast cancer (12), findings currently are not sufficiently robust to be used to define a subtype of primary breast cancers optimally suited for hormonal therapy on the basis of amplification. Further independent analyses of large series of breast cancers are warranted to determine the definite prevalence of *ESR1* amplifications and its potential clinical significance.

Mechanism of Action: Genomic

ER and PgR function as tissue-specific and ligand-dependent transcription factors. Binding hormone to its receptor leads to a conformational change in the receptor and induces dimerization. The ligand/receptor complex then binds directly or indirectly to response elements in the promoter regions of responsive genes, enhancing transcription. The precise cellular response depends on tissue-specific nuclear coregulatory proteins, designated coactivators, and corepressors. More than 170 coregulatory proteins have been identified.

In the absence of hormone, histone deacetylase (HDAC) and receptor corepressors (such as N-CoR and SMRT) are bound to the receptor. Histone deacetylation silences or inhibits transcription by causing DNA to wrap more tightly around the core histone proteins. Once hormone binds to receptor, the activated complex displaces the repressor proteins, and acetyltransferases are recruited along with coactivator proteins (such as p160 coactivator, steroid receptor coactivator [SRC1], transcriptional inhibitory factor [TIF2], amplified in breast 1 [AIB1]) complex). The coactivators appear to cycle on and off the promoter during hormone treatment (13). There is therefore a dynamic and complex

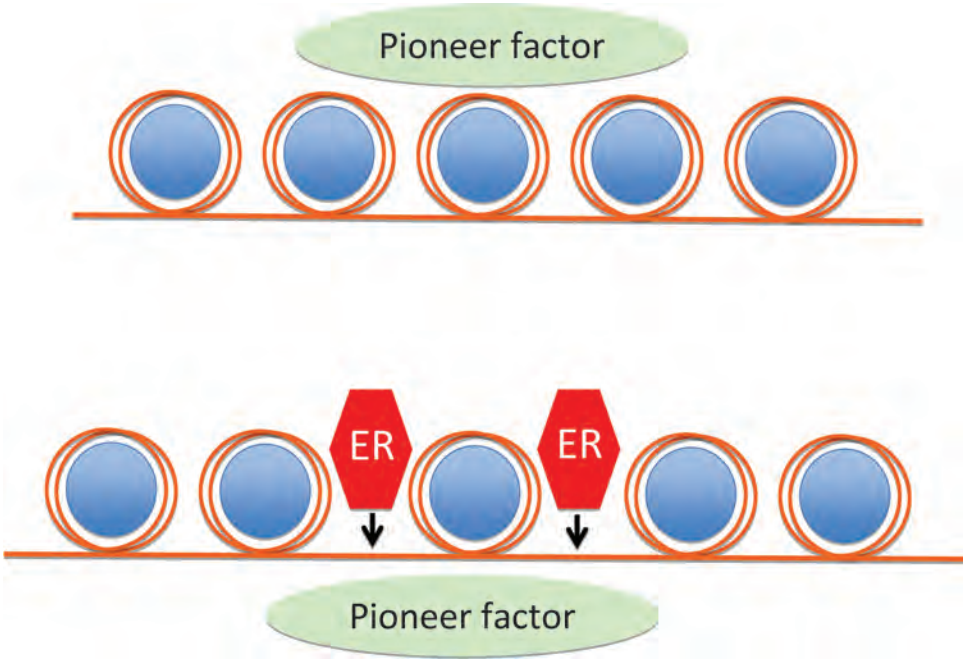

FIGURE 26-2 Mode of putative ER pioneer function. Upper panel: pioneer factor associates directly with compacted chromatin and provides accessibility to transcription factors such as ER to bind to DNA largely at oestrogen response elements. (Adapted from Jozwik KM, Carroll JS. Pioneer factors in hormone-dependent cancers. *Nature Reviews Cancer* 2012;12:381–385.)

array of proteins present on estrogen regulated promoters, many of which coordinately contribute to the hormonal regulation of gene expression.

Recent data indicate that the so-called pioneer factor FOXA1 cooperates with ER also to bind at large numbers of nonpromoter sites across the genomes (Fig. 26-2). The points through the genome that bind FOXA1 or ER vary among breast tumors and are affected by external influences such as growth factors (14).

Phosphorylation of ER coregulators is important in the transduction of signaling by the ER pathway. It can augment ER dependent transcription, even in the absence of ligand or in the presence of antiestrogens, by increasing subcellular nuclear localization and recruitment of other transcriptional coregulators to the receptor–promoter complex. Some coactivators, for example AIB1, are often gene-amplified or overexpressed in breast tumor cells. This may have clinical significance, and AIB overexpression has been associated with tamoxifen resistance, poor disease-free survival being observed after adjuvant tamoxifen therapy in patients whose tumors express high levels of both the ERBB2 oncogene, and the ER coactivator AIB1 (15). It may be the relative balance of bound coregulators that determines response to therapy.

Mechanism of Action: Nongenomic Activities

In addition to ER genomic activity in the nucleus, rapid effects of estrogens and plasma membrane estrogen binding sites have been described. It is possible that ER, PgR, and other steroid receptors can therefore mediate signaling cascades originating from the membrane or the cytoplasm through direct activation of signal transduction mediators. This nongenomic ER action occurs within seconds or minutes and is independent of gene transcription. Accruing evidence also suggests that such signaling may be associated with the growth and survival of breast cancer cells (16).

The identity of nongenomic receptors, their subcellular localization, and precise mechanism of action are still controversial and the topics of active research. However, immunohistochemical, biochemical, and genetic studies suggest that a subpopulation of the classic ERα and β subtypes located outside the nucleus and closely related nonclassic short forms of ERα may act as transducers of rapid estrogen signaling (17). These membrane and cytoplasmic ERs appear to transmit signals through kinase cascades, including growth factor receptors, cellular tyrosine kinases, and through calcium, cyclic adenosine monophosphate (cAMP), and other second messengers ultimately to regulate transcription in the nucleus (18). Membrane-initiated ER activity via growth factor signaling cascades can, in turn, modulate the activity of nuclear ER and its sensitivity to endocrine therapy (19).

In addition, nongenomic activity is also influenced by other cellular ER coregulatory proteins and by other pathways functioning in a given tumor. Increased expression of tyrosine kinase receptors (TKRs), such as in tumors amplified for HER2, can significantly augment ER nongenomic activity in response to both estrogen and tamoxifen (19).

Growth Factor and Estrogen Receptor Crosstalk–Implications for Hormone Resistance

Molecular bidirectional crosstalk occurs between growth factors, other signaling pathways, and the ER pathway. This crosstalk may be important in modulating ER activity and tumor response to endocrine therapies (20). For example, the bidirectional interaction between ER and the TKR pathway EGFR/HER2 can activate growth factor pathways by increasing the expression of ligands (i.e., transforming growth factor [TGF] α, amphiregulin), receptors (i.e., IGF-1), or other signaling intermediate molecules (e.g., insulin receptor substrate-1 [IRS-1]). Signaling through the HER pathway can also activate the transcriptional function of ER in the nucleus by phosphorylating coactivators and corepressors as well as ER itself (19).

There are also data that suggest that breast tumors with increased expression of growth factor signaling components, particularly of the EGFR/HER2 pathway, are associated with a poor response to tamoxifen (15,21). Additionally, neoadjuvant trials observed higher response rates to aromatase inhibitors in HER2-overexpressing tumors as compared with those to tamoxifen (22,23).

Although ER and HER receptors can amplify each other's signals, inhibitory actions have also been observed. Activation of ER can down-regulate the expression of the HER receptor family, including EGFR1 and HER2, and HER signaling can down-regulate the expression of ER and PgR (24). It seems likely that the interaction between FOXA1 and ER in eliciting estrogen-dependent transcription is affected by phosphorylation of FOXA1, but the details of this remain to be elucidated.

Crosstalk raises the possibility that in some breast cancers, a simultaneous blockade of both ER and HER signaling pathways may be required to bypass resistance mechanisms and achieve optimal treatment benefit. Two recently reported randomized phase II trials comparing tamoxifen with or without gefitinib and anastrozole with or without gefitinib support this idea (25,26).

OVERALL IMPORTANCE OF RECEPTORS IN CLINICAL BREAST CANCER

Approximately 30% to 40% of patients with ER positive metastatic disease responds to first-line hormonal therapies, and another 20% experience disease stabilization (27). Adjuvant hormonal therapy approximately halves the recurrence rate of patients with ER positive breast cancer. Hormonal therapy is also relatively nontoxic and therefore is a first-line option for virtually all patients with ER positive disease in both early and advanced disease. It is clear, particularly in the adjuvant setting (28) that patients with ER negative tumors do not derive benefit from endocrine treatment. Thus, ER acts as both a target and a biomarker for endocrine treatment.

The ER pathway can be targeted either by strategies that act on the receptor itself (i.e., selective ER modulators, such as tamoxifen, or potent pure antagonists that can degrade the receptor, such as fulvestrant) and by approaches that deprive the receptor of estrogen (i.e., aromatase inhibition and ovarian ablation). PgR is generally measured as a marker of an intact oestrogen-responsive pathway, and in the metastatic setting, it can aid in predicting a greater or lesser chance of response. However, in early breast cancer, PgR is helpful as a prognostic but not predictive marker of endocrine treatment benefit.

Before considering the importance of ER and PgR in breast cancer in more detail, it is instructive to understand the methodologies for their measurement in tissues.

METHODS FOR MEASURING ESTROGEN AND PROGESTERONE RECEPTORS

Assessment of ER status should be undertaken in all invasive breast cancers. Measurement of PgR is less important for selecting patients for endocrine therapy given that benefit is similar in ER+ PgR– and ER+ PgR+ cases. However, it is helpful in identifying the small population of ER– PgR+ tumors that merit endocrine therapy, and the identification can act as a quality control for ER measurement. Although ER status provides prognostic information, this is secondary to its value to assess the likelihood that a patient will respond to hormonal therapies.

Early studies relied on radiolabeled ligand-binding assays, such as the dextran-coated charcoal (DCC) method, which was rigorously validated and standardized in the United States. These methods were replaced in the 1990s with immunohistochemical (IHC) assays, which until recently have been subject to lower levels of QA.

Dextran-Coated Charcoal Ligand-Binding Assay (DCC-LBA)

The first assays of ER in breast cancer were introduced in the mid-1970s and were performed on crude tumor cytosols derived by centrifugation after homogenization. Tumor cytosols were incubated with high specific-activity radiolabeled steroid (estrogen or progestin), and the results reported as femtomoles (fmol) of receptor protein per milligram (mg) of total cytosol protein having been calculated from Scatchard plots in most instances (29). Although not used today, an understanding of the DCC assay is important because the data relating clinical benefit from endocrine therapy have been derived almost exclusively using this assay. The most widely used definition of positivity was at least 10 fmol/mg protein, but some described levels of more than 3 to 9 as borderline positive and negative as less than 3. Several disadvantages of the DCC assay existed, including variable tumor cellularity and heterogeneity as well as the requirement for fresh or snap-frozen tissue. These assays provide an overall score for the entire fragment of the tumor including neoplastic and non-neoplastic cells and may give false results, depending on the relative proportion of cancer versus other cell types within the tumor. Breast cancers display a broad dynamic range in ER and PgR expression using these assays. Overview analysis of 10,000s of patients treated with adjuvant tamoxifen showed little or no benefit for tumors with less than 10 fmol ER/mg protein, yet recurrence was reduced by about one-third in patients with tumors with 10 to 19 fmol/mg and by about one-half in those ≥200 fmol/mg. Mammographic screening dramatically reduced the average size of breast cancer below that required for the DCC assay. This and the availability of specific antibodies to ER and PgR led to the DCC no longer being performed for clinical management.

Immunohistochemical Assays

The development of specific, reliable, and commercially available ER and PgR antibodies (30) allowed the development of robust IHC technologies, and these are now virtually the only assays used to measure receptor levels. IHC allows for the determination of receptor status at the individual cell level, accommodating the problem of tissue heterogeneity within the tumor. IHC assays are less labor intensive and less expensive than extraction assays. They are also amenable to small tumors, and importantly, they can be performed on formalin-fixed, paraffin-embedded tissue, including archival tissues. IHC is also not affected by bound ligand (an issue with the DCC assay in pre-or perimenopausal patients).

IHC is performed on thin sections of formalin-fixed tissue that are subject to one of a number of antigen retrieval methods. This is followed by incubation of the section with a primary antibody directed against ER or PgR. Then a number of secondary detection systems, such as the use of secondary antibodies that have been conjugated to an enzyme such as horseradish peroxidase, are applied. The sections can finally be counterstained and viewed microscopically. For both ER and PgR, the staining produces a predominantly nuclear stain. The analytical systems have become increasingly sensitive and have resulted in most tumors being either completely negative or high positives (31,32). Several scoring systems have been developed and implemented. Examples of ER and PgR staining are shown in Figure 26-3.

Comparison of Assay Methods and Standardization

There have been very few assessments of the relationship between IHC staining levels and benefit from endocrine

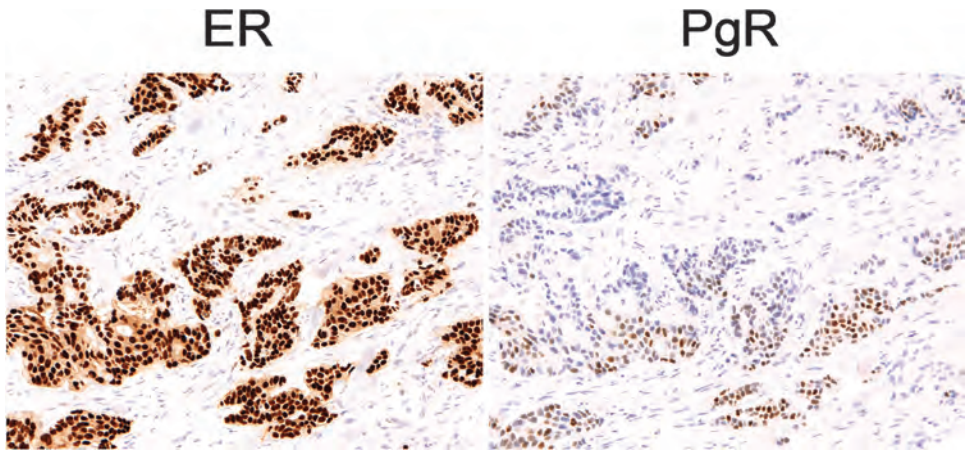

FIGURE 26-3 Examples of strong ER and weak PgR positive immunohistochemical staining in the same tumor. Brown nuclei are positively stained.

therapy, but those that exist and others that assessed prognosis either in untreated or hormonally treated tumors show good, although not perfect, concordance. When hormone receptor status of tumors determined by IHC assay has been compared with that determined by extraction assays, discordances between 10% and 30% have been reported for both ER and PgR status (33,34). In some cases, IHCs have been found to have superior ability to predict hormone response in patients (35). Regan et al. (36) reported that, for ER status, concordance between IHC and DCC assays was higher among postmenopausal women (88%) than among those who are premenopausal (81%), possibly because of the interference that can occur in the DCC with high premenopausal estrogen levels. In contrast, concordance for PgR status was marginally lower in postmenopausal patients (76% vs. 80% premenopausal).

Like other IHCs, IHC staining for ER and PgR can be significantly affected by a variety of pre-analytic factors, including the efficiency of antigen retrieval and the time of tissue fixation (37). Hormone receptors degrade in unfixed tissue; thus, avoidance of unfixed tissue sitting at room temperature is important. Given that it may take many hours for formalin to fully penetrate to the center of a large excised tumor or mastectomy specimen tissue, slicing to improve penetration is needed to avoid artifacts such as that revealed in the higher levels of ER observed in core-cuts versus excision biopsies of the same tumor. Numerous other pre-analytical and analytical factors can affect ER IHC results. In the absence of good-quality control and external quality assurance programs, these can lead to serious errors in ER measurement and inappropriate treatment decisions.

In recognition of this, the American Society of Clinical Oncology and College of American Pathologists (ASCO/CAP) jointly convened an expert panel in 2008 to develop evidence-based guidelines that were published in 2010 and have subsequently been widely adopted (38). A key recommendation was that ER and PgR be measured on all invasive breast cancers but with no agreement about the value of this in DCIS because the evidence is equivocal regarding the efficacy of tamoxifen in preventing progression of or recurrence from this disease being restricted to ER negative disease.

Other key recommendations included ER or PgR having the same cutoff of ≥1% cells being accepted as positive. Negativity should be ascribed if <1% nuclei are positive in samples where some nontumor nuclei exhibit staining and act as an internal positive control. The data directly supporting this are not as strong as one might wish as they are derived predominantly from a paper by Harvey and colleagues (35) that demonstrated prognostic but not necessarily predictive significance of such low percentages of cells staining. A low cutoff is, however, supported in general by the significant benefit from tamoxifen noted above in tumors with only 10 to 19 fmol/mg protein and should minimize the risk of false negativity (39). The Harvey paper describes the use of what became known as the Allred score (Allred being the senior author) that is created by the addition of separate scores based on the percentage of cells stained and the intensity of staining to give a score of 0 or between 2 and 8 in which values of at least three were positive. ASCO/CAP recommended that the percentage of cells and intensity of staining should be noted because these can provide ongoing data on assay quality and may be helpful as contributors to prognostic evaluation (38). The derivation of the Allred score is shown in Figure 26-4 and together with that of a Quickscore (40) and the H-score (41) in Table 26-1. The latter has advantages over the Allred score for those interested in deriving

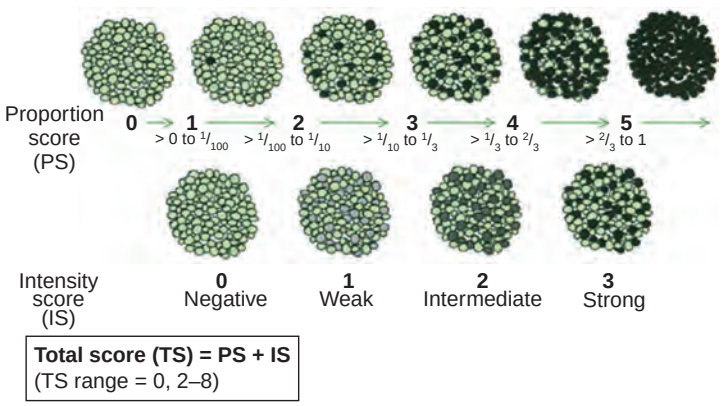

FIGURE 26-4 Derivation of the widely used Allred score. (Harvey JM, Clark GM, Osborne CK, et al. Estrogen receptor status by immunohistochemistry is superior to the ligand-binding assay for predicting response to adjuvant endocrine therapy in breast cancer. *J Clin Oncol* 1999;17:1474–1481.)

TABLE 26-1

Derivative Scores Commonly Used for Semiquantitation of ER and PgR Immunohistochemical Staining

	Categories		
Name	*Percent*	*Intensity*	*Calculation to Give Score*
Allred (35)	0 None 1 <1 2 1–10 3 10–33 4 33–66 5 66–100	0 None 1 Weak 2 Intermediate 3 Strong	Intensity category + Percentage category
Quickscore (40)	1 0–4 2 5–19 3 20–39 4 40–59 5 60–79 6 80–100	0 None 1 Weak 2 Intermediate 3 Strong	Intensity category × Percentage category
H-score (41)	Continuous	0 None 1 Weak 2 Intermediate 3 Strong	Percentage staining intensity 1 + 2 × Percentage staining intensity 2 + 3 × Percentage staining category 2

a quantitative score for ER or PgR because the Allred score markedly compresses higher values into a small number of categories, but it is far more laborious and is unnecessary for describing positive or negative status.

Using both the Allred Score (AS) and a manual estimate of the percentage of ER positive tumor cells in a series of 800 breast cancers, it has been reported that ER staining using different methodology has a near bimodal frequency distribution (Fig. 26-5) (31). Most breast cancers were either entirely ERα negative or unambiguously ERα positive; weak ERα positivity was rare. These results are similar to those reported by others using percentage positivity scoring in a series of more than 5,900 breast cancers (32). These data may be on the extreme side but in general reflect the experience of most pathologists using modern methods that relatively few tumors express low levels of positive staining. This distribution, which differs from that reported by Harvey et al., is likely to result from the increasing sensitivity of modern IHCs that also reduces the likelihood of false negativity.

Where quantitation of ER IHC is desired, there can be some value in using an image analysis system. Of note, the frequency distribution from these automated systems is continuous, similar to that obtained with DCC assay and with RNA analyses. The linearity of the image analysis systems is accomplished by their reliance on fluorescent labeling that provides a linear quantitative signal. The need to identify the receptor staining as being in malignant epithelial cells still requires visual assessment, but this can be aided by dual staining systems, such as with the AQUA, and pattern recognition systems for identifying malignant cells are in development.

RNA-Based Assays

Accurate quantitation of ER expression may also be achieved by RNA-based assays, such as quantitative reverse transcription-polymerase chain reaction (qRT-PCR). The development of the 21-gene Onco*type* DX qRT/PCR assay using fixed tissue

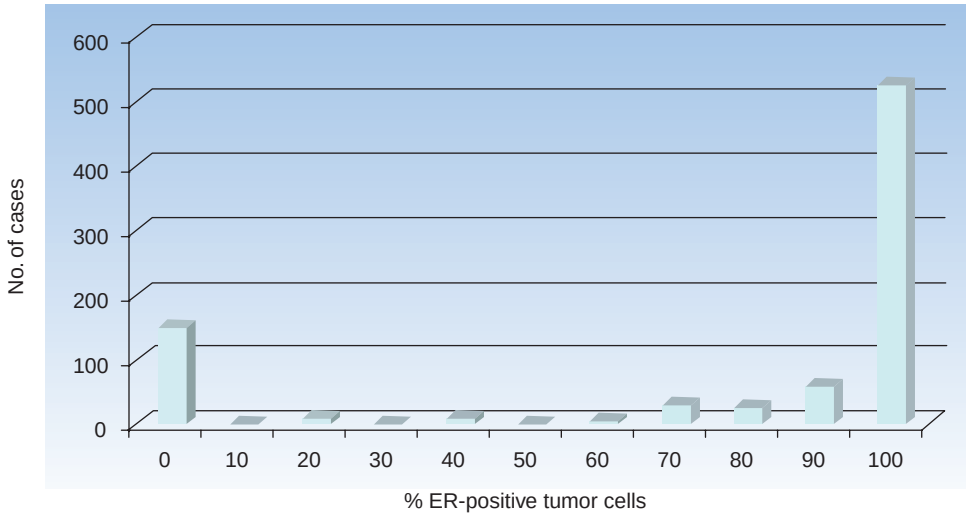

FIGURE 26-5 A frequency distribution of the percentage of cells showing nuclear staining for estrogen receptor among 825 primary breast cancers (31).

material showed that it is possible to measure ERα and PgR RNA levels reliably from archived tissues (42). Oncotype DX RT-PCR assay exhibited a continuous distribution of expression over a 3,000-fold and 1,000-fold range, respectively, for ER and PgR (43). Although qRT-PCR has emerged as an alternative method for determining hormone receptor status, the development of robust cutoffs for hormone sensitivity remain a challenge. A number of studies have showed a high degree of concordance between the two analytical approaches, particularly for ERα (43). In ECOG 2197 samples, measuring ERα by qRT-PCR was statistically superior to IHC in predicting relapse in tamoxifen-treated, ERα positive patients (43), but IHC for PgR outperformed RNA-based assays.

One strategy under investigation to augment the predictive value of hormone receptors is the evaluation of estrogen-regulated genes determined by RNA microarray analysis (44,45). Profiling with expression arrays allows for the simultaneous assessment of thousands of mRNA species in tumor samples, but smaller numbers may be useful, such as with the sensitivity to endocrine therapy (SET) score (46), or the eight-gene (and housekeeper genes) EndoPredict (47). These indices show an association with outcome on endocrine therapy but have not established their validity for selecting whether or not to use endocrine therapy.

A strategy has been developed to explore ER positive patients to endocrine therapy for the short period between diagnosis and excision (48). The assessment of changes in markers of proliferation such as Ki-67 or estrogen responsive genes may indicate an estrogen-dependent tumor. Change in Ki-67 is now widely accepted as an intermediate endpoint for assessing the comparative effectiveness of endocrine therapies.

RECEPTORS FOR THE CLINICAL MANAGEMENT OF BREAST CANCER

The place of ER and, to a lesser extent, PgR in selecting patients for tamoxifen therapy is well established (27). There are, however, several other potential roles in clinical management, including (a) predicting response to newer endocrine modalities such as AIs and fulvestrant in advanced disease; (b) predicting clinical benefit from adjuvant therapy with endocrine agents and chemotherapeutic drugs; (c) managing non-invasive disease; (d) using ER and PgR as prognostic factors; and (e) including ER and PgR as factors within predictive/prognostic panels such as IHC4 and as RNA in Oncotype DX.

Estrogen and Progesterone Receptors as Predictive Factors for Hormonal Therapy in Advanced Disease

Groundbreaking studies carried out in the early 1970s demonstrated that ER status might be used as a predictor of response to endocrine therapy in advanced breast cancer. ER positive disease had substantially higher response rates to a variety of hormonal therapies with only very rare responses in ER negative tumors (27). Subsequently, studies performed over the next 30 years confirmed these original observations and demonstrated that approximately 50% to 60% of all ER positive patients showed an objective response to first-line hormonal therapy; in contrast, only 5% to 10% of ER negative tumors responded (these responses may represent false negative assay results). Patients relapsing after successful endocrine treatment often benefit from a new second-line endocrine therapy that lacks cross resistance with the primary agent. ER status is also important in predicting benefit from such second-line and subsequent hormonal treatments.

Third-generation aromatase inhibitors (AIs) and "pure" antioestrogens were approved as first-line treatment for postmenopausal patients with MBC about 15 years ago. To address the relationship between hormone receptor status and outcome to AIs in MBC patients, Buzdar et al. (49) reviewed data on AIs from phase III trials. Positive hormone receptor status (ER, PgR, or both) was important in determining an improved time to progression (TTP) with the use of first-line treatment with these AIs. More recently, the AIs were approved for use in adjuvant treatment. The restriction of recruitment within these trials to ER positive patients and the absence of a nontreatment arm for comparison do not allow the direct assertion of no benefit in ER negative tumors, but a wealth of indirect clinical and laboratory evidence suggests this position. In advanced disease, a 7% objective response rate was observed to third generation AIs in 29 ER negative cases (50).

Multiple clinical trials have also shown that increasing levels of ER and PgR are also associated with better response, longer time to treatment failure, and longer survival (38). Although ER and PgR are correlated, PgR appears to provide information independent of ER with response rate higher by one-third in patients with ER positive/PgR positive tumors in comparison with patients with ER positive/PgR negative tumors. Higher PgR and Ki-67 levels are significantly associated with increased and decreased TTF, respectively, in ER positive patients receiving AI treatment of advanced disease. However, the higher proliferation seen in PgR negative tumors does not explain the poorer clinical responsiveness of this subgroup (50).

Hormone receptor status of metastases does not always correlate with that of the primary tumor with approximately 20% to 30% conversion rate from ER positive to ER negative and much less frequently from ER negative to ER positive at relapse (51). The receptor status of the metastasis may be more predictive of response. Thus, one study showed that, although 74% of patients with ER positive primary tumors whose recurrent tumors retained ER expression responded to endocrine therapy, only 12% of patients with ER positive primaries and ER negative metastases likewise responded (51). Similar discordances between hormone receptor content of primary breast cancer versus MBC have also been documented, and loss of ER may be associated with a significantly shorter median survival. The metastatic tumor ER status was shown to be a better predictor of survival than the primary tumor ER status (51). In biopsies from patients who developed resistance to tamoxifen, changes in hormone receptor status, as well as in other signaling pathway molecules, such as ERBB2, have also recently been documented (52). Similarly, a proportion of PgR positive tumors also lose PgR expression in their metastasis, and loss of PgR in sequential biopsies, particularly with intervening endocrine therapy, is associated with poorer survival as compared with tumors retaining PgR (53). A recent study compared ER, PgR, and HER2 expression in a large number of paired primary breast carcinomas and lymph nodes (54). Overall, 46.9% cases had disparate breast cancer/node receptor status of at least one receptor. Many of the differences in expression between primary tumor and node were large magnitude (greater than fivefold) changes. Triple-negative phenotype changed in 23.1% of cases. Different explanations have been suggested for this discordance, including (a) intratumor heterogeneity of breast cancer, which can lead to clonal selection of different clones with distinct hormone receptor properties that can change over time; (b) changes within single cells themselves as an adaptive mechanism for treatment; (c) tumor

dedifferentiation with the development of metastasis; or (d) technical laboratory difficulties in hormone receptor assessment of small biopsy specimens. Regardless of the cause, the high level of discordance between primary and metastatic disease has increased the frequency of biopsy at progression. Most oncologists nonetheless take the view that a trial of endocrine therapy is appropriate even when ER negativity has emerged in a metastasis. The less common conversion from ER negativity to positivity can, therefore, be of more clinical relevance because treatment with an endocrine agent would then be instigated.

Approximately 5% of breast cancers have an ER negative, PR positive phenotype (55). Although the phenotype may be real, it also may be artifactual, resulting from false negative ER assays. These tumors still benefit from endocrine therapy, although some data suggest a worse clinical outcome than ER positive tumors (55).

Adjuvant Therapy

As noted above, the EBCTCG overview analyses have provided conclusive evidence that overall ER negative tumors gain no significant benefit from tamoxifen therapy, but there is substantial benefit in tumors that have even very low levels (Figs. 26-6 and 26-7) (39). There is a small group of ER negative PgR positive tumors, and a small amount of

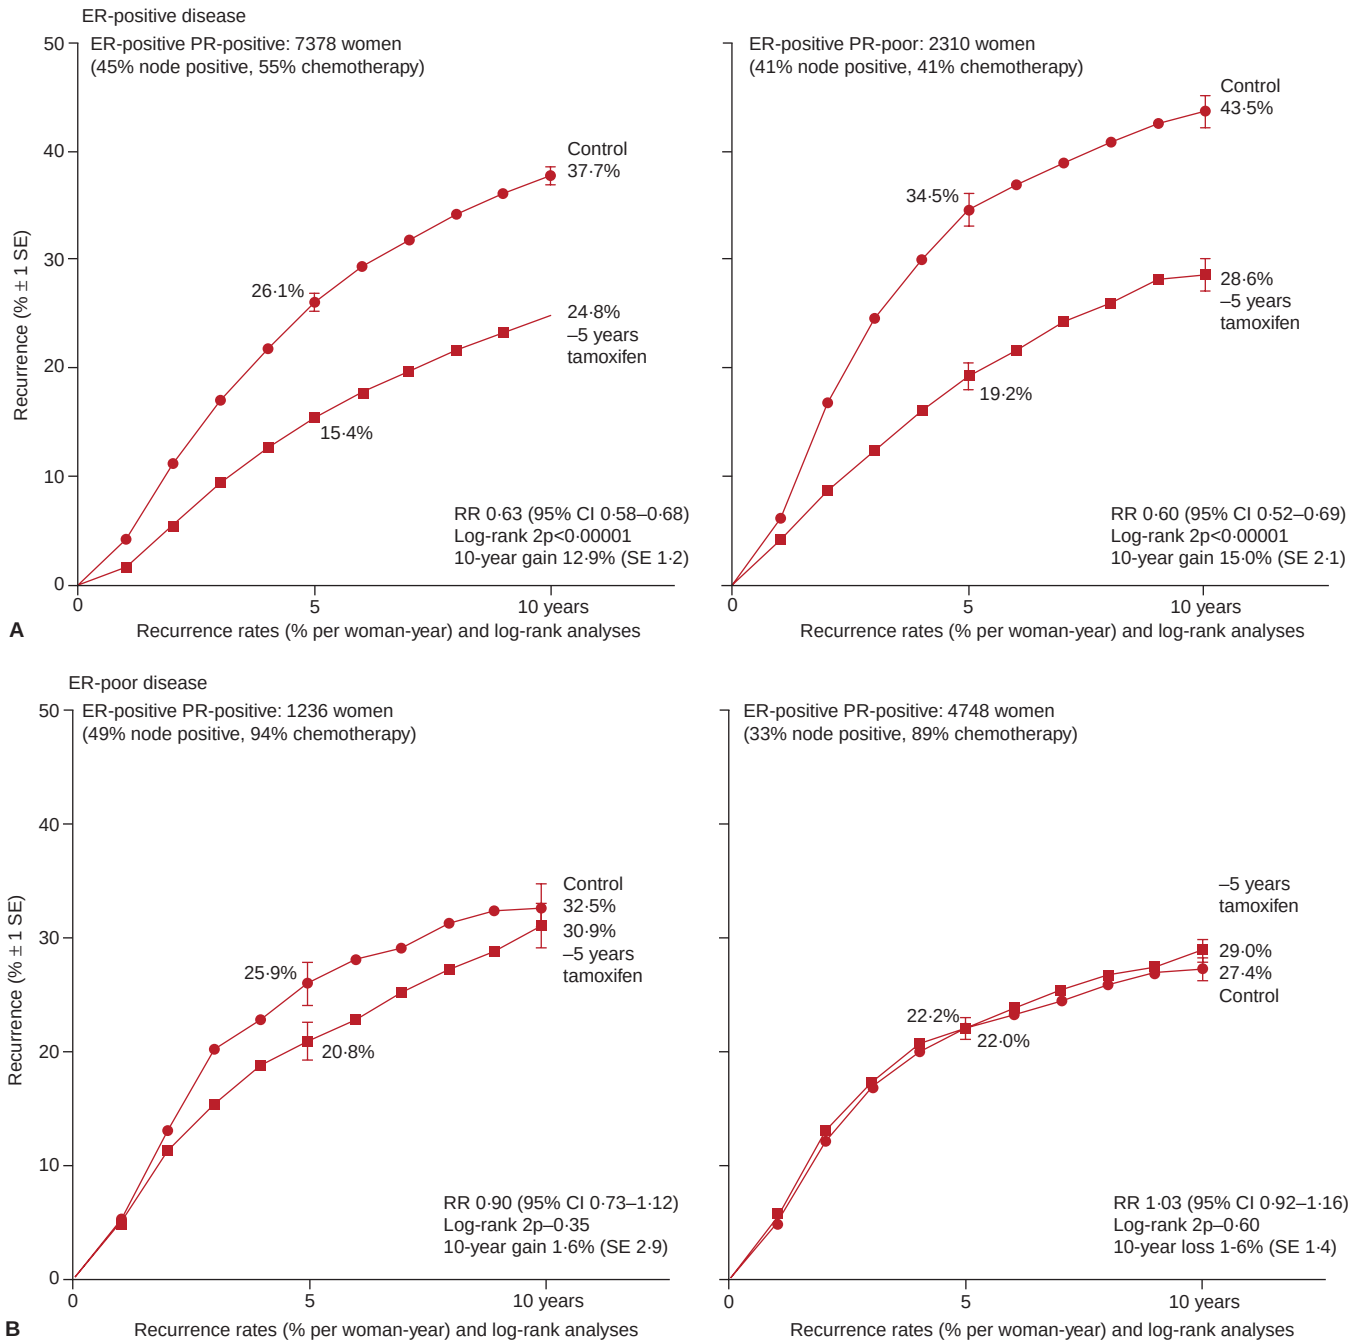

FIGURE 26-6 Impact of **(A)** ER and **(B)** PR status on risk of recurrence from about 5 years of tamoxifen versus no tamoxifen (70). ER and PR were measured using the ligand binding assay.

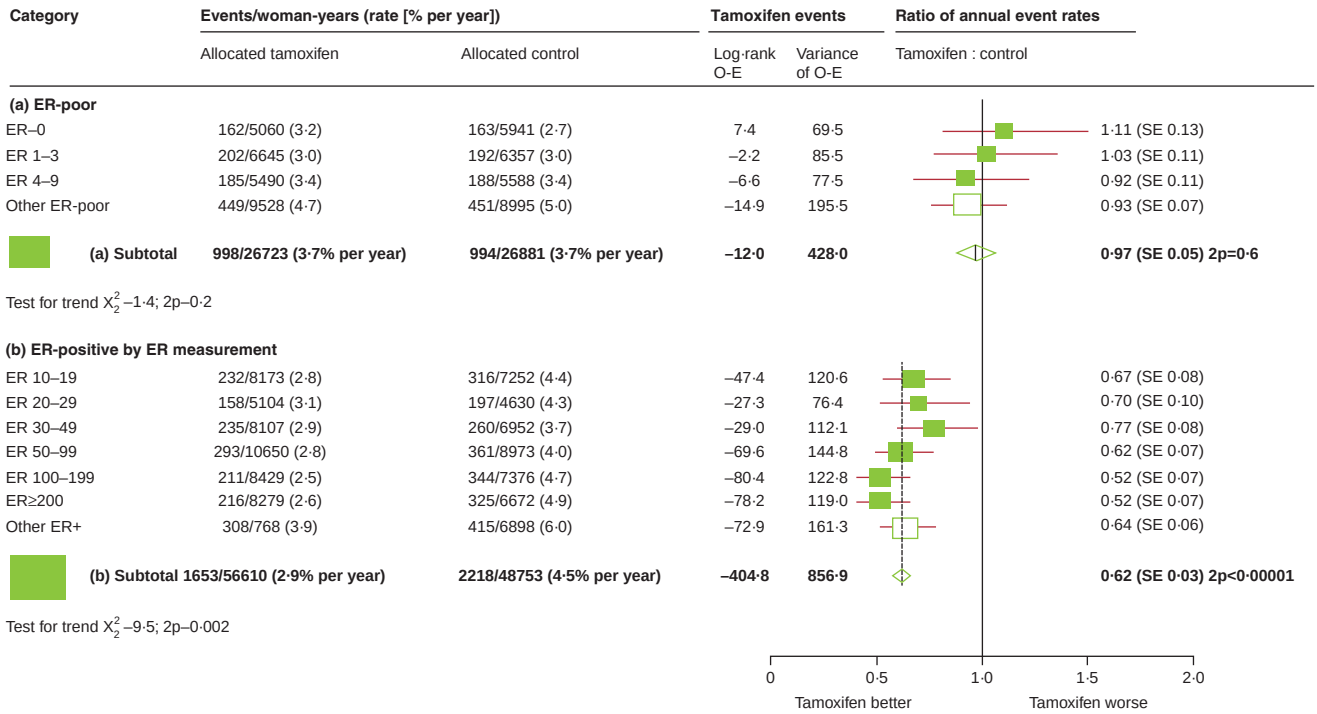

FIGURE 26-7 Degree of benefit from about 5 years of adjuvant tamoxifen according to levels of ER as measured using the ligand binding assay. (From Early Breast Trials Collaborative Group (EBCTCG), Davies C, Godwin J, et al. Relevance of breast cancer hormone receptors and other factors to the efficacy of adjuvant tamoxifen: patient-level meta-analysis of randomised trials. *Lancet* 2011; 378:771–784.)

benefit may occur in these, but the small number of cases makes this uncertain. The percentage of such tumors in most recent series is only around 1% to 2%, and this may be in part because of tissue heterogeneity, false negative ER assays, or false-positive PgR assays.

Given that few ER negative tumors were included in adjuvant trials of aromatase inhibitors of GnRH agonists, there is no direct evidence that they are refractory to such treatments, but a wealth of circumstantial evidence supports this such that these modern therapies are applied to only ER positive cases.

For many years, PgR-positivity has been regarded as an indicator of an intact ER signaling axis and led to a view that ER positive PgR positive cases should gain more benefit from tamoxifen or other endocrine therapy than ER positive PgR negative cases. Some large nonrandomized studies have indicated that PgR is an independent predictive factor for benefit from adjuvant endocrine therapy (56), but evidence from the overview analyses of randomized studies indicates that this is not the case and that relative benefit is very similar between positive and negative cases (39): Indeed, the absolute degree of benefit in PgR negative cases is greater than that in PgR positive ones because of their poorer prognosis (Fig. 26-6).

There have been numerous publications on the possible differential benefit from aromatase inhibitors versus tamoxifen in large adjuvant trials. An initial hypothesis-generating study from the ATAC trial of anastrozole versus tamoxifen reported that PgR negativity as measured by locally performed assays was associated with a markedly greater relative benefit from the aromatase inhibitor. However, a validation study performed on centrally determined PgR status failed to support this (57). An overview analysis that also incorporated data from the BIG1-98 study of letrozole versus tamoxifen found no significant interaction between treatment and PgR status as was the case in trials that switched from tamoxifen to an aromatase inhibitor after 2 to 3 years (58).

Although the status and expression levels of ER or PgR do not provide guidance to the relative benefit from these endocrine therapies, data from the same trials provide strong evidence for levels of expression of both receptors being associated with residual risk (57). The integration of these into single scores such as with the IHC4 (59), which also incorporates Ki-67 and HER2, has been found to predict long-term outcome after 5 years of adjuvant endocrine therapy at least as well as Oncotype DX. For widespread application of these as tests for patient management, greater consistency in measurement of the receptors by IHC will be needed, but the potential for affecting choice of whether or not to treat additionally with adjuvant chemotherapy was shown in a study of 101 patients with recommendations on the treatment of about one-third of patients being affected (60).

Estrogen Receptor in Noninvasive Breast Cancer

ER occurs in approximately 50% to 60% of DCIS tumors in which it is a good prognostic indicator with expression being inversely related to nuclear grade. ER negative tumors are more likely to recur than are ER positive tumors (61).

Although tamoxifen after local excision for DCIS (with or without adjuvant radiotherapy) reduces the risk of recurrent DCIS (in the ipsi and contralateral breast), there is still clinical uncertainty as to whether postoperative hormonal

treatment after surgery confers benefit in overall survival and incidence of recurrent carcinoma. However, in one influential study (NSABP B-24) that randomized 1,804 patients with DCIS undergoing excision and radiation for 5 years of adjuvant tamoxifen versus placebo, the tamoxifen arm was associated with about 40% reduction in all breast cancer events, which were largely confined to those patients whose original DCIS expressed ER (62). Because the results were intuitive and consistent with previous studies of invasive/metastatic breast cancer, the ASCO/CAP Breast Tumor Markers Guideline Panel indicated value in assessing ER in patients with DCIS (38). However, the panel recommended leaving it to patients and their physicians to decide on testing rather than making a formal recommendation. PgR status has been investigated in two large observational studies totalling 182 women with DCIS. The risk of ipsilateral breast tumor recurrence was lower in PgR positive tumors in both studies. However, on pooling data in a meta-analysis, the overall 44% decreased risk for recurrence failed to reach significance. PgR is not routinely measured in DCIS.

Estrogen and Progesterone Receptors as Prognostic Factors

Although ER is routinely used as a predictive factor, it can also be employed prognostically. In historic studies, women with ER positive tumors not receiving systemic therapy after surgery have rates of recurrence at 5 years, which are 5% to 10% lower than in those with ER negative tumors. However, ER may be a time-dependent variable, and studies with longer follow-up suggest that, with time, different rates of relapse and death significantly diminish and eventually disappear (63). It is possible therefore that ER status is associated with indolent, slow-growing tumors and less with metastatic potential. ER positive tumors are more frequently found in older patients; are more likely to have a well-differentiated histology, lower fraction of dividing cells; are diploid; are less likely to exhibit a mutation, loss, high expression, or amplification of breast cancer related genes such as TP53, *ERBB2*, or EGFR and have a luminal subtype of breast cancers by molecular gene expression profiling.

The utility of PgR as a prognostic factor in the absence of endocrine therapy is still an area of debate; some studies are supportive, but other data are not. Among ER positive tumors, PgR positive tumors are likely to be smaller in size, to have a lower S-phase fraction, and to be diploid. ER positive/PR negative tumors, in comparison to ER positive/PgR positive tumors, have twice as many DNA copy number changes, including specific regions of gain or loss (64). PgR loss correlates with the aggressive luminal B breast cancer subtype with EGFR and ERBB2 expression and with a gene signature of the PI3K/Akt/mTOR oncogenic pathway (64).

Multi-Parameter Testing in ER/PgR Positive Tumors

ER's being a pure prognostic factor is moot because virtually all ER positive patients will receive endocrine therapy, and its value as a biomarker of long-term outcome needs to be interpreted in that setting. Over recent years, a series of prognostic indices and molecular signatures have been developed to combine a variety of markers with ER and PgR for the evaluation of residual risk of recurrence in ER positive patients. These indices and molecular/genetic signatures include the sensitivity to endocrine therapy (SET) index (46) (derived from genes correlated with ER) and Adjuvant online! (65), genomic grading Index (66), IHC4 (59), Mamma-Print (67), and Oncotype DX (42) (which have been derived more empirically).

The SET index is based on the principle that expression of genes correlated with ER might predict response to endocrine treatment more accurately than ER expression alone. Microarray gene expression profiling of a discovery set of ER positive tumors resulted in the identification of 165 genes coregulated with ER. This 165-gene signature has been applied to independent data sets composed of microarray samples from patients with ER positive cancers receiving either adjuvant tamoxifen for 5 years, neoadjuvant chemotherapy followed by endocrine therapy (tamoxifen or aromatase inhibition), or no adjuvant systemic treatment. SET was associated with the outcome of patients receiving any type of endocrine treatment (tamoxifen or chemo endocrine treatment) but had no prognostic value in untreated patients (46). This signature has the potential to add additional predictive information to existing clinical-pathological models to determine which patients should receive endocrine therapy.

Several gene signatures illustrate that the molecular profiles of ER positive and ER negative tumors are different, providing convincing evidence that ER positive and ER negative breast cancers are distinct diseases. Thus, the seminal class-discovery studies undertaken by Perou and colleagues (44) and Sorlie and co-workers (68) revealed that ER positive and ER negative breast cancers are fundamentally distinct diseases in molecular terms and revealed the existence of at least four molecular subtypes of breast cancer: namely, luminal (now subdivided into A and B), HER2-enriched, basal-like, and normal breast-like. At the RNA level, the identification of these subtypes was shown to be mainly driven by the expression of ER and ER related genes, proliferation-related genes, and, to a lesser extent, HER2 and genes mapping to the region of the HER2 amplicon (44,68).

Signatures such as MammaPrint, Recurrence Score, and Genomic Grade Index can subdivide ER positive breast cancers (in some cases within others without endocrine therapy) into good and poor prognosis patients. Thus, recent studies have demonstrated that the signatures identify an overlapping group of highly proliferative ER positive tumors that have poor prognosis (69). Although the overlap between the genes that compose each of these signatures is limited, their prognostic impact is largely derived from the quantification of two biological processes: proliferation and ER signaling. This explains why virtually all ER negative cancers and almost all high-grade ER positive cancers are classified as high risk by these methods. The most important practical contribution of genomics to breast cancer management is that the signatures can distinguish low and high risk prognostic groups among ER positive, early stage breast cancers. Thus, these patients are at such low risk of recurrence that gains from chemotherapy are likely to be minimal and the patients may be spared its toxicity. In the past, selection of adjuvant chemotherapy for ER positive cancers was based on tumor size, nodal status, histologic grade, patient preference, and comorbid illnesses. However, none of these variables, with the exception of grade, have a consistent association with sensitivity to chemotherapy.

It is important that the prognostic information from these new molecular indices be integrated with that from classical clinicopathological index for optimal prognostic assessment.

However, the prognostic information provided by signatures may not be above and beyond that offered by semiquantitative assessment of ER, PgR, HER2, and Ki-67; and multi-IHC tests including these markers may accomplish similar risk stratification. For example, the IHC4 test was shown to be just as effective at predicting high and low

risk women as the expensive American Oncotype DX® (59). Oncotype DX® is a valuable method of identifying patients whose breast cancer could recur, but many healthcare systems do not have the money available to use it. IHC4 could make this information available to them without adding significantly to costs and could help reduce spending by cutting unnecessary chemotherapy treatment.

Concluding Remarks

ER and, to a lesser extent, PgR have long been accepted as playing a central role in the pathobiology and treatment of breast cancer; standard practice requires assessment of hormone receptors to select appropriate treatment. Furthermore, genomic analyses reveal a close association between the presence or absence of ER and substantive biological groupings. There is still much to learn about the control of transcription by the receptors, the interaction of treatments with those controls, and how this affects clinical outcome. Better understanding of these may provide new concepts for influencing the receptors' function and improved targeting of therapeutic interventions.

CHAPTER 27

HER2/ERBB2 Testing: Assessment of Status for Targeted Therapies

Michael F. Press and Yanling Ma

CHAPTER CONTENTS

Amplification of the human epidermal growth factor receptor type 2 (HER2 or ERBB2) gene in human breast cancers is an example of an acquired molecular alteration on which human breast cancer cells with this alteration depend for maintenance of a fully malignant phenotype and which has come to represent a molecular subtype of the disease. HER2/ERBB2 (also known as *neu* oncogene) amplification with resultant HER2/ERBB2 protein overexpression has been shown to play a role in sustaining multiple cancer pathways, including self-sufficiency in growth signals, sustained angiogenesis, increased cell division, and enhanced invasion (1,2). Inhibition of HER2/ERBB2 membrane signaling in these cancer cells through administration of humanized anti-HER2/ERBB2 antibodies (trastuzumab [Herceptin], pertuzumab [perjeta], Trastuzumab emtansine) or administration of small molecule inhibitors of HER2/ERBB2 tyrosine kinase activity (lapatinib [Tykerb]) is associated with improved patient outcomes for women with both primary and metastatic disease (3–7). Because improvements in outcome are only documented in women whose breast cancers have alterations in the HER2/ERBB2 gene or protein product, accurate clinical testing for HER2/ERBB2 amplification or overexpression has become an important clinical consideration. The importance of this issue is reflected by the fact that the American Society of Clinical Oncology (ASCO) recommends routine testing of only three predictive markers: estrogen receptor (ER), progesterone receptor (PR), and HER2/ERBB2 in women diagnosed with primary, invasive breast carcinomas.

ASSOCIATION OF HER2/ERBB2 AMPLIFICATION WITH HER2/ERBB2 OVEREXPRESSION

The HER2/ERBB2 gene encodes a 185 kDa monomeric protein also known as phosphoprotein 185 ($p185^{HER2/ERBB2}$). The HER2/ERBB2 protein is a receptor tyrosine kinase that is classified as a member of the epidermal growth factor receptor (EGFR) family of tyrosine kinases based on significant homology to EGFR (8,9). HER2/ERBB2 is a membrane protein expressed at low levels in all epithelial cells in normal fetal and adult tissues (10).

The HER2/ERBB2 gene is amplified, or increased in copy number, in approximately 25% of human breast cancers (11,12) as well as a variable percentage of ovarian (12), bladder (13), endometrial (14), salivary gland (15), esophageal, and gastric cancers (16). HER2/ERBB2 gene amplification has been associated with pathologically increased levels of expression of HER2/ERBB2 messenger RNA (mRNA) and $p185^{HER2/ERBB2}$ protein product (12). Although HER2/ERBB2 gene amplification status and expression level were originally found to be closely associated in 90% of frozen breast cancer specimens (12), subsequent work by the same investigators has demonstrated a near complete concordance between the HER2/ERBB2 amplification status and expression status in the same tissue samples (17,18). The 10% of breast cancers that were originally discordant cases were predominantly stromal-rich breast cancers that were classified as

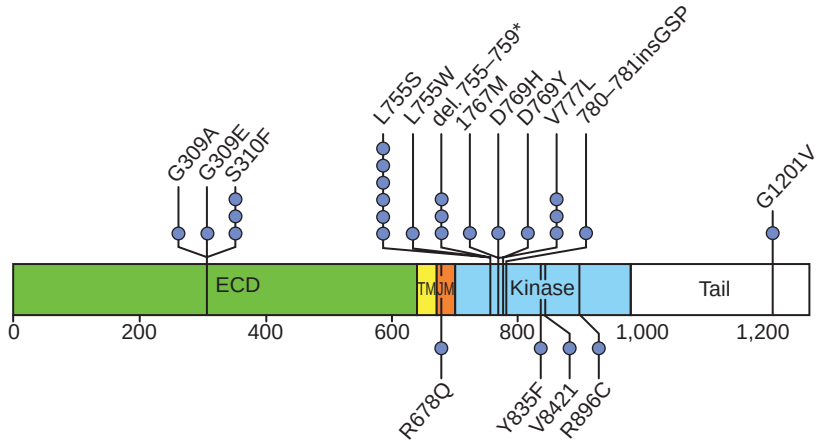

FIGURE 27-1 Schematic illustration of the locations of activating mutations identified in the HER2/ERBB2 gene through genome-wide DNA sequence analyses. The HER2/ERBB2 somatic mutations observed in 25 patients are illustrated with blue circles representing each case with the indicated mutation out of 1,499 with complete genome-wide DNA sequence analysis information available. Two patients had two HER2 somatic mutations each, resulting in a total of 27 mutations in 25 patients. del.755–759* indicates that two patients had del.755–759 and one patient had del.755–759 with a S760A change. ECD, extracellular domain; JM, juxtamembrane region; SNP, single-nucleotide polypeptide; TM, transmembrane region; WT, wild type. (From Bose R, Kavuri SM, Searleman AC, et al. Activating HER2 mutations in HER2 gene amplification negative breast cancer. *Cancer Discov* 2013;3(2);224–237.)

nonamplified, overexpression breast cancers. HER2/ERBB2 gene amplification status had been originally determined by Southern hybridization in these stromal-rich breast cancers and dilution of tumor DNA by more abundant normal DNA resulted in Southern blots that failed to show HER2/ERBB2 gene amplification, owing to the dilution of tumor DNA by the more abundant normal DNA. Reanalysis of these same cases by fluorescence *in situ* hybridization (FISH) permitted a nucleus-by-nucleus evaluation of the HER2/ERBB2 gene copy number and demonstrated HER2/ERBB2 gene amplification in the tumor cell nuclei of these cases that were previously considered not to be amplified (by Southern blot), but had overexpression by Northern hybridization, Western Immunoblot, and frozen section immunohistochemical assay (12). Therefore, one can conclude, when working with frozen tissue specimens, there is a close association between HER2/ERBB2 gene amplification status and overexpression status. That is, when the HER2/ERBB2 gene is not amplified, then the products of the gene are not increased and overexpression is not observed. Similarly, when HER2/ERBB2 gene is amplified, overexpression is consistently observed. Although this close association can be demonstrated in frozen tissue samples, tissue fixation and paraffin embedding of these same specimens lead to difficulties in analysis of protein expression, especially by immunohistochemistry (12,19–21). This problem is addressed subsequently in this chapter when we discuss clinical assay methods for assessment of HER2/ERBB2 status.

IDENTIFICATION OF FUNCTIONALLY ACTIVE MUTATIONS IN HER2/ERBB2

Genome-wide DNA sequence data from eight different studies encompassing 1,499 subjects demonstrated 25 breast cancers with mutations in the HER2/ERBB2 gene, seven of which are activating mutations (22). These seven activating mutations (G309A, D769H, D769Y, V777L, P780ins, V842I, and R896C; Fig. 27-1) represent an alternative mechanism for activation of HER2/ERRB2 in addition to gene amplification. Only one of the mutations (V777L) has been identified in breast cancers with HER2/ERBB2 gene amplification. A HER2/ERBB2 in-frame deletion 755–759, which is homologous to EGF receptor (EGFR) exon 19 in-frame deletions, had a neomorphic phenotype with increased phosphorylation of EGFR or HER3. These HER2/ERBB2 somatic mutations are estimated to be present in approximately 1.6% of breast cancers. While some of these mutations are resistant to lapatinib, all were sensitive to the irreversible HER2/ERBB2 tyrosine kinase inhibitor, neratinib. A clinical trial is in progress to evaluate this approach as a treatment strategy in women whose breast cancers lack HER2/ERBB2 gene amplification.

CLINICAL IMPORTANCE OF HER2/ERBB2 GENE AMPLIFICATION AND OVEREXPRESSION STATUS

HER2/ERBB2 gene amplification or overexpression is a prognostic marker of poor outcome in the absence of adjuvant treatment and an important predictive marker of responsiveness to certain treatments. The HER2/ERBB2 alteration has been associated with an increased rate of metastasis, decreased time to recurrence, and decreased overall survival (11,12,23). HER2/ERBB2 gene amplification is significantly associated with shorter disease-free survival and shorter overall survival in primary, invasive, node-negative breast cancer patients treated with surgery alone, without chemotherapy, without hormone therapy, and without radiation therapy in the adjuvant setting (24). HER2/ERBB2 is a prognostic marker independent of nodal status, tumor size, grade, and hormone receptor status (24).

As a predictive marker, HER2/ERBB2 amplification or overexpression has been correlated with responsiveness to

anthracycline-based chemotherapy (25,26), paclitaxel-containing chemotherapy (27), and, most importantly, trastuzumab (Herceptin) and lapatinib (Tykerb) anti-HER2 targeted therapies. Currently, patients with HER2/ERBB2-positive tumors are treated with therapy directed against the HER2/ERBB2 protein. Humanized antibodies directed against the extracellular domain of the HER2/ERBB2 membrane protein (trastuzumab [Herceptin], pertuzumab [Perjeta], and trastuzumab emtansine [T-DM1]), and a dual tyrosine kinase inhibitor of EGFR and HER2/ERBB2 (lapatinib [Tykerb]), are currently approved by the U.S. Food and Drug Administration (FDA) for use in the treatment of HER2/ERBB2-positive invasive breast cancers. Trastuzumab is approved for use in the treatment of both metastatic and primary, invasive HER2/ERBB2-positive breast cancer. Pertuzumab and lapatinib are approved for the treatment of HER2/ERBB2-positive metastatic breast cancer (28). Clinical trials are in progress to evaluate utility in primary breast cancer with HER2-targeted agents such as lapatinib, pertuzumab, and T-DM1, and newer drugs such as neratinib are being actively tested in the metastatic setting. Several other biological agents directed at HER2/ERBB2 or the pathway are in development. Each of these therapeutic agents requires the use of a companion diagnostic test to select the most appropriate patients for treatment (Table 27-1).

Inaccurate assessment of HER2/ERBB2 status can lead to the inappropriate treatment of breast cancer patients in both the adjuvant and metastatic settings and subject patients to unnecessary risk. With current practice guidelines, false-negative HER2/ERBB2 status is a serious concern because these patients are denied the substantial benefit of HER2/ERBB2 targeted therapies. On the other hand, false-positive HER2/ERBB2 status is also important because cardiac toxicity is a significant risk for patients who are treated with combinations of trastuzumab and anthracycline-containing chemotherapy. For these reasons, accurate determination of HER2/ERBB2 alterations in breast carcinomas, if present, are of critical importance.

DETECTION OF HER2/ERBB2 AMPLIFICATION AND OVEREXPRESSION IN CLINICAL PRACTICE

In 1998, the humanized mouse 4D5 monoclonal antibody trastuzumab (Herceptin), directed against the human epidermal growth factor receptor type-2 (HER2/ERBB2) (7,29), was approved for the treatment of HER2/ERBB2-positive metastatic breast cancer. These patients had been selected for entry to the registration clinical trials of trastuzumab with an immunohistochemistry assay method, known as the *Clinical Trials Assay* (CTA) (7,30–32). The CTA used two different antibodies: 4D5 (the mouse monoclonal antibody used to produce humanized trastuzumab) and CB11 (a mouse monoclonal antibody). Antigen retrieval techniques were used for both antibodies in the CTA. However, because the CTA was not considered appropriate for commercialization, a second immunohistochemistry (IHC) assay method, the Dako HercepTest, was developed for commercial testing of HER2/ERBB2 status to select women for treatment with trastuzumab. This companion IHC assay method to assess HER2/ERBB2 membrane staining was approved by the FDA based on a 79% concordance rate (95% confidence interval [CI], 76%, 82%) between the immunostaining results of the CTA and the immunostaining results of the HercepTest for 548 breast cancer specimens from the National Cancer Institute Cooperative Breast Cancer Tissue Resource, a group of tumors that lacked clinical outcome information. Subsequently, a fluorescence *in situ* hybridization assay method was also approved by the FDA to identify women whose breast cancers had HER2/ERBB2 gene amplification for selection to trastuzumab therapy. This approval was based on a blinded, retrospective analysis of archival tissue sections from the breast cancers of women entered in the H0648g and H0650g registration trials (33). This analysis demonstrated that women entered in the H0648g trial

TABLE 27-1

Clinical Laboratory Assays for HER2/ERBB2 Testing Approved by the U.S. Food and Drug Administration

Year	*Assay Name*	*Method*	*Indication*	*Company*
1997	INFORM HER2[a]	FISH	High-risk for recurrence or disease-related death	Oncor, Inc. (Ventana Medical Systems, Inc.)
1998 2012	HercepTest	IHC	Trastuzumab Pertuzumab	Dako, Inc.
2000	Pathway anti-HER2/neu (CB11[b])	IHC	Trastuzumab	Ventana Medical Systems, Inc. / Roche, Inc.
2002	PathVysion	FISH	Trastuzumab	Vysis, Inc. (Abbott-Molecular)
2004	InSite HER2/neu (CB11) kit[c]	IHC	Trastuzumab	Biogenex Laboratories, Inc.
2005	HER2 FISH pharmDX Kit	FISH	Trastuzumab Pertuzumab	Dako, Inc.
2008	SPOT-Light HER2 CISH kit	CISH	Trastuzumab	Invitrogen, now Life Technologies, Inc.
2011	INFORM HER2	Dual ISH	Trastuzumab	Ventana Medical Systems, Inc. / Roche, Inc.
2011	HER2 CISH pharmDx Kit	Dual ISH	Trastuzumab	Dako, Inc.
2012	Bond Oracle HER2 IHC	IHC	Trastuzumab	Leica Biosystems

[a]INFORM HER-2/neu FISH assay originally approved in 1997 by Oncor, Inc. and subsequently in 2000 by Ventana Medical Systems, Inc. was withdrawn from the market in October 2007. The currently approved "INFORM HER2" has been revised as a SISH assay using a different HER2 DNA probe.
[b]Although originally approved with CB11 mouse monoclonal antibody, this assay currently uses the 4B5 rabbit monoclonal antibody.
[c]The INSITE HER2/neu (CB11) kit was withdrawn from the market in 2006.

of trastuzumab for metastatic disease whose breast cancers were IHC 2+ or 3+ but lacked HER2/ERBB2 gene amplification by FISH did not show any incremental benefit from the addition of trastuzumab to the chemotherapy regimen (33). Those women whose breast cancers were HER2/ERBB2 amplified by FISH and received trastuzumab with chemotherapy had a significantly improved overall survival compared with women whose breast cancers were HER2/ERBB2 amplified and were treated with chemotherapy alone. The separation of the outcomes was greater in this comparison than in the original efficacy population (p = .009) (33).

Three FISH assays, two of which are commercially available (PathVysion by Vysis, Inc., now Abbott-Molecular, Inc., and pharmDx by Dako, Inc.), four IHC assay methods (HercepTest by Dako, Pathway by Ventana Medical Systems/Roche, InSite by Biogenex, and Oracle by Leica), and three chromogenic, silver, or dual (bright field microscopic) *in situ* hybridization (INFORM-HER, originally a FISH assay by Oncor, Inc., is now a bright-field ISH owned by Ventana Medical Systems, Inc.; pharmDx kit by Dako, Inc.; and SPOT-Light by Life Technologies, Inc.) assay methods are approved by the FDA to select women for trastuzumab therapy (Table 27-1).

Because HER2/ERBB2 gene amplification is directly correlated with HER2/ERBB2 expression levels at the mRNA and protein levels, determination of HER2/ERBB2 status could potentially be made at any of these levels and should correspond to the HER2/ERBB2 status determined with any of the other measures. Although this is approximated when frozen tissues are used, the use of formalin-fixed, paraffin-embedded tissues for these determinations introduces practical problems that result in some errors in HER2/ERBB2 characterization, especially when IHC is used to assess HER2/ERBB2 status in formalin-fixed paraffin-embedded tissues. We briefly review the various methods used to assess HER2/ERBB2 in breast cancer specimens, and then compare and contrast the results obtained with different methods of analysis, especially between IHC and FISH. A summary of these techniques is provided in Table 27-2.

CLINICAL ASSAYS FOR ASSESSMENT OF HER2/ERBB2 STATUS

Although HER2/ERBB2 status has been highly concordant among assays of DNA, mRNA and protein in frozen tissues, the current clinical use of paraffin-embedded tissue limits the type of HER2/ERBB2 analyses that can be performed. The types of assay choices for formalin-fixed, paraffin-embedded tissues include FISH, CISH, and SISH to determine gene amplification status; quantitative real-time reverse transcriptase-polymerase chain reaction (RQ-PCR) analysis and microarray-based RNA expression profiles (RNA-EP) to determine HER2/ERBB2 mRNA expression status (34,35); and IHC to determine HER2/ERBB2 protein overexpression status. The most popular of these methods is IHC, with approximately 85% or more (36) primary HER2/ERBB2 assessments being performed with this method. The second most popular method for assessment is FISH, with 6% to 15% of assays performed with this assay method, predominantly for "reflex" FISH testing after primary IHC testing yields an immunostaining score of IHC 2+ (36). The Genomic Health proprietary Oncotype DX 21-gene assay measures messenger RNA for a series of markers including ER, PR, and HER2/ERBB2 and proliferation markers in the clinical setting with ER, PR, and HER2/ERBB2 results now reported separately. A new biotechnology method, nanostring, also measures mRNA from formalin-fixed paraffin-embedded tissues (37). These assay methods are briefly reviewed below.

IMMUNOHISTOCHEMISTRY

Immunohistochemistry uses antibodies that recognize antigenic determinants of the full-length HER2/ERBB2 protein to assess indirectly and qualitatively the overall level of HER2/ERBB2 protein expression in paraffin-embedded tumor samples (Figs. 27-2 and 27-3). Overexpression of the HER2/ERBB2 protein by IHC is associated with a poor patient prognosis because of increased metastatic potential, and it is an independent predictor of disease-free and overall survival in patients with breast cancer containing this alteration (12,38–42).

The Clinical Trials Assay (CTA) (31) is the first clinical assay developed to select women for entry into the clinical trials investigating trastuzumab therapy in metastatic breast cancer patients (7,30,32). The HercepTest (Dako, Carpenteria, California) and the CB11 IHC assays (Pathway, Ventana Medical Systems, Tucson, Arizona), two of the IHC assays currently approved by the FDA for determination of HER2/ERBB2 status, were modeled on the CTA and were approved by the FDA through concordance studies. The HercepTest was approved based on a direct comparison of the agreement rate, or concordance, with the CTA. As summarized above, the agreement rate between these assay methods was 79%. The Ventana Pathway assay used one of the two antibodies from the original CTA, the CB11 anti-ERBB2 antibody, as the detection antibody in the initial formulation of this assay method; however, the 4B5 monoclonal anti-HER2 antibody is used in the current kit. The Pathway IHC method was originally approved by the FDA based on a 92.4% concordance (95% CI, 89.6%–94.7%) with the HercepTest.

The HercepTest utilizes a rabbit anti-human HER2/ERBB2 polyclonal antibody to detect the HER2/ERBB2 protein, whereas the Pathway anti-HER2 (4B5) assay uses a rabbit antihuman monoclonal antibody. The scoring of immunostaining intensity for both of these assay methods is modeled after scoring in the original CTA. The microscopic appearance of the immunostained tumor cell membranes is subjectively graded by a pathologist on a scale of 0 to 3+, with 0 and 1+ considered low expression, 2+ considered indeterminate, and 3+ considered overexpression. To reduce the subjective variation in scoring by different pathologists, a series of cell line controls are used in parallel to provide a comparison with a negative control (0) (MDA-MB-231 cells), a slightly positive control (1+) (MDA-MB-175 cells), and a strongly positive control (3+) sample (SKBR3 cells) for Dako reagents. Alternately, a different set of cell lines is available for Ventana reagents, including a negative control (0) (MCF7 cells), a slightly positive control (1+) (T47D cells), a moderately positive control (2+) (MDA-MB-453), and a strongly positive control (3+) (BT474 cells). Previously in the CTA, IHC2+ immunostaining was considered to be overexpression, but these cases were found to have a highly variable proportion with HER2/ERBB2 gene amplification and it was decided by the College of American Pathologists (CAP) and, more recently, by a joint guideline from the ASCO and the CAP that these cases should be considered *indeterminate* and *reflexed* to FISH for evaluation of HER2/ERBB2 gene amplification to determine the status of the case (43,44). The original CTA and HercepTest scoring system approved by the U.S. Food and Drug Administration (FDA) required a minimum of 10% of tumor cells to be immunostained with a particular intensity for scoring at a particular level; however, initial ASCO-CAP guidelines required the use of 30% as the proportion of tumor cells stained to achieve a particular staining level (43,44) but has been reversed to the FDA-approved 10% proportional requirement in the current

TABLE 27-2

Summary of Assays Used to Determine HER2/ERBB2 Status in Tissue Specimens

Parameter		*HER2/ERBB2 Protein Immunohistochemistry*			*HER2/ERBB2 Gene*			
						FISH	*CISH*	*SISH*
Assay Manufacturer	CTA Home-brew Assay	HercepTest Dako	Pathway Ventana	Oracle Leica	PathVysion Abbott	PharmDx Dako (now Agilent)	SPoT-Light Invitrogen/Zymed (now Life Technologies)	INFORM HER2 Ventana (now Roche)
Methodology	CB11 and 4D5 Monoclonal Antibodies	A0485 Polyclonal antibody	4B5 Monoclonal antibody	CB11 Monoclonal antibody	Directly labeled fluorescent ERBB2 and chromosome 17 centromere probes	Indirectly labeled fluorescence probes for ERBB2 chromosome 17 centromere	Digoxigenin labeled ERBB2 DNA probe and detection via anti-digoxigenin antibody followed by antimouse peroxidase	Dinitro-Phenol ERBB2 probe with detection by enzyme metallography and dig-labeled CEP17 probe
Status	Research Assay used in trastuzumab clinical trials	FDA-approved	FDA-approved	FDA-approved	FDA-approved	FDA-approved	FDA-approved	FDA-approved

Information modified from Wolff AC, Hammond ME, Schwartz JN, et al. American Society of Clinical Oncology/College of American Pathologists guideline recommendations for human epidermal growth factor receptor 2 testing in breast cancer. *J Clin Oncol* 2007;25(1):118–145, with permission.

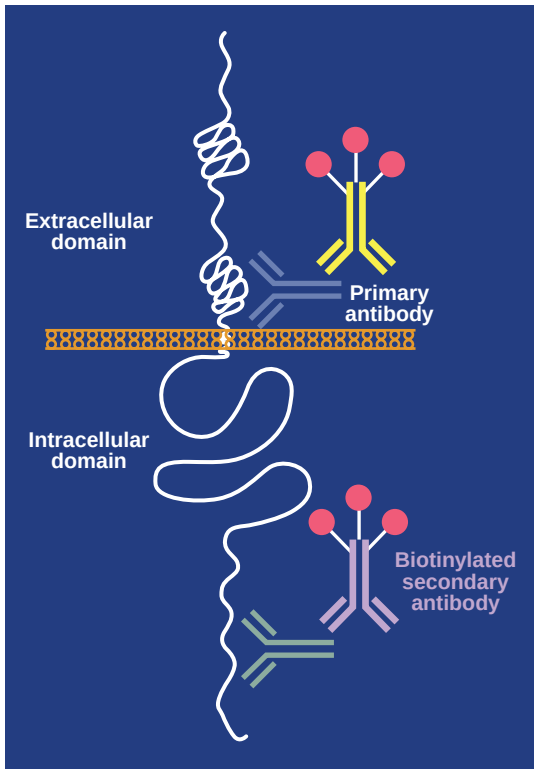

FIGURE 27-2 **Schematic illustration of the Clinical Trials Assay (CTA) to assess HER2/ERBB2 expression by immunohistochemistry.** In the CTA two different primary anti-ERBB2 monoclonal antibodies are used on sequential sections, not on the same section as illustrated in this schematic drawing. One of the primary anti-HER2/ERBB2 antibodies, 4D5, is the mouse monoclonal antibody that was humanized to synthesize trastuzumab. This antibody (*blue*) recognizes an extracellular domain of the HER2/ERBB2 protein. The other antibody, CB11 (*green*), recognizes an intracellular domain of the HER2/ERBB2 protein. These antibodies are each identified by biotinylated secondary antimouse IgG antibodies (*yellow* and *purple*) decorated with horseradish peroxidase (*red*). The site of HER2/ERBB2 is recognized by light microscopic identification of a diaminobenzidine reaction product deposited by the action of horseradish peroxidase. (Courtesy of Allison Bruce, Noel Dybdal, and Genentech.)

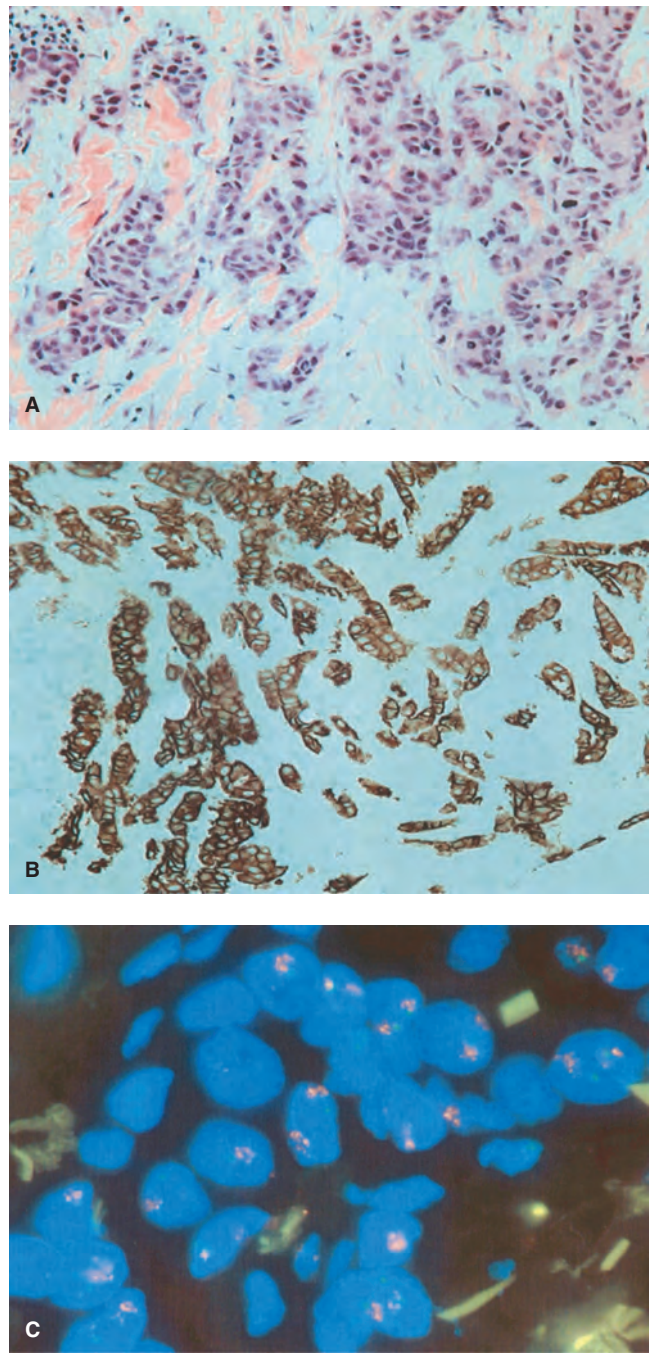

FIGURE 27-3 **Infiltrating ductal carcinoma breast cancer with HER2/ERBB2 gene amplification and overexpression.** A formalin-fixed, paraffin-embedded breast cancer is characterized **(A)** for histopathology by hematoxylin-and-eosin staining, **(B)** for HER2/ERBB2 protein overexpression by immunohistochemistry (IHC 3+), and **(C)** for HER2/ERBB2 gene amplification by FISH.

ASCO-CAP guidelines (45). No objective published data demonstrate the need for 10% as a suitable scoring minimum nor were objective data offered for a change from 10% to 30% as the minimum needed for assessment of a particular score such as IHC 3+. In fact, in frozen tissues nearly all tumor cells in a given breast cancer show the same level of immunostaining, either 1+, 2+, or 3+ (12,18), with substantial variability in staining intensity appreciated almost exclusively in the formalin-fixed, paraffin-embedded tissue samples (12,18,19,40). Nevertheless, both the HercepTest and Pathway anti-HER2 assays are approximately 90% accurate at assigning the known, molecularly determined status of breast cancer specimens (20).

The use of IHC to determine HER2/ERBB2 status is appealing for several reasons. HER2/ERBB2 IHC tests are simple, rapid, inexpensive, and easily accommodated by existing surgical pathology laboratory practices. In addition, pathologists have an established familiarity with the IHC technique and reagents. However, application of IHC to assess HER2/ERBB2 status is problematic for a number of reasons. The clinical assays are performed on fixed, paraffin-embedded (FPE) tissues and HER2/ERBB2 IHC analyses of this type of material are associated with several problems (12,18–20,33,40,46–48). Tissue handling, fixation, and

processing can greatly affect immunoreactivity of tissue antigens (12,18,19,49,50). It has been proposed that loss or significant reduction of HER2/ERBB2 immunostaining may occur in approximately 10% of HER2/ERBB2-positive (amplified) samples, owing to formalin fixation (46,47,49) or storage of unstained sections (18,51) before use for IHC. HER2/ERBB2 positivity by IHC in FFPE tissues is dependent on the HER2/ERBB2 antibody used for the protocol (12,19,20). For example, 95% of the HER2/ERBB2-amplified tumors examined were HER2/ERBB2-positive using the CB11 test, but only 84% of these same tumor samples were HER2/ERBB2-positive using the HercepTest (52).

Interpretation of IHC is inherently subjective and qualitative. This leads to observer variability and affects the accuracy of results using the IHC technique (53), although relatively high concordance rates can be achieved among experienced observers using standardized scoring systems (54). Considerable evidence indicates that IHC performance is poorly controlled "in the real world" (43,44,47,55–57). The initial ASCO-CAP guidelines on HER2/ERBB2 testing draw attention to this with the claim that "20% of HER2/ERBB2 assays performed in the field were incorrect" (43,44). The United Kingdom National External Quality Assurance Scheme (UK-NEQAS; see http://www.ukneqasicc.ucl.ac.uk/neqasicc.shtml) documents performance of diagnostic laboratories within the United Kingdom and across Europe and Asia and includes participants from the United States. Data from this scheme shows a marked difference between the levels of acceptable performance for IHC-based assays. Although computerized image analysis could reduce the subjective nature of the pathologist scoring, it cannot address the preanalytic variability owing to tissue fixation and processing. Despite these issues, IHC remains the favored technique to determine the HER2/ERBB2 status of patients in the majority of laboratories. There are continuing efforts being made to standardize IHC testing (45) and increasing numbers of laboratories are participating in the College of American Pathologists proficiency testing program for HER2/ERBB2 testing by IHC (58). Even though the quality of HER2 testing appears to be improving, there is also concern that significant numbers of breast cancer patients who may be eligible for HER2/ERBB2-targeted therapy are either not being tested or the results of these tests are not being used in treatment decisions (36).

The ASCO and the CAP have updated the 2007 Guideline recommendations. As in the original Guideline (43,44), immunohistochemistry remains acceptable as a primary test for HER2 status provided the clinical laboratory has demonstrated a high level of concordance, previously 95% (43,44) and currently 90% (45), for each immunostaining category that will be used to determine eligibility for HER2-targeted therapies (i.e., IHC 0, 1+, and 3+ categories). All IHC2+ cases will continue to be reflexed to FISH for assessment of HER2 status. A review of the literature on the subject demonstrates that few laboratories (4/33) have attained the required 95% concordance between FISH and IHC for all three IHC categories (0, 1+, and 3+) either before or after the 2007 publication of the ASCO-CAP guidelines (Table 27-3), while the majority of these laboratories (17/33) would now be able to achieve the prescribed concordance for all three IHC categories when the required percentage is lowered to 90% concordance.

IN SITU HYBRIDIZATION

A variety of *in situ* hybridization (ISH) techniques—fluorescence *in situ* hybridization (FISH), chromogenic *in situ* hybridization (CISH), and silver *in situ* hybridization (SISH)—have been used to determine HER2/ERBB2 gene amplification status in paraffin-embedded tissue sections (24,59–61) (Figs. 27-3 through 27-6).

HER2/ERBB2 Gene Amplification by Fluorescence *In Situ* Hybridization

Fluorescence *in situ* hybridization is the second most frequently used technique for determination of the HER2/ERBB2 status in clinical practice. As described above, a strong correlation exists between HER2/ERBB2 protein overexpression and HER2/ERBB2 gene amplification. Similar to HER2/ERBB2 overexpression, amplification of the HER2/ERBB2 gene is associated with unfavorable tumor characteristics, such as high nuclear grade and decreased expression of the estrogen and progesterone receptors, and decreased overall and disease-free survival (11,12,62,63).

Currently two FISH tests are approved by the FDA for selection of patients for treatment with the humanized monoclonal antibody trastuzumab: the PathVysion test (Abbott-Vysis Inc., Des Plaines, Illinois) (20,47) and the PharmDx FISH test (Dako) (64,65). The INFORM test (Ventana Medical Systems) (20,24), the first FDA-approved FISH assay, was withdrawn from the market in 2007 (Table 27-1). The PathVysion and PharmDx tests are dual-probe assays, utilizing both a fluorescent tag-labeled DNA probe specific for the HER2/ERBB2 gene and a fluorescent tag-labeled chromosome 17 centromere-specific enumeration probe (CEP) (20,24,47,64). These probes are hybridized to tissue sections under high stringency conditions (Fig. 27-3) and HER2/ERBB2 gene amplification status is assessed by enumeration of HER2/ERBB2 gene copy signals and chromosome 17 centromere signals. When the ratio of ERBB2 gene copies to chromosome 17 centromere copies is greater than or equal to 2.0, HER2/ERBB2 is considered amplified, whereas those with ratios less than 2 are considered nonamplified (18,20,24,45,47). Although a FISH ratio of 2.0 was recommended by the manufacturers and the FDA as the cutoff value for ERBB2 amplification, the 2007 ASCO-CAP guidelines recommend and CAP requires accredited laboratories to use 2.2 as the cutoff for amplification and consider FISH ratios between 1.8 and 2.2 to be *indeterminate* (43,44). Although the original FISH ratio of 2.0 correlates well with overexpression and has been supported by a number of studies of HER2/ERBB2 gene amplification as a prognostic marker (12,24) and a predictive marker of responsiveness to trastuzumab (32,33,66) and lapatinib (46,67,68), the ASCO-CAP guidelines committee offered no objective data for this change in cutoff ratio (43,44). Fortunately, only approximately 2% of unselected breast cancers have FISH ratios in this indeterminate region (18,47). Limited data currently available suggest that breast cancer patients whose cancers have HER2 FISH ratios between 2.0 and 2.2 do respond to trastuzumab with a similar hazard ratio to patients whose breast cancers have HER2 FISH ratios greater than 2.2 (69). Based on these observations the new ASCO-CAP guidelines (45) has reverted to the FDA-approved and manufacturer-approved cutoff of 2.0 with associated criteria for HER2 gene amplification by FISH.

Evaluation of the INFORM-HER test, originally formulated as a FISH assay with a single DNA probe specific for the HER2/ERBB2 gene, showed that a tumor sample needed more than four signals per nucleus to be HER2/ERBB2-amplified (24). In contrast, the ASCO-CAP guidelines recommend and CAP requires accredited laboratories to use 6.0 HER2/ERBB2 copies per tumor cell nucleus as the minimum copy number required for gene amplification with average HER2/ERBB2 copy numbers of 4.0 to 6.0 per tumor cell nucleus to be considered indeterminate, again without data

[a]Inclusion in this tabular summary required a comparison of IHC scores to FISH status in at least 100 cases per study.
[b]The percentage of FISH-positive (ERBB2-gene-amplified) cases within each IHC immunohistochemical category (0, 1+, 2+, 3+) is indicated.
[c]The total number of patients included in each study.
[d]The arithmetic average percentage of patients in the 0/1+, 2+, and 3+ subcolumns.
[e]Some studies reported low expression as pooled 0/1+ rather than separately as 0 and 1+.
Ab, antibody; IHC, immunohistochemistry.

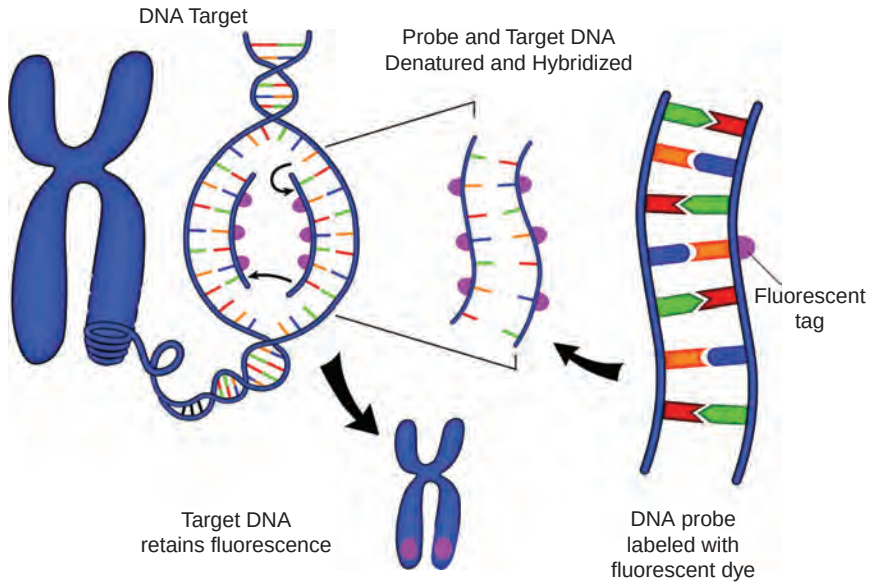

FIGURE 27-4 Schematic illustration of the fluorescence *in situ* hybridization (FISH) technique. Characterization of HER2/ERBB2 gene copy number involves a series of steps. Initially, before probe hybridization DNA-associated proteins are removed with proteinase digestion of all proteins. Subsequently, the double-stranded DNA is denatured by heating to cause separation of the DNA strands. A DNA probe encoding the gene of interest and directly labeled with a fluorescent tag is incubated with the tissue section under high-stringency conditions so the DNA probe binds specifically to the genomic sequence and remains bound to this site following high stringency washes to permit enumeration of the number of gene copies in each nucleus. Although this schematic illustrates hybridization with only one probe, FISH assays for HER2/ERBB2 currently use two different probes, one complementary to the HER2/ERBB2 gene labeled with a red or orange fluorescent tag and a second probe complementary to alpha-satellite DNA of chromosome 17 centromere labeled with a green fluorescent tag for centromere enumeration. (From Wippold FJ II, Perry A. Neuropathology for the neuroradiologist: fluorescence *in situ* hybridization. *AJNR Am J Neuroradiol* 2007;28:406–410.)

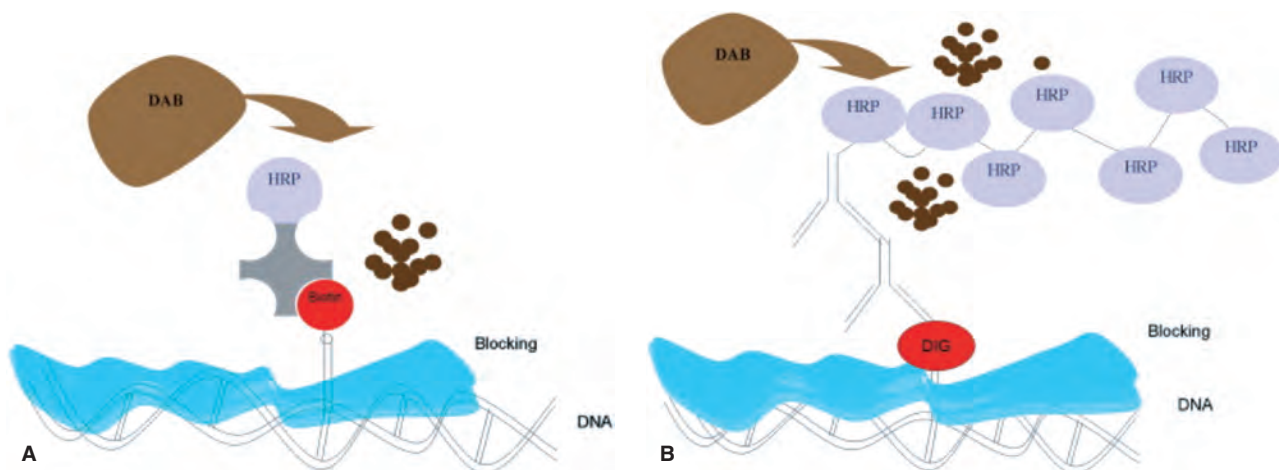

FIGURE 27-5 Schematic illustration of the chromogenic *in situ* hybridization (CISH) technique. (A) Method of localizing HER2/ERBB2 gene in tissue sections involves the use of a biotin-labeled HER2/ERBB2 DNA probe to hybridize specifically with denatured genomic HER2/ERBB2 genetic sequence. The biotin of the hybridized probe is secondarily recognized by horseradish peroxidase (HRP)-labeled avidin. Finally, polymerization of diaminobenzidine (DAB) is catalyzed by HRP to produce a brown precipitate that is microscopically visualized. **(B)** Alternatively, a digoxigen-labeled HER2/ERBB2 DNA probe is hybridized with genomic HER2/ERBB2 sequence. The digoxigen label is bound by an anti-dig mouse monoclonal antibody which is, subsequently, recognized by a secondary anti-mouse IgG rabbit or goat antibody labeled with HRP. The site of this secondary antibody is identified by reaction with DAB to produce a brown precipitate that is identified microscopically. (From Lambros MB, Natrajan R, Reis-Filho JS. Chromogenic and fluorescent in situ hybridization in breast cancer. *Hum Pathol* 2007;38:1105–1122, with permission.)

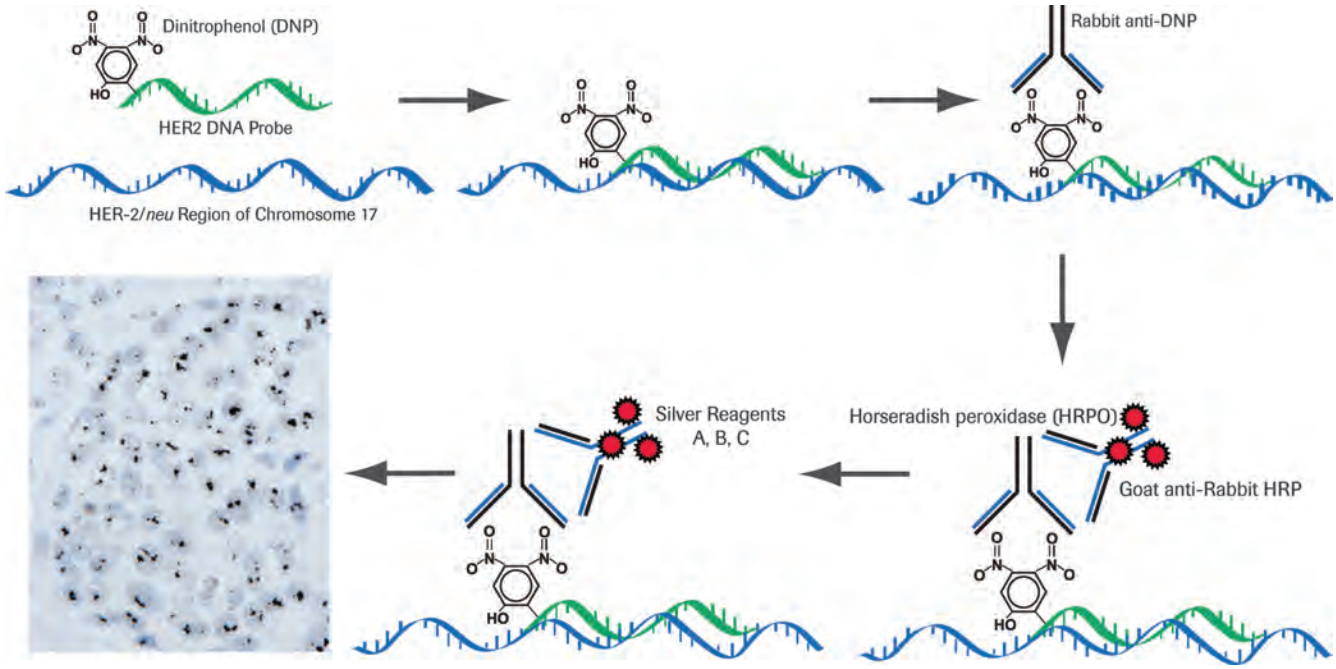

FIGURE 27-6 **Schematic illustration of the silver enhanced *in situ* hybridization (SISH) technique.** SISH is accomplished through horseradish peroxidase catalysis of silver ions to metallic silver leading to the deposition of metal nanoparticles at the site of a target gene hybridized to a DNA probe. SISH detection works as follows: A dinitrophenol (DNP)–labeled probe (upper left), either HER2/ERBB2-specific or chromosome 17 centromere–specific, binds to the genomic DNA target (upper center). A monoclonal rabbit anti-DNP linker antibody binds to the DNP hapten (upper right). The site of this primary antibody is recognized by a second antibody, a goat antirabbit antibody that is labeled with a horseradish peroxidase–labeled (HRP) multimer (lower right). Silver reagents are added to the tissue section, resulting in the deposition of metal nanoparticles at the site of the HRP (lower center), which allow visualization of the *in situ* hybridization signal (lower left). (Reproduced with permission from Ventana Medical Systems, Tucson, Arizona.)

to support a need for this change (43,44). Recent revisions to the ASCO-CAP guidelines have retained 6.0 as the average HER2/ERBB2 gene copy number required for amplification (45). The INFORM-HER FISH assay is no longer commercially available (footnote, Table 27-1). The manufacturer now has a SISH INFORM-HER assay for use with bright field microscopy.

FISH has both disadvantages and advantages. Although a newly marketed HER2 IQFISH pharmDx assay (Dako, Inc.) requires only 1 day for completion, other formulations of the method require 2 days to perform rather than the single day needed for IHC. FISH requires a fluorescence microscope, is interpreted in a darkroom by a pathologist, and the fluorescent signals fade on storage over a period of weeks to months depending on storage conditions. Because of the increased time as well as the use of more expensive reagents, FISH is more expensive than IHC. An additional disadvantage is that some high-volume laboratories use medical technicians, not pathologists, to interpret the signals in tumor cells, leading to some errors in scoring (46) probably related to the technician's inability to distinguish tumor cell nuclei from nuclei of benign reactive cells in some biopsies. An advantage of FISH is that DNA is more stable than protein and, therefore, is relatively insensitive to tissue handling or variations in fixative type or fixation time (70). Indeed, most hybridization failures encountered while performing FISH because of tissue fixation can be remedied by altering the amount of time that samples are exposed to protease digestion solution during the prehybridization phase of the analysis. This relative stability of DNA in FFPE tissues is probably responsible for the increased accuracy of the FISH method relative to IHC (18,47,71). A second advantage of FISH is that results are quantitative and, therefore, interpretation is less subjective. Variability rates between independent observers using FISH is significantly better than IHC (72–75).

HER2/ERBB2 Gene Amplification by Chromogenic *In Situ* Hybridization

A modified *in situ* hybridization technique, chromogenic *in situ* hybridization was developed in 2000 by Tanner et al. (76) and confirmed in multiple laboratories (59,76–80). CISH uses a digoxigenin (DIG)–labeled DNA probe corresponding to the HER2/ERBB2 sequence to localize the HER2/ERBB2 gene in the nuclei of cells (Fig. 27-5). The DIG-CISH probe is hybridized to a tissue section and detected using a fluorescein (FITC)–conjugated anti-DIG antibody followed by a horseradish peroxidase (HRP)–conjugated anti-FITC antibody. The tissue is then treated with diaminobenzidine (DAB), an HRP substrate, staining the region where the probe is bound (80,81). The brown DAB reaction product labels the site of HER2/ERBB2 gene copies that can then be assessed using a standard light microscope. In a second indirect method, the CISH probe is labeled with biotin and hybridized with the tissue section (Fig. 27-5). The tissue is then treated with HRP-conjugated avidin and detected with DAB as in the first method (81). Regardless of which indirect method is utilized, traditional CISH is a single

color assay and an additional slide must be used to determine centromere copy number using a chromosome 17 centromeric probe (81). In addition, CISH does not, in general, permit assessment of the number of HER2/ERBB2 gene copies present in amplified breast cancers because a single large aggregate of reaction product is deposited in the tumor cell nuclei when substantially increased copy numbers are present.

Numerous studies have indicated a good concordance between CISH and FISH with regard to *amplified* versus *not amplified* results in paraffin-embedded breast carcinomas. Hanna and Kwok (82) examined HER2/ERBB2 amplification levels by both FISH and CISH and correlated these results with IHC scores. In IHC-negative patients, the concordance rate between FISH and CISH was 97%. In IHC-positive patients (3+) the concordance rate was 98%. For patients with a 2+ IHC score the concordance rate between FISH and CISH remained high at 93% (82). Similar concordance rates have been reported by other laboratories (76–78,80,81,83–86).

There are several advantages to the CISH technique compared with FISH (Table 27-2). First, CISH probes are generated using subtractive probe technology (80). Using this technology, repetitive DNA sequences that can cause nonspecific hybridization are removed. Therefore, the final probes are very specific and do not require any blocking of nonspecific hybridization with Cot-1 DNA as in traditional FISH assays (80). Second, because the CISH method uses chromogens instead of fluorochromes to label probes, tissue staining is permanent, signals are nonbleaching, and they do not decay over time (81). This allows samples to be archived indefinitely. Third, with the CISH technique gene-copy signals can be assessed using a standard bright-field light microscope, removing the need for a fluorescence microscope, in turn decreasing the cost of the assay (81). Finally, because a light microscope is used to analyze CISH results, CISH permits concurrent analysis of tissue morphology. However, CISH has the disadvantage, described previously, that the number of HER2/ERBB2 gene copies cannot be individually enumerated in breast cancers with HER2/ERBB2 gene amplification because the DAB reaction product results in a large, brown aggregate of reaction product deposited in tumor cell nuclei rather than individual discrete signals that can be counted.

HER2/ERBB2 Gene Amplification by Silver Enhanced *In Situ* Hybridization

Silver enhanced *in situ* hybridization (SISH) is an additional modified *in situ* hybridization technique used to detect gene amplification (Fig 27-6). Instead of being based directly on the traditional FISH technique, SISH is based on an auto-metallographic procedure called gold facilitated auto-metallographic *in situ* hybridization (GOLDFISH), first described by Tubbs et al. in 2002 (61) and Hainfeld et al. in 2000 (87). Briefly, in GOLDFISH a biotin-labeled probe is hybridized to a tissue section. A catalyzed reporter deposition/tyramide signal amplification (CARD/TSA) reaction is then used to amplify the probe signal (88). The sensitivity of the CARD/TSA technique was first demonstrated by Zehbe et al. (88) who utilized the method to detect single copies of the human papillomavirus (HPV) in cell lines. The tissue is finally treated with nanogold particles covalently linked to streptavidin and incubated with GoldEnhance particles that are deposited onto the nanogold particles, making the signal visible by light microscopy (87,89).

Silver enhanced *in situ* hybridization also relies on the action of the peroxidase enzyme linked to a metal to deposit metallic particles at the site of a probe. SISH differs from GOLDFISH in several ways. First, SISH utilizes silver particles instead of gold. Second, the silver particles in SISH are not placed around a metallic core, such as nanogold, but are deposited as a result of direct action of peroxidase on a substrate linked to the metal. Third, SISH does not contain an amplification step in the procedure, such as the CARD/TSA reaction.

Several advantages exist to the SISH technique (Table 27-2). SISH is a sensitive method for detecting gene amplification (60). SISH does not require CARD/TSA amplification. Thus, fewer reagents are required for SISH than for FISH or CISH. Finally, similar to CISH, because no fluorochromes are used to label SISH probes, resulting signals are permanent, not light sensitive, do not decay over time, and may be read using a standard light microscope. The INFORM HER2 Dual ISH assay was approved using a concordance study of 714 breast cancers by comparison with the Abbott-Molecular PathVysion FISH assay. An overall agreement rate of 94% was observed between the two assay methods (Table 27-1).

Enzyme-Linked Immunosorbent Assay for Assessment of HER2/ERBB2 Extracellular Domain in Serum or Plasma

In contrast to IHC, FISH, and alternative FISH techniques, this next technique to determine a patient's HER2/ERBB2 status is not performed directly on the tumor tissue but on the patient's serum or plasma. Since 1991, both manual and automated enzyme-linked immunosorbent assays (ELISA) have been used to measure the amount of soluble HER2/ERBB2 protein extracellular domain (ECD) that is cleaved from cells and shed into patient serum (90) or plasma (91). Because a strong correlation exists between manual and automated results (92–95), both types of assays have been approved by the FDA to manage and monitor women diagnosed with metastatic breast cancer (92).

HER2/ERBB2 ECD can be detected in the plasma of healthy women and ECD levels increase in women diagnosed with both primary and metastatic breast cancer (90,92,96). High concentrations of shed HER2/ERBB2 ECD in serum are reported to correlate with HER2/ERBB2 overexpression (97), increased tumor size (98), higher relapse rates, and poor clinical response to hormone therapy and chemotherapy in patients with metastatic breast cancer (99–101). High HER2/ERBB2 ECD levels are also associated with a shorter progression-free survival (102).

The HER2/ERBB2 ECD test has been suggested as an alternative method to determine a patient's HER2/ERBB2 status. This testing method allows real-time determination of HER2/ERBB2 status and would permit monitoring changes in HER2/ERBB2 levels after surgery (92). However, ERBB2 HER2/ECD tests have not been established as useful in the diagnosis of HER2/ERBB2-positive breast cancer nor in predicting responsiveness to therapies and disease outcome. The results of this test are quantitative and, because the FDA established a cutoff of 15 μ g/L, are not open to subjective interpretation (92). Unlike IHC and FISH, it is impossible to determine the source of the HER2/ERBB2 protein fragment when utilizing this method. Thus, high baseline levels of HER2/ERBB2 ECD may not be caused by direct shedding of the HER2/ERBB2 ECD by tumor, but may be attributed to individual variations in receptor density, tumor burden, the rate of ECD cleavage and release into circulation, and the subsequent degradation of the protein fragment (52,100). In addition, only moderate concordance (87.1%) is found between serum HER2/ERBB2 ECD levels and tissue HER2/ERBB2 levels as measured by IHC and FISH (102,103). Fornier et al. (52) not only observed elevated HER2/ERBB2 ECD levels in breast cancer patients with HER2/ERBB2-positive disease but also among patients with tumors that did not show HER2/ERBB2 overexpression or gene amplification. The HER2/ERBB2 ECD ELISA assay is useful for monitoring recurrent disease among women with established HER2/ERBB2-positive breast cancers.

COMPARISON OF TESTS FOR ASSESSMENT OF HER2/ERBB2 STATUS

Accurate determination of HER2/ERBB2 status is critical in the selection of adjuvant and neoadjuvant therapy for women diagnosed with invasive breast carcinoma as well as women with metastatic disease. Only patients with tumors that overexpress HER2/ERBB2 or exhibit gene amplification are candidates for treatment with targeted therapies directed against the HER2/ERBB2 protein. In patients diagnosed with metastatic breast cancer, clinical benefit from trastuzumab is restricted to HER2/ERBB2-positive tumors as demonstrated by FISH (33). Patients whose breast cancers have gene amplification by FISH but lack overexpression by IHC (IHC ≤2+), the IHC false-negative breast cancer cases, show a clinical benefit from the addition of HER2/ERBB2-targeted therapies to chemotherapy (46). In contrast, those patients with breast cancers lacking HER2/ERBB2 gene amplification by FISH but having IHC 3+ immunostaining, the IHC false-positive cases, show no significant incremental benefit of HER2/ERBB2-targeted therapies beyond that of chemotherapy alone (33). Therefore, differences in the laboratory methods used to assess HER2/ERBB2 status are potentially important. These differences and similarities in HER2/ERBB2 status by FISH and IHC, the concordance rate, for determination of HER2/ERBB2 status are discussed in this section.

As stated previously, assessment of frozen tissue samples shows a direct relationship between HER2/ERBB2 gene amplification and HER2/ERBB2 protein overexpression. When the HER2/ERBB2 gene is amplified, there is consistent concordant overexpression of the receptor. In contrast, when the HER2/ERBB2 gene is not amplified, no increase in receptor expression is observed in frozen tissue samples or in breast cancer cell lines. The association between HER2/ERBB2 gene amplification and protein overexpression has been clearly demonstrated in frozen tissue samples using both IHC and FISH assays. In fixed paraffin-embedded tissue samples, however, equivalent results are more consistently observed when utilizing FISH. Indeed, the fixation and embedding processes not infrequently lead to difficulties and inconsistencies in determining HER2/ERBB2 status when utilizing IHC (12,19–21). This preanalytical variability owing to tissue fixation and processing in addition to the observer variability and subjective interpretation of IHC leads to discordance between IHC and FISH (43,44,48). Because most tissue used to determine HER2/ERBB2 status has been fixed and embedded, this discordance impacts the selection of patients for targeted therapy. To determine if a patient is a candidate for treatment with these HER2/ERBB2 targeting drugs, it is critical to determine a patient's HER2/ERBB2 status accurately. Thus, the method utilized to determine HER2/ERBB2 status is important.

The discordance between the results of IHC and FISH assays for HER2/ERBB2 has been demonstrated in numerous published studies (Table 27-3). In these studies, patients with an IHC score of 0 or 1+ are considered to be HER2/ERBB2-negative, whereas those with a score of 3+ are interpreted as HER2/ERBB2-positive. Patients with an IHC score of 2+ are considered inconclusive or equivocal and are *reflexed* to FISH for assessment of gene amplification (43–45). The greatest discordance between IHC and FISH is observed in patients whose breast cancers are considered equivocal (Table 27-3). Large variations in HER2/ERBB2 amplification rates have been reported for patients in this group (Table 27-3). Indeed, HER2/ERBB2 gene amplification rates in the IHC 2+ group vary from 0% to 97%, although most report amplification rates between 15% and 50% (Table 27-3) (43–45,47,57,104). Because of the large variation in HER2/ERBB2 amplification rates reported for patients with inconclusive IHC results, the ASCO and CAP currently recommend that all patients with inconclusive HER2/ERBB2 IHC results (IHC 2+) undergo reflex reevaluation with FISH for final determination of HER2/ERBB2 status before adjuvant therapy (43–45). The discordance in HER2/ERBB2 status as determined by FISH and IHC is not limited to the IHC 2+ group, although discordance in the 0, 1+, and 3+ IHC categories is more limited.

Although the ASCO-CAP guidelines recommend that the IHC 2+ cases be reflexed to FISH for definitive assessment, the guidelines also accept primary IHC testing as determinative for the IHC 0, 1+, and 3+ categories. They do recommend that any laboratory performing such primary IHC testing to determine HER2/ERBB2 status be able to demonstrate a high level of concordance (>95%) between each IHC category (0, 1+, and 3+) and independently assessed HER2/ERBB2 status by FISH. Unfortunately, the published literature demonstrates that this high level of concordance for all three IHC 0, 1+, and 3+ categories is only seldom achieved (Table 27-3). The percentages in the 0 and 1+ IHC categories shown in Table 27-3 represent the proportion of patients that is HER2/ERBB2-negative by IHC but HER2/ERBB2-amplified by FISH. Although an average of fewer than 10% of patients in the IHC 0 and 1+ categories exhibit amplification of the HER2/ERBB2 gene, because of the large number of breast cancers in this category (approximately 75% of breast cancers) this represents a significant proportion of patients with the HER2/ERBB2 alteration of gene amplification. Indeed, because the HER2/ERBB2 gene is amplified and overexpressed in only approximately 20% to 25% of human breast carcinomas, the 0 and 1+ IHC categories (HER2/ERBB2-negative) contain the most patients. Having as few as 4% of IHC 0/1+ patients with ERBB2 amplification still represents approximately 1 of every 10 women whose breast cancers have this alteration. The percentage of HER2/ERBB2-amplified breast cancers that has IHC 0 or 1+ immunostaining in FFPE samples ranges from approximately 3% to approximately 21%, depending on the study.

Those patients with HER2/ERBB2-negative breast carcinomas by IHC, but with HER2/ERBB2 amplification as determined by FISH, have tumors with biological phenotypes similar to other patients with HER2/ERBB2-amplified breast tumors. All women whose breast cancers have HER2/ERBB2 gene amplification, without exception in frozen tissue, have HER2/ERBB2 overexpression and this overexpression can be obscured by tissue fixation and processing as assessed by IHC staining in a variable proportion of these breast cancers (12). These false-negative IHC assessments, therefore, represent significant diagnostic problems, especially because these women respond to HER2/ERBB2-targeted therapies (46). In these cases, the discordance between HER2/ERBB2 amplification and HER2/ERBB2 overexpression, as determined by FISH and IHC, respectively, results in denial of targeted therapy for patients with HER2/ERBB2-positive tumors that have been shown to respond to treatment (46).

In contrast, the percentage of HER2/ERBB2 not amplified or FISH-negative cases in the IHC 3+ category (Table 27-3) represents patients with strong immunostaining (IHC 3+) for the HER2/ERBB2 protein, as shown by IHC in FFPE tissue, that lack amplification of the HER2/ERBB2 gene. The overall amplification rates for patients in the IHC 3+ group range from 49% to 100%, although most published amplification rates are above 85% with an average of almost 90% showing HER2/ERBB2 gene amplification (Table 27-3). Using an antibody that does not require antigen retrieval for IHC, most of these IHC3+, FISH-negative breast cancers have been shown to have IHC false-positive results (47). As shown in Table 27-3, these IHC3+/FISH-negative breast cancers represent approximately 10% of all IHC3+ cases. This false-positive rate is important because only women with HER2/ERBB2-amplified tumors respond to the HER2/ERBB2-targeted

therapies, trastuzumab and lapatinib (33,46). Indeed, as shown by Mass et al. (33), clinical benefit from trastuzumab therapy in patients diagnosed with metastatic breast cancer is restricted to HER2/ERBB2 FISH-positive patients. Furthermore, inaccurate assessment of HER2/ERBB2 status can lead to the inappropriate treatment of breast cancer patients with trastuzumab, both in the adjuvant and metastatic settings, and subject patients to unnecessary risk. Retrospective evaluation of outcome in the pivotal clinical trials of trastuzumab in women with metastatic breast cancer have shown that these IHC false-positive cases have an approximately 3% (or less) chance of responding to trastuzumab (33) and a similarly low probability of responding to lapatinib (46). Cardiac toxicity is a serious concern in patients with early-stage disease who are treated with both trastuzumab and anthracycline-containing chemotherapy (4-6,105,106). Therefore, as with women diagnosed with 0 or 1+ HER2/ERBB2-negative tumors by IHC, the discordance between HER2/ERBB2 amplification and HER2/ERBB2 overexpression in women with IHC3+/ERBB2-not-amplified tumors can result in inappropriate treatment of patients and, therefore, expose patients to unnecessary risk.

One of the goals of the 2007 ASCO-CAP guidelines committee was to address discrepancies in HER2/ERBB2 testing through standardization of the testing practices. Since publication of these guidelines, the CAP has required adherence to these guidelines for accreditation of HER2/ERBB2 testing laboratories. This has led to a substantial increase in the number of laboratories participating in the CAP proficiency testing programs (58), especially for IHC; however, it has not resulted in a similar reduction in the discrepancies between FISH and IHC testing based on papers published since 2007 (see Table 27-3) or based on single-institution comparisons of testing before and after implementation of the ASCO-CAP guidelines (107).

Inaccurate assessment of HER2/ERBB2 status can lead to inappropriate treatment of breast cancer patients with targeted therapies in both the adjuvant and metastatic settings. This exposes patients to unnecessary risk by either denying HER2/ERBB2-targeted therapies to patients who have a reasonable likelihood of responding to the drugs or by inclusion of patients in HER2/ERBB2-targeted treatment who do not exhibit HER2/ERBB2 amplification or overexpression. These concerns are especially relevant in countries such as the United States where most HER2/ERBB2 testing is performed with IHC assays (36,47,58).

ISSUES RELATED TO RESPONSE OF "HER2/ERBB2-NEGATIVE" BREAST CANCER PATIENTS TO HER2/ERBB2-TARGETED THERAPY

Although a report from the NSABP suggests that *HER2/ERBB2-negative* breast cancer patients in the B-31 trial respond to trastuzumab in the adjuvant setting (108), all of those patients were entered in the clinical trial based on their having *HER2/ERBB2-positive* breast cancer assessed in community laboratories. The NSABP central laboratory HER2/ERBB2-negative breast cancers represent 9.7% of women (174/1787) entered in the trial with follow-up data and this percentage is within the known range of testing variability between selected laboratories (31,43–45,47). Similar observations have been made for HER2/ERBB2-negative metastatic breast cancer patients and response to lapatinib therapy (46). A blinded reanalysis of the HER2/ERBB2-negative metastatic breast cancer patients from the latter clinical trial of lapatinib by a second central laboratory eventually demonstrated that the apparent lapatinib responsiveness of HER2/ERBB2-negative breast cancer patients was due to testing errors in the original large, high-volume laboratory where a medical technician, rather than a board-certified pathologist, assessed HER2/ERBB2 status (46). Since the NSABP has not subjected their central laboratory HER2/ERBB2-negative breast cancers to independent assessment of HER2/ERBB2 status by FISH, these cases could represent HER2/ERBB2 testing errors by FISH, as has already been demonstrated for the EGF 100151 lapatinib clinical trial (46). Nevertheless, the NSABP has initiated the B47 clinical trial of trastuzumab in women with invasive, HER2-low (IHC 1+ or 2+) breast cancer to test this idea.

CONCLUSIONS

Determination of a patient's HER2/ERBB2 status is critical for patients diagnosed with both primary and metastatic breast carcinomas. HER2/ERBB2 status is important for assessment of the patient's prognosis as well as a critically important factor in selecting the optimal chemotherapeutic or biologic treatment for a patient.

MANAGEMENT SUMMARY

Histologic diagnosis of invasive breast carcinoma with evaluation of HER2/ERBB2 status is as follows.

Based on available published evidence as summarized in this chapter we recommend:	Based on consensus of the ASCO-CAP guidelines—committee recommendations:
• Assessment of HER2/ERBB2 status by FISH	• Assessment of HER2/ERBB2 status by either IHC or FISH, although the vast majority (80%) of testing is clearly performed with IHC
• HER2/ERBB2-amplified → ERBB2-targeted therapy (trastuzumab) in combination with chemotherapy (preferably a nonanthracycline (6, 26) chemotherapy regimen)	• HER2/ERBB2-IHC 3+ → ERBB2-targeted therapy (trastuzumab) in combination with chemotherapy
	• HER2/ERBB2-IHC 2+ → reflex to FISH assay to determine HER2 status based on gene amplification
• HER2/ERBB2 not amplified → nonanthracycline (6,26) combination chemotherapy regimen	• HER2/ERBB2-IHC 1+/0 → combination chemotherapy regimen
• FISH failure (1% to 5% of cases) → IHC assessment of HER2/ERBB2 status (0/1+/2+, HER2/ERBB2 low expression; 3+, HER2/ERBB2 overexpression)

CHAPTER 28

Clinical and Pathologic Prognostic and Predictive Factors

Frederick L. Moffat

CHAPTER CONTENTS

Prognostic and predictive factors and biomarkers are critical to clinical decision-making in oncology. A 1991 NIH Consensus Conference (1) stipulated that clinically useful prognostic and predictive factors in breast cancer must meet the following criteria:

1. They must provide significant, independent predictive value, validated by clinical testing.
2. Their identification and measurement must be feasible, reproducible, and widely available with quality control.
3. The results must be readily interpretable by clinicians and have therapeutic implications.
4. Measurement of biomarkers should not consume tissue needed for other tests, especially routine histopathological evaluation.

Prognostic markers provide information on the biological potential and most likely clinical course of a breast cancer irrespective of treatment (2,3). Insight into the natural history of individual breast cancers may provide valuable information regarding the need for systemic adjuvant therapy, but is uninformative with respect to which specific treatment regimen is most likely to be effective.

Predictive factors inform on the likelihood of response of a breast cancer to specific therapies (3). Hormone receptor status predicts the responsiveness or lack of same of a breast cancer to endocrine therapy.

Some tumor biomarkers are of mixed significance. Estrogen receptor expression, while a strong predictor of response to endocrine therapy, is only weakly prognostic. HER2 expression has highly adverse prognostic implications but is predictive of tumor response to anti-HER2 therapy.

Conventional clinicopathological factors such as patient age, menopausal status, race/ethnicity, tumor size, nodal status, lymphovascular invasion, micrometastases or isolated tumor cells in regional lymph nodes, extracapsular extension of nodal metastases, tumor grade, tumor stage, presence or absence of the inflammatory phenotype, markers of tumor proliferation, and hormone receptor and HER2 status continue to be useful in estimating prognosis. The prognostic implications of the intrinsic breast cancer subtypes (4,5), multigene tumor signature assays (6), and clinicopathological response to neoadjuvant systemic therapy (7) offer further opportunities for refinement of clinical decision making in breast cancer.

Numerous potential breast cancer biomarkers have been cited and characterized over the past several decades. Discerning their true magnitude of effect, reliability and clinical utility has been complicated by deficiencies in biomarker assays and measurement, the quality of evidence supporting the potential biomarker status of the factor(s) under study, and failures in clinical trials design and studied patient cohorts and populations to account for and control confounding variables. A number of expert panels have reviewed available information on breast cancer biomarkers and concluded that limitations in available data allow for only the most guarded recommendations (8). For these reasons, significant efforts have been directed toward standardizing the investigation and establishment of clinically relevant biomarkers.

GENERAL CONSIDERATIONS

For prognostic and predictive factors to be clinically useful, they must be detectable and reproducibly measurable by different laboratories at reasonable cost, yielding results promptly for clinical decision making. Their clinical correlations must be clearly defined in terms of their nature (prognostic, predictive, or both), and assay values, whether continuous or categorical, must be reliably associated with patient outcomes. The relevant clinical information being sought must not be available through another more readily accessible factor. The expected differences in outcomes must be significant and important from the patient's perspective. Finally, useful prognostic and predictive factors must provide information upon which a choice among available treatment options can be based (9).

Pure prognostic and predictive factors are schematically depicted in Figure 28-1, panels A and B, respectively.

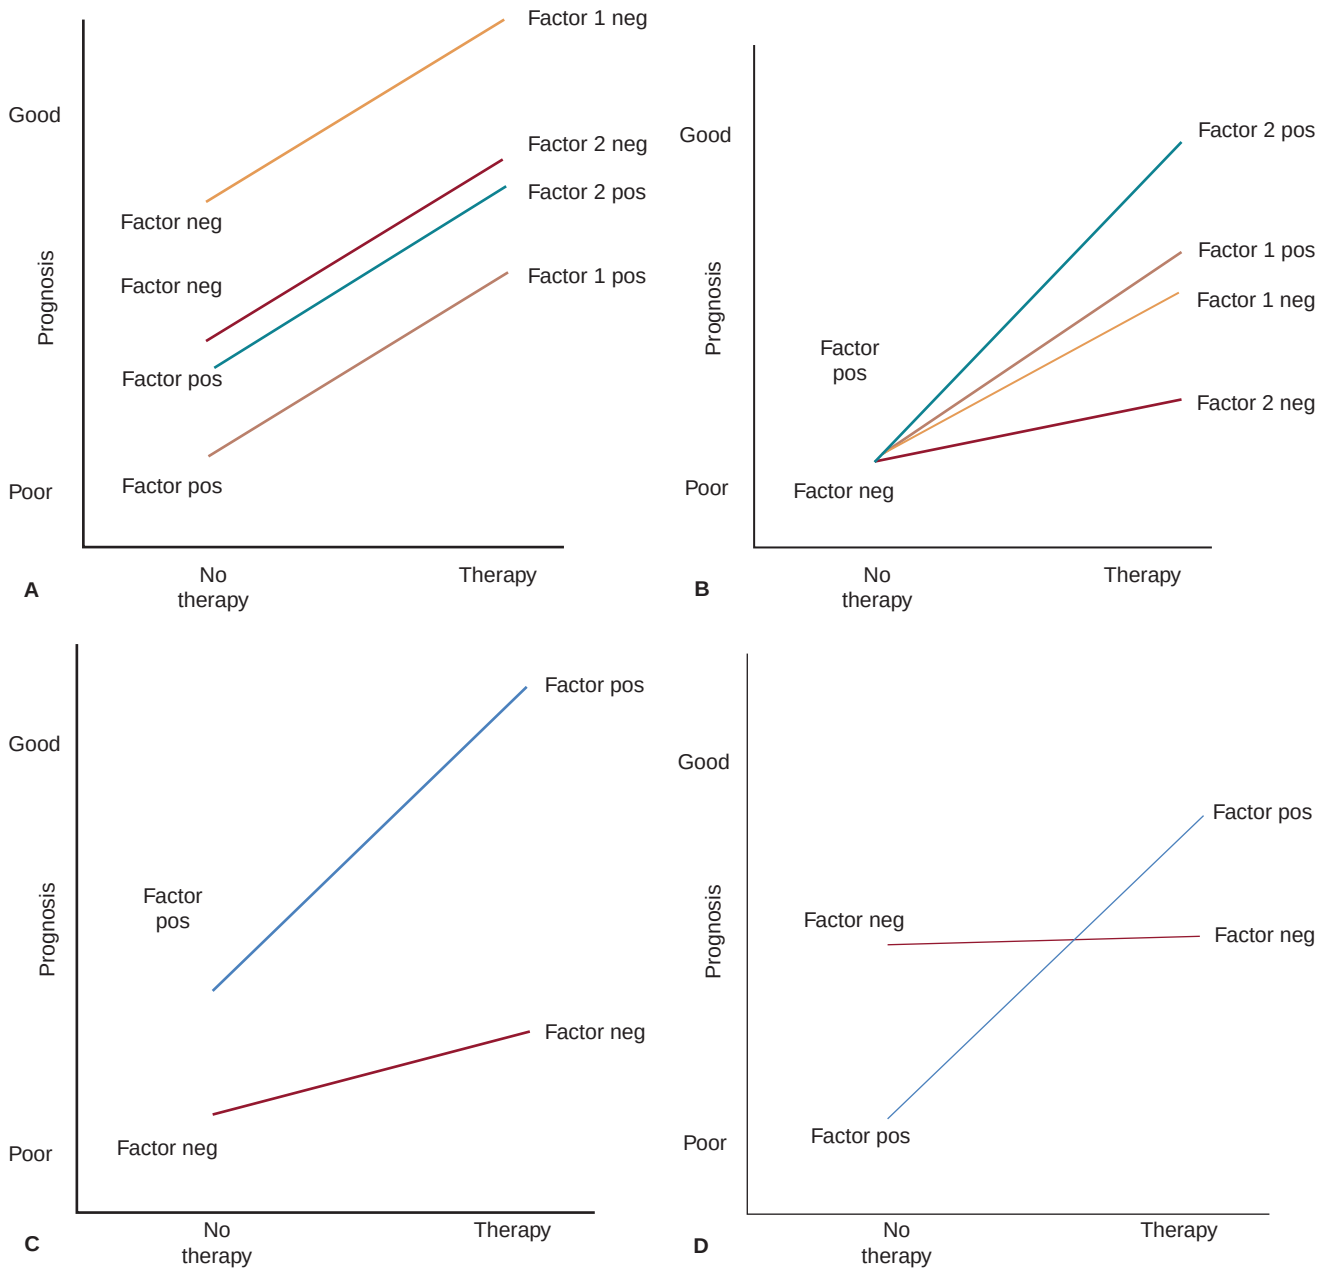

FIGURE 28-1 Schematic representation of prognostic and predictive factors: prognosis versus therapy as binomial variables. **(A)** Pure prognostic factor. **(B)** Pure predictive factor. **(C)** Mixed factor with weakly favorable prognostic effect and strong response to therapy. **(D)** Mixed factor with unfavorable prognosis and strong response to therapy. (Adapted from Henry NL, Hayes DF. Uses and abuses of tumor markers in the diagnosis, monitoring and treatment of primary and metastatic breast cancer. *Oncologist* 2006;11:541–552. Modified from Hayes DF, Trock B, Harris AL. Assessing the clinical impact of prognostic factors: when is "statistically significant" clinically useful? *Breast Cancer Res Treat* 1998;52:305–319, Springer Science and Business Media.)

Prognosis versus therapy are plotted as binomial variables (8,10). A large incremental difference in prognosis related to positive and negative status is observed for factor 1 (a strong prognostic factor such as lymph node status) while that for factor 2 is much smaller (ER status). In panel B, factor 1 is a weak predictive factor while factor 2 is a much stronger one. Hayes et al. (10) proposed that prognostic factors in breast cancer be categorized quantitatively by their associated hazard ratios (HR), HR <1.5 denoting weak factors, 1.5 to 2.0 moderate factors, and >2.0 strong factors. They further proposed a similar rating of the strength of predictive factors by tumor response to and clinical benefit from a specific therapy. "Relative predictive value" (RPV), the ratio of the probability of response to treatment in a factor-positive patient as compared to that in a factor-negative patient, has been proposed as a means of quantifying the strength of predictive factors as weak (RPV = 1 – 2), moderate (RPV = 2 – 4), or strong (RPV > 4).

Panel C in Figure 28-1 represents a mixed prognostic and predictive factor such as ER status, the prognostic effect being weakly favorable and the predictive effect strongly so. Panel D depicts a mixed factor with an unfavorable prognosis but highly responsive to specific therapy, as exemplified by HER2 status.

Statistical significance in marker-positive or marker-negative patient outcomes is not infrequently mistaken for or conflated as evidence of clinical utility. This does not always hold and should never be assumed. Along with the magnitude of the effect and the relevance of the marker, technical reliability and reproducibility are critically important, as is the design and execution of clinical studies (10).

Technical shortcomings related to biomarker assay sensitivity, specificity, reproducibility, and reagent variability can be highly problematic. Standardization of assay methodologies has greatly improved, of late. For example, intra- and interobserver variation, well documented in immunohistochemical assays, has been controlled through automated and semiautomated processes (8).

Determination of cut-off points that distinguish positive from negative results is critical to the development of clinically useful assays. Cut-off points can be set arbitrarily or based on data. Arbitrary cut-off point selection has included the limits of detection of the assay, two standard deviations above the normal mean, the mean value in affected as compared to normal patients, or an arbitrarily defined appropriate percentage of positive cells (8).

Data-derived cut-off points have been based on plots of *p*-values versus outcomes, plots of the magnitude of marker effect versus patient outcome, construction of receiver operating characteristic curves (cut-off points established by determining the optimal trade-offs of sensitivity and specificity in an assay), or subpopulation treatment effect pattern plot (STEPP) analysis (11). The latter methodology evaluates outcomes to specific treatment regimens in subpopulations of patients within randomized trials or meta-analyses (8).

Once established in a test group of patients, cut-off points must be confirmed in a validation patient cohort similar to but completely independent of the initial test group. Having been identified and validated, the clinical value of a new tumor marker relative to well-established prognostic or predictive factors is then confirmed by multivariate analysis. This provides information on the potential clinical utility of the new marker in medical practice.

Study design is key to identifying and establishing new tumor biomarkers. The Tumor Marker Utility Grading System (TMUGS) (12) was developed as a frame of reference for grading the clinical utility of tumor markers based on published evidence. Putative markers are assigned a utility score according to degree of correlation with biological processes and end points (Table 28-1) and favorable clinical outcomes (Table 28-2), as determined by level of evidence (LOE; Table 28-3) (8) and grading of tumor marker studies (Table 28-4) (13).

TABLE 28-1

Scale to Evaluate Tumor Marker for Correlation with Biological Processes and End Points

Utility Scale	*Explanation*
0	Does not correlate with process or expected end point
NA	Data not available on marker correlation with process or end point for that use
+/–	Preliminary data suggestive, but substantially more definitive studies required
+	Assay probably associated with process or end point, but confirmatory studies required
++	Definitive studies show that assay reflects process or end point

From Hayes DF, Bast RC, Desch CE, et al. Tumor marker utility grading system: a framework to evaluate clinical utility of tumor markers. *J Natl Cancer Inst* 1996;88:1456–1466.

LOE levels I and II are the most robust and objective, the ideal level I clinical trial being prospective, randomized, appropriately powered, and designed specifically to evaluate the clinical utility of a putative tumor marker for a discrete, predetermined use. That noted, a clinical trial adequately powered to determine a clinical end point may be underpowered for analysis of tumor marker subgroups by as much as 25%, even when tissue samples are available for all participating patients (8).

Systematic overviews and pooled analyses of well-conducted LOE II studies are essentially equivalent to LOE I evidence. LOE III studies, with their greater variability in patient characteristics and therapies, are better suited to generating hypotheses than contributing clinically useful information (8).

Attention to detail is critical to clinical trials design and conduct. The appropriate patient population must be selected with particular attention to a similar profile among them in terms of known prognostic factors. Trials focused on predictive factors are ideally prospective, randomized, and controlled, comparing patients receiving the intervention in question to untreated controls (8).

The REMARK tool, a standardized reporting schema for tumor marker data, has been developed by the Working Group of the National Cancer Institute and the European Organization for Research and Treatment of Cancer (EORTC) (14). This project was undertaken to eliminate the highly variable and flawed approaches to tumor marker elucidation and to provide a standard template for investigation of potential markers in the future.

PROGNOSTIC FACTORS—CLINICAL

Age

Breast cancer patients aged 35 to 40 years or less at presentation have a significantly worse prognosis than older premenopausal patients or those over the age of 50.

TABLE 28-2

Scale to Evaluate Utility of Tumor Markers for Favorable Clinical Outcomes

Utility Scale	*Explanation*
0	Marker adequately evaluated for specific use; data definitively demonstrate no utility. Marker should not be ordered for that clinical use.
NA	Data not available for the marker for that use because marker has not been studied for that use.
+/–	Data are suggestive that marker may correlate with biological processes and/or end points, and preliminary data suggest that use of the marker may contribute to favorable clinical outcome, but more definitive studies are required. Thus, marker is still considered highly investigational and should not be used for standard clinical practice.
+	Sufficient data available to demonstrate that marker correlates with the biological process and/or biological end point related to its use and that the marker might affect favorable clinical outcome for that use. However, marker still considered investigational and should not be used in standard clinical practice for one of three reasons: 1. The marker correlates with another marker/test that has been established to have clinical utility, but the new marker has not been shown to clearly provide an advantage. 2. The marker may contribute independent information but it is unclear whether the information provides clinical utility because treatment options have not been shown to change outcome. 3. Preliminary data for the marker are quite encouraging, but the level of evidence is lacking to document clinical utility.
++	Marker supplies information not otherwise available from other measures that is helpful to the clinician in decision making for that use, but the marker cannot be used as the sole criterion for decision making. Thus, marker has clinical utility for that use, and it should be considered standard practice in selected situations.
+++	Marker can be used as the sole criterion for clinical decision making in that use. Thus, marker has clinical utility for that use, and it should be considered standard practice.

From Hayes DF, Bast RC, Desch CE, et al. Tumor marker utility grading system: a framework to evaluate clinical utility of tumor markers. *J Natl Cancer Inst* 1996;88:1456–1466.

TABLE 28-3

Levels of Evidence for Grading Clinical Utility of Tumor Markers

Level	*Type of Evidence*
I	Evidence from a single, high-powered, prospective controlled study specifically designed to test marker or evidence from meta-analysis and/or overview of level II and III studies. In the former case the study must be designed so that therapy and follow-up are dictated by protocol. Ideally, the study is a prospective controlled randomized trial in which diagnostic and/or therapeutic clinical decisions in one arm are determined at least in part on the basis of marker results, and diagnostic and/or therapeutic clinical decisions in the control arm are made independently of marker results. However, study design may also include prospective but not randomized trials with marker data and clinical outcome as primary objective.
II	Evidence from study in which marker data are determined in relationship to prospective therapeutic trial that is performed to test therapeutic hypothesis but not specifically designed to test marker utility (i.e., marker study is a secondary objective of the protocol).
III	Evidence from large studies from which variable numbers of samples are available or selected. Therapeutic aspects and follow-up of the patient population may or may not have been prospectively dictated. Statistical analysis for tumor marker was not dictated prospectively at the time of therapeutic trial design.
IV	Evidence from small retrospective studies which do have prospectively dictated therapy, follow-up, specimen selection, or statistical analysis. Study may use matched case-controls, etc.
V	Evidence from small pilot studies designed to determine or estimate distribution of marker levels in the sample population. Study design may include "correlations" with other known or investigational markers of outcome but is not designed to determine clinical utility.

From Hayes DF, Bast RC, Desch CE, et al. Tumor marker utility grading system: a framework to evaluate clinical utility of tumor markers. *J Natl Cancer Inst* 1996;88:1456–1466.

TABLE 28-4

Grade of Tumor Marker Studies for Level of Evidence

Grade	*Study Description*
A	Prospective
B	Prospective, using archived samples
C	Prospective, observational
D	Retrospective, observational

Level of Evidence	*Grade*	*Validation Studies Available*
I	**A**	None required
I	**B**	One or more with consistent results
II	**B**	None or inconsistent results
II	**C**	Two or more, consistent results
III	**C**	None or one, consistent or inconsistent results
IV–V	**D**	Not applicable: LOE IV and V unsatisfactory for determination of biomarker clinical utility

From Simon RM, Paik S, Hayes DF. Use of archived specimens in evaluation of prognostic and predictive biomarkers. *J Natl Cancer Inst* 2009;101:1446–1452.

Chemotherapy is especially effective in premenopausal patients. However, those under 35 years of age receiving chemotherapy for endocrine-responsive breast cancer have a significantly higher risk of relapse than older premenopausal patients with such tumors. In contrast, outcomes among younger and older premenopausal patients receiving chemotherapy for endocrine nonresponsive disease are essentially equivalent (15).

In another meta-analysis (16), higher mortality (HR = 1.55; 95% confidence interval [CI] 1.20–2.00) and locoregional recurrence (HR = 2.34; 1.30–4.24) were observed in patients less than 35 years old as compared to those over 50. Mortality in patients aged 35 to 50 years as compared to those over 50 was no different (HR = 1.01; 0.87–1.16) but locoregional recurrence was more frequent (HR = 1.60; 1.14–2.25).

A SEER analysis of 243,012 breast cancer patients (17) reported that those less than 40 years of age (6.4% of the cohort) were more likely to be African American, single, to have presented with advanced disease, and to have undergone total mastectomy. Their tumors were of higher grade, larger size, and more often estrogen receptor-negative (–), progesterone receptor-negative (PR–), and lymph node-positive. The adjusted HR for mortality among younger women was significantly higher as compared to older patients overall (1.39; 1.34–1.45). For stage I disease, HR for mortality was 1.44 (1.27–1.64) and for stage II breast cancer, 1.09 (1.03–1.15). Among patients with stage IV disease, however, the mortality ratio for younger patients, at 0.85 (0.76–0.95), was significantly lower than for those over 40 years of age.

At 11 years median follow-up, a recent EORTC pooled analysis (18) reported that among patients less than 40 years of age, tumor size, nodal status, and intrinsic molecular subtype were independent prognostic factors for overall survival (OS). Among node-negative patients less than 40, only intrinsic subtype was significant. Ten-year survival among patients with luminal A tumors was 94% as compared to 72% for those with basaloid tumors. In a similar analysis of 315 patients less than 35 years of age (19), the excess risk of recurrence (HR = 1.65; 1.30–2.10) and mortality (HR = 1.78; 1.12–2.85) as compared to older patients was significant. Young patients with luminal B, triple-negative or HER2+ tumors were at particular disadvantage with respect to cancer recurrence and mortality.

Menopausal Status

Menopausal status may be a prognostic proxy for age as implied in the foregoing discussion. That noted, the time course of breast cancer recurrence varies as a function of menopausal status (20). Among node-positive premenopausal patients, the hazard function for relapse has two peaks, the first reaching its maximum 8 to 10 months postoperatively and the second at 28 to 30 months. In contrast, the hazard function in node-positive postmenopausal patients is significantly prolonged, peaking at 18 to 20 months. Primary tumor size correlates directly with the height of the hazard peaks in both pre- and postmenopausal patients, but has no effect on time to recurrence. In node-negative patients, the hazard function for recurrence increases to 18 to 24 months, decreasing somewhat thereafter but of much reduced amplitude at all time-points as compared to patients with positive nodes.

Race/Ethnicity

Five-year relative OS for African American breast cancer patients from 1988 to 2001 was 78% as compared to 90% for Caucasians (21). Stage distribution is less favorable among African Americans, but this factor alone does not explain the observed differences in outcomes. Treatment response rates are similar for African Americans and Caucasians, but African Americans are more likely to present with high-grade and triple-negative cancers and at a younger age. Moreover, there is an excess incidence of ER– inflammatory breast cancer in young African American patients (22).

In China, 20% of breast cancer patients are younger than 40 years of age as compared to only 6% of Caucasian patients in the United States. Moreover, the nonluminal HER2+ subtype with its earlier age of onset, poorer prognosis, and more advanced stage at presentation accounts for 26% to 31% of cases in China as compared to only 19% to 23% in Caucasian Americans (23).

Clinical Tumor Size

Clinical and radiographic estimates of primary tumor size tend to overstate the true dimensions of primary invasive breast cancers, especially small lesions, because of tumor-associated desmoplasia and *in situ* disease (24,25).

The pathological dimensions of the invasive component are the accepted standard for determining primary tumor stage.

Clinical Stage

Clinical and pathological stage are critically important in treatment selection and outcomes. At present, the relevance of clinical staging relates primarily to locoregionally advanced disease presenting as a large primary breast tumor with or without one or more of the so-called grave signs (necrotic, fungating, and/or ulcerating tumor eroding through the breast skin with or without localized reactive cutaneous inflammation, *peau d'orange,* tumor invasion of the chest wall, and/or bulky nodal disease in axillary, internal mammary, and supraclavicular lymphatic basins). The most feared clinical presentation by far is inflammatory/T4d breast cancer with its sudden onset and rapid progression, often attended by bulky, fixed, or confluent disease in one or more nodal basins. Detectable distant metastases are present in 40% of these patients at the time of diagnosis (22,26). The inflammatory phenotype, historically a harbinger of profoundly aggressive cancer biology and impending mortality, retains its grim prognostic implications even now, at least in relative terms.

Locoregionally advanced breast cancers are not infrequently unresectable or only marginally operable at presentation. These and inflammatory cancers remain the preeminent indications for neoadjuvant systemic therapy (27).

PROGNOSTIC FACTORS—PATHOLOGIC

In an overview of systematic reviews and meta-analyses published from 1999 through 2007 (28), the American Society of Clinical Oncology (ASCO) updated recommendations on breast cancer tumor markers. The data regarding DNA flow cytometric parameters were insufficient to impute any prognostic value to their routine use. Data on markers of tumor proliferation such as Ki-67, cyclin D, cyclin E (whole or fragments), p27, p21, thymidine kinase, topoisomerase IIα, and others were likewise inadequate to establish prognostic significance.

ASCO recommended assaying for HER2 expression in all primary breast cancers to identify those susceptible to anti-HER2 therapy. While HER2 amplification, overexpression, and the presence of circulating HER2 extracellular domain correlated with poor prognosis, the final consensus statement concluded that circulating HER2 extracellular domain was of no prognostic utility (28).

It was acknowledged that the evidence that anthracycline-based chemotherapy provides greater benefit for HER2+ breast cancer was only LOE II (prospective trials with marker utility as a secondary end point), whereas LOE I evidence had shown that anthracycline and nonanthracycline chemotherapy have equivalent activity in these patients. HER2 amplification and/or overexpression in hormone receptor-positive breast cancers was not deemed a contraindication to endocrine therapy in hormone receptor-positive breast cancer (28) despite resistance to endocrine therapy conferred by HER2 positivity, resulting in reduced efficacy (29–31).

Citing a paucity of evidence, ASCO recommended against p53, cathepsin D, bone marrow micrometastases, or circulating tumor cells for prognostication or therapeutic decision making. Urokinase plasminogen activator (uPA) and plasminogen activator inhibitor 1 (PAI-1) were considered prognostically significant in newly diagnosed node-negative breast cancer. Low levels of both markers correlated with low risk, especially in hormone receptor-positive disease treated with endocrine therapy; chemotherapy was known to provide very little benefit in these circumstances. In patients with high levels of uPA and PAI-1, CMF chemotherapy provided a substantial survival benefit over observation alone. Overexpression of both factors is associated with a twofold to eightfold increased risk for breast cancer recurrence and mortality (28).

In contrast, there was general agreement at the 2009 St. Gallen Consensus Conference that uPA and PAI-1 were of no prognostic utility (32) primarily because of the practical difficulties in measuring them (M. Morrow, personal communication).

Primary Tumor Size

A SEER analysis for 1988 to 2001 on 302,763 patients (21) reported 5-year relative survival rates for all stages and ages as a function of primary tumor size. Among those with tumors 0.1 to 0.9 cm, survival was 100%; 91.8% for tumors measuring 1.0 to 1.9 cm; 75.7% for lesions 2.0 to 2.9 cm; 61.3% for tumors 3.0 to 3.9 cm; 54.2% for tumors 4.0 to 4.9 cm; 45.7% for tumors 5.0 to 9.9 cm; and 27.0% for diffuse primary tumors.

Five-year relative survival in the SEER analysis (21) of patients with primary disease confined to the breast parenchyma was 93%, 71.7% when subcutaneous tissues were invaded, 69.2% when the pectoralis fascia was invaded, 62.2% when tumor invaded the chest wall (ribs, muscle or both), 47.3% when extensive skin involvement was present, and 39.9% in patients with inflammatory cancer. Of those with documented distant disease at the time of breast cancer diagnosis, only 18.7% survived 5 years.

Regional Lymph Node Status

Nodal status is the most powerful clinicopathological prognostic variable for locoregional stage breast cancer (33,34). The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-04 and B-06 randomized trials (35,36) demonstrated that mortality as a function of number of positive lymph nodes behaves as a continuous variable, with steepening of the upward trajectory of mortality appearing at between three and four positive nodes. Ten-year survival in the B-04 trial with 0, 1 to 3, 4 to 9, and 10 or more positive nodes was 67%, 47%, 30%, and 12%, and, in B-06, 75%, 62%, 42%, and 20%, respectively. The differences in survival between these trials were largely attributable to the use of adjuvant chemotherapy in node-positive patients in B-06; patient accrual to B-04 was completed prior to the advent of adjuvant systemic therapy.

The incidence of positive regional nodes varies directly with primary tumor size. In an analysis of 2,233 breast cancer patients (37), positive nodes were present in 11% of patients with tumors of 0.1 to 0.9 cm, 30% with tumors of 1.0 to 1.9 cm, 40% with tumors of 2.0 to 2.9 cm, 50% with tumors of 3.0 to 3.9 cm, and 52% with tumors of 4.0 to 4.9 cm. The relationship between presence of nodal metastases and primary tumor size varies among the intrinsic molecular subtypes, luminal B and HER2+ tumors being more likely to be node-positive (52% and 57%, respectively) than luminal A or basal cancers (43% and 44%). The incidence of four or more positive nodes also varied from 11% for luminal A and 14% for basal cancers to 20% for luminal B and 28% for HER2+ tumors (38).

A logistical regression analysis of the SEER data (21) on incidence of nodal metastases versus primary tumor size is shown in Figure 28-2. Incidence of nodal involvement increased in direct proportion to primary tumor size up

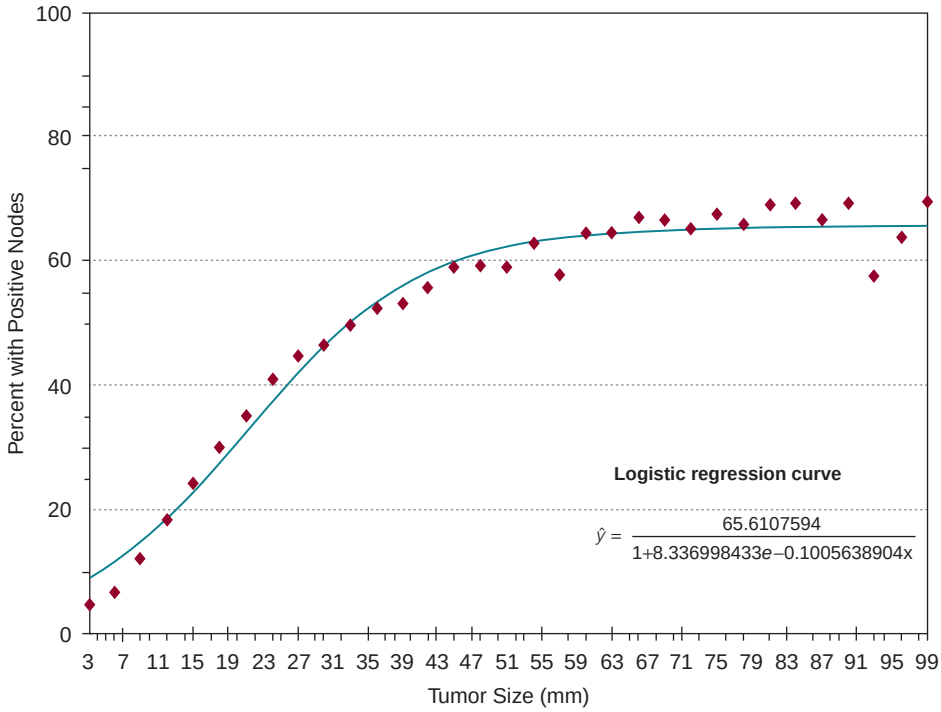

FIGURE 28-2 Presence of positive regional lymph nodes by primary tumor size 12 SEER areas, 1988–2001. (Redrawn from Ries LAG, Young JL, Keel GE, et al., eds. SEER survival monograph: cancer survival among adults: U.S. SEER Program, 1988–2001, patient and tumor characteristics. NIH Pub. No. 08-6215. Bethesda, MD: National Cancer Institute, SEER Program, 2007.)

to 54 mm, reaching a plateau at over 60% thereafter. Five-year relative survival varies inversely as a function of both primary tumor size and number of involved regional lymph nodes (Fig. 28-3).

A "binary-biological" mathematical model of breast cancer and melanoma metastasis reported by Chen et al. (39) incorporated primary tumor size, lymph node status, and other prognostic factors to estimate "cancer lethality" in individual patients. This model was capable of estimating the probability of mortality as a function of all, some, or single independent variables in isolation. In over 375,000 breast cancer patients, positive lymph node status was found to be a strong predictor of breast cancer mortality. Nodal metastasis was associated with intermediate and high tumor grade, ductal histology, African American race, male gender, young age, the inflammatory phenotype, Paget's disease, ER+PR+ and ER–PR– tumors. Nodal metastases were significantly less prevalent among low-grade tumors and cancers of tubular, comedo, medullary, mucinous, cribriform, or papillary histology.

Using a forerunner of the binary-biological mathematical model, an earlier analysis (37) had shown that 15-year Kaplan-Meier death rates were 26% for patients with one positive node, 34%, 37%, and 57% for two, three, and four involved nodes, respectively.

Nodal Micrometastases and Isolated Tumor Cells

The advent of sentinel lymph node biopsy (SLNB) has spawned numerous research initiatives, among them the relationship of prognosis to nodal tumor burden and extent of axillary surgery. Nodal micrometastases (MM - pN1mi), defined as metastatic disease measuring > 0.2 to ≤ 2.0 mm,

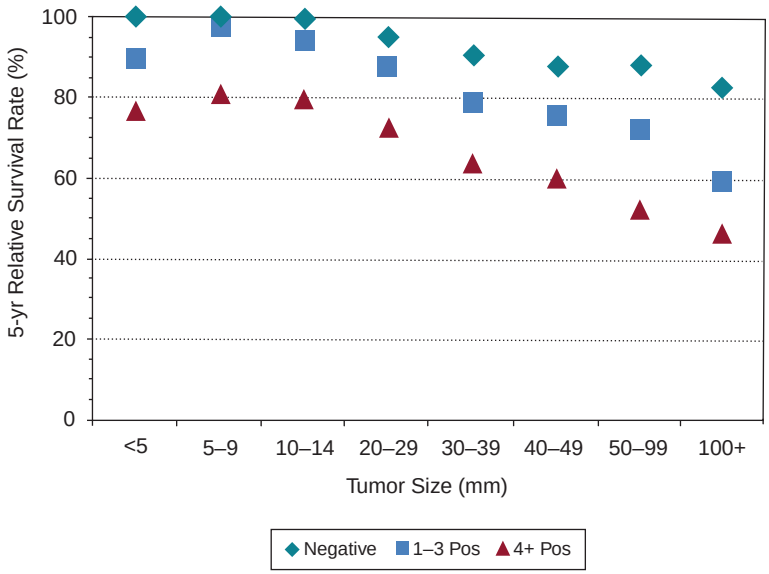

FIGURE 28-3 Five-year relative survival rates by primary tumor size and number of positive lymph nodes: Ages 20+, 12 SEER areas, 1988–2001. (Redrawn from Ries LAG, Young JL, Keel GE, et al., eds. SEER survival monograph: cancer survival among adults: U.S. SEER Program, 1988–2001, patient and tumor characteristics. NIH Pub. No. 08-6215. Bethesda, MD: National Cancer Institute, SEER Program, 2007.)

and isolated tumor cells (ITC - pN0[i+]), defined as single tumor cells or metastatic deposits ≤ 0.2 mm, have been a recent focus of clinical investigation.

Studies of the presence or absence of nodal MM or occult metastases were reported in 297,533 breast cancer patients, 265,638 for whom submitted axillary nodes were evaluated only by single pathological sections, 7,740 in whom retrospective examination of negative nodes for occult nodal metastases by step sectioning and/or immunohistochemistry (IHC) was undertaken, and 4,155 patients in whom intensified workup of sentinel but not nonsentinel nodes was carried out (40). The presence of MM in the first cohort was associated with poor OS (HR for mortality 1.44; 1.29–1.62) while in the two occult metastasis cohorts, the presence of MM portended poor 5-year DFS (HR = 1.55; 1.32–1.82) and OS (HR = 1.45; 1.11–1.88).

The population-based MIRROR study of survival by tumor burden per sentinel lymph node (SLN) compared 856 node-negative patients who did not undergo adjuvant therapy, 856 patients with ITC or MM who also did not receive adjuvant therapy, and 995 patients with ITC or MM who underwent adjuvant therapy (41). At a median follow-up of 5.1 years, adjusted HR for disease events among patients with ITC who did not undergo adjuvant therapy was 1.50 (1.15–1.94) as compared to node-negative patients. Among those with MM, adjusted HR was 1.56 (1.15–2.13). Among patients with ITC or MM who were treated with adjuvant therapy, the adjusted HR for disease events was 0.57 (0.45–0.73) as compared to untreated patients with ITC or MM.

A subsequent analysis (42) of patients completing at least 5 years' follow-up confirmed that among untreated patients, 24.9% had had a disease event as compared to only 16.8% of those receiving adjuvant therapy ($p < .01$). Cost-effectiveness analysis demonstrated that the extrapolated mean cumulative costs per patient beyond 18 years were significantly lower among those receiving adjuvant therapy for sentinel node ITC or MM.

While nodal ITC and MM may be prognostic, whether axillary lymphadenectomy is justified for these remained to be determined. Several LOE I prospective observational and randomized clinical trials of SLNB have reported within the past 2 years. At a median follow-up of 8.4 years, the American College of Surgeons Oncology Group (ACoSOG) Z0010 study (43) of 5,539 patients with T1,T2N0M0 breast cancer reported no differences in locoregional or distant recurrence between the 3,904 patients with negative SLNs and the 1,625 in whom SLN metastases were detected only by IHC. ACoSOG Z0011 (44), a prospective randomized non-inferiority trial of 891 patients with T1-T2 invasive cancer comparing SLNB alone to axillary dissection, demonstrated no significant survival differences between the two treatment arms at a mean follow-up of 6.3 years.

The International Breast Cancer Study Group (IBCSG) 23-01 prospective randomized clinical trial (45) in patients with ≤5 cm breast cancer and nonpalpable nodes recently reported at a median follow-up of 5 years. Patients in whom SLNB revealed one or more MM-involved lymph nodes without extracapsular extension were randomized (1:1 ratio) to observation or axillary dissection. Survival did not differ between the two arms of the study.

The NSABP B-32 prospective randomized trial (46) comparing SLNB alone to SLNB plus axillary dissection reported that occult metastases, defined as tumor found on additional 2.0-mm step-sectioning of negative SLNs, were independently prognostic, but the incremental difference in outcome at 5 years was only 1.2%. A clinically insignificant difference in patient outcomes reached statistical significance solely due to the trial's large sample size (3,887 patients). As compared to no metastases, SLN ITC were associated with an increased HR for mortality, although the associated reduction in OS was only 0.6% at 5 years. ITC were less significant than MM for every outcome evaluated. The concept of degrees of nodal tumor burden was validated and formal lymphadenectomy shown to be unnecessary in the absence of SLN macrometastases.

Most patients in these four prospective trials had indications other than nodal status for adjuvant therapy, and this may have contributed to the absence of survival differences between the surgical treatment arms.

Patani and Mokbel (47) reviewed published studies on the prognostic and biological significance of ITC and MM, highlighting their significant disparities with respect to findings and conclusions. Some studies showed no associations with outcome while others reported that ITC and MM are prognostically adverse and portend an excess risk of distant disease, locoregional recurrence, and up to a 64% likelihood of non-SLN nodal metastases. There is as yet no clear consensus on optimal analytical methods for identifying SLN metastases, particularly cytokeratin IHC and molecular analysis. In considering all available data, it was posited that reliable analytical distinction of ITC from MM in SLNs could make possible a triage of affected patients into node-negative (ITC) and node-positive (MM) treatment paradigms from the standpoint of adjuvant therapy and further axillary intervention.

Extracapsular Extension of Nodal Metastases

Extracapsular extension (ECE) of metastatic tumor in regional nodes is an adverse prognostic factor in breast cancer. Among 263 breast cancer cases in 260 patients with T1 or T2 disease who underwent sentinel node biopsy, 74 had positive sentinel nodes and 70 of these patients underwent completion axillary dissection. Nonsentinel node metastases were found in 29 of these 70 patients. ECE was present in the sentinel nodes of 18 patients and 78% of these had further axillary disease as compared to only 29% of those without ECE ($p = .0003$). ECE was associated with a greater number of positive axillary nodes (7.6 vs. 2.5; $p = .006$) (48).

An analysis of 376 patients with node-positive pT1 and pT2 breast cancer from a prospective database of 1,142 patients reported ECE in 47%. ECE correlated with lymphatic and vascular invasion within the breast parenchyma, an increased risk of regional recurrence (13.4% vs. 6.6%; $p = .37$) and distant metastasis (43% vs. 16.2%; $p < .001$) (49).

At 14 years' median follow-up of 1,475 premenopausal node-positive patients in the IBCSG Trial VI randomized to 3, 6, or 9 courses of CMF, locoregional failure rates among the 933 patients for whom information was retrospectively obtained on the presence or absence of ECE were calculated. ECE correlated strongly with number of positive lymph nodes ($p < .0001$). For patients with and without ECE, local recurrence rates were 14.6% and 11.6% ($p = .05$), axillary recurrences 4.1% and 2.1% ($p = .09$), and supraclavicular failures 9.8% and 5.8% ($p = .004$), respectively. These differences were not significant after adjusting for number of positive nodes and other baseline prognostic factors (50).

Tumor Grade

The most widely used tumor grading schema is the Nottingham method, known in North America as the Elston-Ellis modification of the Scarff-Bloom-Richardson (SBR) breast cancer grading system. Glandular/tubular formation, nuclear pleomorphism, and mitotic count are each scored on a scale of 1 to 3. These are summed to give an aggregate score classifying the tumor as low (3–5), intermediate (6–7), or high (8–9) grade.

In a consecutive series of 2,219 operable breast cancers, Rakha et al. (51) reported that SBR grading was closely associated with patient outcomes, the most marked difference being between grade 1 and grade 3 ($p < .001$ for breast cancer–specific survival and disease-free survival [DFS]). The differences in survival between grades 3 versus 2 and grades 2 versus 1 were also highly significant. SBR grade was an independent prognostic factor relative to tumor size and nodal status and remained significant in multivariate Cox regression, with the exception of DFS for grade 2 versus grade 1 cancers.

The Elston and Ellis modification of the SBR grading system was necessitated by the lack of concordance in tumor grading between pathologists and institutions, and has proven highly salutary (52). Identification and analysis of 97 cell cycle regulation and proliferation genes associated with histological tumor grade demonstrated that a derived "gene expression grade index" was highly associated with histological grades 1 and 3, while the genetic expression grade indices of grade 2 lesions spanned the entire range of values for all grades. Gene expression grade index tended to reclassify grade 2 cancers into two groups, one at high and the other at low risk of recurrence (53).

The SEER analysis (21), using a four-grade schema, reported relative 5-year survival of 100% for grade 1 tumors and 93.2%, 77.6%, and 78.6% for grades 2 to 4, respectively. For stage II, III, and IV patients, histological grade was prognostically significant.

Tumor Histology

Adenocarcinoma of the breast includes a variety of histological subtypes, the commonest being ductal, lobular, mixed ductal and lobular, and "not otherwise specified" (NOS). Five-year relative survival for these histologies from the SEER data (21) was 87.5%, 91.6%, 92.9%, and 62.2%, respectively. The less common indolent histological variants include mucinous (5-year relative survival 98.3%), tubular (100%), adenoid cystic/cribriform (100%), medullary (89.5%), papillary (94.5%), and comedocarcinoma (89.9%). Only 34.2% of patients with inflammatory cancer survived 5 years as compared to 82.6% with Pagetoid cancer, 81.7% with scirrhous adenocarcinoma, and 64.8% of patients with nonadenocarcinomas.

Tumor Stage

Pathological TNM tumor staging is key to prognostication and treatment recommendations. In the SEER analysis (21), the 5-year relative survival for stage 0 and stage I breast cancer was 100%, 86% for stage II, 57% for stage III, and 20% for stage IV (Fig. 28-4).

Lymphovascular Invasion

LVI is an adverse prognostic variable in breast cancer. In a large national cancer registry study of 15,659 patients accrued between 1996 and 2002 (54), LVI was identified in 15%. Median follow-up was 6.4 years for DFS and 7.7 years for OS. Five-year DFS was significantly lower among affected patients at 54.5% (95% CI 52.4–56.6%) as compared to those without LVI (79.5%; 78.7–80.2%). OS was also significantly lower at 66.0% (64.1–67.9%) as compared to 87.3% (86.7–87.8%) among patients without LVI. These differences persisted on multivariate analysis.

However, LVI was associated with adverse outcome only in patients already at high risk of recurrence, and had no adverse effect on patients considered low risk on the basis of other factors. This finding was at odds with the 2007 St. Gallen Consensus (55) which concluded that among patients at low risk for relapse, LVI elevated affected patients into the moderate-risk category.

Lee et al. (56) studied the prognostic influence of LVI in patients with node-negative breast cancer, stratifying them by time period and adjuvant therapy; 990 patients diagnosed in 1974–1988 who received no adjuvant therapy and 1,765 diagnosed in 1988–2000 who did. Median follow-up of the two groups was 13 and 6.8 years, respectively. LVI was identified in 19% of tumors and was associated with larger tumor size, high grade, and young age. On multivariate analysis, OS was independently associated with LVI, tumor grade, and tumor size in both cohorts.

Interobserver variation with respect to LVI in breast cancer can be problematic, and thus five criteria must be satisfied for a diagnosis (57). Historically, retraction artifact due to processing has been cited as a significant cause. Recent research suggests that this entity may not always be due to tissue fixation, but can itself be an indicator of poor prognosis related to tumor–stromal interactions.

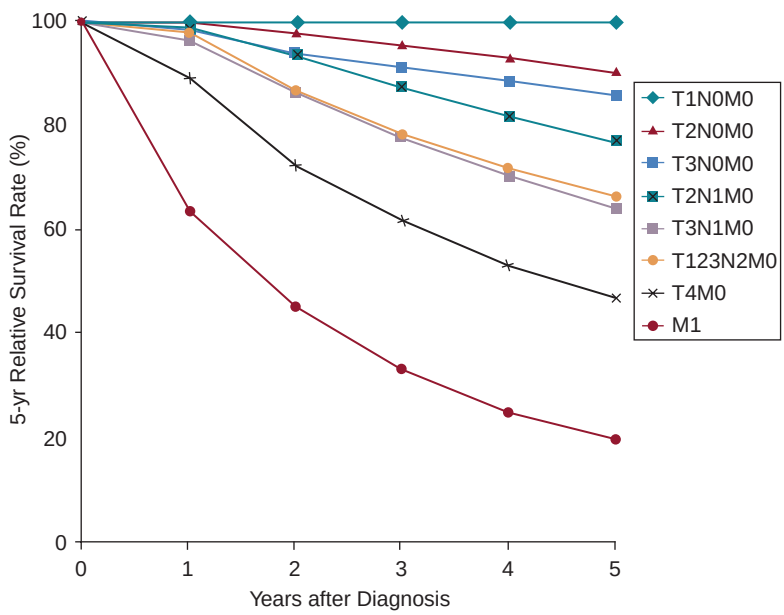

FIGURE 28-4 Five-year relative survival rates by TNM stage. Ages 20+, 12 SEER areas, 1988–2001. (Redrawn from Ries LAG, Young JL, Keel GE, et al., eds. SEER survival monograph: cancer survival among adults: U.S. SEER Program, 1988–2001, patient and tumor characteristics. NIH Pub. No. 08-6215. Bethesda, MD: National Cancer Institute, SEER Program, 2007.)

Hormone Receptor Status

The reader is referred to Chapter 26 for a detailed discussion of the prognostic impact of tumor ER and PR receptor status.

HER2 Amplification or Overexpression

HER2 amplification or overexpression is present in at least 15% to 20% of the annual breast cancer burden and is an independent indicator of poor prognosis (58). HER2 receptor expression augments tumor cell proliferation, mobility, invasiveness, and survival through signal transduction initiated by HER2 homodimerization or heterodimerization with HER1, HER3, and/or HER4, among other mechanisms.

Measures of Tumor Proliferative Activity

Numerous measures of tumor cell proliferation have been studied including thymidine labeling index, flow cytometry and S-phase fraction, thymidine kinase, cyclins D and E and their inhibitors p27 and p21, topoisomerase IIα, p53, bax, bcl-2, and Ki67, among others. Colozza et al. (59) reviewed 135 studies of these tumor proliferative factors in 159,516 breast cancer patients published prior to June 2004.

Methodological shortcomings precluded attribution of prognostic or predictive significance to any of these potential markers. The retrospective status of most of the included studies, disparities in the handling and preservation of archived materials, the small number of patients per study and frequent recourse to subset analysis, confounding heterogeneities within and between patient populations, significant variation in cut-off points and the methods used to measure biomarkers, lack of standardization and quality control methodologies of the various assays used, and the relatively short median follow-up reported in some studies were all contributing factors (59).

Mitotic index (MI), one of the three elements of SBR tumor grading, has been cited as the strongest prognostic discriminant in node-negative breast cancer patients aged less than 71 years in the Multicenter Morphometric Mammary Carcinoma Project, a national database of 3,479 patients (60). Of these, 853 had node-negative, small, and/or low-grade cancers and therefore did not receive systemic adjuvant therapy. In multivariate analysis, MI was the most significant predictor of survival among all variables evaluated, rendering insignificant both pleomorphism and tubular formation, the other two components of the SBR tumor grading paradigm. MI ≥10 identified patients at high risk who should be offered adjuvant therapy. In a subsequent analysis (61), MI was superior to Norwegian Breast Cancer Group guidelines and the online program Adjuvant! in node-negative patients aged less than 55 years. However, in 477 patients analyzed by REMARK criteria who did not receive adjuvant therapy, MI provided no prognostic advantage over standard SBR grade (62).

Ki67 expression in breast cancer has been further investigated for prognostic significance since the analysis of Colozza et al. (59) and the ASCO overview (28). This marker of proliferation has recently been evaluated using the REMARK tool (14) and determined to be an independent prognostic factor for DFS (HR 1.05–1.72) in multivariate analysis of prospective randomized clinical studies. In the neoadjuvant setting, high Ki67 is associated with pathological complete response (pCR) (63).

Luporsi et al. (64) reported a meta-analysis of 71 studies of Ki67, 17 of these prospective. Ten studies of 9,185 patients evaluated this marker for prognostic significance, three studies of 411 patients for prognostic and predictive significance, and four studies of 520 patients for predictive significance. Ki67 was an independent prognostic factor in multivariate analysis of DFS (HR 1.05–1.72) in 7 reports but prognostic for OS only in one trial. The REMARK scores for the included studies ranged from 9 to 18 (median 12), and the LOE for Ki67 as a prognostic factor for DFS was IB as the trials were randomized and slide review was centralized. Only one study with LOE IIB concluded that elevated Ki67 was predictive of chemotherapeutic responsiveness.

Endocrine therapy profoundly inhibits tumor proliferation. Anastrozole suppresses Ki-67 expression at 2 and 12 weeks by 76% and 82%, respectively, as compared to 60% and 62% for tamoxifen and 64% and 61% for combined therapy (63). The IMPACT Trialists Group (65) compared Ki67 expression in tumor biopsy samples procured before and after 2 weeks of presurgical treatment with anastrozole, tamoxifen, or anastrozole plus tamoxifen in 158 patients with ER+ primary disease. On multivariate analysis, high Ki-67 expression after endocrine therapy was significantly associated with reduced recurrence-free survival (RFS), whereas high Ki-67 at baseline was not. Large baseline tumor size and lower ER expression after endocrine treatment also correlated with poorer RFS ($p < .001$ and $p < .04$, respectively).

Response to neoadjuvant chemotherapy and prognosis were analyzed in 552 patients as a function of high versus low tumor Ki-67 expression (66). Ki-67 was an independent predictor of pCR (HR 3.5; 1.4–10.1), 113 of 390 patients (29%) with high Ki-67 attaining pCR status as compared to only 7 of 162 patients (4.3%) with low Ki67. Mean Ki-67 value in patients with pCR was 50.6 as compared to 26.7 in those with less than pCR.

PREDICTIVE FACTORS

In 2007, ASCO recommended that ER and PR always be measured on primary and, when possible, metastatic breast cancer specimens to establish or rule out possible benefit from endocrine therapy. The predictive value of HER2 gene amplification and/or overexpression was affirmed as essential in determining whether trastuzumab and/or newer anti-HER2 agents should be prescribed to individual patients (28).

Hormone Receptor Status

This is discussed in detail in Chapter 26.

HER2 Amplification and/or Overexpression

HER2-positive breast cancer predictably responds to HER2-targeted therapies. These include the monoclonal antibodies trastuzumab and pertuzumab, the dual HER1 and HER2 tyrosine kinase inhibitor lapatinib, and the immunoconjugate trastuzumab-DM1, with other agents in development.

The ASCO overview (28) acknowledged that evidence that anthracycline-based chemotherapy provides greater benefit for HER2+ breast cancer was only LOE II (prospective trials with marker utility as a secondary end point), whereas LOE I evidence had shown that anthracycline and nonanthracycline chemotherapy have equivalent activity in these patients.

In prospective randomized adjuvant and neoadjuvant trials for HER2+ disease, survival was increased and recurrence rates reduced by trastuzumab. At almost 4 years' median follow-up, DFS and OS in patients randomized to trastuzumab plus anthracycline-based chemotherapy were significantly increased as compared to chemotherapy alone ($p < .001$ for both). Mortality in the trastuzumab arm was 39% less than that in the chemotherapy control arm (67).

At 65 months' median follow-up of a three-armed trial of trastuzumab (68), DFS and OS of patients randomized

to docetaxel, carboplatin plus trastuzumab (TCH), anthracycline chemotherapy plus trastuzumab, or anthracycline chemotherapy alone were reported. While there was no difference in survival between the two trastuzumab arms, the anthracycline control arm fared significantly worse. However, cardiotoxicity in the TCH arm was significantly less as compared to anthracycline chemotherapy plus trastuzumab.

Hayes et al. (69) hypothesized that HER2 expression/amplification would predict benefit from high-dose doxorubicin, addition of paclitaxel following adjuvant doxorubicin and cyclophosphamide, or both. In an analysis of 1,500 randomly selected node-positive patients from a cooperative group prospective randomized trial, no interaction was observed between HER+ status and doxorubicin doses above 60 mg/m^2, but HER2 positivity was associated with a significant benefit from paclitaxel (HR = 0.59; p = .01). Paclitaxel provided no benefit for patients with HER– ER+ breast cancers.

In a meta-analysis (70) of 9,117 patients in five prospective randomized trials of adjuvant trasuzumab, the HR for mortality for anti-HER2 treatment was 0.52 (95% CI, 0.44–0.62). Recurrence was significantly lower (HR = 0.53; 95% CI 0.46–0.60) as was the incidence of distant metastasis (6% vs. 10.8%, p < .00001). Another meta-analysis (71) of 515 patients in five randomized neoadjuvant trials of chemotherapy with or without trastuzumab reported an odds ratio for pCR of 1.85 (95% CI, 1.39–2.46) among trastuzumab-treated patients (p < .001).

Pertuzumab and trastuzumab bind to different HER2 epitopes and are complementary in their mechanisms of action. In patients with stage IV breast cancer, pertuzumab plus trastuzumab and docetaxel resulted in improved survival as compared to trastuzumab and docetaxel alone (mortality HR = 0.62; 0.51–0.75, p < .001) (72).

Randomized neoadjuvant trials of the anti-HER2 monoclonal antibodies trastuzumab and pertuzumab and the tyrosine kinase inhibitor lapatinib, singly and in combination, have yielded significant pCR rates when administered with cytotoxic chemotherapy in HER2+ breast cancer. Dual anti-HER2 therapies in the neoadjuvant setting demonstrate additive activity and perhaps synergy as evidenced by the superior pCR rates in patients so treated (71,73).

The loss of HER2 expression in residual disease following neoadjuvant chemotherapy and trastuzumab is associated with a higher rate of relapse, as is high Ki-67 expression in residual tumor following neoadjuvant therapy (74).

Predictive Pathological Factors: Future Possibilities

Predictive biomarkers for the basal-like intrinsic subtype, triple-negative, and claudin-low tumors are lacking. Chemotherapy is the only adjuvant option currently available. Alkylating agents and the platinum salts in particular have shown efficacy through DNA-disrupting activity and interference with tumor cell DNA repair mechanisms (75–77).

Poly(ADP-ribose) polymerase (PARP) identifies DNA damage and promotes repair of single-strand breaks through base excision pathways (77). This enzyme is expressed in all intrinsic breast cancer subtypes. *In vitro,* PARP inhibition is lethal to *BRCA*-deficient cancer (78). The PARP inhibitors iniparib and olaparib have yielded encouraging preliminary results in *BRCA*-associated and triple-negative breast cancer (77).

Despite their low expression of proliferative genes, claudin-low cancers have a particularly guarded prognosis. They overexpress genes related to mesenchymal differentiation and the epithelial–mesenchymal interface, and can exhibit a cancer stem cell phenotype. They present clinically as high-grade infiltrating ductal cancers with metaplastic or medullary features, and 80% are triple negative. They respond poorly to neoadjuvant chemotherapy. Of all the basaloid intrinsic subtypes, these tumors pose an especially difficult challenge. Clinically useful biomarkers are urgently needed for these and other triple-negative cancers within the basal-like and other intrinsic subtypes (75).

Tumor ER, HER2, and Ki-67 expression frequently change in the course of neoadjuvant therapy, with important prognostic and predictive implications. Core needle biopsy of residual tumor with measurement of ER after neoadjuvant endocrine therapy not infrequently reveals reduced ER expression, predicting abrogation or complete loss of susceptibility to endocrine agents. So too, HER2+ breast cancers treated with neoadjuvant trastuzumab and chemotherapy may cease to express HER2, a finding that correlates with significantly increased risk of relapse of disease (74).

Reduced tumor cell Ki-67 expression after 2 to 12 weeks of endocrine therapy correlates with a good clinical outcome while high Ki-67 portends the opposite, as already noted (61,63). Elevated pretreatment Ki-67 expression predicts a high probability of attaining pCR with neoadjuvant chemotherapy (64,66).

In the POETIC trial (63), postmenopausal ER+ patients are randomized (2:1) to 2 weeks of neoadjuvant aromatase inhibition or no presurgical therapy. Tumor Ki-67 expression is assayed 2 weeks before and again 2 weeks following the presurgical intervention. The potential utility of Ki-67 expression before and after endocrine therapy in predicting RFS is a secondary aim. Serial core biopsies of residual tumor for assays of tumor biomarkers during or following adjuvant or neoadjuvant systemic therapy may prove salutary for prognostication and determination of optimal systemic therapy for the individual patient and her tumor.

MANAGEMENT SUMMARY

- Prognostic and predictive factors must provide independent and significant value, validated by clinical testing. Their identification and measurement must be feasible, reproducible and widely available, and the results interpretable and therapeutically useful.
- Prognostic factors inform on the biological potential and probable clinical course of a breast cancer irrespective of treatment.
- Predictive factors provide information on the responsiveness of a breast cancer to specific therapies.
- Clinical prognostic factors currently include young age (less than 35 to 40 years), race/ethnicity, clinical primary tumor size and nodal status, clinical staging, and clinical response to neoadjuvant systemic therapy.
- Pathological prognostic factors currently include primary tumor size (invasive component only), direct extension of primary tumor beyond the breast parenchyma, regional nodal status by degree of metastasis and number of nodes involved, tumor grade, tumor histology, pathological TNM stage, lymphovascular invasion, extranodal extension, tumor hormone receptor status, tumor HER2 amplification/overexpression, tumor Ki-67 expression, and pathological response to neoadjuvant systemic therapy.

- Predictive factors currently include tumor hormone receptor status and HER2 expression.
- Tumor biomarkers are lacking for basaloid, triple-negative and claudin-low breast cancers. Alkylating chemotherapy agents, platinum-based regimens, and PARP inhibitors are under investigation for efficacy related to their tumor DNA-disrupting mechanisms of action.
- ER, HER2, and Ki-67 expression by tumor can change quantitatively over the course of treatment, with consequences both bad and good. Investigation of interval core biopsy of residual tumor for serial measurements of biomarkers in the course of neoadjuvant systemic therapy is currently in progress.

CHAPTER 29

Genomics, Prognosis, and Therapeutic Interventions

Lisa A. Carey, Maggie Chon U Cheang, and Charles M. Perou

CHAPTER CONTENTS

CURRENT OVERVIEW

The rapid advancement of high-information content technologies has resulted in the completion of numerous molecular profiling studies of breast cancers. Global gene expression profiling, massively parallel sequencing (MPS), array-comparative genomic hybridization (aCGH), and reverse phase protein arrays (RPPA) have allowed scientists to profile RNA, DNA, and proteins in hundreds of human breast tumor tissues in a speedy fashion. To fully decipher the mountains of data generated from these 'omics' approaches, and to translate the findings into the clinical setting is challenging, but, undoubtedly, is also one of the highest research priorities for the next few years. In this chapter, we will review how genomics have informed our understanding of the heterogeneity of breast cancer and how it is currently being used for prognostication and therapeutic decision-making. The promise of gene expression patterns, when possibly coupled with somatic mutational profiles, is the near future when we will be able to use the detailed tumor-specific, and patient-specific, information as a means to personalize therapy for breast cancer patients.

Breast cancer is a known heterogeneous disease comprised of a growing number of recognized biologic subtypes. Clinicians and researchers have noted the variations in risk factors, response to therapy, and clinical behavior according to hormone receptor status (i.e., Estrogen Receptors [ER] and Progesterone Receptors [PR]) for several decades. More recent data has also implicated HER-positive breast cancers as possessing unique characteristics, such as responsiveness to anthracyclines (1). Traditional single marker approaches to biomarker identification is limited by the fact that seldom is one gene/protein responsible for the entire action of a cellular pathway. Even more importantly, single marker studies do not address the important relationships among and within different pathways, which are increasingly becoming needed to predict tumor behavior and response to therapy.

As mentioned earlier, MPS is a new and powerful tool for the study of human cancers. The first commercially available MPS platform was the 454 technology by Roche Applied Sciences (2). As of today, other platforms available in the market include the HiSeq and MiSeq Systems by Illumina, Ion Torrent PGM and Proton by Life Technologies, and PacBio RS by Pacific Biosciences. Each technology uses a proprietary approach to sequence molecules of DNA; however, all result in the generation of tens of thousands, to even tens of millions, of sequence 'reads,' which are then used to reconstruct the genomic DNA sequence (or mRNA sequence) of a gene or genome. Although the clinical integration of targeted sequencing assays may still be a few years away, in 2012, eight published landmark studies all applied MPS and/or other DNA-based 'omic' technologies to create a comprehensive catalog of somatic mutational events that are driving breast cancer pathogenesis (3–10). This new MPS data, and the older gene expression array data, provide the genetic framework for personalized medicine as follows.

GENE ARRAYS

DNA microarrays have been used as a means to better understand tumor biology and to predict outcomes and response to therapy. Gene expression microarrays measure the level

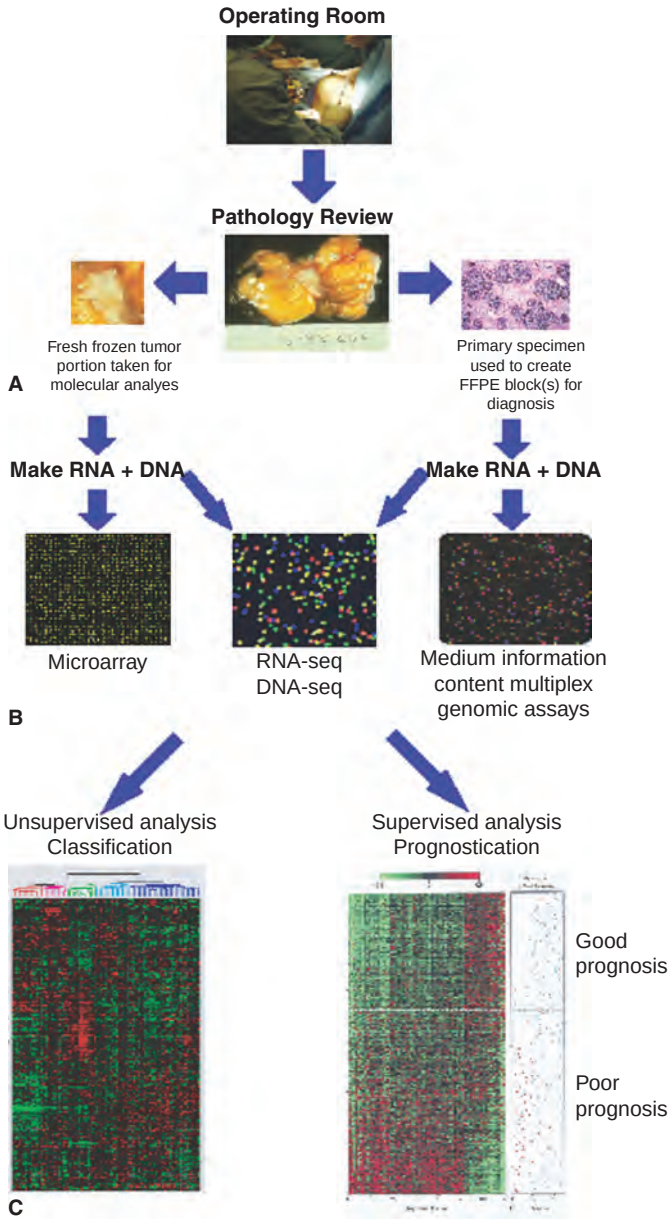

FIGURE 29-1 Overview of gene expression analysis of human tumors. **(A)** Tumors are collected in the operating room and often split into multiple aliquots. **(B)** Nucleic acids (i.e., RNA and DNA) are isolated and can be assayed on a variety of technologies. **(C)** Unsupervised and supervised analyses are performed to identify tumor subtypes and/or to develop predictors of outcomes or response to therapy.

of expression of a particular gene by quantitatively determining the level of mRNA transcripts, which can be initially compared to a reference sample (as in the case of two-color arrays like those produced by Agilent), or directly compared to other tumors or normal tissues (as in the case of one-color arrays like those produced by Affymetrix). The arrays themselves currently include essentially all human genes that are encompassed in thousands to millions of features/probes that are either oligonucleotides, or PCR amplified cDNA inserts. These sequences represent known, unknown but validated, and hypothetical genes, and all approximately 37,000 genes in the human genome can be included (~25,000 protein coding genes, ~12,000 non-coding RNAs). A tumor is processed for RNA, which is used to generate either complementary DNA or RNA, labeled with a fluorescent probe. These fluorescent probes are then either directly applied to a gene array alone (one-color arrays), or combined with a second fluorescently labeled reference sample and then both are applied to an array (two-color array, in which, by convention, the color 'red' is used for the sample of interest and the color 'green' for the common reference sample). The remainder of the assay is basically a Southern blot with nucleic acid hybridization reactions occurring and binding, and with the intensity(s) of the nucleic acids that hybridize to the individual gene probes reflecting the relative amounts of tumor mRNA. In the case of a two-color microarray the 'green' signal predominance reflects low expression and 'red' predominance reflects high expression of that gene in the tumor relative to the reference (Fig. 29-1). Thus, in a two-color array it is not the value of the tumor versus the reference that is of greatest interest, but the ratio of tumor/reference for each gene that is used as a quantitative measure of that gene. This value is then used to compare tumor to tumor, and tumor to normal; in this way, once a two-color microarray gives a tumor/reference value, it is used nearly identically to the one-color microarray absolute intensity values, and thus, once the user gets past these initial different data processing steps, all downstream analysis steps are similar.

MOLECULAR PROFILING OF BREAST CANCERS BY GENE EXPRESSION ARRAYS

Most breast cancer molecular profiling studies have focused upon gene/mRNA expression. Multiple approaches to analyzing gene expression microarrays exist; however, it is self-evident that the answer one gets from genomic analysis depends upon the question one asks. For example, *unsupervised* analyses (which use no external guide) can identify whether there are molecularly identifiable tumor subtypes, also called "class discovery," while *supervised* analyses (analyzed with a particular clinical endpoint in mind) can identify if there are genes correlated with relapsed patients versus those that did not relapse (prognostic profiles), or related to patients who responded to a particular therapy versus those that did not (predictive profiles), which are also called "class comparisons" (11,12). It is tempting to assume that the individual genes that are identified using these methods may themselves be causal in creating the subtype, or the clinical characteristic, and sometimes they are; however, in truth, the identified genes themselves may be mere proxies for genetic events or pathway activation and may not themselves be the cause. A third category of analysis, called "class prediction," first uses a prespecified gene list (typically coming from a supervised analysis) and a given sample set (and classification rule) that is then used to assign a new individual tumor to a particular category, such as a genomic-based class; all genomic tests offered in the clinic should have reached the class prediction stage.

The molecular profiling of breast cancer has provided important information for three major questions: (1) Are there subtypes of breast cancer based on biological differences? (2) Are there gene expression profiles that can distinguish poor from good prognosis patients, thus allowing us to make better-informed decisions regarding adjuvant therapy? (3) Are there gene expression profiles that can predict which tumor will respond to a specific therapy? These questions, and others, will be addressed in the following sections.

BREAST CANCER INTRINSIC SUBTYPES

In 2000, Perou and colleagues used a semi-supervised approach to identify naturally occurring breast cancer subtypes in a population of 40 patients with locally advanced disease treated with neoadjuvant chemotherapy (13). They identified 496 genes termed the "intrinsic gene set" that showed little variance within repeated tumor sample, but high variance across different tumors, and then used this gene set for potential subtype discovery. Among these breast cancers, they found that the patterns of expression of these genes segregated the tumors into four subtypes, and in Sorlie et al. (2001), they identified a fifth possible subtype (14). The five 'intrinsic' subtypes are so-called because the gene list that defines them reflects intrinsic properties of breast cancers rather than being contributed by other cell types or augmented by drugs. These subtypes have been consistently identified in independent datasets using multiple different technologies (15–21), are conserved across ethnic groups, and are present in preneoplasia (21,22). Reassuringly, the intrinsic subtypes are segregated by expression of hormone receptors and the genes they regulate (and actually include ER, PR, and HER2), supporting earlier epidemiologic and biomarker studies suggesting that ER positive and ER negative breast cancer are different. At least two hormone receptor positive subtypes were identified and are called "Luminal A" and "Luminal B." Conversely, there are several subtypes characterized by low expression of hormone receptors, one of which is called the "HER2-enriched" subtype (HER2-E) and another called the "Basal-like" subtype (Fig. 29-2A). The fifth subtype, the normal-like, is less clearly a subtype rather than a likely technical artifact possibly caused by too much normal contaminating tissue. A new possible subtype, named Claudin-low, has been recently identified, which is characterized by low to absent expression of cell adhesion genes including Claudin 3, 4, 7, and E-cadherin (23). Although the intrinsic subtypes were identified without any knowledge of outcomes, these subtypes have strong prognostic implications (Fig. 29-2B); in particular, patients with Basal-like, Claudin-low, HER2-E, or Luminal B tumors demonstrate a significantly worse outcome compared to patients with Luminal A tumors in datasets from patients treated with no systemic adjuvant therapy, and in patient sets treated more heterogeneously including adjuvant and neoadjuvant chemotherapy (15–19,24,25).

A critical aspect of biomarker biology is validation and the intrinsic subtypes have been validated through multiple common findings including similar distributions on many independent datasets, and similar overall risks/prognoses as well (14,17,19,26). Because the clustering methodology for the initial identification of the intrinsic subtypes is suboptimal for everyday clinical classifications, the development

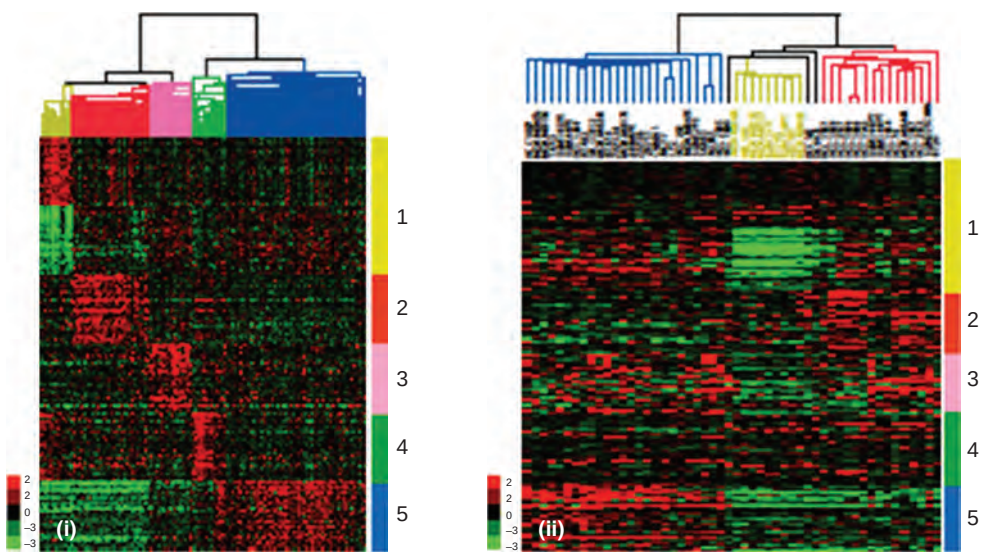

FIGURE 29-2A (A) Gene clusters that characterize each primary human tumor subtype are shown in the human **(i)** and cell line **(ii)** gene expression data sets. In both data sets, array trees have been derived by unsupervised hierarchical clustering using the 1,906 intrinsic genes as described in Parker et al. (29). **(i)** The top 50 upregulated genes associated with each molecular subtype, including the top 50 downregulated genes in Claudin-low tumors, are shown in the UNC337 database that included 320 breast carcinomas and 17 normal tissues. Top genes were selected after performing a two-class Significant Analysis of Microarray (SAM) (false discovery rate = 0%) between each molecular subtype versus others. Luminal A and B subtypes were combined into the luminal subtype. In the tree, the yellow node denotes the Claudin-low tumors. **(ii)** Gene clusters characteristic of each tumor molecular sub-type are shown in 52 breast cancer cell lines. Missing genes have been omitted. In the tree, the yellow node denotes the most highly correlated cell lines that best resemble the Claudin-low subtype. 1 (yellow), Claudin-low gene cluster of upregulated and downregulated genes; 2 (red), basal-like gene cluster; 3 (pink), HER2-enriched gene cluster; 4 (green), normal breast-like gene cluster; 5 (blue), luminal gene cluster. Phenotypic and molecular characterization of the claudin-low intrinsic subtype of breast cancer. *Breast Cancer Research* 2010;12:R68.)

of a robust subtyping method for individual patient samples has been an area of active research. One of the promising approaches for reproducible subtype classifications is based upon identifying a subtypes mean expression profile, called a centroid (17,18,27). Hu and colleagues developed the Single Sample Predictor (SSP) tool to serve as a first generation, unchanging classifier for individual patient samples; the SSP compares the gene expression profile of an unknown sample to a prototypical profile of each intrinsic subtype and classifies the unknown sample according to the profile it most closely matches. Thus, one sample or hundreds of samples can be objectively classified in a reproducible fashion.

Fresh frozen (FF) tumor samples are usually preferred for microarray experiments, therefore limiting the practicability of these approaches for correlative sciences on clinical trials when often only formalin-fixed paraffin embedded (FFPE) tissues are available. However, Mullins and colleagues demonstrated that there was 94% concordance (33 of 35 matched FF-FFPE pairs) when comparing the subtype assignments by centroid-based algorithm from FF tissue by microarray versus FFPE tissue assayed by real-time quantitative reverse transcription-PCR (qRT-PCR) (28). In 2009, Parker and colleagues developed an improved, open-source intrinsic subtype classifier based on a minimal list of 50 genes, commonly known as the PAM50 (29). In this study, 122 matched frozen-FFPE tumor pairs were subjected to both microarray and qRT-PCR analysis, and a centroid-based predictor was developed that used 50 genes, and which could use either FF RNA (microarray) or FFPE RNA (qRT-PCR). This 50-gene subtype predictor provided significant prognostic value independent of the standard clinical parameters in a test set of 761 patients receiving no systemic therapy, and significantly predicted the pathologic complete response (pCR) in a test of 133 patients treated with neoadjuvant taxane and anthracycline regimens (29).

In the same study, the authors also developed several risk models based upon a Cox Modeling approach, which uses the genomic-determined subtype data and a standard clinical variable (tumor size). A Risk of Relapse (ROR) score could be assigned to each test case (that is, a patient sample) using a Cox model based upon a tumors "distance" to the subtype centroids alone (ROR-S), or using subtype correlation along with tumor size (ROR-T) (29). The most current standard for molecular intrinsic subtyping is the PAM50 50-gene test, which includes the above subtypes except the Claudin-low, and is undergoing extensive clinical validation (30–34).

Other approaches to defining the intrinsic subtypes have been attempted using non-microarray-based methods, most often using immunohistochemistry (IHC) (35,36). However, the accuracy using an IHC-based approach is not as great as the multi-gene expression assays, mostly because IHC assessments can be subjective, and suffer from inter-observer and inter-laboratory variations. Despite the limitations of IHC, performing tumor subtyping via IHC is still valuable and has been adopted as a means of classification by the St. Gallen's consensus conference (37); specifically, the indication is that Luminal A patients as defined by this IHC-based definition (i.e., ER+ and/or PR+, HER2-normal, Ki-67 less than 14%), may not be recommended to receive adjuvant chemotherapy given their overall general good prognosis.

Luminal Intrinsic Subtypes

The most common subtypes of breast cancer are the Luminal subtypes, so-called because they have a gene expression pattern reminiscent of the luminal epithelial component of the normal breast (13). These tumors are characterized by expression of the estrogen receptor (ER), progesterone receptor (PR), and genes associated with ER activation such as LIV1, TFF1, and Cyclin D1, as well as expression of luminal cytokeratins 8 and 18 (13,20,38). Within the luminal tumors family there are at least two subtypes, Luminal A and Luminal B, and there are many relevant differences between these two groups. For example, Luminal A tumors generally have high expression of GATA3, ER-regulated genes including PR, low expression HER2 and of the HER2 amplicon expression cluster, and low expression of proliferation-associated genes including Ki-67 (19,25). Conversely, Luminal B tumors tend to be highly proliferative, are sometimes HER2+, and show lower expression of PR (36,39) and of other ER-regulated genes (36,39).

When compared to other breast cancer subtypes, Luminal tumors have a low frequency (fewer than 20%) of TP53 mutations (20,25), with a rate of 12% in Luminal A and a higher frequency of 29% in Luminal B tumors (4), with the presence of mutant TP53 being strongly associated with endocrine therapy resistance (6). Interestingly, ~30% of Luminal B tumors also have amplification of the TP53 antagonist MDM2 (4), thus suggesting that inhibitors for MDM2-p53 interaction might be a potential treatment approach for a subset of the aggressive Luminal B tumors. In addition, The Cancer Genome Atlas (TCGA) data also reported that phosphatidylinositol-3-kinase (PIK3CA) mutations are the most common Significantly Mutated Gene (SMG) in Luminal breast cancers (~40%), hence another potential therapeutic target. In addition, the site of PIK3CA mutation may be subtype-specific where, for example, almost all the "hotspot" E545K mutations occurred in Luminal A subtype (25/27), whereas the other common hotspot (i.e., H1047R) occurred in all of the subtypes (4). Whether adjuvant studies focusing on PIK3CA mutations should stratify by mutation type and intrinsic subtype is debatable, but should be kept in mind as the high correlation between subtype and mutation type is likely an important biological feature of these Luminal A cancers.

In population-based studies that classified tumors using IHC, Luminal A breast cancer is the most common, representing approximately 40% to 50% of tumors while Luminal B comprises approximately 10% to 15% (16,35,36,40,41). Expression array-based profiling studies suggest that Luminal A comprises approximately 30% to 40% and Luminal B approximately 20% of breast cancers (17,42), with Luminal A breast cancers consistently showing a better prognosis than Luminal B (19,20,25,43). Although life history risk factors for all of the subtypes remain complex, it is increasingly clear that most traditional risk factors are primarily risk factors for Luminal breast cancers (44). In addition, the population-based studies also show that premenopausal women, and African-American (AA) women, tend to develop fewer of the good-prognosis Luminal tumors and more of the poor-prognosis Basal-like tumors (described further later), which may contribute to the worse mortality outcomes experienced by groups (i.e., young women, and/or AA women) (16,41). While clinical gene expression-based assays to identify Luminal A and B are not yet formally available, the OncotypeDx Recurrence Score™ (RS) assay includes many genes (HER2, GRB7, ER, SCUBE2, Bcl2, Ki-67, Survivin, MYBL2, and Cyclin B1) that are also used to define Luminal A vs. Luminal B tumors. To more directly compare intrinsic subtyping to the Recurrence Score, Fan et al. ran a research version of both assays on a single data set of patients and showed that 50% of 123 Luminal A tumors had low RS (associated with good outcome) whereas only 2% of Luminal B tumors had low RS (with almost all Luminal B being called RS high) (42) (Table 29-1). On the other hand, Kelly et al. compared the risk assignments between OncotypeDx RS and the research version of intrinsic subtypes by PAM50 qPCR

TABLE 29-1

Prognostic Profile by Intrinsic Subtype

classifier on 151 ER positive stage I–II tumors (45). Seventy percent of Luminal As had low RS and 90% of the high RS tumors were Luminal B. These concordant findings from two different genomic assays validate the genomics approach in general, and highlight the biomarker powers of multi-gene expression assays.

HER2-Enriched Subtype

The hormone receptor-negative subtypes are comprised of the HER2-Enriched (HER2-E) and Basal-like subtypes, although it should be noted that not all HER2-E, and not all Basal-like tumors, are ER/PR negative. The HER2-E subtype has elevated expression of HER2 and many other genes that reside near HER2 in the genome including GRB7 (see section on Recurrence Score) because of HER2 region genomic DNA amplification. These tumors also show low expression of the luminal, hormone receptor-related gene cluster, and low expression of the Basal-like cluster. However, it is imperative to note that many, but not all, clinically defined HER2-positive breast cancers fall into the HER2-enriched category; for example, ~55% of the clinically defined HER2-positive breast cancers (30,46) were ER positive tumors that were classified as luminal subtypes, thus, there exists at least two types of clinically HER2-amplified tumors (i.e., HER2-E and Luminal/HER2+).

Another important feature of tumors in the HER2-Enriched subtype is high expression of the proliferation cluster and, befitting this expression pattern, 75% are high grade tumors and over 70% have p53 mutations (4). This subtype is uncommon, comprising only 5% to 10% of all breast cancers in population-based studies (16). In the era before HER2-targeted therapy, the HER2+/ER– subtype carried a poor prognosis (19,20,25,43,47). Given that there is no apparent interaction between the benefit of HER2-targeted therapy such as trastuzumab and hormone receptor status, it is reasonable to presume that the HER2-E subtype has benefited from the HER2-targeting revolution to the same degree as a HER2-positive Luminal breast cancer (48). The risk factor profile for the HER2-Enriched subtype mirrors the other Luminal tumor subtypes (49), and there is no apparent interaction with race or age (16,41). Aside from HER2 amplification and TP53 mutation, other frequent somatic mutation alterations include PIK3CA (39%) and another PI3K-pathway component (PIK3R1), but with a much lower frequency of 4% (4).

In the clinic, it is known that approximately 50% of patients with clinically HER2+ tumors respond to HER2-targeted therapies like trastuzumab. The TCGA data may provide a rationale for this as one subgroup of clinical HER2+ disease showed high levels of epidermal growth factor receptor (EGFR) and HER2 protein phosphorylation, and this subgroup was largely coincident with the HER2-Enriched subtype (4), whereas the other clinical HER2+ tumors showed the luminal phenotype and lower levels of phosphorylated EGFR and HER2. Whether the HER2-E subtype could be a biomarker for trastuzumab and/or lapatinib sensitivity, and/or HER2 and EGFR protein phosphorylation, could serve as predictive biomarkers, is yet to be determined.

Basal-Like Subtype

The Basal-like subtype is characterized by low expression of the hormone receptors and luminal subtype-related genes, and low expression of HER2 (and lack of gene amplification), thus, most of these tumors are of the so-called "triple negative" classification; however, not all Triple Negative Breast Cancers (TNBC) are Basal-like, and not all Basal-like cancers are TNBC (50) (Fig. 29-3). Other expression features of Basal-like cancers include high expression of the proliferation signature, and high expression of a unique cluster of genes called the basal cluster. The basal gene cluster includes typical basal epithelial cytokeratins (CK) such as CK5, 6, 14, and 17, the epidermal growth factor receptor, c-Kit, Vimentin, P-Cadherin, and αB-crystallin. Massive parallel sequencing

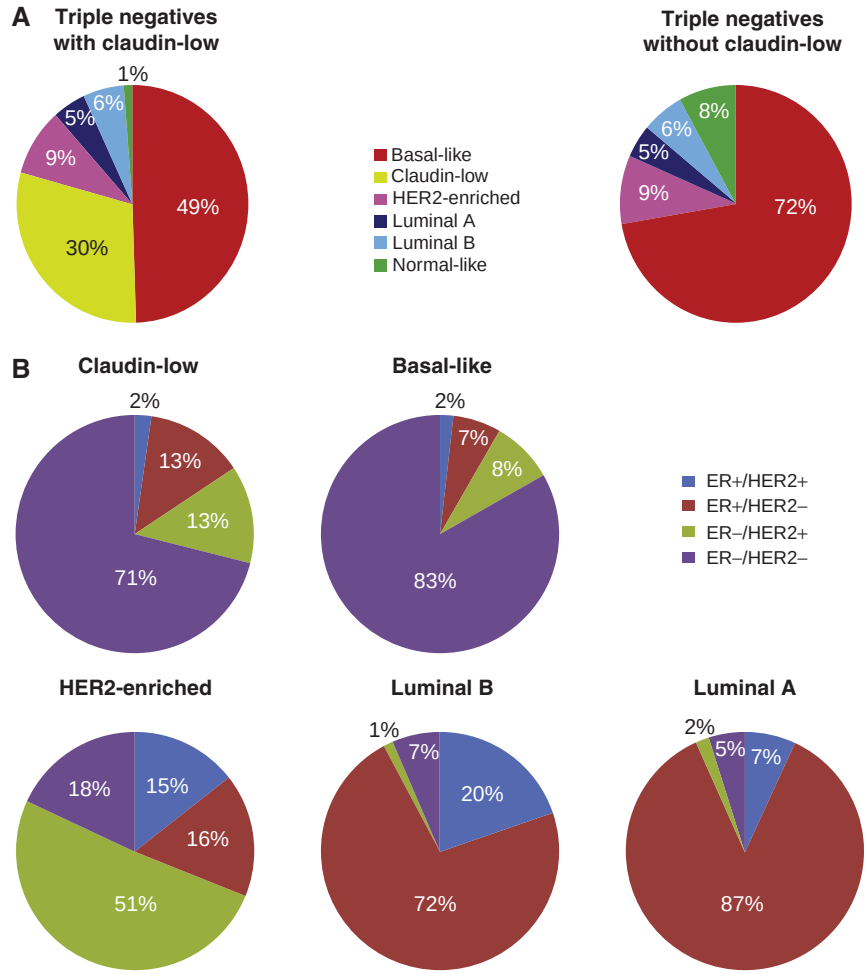

FIGURE 29-3 Distribution of clinical-pathological categories relative to the intrinsic subtypes. **(A)** Intrinsic subtype distribution within the triple-negative tumor category shown with and without Claudin-low tumors. **(B)** Distribution of ER+/HER2+, ER+/HER2+, ER–/HER2– clinical groups in the Claudin-low, Basal-like, HER2-enriched, Luminal B, and Luminal A within each subtype. (From Prat A, Perou CM. Deconstructing the molecular portraits of breast cancer. *Molec Oncol* 2011;5:5–23.)

studies have shown that Basal-like tumors are molecularly distinct from Luminal tumors, and are more similar with tumors arising in the basal layer of epidermis including squamous carcinoma of the lung (51), and epithelial ovarian cancer (4). Although the PIK-pathway appears activated within Basal-like tumors, unlike Luminal subtypes, there is a low frequency of PIK3CA mutations (9%) (4), but higher frequency of PTEN (35%) and INPP4B (30%) loss (i.e., the deletion/mutation of negative regulators for PIK-pathway) (4). Similar to HER2-E subtype, the presence of TP53 somatic mutations (85%) is extremely frequent within Basal-like tumors, which is another property they share with serous ovarian cancers (95% TP53 mutant) (52).

Several risk factors for developing Basal-like subtype tumors have been identified with one of the most intriguing being the link between the Basal-like subtype and *BRCA1* mutation carriers (19,53–55). Women who carry a deleterious mutation in *BRCA1* are at > 50% risk of developing breast cancer, and, when they do, over 80% of the time it is Basal-like. However, while *BRCA1* mutation carriers usually develop Basal-like breast cancer, most Basal-like breast cancers are sporadic and the *BRCA1* gene and protein appear intact in these tumors. A commonly held, but unproven, assumption is that the *BRCA1* pathway is somehow deranged in sporadic Basal-like breast cancer, which, if true, could have important therapeutic implications. From the TCGA data, there is a combined frequency of 20% for *BRCA1* and *BRCA2* mutations (both germline and somatic) in the Basal-like subtype (4). The *BRCA1/2* pathways, which include a number of other genes such as FANC genes, are involved in homologous recombination mediated DNA repair, which is a high fidelity DNA repair pathway. When the homologous recombination pathway is lost or dysfunctional, DNA repair occurs by the more error-prone methods that involve poly (ADP-ribose) polymerase (PARP), which can be inhibited by a novel class of drugs that are being tested in clinical trials (56,57). Loss of normal DNA repair is also implicated in sensitivity to chemotherapy, particularly to DNA-damaging agents such as platinum drugs (58), although recent studies suggest that Basal-like breast cancers may have a general sensitivity to chemotherapy (30,47,59). Gathering the commalities between Basal-like subtype and high-grade serous ovarian cancers together, one might predict that platinum-based chemotherapy might be a potential therapeutic option for Basal-like tumors.

Another notable Basal-like tumor association is between this subtype and race and age. Several independent population-based studies have shown that the Basal-like subtype is more frequent in young women, and in African-American women (16,40,41,60,61). In the Carolina Breast Cancer Study, the Basal-like breast cancers were the most common among premenopausal African-American women (27%), and least common among postmenopausal non– African-American women (9%) (41,62). Basal-like breast cancer carries a poor prognosis in multiple datasets (16,17,19,63) and this has raised the question of whether an excess of this subtype might contribute to the worse outcomes suffered by African-American women with breast cancer.

A variety of methods to identify Basal-like breast cancer have been suggested including gene expression-based methods (17,29), specific IHC-based immunoprofiles (63,64), and the "triple negative" (ER, PR, and HER2) phenotype that is already available in the clinic (47). Each approach has strengths and weaknesses; however, it is important to note that while the majority of TNBC are Basal-like (~75%), up to 25% of Basal-like breast cancers identified by gene expression are positive for either ER, PR or HER2, and thus will be misclassified by the TNBC method (39,65) (see Fig. 29-3); therefore, the use of positive markers to identify Basal-like tumors will likely be needed, and multiple redundant biomarkers for the Basal-like subtype would give the most robust assay possible.

The categorization of breast cancers into Luminal and Basal-like subtypes arises from similarities of their gene expression patterns based upon their inferred normal cell types of origin. These observations raise the question of whether these subtypes arise from different progenitor cells rather than being derived from a common progenitor and acquiring variations during progression. Several lines of evidence support that breast cancer heterogeneity is an early phenomenon with distinct lines of progression for each subtype; these data include the finding that Basal-like, Luminal, and HER2+ subtypes are found in the ductal carcinoma *in situ* stage (22,66,67) Gene copy number aberrations also have characteristic patterns within these invasive subtypes and in DCIS (68,69), and are more frequent in Basal-like breast cancer even at DCIS diagnosis (70).

OTHER BREAST CANCER SUBTYPES

A new and more rare intrinsic subtype (prevalence ~10%), namely Claudin-low, has recently been identified in human tumors, mouse models, and human cell lines (23). The majority of these tumors are high grade, metaplastic and/or TNBC phenotype, and carry a poor prognosis. Claudin-low tumors share some similar gene expression patterns with Basal-like tumors, such as low expression of the Luminal genes (*ESR1, GATA3*, keratins 8 and 19) and HER2 amplicon genes. They differ, however, from Basal-like tumors through the low expression of the proliferation signature, low expression of cell-cell adhesion proteins including Claudin-3, 4, -7, and E-cadherin (23). In comparison to Basal-like as well as other subtypes, Claudin-low tumors are enriched for immune system response genes (*CD4, CD79a*, interleukin 6, or *CXCL2*). Based on genomic analyses, *in vivo* Claudin-low tumors and the human cell lines that show the Claudin-low phenotype (i.e., BT549, MDA-MB231, MDA-MB157, SUM159PT) also have characteristics similar to metaplastic tumors, mammary stem cells (71), and an Invasiveness Gene Set (IGS)/Cancer Stem Cell (CSC) signature (72). The association of Claudin-low tumors with CSC is further supported by limiting dilution transplantation analysis of mouse Claudin-low tumors, where a large proportion (30%–40%) of the tumor cells showed Tumor Initiation Cell activity (73). The best predictor of this subtype to date is a ~800-gene based signature, and there is no robust immunohistochemical surrogate for this subtype, thus imposing a practical challenge to studying this subtype in clinical trials.

Over the last few years, efforts have been made to identify additional possible subtypes within Triple Negative Breast Cancer (TNBC) by applying MPS and/or global gene expression profiling analyses (7,74). When compared with the existing known heterogeneity present within TNBC, the results of one particularly interesting study from Lehmann et al. are highly concordant with intrinsic subtyping in that a Basal-like group is identified, a luminal/Androgen-Receptor positive group is found, as is a mesenchymal/Claudin-low like group; extending these results, Lehmann et al. goes on to show that there exists significant heterogeneity within the tumor microenvironment, namely that there exists TNBC with significant immune cell infiltrates and others without, and some with significant fibroblast invasion and others without. Thus, the heterogeneity within TNBCs included tumor-specific subtypes, as well as potentially important differences within the cellular composition of the microenvironment.

PROGNOSTIC APPLICATIONS OF GENOMICS

Over 90% of breast cancers are identified at a non-metastatic clinically curable stage;, however, all are at risk of subsequent development of metastatic disease. Identifying those at greatest risk of progression is crucial in order to limit the use of potentially toxic drugs to those most likely to benefit. This has been the purpose of prognostic indices in breast cancer. The traditional prognosticators include the Nottingham Prognostic Indicator (NPI), the St. Gallen criteria, the NIH consensus guidelines, and Adjuvant! Online, all of which use criteria like tumor size, grade, lymph node status, and hormone receptor status to predict a patient's clinical outcome. The advent of genomics technology has allowed biology-based prognosticators to be developed. Only a handful of gene expression-based prognosticators, described in the following paragraphs, have been validated and are in clinical use, and in general, these complement, but do not replace traditional prognostic factors like stage.

A separate question is, does a study establishing prognostic relevance also establish therapeutic relevance? In adjuvant therapy, prognostic relevance is often translated into therapeutic relevance simply because risk crosses a threshold for use of conventional adjuvant therapies to reduce risk. There are two caveats to keep in mind when considering multi-gene, expression-based assays in this regard. First, unlike anatomic prognosticators, there may well be an interaction between the nature of the genes included in a particular profile and the benefit of systemic therapy. The most obvious analogy is the interaction between hormone receptor status and benefit of chemotherapy (75). This may mean that the interpretation of benefit may vary by expression profile, and should give warning to clinicians about excessive extrapolation. Second is that establishing therapeutic relevance is typically harder to do than prognostic relevance. Therapeutic relevance requires either a prospective randomized clinical trial designed to test the marker (the holy grail of biomarker levels of evidence) or studies performed in a fairly homogeneous population with prospective ascertainment of clinical data, excellent representation of tumor samples, and *a priori* defined profile definitions (76).

With these caveats in mind, the most clinically relevant scenario for prognostication by genomic signatures is within node-negative breast cancer, as most of these patients do not relapse, yet most receive adjuvant therapy. Five prognostic profiles have shown promise in this arena and are relatively well-characterized, and of these, two are in clinical use in node-negative breast cancer: the Amsterdam 70-gene Mammaprint™ profile, and the OncotypeDX Recurrence Score™. As mentioned earlier, another prognostic profile is the intrinsic subtypes ROR score, which was trained for prognostic purposes on node-negative disease (Table 29-2). It is increasingly clear that the biologic pathways identified by these profiles are independent of anatomic extent of disease, and they may also provide useful information about identifying good-prognosis patients within the node-positive subset (77).

TABLE 29-2

Prognostic Profiles

Profile	*Training Population*	*Validation Population*	*Endpoint*	*Adjusted Hazard Ratio*	*Clinical Use and Notes*
Recurrence Score (Oncotype Dx™) (78)	N = 447 (78) N– or N+ ER+ and ER–, heterogeneous Rx	✓ Subset of prospective clinical trial (NSABP B14) ✓ N= 668 (of 2,617) ✓ N0, ER+ ✓ Tamoxifen only ✓ Followup > 10 years	Distant metastasis at 10 years	3.21 (2.23–4.61)	✓ Predictor of distant relapse in ER+ node-negative. ✓ Predictor of likelihood of chemotherapy benefit in ER+ node positive ✓ Can be performed in fixed archival tissue.
		✓ Subset of prospective clinical trial (ATAC) (79) ✓ N = 1231 (of 5,216) ✓ N0 or N+, ER+ ✓ Tamoxifen or Anastrozole alone ✓ Follow-up > 10 years	Distant metastasis at 10 years	N0: 5.25 (2.84–9.73) N+: 3.47 (1.64–7.38)	
		✓ Subset of prospective clinical trial (SWOG-8814) (77) ✓ N = 367 (of 927) ✓ N+, ER+ ✓ Tamoxifen and CAF–tamoxifen ✓ Follow-up > 10 years	Disease-free survival at 5 yrs vs. tamoxifen only:	Low RS: 1.02 (0.54–1.93) CAF High RS: 0.59 (0.35–1.01) CAF

The Recurrence Score

The 21-gene Recurrence Score assay (RS, OncotypeDx™) was developed using unique methods and represents one of the most validated gene expression assays yet developed (78). Using 447 patients from three available datasets of mostly node-negative, hormone receptor-positive patients, and using a qRT-PCR-based approach that allows examination of limited numbers of genes from formalin-fixed tissue, they correlated gene expression with distant recurrence. From the 250 candidate genes selected based on prior knowledge, 16 cancer-related and 5 reference genes were chosen to be included in the RS assay. This assay can be performed on fixed tumor samples and does not require frozen samples.

The RS was validated in an independent dataset derived from samples collected in the National Surgical Adjuvant Breast and Bowel Project (NSABP) cooperative group B-14 trial, which examined the benefit of adjuvant tamoxifen in patients with hormone receptor-positive, lymph node-negative breast cancer (78). In those patients classified as low risk by the RS (RS <18) only 7% relapsed despite adjuvant tamoxifen, compared to high risk patients (RS > 31) among whom 31% relapsed. Currently, postmenopausal women with ER-positive tumors are often treated with aromatase inhibitors. The prognostic value of RS was further confirmed in the retrospective analysis of the Arimidex, Tamoxifen, Alone or in Combination (ATAC) Trial (79), which evaluated the efficacy and safety of 5 years of anastrozole, tamoxifen, or the combination of both treatments in over 4,000 postmenopausal women (80). The RS was significantly associated with distant metastasis for both node-positive and node-negative tumors, and provided significant independent prognostic information beyond Adjuvant! Online. In the node-negative tumors, the adjusted HR between high and low RS groups was 5.2 (95% CI 2.7–10.1), and the HR between intermediate and low RS groups was 2.5 (95% CI 1.3–4.5). In the node-positive tumors, the adjusted HR between high and low RS groups was 2.7 (95% CI 1.5–5.1) and the HR between intermediate and low RS groups was 1.8 (95% CI 1.0–3.2). The distant metastasis rate for RS low group was 17%, and whether chemotherapy can be spared or needed for patients with node positive/low RS group is a pressing clinical question being addressed in a prospective clinical trial, the RxPONDER trial, described in the following paragraphs.

The RS was further validated in homogeneous patient populations of node-negative or positive, hormone receptor-positive, and endocrine therapy treated women. For this reason, it was not clear if its prognostic ability reflects true prognosis, prediction of lack of tamoxifen benefit, or both. In a population-based case-control study, the RS provided independent prognostic information in untreated patients suggesting a pure prognostic role in addition to the previously suggested predictive one for endocrine sensitivity (81). Fortunately, in addition to predicting worse outcome despite endocrine therapy, a high RS also predicts benefit of chemotherapy (82,83). In SWOG 8814, 1,477 postmenopausal women with node-positive, hormone receptor-positive breast cancer were randomized to tamoxifen alone, cyclophosphamide, doxorubicin, plus fluorouracil (CAF) chemotherapy plus tamoxifen concurrently, or CAF chemotherapy followed by tamoxifen (77); the overall trial revealed a benefit of chemotherapy particularly given sequentially with tamoxifen. The RS was performed in 367 tumors from the sequential CAF-tamoxifen arm of the study, and revealed that in the node-positive population the RS was prognostic across nodal categories. Moreover, the benefit of the addition of CAF to tamoxifen was only seen in those with high RS (Fig. 29-4). The caveat to clinical application of this finding to node-positive breast cancer is that this is an older regimen, and even in the "good risk" low RS group, the long term disease-free survival was only 60%.

The Treatment (**Rx**) for **Po**sitive **N**ode, **E**ndocrine **R**esponsive Breast cancer (RxPONDER) Trial (SWOG S1007, ClinicalTrials.gov identifier NCT01272037) is a large Phase III clinical trial designed to answer the earlier question concerning a possible lack of chemotherapy benefit in low RS and node-positive patients. The study is expected to enroll approximately 4,000 patients with node-positive (1–3 nodes), hormone receptor positive, and HER2-negative tumors and have RS ≤ 25 (i.e., low to intermediate) by Oncotype Dx, with patients being randomized to receive hormonal therapy (tamoxifen citrate, anastrozole, letrozole, or exemestane) with or without chemotherapy. The study also aims to determine the optimal cut off for RS score within node-positive patients.

The OncotypeDX RS assay is recommended as a clinical decision-making tool for patients with hormone receptor-positive, node-negative breast cancer by the American Society of Clinical Oncology (84) and the 2011 St. Gallen International Expert Consensus (37). Meanwhile, the final results from the **T**rial **A**ssigning **I**ndividua**L**ized **O**ptions for Treatment (**Rx**) (TAILORx) is nearing reporting. In this large, multicenter, randomized study, more than 10,000 women diagnosed with hormone receptor-positive, HER2-negative, node-negative breast cancers were accrued. Briefly, patients with RS < 11 received standard hormonal therapy, while patients with RS > 25 received both chemotherapy and hormonal therapy (standard of care), and lastly, patients with RS 11–25 were randomized to receive hormonal therapy alone or chemotherapy followed by hormonal therapy. Results from this study will likely help to determine if patients with intermediate RS will have improved survival outcome by receiving both adjuvant chemotherapy and hormonal therapy rather than hormonal therapy alone.

Finally, the main reclassification effect of the RS when compared with classic biomarkers is from high risk to low risk (85); befitting this effect a recent report confirms that, at least in largely academic practices, the main clinical effect of the RS is to change from planned chemo endocrine therapy to endocrine therapy alone (86). This study was a prospective cohort study, so is without many of the biases of a retrospective study, and can be considered level II evidence of the utility of the RS. Based upon these data, the RS has been accepted by many U.S. insurers and oncologists.

Amsterdam 70-Gene Profile

The Amsterdam 70-gene prognostic profile (Agendia Mammaprint®) was created by supervised analysis of gene expression array data using frozen tumor samples from the Netherlands Cancer Institute. The initial 98 tumors included 78 from node-negative patients under the age of 55 at diagnosis, 34 of 78 (44%) had developed distant metastasis within 5 years and 44 of 78 (56%) had not developed any distant disease. By comparing the gene expression profiles of the tumors with and without subsequent distant metastasis, a signature 70-gene set was identified. Since this initial publication, there have been at least six external validation studies of the 70-gene prognostic profile. The first was a retrospective analysis of 295 patients from the Netherlands Cancer Institute who were under the age of 53 years at diagnosis with T1–2 tumors, either lymph node negative (151 patients) or lymph node positive (144 patients), heterogeneously treated with or without adjuvant therapy and followed for nearly 7 years (87). Of the 295 patients, 180 were classified as having a poor 70-gene signature and 115 as having a good 70-gene signature. The mean five-year survival for the poor 70-gene signature group of patients was 74% versus 97% for the good 70-gene signature patients. This signature was able to predict prognosis regardless of lymph node status and remained significant in multivariate analysis of first

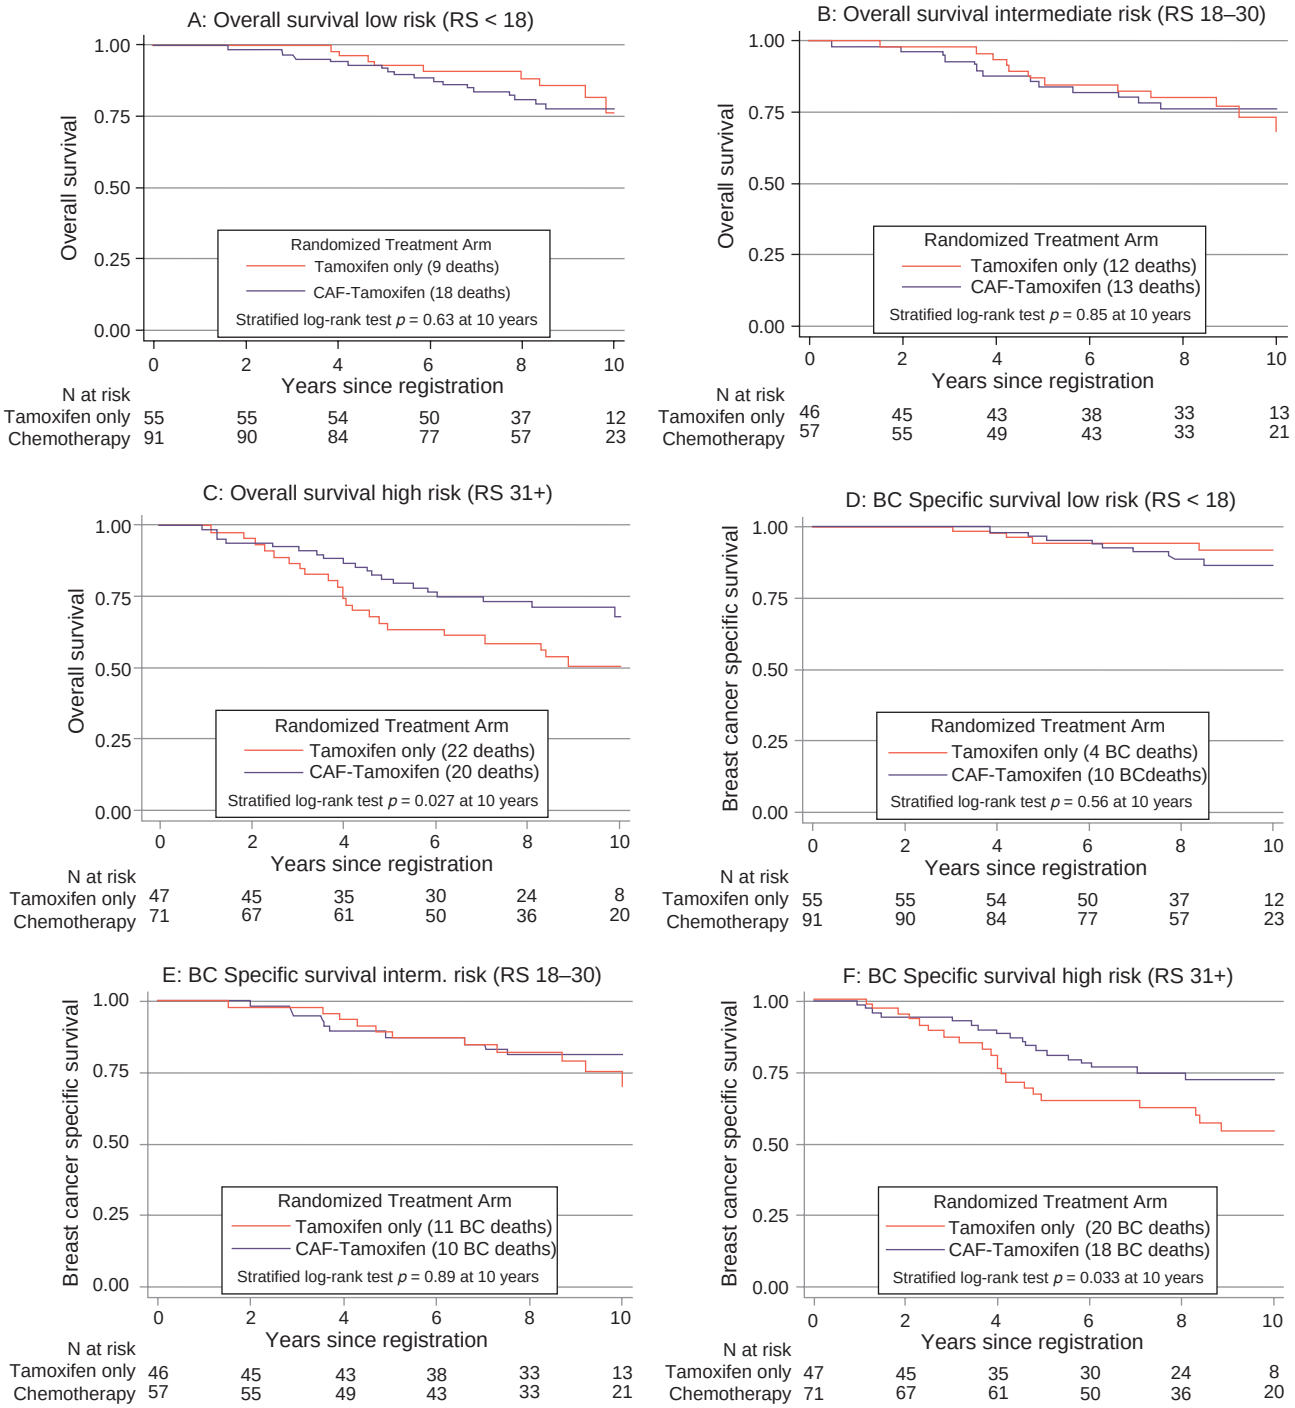

FIGURE 29-4 Secondary endpoints of overall survival by Recurrence Score™ (RS) groups **(A, B, and C)** and the exploratory endpoint of breast cancer specific survival by RS groups **(D, E, and F)**, all adjusted for number of positive nodes on SWOG 8814. (From Albain KS, Barlow WE, Shak S, et al. Prognostic and predictive value of the 21-gene recurrence score assay in postmenopausal women with node-positive, oestrogen-receptor-positive breast cancer on chemotherapy: a retrospective analysis of a randomised trial. *Lancet Oncol* 2010;11:55–65.)

event, as did the traditional prognostic criteria of tumor size, nodal involvement, and use of adjuvant chemotherapy.

A second, less heterogeneous, and truly independent retrospective validation study of the 70-gene prognostic signature was performed in 302 women treated at several European institutions (88). Adjusted for clinical risk as assessed by Adjuvant! Online, the 70-gene prognostic indicator effectively predicted time to distant metastasis (hazard ratio [HR] 2.13, 95% confidence intervals [CI] 1.19–3.82) and overall survival (HR 2.63, 95% CI 1.45–4.79); however, it did not significantly predict disease-free survival (HR 1.36, 95% CI 0.91–2.03) (Fig. 29-5) (88). In additional studies,

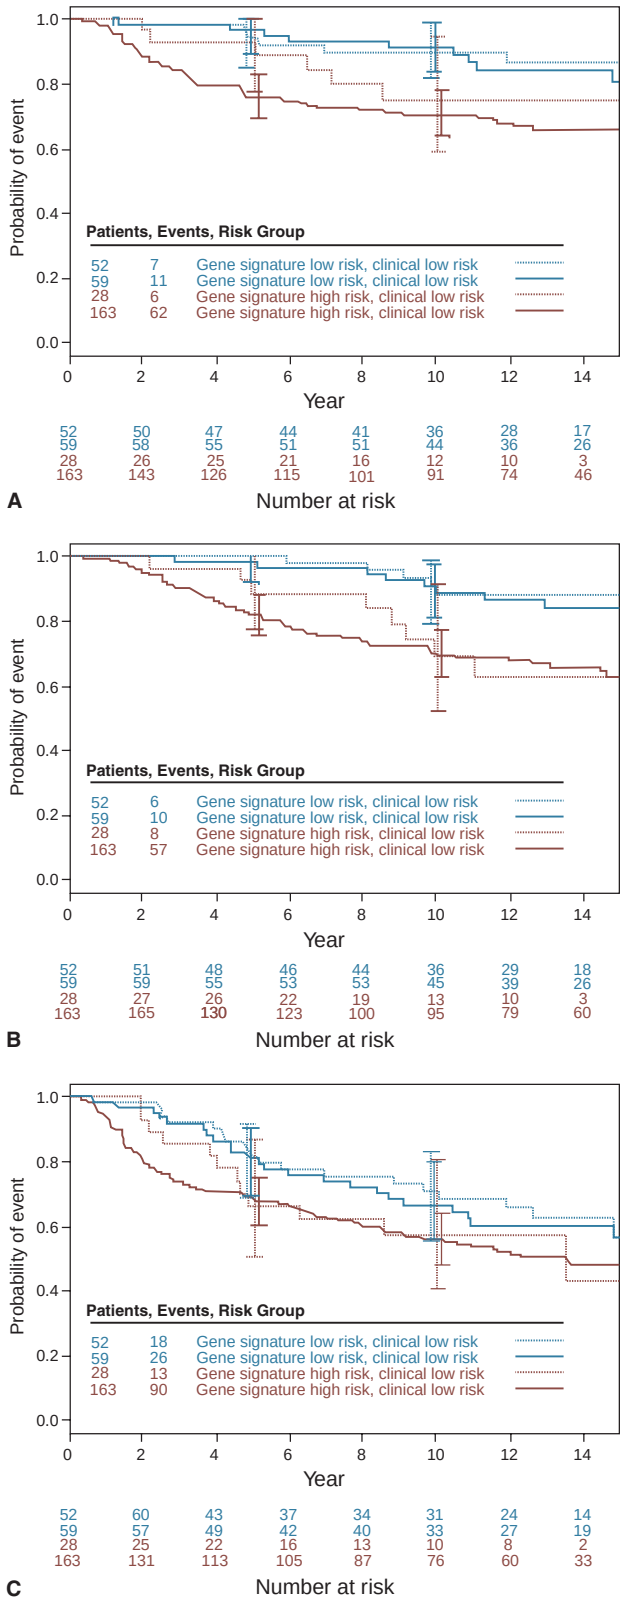

FIGURE 29-5 Outcome among 302 node-negative patients by 70-gene profile and clinical risk (with 95% confidence limits in bars). **(A)** Time to distant metastasis. **(B)** Overall survival. **(C)** Disease-free survival. (From Buyse M, Loi S, van't Veer L, et al. Validation and clinical utility of a 70-gene prognostic signature for women with node-negative breast cancer. *J Natl Cancer Inst* 2006;98(17):1183–1192.)

the 70-gene prognosis signature also predicted metastasis in patients (n = 148) aged 55–70 years, with node negative, T1–2 tumors diagnosed from 1984–1996 (89). Adjusted for the clinical risk features, the signature was again a strong prognostic factor for distant metastasis, especially for the first five years (HR 14.4, 95% CI 1.7–122). The performance of the 70-gene signature was also evaluated in 241 patients with node-positive (1–3 nodes), T1–3 breast tumors diagnosed between 1994 and 2001 at several European institutes (90). Ninety patients (44%) were classified as having good prognosis by the 70-gene signature, and again, the 70-gene signature was significantly prognostic in predicting breast cancer-specific survival beyond the standard clinical variables (HR 7.17, 95% CI 1.81–28.43). There is a strong time dependence of the 70-gene profile, befitting the way it was developed, as it far better predicts early (before 5 years) than later relapse (91). Notably, this profile is also more useful in ER-positive versus ER-negative disease; among ER-positive tumors 50% had low profiles, whereas among ER-negative only 6% showed the favorable profile. These validation studies provided the evidence needed for the development of the MINDACT trial, which is described in the following paragraphs.

One previous obstacle to large-scale use of the 70-gene signature has been the need for a significant amount of frozen tissue, which was a major impediment for use in the United States (92). The Mammaprint assay is now also available for use on FFPE tissues, although there is no information on the concordance with the microarray data from frozen tissue samples. Level I evidence of its clinical utility awaits reporting of the MINDACT Trial (Microarray in Node-Negative and 1 to 3 node positive Disease May Avoid Chemotherapy, Clinical Trials.gov identifier NCT00433589), in which 6,600 women with node-negative (and also node-positive with 1 to 3 nodes affected) breast cancer underwent clinical risk assessment via Adjuvant! Online and the 70-gene prognostic signature, and when these two tests disagreed, patients were randomized to be treated according to the risk assessment by Adjuvant! Online or by 70-gene signature. The two prediction methods will be compared in this randomized subset (93). Based on its development and prognostic validation, the Mammaprint® assay was FDA-approved for use in prognostication in small- to intermediate-sized, node-negative breast cancers in 2007.

Breast Cancer Index

The Breast Cancer Index (BCI) is a prognostic assay for the risk of developing distant metastasis in patients with ER-positive, node-negative tumors. This assay is a combination of a previously identified 2-gene signature (HOX13:IL17BR) and a five-gene tumor molecular grade index ([MGI] *BUB1B, CENPA, NEK2, RACGAP1*, and *RRM2*) (94). The development of the 2-gene signature for outcome predictions started from 22,000-gene arrays performed in 60 node-positive women with hormone receptor-positive breast cancer treated with tamoxifen and followed for at least 5 years (95). HOXB13 was associated with recurrence, while IL17BR was associated with remaining disease-free, making the ratio even more strongly associated with recurrence with an adjusted odds ratio of approximately 7. The MGI was built upon on 39 genes with elevated expression in high-grade tumors (96), and 5 genes functionally involved to different cell cycle phases were eventually picked. Using supervised principal component analysis, an MGI score was calculated based on the expression patterns of these five genes on a population-based series of 236 heterogeneously treated patients (94). Using another similar cohort of 159 patients,

the MGI score was significantly associated with tumor grade and patient outcome. In comparison to the Genomic Grade Index (GGI) (described in the following), both the MGI (AUC = 0.90) and GGI (AUC = 0.92) assays performed equally well to discriminate grade 1 and grade 3 tumors. The GGI is a microarray-based assay based on 97 differentially expressed genes from grade 1 versus grade 3 breast tumors (97). In a retrospective case-control study of 239 ER positive tumors, Ma and colleagues evaluated the individual prognostic value of MGI and the 2-gene HOXB13:IL17BR measured by qPCR TaqMan assay using heterogeneously treated tumors at one institution from 1991 to 1999 (94). The MGI discriminated the grade 1 and grade 3 tumors with 86% accuracy and was found to complement HOXB13:IL17BR in predicting distant metastasis. Patients were classified into three risk groups based upon two cut points (MGI = 0 and HOXB13:IL17BR = 0.06): (a) **low** if low for MGI and low or high HOXB13:IL17BR, (b) **intermediate** if high MGI and low HOXB13:IL17BR, and (c) **high** if high for both MGI and HOXB13:IL17BR. Most notably, when compared to the low risk group, the high risk patients were eight times more likely to develop distant metastasis among the 84 patients with ER positive tumors treated with adjuvant tamoxifen. The prognostic value of this assay for distant recurrence on ER positive tumors was then confirmed using a subset of 588 patients from the randomized Stockholm trial (98).

Subsequently, the Breast Cancer Index (BCI) was developed to provide individual risk assessment. The BCI is a continuous score combining MGI and HOXB13:IL17B using a multivariable Cox model with cubic spline function fit on the 314 tamoxifen-treated patients from the Stockholm trial (98). Tumors were categorized into three risk groups as low risk if BCI < 5, intermediate if 5 ≤ BCI < 6.4, and high risk if BCI ≥ 6.4. The BCI risk-classifier identified patients with significantly different distant metastasis rates at 10-years from the untreated arm from the Stockholm trial (98), with an absolute difference of 20% between the low high-risk groups.

The performance of the BCI assay in predicting risk of distant recurrence beyond standard clinical and pathological variables was further evaluated on the HR-positive and node-negative tumors in the ATAC trial (99). The primary planned endpoints for the BCI were marginally significant (p = .05). Therefore, a new BCI was developed using a different multivariable Cox linear model trained on the untreated patients (n = 274) from the Stockholm trial and re-evaluated on the ATAC trial. Based on the new BCI-linear model, 58% of patients (n = 390) were classified as low, 25% as intermediate (n = 166), and 17% as high (n = 109). The 10-year adjusted HR between high risk and low risk was 4.86 (95% CI 2.58–9.17). Both BCI and RS provided independent prognostic information to predict early recurrence (0–5 years). Although RS did not retain significant prognostic value for late recurrence (>5 years) while the BCI did, the RS algorithm was fixed but the BCI had been modified after the primary analyses on the ATAC trial. Therefore, strictly speaking this cannot be considered a true validation study of the BCI assay. This signature can be performed in FFPE tissue, which makes it of considerable clinical interest, however, given the varying methodologies and cut points in the studies to date, this combinatorial assay of MGI and HOXB13:IL17BR remains intriguing but further implementation awaits ongoing validation studies.

Intrinsic Subtypes and Risk of Recurrence

Using a multivariable Cox Model and a Ridge regression fit, the ROR predictor from the PAM50 assay (29) was trained on a cohort of patients with node-negative tumors who did not receive adjuvant systemic therapy (87). A ROR score can be assigned to each patient sample using (a) correlation to subtypes only (ROR-S) (29), (b) subtype correlation along with tumor size weighted model (ROR-T, previously known as ROR-C) (29,33) and (c) subtype correlation along with proliferation signature and tumor size (ROR-PT) (33). The prognostic value of ROR models were first validated using a heterogeneously treated cohort of 279 patients with old FFPE archival materials and further confirmed on 786 patients with ER-positive tumors homogeneously treated with tamoxifen only (33). Among the node-positive tumors of the tamoxifen-only treated cohort, the ROR-T and ROR-S scores provided the best prognostic models for both relapse free survival and breast cancer specific survival beyond the standard clinical pathological variables and Adjuvant! Online. The 10-year relapse rates for the low-risk groups were between 15% and 20% among these node positive tumors. On the other hand, among the 197 node-negative tumors, among the 31 patients who were classified as low risk, there was only one patient who developed relapse and died of breast cancer over the 15 years of follow-up. The intermediate (n = 145) and high (n = 21) risk groups were significantly associated with worse outcome when compared to the low-risk group. Therefore, similar to the RS and the 70-gene prognostic signatures, the PAM50 ROR score is able to identify a very low-risk group among women with ER positive, node-negative tumors who were treated with adjuvant tamoxifen only.

Both RS and PAM50 ROR assays are optimized to work on FFPE assays. The next logical clinical interest was to perform a direct comparison between the PAM50 ROR scores and RS for prognostication on the same cohort of patients. The translational component of the ATAC trial described earlier with 10-year follow up again proved itself to be an important resource in assessing the performance of PAM50 ROR scores in predicting the risk of distant relapse (32). A total of 940 tumors had been evaluated with both genomic assays (RS and PAM50) as well as the immunohistochemical-based classifier IHC4 (including ER, PgR, Ki-67 and HER2). The PAM50 ROR-defined risk groups were significantly associated with the 10-year distant recurrence in all pre-planned analyses on the whole population, node-negative tumors, and node-positive tumors. Among the 683 node-negative tumors, the addition of ROR provided significant independent prognostic information to the RS (change in likelihood ratio statistics = 8.4), whereas the RS did not provide significant additional prognostic information to the ROR (change in likelihood ratio test statistics = 1.6). Nevertheless, both assays classified a comparable number of patients as low risk, 428 as ROR-low and 434 as RS-low. Even more interestingly, the 10-year distant relapse survival estimates were almost equivalent between these low risk groups of patients (32). Therefore, both PAM50 ROR and RS performed well in identifying patients with ER-positive tumors who may just need endocrine therapy. The prognostic value of PAM50 assay to predict risk of distance recurrence in postmenopausal women with HR-positive tumors who received endocrine therapy has also been recently validated on 1,400 patients from the Austrian Breast & Colorectal Cancer Study Group 8 (ABCSG8) trial (34).

EndoPredict

Another new multi-gene qPCR-based signature known as EndoPredict (EP) had been developed to predict the risk of recurrence within ER-positive, HER2-negative tumors (100). This assay is based on the expression of eight genes, primarily representing proliferation and hormone receptor-related signaling, developed to work on FFPE materials. Using a combined cohort of 1,702 ER-positive, HER2-negative tumors

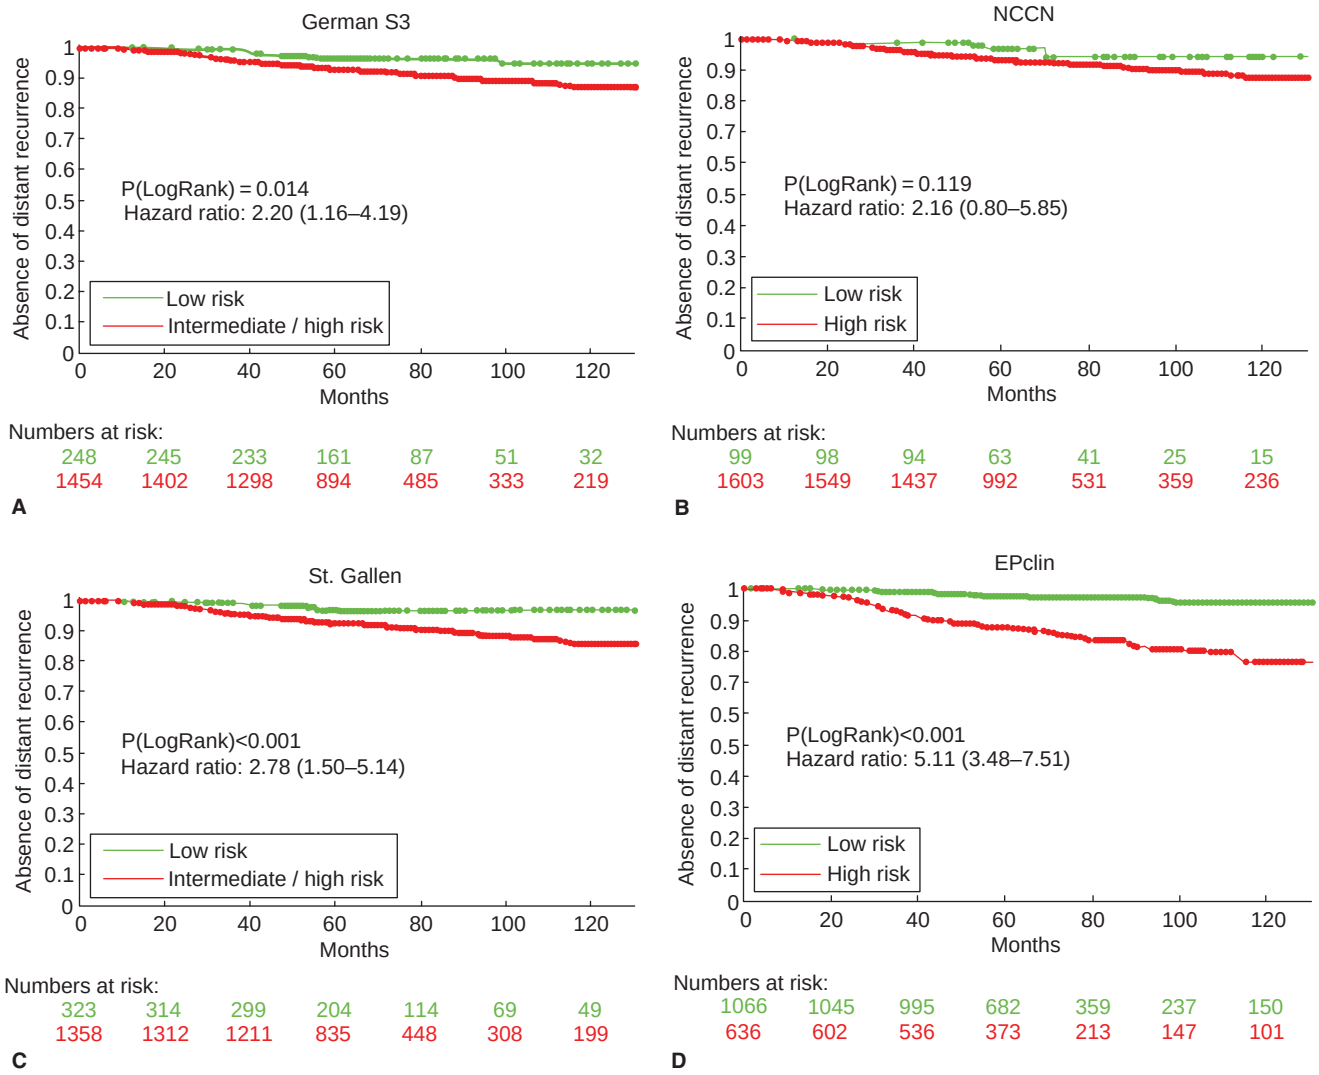

FIGURE 29-6 Kaplan-Meier plot of distant metastasis-free survival by **(A)** German S3, **(B)** National Comprehensive Cancer Center Network (NCCN), **(C)** St. Gallen guidelines, and **(D)** EPClin risk groups. Ninety-five percent confidence intervals (CI) of hazard ratios (HR) are indicated. (From Dubsky P, Filipits M, Jakesz R, et al. EndoPredict improves the prognostic classification derived from common clinical guidelines in ER-positive, HER2-negative early breast cancer. *Ann Oncol* 2013;24(3):640–647.)

treated with endocrine therapy only from two large Phase III trials (ABCSG6 and ABCSG8), ER and the EP assay improved prognostication. Using the clinical guidelines, the 10-year absolute risk differences between the high- and low-risk group were from 6.9% to 11.2%, whereas there was 18.7% difference according to EPClin classification (101) (Fig. 29-6). Of note, the EPClin prognostic signature includes EP, tumor size, and number of nodes in the algorithm. Clearly additional validation is needed; however, it is clear that multiple different gene expression profiling assays are being developed for ER-positive breast cancer patients, most of which are proving valuable information that is not provided by the standard clinical variables.

Other Prognostic Signatures

Of note, the clinical utility of all of the aforementioned prognostic signatures are shown mostly in ER-positive/HER2-negative breast cancers. There are still no similar signatures available for hormone receptor negative or HER2+ positive tumors (102). There have been a very large number of prognostic signatures identified and in development for breast cancer patients and all cannot be discussed in detail here, however, many are related to proliferation. For example, the Genomic Grade Index includes 97 differentially expressed genes between Grade 1 and Grade 3 tumors (97). This histological grade predictor was subsequently validated to be strongly prognostic among patients with grade 2 tumors (43). Another biologically interesting signature is the "wound response" signature that is derived from a set of genes, termed core serum response (CSR) genes, which changed in expression when cultured fibroblasts were activated with serum. Evaluation of the CSR genes suggested that they represented important processes in wound healing like matrix remodeling, cell motility, and angiogenesis, all of which are predicted to play a role in cancer invasion and metastasis (103). Subsequent evaluation of the CSR genes in the same 295-patient dataset used to validate the

Amsterdam 70-gene profile suggested that an activated wound response signature was associated with decreased survival and increased probability of distant metastasis in both univariate and multivariate analyses (104). Lastly, there are literally more than 100 described prognostic signatures for breast cancer, which are too many to detail here. This large number of signatures does suggest that there are common and robust patterns of gene expression that are of biological and clinical value.

PREDICTIVE ARRAY-BASED PROFILES

An area of great interest is the potential of gene expression arrays to predict response, or non-response, to particular regimens, with the hope for individualizing therapy by examining the tumor at the time of diagnosis. A number of predictive genomic signatures that have been, or are being, developed will be summarized here and in Table 29-1. Many of these are often mindful of a particular indication, such as tamoxifen resistance, so are mentioned with predictive signatures, although in many cases these were developed as prognostic as well as predictive profiles.

Prediction of Endocrine Therapy Sensitivity

Because hormone receptor-positive breast cancer is virtually always treated with adjuvant endocrine therapy, identifying how much of an impact upon outcome is prognostic versus predictive can be difficult. The Recurrence Score is both prognostic in the untreated cohort and predictive of tamoxifen benefit in NSABP B-14 (105). The PAM50 Luminal subtypes were also predictive of adjuvant tamoxifen benefit in the NCIC CTG.12 trial, which is a randomized study examining tamoxifen versus placebo in premenopausal women treated with adjuvant chemotherapy (31). Other predictive profiles for endocrine therapy include the 81-gene tamoxifen resistance profile (106), the BCI, and the Sensitivity to Endocrine Therapy (SET) index (107). The SET index was based on the expression of 165 genes that are ER-related and was significantly associated with relapse in patients treated with tamoxifen alone (HR 0.70, 95% CI, 0.56–0.88) and chemotherapy plus endocrine therapy (HR 0.19, 95% CI 0.05–0.69).

An assumption is that predictive profiles developed on tamoxifen will equally predict response to aromatase inhibition. Endocrine sensitivity at this time appears to be a general phenomenon. Comparison of the aromatase inhibitor and tamoxifen arms in ATAC suggested that both RS and PAM50 ROR performed equally well to predict risk of distant recurrence, but could not be used to choose one endocrine approach over another (32,79).

Patients with node-negative and HR+ tumors have good response to endocrine therapy, and hence, typically long survival times. Given extended adjuvant endocrine therapy options, it is important to identify patients who may be associated with increased risk to develop late recurrences, typically defined as those occurring beyond 5 years. Studies using both tamoxifen alone and tamoxifen followed by AI have found that patients treated with extended endocrine therapy for 10 years had better survival than those treated with 5-years of tamoxifen alone. Both the BCI and EPClin score were recently reported to predict late recurrences. In the TransATAC study, the BCI provided additional prognostic information to predict late distant recurrence beyond the standard clinical variables (99), while IHC4 and Recurrence Score did not. Similarly, in a study consisting of 1,702 tumors from patients treated with adjuvant endocrine therapy on the ABCSG6 and ABCSG8 clinical trials, the EPClin score provided significant independent prognostic information for predicting late recurrences. Within the low-risk subgroup of patients, 98% of the patients remained free of distant metastasis (101). In a retrospective study of 222 patients with node negative tumors treated with adjuvant tamoxifen only, the PAM50 ROR-PT score was significantly correlated with 10-year survival, outperforming the Adjuvant! Online and standard clinical variables. The ROR-PT identified a subgroup of patients in whom 5 years of tamoxifen may be adequate treatment given the extreme low rate of late relapses (<2%) in both the 0–5 and 5–10 year window (33). With further validation, it is likely that the clinical utility of extended endocrine therapy could be weighted using EPClin, BCI, or ROR score assignments.

Neoadjuvant endocrine/chemotherapy has been endorsed as an effective research approach to identify or validate biomarkers to predict pathological complete response. In the means of clinical utility, neoadjuvant endocrine therapy has been shown to improve surgical outcomes for postmenopausal women with ER-positive, stage 2 and 3 breast cancer (108). A Preoperative Endocrine Prognostic Index (PEPI) for risk of relapse has been developed on 228 tumors from postmenopausal women with ER+ stage 2 and 3 breast cancers in the P024 neoadjuvant endocrine therapy trial, a study that compared letrozole and tamoxifen for 4 months before surgery (109). The PEPI score integrates the posttreatment ER status, Ki-67 proliferation index, histological grade, pathological tumor size, and node status to predict relapse. Patients with a PEPI score of 0 and low pathological stage (stage 1 or 0) at surgery after neoadjuvant endocrine therapy had a low rate of relapse, and those with a high PEPI score, had a high rate of relapse. Although PEPI score is not a genomic assay, it is a similar 'multi-analyte' tool because it includes multiple variables to predict outcomes. In the ACOSOG Z1031 neoadjuvant aromatase inhibitor trial, there was a significant higher rate of PEPI score 0 in Luminal A versus Luminal B tumors. This again shows the inter-relatedness of multiple genomic and proteomic signatures.

Prediction of Chemotherapy Sensitivity

Chemotherapy efficacy differs according to tumor subtype, in particular between ER-negative and ER-positive subtypes (75), so multi-gene predictors must provide information beyond the available clinical assays. The most clearly developed predictive profile for chemotherapy sensitivity is the Recurrence Score (RS), which is also the only profile tested in the kind of prospectively annotated large datasets that provide reliable evidence of efficacy. In a subset of over 600 tumors from ER-positive node-negative patients in NSABP B-20, the RS predicted sensitivity to methotrexate plus fluorouracil with or without cyclophosphamide (MF/CMF) added to tamoxifen in hormone receptor-positive, node-negative patients (83). Another subset from the SWOG 8814 study examined 367 tumors, and found that the benefit of CAF added to tamoxifen in hormone receptor-positive node-positive disease was primarily among high RS (110). These studies suggest that the RS predicts general sensitivity, or resistance, to chemotherapy, but cannot help to select one regimen over another. The clinical utility of the RS in adding chemotherapy to endocrine therapy in intermediate (11–25) RS scores is being prospectively examined in the TAILORx and RxPONDER trials; however, recognizing the lack of regimen-specificity in the studies to date, the choice of chemotherapy is left to the discretion of the treating physician.

In a recent report, Hatzis et al. reported a chemosensitive prediction algorithm for pathologic response (pathologic complete response or residual burden index I) for patients with HER2-negative tumors treated with sequential neoadjuvant taxane and anthracycline-based regimens (followed

by endocrine therapy if ER-positive), which was developed on a discovery cohort of 310 tumors and tested on a validation cohort of 198 tumors (111). The predictive signature was a combination of probe sets for ER-positive and negative tumors. In the validation cohort, the chemopredictive signature had a positive predictive value (PPV) of 56% and negative predictive value (NPV) of 73% for pathologic complete response; when Luminal B and Basal-like breast cancers were grouped, the PPV was 40% and NPV 78%. The predictive value of intrinsic subtype for neoadjuvant chemotherapy benefit has been demonstrated in multiple datasets, with Luminal A tumors rarely achieving a pathological complete response (pCR), Luminal B tumors showing approximately 10% to 15% pCR rate, and Basal-like and HER2-E subtypes showing high pCR rates (up to 35%) (29,47,59). Chemotherapy specificity was tested on 476 tumors from the NCIC MA.5 trial of premenopausal women with node-positive breast cancers, who were randomized to anthracycline (CEF [cyclophosphamide-epirubicin-fluorouracil]) versus non-anthracyline (CMF [cyclophosphamide-methotrexate-fluorouracil]) chemotherapy (30). The PAM50 assay, particularly the HER2-E subtype, demonstrated the greatest benefit of CEF over CMF with an absolute 5-year RFS and OS difference exceeding 20%, whereas there was a less than 2% difference for the non-HER2-E tumors (i.e., all other subtypes including Basal-like). While these results might be intriguing, additional and larger studies are needed to confirm this finding and the predictive independence of intrinsic subtype over high quality hormone receptor, HER2, and grade assessments in predicting pathologic response to chemotherapy.

The area of greatest interest is in the development of chemotherapy regimen- or agent-specific predictive signatures. There have been several different predictive profiles for docetaxel sensitivity; an 85-gene signature (with cellular redox genes overrepresented) that was approximately 80% accurate in predicting clinical response to the single agent in the neoadjuvant setting (112), a similarly derived 92-gene signature that was nearly 90% accurate (113), and a 50-gene signature derived from cell lines that was 92% accurate when applied to a small neoadjuvant dataset (114). A qRT-PCR-based method for the 92-gene signature plus other candidate genes allowed testing in fixed tissue and found 14 genes predictive of clinical complete response to neoadjuvant docetaxel; however, the false discovery rate (likelihood of finding these genes by chance) was high (115). In a recent report, Martin et al. demonstrated that an 11-gene proliferation score might potentially be useful to identify those with benefit from weekly paclitaxel. In this study, using 820 tumors from the GEICAM/9906 phase III trial that compared adjuvant FEC to FEC followed by weekly paclitaxel (FEC-P), a benefit from paclitaxel was only observed in a group of patients with low PAM50 proliferation score with an unadjusted HR of 0.23 (interaction test $p = .006$). In an independent dataset of tumors from 222 metastatic patients treated on CALGB 9342 and 9840 clinical trials studying weekly versus every-3-week paclitaxel, the low proliferation score had numerically higher benefit from the weekly regimen but this interaction did not reach significance (116). Most of these studies are limited by size, heterogeneity in tumor types, lack of independent validation, and in some cases by endpoints of unclear clinical significance.

A 74-gene predictor of an anthracycline and taxane-based regimen was developed from permutation modeling of a neoadjuvant dataset treated with paclitaxel, fluorouracil, doxorubicin, and cyclophosphamide (24). The investigators developed a 30-probe set predictor that was applied to an independent set of 51 patients. Interestingly, the best predictive model included both genomic and clinical data (117). The same group that identified the 92-gene signature also examined a cohort of patients treated neoadjuvantly with doxorubicin plus cyclophosphamide (AC), and identified 253 genes associated with clinical response (118). As detailed earlier, there are multiple prior and ongoing efforts to develop gene expression signatures of chemotherapy response. It should be noted that most rely upon the neoadjuvant setting for training and discovery, which assumes that the gene sets related to response will also relate to the development of distant disease. Given the tight association of pathologic response to outcome, this may be a reasonable assumption; however, it is unproven. In addition, in assays used for decision-making regarding the use and selection of chemotherapeutic agents, even 10% to 20% inaccuracy may be unacceptable as even a modest benefit of a regimen may be valuable.

PITFALLS AND LIMITATIONS OF APPLIED ARRAY TECHNOLOGIES

The most important pitfall of gene expression based prognostic and predictive profiles has already been highlighted—namely that these are mostly works in progress. Even the most validated assays have been studied in relatively small datasets or as subsets of larger clinical trials. None have met level I criteria for use in clinical decision-making, although both the Recurrence Score (TAILORx and RxPONDER) and the Amsterdam 70-gene prognostic profile (MINDACT) have completed large adjuvant trials and are awaiting results that could be of Level I evidence. Of concern is that the field of breast cancer therapy is rapidly changing, and evidence of prognosis or efficacy of a particular approach can become obsolete during the performance of prospective validation studies. For example, it may take 2 to 3 more years to get the final results of the MINDACT trial that is prospectively testing the value of the 70-gene assay in determining benefit of chemotherapy, and so the difficult question is do we wait until these trial(s) are completed to begin everyday use of these assays? Approaches that will make development and validation of gene expression signatures more nimble are crucial, and the treating oncologist must ask whether retrospective validation is enough evidence to support current clinical use.

Other caveats for genomic studies include the need for exceptional rigor, as always, in the tumor collection, processing, data management, and statistical methods used to analyze gene expression arrays. High dimensional multi-analyte data (like microarrays) are prone to overfitting due to the very high number of genes analyzed, high false negative rates due to the sheer volume and hypothesis-generating nature of arrays, and bias introduced by non-independence of genes from one another and from clinical variables (119). Gene expression pattern reproducibility can also be an issue (120), as can data processing variability and tumor enrichment (53). In fact, one interpretation of the "normal-like" intrinsic subtype is that these are samples with an excess of stroma, and thus these assays may be more sensitive to tumor cell content versus other biomarker methods like IHC. Another methodologic issue is the generalizability and robustness of profiles developed in a certain population when applied to a different population. The importance of the studied population is also highlighted by the Recurrence Score studies demonstrating that while the prognostic implication of the Recurrence Score remains across tumor sizes and nodal categories, smaller tumors have lower risk even if the Recurrence Score is high (81), while node-positive

breast cancer carries a poor prognosis even if the profile is low (110). In other words, biology is not entirely destiny, which again suggests that a combination of genomic and classic biomarker assays is best.

FUTURE DIRECTIONS

The ongoing MINDACT, and the RxPONDER and TAILORx trials could provide level I evidence of the clinical utility of the 70-gene prognosticator and the Recurrence Score assays, respectively; however, even these large scale genomic studies have not addressed all relevant questions. For example, no prognostic profile has yet been developed for hormone receptor-negative breast cancer, and because these tumors also have a heterogeneous prognosis, this would be a clinically valuable direction for researchers to take. Another example might be pharmacogenomics assays aimed at predicting effectiveness or toxicity of drugs based upon inherited variability in drug activation or metabolism, e.g. by cytochrome p450 enzymes (121). Assays for clinically relevant individual cytochrome p450 genes already exist, and investigators and diagnostic companies are developing drug metabolizing enzyme gene arrays that detect genetic variations in multiple genes. These single nucleotide polymorphism (SNP) chips, which detect actual gene variants (rather than gene expression variation), hold great promise, not only for individualizing medicine choices, but also for detecting multiple gene interactions for the risk of breast cancer. As stated before, the future of prognostication and prediction lies in the integration of classic biomarkers like ER status and stage, with genomic biomarkers of the tumor, and with genetic biomarkers of the host, which is occurring and resulting in more accurate outcome predictions for breast cancer patients.

Lastly, with the advent of Massively Parallel Sequencing, it is likely that many of the above mentioned assays will change technologies, moving from microarray-based to sequencing-based. For example, gene expression profiling can now be accomplished using the sequencing and counting of mRNA molecules, which is called mRNA-seq; this approach is more quantitative, more sensitive, and also provides sequence information such that alternative splicing and single nucleotide variants can be simultaneously detected. Thus, as is typically the case, the technology may change, but the basic biomarker that is a gene expression pattern will remain. We are in the age of personalized medicine, and gene expression-based assays helped to bring us here and they are here to stay.

CHAPTER 30

Bone Marrow Micrometastases and Circulating Tumor Cells

Costanza Paoletti, Jeffrey B. Smerage, and Daniel F. Hayes

CHAPTER CONTENTS

INTRODUCTION

The development of distant metastases is the result of the spread of tumor cells through the lymphatic and vascular compartments. In breast cancer, the most important example of this process is the identification of tumor cells in the axillary lymph nodes. Therefore, lymph node staging continues to be one of the most important prognostic variables in early-stage breast cancer. However, axillary staging is far from definitive. Women with newly diagnosed breast cancer who have uninvolved axillary lymph nodes still have a 20% to 30% chance of recurrence. Conversely, even in the absence of adjuvant systemic therapy, roughly half of women with node positive cancer will not have recurrence of their cancer (1). This observation suggests that micrometastatic process might be independent of lymphatic involvement. Therefore, development of new methods to detect and characterize micrometastatic disease might improve the ability to make clinical treatment decisions.

Detection of micrometastases in visceral organs, such as liver or lung, is fraught with considerable logistical and safety concerns. In this regard, bone marrow and blood have been the most commonly studied non-lymphatic sites of micrometastases. The finding of micrometastases in bone marrow or blood is designated as "minimal detectable disease" (MDD). When detected in the bone marrow, MDD has also been called "disseminated tumor cells" (DTCs), while the term "circulating tumor cells" (CTCs) has been used to refer to micrometastases in the blood.

CLINICAL VALUE OF DETECTION OF MICROMETASTASES

Detection, enumeration, and characterization of MDD might have several clinical uses relative to breast cancer. However, to date, few if any practice guidelines have recommended either screening for or monitoring DTCs or CTCs in patients at risk for or affected by breast cancer (2,3).

Why are these guidelines so conservative? There are several criteria that must be met before any tumor biomarker test, including those for MDD, are introduced into clinical care (4–6). First, the specific use must be defined—risk categorization or screening of an unaffected person, or prognosis and/or prediction of benefit from therapy in the adjuvant or metastatic settings, or monitoring for occult metastases or for response or progression in patients who are either free of disease or are being treated for metastatic breast cancer. Second, the assay must have been shown to have analytical validity, which requires evidence of accuracy, reliability, and reproducibility (7). Finally, the biomarker test must have clinical utility. Clinical utility is defined as demonstration that use of the assay to direct patient care improves a patient's outcome when compared to care of the patient without knowledge of the assay results (5,6). High levels of evidence are required to established clinical utility. It is important to distinguish "clinical utility" from "clinical validity." The latter implies that the biomarker test has been shown to separate two subgroups within a population according to outcome or biological characteristics, but the

assay may or may not be useful to care for patients. Taking these considerations in mind, the remainder of this chapter will review methods of detection of MDD and their analytical validity, and the potential clinical uses and evidence for clinical utility of tests for MDD.

METHODS OF DETECTION OF MINIMAL DETECTABLE DISEASE

The greatest barrier in detecting MDD is the accurate separation and identification of cancer cells from other cells that are found within the hematopoietic environment. In this regard, over the past two decades, several methods have been developed to enrich these cells from the bone marrow or hematopoietic environment. These methods have been based on either physical or biological properties, or both, that distinguish MDD from normal hematopoietic cells. Moreover, once the capture step has been concluded, further characterization is required to confirm that the presumed isolated cells are indeed at least epithelial, if not malignant. The most commonly used strategy is to demonstrate that the captured cells are epithelial in origin is by monitoring expression of cytoplasmic cytokeratin (CK) (8). Additional molecular evaluation can be conducted, investigating other established or putative biomarkers that might provide further biological or clinical insight.

Methods to Detect and Characterize DTCs in Bone Marrow

Detection and characterization of DTCs in marrow has involved an initial separation of nucleated cells through density centrifugation, followed by immunostaining for cytokeratin versus hematologic markers. The latter is usually performed on smears on glass slides. Further characterization for other markers of interest, such as tumor-associated antigens, can be performed using immunostaining, reverse transcriptase polymerase chain reaction (RT-PCR), or other molecular techniques (9–16). Standardized guidelines have been developed to reconcile different approaches of DTC quantification (17,18).

Methods to Isolate and Detect CTCs

Although malignant cells were identified in human blood over 150 years ago (19), the technology to capture and characterize CTCs with high analytical validity has only been available over the last decade. Over 40 different devices have been reported to isolate and characterize CTCs from whole blood (20). These are based on exploiting the differences between epithelial CTCs and normal hematopoietic cells in size, weight, electric charge, or flow characteristics or expression of epithelial or cancer-specific markers. Table 30-1 provides a description of these devices as of the publication of this chapter. A more detailed description of these devices is available in a recent review (20).

Currently, the most commonly used strategy to capture CTCs involves coating a solid phase matrix of some sort (magnetic or plastic beads, microposts, fluidic channels, etc.) with an antibody directed against a surface-expressed epithelial marker, usually the epithelial cellular adhesion molecule (EpCAM) (21–23). The only FDA-approved, commercially available assay based on this strategy has been designated CellSearch® (Veridex, LLC; Raritan, NJ), and has been shown in several studies to be associated with worse prognosis in breast as well as colorectal and prostate cancer (24–26).

However, this strategy is not perfect. EpCAM is only expressed by approximately 80% of all breast cancers, and the intra-patient expression of EpCAM by CTCs can be highly variable (27,28). In this regard, EpCAM may be lost by cancer cells that are undergoing epithelial to mesenchymal transformation (EMT), a recently recognized process that may be a fundamental property of the metastatic phenotype (29). Nonetheless, of all the markers studied to date, this strategy is the most clinically practical method to capture epithelial CTCs, and, although not ideal, assays based on this strategy are associated with poor prognosis and can be used to monitor patients with metastatic breast cancer.

After the CTCs have been captured, they must be further characterized to prove that they are non-hematopoietic cells. In the case of most solid cancers, this additional characterization involves demonstration that they are of epithelial origin. Again, the most common strategy has been staining with 4, 6-diamidino-2-phenylindole (DAPI) to demonstrate

the presence of nuclei, and then with fluoresceinated antibodies directed toward CK and CD45 to demonstrate that they are epithelial and not hematopoietic, respectively.

Over 30 other strategies to capture and characterize CTCs have been reported (20). These include use of membrane micropore filters or other devices that separate larger and more rigid epithelial cancer cells from smaller and more flexible hematopoietic cells (30). CTC have also been separated based on microfluidics techniques, which may also incorporate anti-EpCAM capture or not (31). An alternative method has involved smearing whole blood onto a specially charged slide and then identifying the epithelial cells (presumably CTC) by immunofluorescent staining (32,33). Another approach is based on detection of specific proteins secreted only by viable cells using an adaptation of enzyme linked immunoassay technique (Epithelial ImmunoSPOT (EPISPOT) (34). This strategy permits generation of a "protein fingerprint" at the individual cell level.

CTCs can also be presumptively identified by determination of expression of epithelial or cancer-associated genes using RT-PCR (35–37). Quantitative real-time RT-PCR (qRT-PCR) may increase the specificity of this approach by differentiating mRNA derived from non-tumor and tumor cells. This strategy may be used with or without a prior epithelial enrichment. For example, in one commercially available assay (AdnaTestBreastCancer™), epithelial cells are isolated by immunomagnetic beads labeled with antibodies against MUC1 and EpCAM. Real-time PCR is then applied to quantify mRNA transcripts for a variety of epithelial-specific markers such as GA73.3, EpCAM, and human epidermal growth factor-2 (HER2) (38–40).

As with bone marrow, the EPISPOT strategy has also been applied to whole blood to detect CTCs (41). This novel approach appears to have reasonable sensitivity and specificity relative to what has been reported with EpCAM capture, yet may provide an opportunity to characterize non-EpCAM expressing cells with greater clarity.

Each of these methods is predicated on evaluation of a certain volume of blood drawn from the patient and evaluated *ex vivo*. In order to monitor large volumes of blood, Eifler et al. have reported the high recovery of cultured human ovarian cancer cells that had been spiked into whole blood mononuclear fractions separated by leukapheresis (42). However, this approach is not terribly practical as a routine diagnostic assay. Recently, European investigators have reported pilot studies using an indwelling, intravascular guidewire coated with EpCAM monoclonal Ab (NanoDetector®, GILUPI, Greifswald Germany) (43). The catheter remains *in vivo* for 30 minutes, interrogating up to 1,500 mL of blood. This strategy permits collection of a substantially higher number of CTCs over a longer time window than is possible with a single blood draw. Direct comparisons to CellSearch® suggest increased sensitivity, but no data regarding clinical outcomes or clinical utility are available.

SENSITIVITY VERSUS SPECIFICITY IN DTC AND CTC ASSAYS

DTCs and CTCs are rare events in the bone marrow and circulation, respectively. For example, in bone marrow only 1 DTC can be detected for every 10^5 to 10^6 leukocytes (44). Likewise, CTCs are estimated to be present in a ratio of roughly one tumor cell per $1 \times 10^{5-7}$ peripheral mononuclear cells (45). Therefore, it is challenging to reliably separate DTCs and CTCs from the bone marrow and the blood, respectively. Sensitivity might be reduced for one of many reasons. First, most of the available strategies involve *ex vivo, in vitro* assays, limiting the volume of blood that can be interrogated. Second, any *in vitro* assay is fraught with cell loss due to device manipulation, such as flow through the device, incubations, and washings. Efforts to increase sensitivity may, with any assay, be hampered by loss of specificity, as discussed below.

Sensitivity of DTCs

Collection of DTCs requires a bone marrow aspirate and/or biopsy, which can easily be done at the time of surgery. However, for patients not undergoing surgery, bone marrow aspirate and biopsy is not terribly practical. Therefore, most DTC data are derived from patients with newly diagnosed breast cancer, and little if any data are available to estimate the incidence of DTCs in patients with metastatic breast cancer. Using standard techniques, DTCs can be detected in approximately one-third of patients with newly diagnosed, early-stage breast cancer, ranging from 12% to 42% depending on the study and the population selected (46). Following primary and adjuvant systemic therapy, it appears that the incidence of DTCs declines, presumably coincident with efficacy of therapy, although the clinical implications of this effect are not proven (46–48).

The scant data available in metastatic patients suggest that approximately one-fifth or more have DTCs, even without documented bone metastases. Using the EPISPOT assay, the detection of cells that secret MUC1 and/or cytokeratin 19 allowed the detection of viable DTCs in 90% and 54% of patients with metastatic breast cancer and non-metastatic breast cancer, respectively (34).

Sensitivity of CTCs

CTCs are less commonly detected than DTCs in patients with early-stage breast cancer, regardless of the currently available assays used. Several investigators have reported that, using the CellSearch® system, sensitivity ranges between 10% and 25%, when positivity is defined as one or more CTC/7.5–22.5 mL whole blood (49,50). RT-PCR methods appear to detect CTCs in approximately 41% (35,51). Too few studies have been performed with the other assay techniques to provide reliable estimates.

In contrast, CTCs are commonly found in patients with metastatic breast cancer. Using CellSearch®, approximately 70%, 60%, and 50% of patients with metastatic breast cancer have one, two, or five or more detectable CTC/7.5 mL whole blood, respectively. Sensitivity using other assays may be higher.

Specificity of DTCs and CTCs

Specificity has both technical and biologic distinctions. Technically, it is essential to distinguish an identified cell from both normal constituents of the surrounding bone marrow or blood environment. Most assays accomplish this task with accuracy by staining for epithelial and hematopoietic markers, although it is essential to use non-specific quenching techniques to avoid false-positive staining of granulocytes (if using immunohistochemistry) and plasma cells (any technique with a secondary antihuman antibody step). To circumvent these issues of specificity, multiple markers are used for the positive identification of CTCs and dismissal of leukocytes.

It is important to appreciate that some presumed epithelial markers may also be transiently expressed by normal or undifferentiated hematopoietic components of the marrow and blood. For example, MUC1, which is the soluble protein captured by the commonly used CA15-3 and CA27.29

circulating assays, has been shown to be expressed by precursor bone marrow hematopoietic cells (52).

Even with careful attention to separation of epithelial from hematopoietic cells, on occasion, normal subjects are found to have circulating epithelial cells. For example, the CellSearch® assay captures epithelial cells in 1% of normal subjects (21,53). However, analysis by fluorescence *in situ* hybridization (FISH) with multiple chromosomal markers has shown that captured epithelial cells from normal subjects are eusomic, while cells captured by CellSearch® in patients with metastatic breast cancer are almost always aneusomic (54,55). Furthermore, each of the capture strategies described above is really only an imperfect enrichment step. Even if the assay clearly captures well-defined epithelial or malignant cells, secondary analytical steps that do not directly visualize the interrogated cell, such as omics-based multi-gene RT-PCR, may well include contaminating white blood cells that have either simply not been removed or may even be phagocytosing, and therefore nearly covalently attached to, the CTCs.

Even single gene specific RT-PCR methods are plagued by false positive findings, ranging from 10% to 40% (22). These false-positive results are attributed to issues with laboratory technique, primer selection, and illegitimate expression of the target genes in leukocytes. For example, cytokeratin 19 and CEA overexpression can be induced in leukocytes by cytokines and growth factors (56–58). Many strategies have been used to increase the specificity, such as the use of qRT-PCR, which increases specificity compared to nested RT-PCR. As with whole-cell capture devices, qRT-PCR methods are positive in approximately 2% to 6% of normal control populations (59).

In addition to technical specificity, biologic specificity hampers clinical studies of MDD. Biological specificity refers to the detection of DTCs or CTCs that are morphologically malignant, yet may not have the capacity to produce lethal metastases. In this case, the clinician runs substantial risk of overdiagnosis. Indeed, not all MDD has malignant potential. Although detection of MDD in lymph nodes (60), bone marrow (46), and blood (21,50) is consistently associated with a statistically significantly higher risk of a future event, patients with positive findings are not absolutely destined to suffer recurrence, progression, or death in the future. For example, Wiedswang et al. have reported that approximately 15% of women who are free of any evidence of disease 2 to 3 years after initial diagnosis and treatment have positive bone marrow aspirates (47). Although this finding is associated with a statistically significant increase in subsequent relapse and death, many of these women did not suffer recurrence over the succeeding several years of follow-up. Likewise, Meng et al. have identified aneusomic CTCs in blood of approximately one-third of women who were 7 to 15 years after diagnosis but who were free of disease (55). These data suggest that one can identify morphologically distinct, viable DTCs and CTCs, but for one of many reasons they may not have long-term malignant potential. Thus, clinical studies demonstrating robust separation in outcomes are essential before a new assay claiming increased sensitivity is applied to patient care.

MINIMAL DETECTABLE DISEASE AND CLINICAL OUTCOMES

Over the last two decades, several studies have demonstrated that the presence of detectable DTCs or CTCs in patients with both primary and metastatic breast cancer is indicative of a worse prognosis. These studies establish clinical validity of the respective assays. However, only recently have appropriately designed studies been reported that begin to provide insight into clinical utility of these assays for their intended use; in other words, whether and how this information can be used in routine clinical care to improve patient outcomes. Many of the available studies are pilot in nature or conducted as correlative studies of convenience, in which the specimens happened to be available for a given assay. Most of these studies have significant limitations in their ability to assess the value of MDD as either a prognostic or predictive factor in breast cancer. These limitations are largely due to the small size of studies, retrospective acquisition of samples, and wide variations in treatments received by the patients. Thus, while analytical validity and clinical validity have been established for some of the assays (in particular, the CellSearch® system), high levels of evidence demonstrating clinical utility are still lacking.

Prognosis in Early-Stage and Metastatic Stage of Disease for DTCs

Almost all of the data regarding DTCs present in the literature have been generated in early-stage breast cancer and not in the metastatic setting. In a pooled analysis of all available studies, Braun et al. reported that approximately one-third of 4,703 patients with stage I–III breast cancer had detectable DTCs prior to surgery. They showed that the presence of occult cytokeratin positive metastatic cells in early breast cancer is associated with a statistically significantly higher risk of distant metastases and death from death-related causes ($p < .001$) (46). In multivariate analysis, the presence of DTCs was the strongest and most highly significant predictor of death (hazard ratio [HR] = 1.81), disease recurrence (HR = 1.85), and the development of distant metastases (HR = 2.03) (Fig. 30-1). These increased risks were seen in all treatment groups, including patients who only received hormonal therapy, or chemotherapy, and low-risk patients (TNM stage T1N0M0) who did not received any adjuvant systemic therapy.

However, although the pooled analysis demonstrates clinical validity, the clinical utility of these findings is not clear. Given the nature of the pooled studies, adjuvant treatments were variable, representing the local standard of care. Furthermore, although statistically significant, the results may not be clinically relevant. For example, the magnitude of difference in outcomes between those with versus those without MDD was highest in patients who received adjuvant systemic therapy (AST), in particular chemotherapy (Fig. 30-2C and D). Because these patients already received AST, and in the absence of data supporting further or different therapy for such patients, knowledge of this residual risk is of little clinical value.

The most obvious clinical use would be to use DTCs to determine whether to give AST. In this regard, in patients who did not receive AST, the magnitude of the difference in breast cancer–specific survival (BCSS) and disease-free survival (DFS) (Fig. 30-2E and F) between those with positive versus negative nodes is quite small, although still statistically significant. Indeed, even though those with positive DTC had a slightly worse prognosis, it was still quite favorable even without AST. These observations suggest that detection of bone marrow micrometastases in early disease is simply recanting what the clinicians already suspected from analysis of the primary and lymph node status: that patients who received AST had a worse prognosis. Unfortunately, in the very patients for whom further prognostic information would be valuable, the assay was

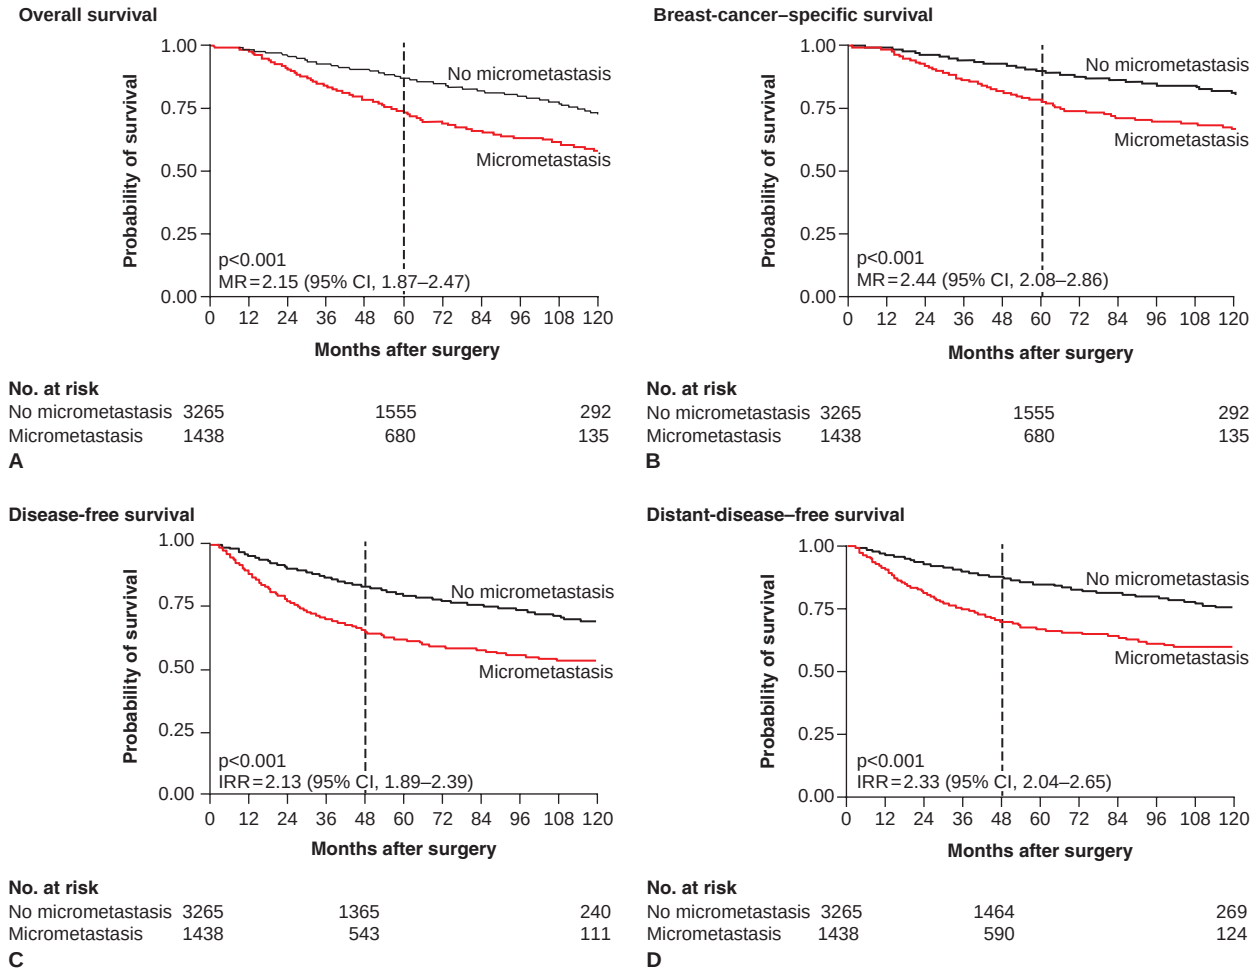

FIGURE 30-1 **Outcome of patients with early-stage breast cancer patients based on disseminated tumor cells. (A)** Overall survival. **(B)** Breast cancer–specific survival. **(C)** Disease-free survival. **(D)** Distant disease–free survival. (From Braun S, Vogl FD, Naume B, et al. A pooled analysis of bone marrow micrometastasis in breast cancer. *N Engl J Med* 2005;253(8):793–802. Copyright © 2005 Massachusetts Medical Society. All rights reserved [46].)

not very informative. Furthermore, because these studies were not conducted to specifically address clinical utility, one cannot determine if lack of MDD might have identified patients whose primary and lymph node status suggested high risk of recurrence but who actually would have done well without AST.

Another appealing use of DTCs in the clinical setting might be to monitor therapeutic efficacy and assessment of response to prior therapy or identify ongoing residual risk during event-free follow-up. In this regard, Wiedswang et al. have reported that of 920 stage I and II patients followed for 0.5 to 85 months, 32% of patients with positive DTCs at any time suffered relapse, compared to 14% of those who remained persistently negative (61). In addition, they and others have reported that the persistence of DTCs after primary and adjuvant therapy was associated with a very poor prognosis (47,62). A pooled analysis has shown that approximately 15% of patients have persistence of DTCs after primary and adjuvant chemotherapy and have a statistically significant higher risk of subsequent recurrence and death during the first 5 years following cancer diagnosis (long-rank test $p < .001$ values for all investigated endpoints) (48).

A more detailed assessment of the potential clinical utility of monitoring MDD (DTCs and CTCs) over time in patients with locally advanced disease undergoing neoadjuvant chemotherapy has been performed in the NeoTax Study. The presence of ≥1 DTC 12 months after the start of neoadjuvant therapy, but not at other time points, was associated with reduced disease-free survival (DFS), breast cancer–specific survival (BCSS), and overall survival (OS). In multivariate analysis, DTC status (</≥1 DTC) at 12 months after the start of neoadjuvant therapy remained as a prognostic factor, and presence of DTCs after neoadjuvant therapy indicated high risk for relapse and death, irrespective of the DTC-status before treatment (63). Although these data need to be confirmed, they suggest that perhaps DTCs might provide additional information to that gained by determination of pathological complete response of the primary breast cancer, which is currently the gold standard surrogate endpoint in this setting (64).

However, once again, the clinical utility of these findings is not clear. The obvious corollary to identification of persistent DTCs is that further alternative, or extended, AST should be delivered. No prospective randomized trial data support additional or alternative therapy to patients who

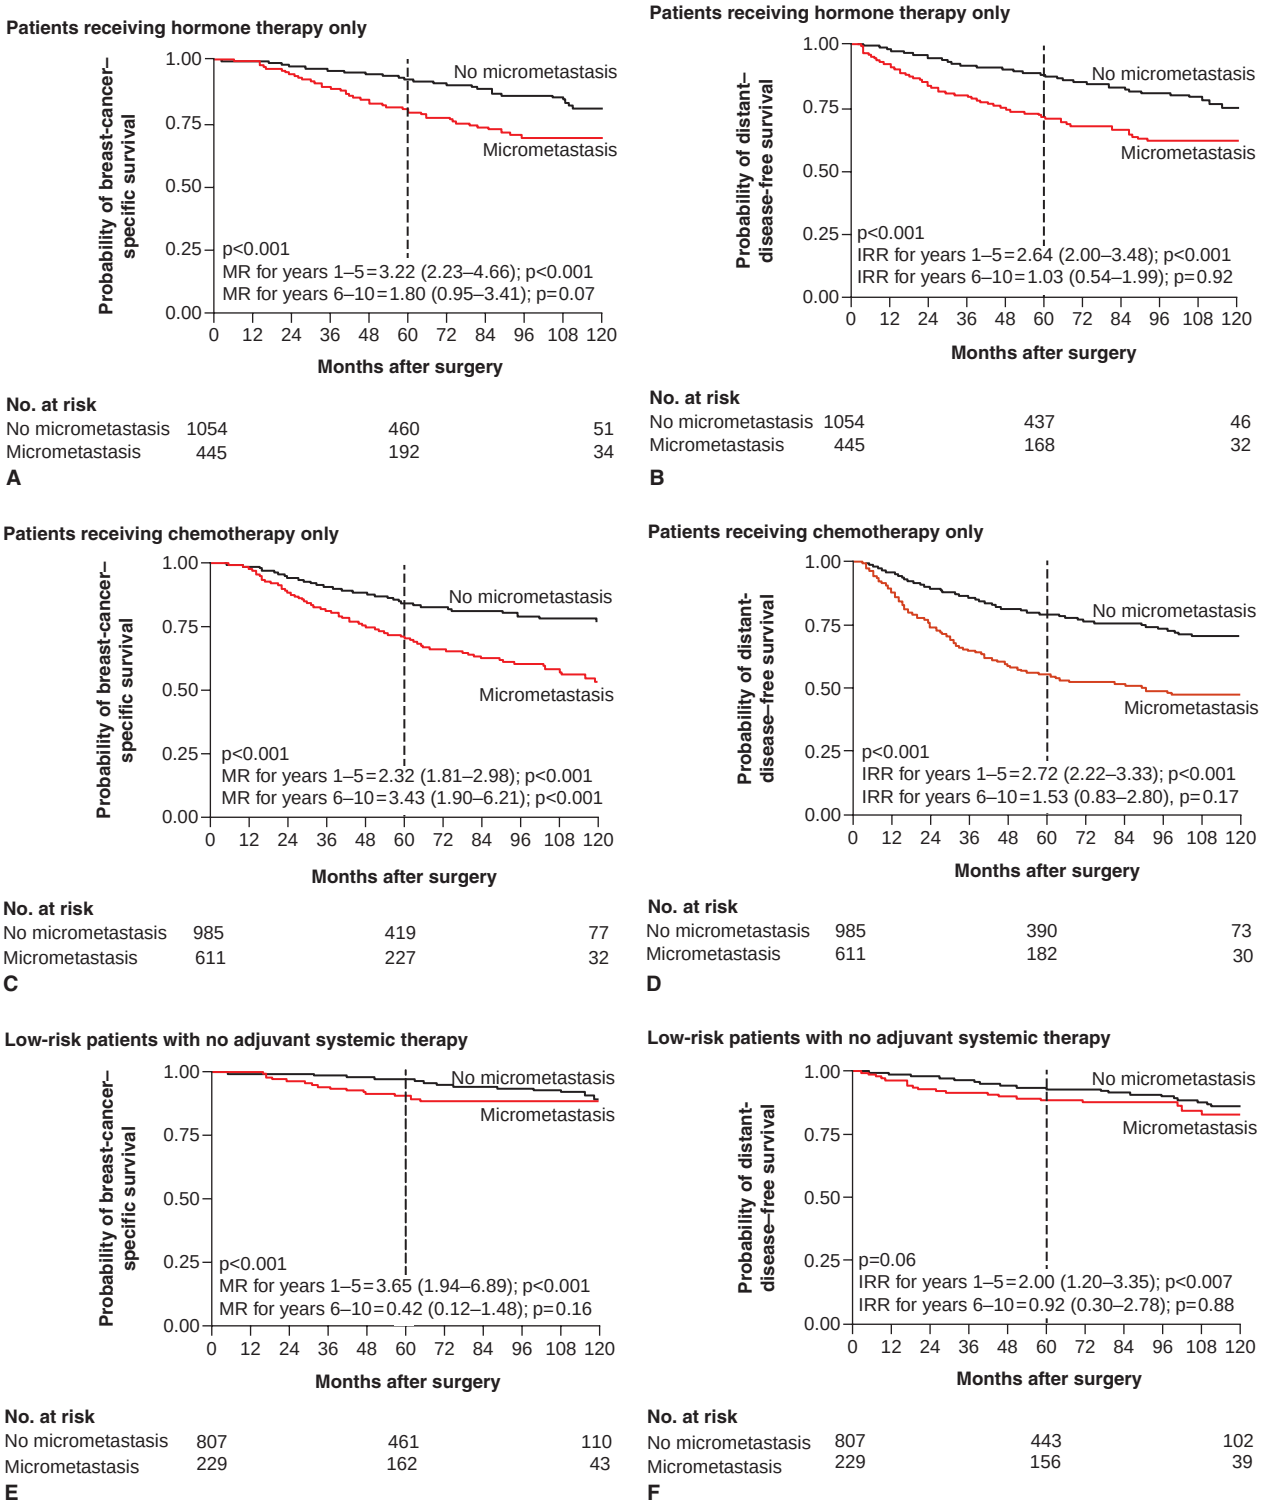

FIGURE 30-2 Outcome of patients with early-stage breast cancer based on disseminated tumor cells among patient subgroups who received adjuvant hormone therapy only, adjuvant chemotherapy, or no adjuvant systemic therapy. either do not have a pCR or who have MDD after neoadjuvant chemotherapy. In this regard, one trial has been conducted (Norwegian NBCG9 [NCT00248703]) in which 1,121 breast cancer patients with pN1-3 or pT1c/T2G2-3pN0 status were analyzed for the presence of DTCs 8 to 12 weeks and 6 months after six cycles of a taxane-free, antracycline-containing adjuvant chemotherapy regimen. If DTCs were present at the second bone marrow biopsy, subsequent taxane-containing chemotherapy was administered, followed by routine clinical and DTC monitoring (65). Preliminary results demonstrate that DTCs were no longer detectable in the majority of patients after docetaxel treatment, but true clinical outcomes (RFS, OS) are pending. Unfortunately, since this trial did not contain a concurrent, randomized untreated control arm, it will be difficult to determine if the addition of the taxane truly improved clinical outcomes.

DTCs might evade the effect of chemotherapy by remaining in a dormant nonproliferative state. Therefore, beside treatment such as chemotherapy, other studies have investigated the therapeutic efficacy of different drugs such as bisphosphonates or novel targeted agents (66–69). For example, results of a phase II pilot trial suggested a reduction in DTCs after 6 months of zoledronate therapy (66). In a separate trial, 96 patients with early-stage breast cancer who had positive bone marrow after cytotoxic treatment were randomly assigned to zoledronate or observation only. The treatment with zoledronic acid was associated with lower incidence of persistently positive bone marrow after treatment, but additional investigation is required to determine whether the reduction in DTCs portends clinical benefit (67). Likewise, an open-label, randomized, phase II trial conducted in locally advanced breast cancer has shown elimination of DTCs by the administration of zoledronic acid (70).

Taken together, these accumulated results suggest that detection of DTCs either before or after therapy is associated with worse prognosis. However, although these data are promising, they only represent clinical validity, but not clinical utility, for any specific intended use. At present, DTCs should not be routinely collected or used to guide therapy in patients with breast cancer.

Prognosis in Early-Stage and Metastatic Stage of Disease for CTCs

Because serial bone marrow sampling is not easily performed within a single patient, serial collection of blood for measurements for CTC enumeration and monitoring might be a better alternative for sequential analysis of MDD. There are only few studies comparing DTC and CTC detection within the same time point, and for the most part they suggest that the detection of DTCs is higher than for CTCs (71–74).

Nonetheless, isolation, enumeration, and characterization of CTCs is an appealing strategy and might have clinical utility. Among the several reported CTC assays, the CellSearch® system or assays that use RT-PCR-based techniques are the most broadly used.

CTCs in Early-Stage Breast Cancer

Both EpCAM-capture based assays and RT-PCR-based assays may provide prognostic information in the early breast cancer setting. A series of studies have been published in which blood samples were prospectively collected and tested, using RT-PCR-based assays, from patients being treated on a variety of clinical trials (35,51,75). The chemotherapies varied, but the criteria for hormonal therapy and for clinical follow-up were all identical. For example, in one study of 167 patients with node-negative breast cancer, those who were CK-19 positive had a higher risk of recurrence (44% vs. 3%, $p = .000001$) and death (19% vs. 1%, $p = .00005$) (Fig. 30-3) after a median follow-up of 55 months (75). In a second study

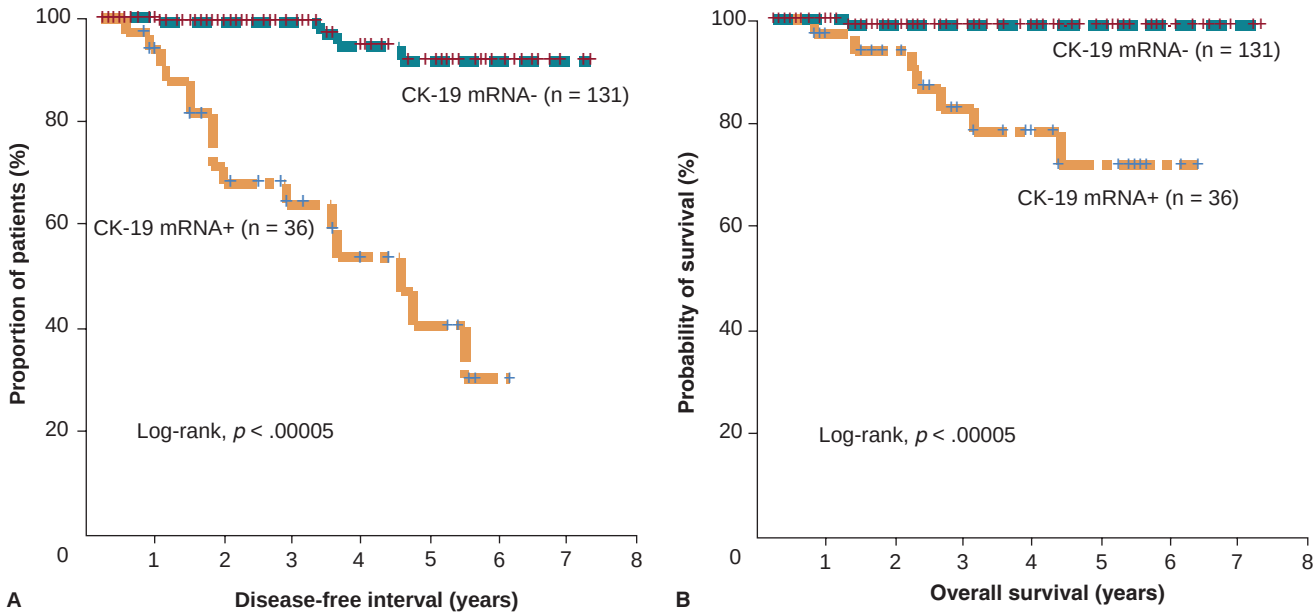

FIGURE 30-3 Outcome of patients with early-stage breast cancer based on circulating tumor cells detected by reverse transcription-polymerase chain reaction assay. (A) Disease-free survival. **(B)** Overall survival. (Adapted from Xenidis N, Perraki M, and Kafousi M, et al. Predictive and prognostic value of peripheral blood cytokeratin-19 mRNA-positive cells detected by real-time polymerase chain reaction in node-negative breast cancer patients. *J Clin Oncol* 2006; 24(23):3756–3762, with permission. Copyright © 2006 American Society of Clinical Oncology. All rights reserved (75).)

by the same investigators but including a higher risk population of 444 patients, CK-19 positive patients were again found to be at significantly higher risk of relapse compared to CK-19 negative patients (30% vs. 15%, $p < .0001$) and death (15% vs. 6%; $p = .001$). In multivariate analysis that included tumor size, lymph node status, and histologic grade, CK-19 positivity was the strongest independent predictor of DFS (HR = 2.4, $p < .001$) and OS (HR = 2.5, $p = .007$) (51).

Other investigators have reported that CTCs as detected by the CellSearch® system are prognostic in early-stage disease (49,50). For example, Lucci et al. reported that 24% of 302 patients with stage 1–3 breast cancer had one or more CTC/7.5 ml whole blood, and that these patients had a higher risk of early recurrence and decreased overall survival (OS) (Fig. 30-4). However, like so many studies in this setting, they did not control for treatment or other variables. Therefore, while this study clearly indicates clinical validity of a highly analytically validated assay for CTCs, it fails to demonstrate clinical utility, as it is not clear exactly who should or should not receive adjuvant systemic therapy.

Several studies have investigated the role of CTCs in the neoadjuvant setting. For the most part, these investigators have shown that persistent detection of CTCs, regardless of the assay, is associated with worse outcome (76–78). However, as with DTCs, none of these studies were designed to determine if this knowledge could or should be used to direct subsequent additional or alternative therapy.

In summary, CTCs appear to be prognostic in early disease in a fashion similar to DTCs, but the clinical utility of this finding is unclear. The results reported to date have been generated in prospective or retrospective registry studies, with no control of primary or adjuvant systemic therapy and no indication of how one might use the data to direct patient care. Although the clinical validity of these findings is of interest, one cannot recommend measurement or use of CTCs in early-stage breast cancer outside of a clinical trial. Indeed, neither the American Society of Clinical Oncology (ASCO) nor the National Cancer Center Network (NCCN) guidelines panels recommends the enumeration of CTCs as either for staging or CTCs in assisting patient care in the non-metastatic setting.

CTCs in Metastatic Disease

Currently, perhaps the most well-established intended use of CTCs is to monitor patients with advanced disease. In this setting, the available assays are reasonably sensitive, and in certain situations, elevated CTCs may be used to help guide clinical decisions.

The majority of clinical outcomes data in the metastatic setting are derived from studies utilizing the CellSearch® assay. In a seminal prospective registry study, 177 patients with metastatic breast cancer who were beginning a new therapy had CTCs determination by CellSearch® and were monitored for outcomes (21). From a training set of 102 patient samples, a level of ≥5 CTC/7.5 mL of whole blood was identified as the threshold that best distinguished progression free survival (PFS) between the two groups. This threshold and its prognostic value were then confirmed in an independent, prospectively collected set of 75 patient samples. Elevated CTCs at baseline predicted extremely short median PFS and OS of 3 and 10 months, respectively. In contrast, patients with <5 CTC/7.5 mL whole blood had median PFS and OS of 7 and 22 months, respectively ($p = .005$). The cumulative effect on prognosis of CTCs at baseline of all patients enrolled in the trial is shown in Figure 30-5A and B.

Although these results are interesting, it is not clear how a pretreatment, baseline CTC prognostic estimate would guide therapy. Based on the worse prognosis inherent in having elevated CTCs at baseline, one might consider an alternative therapy from a previously chosen treatment plan. For example, one might treat a patient with ER-positive breast cancer whose apparent prognosis is quite poor (for example, if she has rapidly progressive visceral disease with end-organ dysfunction) with chemotherapy rather than less toxic endocrine therapy. Likewise, for a patient with hormone refractory disease and very poor prognosis, one might choose to use combination rather than single agent chemotherapy. However, the overall prognosis of patients with elevated baseline CTCs is not as dire as for those with rapidly progressive visceral metastases, and no studies have demonstrated that such an approach is clinically warranted.

Perhaps more interesting, CTC values obtained after one cycle of therapy were associated with even more

robust differences in outcomes, suggesting that those with persistent CTCs were likely on ineffective therapy. The incidence of elevated CTCs (≥5 CTC/7.5 mL whole blood) declines from 50% at baseline to approximately 30% at first follow-up after initiation of therapy (3 to 5 weeks) (21,79). In the original Cristofanilli et al. study, those patients with elevated CTCs at this early time point, regardless of whether they had elevated CTCs at baseline, have a substantially shorter median PFS (2.1 vs. 7 months; $p < .001$) and OS (8.2 vs. > 18, $p = .001$) than those who still had elevated CTCs (Fig. 30-5C and D).

The prognostic role of baseline and follow-up CTC results first observed by Cristofanilli, et al. has been confirmed by several other investigators (79–84). A large pooled analysis (80) including 841 patients coming from six different clinical studies has confirmed the prognostic and predictive validity of CTCs assessed before and during therapy. A high level of CTCs before and during treatment was strongly associated with treatment failure irrespective of clinical variables, disease subtype, type, or line of therapy.

The intriguing observation that failure to rapidly clear CTCs early in the course of therapy has led to speculation

that they might be useful to direct an early change to an alternative treatment plan, rather than persisting until classic clinical and/or radiographic evidence of progression. In this regard, a prospective randomized clinical trial has been conducted in the Southwest Oncology Group (SWOG S0500) to test whether women with metastatic breast cancer who have elevated CTCs after one cycle of first line chemotherapy have improved outcomes as a result of switching early to an alternate therapy (Fig. 30-6). This trial is based on the hypothesis that these patients will have improved outcomes by minimizing the time and toxicity spent on ineffective therapies and by spending more time on effective therapy. Results from this study are expected in late 2013 or early 2014. A similar study is currently ongoing in France (85).

Although preclinical studies have suggested that anti-EpCAM capture strategies such as CellSearch® might be less sensitive or prognostic in basal, or "triple negative," breast cancers, the results from several clinical studies suggest a similar likelihood of having elevated CTC levels and worse outcomes regardless of the hormone receptor or HER2 status of the patient's primary cancer (21,80). However, the assay may not be as prognostically robust for selected subsets. For example, in the original Cristofanilli et al. study, PFS and OS for patients initiating hormonal therapy were similar regardless of baseline CTC levels (21). However, CTCs evaluated at first follow-up in this subset after initiating hormonal therapy predict substantial differences in median PFS (2.3 vs. 8.3 months, p = .15) and OS (10.9 vs. >18 months, p = .002). Although the PFS comparison was not statistically significant, it suggests that CTCs may be able to distinguish patients who are on ineffective hormonal therapy. The subset of patients starting hormonal therapy was small (n = 53), so, the analysis in patients on hormonal therapy was likely unpowered and requires further investigation. Because of the lack of strong statistical significance in the hormonal therapy group, the FDA cleared indication for the CTC assay limited to women undergoing chemotherapy for metastatic breast cancer.

Further analysis of these data suggests that the prognostic value is independent of the line of chemotherapy. The original Cristofanilli et al. (21) publication presented combined data for all patients receiving any line of therapy. Approximately half of these patients were receiving first-line therapy, and a subsequent publication demonstrated that the prognostic information was the same in patients receiving first-line therapy (86).

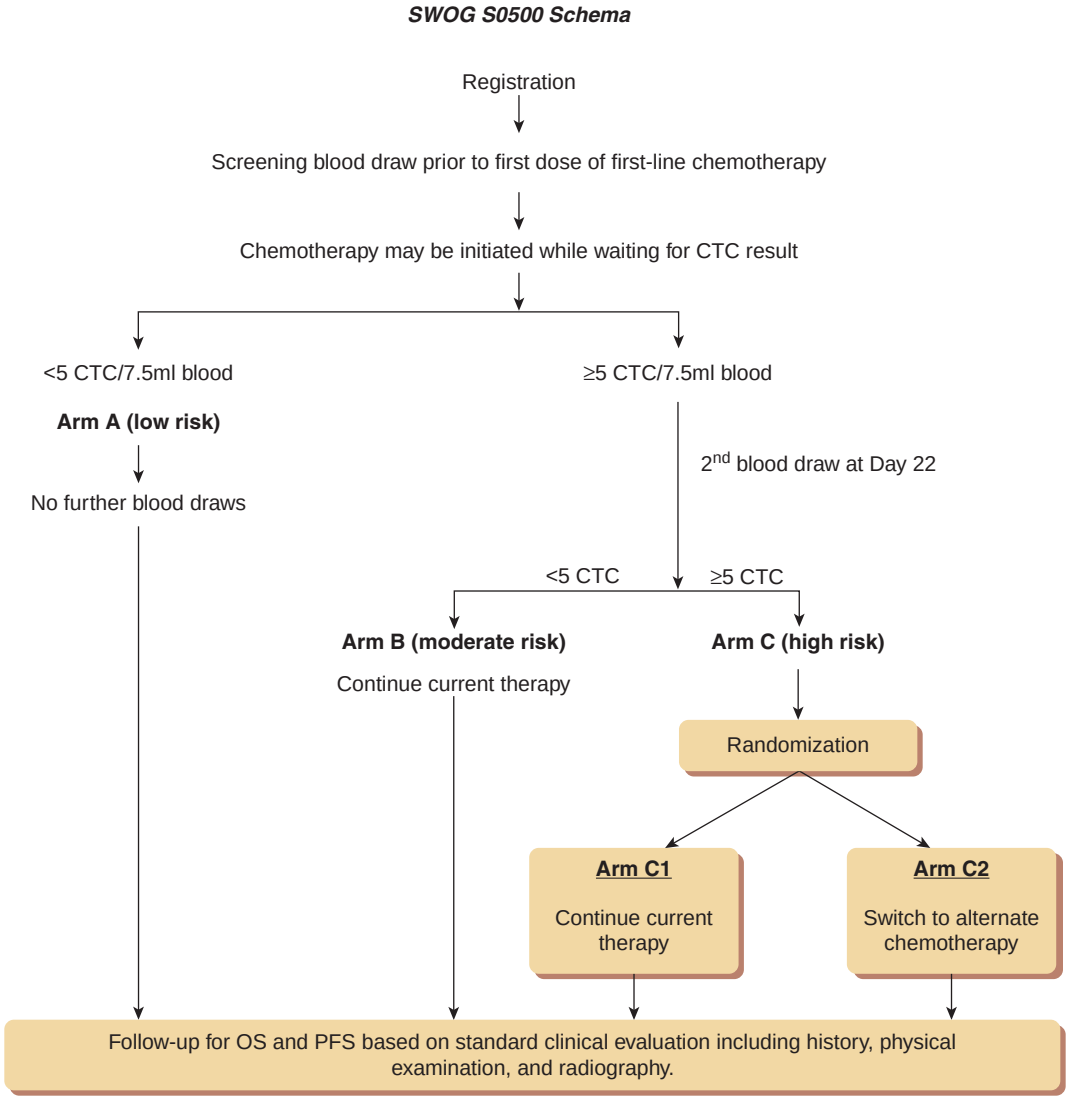

FIGURE 30-6 Schema for Southwest Oncology Group (SWOG) S0500.

Subsequent reports have suggested that elevated CTC levels at any time point are associated with a much higher likelihood of rapid progression (within the succeeding few months) when compared to patients who do not have elevated CTC (79,83). CTC data may be of particular utility as an objective measure to determine progression in patients with non-measurable forms of metastatic breast cancer, which is often subjective, subtle, and difficult. De Giorgi et al. (87) reported that CTC enumeration at follow-up correlated with ^{18}F-FDG PET/CT findings in 78% of the 55 evaluable patients. ^{18}F-FDG-PET/CT findings and follow-up CTC counts were found to be significantly associated with both PFS and OS. Although in multivariate analysis, ^{18}F-FDG PET/CT findings remained as the only predictive factor for OS, the combination of ^{18}F-FDG PET/CT and CTC count might be a potential tool to monitor response to therapy in patients without measurable disease. Rather than performing serial radiographic or scintigraphic imaging, one might use history, physical examination, standard serology (in particular liver function tests), circulating tumor markers (such as MUC1 and/or carcinoembryonic acid assays), and CTCs. If all of these are negative, it appears that the odds of image-documented progression within the next few months are very low, and it is very unlikely that additional inconvenience and cost of imaging would be of value.

More than 50% of patients with metastatic breast cancer do not have measurable disease. Thus, determination of response is quite difficult, and the eligibility requirements for many phase II clinical trials exclude such patients. CTC levels reductions during follow-up may be more predictive of subsequent OS than classically used measures of response, such as history, physical examination, or staging radiographs, even when read by independent reviewers (88). This observation suggests that, in the future, CTC levels might be used in clinical trials to determine response to new drugs or strategies, thus opening accrual to patients who do not have RECIST-defined measurable disease and are currently excluded from participation.

In summary, taken together, the data at present suggest that there is a limited role for monitoring CTCs in the metastatic setting, and the ASCO Tumor Marker Guidelines Committee did not recommend this utility. However, the accumulated data support using CTCs to complement standard circulating markers such as CA15-3, CA27.29, and CEA to monitor patients who have been on a given therapy for some time to help guide whether treatment should be continued without interruption or whether the patient should have restaging imaging to determine if she does or does not have progression (83).

DTCS AND CTCS: PHENOTYPING AND GENOTYPING AND FUTURE RESEARCH

The preceding discussions all point to the potential importance of enumerating DTCs and CTCs in patients with breast cancer. They also, however, highlight the concerns about sensitivity and, in particular, technical and biological specificity. Indeed, the ability to characterize captured CTCs may give insight into which detected cells have true malignant potential and which are more likely impotent, terminally differentiated cells that are detected but have no biological importance.

Breast cancer, perhaps of all the known and treatable malignancies, is a disease for which targeted therapies have been most useful, in particular directed against the estrogen receptor (ER) and ERBB2 (formerly HER2). For example, several recently reported studies have demonstrated that up to 15% of metastases in patients whose original cancer was considered HER2 negative are HER2 positive (89). Taken together, these considerations illustrate the need to not only count *events*, but better characterize the genotype and phenotype of these cells.

Many investigators have developed methods to detect and monitor biologically important markers in both DTCs and CTCs. Genetic changes can be detected in CTCs, including abnormal telomerase activity (90), allelic loss, and/or amplification of multiple oncogenes (91), and aneuploid changes in cellular chromosome content based upon FISH analysis similar to those seen in the primary tumor (54). Indeed, using genome-wide copy number analysis, Magbanua et al. have demonstrated that when compared to matched archival primary tumor, copy number aberrations in CTCs from over 100 patients with metastatic breast cancer have both conserved and divergent genomic alterations (92). Moreover, a recently reported study has demonstrated that overall levels of free DNA are prognostic compared to control levels; that specific mutations in important genes, such as PIK3C can be detected and monitored over time; and that these mutations seemed to correlate with those detected in the patients' cancer (93). In this small study, serial levels of free DNA appeared to be more robust than serial levels of either circulating MUC1 protein (CA15-3) or CTC (CellSearch®). These exciting preliminary results require further conformation to determine whether they have clinical utility for a specific clinical use (94).

Cancer-associated protein expression by DTCs and CTCs can be also be determined, such as HER2 (55,77,95–102), ER (40,103–106), epidermal growth factor receptor (EGFR) (107), MAGE, phosphorylated FAK, the PI3K protein (108), androgen receptor (109), insulin-like growth factor (110), and BCL2. Moreover, using a monoclonal antibody (M30) that detects a neo-antigen exposed in fragmented but not full-length cytokeratin, CTCs undergoing apoptosis can be identified and monitored (111,112).

These molecular markers might be used either as pretreatment predictors of response to targeted therapies, such as antiestrogen or anti-HER2 strategies, or as pharmacodynamics indicators that the therapy is hitting its target, if it results in a known biomarker change such as downregulation (108,113). Investigators have also demonstrated early successes in gene expression profiling (114) and multiplex RT–PCR (115) from CTCs. As each of these methodologies becomes more sophisticated, the ability to isolate, detect, and phenotype these cells will continue to improve.

Characterization of CTCs may also provide insight into the biology and heterogeneity of the metastatic process (116). For example, dormancy and late relapse, especially in patients with luminal cancers, have presented a particularly enigmatic circumstance to clinicians caring for breast cancer patients. As noted previously, DTCs and CTCs can be detected in patients long after prior treatment for early-stage breast cancer. Although this finding is prognostic, many such patients remain free of clinical recurrence (47,55,95,117). Furthermore, many investigators are examining putative stem cell markers, and markers of EMT, that might distinguish CTCs with malignant potential versus those that are impotent (118–122). None of these has as yet gained clinical utility, but they promise to provide even more specific diagnostic tools and perhaps avenues of research for targeted therapies.

Taken together, these results further emphasize the importance of understanding the concept of "biological" false positive findings. In other words, these patients appear to have detectable CTCs but no evidence of progressive disease, living in symbiosis with apparently dormant

metastatic cancers. A more sophisticated understanding of the subsequent changes that may be responsible for late relapses either in the cancers cells themselves or surrounding microenvironment could help select patients who might benefit from extended adjuvant therapy with standard agents, such as antiestrogen therapies, or even novel strategies directed toward the potential driving factors.

SUMMARY

Detection and enumeration of MDD in patients with breast cancer have been of great interest. Several studies have demonstrated the clinical validity of determining the presence or absence and relative quantification of MDD; however, the clinical utility remains elusive for most intended uses. Perhaps the only acceptable use of CTCs is to monitor patients with established metastatic disease to determine whether they are doing well on a given therapeutic approach; or, if CTCs are rising, whether they should have staging imaging performed to evaluate for progression.

However, prospective randomized trials in the adjuvant and metastatic settings are addressing further clinical utilities in other intended uses, such as consideration of an early change in a metastatic regimen. Perhaps more importantly, molecular characterization of DTCs and CTCs might serve as a "liquid biopsy," with exciting implications for treatment based on the real-time biologic and clinically relevant biomarker status of the CTCs. Future trials designed to address clinical utility of DTCs and CTCs are needed to have an impact on patient care.

SECTION VII

Management of Primary Invasive Breast Cancer

CHAPTER 31

Evaluation of Patients for Metastasis Prior to Primary Therapy

Polly Niravath and C. Kent Osborne

CHAPTER CONTENTS

After the diagnosis of breast cancer is established, subsequent evaluation for metastatic disease prior to initiation of primary therapy is a somewhat controversial topic. High-quality evidence in this regard is unfortunately lacking; therefore, there is not a common, standardized approach to staging among practitioners in the United States. However, staging clearly does have important implications on both prognosis and treatment. This chapter aims to shed light on the available evidence to support staging for newly diagnosed breast cancer.

The danger of an overly aggressive staging approach is likely greater than the risks of a more judicious staging philosophy. Increased staging examinations impose unnecessary financial expense on the health care system. Especially when considering the sheer number of breast cancer patients, the societal and economic cost of "overstaging" is quite considerable; worldwide, approximately 1.15 million new cases of breast cancer occur each year (1). Furthermore, many staging modalities are likely to lead to "false positives" that result in needless biopsies that pose potential danger to the patient's health, invoke patient anxiety, increase health care costs, and delay essential treatments.

Currently, in the United States, staging with advanced imaging modalities is becoming more common for early stage breast cancer patients. A review of Medicare records shows that 18.8% of women with stage I or II breast cancer had CT scans, PET scans, and/or brain MRI as part of a staging workup. The use of preoperative staging CT scan increased from 5.7% to 12.4% between 1992 and 2005, and the use of PET scans increased from 0.8% to 3.4% in the same time period. Brain MRI increased from 0.2% to 1.1%, but bone scans actually declined from 20.1% to 10.7% (2). Although the data do not necessarily support staging asymptomatic patients with early stage breast cancer, this practice is clearly increasing in the United States, which leads to increased medical costs and procedures. Also, the use of preoperative CT scans and bone scans have been shown to significantly delay the time from initial breast complaint to the time of breast surgery (3). If the imaging uncovers false positives, delays will, of course, be even longer because biopsies or confirmatory imaging is often ordered as a result of an abnormal staging examination. These delays in the time to surgery represent a needless decrease in the quality of breast cancer care.

INITIAL EVALUATION

After a patient has had a breast biopsy that establishes the diagnosis of breast cancer, the physician should perform a thorough history and physical exam, including complete review of systems. Routine blood tests, including complete blood count and comprehensive metabolic panel, should also be done at this time. If the patient appears to have early stage disease and the evaluation discussed does not indicate distant metastatic disease, then there is no need for preoperative advanced staging modalities. However, if a patient does have signs or symptoms of possible metastatic disease, such as weight loss, bone pain, persistent cough, or elevated alkaline phosphatase, appropriate staging studies should be done at the physician's discretion (see Fig. 31-1).

In the case of patients with locally advanced disease at the time of diagnosis (T2 or larger lesions or palpable lymphadenopathy), neoadjuvant therapy may be an appropriate approach for them. In this case, it would be prudent to obtain staging prior to starting neoadjuvant therapy with CT scan with contrast of the chest, abdomen, and pelvis as well as bone scan.

For those patients who are not receiving neoadjuvant therapy, however, the risk of distant metastasis is better evaluated based on surgical pathologic criteria, such as tumor size and degree of lymph node involvement. Thus, in cases of small breast cancers that are not amenable to neoadjuvant therapy, decisions regarding staging evaluations are best made after surgery because the pathologic stage of the cancer should inform the choice of staging modalities. In this way, many patients with earlier stage disease can be spared unnecessary imaging procedures, and only those with highest risk of disease will receive advanced staging evaluation. Although it is true that some patients with occult metastatic disease may undergo breast surgery prior to discovering the

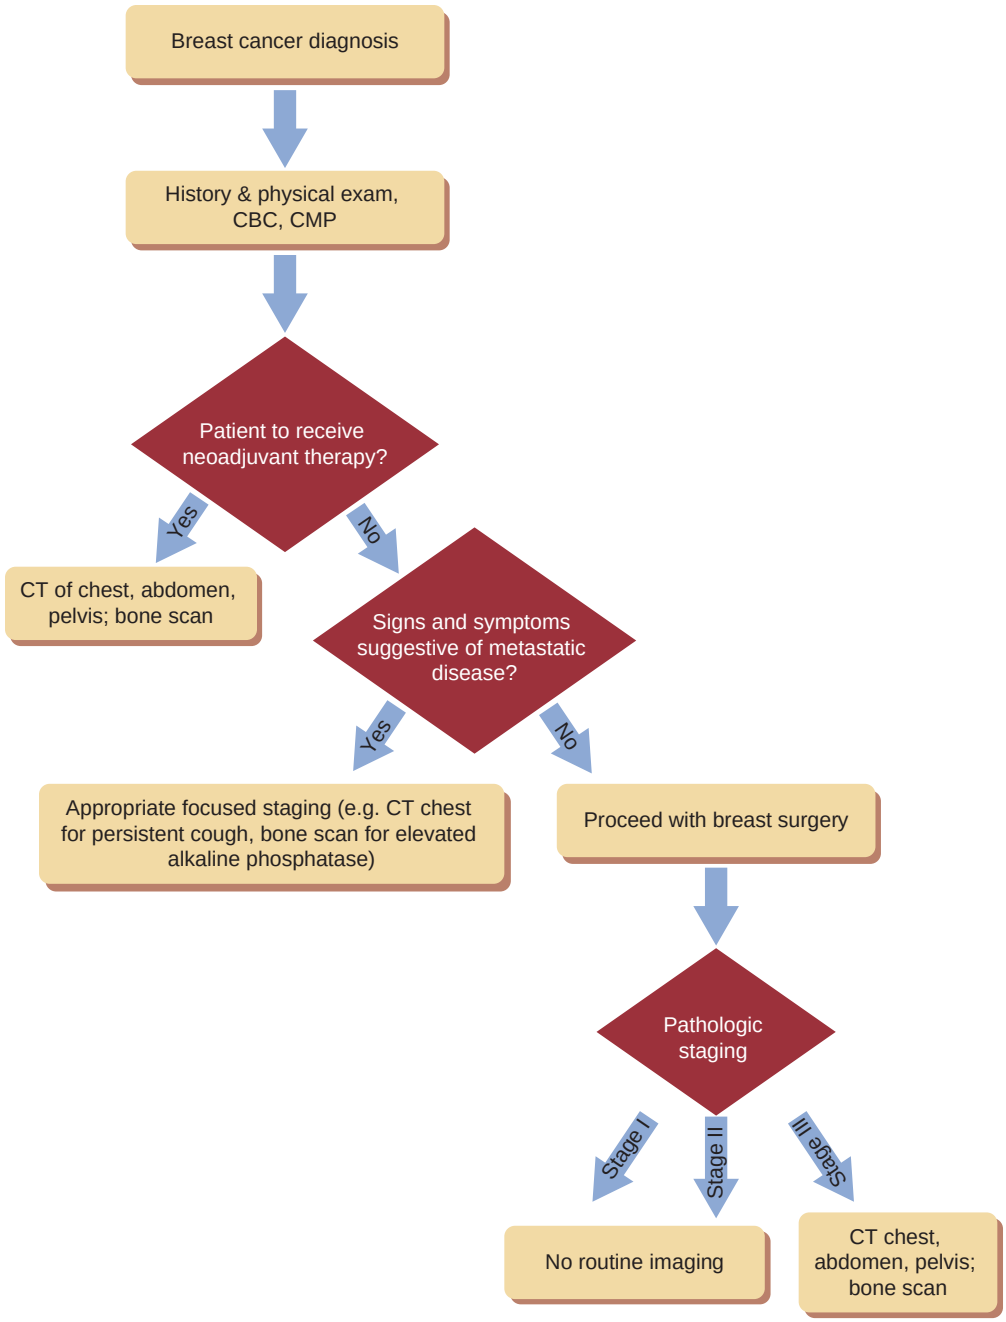

FIGURE 31-1 Proposed staging algorithm.

metastases, there may be some benefit from breast surgery for these patients because retrospective studies have shown increased overall survival in those metastatic patients who have had mastectomy with negative margins at the time of diagnosis (4,5). However, preliminary data from two randomized trials in Turkey and India suggest that there is no overall survival advantage to mastectomy for metastatic patients (6,7), but definitive conclusions about the role of surgery in this setting await additional data. In the meantime, surgery to control local disease is also an important endpoint.

EVALUATION OF THE IPSILATERAL AND CONTRALATERAL BREASTS

At the time of breast cancer diagnosis and prior to breast surgery, each woman should have a bilateral breast exam and mammogram to exclude multicentric disease within the same breast as well as contralateral breast cancer. Depending on the density of the woman's breast and the discretion of the radiologist, breast ultrasound may also be pursued. Ultrasound also affords the possibility to look at the axillary lymph nodes in greater detail than the mammogram does. Please refer to Chapter 12 for more information regarding the use of breast ultrasound in the diagnosis of breast cancer.

Breast MRI is likely the most sensitive imaging modality for comprehensively evaluating the breasts prior to surgery. A large meta-analysis of more than 2,600 newly diagnosed breast cancer patients discovered that 16% of them were found to have additional foci of malignancy in the affected breast. Furthermore, 11.3% converted from wide local excision (WLE) to more extensive surgery, which may have been wider excision or mastectomy. Specifically, 8.1% of the total

group converted from WLE to mastectomy. Conversely, surgery was changed from WLE to mastectomy because of a false positive in 1.1% of women, and surgery was changed from WLE to more extensive excision in 5.5% of patients for a false-positive finding. In this study, for every three women who were found to have additional lesions on MRI, one of the three proved to be a false positive (8).

These risks and benefits are perhaps better weighed when one takes into account the histology of the tumor. It is well known that lobular cancers tend to be more often multicentric and mammographically occult (9). Theoretically, when isolating a high-risk population such as this, the potential benefits of breast MRI may be greater. One retrospective study of 267 breast cancer patients found that 25.5% of patients had more extensive surgery because of preoperative MRI findings. Among these patients, 29% turned out to have had no pathologic verification on surgical specimen to justify the additional surgery. However, when the small subset of lobular carcinoma was studied, 11 of 24 (46%) patients with lobular carcinoma had a change in management because of MRI findings. Furthermore, 9 of these 11 patients had pathologic verification of additional malignancy at the time of surgery, yielding an 82% sensitivity (10). However, it must be noted that ultrasound was not evaluated in this study. In practice, ultrasound is commonly used in conjunction with mammogram to define the extent of disease. Future prospective studies are needed to compare the sensitivity and specificity of combined mammogram and ultrasound to that of breast MRI. Also, it is unknown whether the wider excisions and mastectomies that were prompted by MRI findings would have proven to be clinically relevant. Because almost all women who have lumpectomies will receive adjuvant radiation, it is not known whether the additional surgery truly does lower local recurrence rate as compared to adjuvant radiation. Nonetheless, women with lobular carcinoma may be more likely to have other areas of disease uncovered by MRI, and they are less likely to have false-positive MRI results. Based on the available evidence, breast MRI may be pursued at the physician's discretion in cases of lobular cancer, particularly in the case of a woman with dense breasts on mammogram or high probability of breast cancer. Please refer to Chapter 13 for more information on breast MRI.

BASIC STAGING FOR SYSTEMIC DISEASE (BONE SCAN, LIVER ULTRASOUND, AND CHEST X-RAY)

The scarce data available regarding staging practices in the Unites States reveal that approximately 88% of physicians routinely order staging chest x-rays for all newly diagnosed breast cancer patients, and 39% routinely order bone scans (11). However, the evidence does not support this approach. A systematic review examined the utility of chest x-rays, bone scans, and liver ultrasounds in staging asymptomatic breast cancer patients who have just undergone breast surgery for clinical stage I–III disease (12). The results, among others, are summarized in Table 31-1 (12–16). Clearly, the yield of these staging procedures in uncovering metastatic disease is quite low, particularly in stage I and II disease, and especially when weighed against the risk of false positives, which often necessitate biopsies and provoke anxiety. In fact, when reported, the rate of false positives was far higher than the rate of true positives for all three staging examinations in stage I and II patients.

Based on the available data, routine staging for breast cancer patients with stage I and II disease with bone scan, chest x-ray, and liver ultrasound is not necessary, and it is more likely to lead to false positives than true positives.

CT SCAN

Although chest x-rays, bone scans, and liver ultrasounds clearly have limited utility in evaluation for metastatic disease in early stage patients, many practitioners more commonly use computed tomography (CT) scans of the chest

TABLE 31-1

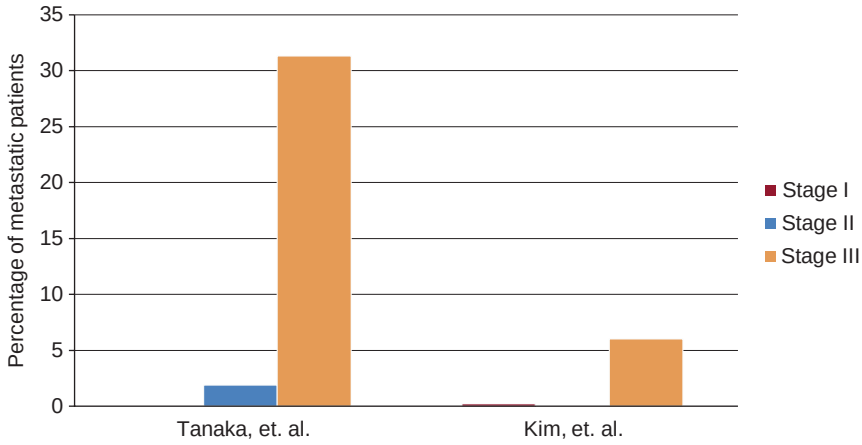

FIGURE 31-2 Metastatic discovery rate as discovered by CT scan. (Data from Tanaka S, Sato N, Fujioka H, et al. Use of contrast-enhanced computed tomography in clinical staging of asymptomatic breast cancer patients to detect asymptomatic distant metastases. *Oncology Letters*. (2012;3(4):772–776; Kim H, Han W, Moon H, et al. The value of preoperative staging chest computed tomography to detect asymptomatic lung and liver metastasis in patients with primary breast carcinoma. *Breast Cancer Res Treat*. 2011;126(3): 637–641.)

and abdomen to stage newly diagnosed breast cancer patients. Within a single institution, retrospective analysis of staging CTs among asymptomatic, newly diagnosed patients yielded newly discovered metastatic disease in 0% of stage I, 1.9% of stage II, and 31.3% of stage III breast cancer patients (17). Another single institution retrospective analysis revealed similar results. Among 1,703 asymptomatic, newly diagnosed breast cancer patients who had preoperative chest CTs that included the liver, 15.6% had an abnormality discovered in the lungs or liver although only 1.5% of the total patients had true metastases. The study did not state how many biopsies were performed for false-positive findings. True metastases were found in 0.2% of stage I patients, 0% of stage II patients; and 6% of stage III patients (18). Thus, there is utility in performing CT scan for stage III patients; however, the risks, including increased medical costs, radiation exposure, and potential for needless biopsies, likely outweigh the benefits in stage I and II patients (see Fig. 31-2). Special caution should be taken in appropriately staging new breast cancer patients.

PET SCAN AND PET/CT

2-18F-fluorodeoxyglucose (FDG) positron emission tomography (PET) scans are a somewhat controversial topic within breast cancer staging with new evidence still emerging. A recent prospective Canadian trial of 325 breast cancer patients evaluated PET scan for uncovering axillary lymph node metastases as well as distant metastases. Although PET scans had high specificity for axillary metastasis, the sensitivity was only 23.7%. Furthermore, PET scan uncovered 0.9% of patients with distant metastases and identified 3% of patients with false positives (19). Similarly, another prospective study showed that PET scan had only 61% sensitivity and 80% specificity for detecting axillary lymph node metastases (20). Clearly, current data suggest that PET scan does not have the necessary sensitivity in the axilla, or the specificity in the rest of the body, to be used as a reliable staging tool.

However, PET scan continues to be studied, and it may play a role in the future in a select subset of patients. For example, those with a higher pretest probability of having metastatic disease are more likely to have metastatic disease uncovered through PET scanning. One prospective study examined 48 women with locally advanced breast cancer (tumors greater than 5 cm, fixed axillary lymph nodes, or inflammatory breast cancer) who had been conventionally staged with chest x-ray, bone scan, and liver ultrasound, or CT scan of the chest and abdomen. Researchers discovered that among patients who had no evidence of metastatic disease on these examinations, 14 of 48 had abnormal FDG uptake, and metastases were suspected in 12 patients, or 25% of the study population. Of these, four patients (8.3%) were found to harbor true metastatic lesions (21). In this particular subset, there may be an advantage of PET scan in detecting occult metastatic disease, but this must be weighed against the risk of false positives that often provoke anxiety and prompt invasive biopsies.

Currently, however, PET/CT scanning is used much more commonly than routine PET scan. PET/CT scan combines PET scan and noncontrast CT scan, allowing for more precise correlation of increased metabolic activity with anatomic imaging. One recent study prospectively examined 103 women with newly diagnosed breast cancer with tumors ≥2 cm. All patients had routine examinations (physical examination, mammography, ultrasound of breast and axilla, chest x-ray, and blood parameters) as well as PET/CT prior to operation. PET/CT displayed a 63% sensitivity and a 97% specificity for axillary lymph node detection, and it was not able to detect any micrometastases. Perhaps most importantly, however, none of the axillary lymph node metastases were discovered only on PET/CT; routine staging examination uncovered all lymph node involvement prior to the surgery. However, PET/CT did identify six cases (5.8%) of distant metastatic cancer that would not have been discovered otherwise, and this information did prompt a change in management from adjuvant to metastatic approach. All six cases that proved to be metastatic on PET/CT scan initially had stage II disease. The PET/CT scan also uncovered two new primary malignancies (ovarian cancer and lung cancer) and seven patients who were found to have supraclavicular or internal mammary lymph nodes; however, management and staging of the breast cancer did not change for these nine patients. Essentially, in terms of breast cancer treatment, PET/CT prompted an important change in management in 5.8% of cases (22). However, it is unclear whether PET/CT scan was truly necessary to uncover these metastatic sites because CT scan may have potentially made the same discoveries, but none of the patients had CT scan prior to PET/CT in this study.

Based on a meta-analysis of five studies investigating both conventional imaging (chest x-ray, bone scan, ultrasound, and CT scans) and PET scans or PET/CT scans, the latter was found to have higher median sensitivity for axillary lymph node involvement and distant metastases at 98.7% as compared to conventional imaging sensitivity of 70%. However, specificity data were more variable for PET scanning (23). Consequently, the NCCN Task Force Report

on the use of PET/CT in cancer states that there is no role for PET/CT scan in detection of primary breast cancer, staging of the axilla, searching for distant metastatic disease, or performing posttreatment surveillance (24). Although further research is ongoing at this point, the authors also believe that PET and PET/CT scans should not routinely be used for staging newly diagnosed breast cancer patients at this point.

TUMOR MARKERS

Tumor markers that are sometimes elevated in breast cancer include CA 15-3, CA 27.29, and CEA. Although elevated levels of these markers at the time of breast cancer diagnosis have been shown to correlate with early relapse and death from disease, results have been somewhat conflicting (25–27). Thus, their use as a prognostic marker in the newly diagnosed breast cancer patient is debatable. More importantly, however, these markers have never been proven to be predictive of benefit from treatment. Because they are not likely to change treatment and their interpretation in the setting of early stage disease is unclear, serum breast cancer tumor markers are not recommended as part of routine staging for patients with stage I to III breast cancer (28).

CIRCULATING TUMOR CELLS

Circulating tumor cells (CTCs) may be found in the blood of some breast cancer patients at the time of diagnosis or at any point afterward. These CTCs are believed to represent very early hematogenous dissemination of cells from the breast cancer into the blood. Several methods may be used to enumerate CTCs, although one of the most commonly used methods, which the Food and Drug Administration has also approved, is the CellSearch method. In this method, 7.5 mL of blood is enriched for cells containing the epithelial cell adhesion molecule (CAM)® by using antibody-coated magnetic beads. Then the cells are selected for the ones that are nucleated and stain positive for cytokeratin but negative for CD45 (29). In this way, CTCs can be quantitated per 7.5 mL blood sample. Although baseline levels of circulating tumor cells have been proven to be prognostic for progression-free and overall survival in patients with metastatic breast cancer (30), their significance in early stage breast cancer is less clear. Approximately 10% to 24% of patients with nonmetastatic breast cancer have one or more circulating tumor cells in their blood prior to beginning systemic therapy (29,31). One prospective, single institution study examined 302 patients with stage I to III breast cancer at the time of definitive breast surgery. They found that 24% of patients had at least one circulating tumor cell per 7.5 mL of blood, and at a median follow-up of 35 months, which was associated with poorer progression-free survival (HR 4.62, 95% CI 1.79–11.9) and overall survival (HR 4.04, 95% CI 1.28–12.8) (29). Interestingly, no primary tumor characteristic, including tumor size or pathologic lymph node status, accurately correlated with presence of 1 or more circulating tumor cells. More CTCs had stronger correlation with poor prognosis. Three CTCs as compared to none yielded the sharpest difference in 3-year overall survival with 81% versus 99%. Only 5% of the patients in this study had ≥3 involved lymph nodes (29). Similarly, the SUCCESS trial showed poor prognosis for patients with the presence of circulating tumor cells in the blood at the time of surgery (33). Although CTC quantitation may offer prognostic information at the time of staging, the evidence does not support changing management as a result of baseline circulating tumor cells. In fact, an analysis of the GeparQuattro trial suggested that CTC decline from the time of diagnosis to the completion of neoadjuvant chemotherapy did not correlate with response (32). Thus, it is not recommended as part of routine staging for nonmetastatic breast cancer, and whether it can be used in the adjuvant or neoadjuvant settings to assess response to chemotherapy is not yet clear. See Chapter 30 for more details.

DISSEMINATED TUMOR CELLS

Disseminated tumor cells (DTCs) are cells that are genotypically and phenotypically similar to breast cancer stem cells; these cells are also sometimes called bone marrow micro-metastases. These DTCs are found in the bone marrow of 31% of stage I to III breast cancer patients, and it is associated with poorer overall survival and distant disease-free survival. Those who have DTCs are more likely to have tumors of larger size and higher grade as well as lymph node positivity. However, in multivariable analysis, the presence of DTCs was found to independently be a poor prognostic factor, which is associated with an increase by a factor of 1.93 (95% CI, 1.58–2.36, p value <.001) in death from breast cancer (34). When weighing the issues of cost as well as patient pain and inconvenience from bone marrow biopsy against the relative lack of predictive information provided by DTC enumeration, the procedure is not believed to be warranted in the routine staging of newly diagnosed breast cancer patients at this point.

A SPECIAL WORD ON HIGH-RISK POPULATIONS

Some populations may benefit from more aggressive staging because their pretest probability of metastatic disease is far higher than that of the average breast cancer patient. Patients with inflammatory breast cancer, for example, may be more likely to have metastatic disease discovered on PET scan. One retrospective study that investigated 40 women with unilateral inflammatory breast cancer found that 20 patients had metastatic disease discovered on PET/CT scan, and 7 of these were not known to have had metastatic disease prior to the PET/CT scan. However, of the 20 patients with metastatic disease uncovered on the PET/CT scan, only seven had biopsy confirmation of metastatic disease (35). In a prospective study, 59 women with inflammatory breast cancer were staged with PET/CT scan, and 18 of them (31%) were found to have distant metastatic disease although these metastases were not confirmed by tissue biopsy. Twelve of the patients had metastatic disease *confirmed* by conventional imaging (CT scan and bone scan) (36). Nonetheless, future study in this area may be interesting because women with inflammatory breast cancer tend to have FDG-avid disease, and they have a high probability of metastatic disease.

Similarly, women with four or more positive lymph nodes are much more likely than those with N0 or N1 disease to have distant metastatic disease (37). Staging procedures on these patients is more likely to produce true positives.

SOCIETAL RECOMMENDATIONS

The Cancer Care Ontario Practice Guidelines recommend no routine staging for stage I breast cancers; bone scan only for stage II breast cancer (chest x-ray and liver ultrasound may

be considered for patients with four or more positive lymph nodes); and bone scan, liver ultrasound, and chest x-ray for stage III patients (10). Likewise, the European Society of Medical Oncology (ESMO) recommends staging only with chest x-ray, bone scan, and abdominal ultrasound or CT if the patient has clinically positive axillary lymph nodes, tumor size >5 cm, or clinical signs suggestive of metastatic disease. The National Comprehensive Cancer Network (NCCN) guidelines for breast cancer state that routine baseline staging should be considered for stage IIIA (T3 N1 M0) disease. They recommend a chest CT, abdominal CT (or MRI with or without the pelvis included), and bone scan or fluoride PET/CT. FDG PET/CT is considered optional and is generally used as an adjunct when standard studies are ambiguous; this carries a level 2B recommendation. Furthermore, the NCCN recommends against the use of PET/CT scan for stage I to II patients (38).

MANAGEMENT SUMMARY

- All patient evaluations for breast cancer should begin with a thorough history and physical exam, including a complete review of systems as well as basic laboratory data.
- If the workup does not indicate possible metastatic disease, then surgery should be pursued.
- Those patients who are found to have stage I disease do not need staging examinations.
- Patients with pathologic stage II disease do not routinely need staging examinations. Those patients with multiple positive nodes and unfavorable tumor features may be considered for staging.
- Patients with stage III breast cancer do have a fairly high probability of metastatic disease, warranting the use of routine staging to include bone scan and CT of the chest, abdomen, and pelvis.
- Certain patients with high-risk tumors, such as those with inflammatory breast cancer, may benefit from aggressive preoperative staging, including PET/CT scan.
- PET/CT scans are still being studied for breast cancer staging and should not be routinely used at this point.
- Tumor markers, circulating tumor cells, and disseminated tumor cells should not be used in the staging of newly diagnosed, nonmetastatic breast cancer patients.

CHAPTER 32

Staging of Breast Cancer

Jay R. Harris

CHAPTER CONTENTS

Staging refers to the grouping of patients according to the extent of their disease. Staging is useful in (a) estimating prognosis for an individual patient, (b) comparing the results of different treatment programs, and (c) it may help in selecting treatment for an individual patient. Staging can be based on either clinical or pathologic findings. The staging of cancer is determined by the American Joint Committee on Cancer (AJCC). The AJCC comprises six founding organizations, four sponsoring organizations, and seven liaison organizations. Membership is reserved for those organizations whose missions or goals are consistent with, or complementary to, those of the AJCC. The founding organizations include the American Cancer Society, the American College of Surgeons, the American Society of Clinical Oncology, Centers for Disease Control and Prevention, National Cancer Institute, and the College of American Pathologists.

The AJCC staging system provides a strategy for grouping patients with respect to prognosis. The AJCC system uses the TNM classification where **T** describes the size of the primary and whether it has invaded nearby tissue, **N** describes the nearby (regional) that are involved, and **M** describes distant metastases. However, TNM staging, while still important, has been superseded by rapidly evolving molecular characterizations of breast cancers, which more precisely define subgroups with different outcomes, both in terms of prognosis and response to specific treatments. Therapeutic decisions are now formulated in part according to staging categories, but primarily according to tumor size and grade, lymph node status, estrogen-receptor and progesterone-receptor levels in the tumor tissue, human epidermal growth factor receptor 2 (*HER2/neu*) status, menopausal status, and the general health of the patient. Since the last edition, the development and use of multi-gene diagnostic tests, such as Oncotype Dx® and MammaPrint®, have increased substantially and it is anticipated that there will be further developments along these lines.

Staging is still important to determine whether the patient is operable. Generally, any patient with Stage 3B (or 4) is not considered operable. Such patients are treated with initial systemic therapy, discussed in the chapter on locally-advanced and inflammatory breast cancer (Chapters 58 and 59).

The AJCC system is both a clinical and pathologic staging system and is based on the TNM system, in which "T" refers to tumor, "N" to nodes, and "M" to metastasis. The current version is the Seventh Edition of the system and is provided later in this chapter (1).

Pathologic staging can be performed in patients treated with initial definitive surgery or in patients treated with initial (pre-operative or neoadjuvant) systemic therapy followed by definitive surgery. The AJCC system details rules for classification, definition of the anatomy, and stage groups. It represents a significant change from the Sixth Edition, published in 2003. A summary of the changes is given below.

SUMMARY OF CHANGES

Tumor (T)

- Identified specific imaging modalities that can be used to estimate clinical tumor size, including mammography, ultrasound, and magnetic resonance imaging (MRI).
- Made specific recommendations that (i) the microscopic measurement is the most accurate and preferred method

to determine pT with a small invasive cancer that can be entirely submitted in one paraffin block, and (ii) the gross measurement is the most accurate and preferred method to determine pT with larger invasive cancers that must be submitted in multiple paraffin blocks.
- Made the specific recommendation to use the clinical measurement thought to be most accurate to determine the clinical T of breast cancers treated with neoadjuvant therapy. Pathologic (posttreatment) size should be estimated based on the best combination of gross and microscopic histological findings.
- Made the specific recommendation to estimate the size of invasive cancers that are unapparent to any clinical modalities or gross pathologic examination by carefully measuring and recording the relative positions of tissue samples submitted for microscopic evaluation and determining which contain tumor.
- Acknowledged "ductal intraepithelial neoplasia" (DIN) as uncommon, and still not widely accepted, terminology encompassing both DCIS and ADH, and clarification that only cases referred to as DIN containing DCIS (±ADH) are classified as Tis (DCIS).
- Acknowledged "lobular intraepithelial neoplasia" (LIN) as uncommon, and still not widely accepted, terminology encompassing both LCIS and ALH, and clarification that only cases referred to as LIN containing LCIS (±ALH) are classified as Tis (LCIS).
- Clarified that only Paget's disease NOT associated with an underlying noninvasive (that is, DCIS and/or LCIS) or invasive breast cancer should be classified as Tis (Paget's) and that Paget's disease associated with an underlying cancer be classified according to the underlying cancer (Tis, T1, and so on).
- Made the recommendation to estimate the size of noninvasive carcinomas (DCIS and LCIS), even though it does not currently change their T classification, because noninvasive cancer size may influence therapeutic decisions, acknowledging that providing a precise size for LCIS may be difficult.
- Acknowledged that the prognosis of microinvasive carcinoma is generally thought to be quite favorable, although the clinical impact of multifocal microinvasive disease is not well understood at this time.
- Acknowledged that it is not necessary for tumors to be in separate quadrants to be classified as multiple, simultaneous, ipsilateral carcinomas, providing that they can be unambiguously demonstrated to be macroscopically distinct and measurable using available clinical and pathologic techniques.
- Maintained that the term "inflammatory carcinoma" be restricted to cases with typical skin changes involving a third or more of the skin of the breast. While the histologic presence of invasive carcinoma invading dermal lymphatics is supportive of the diagnosis, it is not required, nor is dermal lymphatic invasion without typical clinical findings sufficient for a diagnosis of inflammatory breast cancer.
- Recommend that all invasive cancer should be graded using the Nottingham combined histologic grade (Elston-Ellis modification of Scarff–Bloom–Richardson grading system).

Nodes (N)

- Classification of isolated tumor cell clusters and single cells is more stringent. Small clusters of cells not greater than 0.2 mm, or nonconfluent or nearly confluent clusters of cells not exceeding 200 cells in a single histologic lymph node cross section are classified as isolated tumor cells.
- Use of the (sn) modifier for sentinel node has been clarified and restricted. When six or more sentinel nodes are identified on gross examination of pathology specimens the (sn) modifier should be omitted.
- Stage I breast tumors have been subdivided into Stage IA and Stage IB; Stage IB includes small tumors (T1) with exclusively micrometastases in lymph nodes (N1mi).

Metastases (M)

- Created new M0(i+) category, defined by presence of either disseminated tumor cells detectable in bone marrow or circulating tumor cells or found incidentally in other tissues (such as ovaries removed prophylactically) if not exceeding 0.2 mm. However, this category does not change the stage grouping. Assuming that they do not have clinically and/or radiographically detectable metastases, patients with M0(i+) are staged according to T and N.

Postneoadjuvant Therapy (yc or ypTNM)

- In the setting of patients who received neoadjuvant therapy, pretreatment clinical T (cT) should be based on clinical or imaging findings.
- Postneoadjuvant therapy T should be based on clinical or imaging (ycT) or pathologic findings (ypT).
- A subscript will be added to the clinical N for both node negative and node positive patients to indicate whether the N was derived from clinical examination, fine-needle aspiration, core needle biopsy, or sentinel lymph node biopsy.
- The posttreatment ypT will be defined as the largest contiguous focus of invasive cancer as defined histopathologically with a subscript to indicate the presence of multiple tumor foci. *Note:* Definition of posttreatment ypT remains controversial and an area in transition.
- Posttreatment nodal metastases no greater than 0.2 mm are classified as ypN0(i+) in patients who have not received neoadjuvant systemic therapy. However, patients with this finding are not considered to have achieved a pathologic complete response (pCR).
- A description of the degree of response to neoadjuvant therapy (complete, partial, no response) will be collected by the registrar with the posttreatment ypTNM. The registrars are requested to describe how they defined response (by physical examination, imaging techniques [mammogram, ultrasound, magnetic resonance imaging (MRI)] or pathologically).
- Patients will be considered to have M1 (and therefore Stage IV) breast cancer if they have had clinically or radiographically detectable metastases, with or without biopsy, prior to neoadjuvant systemic therapy, regardless of their status after neoadjuvant systemic therapy. (Tables 32-1 through 32-5)

INTRODUCTION TO THE STAGING SYSTEM

This staging system for carcinoma of the breast applies to infiltrating (including microinvasive) and *in situ* carcinomas. Microscopic confirmation of the diagnosis is mandatory, and the histologic type and grade of carcinoma should be recorded.

Anatomy

Primary Site

The mammary gland, situated on the anterior chest wall, is composed of glandular tissue with a dense fibrous stroma. The glandular tissue consists of lobules that group together into 15 to 25 lobes arranged approximately in a spokelike

TABLE 32-1

Primary Tumor (T)[a]	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma *in situ*
Tis (DCIS)	DCIS
Tis (LCIS)	LCIS
Tis (Paget)	Paget's disease of the nipple NOT associated with invasive carcinoma and/or carcinoma *in situ* (DCIS and/or LCIS) in the underlying breast parenchyma. Carcinomas in the breast parenchyma associated with Paget's disease are categorized based on the size and characteristics of the parenchymal disease, although the presence of Paget's disease should still be noted.
T1	Tumor ≤20 mm in greatest dimension
T1mi	Tumor ≤1 mm in greatest dimension
T1a	Tumor >1 mm but ≤5 mm in greatest dimension
T1b	Tumor >5 mm but ≤10 mm in greatest dimension
T1c	Tumor >10 mm but ≤20 mm in greatest dimension
T2	Tumor >20 mm but ≤50 mm in greatest dimension
T3	Tumor >50 mm in greatest dimension
T4	Tumor of any size with direct extension to the chest wall and/or to the skin (ulceration or skin nodules)[b]
T4a	Extension to the chest wall, not including only pectoralis muscle adherence/invasion
T4b	Ulceration and/or ipsilateral satellite nodules and/or edema (including peau d'orange) of the skin, which do not meet the criteria for inflammatory carcinoma
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma

DCIS, ductal carcinoma in situ; LCIS, lobular carcinoma in situ.
[a]The T classification of the primary tumor is the same regardless of whether it is based on clinical or pathologic criteria, or both. Size should be measured to the nearest millimeter. If the tumor size is slightly less than or greater than a cutoff for a given T classification, it is recommended that the size be rounded to the millimeter reading that is closest to the cutoff. For example, a reported size of 1.1 mm is reported as 1 mm, or a size of 2.01 cm is reported as 2.0 cm. Designation should be made with the subscript "c" or "p" modifier to indicate whether the T classification was determined by clinical (physical examination or radiologic) or pathologic measurements, respectively. In general, pathologic determination should take precedence over clinical determination of T size.
[b]Invasion of the dermis alone does not qualify as T4.

pattern. Multiple major and minor ducts connect the milk-secreting lobular units to the nipple. Small milk ducts course throughout the breast, converging into larger collecting ducts that open into the lactiferous sinus at the base of the nipple. Most cancers form initially in the terminal duct lobular units of the breast. Glandular tissue is more abundant in the upper, outer portion of the breast; as a result, half of all breast cancers occur in this area.

Chest Wall

The chest wall includes ribs, intercostal muscles, and serratus anterior muscle, but not the pectoral muscles.

Regional Lymph Nodes

The breast lymphatics drain by way of three major routes: axillary, transpectoral, and internal mammary. Intramammary lymph nodes are coded as axillary lymph nodes for staging purposes. Supraclavicular nodes (SCLNs) are classified as regional lymph nodes for staging purposes. Metastasis to any other lymph node, including cervical or contralateral internal mammary lymph nodes, is classified as distant (M1).

The regional lymph nodes are as follows:

1. Axillary (ipsilateral): interpectoral (Rotter's) nodes and lymph nodes along the axillary vein and its tributaries that may be (but are not required to be) divided into the following levels:
   a. Level I (low-axilla): lymph nodes lateral to the lateral border of pectoralis minor muscle.
   b. Level II (mid-axilla): lymph nodes between the medial and lateral borders of the pectoralis minor muscle and the interpectoral (Rotter's) lymph nodes.
   c. Level III (apical axilla): lymph nodes medial to the medial margin of the pectoralis minor muscle, including those designated as apical.
2. Internal mammary (ipsilateral): lymph nodes in the intercostal spaces along the edge of the sternum in the endothoracic fascia.
3. Supraclavicular: lymph nodes in the supraclavicular fossa, a triangle defined by the omohyoid muscle and tendon (lateral and superior border), the internal jugular vein (medial border), and the clavicle and subclavian vein (lower border). Adjacent lymph nodes outside of this triangle are considered to be lower cervical nodes (M1) (1).

Metastatic Sites

Tumor cells may be disseminated by either the lymphatic or the blood vascular system. The four major sites of involvement are bone, lung, brain, and liver, but tumor cells are also capable of metastasizing to many other sites.

Rules for Classification

Clinical Staging

Clinical staging includes physical examination, with careful inspection and palpation of the skin, mammary gland, and lymph nodes (axillary, supraclavicular, and cervical), imaging, and pathologic examination of the breast or other

TABLE 32-2

Regional Lymph Nodes (N)

	Clinical
NX	Regional lymph nodes cannot be assessed (e.g., previously removed)
N0	No regional lymph node metastases
N1	Metastases to movable ipsilateral level I, II axillary lymph node(s)
N2	Metastases in ipsilateral level I, II axillary lymph nodes that are clinically fixed or matted OR Metastases in clinically detected[a] ipsilateral internal mammary nodes in the *absence* of clinically evident axillary lymph node metastases
N2a	Metastases in ipsilateral level I, II axillary lymph nodes fixed to one another (matted) or to other structures
N2b	Metastases only in clinically detected[a] ipsilateral internal mammary nodes and in the *absence* of clinically evident level I, II axillary lymph node metastases
N3	Metastases in ipsilateral infraclavicular (level III axillary) lymph node(s) with or without level I, II axillary lymph node involvement OR Metastases in clinically detected[a] ipsilateral internal mammary lymph node(s) with clinically evident level I, II axillary lymph node metastases OR Metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastases in ipsilateral infraclavicular lymph node(s)
N3b	Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastases in ipsilateral supraclavicular lymph node(s)

[a]Clinically detected is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on fine-needle aspiration biopsy with cytologic examination. Confirmation of clinically detected metastatic disease by fine-needle aspiration without excision biopsy is designated with an (f) suffix, for example, cN3a(f). Excisional biopsy of a lymph node or biopsy of a sentinel node, in the absence of assignment of a pT, is classified as a clinical N, for example, cN1. Information regarding the confirmation of the nodal status will be designated in site-specific factors as clinical, fine-needle aspiration, core biopsy, or sentinel lymph node biopsy. Pathologic classification (pN) is used for excision or sentinel lymph node biopsy only in conjunction with a pathologic T assignment.

TABLE 32-3

Pathologic (pN)[a,b,c]

pNX	Regional lymph nodes cannot be assessed (e.g., previously removed or not removed for pathologic study)
pN0	No regional lymph node metastasis identified histologically
Note: ITCs are defined as small clusters of cells ≤0.2 mm, or single tumor cells, or a cluster of <200 cells in a single histologic cross-section. ITCs may be detected by routine histology or by IHC methods. Nodes containing only ITCs are excluded from the total positive node count for purposes of N classification but should be included in the total number of nodes evaluated.	
pN0(i–)	No regional lymph node metastases histologically, negative IHC
pN0(i+)	Malignant cells in regional lymph node(s) ≤0.2 mm (detected by H&E or IHC including ITC)
pN0(mol–)	No regional lymph node metastases histologically, negative molecular findings (RT-PCR)
pN0(mol+)	Positive molecular findings (RT-PCR), but no regional lymph node metastases detected by histology or IHC
pN1	Micrometastases OR Metastases in 1–3 axillary lymph nodes AND/OR Metastases in internal mammary nodes with metastases detected by sentinel lymph node biopsy but not clinically detected[b]
pN1mi	Micrometastases (>0.2 mm and/or >200 cells but none >2.0 mm)
pN1a	Metastases in 1–3 axillary lymph nodes, at least one metastasis >2.0 mm
pN1b	Metastases in internal mammary nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected[b]
pN1c	Metastases in 1–3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected

TABLE 32-3 *(Continued)*

Pathologic (pN)[a,b,c]	
pN2	Metastases in 4–9 axillary lymph nodes OR Metastases in clinically detected[b] internal mammary lymph nodes in the *absence* of axillary lymph node metastases
pN2a	Metastases in 4–9 axillary lymph nodes (at least 1 tumor deposit >2 mm)
pN2b	Metastases in clinically detected[c] internal mammary lymph nodes in the *absence* of axillary lymph node metastases
pN3	Metastases in ≥10 axillary lymph nodes OR Metastases in infraclavicular (level III axillary) lymph nodes OR Metastases in clinically detected[c] ipsilateral internal mammary lymph nodes in the *presence* of one or more positive level I, II axillary lymph nodes OR Metastases in >3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected[b] OR Metastases in ipsilateral supraclavicular lymph nodes
pN3a	Metastases in ≥10 axillary lymph nodes (at least 1 tumor deposit >2.0 mm) OR Metastases to the infraclavicular (level III axillary lymph) nodes
pN3b	Metastases in clinically detected[c] ipsilateral internal mammary lymph nodes in the *presence* of one or more positive axillary lymph nodes OR Metastases in >3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected[b]
pN3c	Metastases in ipsilateral supraclavicular lymph nodes

Posttreatment ypN

–Posttreatment yp "N" should be evaluated as for clinical (pretreatment) "N" methods above. The modifier "sn" is used only if a sentinel node evaluation was performed after treatment. If no subscript is attached, it is assumed that the axillary nodal evaluation was by AND.
–The X classification will be used (ypNX) if no yp posttreatment sn or AND was performed.
–N categories are the same as those used for pN.

AND, axillary node dissection; H&E, hematoxylin and eosin stain; IHC, immunohistochemical; ITC, isolated tumor cells; RT-PCR, reverse transcriptase/polymerase chain reaction.
[a]Classification is based on axillary lymph node dissection with or without sentinel lymph node biopsy. Classification based solely on sentinel lymph node biopsy without subsequent axillary lymph node dissection is designated (sn) for "sentinel node," for example, pN0(sn).
[b]"Not clinically detected" is defined as not detected by imaging studies (excluding lymphoscintigraphy) or not detected by clinical examination.
[c]"Clinically detected" is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on fine-needle aspiration biopsy with cytologic examination.

TABLE 32-4

Distant Metastases (M)	
M0	No clinical or radiographic evidence of distant metastases
cM0(i+)	No clinical or radiographic evidence of distant metastases, but deposits of molecularly or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue that are ≤0.2 mm in a patient without symptoms or signs of metastases
M1	Distant detectable metastases as determined by classic clinical and radiographic means and/or histologically proven >0.2 mm

Posttreatment yp M classification. The M category for patients treated with neoadjuvant therapy is the category assigned in the clinical stage, prior to initiation of neoadjuvant therapy. Identification of distant metastases after the start of therapy in cases where pretherapy evaluation showed no metastases is considered progression of disease. If a patient was designated to have detectable distant metastases (M1) before chemotherapy, the patient will be designated as M1 throughout.

TABLE 32-5

Anatomic Stage/Prognostic Groups[a,b]

Stage	*T*	*N*	*M*
0	Tis	N0	M0
IA	T1[a]	N0	M0
IB	T0	N1mi	M0
	T1[b]	N1mi	M0
IIA	T0	N1[b]	M0
	T1[a]	N1[b]	M0
	T2	N0	M0
IIB	T2	N1	M0
	T3	N0	M0
IIIA	T0	N2	M0
	T1[a]	N2	M0
	T2	N2	M0
	T3	N1	M0
	T3	N2	M0
IIIB	T4	N0	M0
	T4	N1	M0
	T4	N2	M0
IIIC	Any T	N3	M0
IV	Any T	Any N	M1

[a]T1 includes T1mi.
[b]T0 and T1 tumors with nodal micrometastases only are excluded from Stage IIA and are classified Stage IB.
–M0 includes M0(i+).
–The designation pM0 is not valid; any M0 should be clinical.
–If a patient presents with M1 prior to neoadjuvant systemic therapy, the stage is considered Stage IV and remains Stage IV regardless of response to neoadjuvant therapy.
–Stage designation may be changed if postsurgical imaging studies reveal the presence of distant metastases, provided that the studies are carried out within 4 months of diagnosis in the absence of disease progression and provided that the patient has not received neoadjuvant therapy.
–Postneoadjuvant therapy is designated with "yc" or "yp" prefix. Of note, no stage group is assigned if there is a complete pathologic response (CR) to neoadjuvant therapy, for example, ypT0ypN0cM0.

tissues as appropriate to establish the diagnosis of breast carcinoma. The extent of tissue examined pathologically for clinical staging is not so great as that required for pathologic staging (see next section, Pathologic Staging). Imaging findings are considered elements of staging if they are collected within 4 months of diagnosis in the absence of disease progression or through completion of surgery(ies), whichever is longer. Such imaging findings would include the size of the primary tumor and of chest wall invasion, and the presence or absence of regional or distant metastasis. Imaging findings and surgical findings obtained after a patient has been treated with neoadjuvant chemotherapy, hormonal therapy, immunotherapy, or radiation therapy are not considered elements of initial staging.

Pathologic Staging

Pathologic staging includes all data used for clinical staging, plus data from surgical exploration and resection as well as pathologic examination of the primary carcinoma, regional lymph nodes, and metastatic sites (if applicable), including not less than excision of the primary carcinoma with no macroscopic tumor in any margin of resection by pathologic examination. A cancer can be classified pT for pathologic stage grouping if there is only microscopic, but not macroscopic, involvement at the margin. If there is tumor in the margin of resection by macroscopic examination, the cancer is coded pTX because the total extent of the primary tumor cannot be assessed. If the primary tumor is invasive and not only microinvasive, resection of at least the low axillary lymph nodes (Level I)—that is, those lymph nodes located lateral to the lateral border of the pectoralis minor muscle—should be performed for pathologic (pN) classification. Such a resection ordinarily includes six or more lymph nodes. Alternatively, one or more sentinel lymph nodes may be resected and examined for pathologic classification. Certain histologic tumor types (pure tubular carcinoma <1 cm, pure mucinous carcinoma <1 cm, and microinvasive carcinoma) have a very low incidence of axillary lymph node metastasis and do not usually require an axillary lymph node dissection. Cancerous nodules in the axillary fat adjacent to the breast, without histologic evidence of residual lymph node tissue, are classified as regional lymph node metastases (N). Pathologic stage grouping includes any of the following combinations of pathologic and clinical classifications: pT pN pM, or pT pN cM, or cT cN pM. If surgery occurs after the patient has received neoadjuvant chemotherapy, hormonal therapy, immunotherapy, or radiation therapy, the prefix "y" should be used with the TNM classification (e.g., ypTNM).

TNM CLASSIFICATION

Primary Tumor (T)

Determining Tumor Size

The clinical measurement used for classifying the primary tumor (T) is the one judged to be most accurate for that particular case (i.e., physical examination or imaging such as mammography or ultrasonography). The pathologic tumor size for the T classification is a measurement of *the invasive component only*. For example, if there is a 4.0-cm intraductal component and a 0.3-cm invasive component, the tumor is classified T1a. The size of the primary tumor is measured for T classification before any tissue is removed for special studies, such as for estrogen receptors. In patients who have received multiple core biopsies, measuring only the residual lesion may result in significantly underclassifying the T component and thus understaging the tumor. In such cases, original tumor size should be reconstructed on the basis of a combination of imaging and all histologic findings.

Tis Classification

Carcinoma *in situ,* with no evidence of an invasive component, is classified as Tis, with a subclassification indicating type. Cases of ductal carcinoma *in situ* and cases with both ductal carcinoma *in situ* (DCIS) and lobular carcinoma *in situ* (LCIS) are classified Tis. LCIS is increasingly defined as a risk factor for subsequent breast cancer, although there is some evidence that it may occasionally be a precursor of invasive lobular carcinoma. For example, this may be the case with LCIS with more atypical cytology (pleomorphic), as well as more extensive and locally distorting examples of well-developed LCIS. Regardless of this controversy, LCIS is reported as a malignancy by national database registrars and should be designated as such in this classification system (e.g., Tis [LCIS]). Paget's disease of the nipple without an associated tumor mass (clinical) or invasive carcinoma (pathologic) is classified Tis (Paget's). Paget's disease with a demonstrable mass (clinical) anywhere in that breast or an invasive component (pathologic) is classified according to the size of the tumor mass or invasive component.

Microinvasion of Breast Carcinoma

Microinvasion is the extension of cancer cells beyond the basement membrane into the adjacent tissues with no focus more than 0.1 cm in greatest dimension. When there are multiple foci of microinvasion, the size of only the largest focus is used to classify the microinvasion. (Do not use the sum of all the individual foci.) The presence of multiple foci of microinvasion should be noted or quantified, as it is with multiple larger invasive carcinomas.

Multiple Simultaneous Ipsilateral Primary Carcinomas

The following guidelines are used in classifying multiple simultaneous ipsilateral primary (infiltrating, macroscopically measurable) carcinomas. These criteria do not apply to one macroscopic carcinoma associated with multiple separate microscopic foci. Most conservatively, tumors are defined as arising independently only if they occur in different quadrants of the breast.

1. Use the largest primary carcinoma to designate T classification. Do not assign a separate T classification for the smaller tumor(s).
2. Enter into the record that this is a case of multiple simultaneous ipsilateral primary carcinomas. The outcome of such cases should be analyzed separately.

Simultaneous Bilateral Breast Carcinomas

Each carcinoma is staged as a separate primary carcinoma in a separate organ.

Inflammatory Carcinoma

Inflammatory carcinoma is a clinicopathologic entity characterized by diffuse erythema and edema (*peau d'orange*) of the breast, often without an underlying palpable mass. These clinical findings should involve most of the skin of the breast. Classically, the skin changes arise quickly in the affected breast. Thus, the term *inflammatory carcinoma* should not be applied to a patient with neglected locally advanced cancer of the breast presenting late in the course of her disease. On imaging, there may be a detectable mass and characteristic thickening of the skin over the breast. This clinical presentation is due to tumor emboli in dermal lymphatics, which may or may not be apparent on skin biopsy. The tumor of inflammatory carcinoma is classified T4d. It is important to remember that inflammatory carcinoma is primarily a clinical diagnosis. Involvement of the dermal lymphatics alone does not indicate inflammatory carcinoma in the absence of clinical findings. In addition to the clinical picture, however, a biopsy is still necessary to demonstrate cancer either in the dermal lymphatics or in the breast parenchyma itself.

Skin of Breast

Dimpling of the skin, nipple retraction, or any other skin change except those described under T4b and T4d may occur in T1, T2, or T3 without changing the classification.

Regional Lymph Nodes (N)

Macrometastasis

Cases in which regional lymph nodes cannot be assessed (previously removed or not removed for pathologic examination) are designated NX or pNX. Cases in which no regional lymph node metastasis is detected are designated N0 or pN0.

In patients who are clinically node positive, N1 designates metastasis to one or more movable ipsilateral axillary lymph nodes, N2a designates metastasis to axillary lymph nodes that are fixed to each other (matted) or to other structures, and N3a indicates metastasis to ipsilateral infraclavicular lymph nodes. Metastases to the ipsilateral internal mammary nodes are designated as N2b when they are detected by imaging studies (including computed tomography [CT] scan and ultrasonography, but excluding lymphoscintigraphy) or by clinical examination and when they do not occur in conjunction with metastasis to the axillary lymph nodes. Metastases to the ipsilateral internal mammary nodes are designated as N3b when they are detected by imaging studies or by clinical examination and when they occur in conjunction with metastasis to the axillary lymph nodes. Metastases to the ipsilateral SCLNs are designated as N3c regardless of the presence or absence of axillary or internal mammary nodal involvement.

In patients who are pathologically node positive with one or more tumor deposits greater than 2 mm, cases with 1 to 3 positive axillary lymph nodes are classified pN1a, cases with 4 to 9 positive axillary lymph nodes are classified pN2a, and cases with 10 or more positive axillary lymph nodes are classified pN3a. Cases with histologically confirmed metastasis to the internal mammary nodes, detected by sentinel lymph node dissection but not by imaging studies (excluding lymphoscintigraphy) or clinical examination, are classified as pN1b if occurring in the *absence* of metastasis to the axillary lymph nodes and as pN1c if occurring in the *presence* of metastases to one to three axillary lymph nodes. (If four or more axillary lymph nodes are involved, the classification pN3b is used.) Clinical involvement with histologic confirmation of the internal mammary nodes by imaging studies (excluding lymphoscintigraphy) in the absence or presence of axillary nodal metastases are classified as pN2b and pN3b, respectively. Histologic evidence of metastasis in ipsilateral SCLNs is classified as pN3c. A classification of pN3, regardless of primary tumor size or grade, is classified as stage IIIc. A case in which the classification is based only on sentinel lymph node dissection is given the additional designation (sn) for "sentinel node"—for example, pN1(sn). For a case in which an initial classification is based on a sentinel lymph node dissection but a standard axillary lymph node dissection is subsequently performed, the classification is based on the total results of the axillary lymph node dissection (i.e., including the sentinel node).

Isolated Tumor Cells and Micrometastases

Isolated tumor cells (ITCs) are defined as single cells or small clusters of cells not greater than 0.2 mm in largest dimension, usually with no histologic evidence of malignant activity (such as proliferation or stromal reaction). If an additional immunohistochemistry (IHC) examination was made for ITCs in a patient with histologically negative lymph nodes, the regional lymph nodes should be designated as pN0(i–) or pN0(i+), as appropriate.

Micrometastases are defined as tumor deposits greater than 0.2 mm but not greater than 2.0 mm in largest dimension that may have histologic evidence of malignant activity (such as proliferation or stromal reaction). Cases in which only micrometastases are detected (none greater than 2 mm) are classified pN1mi. The classification is designated as (i+) for "immunohistochemical" if micrometastasis was detected only by IHC (e.g., pN1mi (i+)).

If histologically and immunohistochemically negative lymph nodes are examined for evidence of metastasis using molecular methods (reverse transcriptase polymerase chain reaction [RT-PCR]), the regional lymph nodes are classified as pN0(mol–) or pN0(mol+), as appropriate.

Distant Metastasis (M)

Cases in which distant metastasis cannot be assessed are designated MX, cases in which there is no distant metastasis are designated M0, and cases in which one or more distant metastases are identified are designated M1. A negative clinical history and examination are sufficient to designate a case as M0; extensive imaging or other testing is not required. Note that positive SCLNs are now classified as N3 rather than M1.

DEFINITION OF TNM

Primary Tumor (T)

Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, or T3). If other measurements, such as mammographic or pathologic measurements, are used, the subsets of T1 can be used. Tumors should be measured to the nearest 0.1-cm increment.

TX Primary tumor cannot be assessed
T0 No evidence of primary tumor
Tis Carcinoma *in situ*
Tis (DCIS) Ductal carcinoma *in situ*
Tis (LCIS) Lobular carcinoma *in situ*
Tis (Paget's) Paget's disease of the nipple with no tumor

Note: Paget's disease associated with a tumor is classified according to the size of the tumor.

T1 Tumor 2 cm or less in greatest dimension
T1mic Microinvasion 0.1 cm or less in greatest dimension
T1a Tumor more than 0.1 cm but not more than 0.5 cm in greatest dimension
T1b Tumor more than 0.5 cm but not more than 1 cm in greatest dimension
T1c Tumor more than 1 cm but not more than 2 cm in greatest dimension
T2 Tumor more than 2 cm but not more than 5 cm in greatest dimension
T3 Tumor more than 5 cm in greatest dimension
T4 Tumor of any size with direct extension to (a) chest wall or (b) skin, only as described below
T4a Extension to chest wall, not including pectoralis muscle
T4b Edema (including *peau d'orange*) or ulceration of the skin of the breast, or satellite skin nodules confined to the same breast
T4c Both T4a and T4b
T4d Inflammatory carcinoma

Regional Lymph Nodes (N)

Clinical

NX Regional lymph nodes cannot be assessed (e.g., previously removed)
N0 No regional lymph node metastasis
N1 Metastasis to movable ipsilateral axillary lymph node(s)
N2 Metastases in ipsilateral axillary lymph nodes fixed or matted, or in clinically apparent ipsilateral internal mammary nodes in the *absence* of clinically evident axillary lymph node metastasis
N2a Metastasis in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures
N2b Metastasis only in clinically apparent* ipsilateral internal mammary nodes and in the *absence* of clinically evident axillary lymph node metastasis
N3 Metastasis in ipsilateral infraclavicular lymph node(s) with or without axillary lymph node involvement, or in clinically apparent* ipsilateral internal mammary lymph node(s) and in the *presence* of clinically evident axillary lymph node metastasis; or metastasis in ipsilateral SCLNs with or without axillary or internal mammary lymph node involvement
N3a Metastasis in ipsilateral infraclavicular lymph node(s)
N3b Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c Metastasis in ipsilateral SCLNs

Pathologic (pN)†

pNX Regional lymph nodes cannot be assessed (e.g., previously removed, or not removed for pathologic study)
pN0 No regional lymph node metastasis histologically, no additional examination for ITC

Note: ITC are defined as single tumor cells or small cell clusters not greater than 0.2 mm, usually detected only by IHC or molecular methods but which may be verified on H&E stains. ITCs do not usually show evidence of malignant activity (e.g., proliferation or stromal reaction).

PN0(i–) No regional lymph node metastasis histologically, negative IHC
PN0(i+) No regional lymph node metastasis histologically, positive IHC, no IHC cluster greater than 0.2 mm
PN0(mol–) No regional lymph node metastasis histologically, negative molecular findings (RT-PCR)‡
PN0(mol+) No regional lymph node metastasis histologically, positive molecular findings (RT-PCR)‡
PN1 Metastasis in one to three axillary lymph nodes, or in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent
PN1mi Micrometastasis (greater than 0.2 mm, none greater than 2.0 mm)
PN1a Metastasis in one to three axillary lymph nodes
PN1b Metastasis in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent*
PN1c Metastasis in one to three axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent.* (If associated with greater than three positive axillary lymph nodes, the internal mammary nodes are classified as pN3b to reflect increased tumor burden.)
pN2 Metastasis in four to nine axillary lymph nodes, or in clinically apparent internal mammary lymph nodes in the *absence* of axillary lymph node metastasis
pN2a Metastasis in four to nine axillary lymph nodes (at least one tumor deposit greater than 2.0 mm)
pN2b Metastasis in clinically apparent† internal mammary lymph nodes in the absence of axillary lymph node metastasis

*_Clinically apparent_ is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination or grossly visible pathologically.
†Classification is based on axillary lymph node dissection with or without sentinel lymph node dissection. Classification based solely on sentinel lymph node dissection without subsequent axillary lymph node dissection is designated (sn) for "sentinel node," e.g., pN0(i+)(sn).
‡RT-PCR, reverse transcriptase/polymerase chain reaction.

pN3 Metastasis in 10 or more axillary lymph nodes, or in infraclavicular lymph nodes, or in clinically apparent† ipsilateral internal mammary lymph nodes in the *presence* of 1 or more positive axillary lymph nodes; or in more than 3 axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes; or in ipsilateral SCLNs

pN3a Metastasis in 10 or more axillary lymph nodes (at least one tumor deposit greater than 2.0 mm), or metastasis to the infraclavicular lymph nodes

pN3b Metastasis in clinically apparent† ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes; or in more than three axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent*

pN3c Metastasis in ipsilateral SCLNs

Distant Metastasis (M)

MX Distant metastasis cannot be assessed
M0 No distant metastasis
M1 Distant metastasis

STAGE GROUPING

Stage 0	Tis	N0	M0
Stage I	T1†	N0	M0
Stage IIA	T0	N1	M0
	T1†	N1	M0
	T2	N0	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
Stage IIIA	T0	N2	M0
	T1†	N2	M0
	T2	N2	M0
	T3	N1	M0
	T3	N2	M0
Stage IIIB	T4	N0	M0
	T4	N1	M0
	T4	N2	M0
Stage IIIC	Any T	N3	M0
Stage IV	Any T	Any N	M1

Note: Stage designation may be changed if postsurgical imaging studies reveal the presence of distant metastases, provided that the studies are carried out within 4 months of diagnosis in the absence of disease progression and provided that the patient has not received neoadjuvant therapy.

Clinically apparent is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.
†T1 includes T1mic

HISTOPATHOLOGIC TYPE

The histopathologic types are the following:

In Situ Carcinomas

NOS (not otherwise specified)
Intraductal
Paget's disease and intraductal

Invasive Carcinomas

NOS
Ductal
Inflammatory
Medullary, NOS
Medullary with lymphoid stroma
Mucinous
Papillary (predominantly micropapillary pattern)
Tubular
Lobular
Paget's disease and infiltrating
Undifferentiated
Squamous cell
Adenoid cystic
Secretory
Cribriform

HISTOLOGIC GRADE (G) (NOTTINGHAM COMBINED HISTOLOGIC GRADE IS RECOMMENDED)

All invasive breast carcinomas with the exception of medullary carcinoma should be graded. The Nottingham combined histologic grade (Elston-Ellis modification of Scarff-Bloom-Richardson grading system) is recommended. The grade for a tumor is determined by assessing morphologic features (tubule formation, nuclear pleomorphism, and mitotic count), assigning a value of 1 (favorable) to 3 (unfavorable) for each feature, and adding together the scores for all three categories. A combined score of 3 to 5 points is designated as grade 1; a combined score of 6 or 7 points is grade 2; a combined score of 8 or 9 points is grade 3.

GX Grade cannot be assessed
G1 Low combined histologic grade (favorable)
G2 Intermediate combined histologic grade (moderately favorable)
G3 High combined histologic grade (unfavorable)

These tentative observations, coupled with the overall sparseness and variability of the information, strongly suggest that the available data are not yet mature enough to offer guidance in incorporating histologic grade into the staging system for breast cancer. Because the evidence indicating that histologic grade is an important prognostic factor in breast cancer is so robust, it seems certain that emerging data will support the incorporation of grade into the AJCC staging system in the near future.

CHAPTER 33

Mastectomy

Monica Morrow and Mehra Golshan

CHAPTER CONTENTS

HISTORY OF MASTECTOMY

The origin of the word *mastectomy* is the Greek term *mastos*, meaning the breast. Over the past century, the procedure has evolved considerably from the initial descriptions by Halsted and Meyer in the mid-1890s. In 1894, William Stewart Halsted published the Johns Hopkins Hospital experience with radical mastectomy, reporting a remarkable local regional control rate of 73% with no operative mortality (1). The actuarial survival rate was double that of untreated patients, with a 5-year survival rate of 40%, despite the advanced stage of many of the tumors and the lack of any adjuvant therapy. At that time, the success of the procedure was attributed to the en bloc removal of the breast and its draining lymphatics, and, after this report, the radical mastectomy remained the standard of care until the 1970s.

It eventually became apparent that the radical mastectomy failed to cure many women with breast cancer, and this was attributed by some to its failure to include all of the draining lymphatics of the breast in the en bloc resection. The extended radical mastectomy, which included the en bloc resection of the internal mammary nodes and the medial ribs, was developed to address this issue. After a randomized trial failed to demonstrate a survival benefit for this more morbid procedure (2), it was abandoned. The adoption of the modified radical mastectomy, a term used to describe a variety of surgical procedures that included removal of the entire breast and the axillary nodes but not the pectoralis major muscle, represented a major departure from the Halstedian principles of en bloc cancer surgery. Only 2 relatively small randomized trials directly compared radical and modified radical mastectomy, and neither found a survival difference. The major impetus for abandoning radical mastectomy was the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-04 trial. This study randomized clinical node negative women to radical mastectomy, simple mastectomy with node field irradiation, or simple mastectomy with no axillary surgery and delayed axillary dissection if clinical axillary metastases developed. After 25 years of follow-up, no survival differences have ever been apparent between treatments (3). Remarkably, in this trial done prior to the use of any adjuvant systemic therapy, although 40% of patients in the radical mastectomy group had axillary nodal metastases, only 18.5% of those randomized to the simple mastectomy and axillary observation group developed axillary first failure. This trial was a watershed in our understanding of the biology of breast cancer and paved the way for trials of breast-conserving therapy (Chapter 35), the use of immediate breast reconstruction (Chapter 36), and, ultimately, abandonment of axillary dissection in patients with a positive sentinel node undergoing breast-conservation therapy (Chapter 37).

PATIENT SELECTION AND CRITERIA FOR INOPERABILITY

Patient evaluation and relative and absolute contraindications to breast-conserving therapy necessitating mastectomy are discussed in detail in Chapter 35. Briefly, contraindications result from the inability to reduce the tumor burden to a microscopic level, where it is likely to be controlled by radiotherapy, and the inability to safely deliver radiotherapy. Thus, multicentric disease, extensive malignant-appearing microcalcifications, and inability to obtain negative margins are contraindications related to disease burden, while a history of prior irradiation to the breast region and early pregnancy are contraindications related to the inability to safely irradiate the patient. Most women with stage 1 and 2 breast cancer are candidates for breast conservation. In a population-based study of 1,984 women treated in 2005–2006, 13% were felt to have contraindications to breast conservation, and 9% attempted lumpectomy but were converted to mastectomy. Additionally, 9% of women opted to undergo mastectomy in the absence of contraindications to breast conservation (4). Mastectomy today refers to total or complete mastectomy, with axillary staging with sentinel node biopsy in the clinically node-negative patient, or needle biopsy in the patient with clinically suspicious nodes. Mastectomy with axillary dissection is termed modified radical mastectomy. There are virtually no indications for radical mastectomy as an initial management approach to breast cancer at this time. However, there are some patients whose disease is too advanced to be approached with any

type of mastectomy as initial therapy, and would be treated with drug therapy and/or radiation first.

Criteria for inoperability were described by Haagensen in 1943 based on outcomes of patients treated between 1915 and 1935 (5) and remain surprisingly relevant today. They include inflammatory carcinoma, satellite skin nodules, extensive edema of the skin of the breast, ulceration, and fixation of the tumor to the boney chest wall. Edema of the ipsilateral arm, fixed axillary nodes, and supraclavicular metastases are all indications of inoperable nodal disease. Inoperability is readily apparent based on a physical examination. Patients with small areas of skin ulceration due to very superficial tumors are not uniformly inoperable. Involvement of the pectoralis major by tumor is not an indication of inoperability, nor is it incorporated in the TNM staging system. In practice, there is no indication today for resection of the pectoralis major (radical mastectomy) as a primary surgical approach. Patients with large tumors involving a substantial amount of the pectoral muscle should be treated with neoadjuvant therapy, as should patients with classic signs of inoperability (see Chapter 58, Locally Advanced Breast Cancer). In contrast, patients with T1 and T2 tumors located posteriorly in the breast do not a priori require neoadjuvant therapy because they appear to abut the pectoral muscle and may be treated with mastectomy or breast conservation. If a tumor involves the pectoral muscle at surgery, a piece of the muscle can be removed to obtain an adequate margin. Patients presenting with distant metastases and an intact primary tumor are not offered initial local therapy, but may be treated surgically if they have a limited number of metastatic sites and a good response to systemic therapy. This controversial area is discussed in detail in Chapter 68.

Current Technique

Approaches to mastectomy currently in use include total or simple mastectomy, skin-sparing total mastectomy to facilitate immediate breast reconstruction, and nipple sparing mastectomy. The approach to the axilla is independent of the type of mastectomy performed and is discussed in detail in Chapters 37 and 38. The total mastectomy procedure includes the removal of the entire mammary gland, with dissection extending superiorly to the clavicle, inferiorly to the rectus sheath insertion, medially to the sternal border, and laterally to the latissimus dorsi muscle. When axillary dissection is not performed, care must be taken to remove the entire axillary tail of the breast by extending the dissection superiorly along both the pectoralis minor and the latissimus dorsi muscles until the axillary investing fascia is entered or the sentinel node biopsy cavity is encountered. The posterior boundary of the dissection is the pectoralis major fascia. This fascia was initially thought to be an anatomic barrier to the lymphatic spread of cancer, a concept now recognized to be invalid since lymphatics penetrate the fascia, but the fascia may be preserved to facilitate expander/implant reconstruction. The flap thickness should result in removal of all of the breast parenchyma while leaving a layer of subcutaneous fat and superficial vasculature to minimize the risk of necrosis (Fig. 33-1). The flap thickness will vary with the amount of subcutaneous fat and surgical technique; however, flaps thicker than 5 mm are associated with significant residual glandular breast tissue (6).

Unfortunately, no reliable technique allows for intraoperative assessment of flap thickness. Flaps can be raised with the knife, scissor, or electrocautery, and there is no evidence of superiority of one technique. Some groups advocate the use of breast tumescence (a combination of lactated ringers and lidocaine/marcaine with epinephrine) to minimize

FIGURE 33-1 Flap thickness at the time of a modified radical mastectomy.

the blood loss seen with sharp dissection. Advocates of this approach believe it minimizes thermal damage to the flap, although data on its benefits and complications are sparse (Fig. 33-2). When immediate reconstruction is not performed, the goal is to remove the breast and its excess skin so the chest wall is flat without redundant skin. A smooth chest wall surface helps to facilitate an appropriate fit for a breast prosthesis. In addition, redundant skin is difficult to care for and becomes scarred to the chest wall, so it is not useful for delayed reconstruction. Incision placement should be determined by the shape of the breast, and extending incisions medially to where they are visible in clothing is unnecessary. Transverse incisions are associated with a lower rate of skin necrosis than vertical ones. In general, the pectoralis minor muscle should be preserved. Division of its tendon facilitates access to level III lymph nodes when there is extensive axillary disease, and the muscle may be resected in the case of a bulky adherent tumor, although in the era of neoadjuvant therapy, this scenario is uncommon.

Mastectomy is an extremely safe operation that can be performed on women of all ages and on those with significant co-morbidities with a low risk of operative mortality. In a United States Department of Veterans Affairs study of 408 patients undergoing mastectomy, 73% of whom were age 50 years or older, the 30-day operative mortality rate and rate

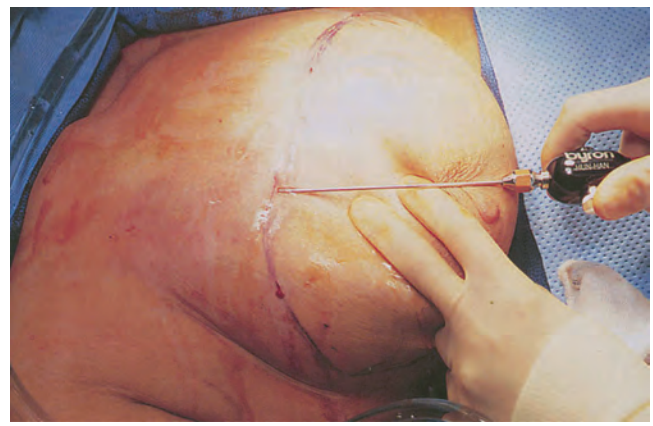

FIGURE 33-2 Tumescent injection to reduce bleeding and facilitate knife dissection.

of operation-related readmissions were both less than 1% (7). The most common complications perioperatively were superficial wound infections, seen in 6% of patients. The National Surgical Quality Improvement Program's (NSQIP) Patient Safety in Surgery study collected data on breast surgery from 14 universities and 4 community centers. The mastectomy mortality rate was 0.24%, and the 30-day morbidity rate was 5.7% with a 3.6% incidence of wound complications (8). Factors that predispose to infection include the use of a two-step procedure (i.e., initial surgical biopsy or attempted lumpectomy) and prolonged suction catheter drainage. Early infections present as cellulitis, whereas those occurring later present as abscess. *Streptococcus* and *staphylococcus aureus* are the most common etiologic organisms. Because the incidence of infection after mastectomy is so low, the cost effectiveness of routine prophylactic antibiotic use is uncertain, although Platt et al. (9) did demonstrate that a single dose of preoperative cephalosporin reduced the incidence of infection by 38%. Antibiotics are routinely given to patients having immediate reconstruction and those who have had prior open surgery. Seroma formation is a universal occurrence after mastectomy and should not be considered a complication; drains are routinely placed to allow fusion of the dermal layer to the chest wall. Flap necrosis has become less common as abandonment of the Halstedian concepts of breast cancer surgery meant that extremely thin skin flaps and removal of large amounts of skin were no longer felt to be important to cure of breast cancer. Most flap necrosis is partial thickness and occurs adjacent to the incision line (Fig. 33-3). Skin necrosis can be minimized by avoiding removal of the subcutaneous fat layer from the flaps, closure under tension, and pressure dressings, all of which decrease the already compromised blood supply to the skin. Postoperative phantom breast syndrome is well described and occurs in approximately 25% of women after mastectomy (10). Chronic pain was previously thought to be an uncommon sequelae of mastectomy, but prospective cohort studies suggest that this syndrome is seen in 40–50% of women (11,12). In one study, half of women who had postmastectomy pain in the early postop period had persistent pain a mean of 9 years after surgery (12). Young age is associated with a higher risk of postmastectomy pain syndrome in most studies. The pain is thought to be neuropathic in etiology, and the outcome of physical therapy and pharmacologic intervention has varied. Patients should be advised preoperatively that they will experience a loss of chest wall sensation with mastectomy, with return of a variable degree of feeling beginning about 1 year postoperatively.

FIGURE 33-3 Partial thickness flap necrosis adjacent to the incision line in a skin-sparing mastectomy. The eschar is beginning to separate.

Skin-Sparing Mastectomy

When immediate reconstruction is planned, a skin-sparing approach is preferred. First described by Toth and Lappert (13) in 1991, this procedure removes the nipple, areola, and the breast parenchyma, while maintaining the overlying breast skin as an envelope for the reconstruction. Traditionally, surgical biopsy scars have been removed because they are potentially contaminated with cancer cells. Whether this is necessary is uncertain. Since DCIS and stage 1 and 2 breast cancer are not diseases of the skin, skin-sparing mastectomy should not increase the rate of chest wall recurrence. However, it is technically more difficult to perform a mastectomy through a small skin-sparing incision, and care must be taken to ensure that tissue is removed to the standard anatomic limits of a mastectomy. Adequate exposure is gained through incision, rather than excision, of the skin. A 2012 meta-analysis compared rates of local recurrence after mastectomy and immediate reconstruction to rates of local recurrence after mastectomy alone in 3,710 patients, all from retrospective cohort studies. The odds ratio for local recurrence was 0.98 (95% CI, 0.62–1.54) (14). In studies specifically examining skin-sparing mastectomy for DCIS, reported rates of local recurrence range from 0 to 3.8% (15), similar to the 1.4% incidence reported for conventional mastectomy (16). Initial concerns that immediate breast reconstruction might impede the detection of local recurrence have not been proven to be true. The majority of local recurrences occur in the skin or subcutaneous fat, and their detection is not affected by the presence of an underlying reconstruction.

Nipple- or Areolar-Sparing Mastectomy

Nipple- and areolar-sparing mastectomy (NSM), also known as total skin-sparing mastectomy, has become increasingly popular due to the excellent cosmetic results that can be achieved in properly selected patients. The oncologic concerns raised by NSM include the possibility that occult cancer will be left behind in the nipple-areolar complex (NAC) and the need to leave behind some breast tissue beneath the NAC to provide a blood supply, raising the possibility that new cancers could develop in this tissue in the future. The reported rates of occult nipple involvement with cancer vary from 5% to 58% (17). This wide variation is secondary to differences in both patient populations studied and the extent of histologic evaluation of the NAC. Brachtel et al. performed a prospective study of 316 consecutive mastectomy specimens, 232 in patients with cancer with grossly normal nipples (18); although the median distance from the primary tumor to the nipple was 4 cm, 21% of cases had tumor involving the nipple. The NAC involvement was DCIS in 62% of cases and invasive in the remainder. On multivariate analysis, tumor size, the distance from the tumor to the nipple, and HER2 amplification were significant predictors of nipple involvement. Intraoperative frozen section is commonly used to identify unsuspected involvement of the NAC, with reported false-negative rates ranging from 1% to 3% in small studies. However, in a study of 1,001 NSMs, Petit et al. found a false-negative rate of 8.6% for frozen section (19). The frozen section is performed on the subareolar breast tissue. Brachtel et al. reported that of 45 patients with histologic involvement of the nipple in their series, 36 had involvement of the subareolar tissue, and in 9, tumor was

present only in the nipple, resulting in a sensitivity of 80% for frozen section of the subareolar tissue and a negative predictive value of 96% (18). Efforts to detect NAC involvement with preoperative imaging have not proven to be particularly successful to date. Sacchini examined the use of magnetic resonance imaging in 125 patients, 41 with DCIS, and the remainder with invasive carcinoma, and found a sensitivity of 57% and a specificity of 85.5% for the detection of tumor in the NAC. Sensitivity was 75% for invasive cancer and 33% for DCIS. The risk of future cancer in the retained NAC is related to the amount of underlying breast tissue. Even when very thin nipple flaps are created, this remains a potential problem. In a study of 62 BRCA mutation carriers, 15 (24%) were found to have terminal duct lobular units (TDLU) in the NAC. Some have advocated nipple removal with preservation of the areola to avoid this problem, but in this study, only 3 of the 15 cases had TDLUs confined to the nipple papilla (20). In addition to concerns about recurrence in the retained NAC, the decreased exposure from the limited incisions used for NSM (discussed below) raises the possibility of an increased risk of recurrence elsewhere on the chest wall due to retained breast tissue (Fig. 33-4). In spite of these theoretical concerns, initial reports of outcomes of NSM have been largely favorable. In a 2013 review of oncologic outcomes in 10 studies including 1,148 mastectomies, the locoregional recurrence rate was 2.8% (21). However, the median follow-up was only 2 years. A definite note of caution regarding the safety of NSM was sounded by the report from Petit et al. describing the vast experience of the European Institute of Oncology with NSM (22). They reported 772 patients with invasive cancer and 162 with DCIS, and all received intraoperative radiotherapy to the NAC at a dose of 16 Gy. With a median follow-up of 50 months, the 5-year local recurrence rate for the invasive cancer patients was 4.4%, and the recurrence rate was 7.8% for those with DCIS. As illustrated in Table 33-1, the majority of these recurrences did not occur in the NAC but elsewhere on the chest wall. When this study was initially reported at 20 months follow-up, there were no recurrences in the NAC, and the overall rate of local recurrence was only 1.4% (19), illustrating the need for adequate follow-up to determine the safety of this operative approach. In this series, recurrence in the NAC presented as Paget's disease in 20% of cases (23), and this type of recurrence was associated with DCIS or an invasive carcinoma with an extensive intraductal component at initial presentation as well as HER2 overexpression.

TABLE 33-1

Local Recurrence After Nipple-Sparing Mastectomy

5-Year Rate of Local Recurrence	*Invasive Cancer*	*DCIS*
	n = 772	**n = 162**
Nipple areolar complex	0.8%	2.9%
Chest wall	3.6%	4.9%

Median follow-up: 50 months. All patients received 16 Gy to the nipple areolar complex.
DCIS, ductal carcinoma in situ.
Data from Petit JY, Veronesi U, Orecchia R, et al. Nipple-sparing mastectomy with nipple areola intraoperative radiotherapy: one thousand and one cases of a five years experience at the European Institute of Oncology in Milan (EIO). *Breast Cancer Res Treat* 2009;117(2):333–338.

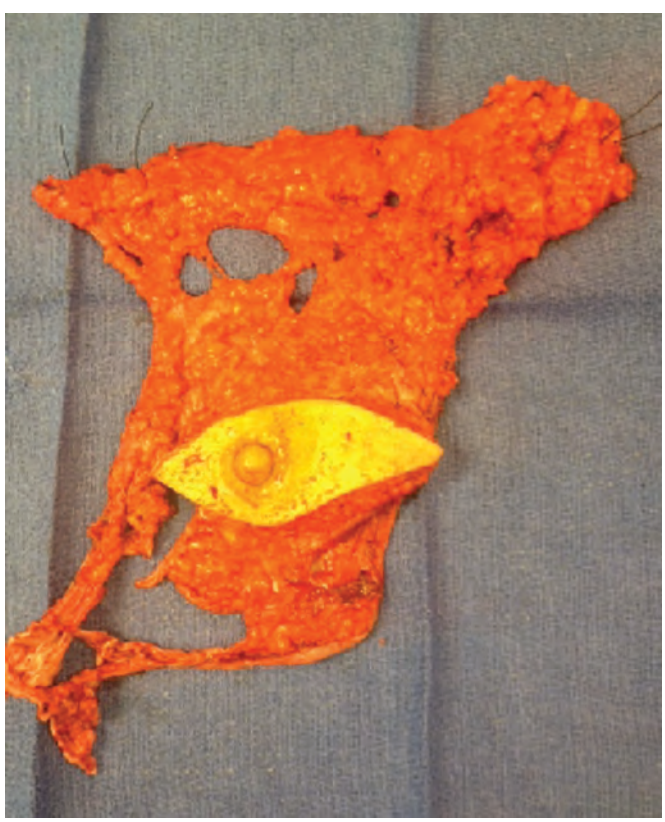

FIGURE 33-4 Retained breast tissue after nipple-sparing mastectomy in a patient who developed recurrent DCIS at a distance from the nipple.

Non-Oncologic Outcomes of NSM

The non-oncologic outcomes of interest after NSM are the incidence of nipple necrosis, retention of sensation in the nipple, and the overall cosmetic result. In a review of 3,091 mastectomies, some degree of nipple necrosis was reported in 9.1% of cases, with complete necrosis in 2%. Additionally, some degree of skin flap necrosis was seen in 9.5% of cases, with a 3.4% incidence of expander-implant loss (21). Factors associated with nipple necrosis include smoking, thin areolar flaps, circumareolar incisions, and flap reconstruction or placement of permanent implants (as opposed to tissue expanders) (17). Sensation after NSM has not been systematically evaluated in a prospective fashion. Petit et al. reported that nipple sensation was generally lost, with a rating of 2/10 to light touch; some recovery was seen in 15% of 1,001 patients at 1 year (19). In this study, both patients and surgeons evaluated the overall cosmetic outcome as 8/10. In contrast, in a series of 54 NSMs from the University of Texas MD Anderson Cancer Center, the cosmetic appearance of the NAC was rated by surgeons as poor or unacceptable in 44% of cases (24). Studies comparing cosmetic outcomes after NSM (Fig. 33-5A) and skin-sparing mastectomy with nipple reconstruction (Fig. 33-5B) were not identified during literature review for this chapter.

Patient Selection and Technique

Clinical evidence of NAC involvement is an absolute contraindication to NSM, as are T3 and T4 cancers and tumors within 1 cm of the nipple. The procedure should be used with caution in patients with cancers larger than 3 cm, particularly larger cancers in small breasts, and those with DCIS extensive enough to necessitate mastectomy. The ideal candidate for NSM is the patient with a small peripheral tumor who is a

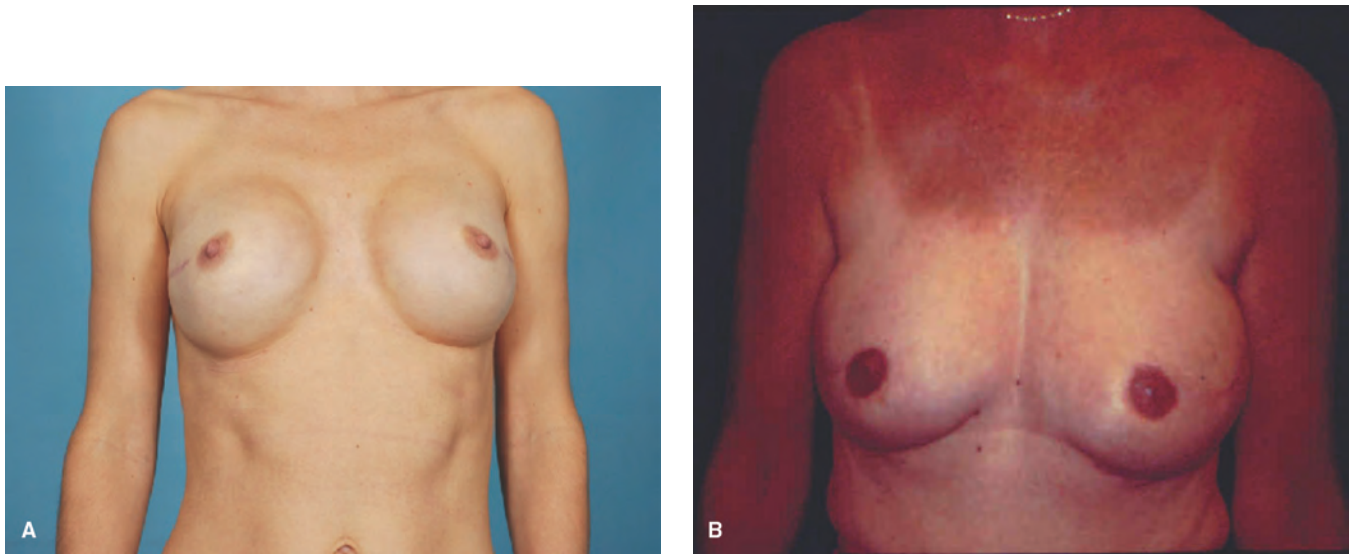

FIGURE 33-5 **(A)** Breast appearance after bilateral nipple-sparing mastectomy. **(B)** Breast appearance after bilateral skin-sparing mastectomy and nipple reconstruction.

candidate for breast conservation, but who wishes to undergo a mastectomy. Women undergoing prophylactic mastectomy are also appropriate candidates, although the impact of leaving behind breast tissue on the risk of subsequent cancer development in BRCA mutation carriers is unknown at this time. Circumareolar incisions should be avoided. Lateral incisions or inframammary incisions are preferable for preserving the blood supply to the NAC, with the choice depending upon breast size and the distance from the inframammary fold to the clavicle. The use of intraoperative frozen section and marking the subareolar region of the mastectomy specimen facilitate evaluation of the adequacy of the procedure. At present, patients should be counseled that in the absence of high-quality prospective studies and long-term follow-up, NSM cannot be considered the standard approach to mastectomy but is an option for selected patients with favorable cancers. Patient education about the risks, uncertainties, and alterations in nipple sensation is essential.

Intramammary Lymph Node Metastases

Intramammary lymph nodes are usually incidental findings, and the reported incidence varies from 1% to 48% (25). In the 7th Edition of the American Joint Committee on Cancer staging system, there is no distinction made between intramammary nodes and axillary nodes, with metastases to either group classifying the patient as at least N1. Metastases to the intramammary nodes are highly correlated with axillary nodal metastases, and approximately 60–80% of patients with intramammary metastases have concurrent axillary disease (26,27). In the era of sentinel lymph node biopsy, the clinical question of whether the presence of an intramammary node metastasis in conjunction with a negative axillary sentinel node biopsy is an indication for axillary dissection has arisen. A literature review identified only 28 reported cases with a positive intramammary node and a negative axillary sentinel node out of a pool of 27,238 patients. A completion axillary dissection was performed in 14 of the 28 cases, and no axillary nodal disease was identified (26). Although the evidence is limited, intramammary node metastasis alone should not be considered an indication for axillary dissection. Prognostically, they have the same impact as axillary nodal metastases.

Margin Status and Local Recurrence

Axillary nodal status is the most important predictor of local-regional recurrence (LRR) after mastectomy. Other factors, including molecular subtype (as approximated by immunohistochemical markers), tumor size and grade, and age, have also been associated with LRR. The diagnosis, management, and prognosis of LRR after mastectomy are discussed in detail in Chapter 69. The impact of mastectomy margin status on recurrence is controversial and will be reviewed here. The literature on this subject is extremely variable, in part because margins were not routinely assessed in many studies, techniques of pathologic processing varied, and, as is the case with margins in breast-conserving therapy, no standard definition of a close margin was employed. Most studies examining margins have considered only the posterior margin. Assessment of anterior margins, particularly in skin-sparing mastectomy, is difficult because ink frequently leaks into the crevices of the fatty, irregular breast tissue, resulting in false-positive readings of close or positive margins. Additionally, studies do not always distinguish between invasive and in situ cancer in proximity to the margin, and it is not clear that DCIS close to a margin is important when there is no residual breast tissue. Positive margins are uncommon, seen in only 2.5% of 12,552 mastectomies reviewed by Rowell (28). Close margins, defined as anywhere from <2 mm to 1 cm, were present in 8% of 8,964 patients. In five studies in which radiotherapy was not given, the relative risk of LRR was 2.6 (95% CI, 1.8–3.8; $p < .00001$) for those with close or positive margins (28); however, in individual studies in which multivariate analysis was used to control for other factors known to influence LRR, margin status was a significant predictor in two studies and not significant in two others. In two additional studies in which all patients received radiotherapy, margin status was not a predictor of LRR. In a more recent study, Childs et al. assessed the impact of both anterior and posterior margin status on recurrence in a group of 397 women undergoing mastectomy but not radiotherapy between 1998 and 2005 (29). Positive superficial margins were present in 10% of patients, and positive posterior margins were present in 6%. Close margins, defined as <2 mm, were seen in 14% and 9%, respectively. At a median follow-up of 6.7 years, the 5-year rate of LRR was 6.2% for those with positive margins

compared to 1.8% for those with close or negative margins (p = .013). The type of tumor at the margin (invasive vs. DCIS) and which margin was involved were not significant predictors of recurrence. On multivariate analysis, only positive margins and triple-negative subtype were predictors for isolated LRR. Ideally, positive margins are avoided by removing a piece of the pectoral muscle when a tumor is in close proximity to the posterior margin and creating thin skin flaps anteriorly. When margins are truly positive, the use of postmastectomy radiotherapy seems prudent, although communication between the surgeon and the radiation oncologist regarding the intraoperative findings is helpful in making this decision. Given the uncertainty regarding the impact of close margins on LRR, using this as the sole indication for postmastectomy radiotherapy is not advisable. Rather, close margins should be considered in the context of other factors that influence local recurrence when making a decision about the benefits of postmastectomy radiotherapy.

MANAGEMENT SUMMARY

- Mastectomy historically was the primary mode of local therapy for breast cancer. Despite the increased use of breast-conserving therapy, mastectomy remains an option for women diagnosed with breast cancer.
- Criteria of inoperability include inflammatory cancer, skin satellites, ulcerated tumors, and tumors fixed to the bony chest wall. Preoperative chemotherapy or endocrine therapy will render the majority of these cases operable.
- The use of skin-sparing mastectomy to facilitate immediate reconstruction does not increase the risk of local recurrence.
- Nipple-sparing mastectomy leaves behind residual breast tissue, and surgical exposure is more challenging than in a skin-sparing mastectomy. The long-term oncologic results of this procedure are uncertain. Patients with cancers in proximity to the nipple, locally advanced disease, and extensive DCIS are not candidates for this approach.
- Involvement of intramammary lymph nodes has a prognosis similar to axillary node involvement and is associated with axillary metastases. In the uncommon setting of a positive intramammary node and a negative axillary sentinel node, axillary dissection is not indicated.
- Positive mastectomy margins are usually an indication for radiotherapy. The significance of close margins is uncertain, and they should be considered in the context of other factors influencing the risk of local recurrence when making decisions about radiotherapy. Close margins alone do not indicate the need for irradiation.

CHAPTER CONTENTS

INTRODUCTION

Patients with unilateral breast cancer are at increased risk for developing cancer in the contralateral breast. As a result, some patients choose contralateral prophylactic mastectomy (CPM) to prevent cancer in the contralateral breast. Several studies have reported that the CPM rates have markedly increased in recent years in the United States. In this chapter, we will discuss recent CPM trends, potential reasons patients choose CPM, outcomes after CPM, and alternative strategies for managing the increased risk of contralateral breast cancer among survivors of unilateral breast cancer.

CPM TRENDS

Contralateral prophylactic mastectomy is the removal of the normal intact breast among women with unilateral breast cancer. The Surveillance Epidemiology and End Results (SEER) registry began coding CPM in 1998. At that time, the proportion of patients who underwent CPM in the United States was very low (1). However, the CPM rate among all surgically treated patients with invasive breast cancer increased 150% from 1998 to 2003 in the United States (Fig. 34-1). Among mastectomy patients, the CPM rate increased 162% from 1998 to 2003 (Fig. 34-2). These trends were observed for all cancer stages and continued to increase at the end of the study period with no plateau. Among the SEER registries, Atlanta had the highest CPM rates, while Connecticut had the lowest rates. Although significant geographic variations were observed between different SEER registries, no general geographic trends were identified. Similar findings were observed in the SEER database among patients with ductal carcinoma *in situ* (DCIS) (2).

Other studies using different databases have confirmed these findings. Using the American College of Surgeons' National Cancer Data Base (NCDB), Yao et al. reported similar increases in CPM rates from 1998 to 2007; by 2007, the rates were still increasing with no plateau effect (3). In a study using the New York State Cancer Registry, McLaughlin et al. reported that CPM use more than doubled from 1995 to 2005 (4). Single-institutional studies have also demonstrated marked increases in CPM rates (5–7).

In contrast, similar trends have not been observed in Europe. In a single-center study from Switzerland, Güth et al. reported that the CPM rates at an academic surgery center did not increase from 1995 to 2009 (8). The authors concluded that the increased use of CPM was a "trend made in the USA." Another study supports this viewpoint. In an international registry of women with unilateral breast cancer and BRCA mutation, Metcalfe et al. reported that 49% of women in the United States underwent CPM (9). In contrast, the CPM rates for Europe and Israel were only about 10% or less.

Various patient, tumor, and treatment factors are significantly associated with CPM rates (see Table 34-1). Younger women are much more likely to receive CPM (1,3). White race, higher education level, private health insurance, and family history of breast cancer have also been associated with higher CPM rates (1,3,5,7). In the SEER study, the presence of infiltrating lobular histology was one of the strongest predictors of CPM (1). Yet, population-based studies indicate that the risk of contralateral breast cancer is not significantly increased for infiltrating lobular histology as compared with infiltrating ductal histology (10). Multicentric breast cancer has also been associated with higher CPM rates (11). BRCA testing is significantly associated with CPM, even among patients who do not have BRCA mutations. In one single-center study, the CPM rate was 40% among those patients who tested negative for mutations (12). Several studies have reported that preoperative MRI is associated with CPM (5,7,11). Patients treated at comprehensive cancer programs or teaching facilities are more likely to receive CPM (3).

REASONS FOR INCREASED CPM RATES

This trend towards more aggressive breast cancer surgery is curious and counterintuitive in the modern era of minimally invasive surgery. The following section of this chapter is largely speculative because the exact reasons for increased CPM rates in the United States are unknown. However, many factors probably contribute to increased CPM use. Public awareness of genetic breast cancer and increased BRCA testing may partially explain these observations. Improvements in mastectomy (including skin-sparing and nipple-sparing mastectomy) and reconstruction techniques and access to breast reconstruction probably contribute to increased CPM rates.

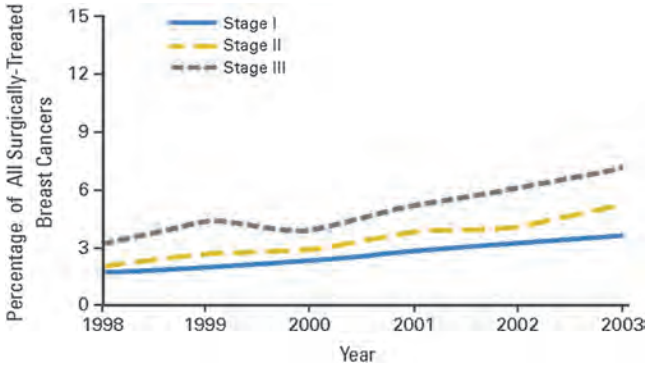

FIGURE 34-1 Overall CPM rates in the United States according to cancer stage. (From Tuttle TM, Habermann EB, Grund EH, et al. Increasing use of contralateral prophylactic mastectomy for breast cancer patients: a trend toward more aggressive surgical treatment. *JCO* 2007;25:5203–5209.)

Moreover, symmetric reconstruction is often easier to achieve after bilateral mastectomy as compared to unilateral mastectomy. Additionally, the native and reconstructed breast age differently, so symmetric outcomes may diminish over time.

Several studies have reported that preoperative breast MRI is associated with higher CPM rates (5,7). The proposed explanation is that MRI findings introduce concern about the opposite breast. For example, a patient is diagnosed with a unilateral breast cancer, and clinical breast examination and mammography of the contralateral breast are normal. The patient is an ideal candidate for breast-conserving treatment. However, an MRI is obtained which demonstrates an occult indeterminate lesion in the contralateral breast. Next, the patient undergoes a second-look (targeted) ultrasound to characterize this MRI finding. The ultrasound imaging is normal, so she gets called back again for an MRI-guided biopsy, which is negative for cancer. However, the patient decides to have bilateral mastectomy to avoid this stressful scenario again. Preoperative breast MRI probably contributes to increased CPM rates, but the initial observed CPM trends in the United States preceded the widespread use of breast MRI (1,3).

Obesity rates in the United States have markedly increased over the past two decades. An obese woman with large breasts may encounter asymmetry and balance problems after unilateral mastectomy without reconstruction. Also, a plastic surgeon may have technical challenges in achieving a symmetric reconstruction after unilateral mastectomy for an obese woman with large breasts. For some women, bilateral mastectomy with or without reconstruction may provide effective local breast cancer treatment, avoid future radiographic surveillance, and may relieve symptoms from macromastia. Nevertheless, it is not known whether increasing obesity rates are contributing to current CPM trends.

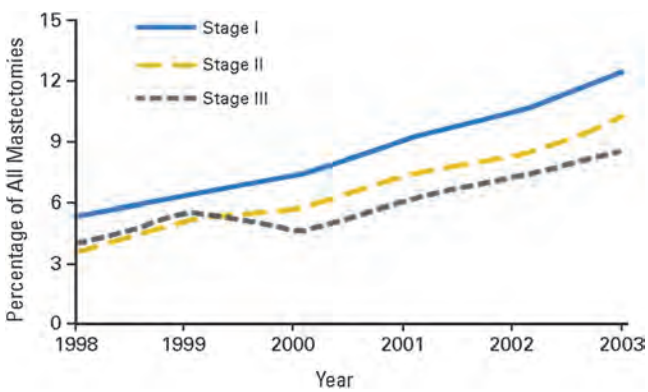

FIGURE 34-2 CPM rates among mastectomy patients according to cancer stage. (From Tuttle TM, Habermann EB, Grund EH, et al. Increasing use of contralateral prophylactic mastectomy for breast cancer patients: a trend toward more aggressive surgical treatment. *JCO* 2007;25:5203–5209.)

Breast reconstruction
Facility type

Another possible explanation for the increased CPM rates is that some patients may considerably overestimate their risk of contralateral breast cancer. Previous studies have reported that women with early breast cancer markedly overestimate their risk of recurrence (13). In a recent survey of 350 mastectomy patients, Han et al. reported that the most common reason for CPM was worry about contralateral breast cancer (14).

The annual rates of metachronous contralateral breast cancer for women with unilateral breast cancer are fairly constant (10). In an analysis of the SEER database, Gao et al. reported that medullary carcinoma, black race, and age >55 years were associated with significantly higher rates of contralateral breast cancer (10). The incidence of contralateral breast cancer was not significantly different for DCIS or infiltrating lobular as compared with infiltrating ductal carcinoma. The Early Breast Cancer Trialists' Collaborative Group recently updated their meta-analyses and reported that the annual rate of contralateral breast cancer was about 0.4% for patients with estrogen receptor-positive breast cancer treated with tamoxifen; the annual rate of contralateral breast cancer was about 0.5% for patients with estrogen receptor-negative breast cancer (15). All age, tumor, and treatment subgroups had rates less than 0.7%/year. Thus, the 10-year cumulative risk of contralateral breast cancer is about 4% to 5%. In fact, the risk of contralateral breast cancer may be even lower for patients diagnosed today. Nichols et al. reported that the rates of metachronous contralateral breast cancer have significantly decreased since 1985 largely because of adjuvant systemic therapies (16).

Abbott et al. recently published the results of a prospective single-center study designed to determine patients' perceived risk of contralateral breast cancer (17). Patients completed a standardized survey prior to surgical

consultation and were asked to estimate their risk of contralateral breast cancer. Patients substantially overestimated their 10-year cumulative risk of contralateral breast cancer, with a mean perceived risk of 31.4%. Also, an increased perceived risk of contralateral breast cancer was significantly associated with measurements of psychological distress.

Moreover, some patients may overestimate the oncologic benefits of CPM. In a review of open-ended comments from women who underwent CPM, Altschuler et al. recorded comments such as "I do not worry about recurrence," and I am "free of worries about breast cancer" (18). Such comments suggest a lack of understanding of the benefits of CPM, as removal of the normal contralateral breast does not treat systemic metastases from the known ipsilateral breast cancer.

OUTCOMES AFTER CPM

Several studies have demonstrated that CPM is effective in reducing the risk of contralateral breast cancer. In a study of 745 breast cancer patients with a family history of breast cancer, McDonnell et al. reported that CPM reduced the incidence of contralateral breast cancer by more than 90% (19). In a retrospective study of 239 patients, Goldflam et al. reported that only 1 contralateral breast cancer (0.4%) developed after CPM (20). Depending upon the statistical methods used, CPM reduces the risk of contralateral breast cancer by about 90%.

However, the effectiveness of CPM in reducing breast cancer mortality is not as clear. The only plausible way that CPM improves breast cancer survival is by reducing the risk of a potentially fatal contralateral breast cancer. A recent survival analysis of the SEER database included patients with unilateral breast cancer diagnosed between 1998 and 2003 (21). The authors concluded that CPM is associated with a small improvement (4.8%) in 5-year breast cancer specific survival rates for young women with early-stage estrogen receptor-negative breast cancer. However, the cumulative incidence of contralateral breast cancer was less than 1% in this study; so, the apparent survival benefit is most likely due to selection bias. In a retrospective single-center study, Boughey et al. reported that CPM was associated with improved overall survival and disease free survival rates (22). However, a recent Cochrane review of published CPM studies concluded that "there is insufficient evidence that CPM improves survival" (23).

Despite the results of retrospective or cancer registry studies, CPM is not likely to improve breast cancer survival rates for patients who do not have BRCA mutations. For these patients, the 10-year cumulative risk of contralateral breast cancer is about 4% to 5%; most metachronous contralateral breast cancers are stage I or IIA with a 10-year mortality rate of about 10% to 20%. Thus, the 20-year mortality rate from a contralateral breast cancer is about 1% or less. In addition, many patients die from systemic metastases from their known ipsilateral breast cancer or from other causes during 20-year follow-up. Finally, CPM does not prevent all contralateral breast cancers. Thus, CPM will not decrease breast cancer mortality rates for most breast cancer patients without BRCA mutations.

On the other hand, for patients with BRCA-associated unilateral breast cancer, the annual risk of contralateral breast cancer is about 4% per year with a cumulative 10-year risk of contralateral breast cancer of about 40% (24). Thus, the possibility of developing a potentially fatal contralateral breast cancer is substantially higher among breast cancer patients with a BRCA mutation. The relative risk reduction of CPM is similar for patients with and without BRCA mutations. Using Markov modeling, Schrag et al. estimated that CPM would increase life expectancy by 0.6 to 2.1 years for a 30-year old patient with a BRCA mutation (25). Patients with unilateral breast cancer who have received supradia-phragmatic radiotherapy for Hodgkin's lymphoma may also potentially benefit from CPM because the annual risk of contralateral breast cancer is about 3% to 4% per year (26). Clearly, randomized trials comparing CPM with no CPM for either selected (BRCA mutations) or heterogeneous patients are not feasible.

Contralateral prophylactic mastectomy is an irreversible procedure and is not risk free. Severe complications after CPM may potentially delay recommended adjuvant therapy and may require additional surgical procedures and subsequent loss of reconstruction. The overall complication rate after bilateral mastectomy and reconstruction is about 15% to 20% (20). About half of the complications are secondary to the prophylactic mastectomy. Even without complications, these operations are long (often 5 to 6 hours) and require 2 to 3 days of inpatient hospital care, drainage catheters, and 3- to 4-week overall recovery.

Despite potential risks and complications, most patients are satisfied with their decision to undergo CPM. The greatest reported benefit contributing to patient satisfaction is a reduction in breast cancer related concerns. Frost et al. reported that 83% of patients were either satisfied or very satisfied with their decision to undergo CPM at a mean of 10 years after surgery (27). Some women have negative psychosocial outcomes following CPM, most often related to high levels of psychological distress, sexual function, and body image or poor cosmetic outcome (18). Montgomery et al. reported that the most common reasons for regret after CPM were a poor cosmetic outcome and diminished sense of sexuality (28).

ALTERNATIVES TO CPM

Patients with unilateral breast cancer have options that are less drastic than CPM. Surveillance with clinical breast examination, mammography, and potentially breast MRI may detect cancers at earlier stages. Several prospective randomized trials have demonstrated that tamoxifen, given as adjuvant therapy for estrogen receptor-positive breast cancer, significantly reduces the rate of contralateral breast cancer. In the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-14 study, 2,892 women with node-negative, estrogen receptor–positive breast tumors were randomly assigned to either tamoxifen (20 mg/d) or placebo for at least 5 years (29). After an average follow-up of 53 months, 55 contralateral breast cancers developed in placebo-treated women and 28 developed in the tamoxifen-treated women (p = .001).

Aromatase inhibitors may reduce the risk of contralateral breast cancer as much as, or even more than, tamoxifen (30). The ATAC (Arimidex, Tamoxifen Alone or in Combination) Trial demonstrated that anastrozole was superior to tamoxifen in preventing contralateral breast cancer in postmenopausal women. Ovarian ablation and cytotoxic chemotherapy also reduce the risk of contralateral breast cancer (31).

CONCLUSIONS

Increasingly more patients in the United States with invasive breast cancer and DCIS undergo CPM to prevent contralateral breast cancer. Patient, tumor, and treatment factors are

associated with increased use. Indeed, CPM does reduce the risk of contralateral breast cancer, but does not impact breast cancer survival rates. Controversy exists about whether the physician or patient should initiate the discussion of CPM. If a patient appropriately chooses breast-conserving surgery, then CPM is not a relevant treatment. For patients who undergo mastectomy, CPM may be a reasonable option, particularly if a patient has a BRCA mutation, strong family history, is obese, or if imaging of the contralateral breast is difficult. Recent studies have demonstrated that many patients are not well informed about the risk of contralateral breast cancer or the benefits of CPM. Physicians need to provide breast cancer patients with accurate information on the risk of contralateral breast cancer and on the risks and benefits of CPM. In addition, physicians should encourage appropriate patients to consider less drastic options (e.g., endocrine therapy) to reduce the risk of contralateral breast cancer.

Presently, no study has prospectively evaluated the complex decision-making processes that lead to CPM. Future research should include development of models and instruments to elucidate these processes. Also, the surgeon's role and influence in choice of breast cancer surgery should be evaluated. Finally, decision aids should be developed for breast cancer patients and physicians.

MANAGEMENT SUMMARY

- The annual risk of developing contralateral breast cancer is about 0.5% per year among patients without BRCA mutations.
- The annual risk is about 4% per year among patients with BRCA mutations.
- Many patients substantially overestimate their risk of contralateral breast cancer.
- Contralateral prophylactic mastectomy reduces the risk of contralateral breast by 90% or more.
- Contralateral prophylactic mastectomy does not improve breast cancer mortality rates.
- The rates of contralateral prophylactic mastectomy have markedly increased in the United States in recent years.
- Physicians should discuss alternative approaches to contralateral prophylactic mastectomy including surveillance and endocrine therapy.

CHAPTER 35

Breast-Conserving Therapy

Jay R. Harris and Monica Morrow

CHAPTER CONTENTS

Breast-conserving therapy (BCT), a combination of breast-conserving surgery (BCS) followed by whole breast irradiation, is an established standard of care for local-regional treatment for early-stage breast cancer. The first clinical trials investigating BCT began more than three decades ago. The outcome data from these trials, including a meta-analysis of all of the trials (1), provided clear evidence that breast-conserving surgery followed by whole breast radiation achieved long-term survival equivalent to mastectomy.

Currently, most patients with newly diagnosed breast cancer are candidates for BCT. The increased use of mammographic screening, and improved public education about breast cancer, have dramatically increased the percentage of cases that present with early-stage disease. Studies have demonstrated that BCT positively impacts patient well-being and quality of life. Over time, as experience has been gained with BCT and the use of adjuvant systemic therapy has become routine even for patients with stage 1 breast cancer, rates of local recurrence (LR) after BCT have declined to less than 0.5% per year (2). Despite the established efficacy and excellent outcomes of BCT, recent data show an increase in the utilization of therapeutic mastectomy and prophylactic contralateral mastectomy, particularly among younger patients (3).

This chapter will review the progress that has been made in BCT, including the current selection criteria for BCT, the importance of radiation therapy (RT) as a component of BCT, comparing the approaches of conventional whole breast irradiation versus accelerated whole breast irradiation versus accelerated partial breast irradiation, the patient-, treatment-, and tumor-related factors that influence outcome, and the technical details of optimizing both surgical and radiation treatment of early-stage breast cancer.

SELECTION CRITERIA FOR BREAST-CONSERVING THERAPY

BCT is generally reserved for patients with tumors smaller than 5 cm. However, more important than absolute tumor size is the relationship between tumor size and breast size. The tumor must be small enough, in relation to the size of the breast, to permit the tumor to be resected with clear margins and an acceptable cosmetic result. In patients with invasive breast cancer in which the tumor-to-breast size ratio is unfavorable, preoperative chemotherapy or endocrine therapy can be used to decrease the tumor size sufficiently to permit BCT (see Chapters 54 and 55).

The 2012 National Comprehensive Cancer Network (NCCN) guidelines to contraindications for BCT requiring RT include:

Absolute Contraindications

- Prior RT to the breast or chest wall
- Breast cancer early in a pregnancy that would necessitate RT during pregnancy
- Diffuse suspicious, malignant-appearing microcalcifications
- Widespread disease that cannot be incorporated by excision through a single incision that achieves negative margins with a satisfactory cosmetic result

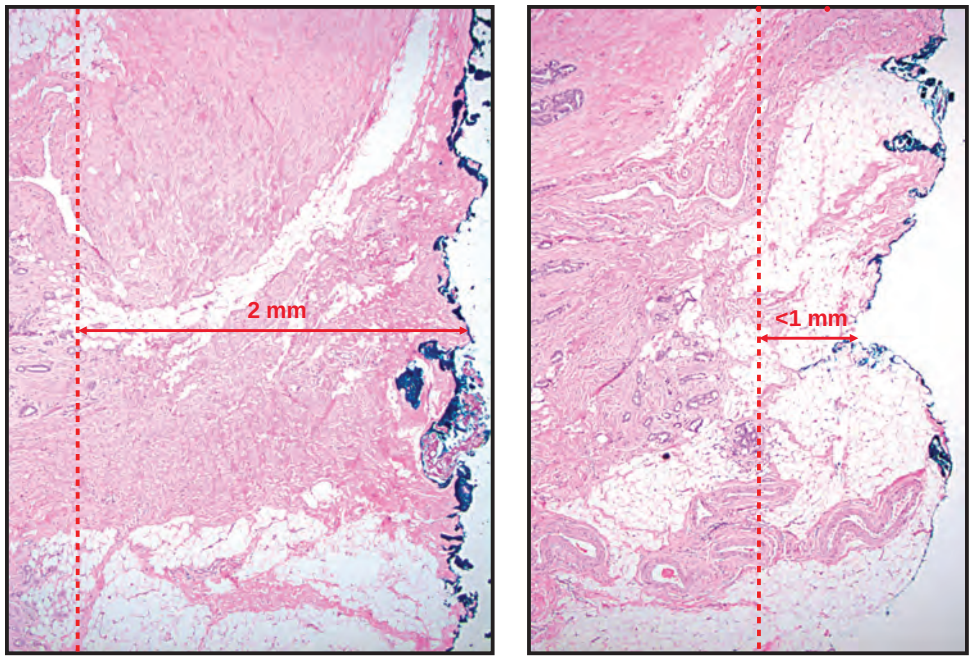

FIGURE 35-1 **Sampling error and margin assessment.** On the left is an initial section with a margin width of 2 mm. A slightly deeper section, shown on the right, was taken for special studies and showed a margin width of less than 1 mm.

Relative Contraindications

- Active connective tissue disease involving the skin (especially scleroderma and lupus, but not rheumatoid arthritis)
- Focally positive margin in the absence of an extensive intraductal component (see below)
- Women with a known or suspected genetic predisposition to breast cancer

The evaluation for BCT includes a history, physical exam, and diagnostic mammography. Using this approach, patients suitable for BCT can be identified with a high degree of success as illustrated by a population-based study of 800 women attempting BCT in which surgery was successful in 88%. Of the 12% who were converted to mastectomy, re-excision was attempted in only one-third, suggesting that the 88% is a minimum estimate (4). There is controversy regarding the role of additional imaging studies, particularly magnetic resonance imaging (MRI) of the breast, in selecting patients for BCT. A meta-analysis of 3,112 patients in 9 studies with comparison cohorts treated with and without MRI found no difference in the need for re-excision or unexpected conversion to mastectomy, after age adjustment, in patients managed with and without MRI (5). The lack of impact of MRI on LR rates is discussed in the following section in the context of margins.

MARGINS AND LOCAL RECURRENCE

Margin width is assessed by applying ink (ideally colored to reflect the individual margins) to the surface of the specimen. Margin width is the distance between tumor cells and inked surface. A *negative margin* is defined by "no ink on any cancer cells." Despite the NCCN guidelines, what constitutes an adequate margin is controversial (6). In surveys, no single margin width is endorsed by more than 50% of respondents (7,8). Many practitioners favor a margin of 2 mm or even greater. As a result, re-excision is commonly used, even with a negative margin. Part of this is due to difficulties in margin assessment. Specimen processing is not standardized and varies between institutions. Sampling error is another difficulty. Even with fastidious assessment of margins, however, only a very small percentage of the entire margin is assessed. This is illustrated in Figure 35-1. On the left is an initial section with a margin width of 2 mm. A slightly deeper section, shown on the right, was taken for special studies and showed a margin width of less than 1 mm. A meta-analysis of 21 studies reporting LR relative to margin width showed that LR was significantly greater with a positive margin than a negative margin, but increasing margin width did not significantly decrease LR (9).

It is becoming increasingly clear that factors other than margin width are the primary determinants of local control. In more recent studies, which include the routine use of adjuvant systemic therapy, substantially reduced rates of LR have been seen. This is illustrated in the 10-year rates of LR in successive National Surgical Adjuvant Breast and Bowel Project (NSABP) trials in node-negative patients treated with BCT (2). In NSABP B-13, which randomized patients with estrogen receptor (ER) negative cancer to adjuvant chemotherapy or not, 10-year LR was 15.3% without chemotherapy and only 2.6% in patients with chemotherapy. Similarly, in NSABP B-14, which randomized patients with ER positive cancer to adjuvant tamoxifen or placebo, 10-year LR was 11.0% with placebo and only 3.6% in patients treated with tamoxifen. During these trials, the NSABP used "no ink on tumor" as the definition of a negative margin. Studies examining the impact of adding trastuzumab to adjuvant chemotherapy in women with HER2-overexpressing tumors demonstrate an additional 40% reduction in the risk of LR, with a median follow-up of 1.5 to 2.0 years (10). In a retrospective study from Memorial Sloan-Kettering Cancer Center, 3-year rates of LR decreased from 7% to 1% in patients with HER2-overexpressing tumors after the addition of trastuzumab to chemotherapy (11). Updated results from Dana-Farber Cancer Institute/Brigham and Women's Hospital, and Massachusetts General Hospital included 1,434 patients; 91% were treated with adjuvant systemic therapy (not including trastuzumab), and with a median follow-up time of 85 months, the 5-year rate of LR was 1.6% and the overall crude rate of LR was 3.1% (12). (These rates are expected

to double at a median follow-up of 10 years.) In this study, as well as several others, the main prognostic factor for LR was biologic subtype approximated by hormonal receptors, HER2 status, and histologic grade, with Luminal A = HR+, HER2-, Gr 1-2; Luminal B = HR+, HER2-, Gr 3; Luminal-HER = HR+, HER2+; HER2 = HR-, HER2+; and triple negative = HR-, HER2-. The crude rate of LR by subtype was 1.5% for Luminal A, 4.0% for Luminal B, 1.0% for Luminal-HER, 10.9% for HER2+, and 8.8% for triple-negative cancers. Age was also in the final model, but the magnitude of the effect was much smaller, with a crude rate of LR of 6.5% for the patients in the lowest age quartile (ages 23 to 46) compared with only 0.9% for patients in the highest age quartile (ages 64 to 88). Margin status was not in the final model of prognostic factors for LR. These and other data indicate that the biological features of the tumor are most important in determining the risk of LR. Studies examining the relationship between molecular subtype, as approximated by receptor status, and LR are summarized in Table 35-1 (12–14). Although definitions of the Luminal B subtype have varied over time, the lowest rates of LR are consistently seen in patients with Luminal A cancers and the highest rates in those with triple-negative cancers (12–14), and this relationship persists even for T1a, b and microinvasive cancers (15) and in patients receiving neoadjuvant chemotherapy (16). The higher rates of LR in patients with triple-negative cancers have raised concern that these patients might benefit from treatment with mastectomy. However, patients with triple-negative cancers have the highest LR risk after both BCT and mastectomy, and retrospective studies do not demonstrate an improvement in local control after mastectomy compared to lumpectomy and radiation, even in this more aggressive tumor subset (17–19). In multivariable analyses controlling for both conventional prognostic factors and biologic subtype, type of surgical procedure (mastectomy vs. BCT) is not a clinically significant predictor of LR for neither high-risk triple negative patients (18) nor the lower-risk ER positive subset (20).

There are additional lines of evidence that widely negative margins are not required (in the large majority of patients) for successful BCT when routine adjuvant systemic therapy is employed. Multiple studies have demonstrated that breast MRI in patients with a known primary identifies multifocal and multicentric cancers (located at a considerable distance from the known primary) in about 11% of patients (21) and triples the age-adjusted odds ratio of an initial mastectomy rather than BCT (5); however, the available studies do not demonstrate lower rate of LR with BCT in patients receiving MRI compared to those who have not (22,23). Additional evidence for the concept that minimizing the subclinical tumor burden is not critical for reducing LR in the current era of multimodality treatment comes from the results of the American College of Surgeons Oncology Group (ACOSOG) Z0011 trial. In that study, women undergoing breast-conserving surgery, sentinel node biopsy, and whole breast irradiation, who had metastases in one or two sentinel lymph nodes, were randomized to axillary dissection or no further axillary treatment. All patients received adjuvant systemic therapy. In spite of the finding of additional nodal metastases in 27% of the axillary dissection group, only 0.9% of patients in the sentinel node-only group experienced a first recurrence in the axilla (24).

In considering the use of margins in BCT, it is useful to note that breast cancers are very often multifocal, with at least 40% of cases having microscopic foci greater than 2 cm from the edge of the cancer. This frequency is not influenced by tumor size, and these microscopic foci are more often ductal carcinoma *in situ* (DCIS) than invasive cancer. *A key concept in the practice of BCT is that margin evaluation (and mammography) are used to insure that there is only limited residual cancer capable of being eradicated with conventional doses of RT, but not to insure there is no cancer remaining.*

Thus, the current evidence indicates that in the context of highly effective systemic therapy, no ink on tumor is a sufficient margin for the large majority of patients. However, there are some exceptions, and these include cancers with an extensive intraductal component (EIC), patients receiving preoperative chemotherapy, and pure DCIS. EIC is defined by prominent DCIS within the tumor (~25%) and present in adjacent tissue. The presence of an EIC predicted for LR in patients treated with BCT without margin evaluation; however, EIC ceased to be a prognostic factor for LR with the routine use of margin evaluation. The presence of an EIC also predicts for patients with prominent residual disease after a gross excision of the tumor. Similar considerations exist for patients with pure DCIS, and this is supported by clinical data (25). In both situations, obtaining clearly negative margins is prudent. Finally, since tumors typically respond to preoperative chemotherapy in a honeycomb pattern rather than a concentric pattern, obtaining clearly negative margins is also prudent in the setting of preoperative chemotherapy.

ROLE OF RADIATION THERAPY IN BREAST-CONSERVING THERAPY

Radiation treatments play an important role in successful BCT for patients with invasive breast cancer. It has been clearly demonstrated that radiation treatment of the ipsilateral breast reduces the probability of LR after lumpectomy. More importantly, meta-analyses from the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) of all the randomized prospective trials comparing BCS or mastectomy with or without postoperative RT indicate that by eradicating persistent local disease after surgery, RT use reduced the risk of

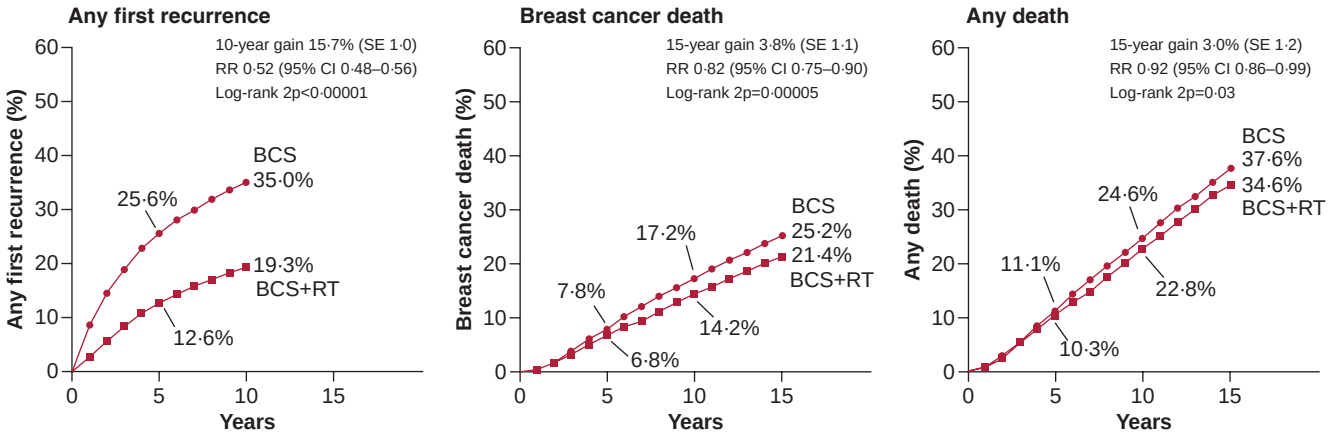

FIGURE 35-2 The data from the EBCTCG meta-analysis of trials investigating breast-conserving surgery with or without breast radiation. Effect of RT after BCS on 10-year risk of any (local-regional or distant) first recurrence and on 15-year risks of breast cancer death and death from any cause in 10,801 women (67% with pathologically node-negative disease) in 17 trials. (From Early Breast Cancer Trialists' Collaborative Group (EBCTCG). Effect of radiotherapy after breast-conserving surgery on 10-year recurrence and 15-year breast cancer death: meta-analysis of individual patient data for 10,801 women in 17 randomised trials. *Lancet* 2011;378:1707–16, with permission.)

subsequent death from breast cancer. The first analysis was published in 2005 and described a 4 to 1 ratio between avoiding LR at 5 years and improving survival at 15 years. After either BCS or mastectomy, RT proportionally reduced LR by 70%. An updated analysis was published in 2011 restricted to patients treated with BCS (26). In this updated analysis, 7 trials of BCS in low-risk patients, most treated with adjuvant hormonal therapy and randomized to breast RT or not, were added to the original 10 trials in the 2005 publication for a total of 10,801 women, 3,143 deaths, and a median woman–years at risk of 9.5. Importantly, the EBCTCG moved from assessing the effect of RT on LR to its effect on first failure (or first recurrence, either LR or distant metastasis). Although commonly employed in studies on the local treatment of breast cancer, actuarial calculation of time to LR is, strictly, not statistically valid. As shown in Figure 35-2, RT proportionally reduced the annual rate of any failure (LR or distant metastases) over the first 10 years by about half (relative risk [RR] = 0.52) and proportionally reduced the annual rate of breast cancer death by about one-sixth. The absolute benefit of RT was greater in patients with the greater risk of recurrence. In node-negative patients, the absolute benefit was strongly correlated with age (inversely), tumor grade and size, and ER status, with very small absolute benefit seen in some subgroups. The updated EBCTCG analysis still demonstrates that local treatment is linked to improved long-term survival; however, the new 4:1 ratio is between the reduction in first failure at 10 years (not the reduction in LR at 5 years) and the reduction in mortality at 15 years.

Do All Patients Treated with Breast-Conserving Therapy Require Radiation?

The initial trials that demonstrated a clear benefit for radiation in BCT included populations that were heterogeneous with respect to risk factors associated with LR. Therefore, the second generation of clinical trials studying BCT investigated whether radiation could be safely omitted in favorable subgroups. Unfortunately, most of these studies were unsuccessful in positively answering the question. For example, a single-arm, 82-patient prospective trial conducted at Harvard Medical School investigated whether breast radiation could be omitted in patients with pT1N0 breast cancer without an extensive intraductal component or lymphovascular space invasion that was excised with 1 cm or greater margins. Despite these favorable features, the trial was closed early after the breast recurrence rate exceeded the predefined stopping rules. The LR rate after a median follow-up of 86 months was 23% (27). These recurrence rates were similar to those seen in a trial from the Milan Cancer Institute that randomized women with tumors 2.5 cm or smaller to a quadrantectomy and axillary dissection without radiation or this same surgery followed by breast irradiation. Despite a more extensive surgical procedure than what is routinely utilized in most North American trials, the 10-year risk of in-breast recurrence was markedly higher in the absence of RT (24%) compared with patients who received RT (6%) ($p < .001$) (28). Randomized trials from Sweden and Finland have also attempted to specifically address whether patients with stage I disease require RT after BCT, and in both of these studies, the use of radiation led to a highly significant improvement in local outcomes (29,30). Finally, it is also clear from several trials that the use of adjuvant chemotherapy does not obviate the need for breast irradiation. For example, in the NSABP B-06 trial, chemotherapy was used for patients with lymph node-positive disease, and these patients had a 44% 20-year risk of in-breast recurrence without radiation compared to a rate of only 9% for those treated with lumpectomy, radiation, and chemotherapy (31).

The most recent randomized trials attempting to identify a favorable cohort with a low risk of in-breast recurrence without radiation have focused on postmenopausal women with hormone receptor positive stage I disease treated with breast-conserving surgery and hormonal therapy. The data from these trials are shown in Table 35-2 (32–37) and demonstrate that the combined modality treatment of breast-conserving surgery, radiation, and adjuvant hormonal therapy is associated with a very low 5-year risk of in-breast or local-regional recurrence.

LR, local recurrence; L-RR, local-regional recurrence; CALGB, Cancer and Leukemia Group-B.

In contrast, data from the Scottish trial and the NSABP B-21 trial suggest that the risk of in-breast recurrence remains clinically relevant with BCS and hormonal therapy alone. The one cohort of patients for whom BCS without radiation might be considered as an appropriate option are elderly females with an ER positive stage I breast cancer who are treated with hormonal therapy. The Cancer and Leukemia Group-B (CALGB) Intergroup trial randomized women 70 years of age and older with these disease characteristics to breast-conserving surgery plus tamoxifen or BCS, tamoxifen, and breast irradiation (35). With a median follow-up of 95 months, radiation reduced the local-regional recurrence from 7% to 1% (36). It should be noted that approximately 1 of 6 of these patients enrolled in this study died of intercurrent disease by 5 years. Therefore, how these data should be applied to women over 70 years of age who have a longer life expectancy is less clear. To further study this question, investigators from Yale University reviewed the Surveillance, Epidemiology and End Results (SEER)-Medicare Database and identified 8,724 patients who met the eligibility criteria for this trial. They found similar 5-year outcome rates as those reported in the Intergroup trial (38). However, these investigators also were able to analyze patient subsets and found that the benefits of RT were of a clinically relevant magnitude for patients aged 70 to 79 who had no comorbidities. In contrast, those patients 80 years or older and those with multiple comorbidities had a higher risk of dying from non-breast-cancer–related causes within 5 years and therefore were not at high risk of developing an in-breast recurrence.

In conclusion, all of the clinical studies to date have indicated that without breast irradiation, the risk of LRs after breast-conserving surgery alone is too high and, therefore, breast irradiation should be considered a standard component of treatment for all women with early-stage invasive disease. This has become more feasible with the development of hypofractionated (shorter-course) approaches discussed later. Thus far, the attempts to define subsets of breast cancer patients with favorable early-stage disease that may not require RT by using standard clinical and pathologic criteria have been unsuccessful, with the possible exception of women over 70 years of age with stage I, ER positive disease who are willing to be treated with hormonal therapy. Studies are underway to find molecular markers that can reliably identify patients who may be adequately treated with breast-conserving surgery alone without the need for radiation.

Patient-Related, Disease-Related, and Treatment-Related Factors Associated with Local Outcome after Breast-Conserving Therapy

Patients treated with BCT have excellent rates of local control. The EBCTCG meta-analysis of the first generation of clinical trials investigating breast conservation reported a 5-year in-breast recurrence rate of 6.7% for patients with node-negative disease and 11% for those with node-positive disease (1). The respective 10-year in-breast recurrence rates for these cohorts were 10% and 13.1%, respectively. As previously indicated, there have been a number of changes that occurred over the past few decades that have favorably affected these rates. In part, these changes have come from a greater understanding of patient, disease, and treatment factors that are associated with LRs, and this has helped to refine the selection criteria for breast conservation and has led to changes in treatment techniques to improve outcomes.

Patient-Related Factors. An important patient-related factor that affects in-breast recurrence rates is patient age. Several single-institution studies have reported that young patient age, usually defined as age less than 30 to 40 years, is associated with an increased risk of local recurrence (LR), distant metastases (DM), and reduced disease-specific survival (39–42). This finding was also noted in an European Organisation for Research and Treatment of Cancer (EORTC) randomized trial that investigated the use of a tumor bed boost after whole breast irradiation. Overall, when patients from both arms of the study were evaluated, the 5-year in-breast recurrence rate for patients 40 years of age or less was 15%, compared to rates of 7% for patients aged 41 to 50 years, 4% for patients aged 51 to 60 years, and 3% for patients older than 60 years of age (39). Younger age has also been shown in some studies to adversely affect LR rates after mastectomy. A study from investigators at the University of Texas MD Anderson Cancer Center retrospectively evaluated the local-regional treatment outcome of 668 breast cancers in patients 35 years of age or less (40). In this series, patients with stage I disease who were treated with chemotherapy had acceptable local-regional treatment outcomes with either BCT or mastectomy. However, the patients with stage II disease treated with BCT (18%) or mastectomy without radiation (23%) had higher 10-year local-regional recurrence rates than those treated with mastectomy and postmastectomy radiation (6%). There is some evidence that the impact of young age on the risk of LR has decreased

over time. In a population-based registry study, Van der Sangen et al. reported that the 5-year risk of LR in women less than 40 years of age undergoing BCT decreased from 11% for those treated from 1993 to 1998, to 3.8% for those treated between 2000 to 2005 (43). How much of the age-related risk of LR is due to a higher proportion of unfavorable cancer subtypes, such as triple-negative disease, is unclear. Cancello et al. retrospectively examined patients enrolled in International Breast Cancer Study Group trials to determine the impact of age within breast cancer subtypes. In patients with Luminal A type tumors, no increase in LR was seen in those under 35 years of age compared to patients aged 35 to 50 years, but for other subtypes, there was a trend for very young age to be associated with an increased risk of LR, although this did not reach statistical significance in some groups due to sample size (44). As noted above in a recent series from the Dana-Farber Cancer Institute/Brigham and Women's Hospital, and Massachusetts General Hospital in Boston, age was also in the final model along with subtype, but the magnitude of the effect was much smaller than for subtype, with a crude rate of LR of 6.5% for the patients in the lowest age quartile (ages 23 to 46) compared with only 0.9% for patients in the highest age quartile (ages 64 to 88). Additionally, both poor prognosis Amsterdam genetic signatures and high 21 gene recurrence scores (Oncotype Dx) are more frequent in younger women (45,46); as a result, further research evaluating the interaction between molecular subtype and age is needed. At present, young age alone should not be considered a contraindication to BCT.

A second, important patient-related factor that can influence rates of LR is the presence of a germline mutation in *BRCA1* or *BRCA2*. Investigators from Yale University determined *BRCA* gene status in 127 patients, 42 years of age or less, who were treated with lumpectomy and radiation, and found 22 with deleterious mutations. After 12 years, the rates of ipsilateral breast recurrence (49% vs. 21%; $p = .007$) and contralateral cancer (42% vs. 9%; $p = .001$) were both significantly higher in the patients with *BRCA* mutations (47). Many of these ipsilateral breast recurrences may actually be second breast cancers. Also, these high rates of in-breast recurrence may be significantly less in carriers who have undergone a bilateral oophorectomy. This finding was noted in a multicenter retrospective study that did not find an overall difference in the 10-year rate of in-breast recurrence in mutation carriers (12%) versus matched controls (9%). However, mutation carriers who had not had a bilateral oophorectomy experienced increased rates of in-breast recurrence compared to controls (hazard ratio [HR] 1.99; $p = .04$) (48). Age at initial cancer diagnosis also impacts the risk of subsequent cancers in the ipsilateral breast. Table 35-3 (47–50) displays published studies that have evaluated the rates of ipsilateral tumor recurrences and of contralateral breast cancer in *BRCA* mutation carriers. The choice of mastectomy versus BCT is influenced by patient preference, age, stage, and whether the mutation is in *BRCA1* or *BRCA2*. Younger patients with early-stage breast cancer are encouraged to have mastectomy. Older patients can be considered for BCT, particularly if the breast cancer is more advanced and/or *BRCA2* associated (see Chapter 17).

Disease-Related Factors. One of the most important pathologic factors that affects rates of local control after BCT is surgical margins. When BCT was first introduced, the importance of achieving histologically negative margins was not recognized, and a number of patients in early BCT publications had either unknown margin status or positive surgical margins. Retrospective analyses indicated that such patients had higher rates of LR, particularly if the disease had an extensive intraductal component (defined as tumors that are predominantly non-invasive or tumors with a DCIS component comprising at least 25% and with DCIS present in surrounding normal breast tissue) (51). The fact that biologic factors are increasingly recognized as determinants of LR after both mastectomy and BCT has been discussed in detail, as has the role of systemic therapy in reducing LR and the lack of evidence that margins more widely clear than tumor not touching ink are necessary for the majority of breast cancer patients. The presence of ink on tumor remains an indication for re-excision, but when re-excision carries a significant aesthetic consequence, the degree of margin involvement should be considered. Specifically, some retrospective series have found that patients with a focally positive margin have better outcomes that those with margin involvement over a wider area. In one study, Vicini et al. (52) retrospectively reassessed margin status in 607 cases treated with BCT and reported a 12-year in-breast recurrence rate of 9% in patients with negative margins, 6% when a small amount of disease was close to the margin, 18% for those with an intermediate degree of disease close to the margin, 24% for those with a large volume of disease close to margin, and 30% for those with a positive margin. It is also useful to note that margins at the skin anteriorly or at the pectoral fascia posteriorly are not of concern since breast tissue does not extend beyond those margins. Good communication between the surgical and radiation oncologists is important in this regard.

Not surprisingly, the importance of margin status on LR is also affected by other factors, such as age, use of systemic therapy, and timing of radiation delivery. Park et al. (53) reported that the use of systemic treatments reduced the in-breast recurrence rates for patients with focally positive margins (8-year rate of 7%), whereas higher rates were seen in those with focally positive margins who did not receive systemic therapy and in all patients with more diffusely positive margins. Jobsen et al. (54) showed that

Yale (63)	548: chemotherapy or tamoxifen	7	12	6

margin status was of particular importance in women 40 years of age or less. In this younger cohort, the risk of in-breast recurrence according to margin status was 37% in those with positive margins compared with only 8% in those with negative margins. Finally, in a randomized prospective trial, investigators from Harvard Medical School found that patients with close or positive margins had a high rate of LR if radiation was delayed in order to first deliver adjuvant chemotherapy, but if negative margins were achieved, there was no adverse affect of radiation delay in local control (55).

Taken together, these data suggest that margin status correlates with long-term local control for patients treated with BCT. It is therefore reasonable to recommend re-excision for patients with positive margins and individualize treatment recommendations for patients with close margins. Other disease-related factors that have been correlated with local control rates include the presence of multicentric disease, histology of the tumor, lymphovascular space invasion, and the stage of disease. Limited data suggest that *gross multicentric disease*, defined as separate foci of disease in different quadrants of the breast, adversely affects local outcome (56). However, given the improvement in local control seen since the time that multicentricity was identified as a contraindication to BCT, this issue is being revisited in a prospective trial which should provide more definitive information. Most tumor histologies have similar LR rates when all other factors are equal. For example, Salvadori et al. (57) reported that the in-breast tumor recurrence rate for 286 cases of lobular cancer was 7% and was equivalent to the rate for those patients with infiltrating ductal carcinoma. Similarly, investigators from the University of Texas MD Anderson Cancer Center reported a 7% 10-year recurrence rate for patients with lobular carcinoma versus a 9% rate for those with invasive ductal carcinoma (58). One unusual histology that may be associated with higher rates of LR after BCT and mastectomy is metaplastic carcinoma (59). Lymphovascular space invasion has also been noted by multiple authors to be associated with increased rates of in-breast recurrence after BCT (30,60), but is also associated with increased rates of chest wall recurrence after mastectomy. Finally, stage of disease has a relatively minor influence on the likelihood of LR. In the EBCTCG meta-analysis of data from randomized trials, the 5-year risk of LR was 11% in patients with positive lymph nodes versus 7% for those with negative lymph nodes (1). Investigators from the University of Texas MD Anderson Cancer Center found that stage was an important factor in LR rates for young breast cancer patients. The 10-year rate of LR after BCT, radiation, and chemotherapy for patients 35 years of age or less was 12% for those with stage I disease and 18% for those with stage II disease (40).

Treatment-Related Factors. Systemic treatments reduce the risk of recurrence in the ipsilateral breast in patients who are treated with whole breast irradiation. Table 35-4 (32,61–63) shows data from prospective trials and single-institution studies highlighting this benefit. In the NSABP B-21 trial, which enrolled patients with lymph node-negative breast tumors smaller than 1 cm, the crude rate of LR was only 3% in patients treated with BCT and tamoxifen compared with 7% in women treated with BCT without tamoxifen (32).

A tumor bed boost after whole breast irradiation is another treatment-related factor that can decrease the risk of in-breast recurrence. The first randomized trial investigating the impact of a 10-Gy boost after 50 Gy of breast irradiation was performed in Lyon, France. The use of a boost led to a small but statistically significant reduction in the rate of LR at 5 years (3.6% vs. 4.5%; $p = .04$) (64). The EORTC has subsequently published a much larger trial that randomized patients to receive or not receive a 16 Gy boost after 50 Gy of whole breast radiation treatment. The use of a boost reduced the risk of an in-breast recurrence at 5 years by 40% ($p < .001$, the absolute reduction in risk at 5 years was ~4%) (39,65). Patients of all ages achieved the same proportional benefit from the boost, but the absolute benefit was greatest in the younger patients. At 10-years, the risk of in-breast recurrence was reduced with a tumor bed boost from 10.2% to 6.2% (65). The 10-year results of the EORTC trial for patients divided according to age are shown in Table 35-5 (65).

TABLE 35-5

Ten-Year In-Breast Recurrence Rates of the European Organisation for Research and Treatment of Cancer Boost versus No Boost Trial for Patients Divided According to Age

	Boost (%)	*No Boost (%)*

Age ≤40 yrs	23.9	13.5
Age 41–50 yrs	12.5	8.7
Age 51–60 yrs	7.8	4.9
Age ≥60 yrs	7.3	3.8

Data from Bartelink H, Horiot JC, Poortmans PM, et al. Impact of a higher radiation dose on local control and survival in breast-conserving therapy of early breast cancer: 10-year results of the randomized boost versus no boost EORTC 22881-10882 trial. *J Clin Oncol* 2007;25:3259–3265 (65).

INTEGRATION OF RADIATION WITH SYSTEMIC TREATMENT

Most patients with early-stage breast cancer are treated with surgery, systemic therapy, and RT, and therefore the sequencing of RT with systemic treatments remains an important clinical question. To determine the optimal sequencing schedule of chemotherapy and radiation, investigators from the Harvard Medical School/Dana-Farber Cancer Institute conducted a randomized trial that compared four cycles of doxorubicin-based combination chemotherapy followed by RT or RT followed by the same chemotherapy. The updated results showed no statistically significant differences in LR, distant metastasis, or overall survival between the two groups (55). Patients with close surgical margins had an increased risk of LR when sequenced with chemotherapy followed by radiation, suggesting that re-excision should be considered for such patients. A second important study from the CALGB addressed whether a more extended delay in radiation in order to treat with both anthracyclines and taxanes increased LR risk. These investigators reported that those treated with paclitaxel after anthracyclines had lower risks of isolated local-regional recurrence than those treated with just four cycles of anthracyclines (3.7% vs. 9.7%, respectively; $p = .04$) (66). Given this information, it has become standard that patients receive initial chemotherapy followed by RT.

There are no randomized trials that directly compared concurrent tamoxifen and radiation versus radiation followed by tamoxifen. However, three recent retrospective reports found no difference in outcome according to the sequencing of radiation and hormonal therapy. Pierce et al. (67) examined this question in 309 patients treated within the Southwest Oncology Group and found 10-year rates of recurrence of 7% with concurrent treatment versus 5% with sequential therapies ($p = .54$). Ahn et al. (68) from Yale University examined this issue in 495 patients treated with breast conservation and also found no difference in local control, development of DM, and overall survival after 10 years. Finally, Harris et al. (69) from the University of Pennsylvania conducted a similar analysis and also found very similar results.

Finally, for patients receiving adjuvant trastuzumab, most have continued this therapy concurrently during the course of radiation, and the data thus far suggest that this combination is not associated with increased complication rates. Data from the NSABP B-31 trial showed a rate of congestive heart failure of 3.2% for patients treated with trastuzumab and left-sided radiation compared to a rate of 4% for those treated with trastuzumab and no left-sided radiation ($p = .80$) (70). These data were supported by the North Central Cancer Treatment Group N9831 trial that compared the rate of cardiac events in patients treated with trastuzumab with (1.5%) or without (6.3%) radiation (71). Furthermore, none of the radiation-associated adverse events were increased in those treated concurrently with trastuzumab versus those who were not.

Treatment Techniques for Breast-Conserving Therapy

Surgical Technique

The surgical incision should be close enough to the primary tumor to allow adequate exposure. Although circumareolar incisions provide the best cosmetic results, the size of the areola and the distance from the tumor to the areola should be considered when selecting an incision. To optimize the cosmetic outcome, biopsy incisions in the upper breast are usually oriented in a curvilinear fashion, and biopsy incisions in the lower breast are oriented in a radial fashion. For all but superficial cancers, preserving the breast tissue anterior to the lesion by incising it, rather than excising it, will help to maintain breast contour. Clips are placed to mark the extent of the resection cavity and are very helpful in planning the radiation boost. Deep parenchymal sutures may be used for closing the defect, especially in patients who undergo large-volume excisions. In patients with prominent calcifications, a postoperative mammogram is obtained before the initiation of RT. (This is particularly true if the specimen mammogram does not provide clear evidence that all suspicious calcifications have been removed.) If the postoperative mammogram reveals residual calcifications at the lumpectomy site, localization and re-excision should be performed to remove all suspicious microcalcifications. With standard resections, patient satisfaction with the cosmetic outcome is high, with 90% rating their cosmetic outcomes as "excellent" or "good."

Recently, there has been great interest in *oncoplastic surgery* defined as the use of plastic surgical techniques of tissue rearrangement and contralateral symmetry procedures to improve the aesthetic outcome of BCT. Much of the impetus for oncoplastic surgery comes from the belief that the removal of large amounts of normal breast tissue to obtain more widely clear margins decreases the risk of LR. As previously discussed, evidence to support this belief is lacking. Neoadjuvant chemotherapy to shrink large tumors prior to surgery is an alternative approach that has been proven to be safe and effective in prospective randomized trials, and, in patients who will need chemotherapy anyway, has the advantage of not requiring a more extensive surgical procedure. Thus, the pool of patients requiring oncoplastic surgery is relatively small. To date, there are very limited data regarding cosmetic outcomes and LR risks with this approach. In one study of 127 patients who were offered both conventional BCT or oncoplastic surgery, patient satisfaction with cosmetic outcome did not differ between groups (72). In addition to the lack of clear evidence of benefit, the tissue rearrangement frequently makes tumor bed localization for radiation boost treatment more difficult and can lead to difficulties with re-excisions should the margins be positive.

Technique of Conventional Radiation Treatments

Conventional radiation treatments have targeted the entire ipsilateral breast and treated this region to a dose of 45 to 50 Gy delivered in 25 to 28 daily fractions. Subsequently, a 1.5 to 2.0 cm volume around the surgical cavity is treated as a tumor bed boost field with an additional 10 to 16 Gy in 5 to 8 daily fractions, typically using electron beam. Treatments are given in an outpatient setting and each daily treatment takes approximately 15 minutes in the treatment room. The entire course of therapy is typically 6 weeks.

Contemporary whole breast irradiation begins with CT-based planning. Patients are typically treated supine with arms above the head. Other positions, such as prone or lateral decubitus, can be useful for patients with large or pendulous breasts. Left-sided tumors can be treated using a heart block, prone technique, or breath-holding techniques to avoid direct heart irradiation, but patient cooperation and special in-room patient position monitoring are required for the breath-holding technique. Contouring breast cancer volumes is important, and the mean heart dose should be determined. An atlas for contouring is available from the RTOG/NRG Group at http://www.rtog.org/corelab/ContouringAtlases/BreastCancerAtlas.aspx. Late cardiac effects of radiation are dependent on the mean

heart dose and influenced by the presence of cardiac risk factors (73).

Whole breast irradiation is usually delivered via tangent fields using high-energy x-rays. Typically, two opposed photon fields that tangentially cover the anterior chest and minimize the intrathoracic normal tissue are used to treat the breast. An example of such fields is shown in Figure 35-3. Forward planning techniques allow addition of sub-fields to optimize dose homogeneity; intensity modulated radiation treatment (IMRT) is typically not required and can be associated with increased low-dose radiation to adjacent normal tissues. An example of treatment fields used to modulate the intensity of the RT is shown in Figure 35-4. In some cases, the use of higher linear accelerator energies, such as 10 MV or a mixture of 15 and 6 MV, is needed to assure adequate dose homogeneity. Adequate dose homogeneity by selection of beam energy and modulation of beams has been shown to minimize acute skin reactions and maximize long-term cosmetic results. Three-dimensional treatment planning of the boost fields helps to select the appropriate energy to ensure optimal efficacy and safety. Figure 35-5 shows an example of a tumor bed boost field.

Standard tangent fields cover a substantial percentage of level I and II axillary nodes. High tangent techniques can be used to treat a greater percentage of the axilla. Provider-assessed rates of fibrosis and telangiectasias were increased

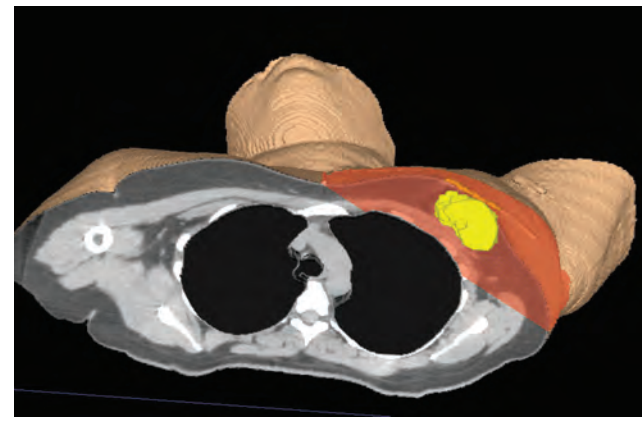

FIGURE 35-3 **A skin rendering and axial image of medial and lateral tangential photon fields typically used to treat the breast.** The two fields are opposed such that the dose fall-off over depth is matched to provide a homogeneous distribution of dose. Angles of beam entrance and exit are selected to minimize dose to intrathoracic structures. In this figure, the tumor bed location within the breast has been contoured on sequential axial slices and reconstructed as a solid yellow contour.

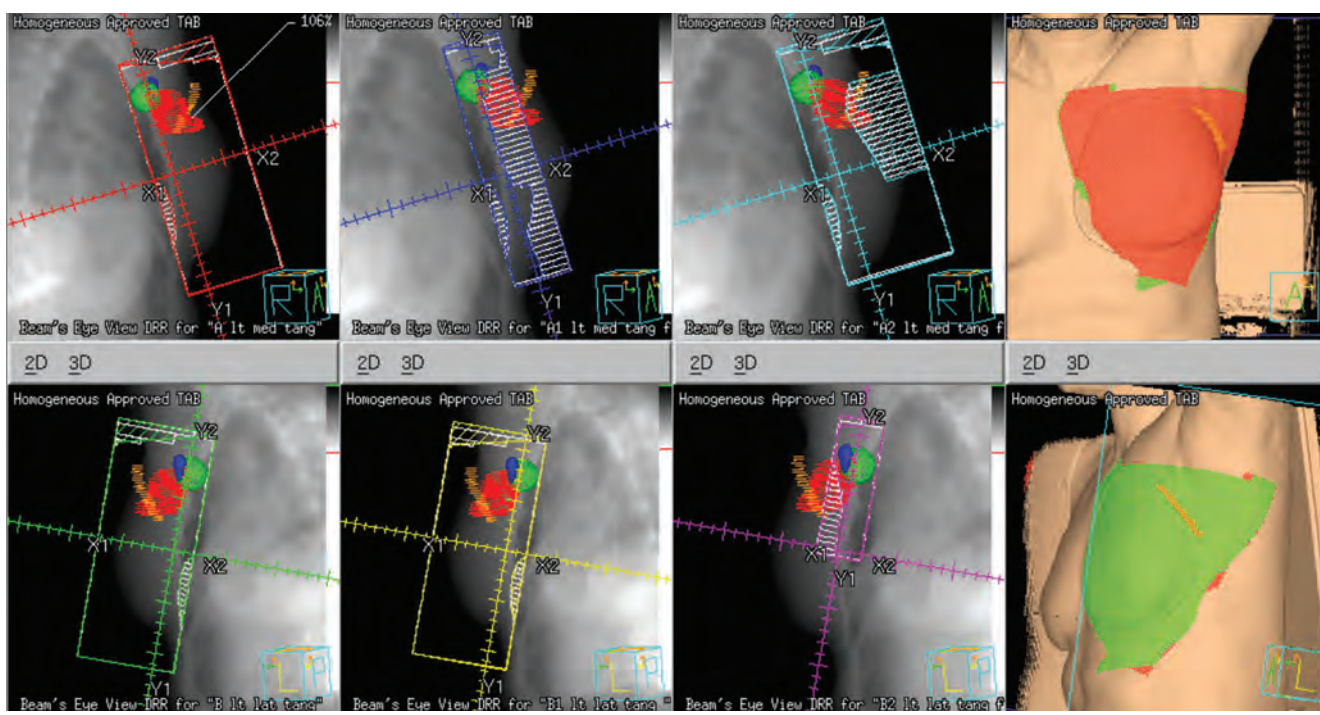

FIGURE 35-4 **An example of modulated radiation treatment fields used to treat the breast.** Two opposed medial and lateral tangent fields generate a dose distribution in the breast that has excess dose in the thinner areas of the breast, such as the apex, where the distance traveled by the beam and resulting dose fall-off is less (relative to the base of the breast). Resulting "hot spots" are subsequently blocked by subfield created by inserting multi-leaf collimators located within the head of the linear accelerator and blocking dose to these regions. A multi-leaf collimator that shielded the heart was also used in the inferior portion of all of the fields in this particular case.

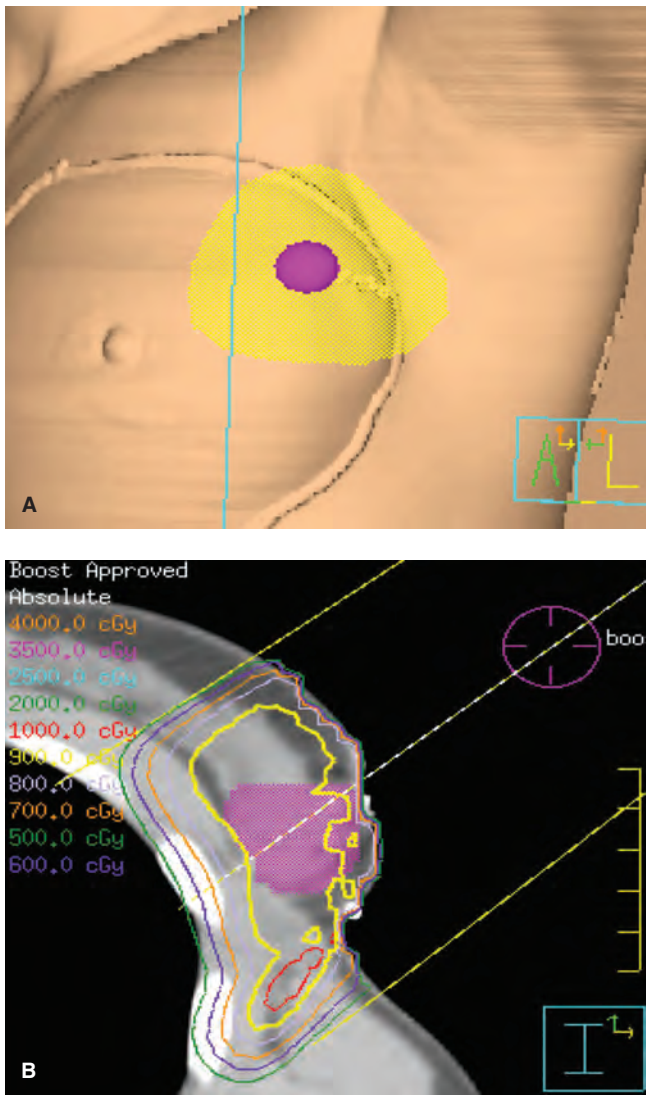

FIGURE 35-5 A skin rendering **(A)** and axial image **(B)** of a boost electron field to supplement the radiation dose to the tumor bed after completion of whole breast radiation treatment. The axial image shows the tumor bed contoured in pink with the isodose curves of the single electron beam. The selection of electron beam energy determines the penetration distance of the electron beam dose and allows the appropriate isodose curve to adequately encompass the target volume.

with addition of a boost, but patient-reported cosmetic outcomes did not differ.

ACCELERATED WHOLE BREAST AND PARTIAL BREAST IRRADIATION

The protracted nature of radiation treatments can place hardships on patients and medical systems. Accordingly, there has been an interest in studying whether the treatment course can be shortened without compromising the efficacy or increasing the toxicity of the therapy. Accelerated (or hypofractionated) whole breast irradiation (AWBI) shortens the length of the treatment course and has become more feasible due to two major developments:

1) technical improvements in the delivery of breast irradiation that result in a much higher level of radiation dose homogeneity; and
2) a better understanding of the biologic equivalence of accelerated and conventional dose schedules.

Several large randomized trials have investigated AWBI in the treatment of early breast cancer (Table 35-6) (74–77). In each of these trials, hypofractionated schedules were compared to conventional whole breast irradiation of 50 Gy in 2 Gy daily fractions. Doses in the experimental arms varied from 39 Gy in 13 fractions in the RMG/GOG and START A trials to 42.5 Gy in 16 fractions in the Canadian trial. No significant differences in overall local control rates between conventional and hypofractionated arms were noted in any of these trials. Given its large size and long follow-up, the Canadian trial, in particular, has been widely considered to be practice changing. In an exploratory subset analysis, women with grade 3 tumors had a 15.6% rate of LR in the hypofractionated arm of the Canadian trial versus 4.7% in the conventional fractionation arm (p = .01). This difference, however, was not seen in other large retrospective patient populations or in the START A and B trials. The 10-year results of the START A and B trials were presented at the 2012 San Antonio Breast Cancer Symposium. Rates of LR were comparable in all treatment arms. These results are confirmatory to the Canadian trial results.

The cosmetic implications of AWBI were also assessed in these trials and were quite favorable. In the START B trial, normal tissue effects were better in patients treated with 40 Gy in 15 fractions compared with 50 Gy in 25 fractions. Comparable cosmetic outcomes and toxicities were seen in the two arms in the Canadian trial. Continued follow-up will be needed to determine how long-term cosmetic effects and toxicity of AWBI compare to conventional whole breast irradiation.

Based on the available data, a task force of the American Society for Radiation Oncology (ASTRO) has developed guidelines for the use of AWBI (78). The task force favored a dose schedule of 42.5 Gy in 16 fractions (Canadian) and its use in patients 50 years of age or older with pT1-2N0 cancer treated with BCS and not treated with adjuvant chemotherapy where the dose homogeneity is within +/-7% and the heart can be excluded from direct irradiation. There was no agreement on the use of a boost. 40 Gy in 15 fractions was adopted as the United Kingdom standard for all patients with invasive breast cancer in 2009.

Additional follow-up is being obtained on the first generation AWBI trials, and multiple second-generation AWBI trials have already been launched. Trial designs vary and it is likely that the results of these trials will expand the accepted indications and dose schedules for AWBI.

Rationale for Accelerated Partial Breast Irradiation

Although whole breast irradiation remains the most common technique for delivery of radiation as part of BCT, APBI has been employed for many years, and there is widespread interest surrounding its use. The rationale for APBI stems from the observation that the majority of in-breast recurrences occur near the primary tumor site. Therefore, confining radiation to the area immediately surrounding the tumor may provide equivalent rates of primary tumor control while sparing radiation to regions that are at low risk of harboring clinically relevant microscopic disease. APBI can also

potentially minimize dose to adjacent normal structures, including the heart, lungs, ribs, and soft tissues, which could reduce the risk of radiation-induced late complications.

Because less total tissue is irradiated, higher daily doses can be delivered over fewer fractions, making treatment more convenient for patients. Shorter courses could also improve compliance with radiation in the elderly and geographically isolated populations, both of which have been shown to have lower compliance with radiation following BCS. Finally, some forms of APBI could improve efficiency and decrease cost of treatment.

Accelerated Partial Breast Irradiation Techniques and Non-randomized Experiences

Several techniques have been developed to deliver APBI. Although the modalities vary significantly, all are designed to deliver therapeutic doses to the tissue near the surgical cavity that is felt to be at highest risk of recurrence.

External beam radiation techniques similar to those used for whole breast irradiation have been adapted to deliver APBI. These techniques have the advantage of being noninvasive and can utilize many of the same treatment planning and delivery tools as whole breast irradiation. Typical doses are 36 to 38.5 Gy in 10 fractions delivered twice daily over 5 days. Conformal 3D-RT or IMRT planning can be used, and a variety of beam arrangements have been described. Early results from a number of institutional reports look favorable. Efficacy data from RTOG 0319, a Phase I/II trial with 58 patients, showed an LR rate of 6% (4% within the treatment field), and 2 patients with a grade III skin toxicity at 4.5 years. No clear dose-toxicity relationship has been identified—although initial results are promising— but long-term follow-up is lacking (79). Whelan et al. reported at the October 2012 ASTRO meeting that the cosmetic results in the recently closed Canadian Randomized Trial of Accelerated Partial Breast Irradiation (RAPID) trial (discussed below) for patients on the APBI arm were significantly worse than for patients treated on the conventional whole breast irradiation arm. In the Canadian RAPID trial, the doses and techniques used were similar to the external beam treatment for APBI in the NSABP B-39/RTOG 0413 trial, and the cosmetic results were assessed by the use of photographs, a nurse, the patient, and a panel of blinded physicians.

Interstitial brachytherapy using multiple catheters and high-dose rate (HDR) or low-dose rate (LDR) sources was originally developed to deliver a boost dose to the surgical cavity following whole breast irradiation, but was adapted to deliver APBI. The number and position of catheters is determined by the size and shape of the surgical cavity. Once inserted, the catheters are after-loaded at predetermined locations in order to deliver the target dose to the breast tissue immediately surrounding the surgical cavity. Iodine-125 sources are typically used for LDR delivery and are prescribed to 45–50 Gy. Iridium-192 is the most common HDR source and is prescribed to 34 Gy, typically given over 10 fractions (twice daily for 5 days). Due to the steep dose falloff, interstitial brachytherapy allows for rapid delivery of high radiation doses to target tissues with nearly complete sparing of surrounding normal structures. However, due to the invasive nature of the procedure, infection, fat necrosis, or scarring can occur.

Several interstitial brachytherapy experiences for early-stage breast cancer have been published. RTOG 95-17 enrolled 100 stage I/II breast cancer patients who were treated with catheter-based HDR or LDR brachytherapy. LR rates for HDR and LDR techniques were 3% and 6%, respectively. A separate toxicity analysis revealed 2 grade 3–4 toxicities with HDR and 3 grade 3–4 toxicities with LDR. The 10-year cumulative incidence of LR in a series of patients treated with interstitial brachytherapy at William Beaumont Hospital was 5%, with a matched-pair analysis showing similar outcomes to patients treated with whole breast irradiation (80). The 5-year rate of fat necrosis in these patients was 11%, but 95% to 99% of cosmetic outcomes were reported as good to excellent. However, 12-year updated results from a series of 50 patients treated with LDR interstitial brachytherapy from Massachusetts General Hospital showed 6 cases of LR (12%), lower rates of acceptable cosmetic results (67% good-excellent, 54% moderate-severe fibrosis), and more treatment-related toxicity with longer follow-up (81). While in retrospect, the technique of interstitial implant in this trial was not ideal, the results illustrate the need for very long follow-up to adequately assess both local tumor control and toxicity with unconventional fractionation.

Intracavitary brachytherapy is an alternative brachytherapy technique that can be used to deliver APBI. The most commonly used intracavitary device is the MammoSite® applicator (Hologic, Bedford, MA), which has been United States Food and Drug Administration (FDA)-approved since 2002. The device is inserted into the lumpectomy cavity during surgery or several days following surgery (after pathologic confirmation of margin status) and inflated. A computed tomography (CT) is obtained for treatment planning, and Iridium-192 is afterloaded into a single lumen in the center of the balloon to deliver the prescribed dose at the surface of the lumpectomy cavity surrounding the balloon. Alternate devices with multiple lumens are also available and allow for greater flexibility in treatment planning. A dose of 34 Gy is delivered in 3.4 Gy fractions given twice daily over 5 days. Following treatment, the balloon is deflated and removed. Advantages of intracavitary brachytherapy include its ease of use compared to interstitial techniques and its reproducibility in delivery of radiation dose to the balloon surface. However, problems with dose homogeneity can occur when the surgical cavity is irregularly shaped, and treatment of superficial cavities can lead to a high skin dose and increased toxicity. The 5-year rate of LR in over 1,400 patients enrolled on the MammoSite registry is 3.8%, with good-to-excellent cosmetic results reported in 90.4%. Two-year data from a multi-institutional series of 483 patients treated using the MammoSite applicator show a 1.6% LR rate and 90% good-to-excellent cosmetic outcomes. A recent population-based retrospective analysis of 92,735 older women treated with brachytherapy-based APBI showed a significantly increased incidence of subsequent mastectomy as well as higher rates of postoperative complications, breast pain, fat necrosis, and rib fracture with brachytherapy compared to whole breast irradiation (82).

Intraoperative radiation is another technique for delivery of APBI and is administered in a single fraction to the lumpectomy cavity immediately following tumor removal. One technique, targeted intraoperative radiotherapy (TARGIT), employs low-energy x-rays emitted from a source located at the center of a spherical applicator placed within the surgical cavity. The prescription dose of 20 Gy at 0.2 cm depth and 5 Gy at 1.0 cm depth is delivered over several minutes, after which the applicator is removed and the surgical incision closed. The technique has been criticized for not delivering adequate dose to a sufficient margin around the cavity. Another technique, intraoperative electron beam radiotherapy (ELIOT), employs a dedicated linear accelerator in the operating room to deliver electron beam radiation. Although not widely practiced in the United States,

intraoperative radiation has the advantage of being completed in a single day and treats the operative bed in its native state prior to surgical closure. In a series of more than 1,800 women treated with quadrantectomy followed by intraoperative radiation with electrons, the rates of LR and new primary ipsilateral cancers at 36 months were 2.3% and 1.3%, respectively, while rates of fat necrosis and fibrosis were 4.2% and 1.8%, respectively (83). Another disadvantage of intraoperative radiation is that pathologic information regarding margin status and lymph node involvement are not available at the time of treatment. If unfavorable pathologic features are found, subsequent whole breast irradiation can be administered. When used as a boost prior to planned postoperative whole breast irradiation, intraoperative delivery of 20 Gy to the surgical cavity was associated with a 5-year LR rate of 1.7%.

Randomized Trials Comparing Accelerated Partial Breast Irradiation to Whole Breast Irradiation

Four randomized trials have been published that compared conventional whole breast irradiation to APBI (Table 35-7) (84). The first published trial was conducted at Christie Hospital in Manchester, United Kingdom, and randomized over 700 women to receive external beam APBI to the surgical cavity or an accelerated course of whole breast irradiation. With follow-up of 8 years, there was no difference in overall or disease-specific survival, but LR was significantly higher in the APBI arm compared to the whole breast irradiation arm (25% vs. 13%; p = .00008). The LR rate was 22% in the APBI arm versus 12% in the whole breast irradiation arm for women with invasive ductal carcinoma, and 43% in the APBI arm versus 17% in the whole breast irradiation arm for patients with invasive lobular carcinoma. The results of the trial suggest superior local control with whole breast irradiation, but several factors limit its applicability. Microscopic margin status was not evaluated in these patients, and axillary lymph node staging was not performed. The doses used for whole breast irradiation are significantly lower than typically used today, and no boost was given. Many patients had poor prognostic factors, including large tumor size, non-ductal histology, high grade, and the presence of lymphovascular invasion that today would prompt more aggressive therapy.

The second published, randomized APBI experience is from Leeds Hospital, United Kingdom. Women were also randomized to external beam APBI or an accelerated course of whole breast irradiation. At 8 years median follow-up, there were 4 LRs in the whole breast irradiation arm compared to 10 in the APBI arm (p = .07), and 4 isolated axillary recurrences in the whole breast irradiation arm compared to 10 in the APBI arm (p = .05). Once again, the lack of microscopic margin status severely limits the findings of this trial.

A randomized trial comparing conventional whole breast irradiation to APBI was also conducted in Hungary. The majority of APBI patients underwent multi-catheter Iridium-192 brachytherapy, while a smaller percentage who were technically unsuited for brachytherapy were treated using external beam APBI. At a median follow-up of 66 months, LR as a first event occurred in 6 patients (4.7%) in the APBI arm and 4 patients (3.1%) in the whole breast irradiation arm. In the APBI arm, 2 of the 6 IBTR's were in the treated volume or its margin. The rate of excellent-to-good cosmetic results was 77.6% in the APBI arm and 62.9% in the whole breast irradiation arm (p = .009). In a separate publication, the reported rates of asymptomatic or symptomatic fat necrosis at 4 years did not differ between whole breast irradiation and APBI patients (84). The trial is limited by the relatively small number of patients, short follow-up, and variability in treatment within each arm across institutions.

The most recent published trial comparing conventional whole breast irradiation to APBI is the TARGIT-A trial. APBI patients underwent wide-local excision plus sentinel lymph node biopsy or axillary dissection followed by TARGIT to a prescribed surface dose of 20 Gy. Fourteen percent of patients treated with TARGIT had adverse pathologic features on final pathology and subsequently underwent whole breast irradiation. With 4 years of median follow-up, there were 6 LR's in the TARGIT arm versus 5 in the whole breast irradiation arm, and 4 axillary recurrences in the TARGIT arm versus 3 in the whole breast irradiation arm. The number of patients with major toxicity was similar between arms; however, the type of complications varied. Seroma requiring 3 or more aspirations occurred more frequently in the TARGIT arm (2.1% vs. 0.8%; p = .012), while RTOG grade 3 toxicity was more common in the whole breast irradiation arm (2.1% vs. 0.5%; p = .002).

The results of 3 of these APBI trials have been analyzed in a meta-analysis. Although enrollment criteria and APBI techniques vary widely across studies, no difference in survival was noted in patients treated with APBI versus whole breast irradiation (p = .55). APBI was associated with a higher risk of IBTR (odds ratio [OR] 2.15; 95% confidence interval [CI] 1.40–3.31) and axillary (OR 3.43; 95% CI, 2.06–5.72) recurrence.

Consensus Guidelines and Usage for Accelerated Partial Breast Irradiation

Given the expanding use of APBI in the treatment of early-stage breast cancer, task forces representing several professional societies have published consensus statements regarding its usage. ASTRO defined categories of patients for whom APBI is deemed *suitable, cautionary*, or *unsuitable* (85).

- Suitable patients are those ≥60 years of age with small, unifocal tumors of ductal or other favorable histologic subtype without nodal involvement who have undergone complete surgical excision with negative margins and had not received neoadjuvant chemotherapy. Only patients in the suitable category are recommended to undergo APBI outside of a clinical trial.
- Cautionary patients are those with larger tumors, less-favorable histology, an EIC, pure DCIS, or close surgical margins.
- Young patients or patients with large tumors, positive margins, unfavorable pathologic features, or involved lymph nodes are considered unsuitable candidates for APBI.

There is ongoing debate about whether more groups of patients should be considered suitable. Due to the variability of technical factors and the short available follow-up, recommendations regarding APBI technique and treatment planning were not addressed. Support for these guidelines is seen in a retrospective study of 1,822 patients with ELIOT as the sole radiation modality. The 5-year rate of LR for suitable, cautionary, and unsuitable patients were 1.5%, 4.4%, and 8.8%, respectively (p = .0003).

The American Brachytherapy Society (ABS) Breast Brachytherapy Task Group recommends limiting APBI with interstitial or intracavitary brachytherapy to patients ≥50 years of age with invasive ductal tumors measuring ≤3 cm and with no nodal involvement (86). Multifocal disease and EIC are considered relative contraindications.

Despite the recommendations of such task forces, APBI usage and techniques vary widely. A 2011 analysis of Medicare data suggests that the use of brachytherapy following breast-conserving surgery has increased from <1% of new breast cancer cases in 2001 to 10% of cases in 2006. This increase has correlated with FDA approval of MammoSite and its reimbursement by Medicare. A similar analysis of the SEER database shows the percentage of women receiving brachytherapy-based APBI increased from 0.4% in 2000 to 6.6% in 2007. In the study, 65.8% of treated patients were classified as cautionary or unsuitable based on ASTRO criteria.

Although its use is increasing, the growth in APBI is variable across patient demographics and regions. Brachytherapy-based APBI was more common among Caucasian patients and those with non-HMO insurance. Metropolitan regions, regions with higher median incomes, and regions with lower densities of radiation oncologists were also more likely to have higher rates of APBI.

Ongoing or Recently Closed Studies

Several randomized trials comparing APBI to WBI are ongoing (Table 35-8). The NSABP B-39/RTOG 0413 trial is the largest of these trials, and as of November 2012 has nearly completed randomization of 4,300 post-lumpectomy patients to conventional whole breast irradiation or APBI using multi-catheter brachytherapy, balloon catheter brachytherapy, or external beam radiation. Randomized trials are also underway in other countries and compare APBI to conventional whole breast irradiation or AWBI. Although many of these trials are accruing briskly and early toxicity results may be available in the next several years, many more years will be required before data regarding long-term efficacy and safety are available. In total, over 14,000 patients have been accrued in randomized phase III trials of APBI (compared to less than 4,100 patients in the trials that established the equivalence of BCT to mastectomy), so definitive results should become available with time. In May 2012, the first results of the ELIOT trial were presented at the Groupe Européen de Curiethérapie-European Society for Radiotherapy and Oncology (GEC-ESTRO) meeting showing a 5-year IBTR rate of 0.7% for conventional whole breast irradiation and 5.3% for patients treated with ELIOT.

In the current situation, where definitive results from trials comparing conventional whole breast irradiation, AWBI, and APBI are not available, there will inevitably be controversy where experts will differ in their opinions. It should also be noted that the time course to assess efficacy and safety in local treatment of the breast is protracted, and many of the early assessments of the results of BCS and whole breast irradiation underestimated late LRs and side effects. Long-term follow-up provided information and refinements in techniques that helped to insure that current BCS and whole breast irradiation would be safer and more effective. It is likely that there will be similar evolutions in the techniques of these various newer approaches and that there will be roles for conventional whole breast irradiation, AWBI, and APBI in the future.

Indications for Targeting Lymph Nodes in the Radiation Treatment Volume

In addition to treatment of the breast, radiation treatments are highly effective in eradicating microscopic disease within regional lymph nodes. Accordingly, treatment of lymph node regions is indicated for appropriately selected patients. Patients with a negative sentinel lymph node biopsy are at very low risk for residual nodal disease; and therefore, radiation of lymphatics is generally not indicated. Breast irradiation incidentally includes irradiation of most level I axillary nodes, and it has been shown that axillary recurrence is lower in BCT sentinel-node negative patients than in sentinel-node negative mastectomy patients. However, radiation of the lymphatics is indicated for selected patients with stage II disease and patients treated with BCT who are found to have four or more positive lymph nodes. Prospective clinical trials are currently being conducted to further define the risks, benefits, and indications for radiation of regional lymph nodes. The use of regional node irradiation may undergo substantial revision with publication of the results from MA.20 and EORTC 22922/10925, both testing the role of nodal irradiation in low-to-moderate risk BCT patients (87,88). The 5-year results of MA.20 were presented at the 2011 American Society of Clinical Oncology annual meeting by Whelan et al. and demonstrated significantly lower rates of local-regional recurrence and also of DM, and a trend to improved survival with nodal irradiation.

Treatment of the regional nodes requires additional fields. The radiation oncologist needs to decide whether to treat just level III and the supraclavicular nodes, or to also treat the full axilla. This depends on the thoroughness of the level I/II axillary dissection (by review of the operative note and/or discussion with the surgeon), the percentage of nodes that are positive (especially if >50% positive), and the presence or absence of significant (>2 mm) extranodal extension. There are no evidence-based guidelines for making this decision, and the decision needs to consider that the combination of a full level I/II dissection and full axillary irradiation results in a high likelihood (~30%) of lymphedema. When treating just level III and the supraclavicular nodes, the lateral border of the third anterior field is at the coracoid process with the depth measured in the individual patient. When including the full axilla, the lateral border is determined by contouring the axillary nodes/volume and, in nearly all cases, a posterior field is also needed to assure adequate dose homogeneity. When treating the internal mammary nodes, the nodes in the first three interspaces need to be contoured and can either be included in the tangents (partially wide tangents) or by use of a separate e-beam field matched to the tangents. The former is preferred, if possible, to avoid overlap of fields.

Based on the results of ACOSOG Z0011 (24), radiation oncologists are frequently asked to treat BCT patients following sentinel node biopsy with one or two positive sentinel nodes without completion axillary dissection. In the trial, patients were treated with breast tangents without use of a third field; however, patients in the trial were thought to be a particularly favorable subset: 46% of the positive sentinel nodes were micrometastases, and only 27% of patients randomized to completion dissection had additional positive axillary nodes, raising the possibility that axillary irradiation might be beneficial in a more diverse patient population. Results from Memorial Sloan-Kettering Cancer Center of a prospective study of 290 consecutive patients with sentinel node macrometastases meeting ACOSOG Z11 eligibility criteria (clinical T1, 2 and N0, no neoadjuvant therapy undergoing BCT) provide additional information relevant to this discussion. Axillary dissection was indicated in only 16.5% of patients on the basis of 3 or more sentinel nodes with metastases or gross extranodal extension. The median age of patients undergoing sentinel node biopsy alone was 58 years compared to 59 years for those requiring dissection

Ongoing Accelerated Partial Breast Irradiation Trials

Trial (Reference)	*Opened*	*Accrual*	*Inclusion Criteria*	*Surgery*	*PBI Technique*	*WBI Technique*	*Primary Endpoint*	*Secondary Endpoints*
NSABP B39/ RTOG 0413	3/2005	4,300 (Goal)	Stage 0, I, II tumor ≤3 cm, ≤3 positive LNs (closed to low risk in 2007)	Lumpectomy to uninvolved margins and ALND or SLNB	3D-CRT 38.5 Gy in 10 fx or multicatheter brachy therapy 34 Gy in 10 fx or intracavity brachytherapy 34 Gy in 10 fx	50 Gy in 2 Gy fx or 50.4 Gy in 1.8 Gy fx ± tumor bed boost to 60.0-66.6 Gy	IBTR	OS, RFS, distant DFS, toxicity, cosmesis, QOL
Canadian RAPID	1/2006	2,135 (Closed)	≥40 y of age, tumor ≤3 cm, pN0	Lumpectomy to uninvolved margins and negative ALND or SLNB	3D-CRT 38.5 Gy in 10 fx	42.5 Gy in 16 fx over 22 days or 50 Gy in 25 fx (if large breasts) ± 10 Gy tumor bed boost	IBTR	OS, DFS, EFS, toxicity, cosmesis, QOL, cost effectiveness
MRC IMPORT-LOW	9/2006	2,100 (Closed)	≥50 y of age, IDC ≤2 cm, grade 1–2, ≤pN1mi	Lumpectomy with ≥2 mm margins and ALND or SLNB	Arm 1: 40 Gy in 15 fx to tumor bed Arm 2; 40 Gy in 15 fx to tumor bed *plus* 36 Gy in 15 fx to remainder of breast	40 Gy in 15 fx		
ELIOT	11/2000	1,300 (Closed)	>48 y of age, tumors ≤2.5 cm, tumor location not amenable to ELIOT (axillary tail, close to skin)	Quadrantectomy and ALND or SLNB	Intraoperative electron beam 21 Gy in 1 fx to applicator surface	50 Gy in Gy fx ± 10Gy boost to tumor bed		
University of Florence	9/2005	520 (Goal)	>40 y of age, tumors ≤2.5 cm	Lumpectomy with ≥5 mm margins	IMRT 30 Gy in 5 fx to tumor bed	50 Gy in 25 fx		Initial toxicity analysis: grade 1 and 2 toxicity 22% and 19% for WBI vs. 5% and 0.8% for PBI
GEC-ESTRO	5/2004	1,195 (Closed)	>40 y of age, stage 0–II, tumors ≤3 cm, no EIC, ≤pN1mi	Lumpectomy with ≥2 mm margins (≥ 5 mm if DCIS or ILC)	HDR 32.0 Gy in 8 fx *or* HDR 30.3 Gy in 7 fx *or* PDR 50 Gy at 0.6-0.8 Gy/hr	50.0-50.4 Gy in 25–28 fx plus 10 Gy tumor bed boost	IBTR	OS, DFS, distant DFS, toxicity, cosmesis, QOL initial toxicity analysis: grade 3 dermatitis 7.1% for WBI versus 0.2% for PBI ($p < .0001$)

PBI, partial breast irradiation; WBI, whole breast irradiation; NSABP, National Surgical Adjuvant Breast and Bowel Project; RTOG, Radiation Therapy Oncology Group; LNs, lymph nodes; ALND, axillary lymph node dissection; SLNB, sentinel lymph node biopsy; 3D-CRT, 3D conformal radiation therapy; IBTR, ipsilateral breast tumor recurrence; OS, overall survival; RFS, recurrence-free survival; DFS, disease-free survival; QOL, quality of life; RAPID, Randomized Trial of Accelerated Partial Breast Irradiation; EFS, event-free survival; IDC, invasive ductal carcinoma; ELIOT, intraoperative electron beam radiotherapy; GEC-ESTRO, Groupe Européen de Curiethérapie—European Society for Radiotherapy and Oncology; ILC, invasive lobular carcinoma.

(p = .54), and 13% of patients in both groups were younger than 45 years of age. ER, PR, and HER2 status did not differ between patients undergoing sentinel node biopsy alone or axillary dissection, and 84% and 83% respectively were ER and/or PR positive and HER2 negative. Nomograms are available from Memorial Sloan-Kettering Cancer Center (www.mskcc.org/cancer-care/adult/breast/prediction-tools) and from The University of Texas MD Anderson Cancer Center (www3.mdanderson.org/app/medcalc/bc_nomogram2/index.cfm?pagename=nsln) to estimate the likelihood of positive nonsentinel nodes. Using the Memorial Sloan-Kettering nomogram, the median likelihood of additional positive nodes in the sentinel node-only group in the prospective Memorial Sloan-Kettering Cancer Center cohort was 34%, similar to what was found in ACOSOG Z11. This nomogram is not used at Memorial Sloan-Kettering Cancer Center to determine the need for axillary dissection nor the need for axillary irradiation. At a median follow-up of 13 months (range, 1–29 months), no axillary recurrences have occurred in this patient cohort, but longer follow-up is needed. At this time, it is uncertain whether or not additional fields are needed to treat the full axilla in patients estimated to have a high risk of positive non-sentinel nodes. If a decision is made to add additional fields, the full axilla should be treated.

Morbidity of Whole Breast Irradiation

Treatments require only 15 to 30 minutes each day, and most patients can continue their daily routines with minimal interruptions. Two short-term complications that occur in the majority of patients are fatigue and mild breast dermatitis. The degree of fatigue varies a great deal among individuals and generally improves to baseline within a month after treatment. In some patients, fatigue can last for months. The skin reactions associated with radiation delivered with modern techniques are typically mild. Erythema, warmth, mild discomfort, and pruritis typically develop toward the end of treatment and improve shortly after treatment completion. Some patients experience desquamation, especially if skin folds are present. Patients commonly experience "twingy" breast pain for an extended period of time. Post-treatment skin edema and mild hyperpigmentation may persist many months.

Modern treatments are very safe, with a very low likelihood of a permanent normal tissue injury. The most common complication after irradiation is mild fibrosis of breast tissue. However, most series report that 80% to 95% of patients have good to excellent aesthetic outcomes after breast irradiation to total doses of 45.0 to 50.4 Gy in daily fractions of 1.8 to 2.0 Gy (89). The development of a second cancer induced by radiation treatments of the breast is a very unusual event. In an analysis based on the Connecticut cancer registry database of 41,109 breast cancer patients, Boice et al. (90) reported that breast irradiation may increase the incidence of contralateral breast cancer in women 45 years of age or less who survived for at least 10 years after diagnosis (RR 1.33). The EBCTCG meta-analysis of the data from all radiotherapy trials in breast cancer (including trials investigating postmastectomy radiation) reported a 1.18 ratio of rates for developing a second breast cancer for irradiated vs. nonirradiated patients (p = .002) (1). Given these data, it is important to optimize techniques to minimize scatter radiation dose to the contralateral breast. The newer modulated techniques that provide three-dimensional dose compensation with multileaf collimated subfields have the additional benefit of decreasing the dose to the contralateral breast by 65% to 82% (91). The EBCTCG meta-analysis also indicated an increased risk of lung cancer development in patients who received radiation (HR, 1.61), although this included patients receiving older techniques of postmastectomy RT where the amount of lung irradiated is much greater than with currently used breast irradiation (1). Data from the NSABP indicated that this risk was dependent in part on the volume of lung included in the radiation fields. Specifically, an increased risk was found in patients treated in the NSABP B-04 trials where treatment included multiple fields to target the regional lymphatics in addition to the breast and chest wall, but not the B-06 trial where breast-only treatment fields were used (92). Smoking is recognized as an important cofactor for the development of lung cancer after breast cancer radiation treatments. Kaufman et al. (93) conducted a population-based case-control study using the Connecticut Tumor Registry and reported that non-smoking breast cancer patients who received radiation did not have a higher risk of lung cancer development, but irradiated breast cancer patients who were smokers did have a significantly increased risk. These data were similar to a case-control study published by the group from the University of Texas MD Anderson Cancer Center who also found that smoking was a significant independent risk factor for lung carcinoma after breast cancer, and that smoking and radiation combined enhanced the effect of either alone (94). A rare, but frequently fatal, radiation-related malignancy is lymphangiosarcoma of the treated skin. This is an unusual second cancer in that it can be seen prior to 5 years post treatment.

One of the most significant potential sequelae of whole breast irradiation is cardiovascular disease with associated cardiac-related death. The meta-analysis from the EBCTCG indicated that patients treated with radiation had a 1.27 RR of death from heart disease compared to the patients who did not receive radiation (1). This result was predominantly seen in relatively older postmastectomy radiation studies that utilized treatment techniques and dose schedules no longer in use. With the advent of improved technologies, radiation treatments are much less likely to cause adverse cardiac events. For example, a study evaluating the SEER database suggested that radiation treatments increased cardiac-related deaths for patients treated in the 1970s, but there was no increase in cardiac deaths in the patients treated in the 1980s (95). Similarly, a study that evaluated the SEER-Medicare database found no increase in cardiac events in patients over 65 years of age who were treated with radiation for a left-sided breast cancer (96). However, a study from the University of Pennsylvania indicated that patients treated with radiation as a component of BCT for a left-sided breast cancer had an increased risk of coronary artery disease compared to those treated for a right-sided breast cancer (97). Additionally, investigators from Duke University have shown that inclusion of some of the left ventricle in tangential fields used to treat left-sided breast cancers can result in cardiac perfusion abnormalities (98). The period from treatment to radiation-induced cardiac disease is protracted and typically greater than 10 to 15 years, so avoiding direct cardiac exposure is particularly important in younger patients.

Based on these data, it is very important that the risk of radiation-associated heart disease be minimized or completely avoided by ensuring that the heart is not within the treatment fields. For patients with upper outer quadrant tumors, a small heart block can be used, which shields a small volume of the far medial and far lateral lower breast tissue. Studies have reported that use of heart blocks do not increase the risk of in-breast recurrence (99). For tumors in the lower quadrants, new techniques are available to physically displace the heart from the tumor bed through breath-hold techniques.

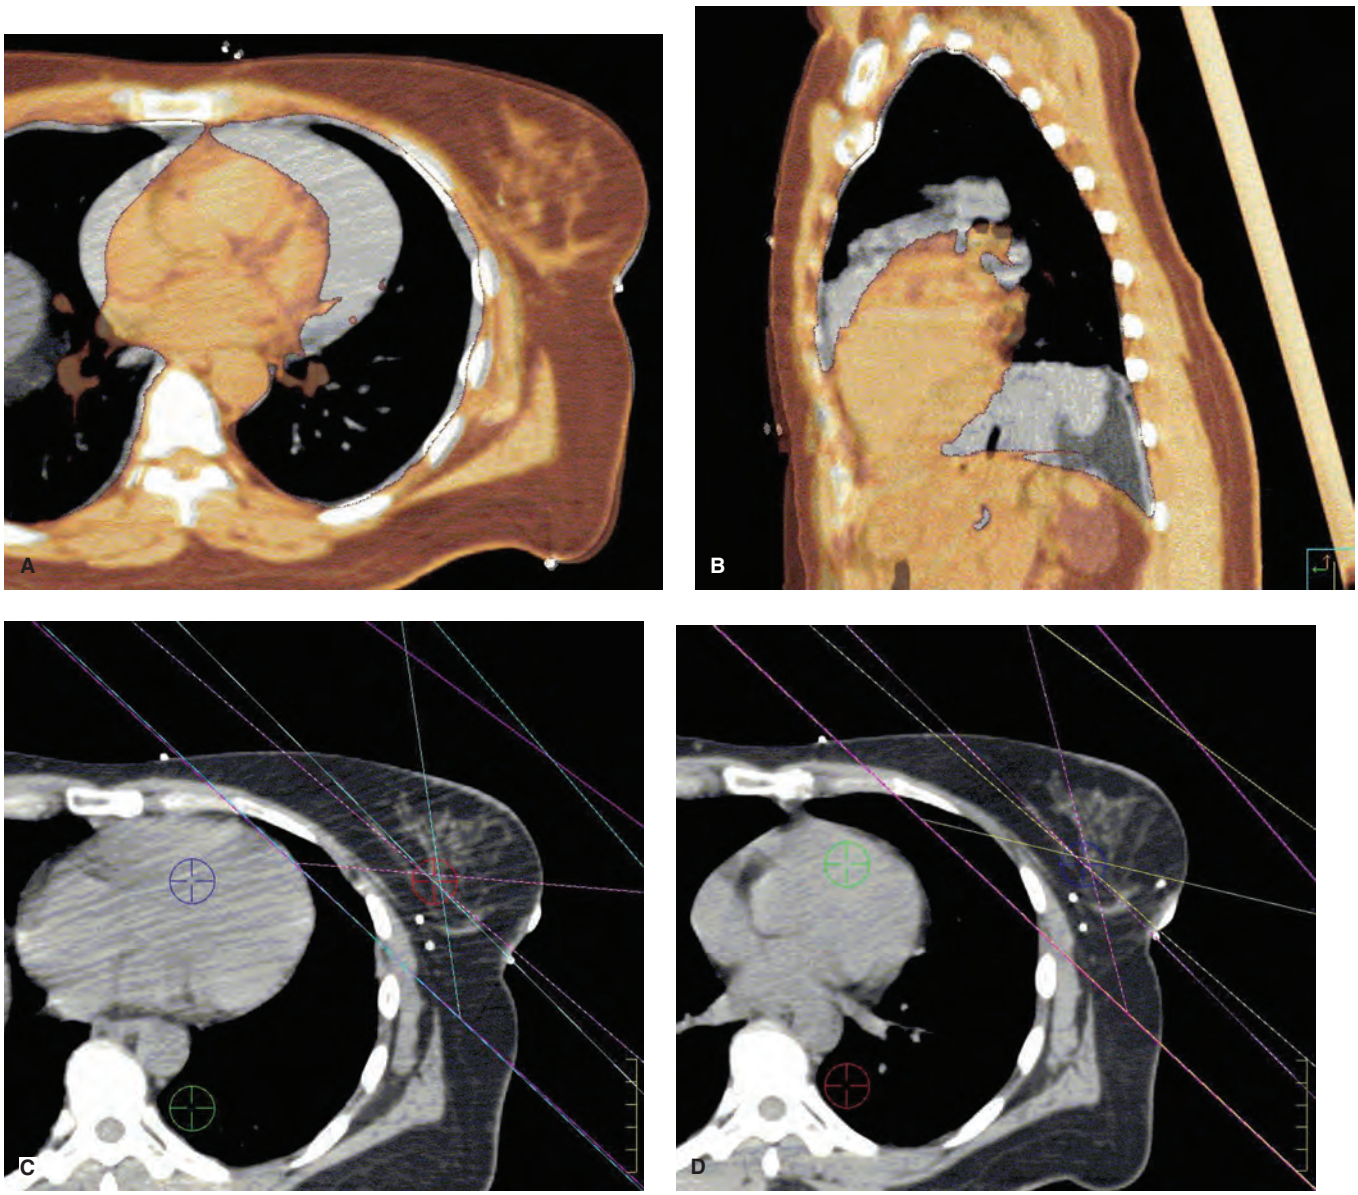

FIGURE 35-6 **An example of a treatment that is gated to deep inspiration in order to displace the heart from the radiation field.** As seen on the fused axial **(A)** coronal **(B)** image of a free-breathing scan and a breath-hold scan, deep inspiration lowers the diaphragm and displaces the heart inferomedially. The next two axial images show the relationship of the heart to the radiation fields under free-breathing conditions **(C)** and breath-hold conditions **(D)**. In this example, the treatment beam is only turned on during breath-hold periods to ensure that the heart is outside of the field.

In this procedure, patients can monitor their respiratory cycle and hold their breath in a predefined volume that achieves cardiac displacement. During deep inspiration, the diaphragm pulls the heart down and medial relative to the left breast. An example of this technique is shown in Figure 35-6. In-room monitoring is necessary to make sure that the patient is in the correct position for treatment, and a variety of techniques are available to do this. For patients with superficial tumors, another approach to avoiding cardiac irradiation is to use a prone (or decubitus), rather than supine, technique. Nodal irradiation, particularly full axillary RT combined with axillary dissection, increases the risk of lymphedema and rarely results in brachial plexopathy, a devastating complication that can lead to loss of function in the arm.

POSTOPERATIVE SURVEILLANCE

In patients who are treated with BCS and postoperative RT, annual mammography and physical exam one to two times yearly are appropriate follow-up procedures given the low risk of both ipsilateral recurrence and contralateral cancer in most patients. Some groups obtain a new baseline mammogram of the treated breast 4 to 6 months after the completion of RT, although the value of this remains unproven.

MANAGEMENT SUMMARY

- Based on long-term results demonstrating both efficacy and safety, BCT consisting of breast-conserving surgery for removal of the primary with negative margins of resection followed by whole breast irradiation is an appropriate option for the majority of patients with early-stage breast cancer.
- No patient subset based on clinical and pathology features has been identified that has a low risk of LR without RT. Breast-conserving surgery and hormonal therapy is an option in elderly women with small node-negative, hormone receptor positive breast cancer, particularly if the patient has co-morbid illnesses. However, short-course breast irradiation is also an option.
- Whole breast irradiation reduces the 10-year risk of any first recurrence with a rate ratio of about half (0.52, $2p < 0.00001$), and reduces the 15-year risk of breast cancer death with a rate ratio of about one-sixth (0.82, $2p = 0.00005$).
- Following whole breast irradiation, a boost of additional irradiation is given to the primary site, particularly in younger patients.
- Absolute contraindications to BCT include previous RT to the chest or breast, RT required during a pregnancy, diffuse malignant appearing microcalcifications on mammography, and inability to achieve a negative margin of resection. The use of BCT is generally contraindicated in patients with multicentric cancer or with active connective tissue disease involving the skin.
- Patients can be reliably selected for BCT with a history, physical examination, and diagnostic mammography. Evidence that MRI or screening whole breast ultrasound improves outcomes is lacking.
- A margin with no ink on tumor is sufficient for the majority of patients undergoing breast conservation. Factors, such as patient age, ER, progesterone receptor, and HER2 status, amount of tumor close to the margin, and use of neoadjuvant chemotherapy need to be considered when determining if larger margins are needed in individual cases.
- The use of adjuvant systemic therapy developed to reduce distant metastasis has been demonstrated to substantially reduce LR when combined with breast irradiation.
- When a patient will receive both BCT and adjuvant chemotherapy, RT generally follows chemotherapy. Adjuvant hormonal therapy or trastuzumab can be given with or after RT.
- Computed tomography simulation with contouring of critical volumes is important and should be done for all patients, especially those with left-sided breast cancer. The treatment technique should attempt to exclude the heart from the treatment fields. Appropriate measures should be used to provide homogeneous irradiation.
- Accelerated whole breast irradiation and APBI are appropriate options for patients considered suitable by ASTRO consensus guidelines. There is limited level I data supporting APBI, however.

CHAPTER 36

Breast Reconstruction

Babak J. Mehrara and Alice Y. Ho

CHAPTER CONTENTS

Breast reconstruction is an important component of breast cancer management and improves quality of life and psychosocial well-being (1). Improvements in techniques have resulted in more natural reconstructions, decreased morbidity, and improved outcomes. Breast reconstruction has traditionally been considered reconstruction after mastectomy, however, more recent studies have reported improved outcomes even after segmental resection in some circumstances. Therefore, plastic surgeons are important members of a multidisciplinary breast team and by working closely with breast surgeons, medical oncologists, and radiation oncologists, they can help individualize and optimize breast cancer care.

In general, most women who undergo breast surgery for cancer treatment are candidates for reconstruction and there are no absolute contraindications. However, most reconstructive surgeons consider inflammatory breast cancer requiring massive skin resection and significant medical comorbidities that increase risk of medical complications as relative contraindications. In addition, reconstruction in women who will require postmastectomy radiation therapy is hotly debated and the ideal approach remains unknown. However, even in these circumstances reconstruction is warranted in some cases and must be considered on an individual bases. For example, a patient with inflammatory breast cancer who requires extensive skin resection may need reconstruction as a component of her care simply to close the resulting mastectomy skin defect.

The type of reconstruction that is performed is dependent on a number of factors including oncologic considerations, patient desires and expectations, body habitus, and surgical risk factors. Patients should be evaluated by a qualified plastic surgeon who can evaluate these considerations and advise the patients on their best reconstructive option and the ideal time to initiate the process based on their individual circumstances.

IMMEDIATE VERSUS DELAYED RECONSTRUCTION

Reconstruction can be performed either at the time of mastectomy or segmental breast resection or in a delayed manner after adjuvant treatment is completed. The timing of reconstruction is dependent on oncologic considerations and patient factors. In general, the vast majority of patients are candidates for immediate reconstruction and this approach has a number of advantages. For example, reconstruction at the time of mastectomy is associated with improved aesthetic outcomes by preserving the breast shape and envelope (Fig. 36-1). Immediate reconstruction is also easier to perform technically since there is usually less scarring and contracture. Immediate reconstruction does not delay or hinder diagnosis of a recurrence and, in most cases, does not alter its treatment (2). In addition, immediate reconstruction has important psychological benefits resulting in decreased anxiety and improved self-image, and enabling patients to cope with their diagnosis and treatment (3). From a practical standpoint, immediate reconstruction saves the patient an additional trip to the operating room.

There are, however, some potential disadvantages to immediate reconstruction. One consideration is an increased risk of complications associated with combining oncological treatment and reconstruction. Although this idea makes intuitive sense, very few studies have actually compared complication rates in the same patient cohorts. In addition, the majority of complications that occur in the setting of immediate reconstruction are minor in nature and rarely delay adjuvant therapy (4,5). Mastectomy skin flap necrosis is much more common after immediate reconstruction and likely reflects the more extensive dissection that is performed at the time of mastectomy. Some patients are

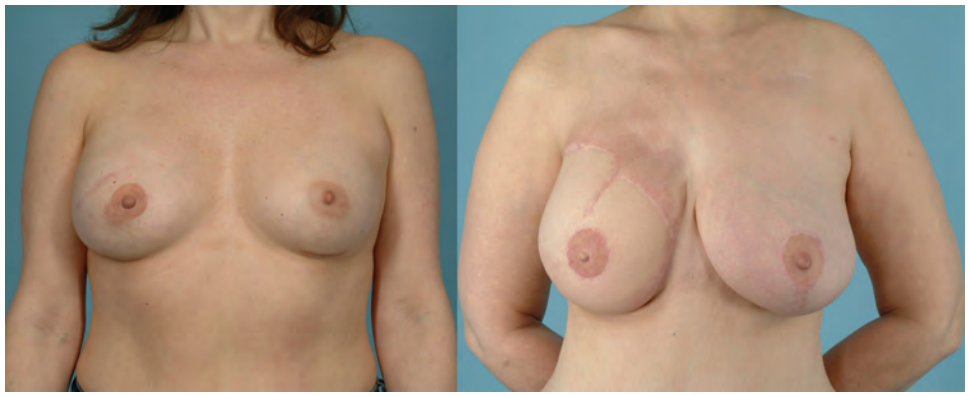

FIGURE 36-1 Postoperative photographs of patients with right breast cancer treated with immediate (*left*) or delayed (*right*) TRAM flap reconstruction. Note that although both outcomes have excellent shape or contour, patients treated with delayed reconstruction have longer and more noticeable scars.

also overwhelmed with the number of decisions they need to make for immediate reconstruction, leading to increased anxiety in some cases.

IMPLANT VERSUS AUTOGENOUS RECONSTRUCTION

Breast reconstruction can be categorized broadly into implant based or autologous tissue (i.e., the patient's own tissue) reconstruction (Table 36-1). Implant reconstructions make up the bulk of breast reconstructions that are performed annually in the United States. Implant reconstruction is simpler to perform, is associated with low rates of complications, and does not significantly increase hospital stay or recovery as compared with mastectomy alone. Although most patients are candidates for implant reconstruction, there are some relative contraindications including severe medical comorbidities, oncologic factors necessitating massive skin excision, severe immune deficiency, heavy smoking history, massive obesity, and history of breast irradiation. These circumstances increase the rates of complications associated with implant reconstruction, but do not preclude their use in select cases.

TABLE 36-1

Advantages and Disadvantages of Implant-Based or Autogenous Tissue–Based Breast Reconstruction

	Advantages	*Disadvantages*
Implants		
	Simple	Implant leak
	Low operative morbidity	Implant infection
	Short hospital stay	Feel and shape
	Quick recovery	Contralateral symmetry
		Capsular contracture
Autogenous Tissues		
	Softer, more natural	Longer operation
	Symmetry	Longer recovery
	Ages with patient	Donor site issues
	No capsule	

A disadvantage of implant reconstructions is that implants require maintenance and need to be replaced if they rupture or leak. Although implant technology has improved considerably over the past two decades, most modern implants have an average life span of approximately 10 years. A recent study demonstrated a 4-year leak rate of 4% to 15% in saline implants depending on the manufacturer used (6). In addition, because implants are a foreign substance and are placed underneath the pectoralis muscle, these reconstructions do not feel as natural as a normal breast. It is also difficult to obtain perfect or near perfect symmetry with implants in unilateral reconstructions even when contralateral symmetry procedures such as augmentation, reduction, or mastopexy are performed. Asymmetry of implant reconstructions with the normal breast tends to worsen over time, particularly if patients gain or lose weight, since the implant size does not change and the implant pocket does not sag. Thus, although aesthetic results have improved over the years, the primary goal of implant reconstructions is to have reasonable symmetry in clothes, a bra, or a bathing suit. By far the biggest disadvantage of implant reconstructions is the potential for developing capsular contracture. A capsule is a fibrous covering that develops around any prosthetic device that is placed subcutaneously. Capsular contracture develops when the capsule surrounding the implant becomes thickened and tight, causing patients to complain about tightness, pain, or implant malposition. The degree of contracture can be quantified using the Baker scale and uses a four-point scale based on physical exam and symptoms. Grade I is a normal-appearing, soft breast; grade II refers to breast implants that are firm but appear normal; grade III includes implants that are firm and appear abnormal; grade IV capsular contracture is the most severe and includes breasts that are hard, painful, and appear abnormal often with severe distortion. Most women who undergo implant reconstruction have grade I or II capsular contracture (89.6%) (7).

Breast reconstruction can also be performed using a patient's own tissues (autologous reconstruction). In these procedures, a combination of skin, fat, and muscle is transferred to the breast to reconstruct either the entire breast or a portion thereof. Tissues can be transferred from adjacent areas such as the back (latissimus flap) or abdomen or from sites located distant to the breast including the gluteal region or the inner thigh. Reconstruction can be performed either purely with autologous tissues or in combination with an implant. Autologous tissues are transferred to the breast site either by keeping their local blood supply intact (pedicled flaps) or by disconnecting and reconnecting the arterial and venous circulation using microsurgical techniques (microsurgical or free flaps). Similar to implants, autologous tissue reconstruction has high success rates and patient satisfaction.

Autologous tissue reconstruction is indicated in women who wish to avoid using implants, have failed implant reconstruction previously, or who are poor implant reconstruction candidates. For example, a patient who has undergone mastectomy and radiation is unlikely to have a successful reconstruction using an implant alone since the remaining mastectomy skin has been injured. In these circumstances, a portion of the damaged mastectomy skin is usually replaced by healthy tissues from a distant flap donor site and reconstruction is completed. Another example is a patient who has very large, ptotic breasts that are unlikely to be adequately matched with an implant reconstruction.

The main advantage of autologous tissues is the fact that reconstruction is performed with *living* tissues. These tissues age with the patient, changing over time to maintain symmetry with the contralateral breast. In contrast to implants, autologous tissues are tailored to the patient and more likely to have symmetry immediately after reconstruction. Tissue reconstructions feel and look more natural because, unlike implants, the tissues are placed in the subcutaneous plane simply replacing the breast rather than in a subpectoral position. Tissue reconstructions also do not develop fibrous capsules and can help replace damaged tissues to break up scar and relieve contracture. As a result of these advantages, tissue-based reconstructions are considered the gold standard for aesthetic reconstruction.

Of course, all good things come at a cost. The "cost" in the case of autologous tissues is donor site morbidity that increases recovery time and can have long-term consequences. At the minimum, patients reconstructed with their own tissues will have donor site scarring that in some cases may be unaesthetic. Chronic donor site pain and bothersome loss of sensation have also been reported for patients reconstructed with various types of autogenous tissues. Functional issues such as abdominal wall weakness, bulging, or hernia complicate abdominal tissue–based reconstructions in some patients. Similarly, patients reconstructed with latissimus flaps may have decreased upper extremity strength and range of motion that in some cases may necessitate physical therapy.

IMPLANT-BASED RECONSTRUCTION

In general, most patients are candidates for implant reconstruction including elderly patients and those with medical comorbidities that may preclude more complex forms of reconstruction. Absolute contraindications to implant reconstruction include severe tissue deficiency from resection or secondary to tissue damage from radiation. Relative contraindications for implant reconstruction are severe life-threatening medical comorbidities, massive obesity, and possibly long-standing heavy cigarette smoking. Some surgeons also consider the need for postmastectomy radiation therapy as a relative contraindication; however, this concept has been debated and there is no uniform consensus.

The ideal patient for implant reconstruction is thin, has moderate-sized breasts (B to C cup), minimal ptosis, and well-defined breast shape (Fig. 36-2). Although most women who undergo implant reconstruction do not have these characteristics, reasonable reconstructions with good symmetry in clothes, bra, or bathing suits is possible, particularly if contralateral breast symmetry procedures are performed. These issues are less critical in bilateral reconstructions since a similar implant is used for the contralateral breast, resulting in even better symmetry, and likely contributes to the higher rates of satisfaction in this cohort (8).

It is difficult to achieve symmetry with implant-based reconstructions in women with either very small or very large breasts. Reconstruction of very small breasts is complicated by the fact that low-volume implants needed in these cases typically have a small base diameter (the width of the implant). This issue makes it difficult to simultaneously match the volume and diameter of the breast, resulting in a wide space between the breasts. An alternative approach for improved symmetry in these cases may be contralateral augmentation to increase the volume of the normal breast.

Reconstruction of massive breasts or very obese patients with implants is also difficult due to the fact that the largest implant currently available in the United States is 800 to 850 cc. Although this is a large size, and suitable for most large-breasted women, in some women with massive breasts or those who are morbidly obese, these large implants are simply inadequate volume to achieve sufficient projection for an aesthetic outcome or to match the contralateral breast. Even if a large reduction is performed in the contralateral breast, these procedures may be inadequate to sufficiently decrease the volume, projection, or base diameter of the remaining breast, resulting in a reconstructed breast that is too small, flat, or narrow, respectively, to fit the patient's chest wall. In these cases, patients may require a small external prosthesis for improved symmetry or may be advised to undergo reconstruction with alternative measures.

Implant reconstruction can be performed either immediately after mastectomy or in a delayed fashion. The ideal incision for implant reconstruction is debated; however, incisions placed along the lines of relaxed skin tension lines (i.e., Langer's lines) are selected by most surgeons since these incisions enable maximal skin expansion. Skin-sparing

FIGURE 36-2 Pre- (*left*) and postoperative (*right*) photographs of a patient 1.5 years following reconstruction with bilateral silicone implants.

mastectomies in appropriate candidates preserve the breast envelope and enable more rapid expansion. Skin preservation is important even in non-skin-sparing procedures since there is a limit to the amount of expansion that can be performed. Overexpanded skin may become thin, shiny, and lose elasticity, resulting in impaired aesthetics, discomfort, and implant exposure. Although the oncologic risks of nipple-sparing mastectomy is still undefined and remains a source of debate, there is little doubt that these techniques have excellent cosmetic outcomes in appropriately selected patients.

The majority of implant reconstructions are performed as a two-step procedure with placement of a tissue expander initially and then conversion to a permanent implant at a later time. Tissue expander sizing is based on the dimensions of the breast pocket (width and height) and to a lesser degree the volume of the breast. With popularization and wide adoption of skin-sparing and nipple-sparing mastectomies, several groups have reported single-stage direct to implant reconstructions that avoid expander insertion (since the skin does not need to be expanded). In general, these studies have reported good to excellent results with reasonable safety profiles; however, the vast majority of these reports maintain that careful patient selection is important. These studies require validation in large prospective studies as most reports have been on limited numbers of patients and performed in a retrospective manner.

Implants and expanders for breast reconstruction are placed underneath the pectoralis major muscle. Total submuscular coverage of the implant can be obtained by elevating a portion of the rectus abdominis fascia inferiorly and serratus anterior muscle or fascia laterally to completely cover the expander. This technique is thought to decrease implant infections by providing vascularized coverage (7).

Some surgeons have criticized the total submuscular coverage technique with concerns about lower pole expansion, implant projection, and maintenance of the inframammary fold. These concerns have led to a variety of techniques including dis-insertion of the inferior insertion of pectoralis major muscle or the use of acellular dermal matrices. Over the past 10 years or so, the use of acellular dermal matrices such as AlloDerm or FlexHD to provide lower pole coverage of the expander/implant have gained significant popularity. In these procedures, the pectoralis major muscle is elevated and dis-inserted inferiorly. The lower/lateral portion of the implant is then covered with acellular dermis sutured inferiorly to the inframammary fold/lateral chest wall, and superiorly to the elevated pectoralis major muscle. Although some authors have reported excellent cosmetic results with low rates of complications (9), other reports have suggested that the use of acellular dermal matrices is associated with small, though statistically significant increases in the risk of implant infection and reconstructive failure (10). Large, prospective studies will be necessary to resolve this debate.

Once the expander is placed in the subpectoral pocket, the expander is filled intraoperatively with the final volume determined by tension on the skin and muscle. Expander filling in the office starts usually 2 weeks after surgery with 30 to 120 cc of sterile normal saline per expansion until the final volume is reached. If chemotherapy is not needed, then exchange to permanent implant is performed once the mastectomy skin flaps have completely healed. These procedures are usually performed 4 to 12 weeks following completion of chemotherapy in patients who required adjuvant treatments. The second stage of reconstruction is usually performed in an outpatient setting.

The main advantage of saline implants is the fact that if they leak, then the saline solution is simply absorbed and the implant is exchanged. However, saline implants tend to have more visible rippling and are not as comfortable as silicone implants. This latter contention is supported by recent studies utilizing validated quality of life questionnaires showing that patients with silicone implants have higher quality of life and increased satisfaction as compared with saline implants (11).

The main disadvantage of silicone implants is that leaking silicone is not absorbed and requires surgical removal. The leaking silicone is usually contained in the breast implant pocket; however, silicone extravasation can cause inflammation and capsular contracture and may be taken up by regional lymph nodes. Anecdotal reports in the late 1980s linked leaking silicone implants with a variety of ailments including autoimmune disorders and increased risk of malignancies, leading to the withdrawal of these implants by the Food and Drug Administration (FDA) in 1992 (except for procedures performed as a part of an FDA-approved research protocol). However, large-scale studies performed both in the United States and in Europe failed to find a statistically significant relationship in these outcomes and the implants are now approved by the FDA both for reconstructive and cosmetic procedures. Recent reports have suggested that textured implants in general (both saline *and* silicone) may be associated with a rare form of lymphoma, with an estimated incidence of 1 in 1 million; however, these reports need further study and validation (12).

Advancements in implant technology have introduced newer silicone implants filled with a silicone gel that is semisolid and therefore thought to be less likely to leak. These implants, referred to as form-stable, cohesive, or "gummy bear" implants, have some advantages including better shape in some patients and possibly a lower risk of leakage; however, long-term studies are needed to confirm these concepts.

Implant reconstructions are safe and well tolerated with low rates of major and minor complications (5). There were no cases of life-threatening complications (pulmonary embolus, myocardial infarction, major systemic complication) in a recent review of over 1,170 consecutive reconstructions performed at Memorial Sloan-Kettering Cancer Center (5). The majority of complications that did occur were minor and included skin necrosis (8.7%), infections (3.4%), infection requiring implant removal (1.5%), and seroma/hematoma (3.2%).

Capsular contracture is the most significant long-term risk with implant reconstructions and remains a problem even with improvements in implant technology and surgical techniques (7). The reported rates of capsular contracture vary significantly likely due to the fact that the diagnosis of this complication is somewhat arbitrary and not uniform. Most studies use the Baker scale as noted above; however, this scale has been criticized since it is not quantitative and primarily dependent on subjective assessment of "normal" or "abnormal" breast shape. This subjective assessment is likely responsible for the significant variability in the reported rates of capsular contracture and overall success rates of implant reconstructions in the plastic surgery literature.

Another important issue in comparing aesthetic outcomes in implant reconstruction is the methods used for analysis. By far the vast majority of previous studies have relied on photographic analysis by surgeons or laypeople to analyze various measures including symmetry, scars, volume, shape, and so on. Although these results are important and provide useful information, they do not address patient perceptions and may either over- or underestimate the success rates of various reconstructive needs. This deficiency

has been addressed recently with the use of validated patient reported outcome studies such as the Breast-Q, which aim to analyze how patients perceive their reconstruction in terms of physical, psychosocial, and sexual well-being as well as satisfaction with breast, outcomes, and care (13). The addition of these measures is exciting and provides surgeons with better insight about how patients perceive their reconstruction. This information can therefore help guide reconstructive techniques, preoperative teaching and preparation, and critical analysis of outcomes that can be standardized across centers.

In the past, a major concern limiting access of patients to immediate reconstruction was a hypothetical increase in the risk of breast cancer or delay of diagnosis of a recurrence in this setting. However, several large-scale studies have shown that immediate reconstruction with implants has little effect on recurrence, survival, or diagnosis of recurrence (5). The majority of recurrences in these cases were skin or subcutaneous in nature and identified by routine physical exam or serological markers. For this reason, follow-up of patients with implant reconstruction is usually limited to careful physical exams rather than mammography or other radiological measures. Even when patients were discovered to have a recurrence, implant reconstruction in the majority of cases did not alter additional treatment (5).

A number of risk factors predict complications after implant based breast reconstruction. In a study of 1,170 consecutive reconstructions using multivariate analysis, McCarthy and colleagues demonstrated that obesity, hypertension, age greater than 65, and smoking were independent predictors of complications (2). The adjusted odds ratio of these factors ranged between 1.8 (obesity and smoking) to more than 2 (hypertension and age over 65). Univariate analysis of reconstructive failure demonstrated that obesity, smoking, and hypertension significantly increased the risk of reconstructive failure (i.e., implant removal).

Several studies have reported satisfaction with implant reconstructions and most have reported high rates of satisfaction in the early years following reconstruction. However, a consistent theme is decreasing satisfaction over time that may be attributable to a number of factors including lack of change in the implant over time, the need for implant maintenance (either for symmetry or due to rupture), and capsular contracture. Many of the reported studies have used nonvalidated questionnaires, thereby making their findings somewhat less useful. However, recent reports have begun to use validated patient reported outcomes in large populations of patients enabling us to better understand the factors that contribute to patient satisfaction AND dissatisfaction after mastectomy and implant reconstruction.

LATISSIMUS FLAP

The latissimus flap is a commonly used method for breast reconstruction and involves subcutaneous tunneling of the ipsilateral latissimus dorsi muscle with or without skin or subcutaneous tissues to the breast area (Fig. 36-3). In most patients the latissimus flap does not have enough volume for a full breast reconstruction, and for this reason, it is usually combined with an immediate implant or expander placement.

The latissimus flap can be used in primary breast reconstruction after mastectomy or as a salvage procedure for patients who have failed other forms of breast reconstruction. Although most surgeons use the latissimus flap for unilateral reconstructions, bilateral reconstructions have also been reported. The use of the latissimus flap enables the plastic surgeon to transfer a considerable amount of soft tissues to the breast and can result in excellent reconstructions particularly in women who have large, ptotic breasts, or those who have undergone a previous subglandular

FIGURE 36-3 Pre- (*top left*) and postoperative (*top right*) photographs of a patient 1 year following right breast reconstruction with a latissimus dorsi flap and silicone implant. Donor site scar is also shown (*bottom*).

breast augmentation. The latissimus flap is an excellent option in morbidly obese patients with massive breasts (14) and in smokers, although the risk of minor wound healing complications in this population remains elevated as compared with normal weight women and nonsmokers, respectively.

The main contraindication to the latissimus flap is a previous thoracotomy operation that transects the latissimus muscle/pedicle, or a history of pedicle ligation. The blood supply or pedicle for the latissimus dorsi flap is the thoracodorsal vessels, which may on occasion be injured during the course of axillary lymph node biopsy or dissection. Testing the ability of the patient to flex the latissimus dorsi muscles is a simple way to test the integrity of the pedicle vessels since the thoracodorsal nerve, artery, and vein are intimately associated. Therefore, if the thoracodorsal nerve function is preserved it is likely that the vessels are likewise preserved. Even if the thoracodorsal vessels have been ligated, the latissimus flap can be transferred based on retrograde flow from the serratus anterior muscle–long-thoracic vessels, although these procedures increase the risk of venous hypertension.

A variety of skin paddle designs have been reported for the latissimus transferring a variable amount of skin and soft tissues to the breast. In some cases, no skin is necessary in which case the muscle can be harvested through several short incisions to decrease the donor site scarring. The horizontal (bra-line incision) is commonly performed and best for skin-sparing mastectomies in which the latissimus skin paddle is used to reconstruct the defect that remains after resection of the nipple–areola complex. The oblique flap design has a more noticeable donor site scar but is more useful if a larger skin paddle, such as may be needed in a delayed reconstruction, is necessary. The Fleur-de-lis modification combines both vertical and horizontal components and enables transfer of a large amount of tissues in many cases obviating the need for an implant (15). However, this flap design results in a T-shaped scar with a confluence of three incisions at the point of maximal tension and can be, as a result, associated with increased rates of donor site wound healing complications and contour deformity. Harvesting subcutaneous fat located below Scarpa's fascia and transferring parascapular and lumbar fat together with the latissimus dorsi muscle can increase the volume of the latissimus flap and may obviate the need for an implant in some cases.

In most cases an implant is also necessary to obtain the necessary volume and projection of the contralateral breast. In some cases (i.e., skin-sparing mastectomy with good skin flaps) it is possible to place an immediate implant for reconstruction. However, most commonly, a tissue expander is placed in order to adjust for latissimus muscle atrophy and to more slowly expand the breast pocket. This expander is replaced as an outpatient procedure 3 to 5 months later with a permanent implant.

The latissimus flap has low complications rates with a very low reported incidence of total flap loss even in high-risk patients (e.g., obese) (14). However, partial necrosis of the distal portions of the flap does occur on occasion, particularly in smokers and obese patients. This region can usually be excised during the course of the procedure with limited consequences. The most commonly reported early complication of the latissimus flap is donor site seroma formation, resulting in prolonged need for subcutaneous drains. The incidence of this complication can be greatly decreased with quilting sutures placed in the subcutaneous tissues to close off the dead space that is created from wide skin flap elevation (16). Hematomas can also be problematic if care is not taken to securely ligate intercostal perforators to the flap.

Late complications of the latissimus flap include donor site pain or tightness, widened scar, decreased range of motion, and implant-related complications (17). Surprisingly, most patients do not complain of long-term weakness from latissimus harvest, although careful pre- and postoperative quantitative analyses of back muscle function have been performed only in relatively small studies (18). Widened scars may also occur as a consequence of these factors and is particularly problematic in oblique incisions since these incisions crosa relaxed skin tension lines. Unfortunately, these incision patterns are necessary in some patients because they provide the greatest amount of skin on the breast for reconstruction. Limitation of ipsilateral arm range of motion and frozen shoulder may be problematic in some patients (19). This is of particular concern in elderly patients, those previously treated with axillary lymph node dissection and radiation, and patients with preexisting shoulder pathology. Aggressive physical therapy and rehabilitation may be necessary in these cases.

Implant-related issues (infection, rupture, capsular contracture) are also a source of complications in latissimus flap reconstruction. The reported rates of infection after latissimus flap reconstruction are variable; however, most studies report low single digit rates of infection and implant/expander loss (20). The rates of capsular contracture after latissimus flap transfer have been reported by only a few studies and, although somewhat variable, the incidence of severe capsular contracture (Baker grade III or IV) is low (3.6%) (21). The rate of significant capsular contracture is increased in women with a history of prior breast irradiation even when reconstruction is performed with a latissimus dorsi flap. For example, in a retrospective study of 35 patients with prior breast irradiation treated with salvage mastectomy and latissimus dorsi flap reconstruction, Disa et al. found that 17% of patients developed grade III capsular contracture after a mean follow-up of 4.1 years (22).

ABDOMINAL FLAPS

In 1982, Hartrampf and colleagues pioneered the use of abdominal-based flaps for breast reconstruction and, in doing so, revolutionized modern breast reconstruction techniques (23). These authors demonstrated for the first time that large amounts of skin and subcutaneous fat can be transferred based on the blood supply of the rectus muscle, thereby enabling surgeons to reconstruct breasts without implants. More importantly, development of the transverse rectus abdominis myocutaneous flap (TRAM) flap demonstrated that it is possible to combine reconstruction with aesthetic principals and elevated the goals of reconstruction from "restoration of a breast mound" to a natural looking and feeling reconstruction that ages with the patient and in some cases is indistinguishable from a normal breast (Fig. 36-4). These concepts also applied to the donor site of the TRAM flap that, contrary to other options available at the time (i.e., latissimus dorsi flap), could actually improve the contour of the abdomen rather than create unsightly scars. Over the years, the techniques of TRAM flap reconstruction have evolved to limit donor site morbidity by decreasing the amount of rectus muscle and fascia that is harvested and improving the blood supply of the tissues. As a result of these advancements, the TRAM flap is considered the gold standard for aesthetic breast reconstruction by which all other forms of reconstruction are judged.

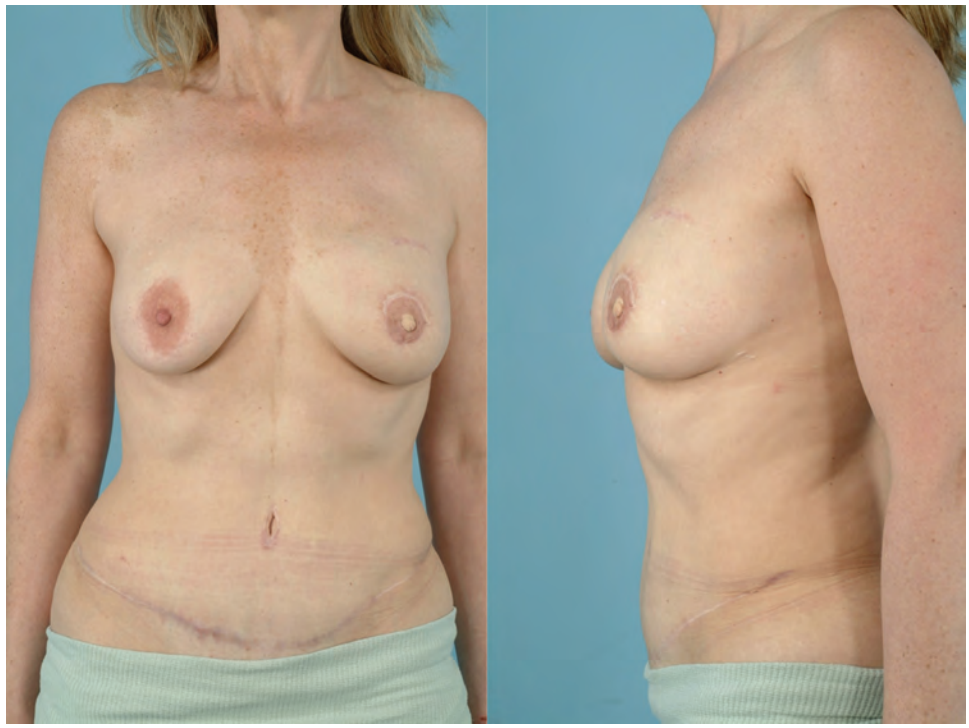

FIGURE 36-4 One-year postoperative photographs of a patient reconstructed with a left unilateral DIEP flap.

The TRAM flap is indicated for unilateral or bilateral breast reconstruction in patients who have an appropriate body habitus and are motivated to have autologous reconstruction. The ideal patient for a TRAM flap has enough tissues in the lower abdominal areas to aesthetically replace the volume of the breast with adequate skin laxity to enable closure of the abdominal defect. TRAM flaps can also be used in some patients with adequate skin laxity but insufficient volume; however, in these cases an implant is usually needed to restore the projection of the breast.

Absolute contraindications for TRAM flap reconstruction are previous abdominal operations that have disrupted the blood supply of the TRAM flap. For example, the TRAM flap cannot be performed in patients who have previously undergone abdominoplasty. Relative contraindications for TRAM flap include smoking, the need for postmastectomy radiation therapy, severe medical comorbidities that may increase the risk of prolonged anesthesia or the risk of wound healing complications, and a desire for future pregnancy. A history of neoadjuvant chemotherapy (chemotherapy within 6 weeks of surgery) is associated with an increased rate of wound healing complications; however, in most cases these complications are minor and rarely cause significant morbidity (4).

In the past, many surgeons advised against TRAM flap reconstructions in patients who require postmastectomy chemotherapy; however, several large-scale studies have recently shown that adjuvant therapy is rarely significantly delayed in these patients. For example, in a 10-year retrospective study of 170 patients with stage IIB or worse breast cancer treated at UCLA Medical Center with microsurgical breast reconstruction, chemotherapy was delayed in only 8 patients (4.7%) with a maximal delay of 3 weeks (24). However, these conclusions have been debated depending on the definition of delay that is used. For example, in a relatively small study, Kontos and colleagues compared 27 patients who had immediate breast reconstruction with TRAM flaps with 139 patients who did not and found that the mean time to the start of adjuvant chemotherapy was delayed by 15 days (55 vs. 40) in patients who had immediate breast reconstruction with TRAM flaps (25). In addition, the authors found that fewer patients who had TRAM flap reconstruction initiated their adjuvant treatment within 6, 8, or 10 weeks. Similarly, Lewis and Kontos reviewed the current literature and found that the delivery of adjuvant therapy is delayed in 3% to 72% of patients who undergo autologous tissue reconstruction with an increase of 13% to 36% in the period of time needed to start chemotherapy as compared to patients treated with mastectomy alone (26). Whether or not these delays are clinically significant or if there is a difference when compared to other forms of breast reconstruction (i.e., implants) remains unknown. Nevertheless, patients who will require chemotherapy postoperatively should be advised of this risk in order to make an informed decision.

The TRAM flap has a dual blood supply and can be transferred either as a pedicled flap based on the superior epigastric vessels or as a microsurgical (free) flap based on the inferior epigastric artery and vein. In the United States, pedicled flaps are more commonly performed as compared to free TRAM flaps due to differences in availability of microsurgeons and the institutional support necessary for the more complex microsurgical procedures. However, the safety and efficacy of pedicled TRAM flaps has long been established by numerous studies demonstrating that, when performed by expert surgeons, these procedures have low rates of morbidity and very low rates of flap loss.

In the pedicled TRAM flap technique, the lower abdominal tissues are harvested together with perforating vessels arising from the upper portion of the ipsilateral or contralateral rectus muscle. The rectus muscle is transected inferiorly and the muscle/flap are tunneled into the breast area by elevating the abdominal skin flaps. This procedure reliably transfers a little more than half of the TRAM flap (the hemi-TRAM ipsilateral to the rectus muscle as well as a small portion of the skin that crosses the midline). In rare cases when the entire TRAM flap skin or volume is needed for reconstruction, both rectus muscles are harvested (bipedicled

TRAM) maximizing the blood supply of the overlying skin. For bilateral breast reconstruction, the TRAM flap is divided in the midline and the tissues are transferred by harvesting both rectus muscles and transferring each hemi-TRAM individually into the breast. The fascia is either repaired primarily, or, more commonly repaired with mesh. The skin donor site is then closed using standard abdominoplasty techniques to recontour the abdomen.

A "supercharged" pedicled TRAM flap is a technique in which the abdominal flap is transferred to the breast based on the superior epigastric vessels and, in addition, the inferior epigastric vein is re-anastomosed to improve venous drainage. These procedures primarily developed as a bridge to the adoption of microsurgical flaps and aimed to address the theoretical disadvantages of both types of procedures: impaired blood supply of pedicled flaps and the risk of total flap loss with microsurgical flaps. However, as experience with microsurgical TRAM flaps increased the risk of total flap loss approximated that of pedicled flaps (<1%) leading to more widespread adoption of free flap transfers.

Microsurgical or free TRAM flaps were developed in an effort to improve the blood supply of the skin paddle and to decrease the amount of rectus muscle that is harvested, thereby decreasing abdominal wall morbidity. These efforts were based on anatomic studies demonstrating that the dominant blood supply of the TRAM flap is based on the inferior epigastric vessels with the superior epigastrics serving a secondary role. Early studies demonstrated clearly that the blood supply of the TRAM flap is improved with microsurgical transfer. In these cases, similar to the pedicled TRAM, all of the tissues ipsilateral to the rectus muscle are well perfused. The difference, however, is the amount of tissues that are well perfused across the midline (i.e., contralateral to the rectus muscle/pedicle). In most cases, one-third to one-half of this tissue can be reliably transferred to improve aesthetic reconstruction. Although a wide range of complications rates have been reported, numerous studies have shown that free TRAM flaps have significantly decreased rates of partial flap loss, fat necrosis, and abdominal wall hernia as compared with pedicled TRAM flaps.

In microsurgical TRAM flap procedures, a varying amount of muscle is harvested together with the inferior epigastric vessels that are ligated and transferred to the breast; microsurgical anastomosis is then performed to reestablish blood supply. Efforts aimed at decreasing the abdominal morbidity have led to changes in the amount of muscle that is harvested ranging from the entire width of the muscle (free TRAM) to just the central portion of the muscle, leaving a lateral and/or medial region of the muscle intact (muscle sparing TRAM). More recently, microsurgical techniques have evolved to the point in which the perforating vessels arising from the inferior epigastric artery and vein are dissected out of the rectus muscle thereby preserving the entire muscle. This technique is referred to as a deep inferior epigastric perforator flap (DIEP) or simply a perforator flap. The superficial epigastric vessels can also be used in some patients with suitable anatomy to transfer the lower abdominal skin flap (SIEA flap). These flaps are thought to incur the least amount of damage to the abdominal wall since the rectus fascia and muscle are not incised. However, due to anatomic variability in the size and positioning of the superficial epigastric vessels, this option is available in only 5% to 30% of patients (27).

Common recipient vessels for microsurgical repair include the thoracodorsal artery and vein or the internal mammary artery and vein. Over the past decade or so, most surgeons have shown a preference for the internal mammary vessels based on the fact that these vessels are located more centrally, thereby facilitating flap inset and contouring. This trend has also been influenced by the decreased rates of axillary lymph node dissection that is performed as a consequence of sentinel lymph node biopsy (28). This change in breast cancer management had two effects on microsurgical breast reconstruction. First, the thoracodorsal vessels are no longer exposed during the mastectomy if axillary lymph node dissection is performed. Therefore, exposure would require disruption of the axillary lymphatics and possibly increase morbidity. In addition, reoperation in patients with a false-negative sentinel lymph node biopsy potentially increases the risk of injury to the vascular pedicle of the TRAM flap if anastomosis is performed in the axilla.

The routine use of anticoagulants after microsurgical breast reconstruction is debated and a variety of approaches including no anticoagulation, aspirin, low molecular weight heparin, intravenous heparin, or a combination of the above have been reported (29). However, despite the debate, the routine use of anticoagulants to prevent deep venous thrombosis is recommended and supported by level 1 prospective studies (30). In the early years of microsurgery, intravenous dextran was used as a volume expander and anticoagulant to reduce the risk of microvascular thrombosis. However, this practice has largely been abandoned based on high rates of systemic complications (congestive heart failure, pneumonia, myocardial infarction). For example, in a prospective, randomized control study of 100 consecutive patients treated with microsurgical free flaps, Disa and colleagues reported a 7.2-fold increase in the risk systemic complications in patients treated with Dextran and aspirin as compared with aspirin alone (31).

The blood supply of microsurgical TRAM flaps is monitored carefully for 3 to 5 days postoperatively. This length of monitoring is based on large retrospective studies demonstrating that the vast majority of microvascular complications occur within the first 72 hours after surgery. For example, Chen et al. retrospectively reviewed their experience with 1,142 free flaps and found that 95.6% of microvascular thromboses occurred within 72 hours of surgery (32). Postoperative monitoring is performed using clinical exam to monitor skin color, temperature, and capillary refill. In addition, a Doppler ultrasound is routinely used to audibly check the blood supply of the TRAM flap. The Doppler primarily provides information about arterial flow; however, careful examination can also provide clues about venous outflow. A number of new technologies, including tissue oximetry and infrared spectroscopy, have been reported to facilitate the diagnosis of microsurgical thrombosis. Early reports with these devices have been promising and warrant additional research (33).

Frequent monitoring of free flaps, particularly in the first 24 to 48 hours after surgery, is critical since multiple studies have shown that earlier diagnosis of microvascular thrombosis is a predictor of salvage versus failure. For example, Bui et al. reported their experience with 1,193 free flaps and found that flaps reexplored within 4 hours of detection of thrombosis were nearly two times more likely to be salvaged than those explored more than 9 hours after detection (34). Although the reported salvage rates for breast microsurgical free flaps vary, most large centers report overall salvage rates of 50% to 80% (35).

The typical recovery period after a microsurgical or pedicled TRAM flap procedure is 6 to 8 weeks. Drains in the abdominal and breast area are typically removed by 2 weeks after surgery. Patients are advised to avoid pressure on the flap for 4 to 6 weeks until the blood supply is reestablished by collateral vessels. During this period they are encouraged to wear a light bra and to wear an abdominal

binder or abdominal support to help decrease abdominal pain and prevent abdominal bulging or hernia. Most patients can return to normal activities of daily living within 6 to 8 weeks and return to work. Adjuvant chemotherapy, if necessary, can also be started at this time.

Breast reconstructions with abdominal flaps are well tolerated with low rates of major complications. In a study of 952 patients who underwent microsurgical breast reconstruction, Mehrara and colleagues reported an overall complication rate of 27.9%, with the majority of these complications (17.3%) comprised of minor complications (4). Less than 1% of patients had a severe or life-threatening complication. Overall, 21% of patients experienced minor complications including fat necrosis (11.2%), infection and wound healing problems (9.2%), abdominal wall laxity or hernia (3%), and transient brachial plexus injury (1.1%). Major complications occurred in 7.7% of patients and consisted of flap loss (0.5%), partial flap loss (2.3%), hematoma (2%), moderate-severe congestive heart failure (0.9%), sepsis (0.3%), and deep venous thrombosis (0.1%). There were no deaths and only one patient required prolonged ICU care. Similar low (i.e., <1%) rates of total flap loss for free muscle sparing and deep inferior epigastric artery perforator flap reconstructions (DIEP) have more recently been reported in large-scale studies from other major medical centers (36,37).

A recent prospective study that performed bilateral duplex ultrasound examination in 118 patients who underwent microsurgical TRAM flap breast reconstruction demonstrated that as many as 3.4% of patients develop so-called silent DVTs (30). Although there were no cases of venous thromboembolism in this report, this complication has been previously reported (4) and deep venous thrombosis prophylaxis with compression, low-molecular weight heparin, and early mobilization is recommended.

Large retrospective studies have also reported low rates of major complications in patients treated with pedicled TRAM flaps. For example, Padubidri et al. reported a 29.6% overall complication rate in 196 pedicled TRAM flaps (38). Similar to the experience with free TRAM flaps, the vast majority of these complications were minor and related to delayed wound healing. In addition, the total flap loss rate of 1% reported in this series was also similar retrospective studies on microsurgical TRAM flap reconstruction. Most studies comparing free and pedicled TRAM flaps have reported lower rates of abdominal wall complications (i.e., hernia or laxity) in patients treated with microsurgical flaps (39). However, the reported rates of these complications vary widely between publications ranging from as low as 0.5% to as high as 15%. This wide range of reports may reflect differences in techniques used abdominal closure rather than perceived benefits of microsurgical harvest. However, recent head-to-head comparisons strongly suggest that muscle-sparing or DIEP flap reconstructions have lower rates of abdominal wall complications. For example, Garvey et al. retrospectively compared 96 DIEP and 94 pedicled TRAMs and reported that abdominal wall hernias occurred more frequently in pedicled TRAMs (16%) as compared with DIEPs (1%) (40).

A number of studies have attempted to determine if patients who undergo microsurgical TRAM flap reconstruction have better abdominal wall function as compared with pedicled TRAMs. In a systematic review of the literature, Atisha and Alderman found that although the objective measures of abdominal wall function were overall better in patients who underwent microsurgical reconstruction as compared with pedicled TRAM flaps, these differences did not reach statistical significance (39). In contrast, studies comparing microsurgical TRAM flaps with DIEP flaps using these measures reported significantly higher flexion ability in patients treated with DIEP flaps. Not surprisingly, patients who had bilateral pedicled or free TRAM flap reconstruction reported a significantly decreased ability to perform sit-ups and decreased subjective ability to perform activities of daily living. Patients who had unilateral reconstructions had similar subjective measures of abdominal function regardless of the type of procedure that was performed. However, the authors note that most studies analyzed in this systematic review had significant limitations in study design, therefore additional prospective studies are required.

In the study by Mehrara et al., obesity (BMI >30 kg/m^2) was a significant independent predictor of complications increasing the risk of overall, major, and minor complications (4). Obese patients were three times more likely to experience partial flap loss or have donor site morbidity. Smoking was associated with increased rates of donor site complications but was not an independent predictor, perhaps due to the very low number of smokers in this series. These findings were supported by a retrospective study of 936 patients treated with microvascular TRAM flaps at the MD Anderson Cancer Center demonstrating a 1.5-fold to 2-fold increase in the risk of donor site and wound healing complications in patients with a BMI >30 as compared with those that had a BMI <30 (41). The risk of complications in obese patients is likely to be even higher in patients who undergo pedicled TRAM flaps. This concept is supported by a retrospective study by Moran and Serletti of 78 obese patients reconstructed with microsurgical TRAM flaps as compared with 36 patients who underwent reconstruction with pedicled TRAM flaps demonstrating a nearly twofold increase in the risk of wound healing complications in obese patients (42).

Interestingly, neoadjuvant chemotherapy also appears to be a significant independent predictor of complications (4). Patients treated with chemotherapy within 6 weeks of surgery were two to three times more likely to experience minor complications comprised primarily of wound healing complications and fat necrosis. Deutsch et al. reported similar results in a retrospective study of 31 patients treated either with pedicled (n = 9) or free (n = 22) TRAM flaps (43). These authors noted a complication rate of nearly 55% with most patients experiencing minor complications that resolved with conservative management.

Not surprisingly, several studies have shown that active smokers have a higher risk of both flap- and wound-related complications following pedicled or free TRAM flap reconstruction. For example, in a retrospective study of 200 patients who underwent pedicled TRAM flap reconstruction over a 10-year period, Ducic and colleagues found that both active and former smokers were at significantly increased risk (twofold increase) of complications including infection and delayed healing in the abdominal and breast sites as compared to never-smokers (44).

Prior abdominal surgery is also associated with increased rates (one- to twofold) of partial flap loss, donor site complications, abdominal wall laxity/hernia, and fat necrosis (4). The most problematic incisions are upper abdominal/subcostal incisions, which result in decreased blood flow to the upper abdominal skin flaps.

Surveillance for breast cancer recurrence in patients treated with TRAM flaps is usually performed with physical examination with confirmation using radiologic studies as necessary. In a retrospective study of 419 TRAM flap breast reconstruction performed in 395 patients with a mean follow-up of 4.9 years, Howard et al. reported a local recurrence rate of 3.8% with a mean time to diagnosis of 1.6 years (45). This rate was in line with long-term local recurrence

rates after mastectomy without reconstruction reported in the literature. In most cases, local recurrences were treated with wide local excision and adjuvant therapy. The TRAM flap required removal in only 3 of 16 patients.

OTHER DONOR SITES

A variety of other donor sites have been reported for microsurgical autologous breast reconstruction. These include the superior gluteal, inferior gluteal, lateral thigh, and gracilis flaps. These flaps can be performed either as myocutaneous flaps (e.g., skin and fat harvested together with a portion of the muscle in which the flap pedicle vessels course) or as perforator flaps in which no muscle is harvested. These options are indicated in women who are not TRAM flap candidates (e.g., inadequate abdominal tissues or abdominal scars) but desire autologous reconstruction, have failed implant reconstruction, or are not candidates for implant reconstruction. Free flaps in general, including these secondary donor sites, are relatively contraindicated in patients with known coagulopathies, patients with severe or potentially life threatening comorbidities, and in heavy smokers.

The gluteal flaps can be based either on the superior or inferior gluteal artery and vein and, in the appropriately selected patient, can be used to transfer large volumes of tissues. Gluteal flaps, similar to the abdominal flaps, can be transferred as a myocutaneous flap (i.e., skin, fat, and portion of the gluteus muscle) or as a perforator flap in which the blood vessels are dissected and the muscle is preserved. Perforator flaps based on the superior gluteal vessels are referred to as superior gluteal artery perforator flaps (SGAPs) while flaps based on the inferior gluteal vessels are termed inferior gluteal artery perforator flaps (IGAPS).

The primary advantage of the gluteal flaps is their utility even in relatively thin women since adequate tissues are available in most patients even when abdominal tissues are insufficient. The main disadvantage of these procedures is the fact that the microvascular anatomy and dissection is more difficult than the TRAM flap. This is particularly true of the superior gluteal flap and is likely the source of the higher reported rates of microvascular complications and flap loss as compared with the TRAM flap. For example, Baumiester et al. retrospectively reviewed their experience with 75 superior gluteal artery perforator flap (SGAP) reconstruction and reported a free flap failure rate of 7% (46). Although this success rate is excellent, it is considerably lower than the rates of success for TRAM or DIEP flaps (>99%) reported in large series from tertiary medical centers. In addition, the gluteal flap donor site can result in contour deformities that may necessitate additional procedures on the contralateral gluteal region for symmetry. Further, sensory changes after may also occur after flap harvest resulting in dysesthesia or discomfort.

Lateral thigh flaps are occasionally used for breast reconstruction and harvest skin and soft tissues in the so-called saddle-bag areas. The blood supply of these flaps is based on the lateral femoral circumflex vessels, which are reliable and relatively easy to dissect. In the appropriately selected patient, a moderate volume of tissues can be transferred. Unfortunately, the donor scars from these flaps are difficult to hide and can be a source of patient dissatisfaction.

Gracilis musculocutaneous flaps have gained some favor for breast reconstruction over the last decade. Although a variety of skin patterns have been described, the transverse upper gracilis (TUG) skin paddle design is most commonly performed. The TUG flap is simple to harvest and can reliably transfer a moderate amount of tissues as a free flap for breast reconstruction. Buntic and colleagues retrospectively evaluated their results with 32 TUG flaps and reported a 100% flap survival rate with no fat necrosis or functional loss (47). The primary disadvantage of this flap is donor site wound healing complications. The incision in this flap design is typically placed just below the inguinal fold and has a tendency to break down as a result of tension with leg abduction. For example, Bunitic et al. reported a 25% wound breakdown rate resulting in delayed healing (47). However, in general, patients are satisfied with these reconstructions as evidenced by a retrospective study by Pulzl and colleagues who evaluated the cosmetic results of 22 patients who underwent TUG flap reconstructions (48). These authors found that 70% of patients had good to excellent scars and all patients would choose the same operation again if given a choice.

MANAGEMENT OF THE CONTRALATERAL BREAST

A major goal of breast reconstruction is to have reasonable symmetry with the remaining breast. In some patients with well-defined breast shape or minimal ptosis it is possible to achieve this goal without altering the contralateral normal breasts. However, in most patients a contralateral procedure such as a reduction, lift, or augmentation can improve symmetry or improve the breast shape. It is important to note that it is rarely possible to achieve exact symmetry after contralateral procedures to match a breast reconstructed with implants. The goal in most instances is to obtain *reasonable* symmetry in clothes, bra, or bathing suit (Fig. 36-5). This goal is attained in most patients and has been shown to be associated with high rates of satisfaction. Contralateral symmetry is more likely to be achieved in patients who have undergone reconstruction with autologous tissues due to a variety of factors including subcutaneous position of the reconstructed tissues, more natural texture and shape, potential for autologous tissues to gain or lose weight with the patient as she ages, and lack of capsular contracture.

Reduction mammoplasty is commonly performed for symptomatic macromastia and is associated with high rates of patient satisfaction and improved quality of life (49). Similarly, reduction mammoplasty is helpful as a symmetry procedure in patients who have undergone breast cancer treatment or mastectomy with reconstruction. These procedures are particularly helpful in implant reconstruction due to limitations in breast implant sizes and shapes and also due to the fact that implants are placed in the submuscular position thereby positioning them higher on the chest wall. Breast reductions are also useful in patients treated with autologous reconstructions, particularly in cases in which the patient has symptomatic macromastia at baseline (i.e., neck or upper back pain, shoulder grooving, inframammary fold irritation).

Many different techniques have been described for breast reduction; however, in the United States the inferior pedicle technique is most commonly performed. In this procedure, the nipple–areola complex is isolated on an inferiorly based breast glandular flap to enable repositioning of the nipple in a more aesthetic manner (i.e., at or just above the level of the inframammary fold and centered on the breast mound). A variety of other breast pedicles (i.e., superior, bipedicled, or central mound) have been described for repositioning of the nipple and have been reported to have excellent results.

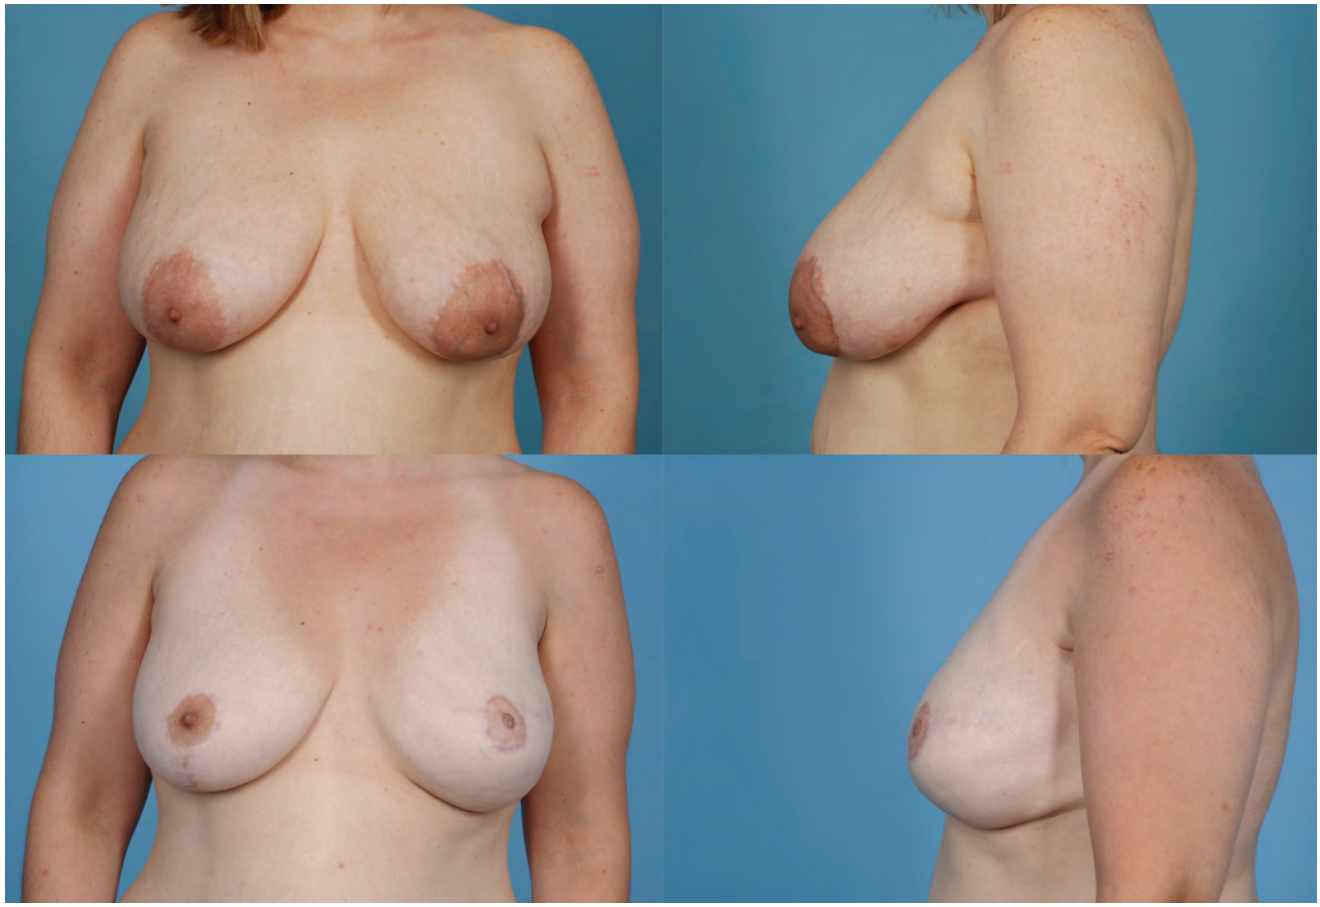

FIGURE 36-5 Preop (*top*) and 2-year postop (*bottom*) photographs of a patient treated with left mastectomy and silicone implant reconstruction and right breast reduction.

The Wise pattern breast reduction pattern is the most common skin pattern design used to reduce and lift the breast and was originally based on patterns used for making bras. In this technique, a variable amount of skin is removed from the horizontal and vertical portions of the breast in order to lift the breast and reposition the nipple centrally on the breast mound. The resulting anchor-shaped incision is the end result. Although some authors have criticized the aesthetic outcomes (long scars, boxy-wide breasts) and durability (late ptosis or bottoming out) of this pattern for breast reduction or lift, it remains the workhorse for most plastic surgeons in the United States. This is based on the fact that if properly performed, the Wise pattern can have excellent cosmetic outcomes and the incisions are mostly hidden in the inframammary fold. However, a number of other patterns have been reported to address some of these concerns. For example, the vertical pattern utilizes only the vertical limb of the incision in an effort to avoid the long horizontal inframammary incision and is useful in some patients (e.g., minimal ptosis or low-volume reductions).

Mastopexy, or breast lift, is performed to remove excess skin and reposition the breast more centrally on the chest. Similar to breast reductions, Wise patterns are used commonly due to their ease and proven reliability. However, other skin patterns such as circumareolar or vertical can also be used depending on the amount of excess skin, breast size and shape, and skin tone. Skin-only mastopexies refer to breast lifts that rely primarily on tightening the breast skin to reshape the breast. However, these procedures often fail to have long-lasting results with stretching of the skin and recurrent ptosis. As a result, a variety of breast parenchymal procedures have been described that aim to lift the breast by reshaping the breast and simply redraping the skin. These techniques are applicable also to some patients for partial breast reconstruction (see below).

Augmentation mammoplasty is also commonly performed as a symmetry procedure after mastectomy reconstruction. These procedures are most useful in small-breasted women to match a contralateral implant reconstruction and can be performed either with or without a simultaneous mastopexy. The mastopexy in these cases is performed to center the nipple–areola complex over the implant or to match the position of the contralateral breast (or both). Augmentation of the nonreconstructed breast can also be performed to match a larger autologous tissue reconstruction. In some cases, augmentation is performed to augment an autogenous tissue reconstruction. This scenario is encountered in cases where the amount of autogenous tissues available (e.g., in the TRAM flap) is inadequate to match the volume or projection of the native breast or in patients who undergo bilateral reconstruction and desire to have increased volume or projection.

Implants used for augmentation are most commonly placed under the pectoralis muscle; however, the implant is not completely covered by the pectoralis. Instead, similar to cosmetic augmentation procedures, implants used for augmentation of the native breast in cancer survivors are covered by only the muscle superiorly. The inferior portion of the pectoralis flap is dis-inserted such that the lower portion of the implant is in a submammary position. This enables

centering of the implant on the breast and avoids upward malposition. Subpectoral implant placement is thought to decrease the rate of capsular contracture, diminish visible rippling of the implant, and facilitate mammographic surveillance of the breast.

The most common surgical complication of breast reduction or mastopexy is minor wound healing complications. These occur most commonly at the "T-point" where the vertical and horizontal incisions come together. Fortunately, most of these complications are minor and heal spontaneously with conservative management. Hypertrophic scars or keloids can also be troublesome particularly in African American or Asian patients. These complications can, on occasion, be treated with steroid injections, laser, or reexcision. Reexcision combined with low-dose radiation therapy delivered directly to the scar immediately after scar excision is very successful with low rates of recurrence but require coordination with radiation oncologist (50).

It is estimated that 3% to 5% of women who undergo mastopexy or reduction experience loss of nipple sensation (51). On rare occasions (<1%), women complain of long-term pain after mastopexy, reduction, or augmentation. The cause of these pain syndromes is unknown but likely reflects nerve damage or scarring. Late infections (more than 3 months after surgery) are also a rare complication but can present with erythema, pain, and fevers. These complications usually respond to antibiotic treatment but on occasion require imaging, long-term antibiotic treatment, or drainage.

Another rare complication in these cases is diagnosis of incidental breast cancers or high-grade lesions. A study of breast reduction in nonselected patients (i.e., not restricted to breast cancer survivors) reported a rate of 1% for incidental breast cancers in the resected specimen. Surprisingly, reports in breast cancer survivors treated with contralateral procedures have reported even lower rates most likely reflecting the fact that this patient population is more closely followed with breast imaging (52). The main problem in cases of incidental breast cancer diagnosis is positive margins. Although it is occasionally possible to return to the OR for additional resection and margin clearance, this is often not possible due to rearrangement of breast tissues and inability to localize precisely the area of resection at the time of the second operation. This situation creates a treatment dilemma and in some cases may require conversion to mastectomy.

PARTIAL MASTECTOMY RECONSTRUCTION

Partial mastectomy reconstruction can be performed either at the time of the initial resection or in a delayed fashion after definitive treatment has been completed. Reconstruction at the time of cancer resection is an option in patients with large or ptotic breasts who desire a breast reduction or lift. These procedures often use standard surgical approaches for reduction or mastopexy and can reshape the breast to minimize contour deformities, nipple malposition, or size asymmetry that may occur after partial breast resection without reconstruction (Fig. 36-6). Partial mastectomy in conjunction with breast reduction may also enable the oncologic surgeon to remove large portions of the breast (larger than would be ordinarily removed during a partial mastectomy), thereby increasing the size of the margin and potentially decreasing the risk of positive margins or local recurrence. A key issue in performing these procedures at the same time as oncologic resection is margin clearance. A positive margin may be more difficult to deal with in this setting because the breast tissue has been rearranged to a certain extent and additional resection may require opening the entire breast incision. Innovative approaches to this problem such as additional margins at the time of resection, marking the borders of the resection with clips, and so called immediate-delayed procedures in which the reconstructive procedure is performed shortly after confirmation of definitive negative permanent margins may decrease the potential for these problems (53).

Breast reduction or lifts are well tolerated and associated with a low rate of complications. The primary complications include minor wound healing issues, seroma, hematoma, loss of nipple sensation, and breast asymmetry. Of these complications, asymmetry is particularly problematic due to the fact that these patients are treated with unilateral radiation therapy that may cause unexpected breast tissue shrinkage or skin fibrosis. For this reason, patients are advised that follow-up procedures may be necessary in the future to correct these problems.

Patients with small or nonptotic breasts may also be candidates for immediate partial breast reconstruction in an effort to avoid mastectomy or significant contour deformities that may result from partial mastectomy. In these cases, local tissue flaps from the back, or more rarely, from the abdomen, are transferred to the breast at the time of tumor resection to replace breast tissue or skin and restore the normal contours of the breast. This approach is somewhat controversial since some reconstructive surgeons argue that a potential option for reconstruction is lost in case the patient has a recurrence and requires a mastectomy. Those in favor of these procedures note that breast recurrence in these patients is relatively infrequent particularly if postoperative radiation is performed and that other options or donor sites are frequently available even if there is a recurrence. Unfortunately, well-controlled patient-reported outcome studies comparing satisfaction and quality of life of patients who undergo partial breast reconstruction with those who had mastectomy and reconstruction or those who had partial mastectomy alone have

FIGURE 36-6 Preop (*left*) and 1-year postoperative (*right*) photographs of a patient treated with right partial breast excision and simultaneous breast reduction.

not been performed and are needed to determine if these procedures are worthwhile.

Plastic surgeons are also frequently consulted for reconstruction of partial mastectomy defects in patients who had previously undergone breast resection and radiation. These patients usually present with breast asymmetry due to resection or radiation-induced fibrosis, contour deformities, or nipple malposition. Asymmetry in these cases is often due to a combination of breast volume deficit and skin fibrosis causing decreased relative ptosis of the radiated breast. Although reconstruction in this setting is more difficult due to increased scarring and history of radiation, a number of techniques are available ranging from relatively simple to more complicated. Naturally, the most important prerequisite is ensuring that the breast is cancer free with imaging procedures as necessary and consultation with the patients' breast surgeon and oncologist.

Simple techniques for delayed reconstruction of partial mastectomy defects include tissue rearrangement, scar releases, breast augmentation, and fat injection. Breast tissue rearrangement or scar releases are occasionally helpful in patients with minor deformities; however, more often than not these procedures are unsuccessful or have limited utility due to breast changes resulting from radiation. Similarly, breast augmentation with implants is rarely indicated in patients who have a history of partial mastectomy and radiation due to the high incidence of capsular contracture. Fat grafting for breast contour deformities has been recently described by a number of groups and shows some promise (54,55). In these procedures, fat is harvested from another region of the body using standard liposuction techniques, washed, and then simply injected into the region of the contour deformity to replace the missing breast tissue and restore the normal shape of the breast. This process may be repeated over several sessions as necessary and is best reserved for patients who have minor volume deficiency rather than combined volume and skin defects. Fat injection is thought to improve breast contour defects not only by restoring volume but also by transferring mesenchymal stem cells that aid in repair of radiation damaged tissues (56). The latter concept is based on the fact that adipose tissues are a known source of pluripotential mesenchymal stem cells (57) and anecdotal reports demonstrating significant tissue improvement after fat injection into chronically radiation-damaged tissues (56).

Fat injection or lipotransfer is simple to perform and well tolerated with a low incidence of reported complications that include minor donor site contour deformities, fat necrosis or oil cysts in the recipient site, reabsorption of the injected fat, and macrocalcifications on mammography (58). Although dramatic improvements in breast shape and contour have been reported in a few relatively small case series, large prospectively performed studies are needed to assess the efficacy and safety of fat injection in partial breast reconstruction. In addition, recent laboratory reports have suggested that transfer of mesenchymal stem cells may alter the behavior of tumor cells in animal models (59); however, retrospective clinical studies have failed to show these adverse effects in patients (58).

More complicated procedures for symmetry in patients with a history of breast conservation include breast reduction or lift and vascularized tissue transfers. Breast reduction/lift is helpful in patients who have macromastia or breast ptosis and are performed using standard techniques (see above on symmetry procedures). Asymmetric skin or breast parenchymal resection on the ipsilateral and contralateral breasts is performed to improve breast symmetry and shape. It is important to note, however, that due to the inherent changes in the breast tissue and skin envelop resulting from radiation it is rarely possible to obtain absolute symmetry or symmetry that is comparable to purely aesthetic breast reductions or mastopexy. Instead, patients are advised that the goal of the procedure is to have improved symmetry. In addition, although these procedures are usually well tolerated with a low risk of wound healing complications, patients with a history of radiation should be advised that they are at higher risk for these events. Of particular concern is the risk of nipple necrosis since the patient's previous surgery or radiation may have disrupted the blood supply to the nipple–areola complex. In these cases, the nipple–areola complex may be replaced as a free graft.

Vascularized tissue transfers can be performed in a delayed setting for patients with significant contour deformities or volume deficiency. In these cases, the breast defect is recreated by completely resecting the scar and surrounding fibrotic tissues, and the volume is restored by transferring tissues from another region (i.e., the back or abdomen) based on a known vascular supply. The latissimus flap or its variant, the thoracodorsal artery perforator flap (TDAP), are commonly used for these procedures due to the proximity of the back to the breast. In these cases, the back skin and subcutaneous tissues are transferred either together with a portion of the latissimus muscle and its blood supply (latissimus flap) or without muscle based solely on a branch of the thoracodorsal artery/vein (TDAP) (60). These procedures are particularly helpful in patients who have large-volume defects of the breast in combination with breast skin deficiencies since the muscle, fat, and subcutaneous tissues of the flap can be used to restore breast volume while the back skin can be used to replace the missing breast envelope.

CHEST WALL COVERAGE

Chest wall coverage, rather than breast reconstruction, is necessary in some patients with extensive or recurrent tumors. This scenario occurs most commonly in patients with large, fungating tumors, recurrent tumors in patients with a history of radiation, and in patients with inflammatory breast cancers. In addition, wide skin resections are also commonly performed in patients with radiation-induced angioscarcomas. In these cases it is often not possible to primarily close the breast skin and additional reconstructive procedures are necessary.

The simplest option for chest wall coverage is a split thickness skin graft. This option is best reserved for patients with relatively small wounds and good recipient beds (i.e., not contaminated or radiated). Skin grafts can also be performed secondarily in some cases after the initial wound is treated with dressing changes or vacuum assisted closure (VAC). The downsides to skin grafting for chest wall coverage include prolonged healing time (often more than 6 weeks), unstable coverage resulting in skin sloughing or complications particularly when postop radiation is needed, and tightness due to skin graft contracture.

Adjacent tissue transfers wherein local tissues are rearranged to provide coverage are an alternative to skin grafting and can be used in patients with larger defects and in those with defects that are unsuitable for grafting (e.g., history of radiation). These procedures include relatively simple operations where the lower mastectomy skin flap is elevated below the inframammary fold and advanced up to close the defect. Alternatively, local rotation flaps such as an external oblique flap based on perforating blood vessels

arising from the intercostal arteries and veins in the external oblique muscle can be performed to rotate large areas of vascularized skin into the chest wall defect. This procedure is simple to perform, does not require intraop repositioning, and can be used safely to cover large defects of the lower breast even in patients who have significant comorbid conditions (61).

Pedicled flaps are also useful for chest wall coverage and can provide massive amounts of skin with or without muscle to cover complex defects. The pedicled latissimus flap is a reliable means of transferring a large amount of muscle and some skin to provide coverage of complex defects such as composite skin/skeletal resections of the chest wall. Pedicled TRAM flaps can also be performed in patients with suitable abdominal donor sites and can provide large amounts of skin for chest wall coverage. However, closure of the abdominal donor site may result in increasing the size of the breast wound (by pulling the abdominal skin inferiorly). In addition, the blood supply to the pedicled TRAM flap may be inadequate in some patients thereby increasing the risk of partial flap loss and wound healing complications. A safer pedicled option in these cases may be a vertically oriented rectus myocutaneous flap (vertical rectus abdominis myocutaneous or VRAM flap) (62). In this scenario the skin paddle is oriented vertically over the rectus muscle thereby improving the blood supply. In addition, closure of the VRAM donor site does not change the size of the breast/chest wall defect. The omentum flap can be used to provide coverage of chest wall defects; however, concerns about donor site morbidity (adhesions, abdominal hernia) and the need for skin grafting limit its utility.

Free flaps provide the most freedom in transferring tissues for chest wall coverage because the tissues are anastomosed to vessels located anatomically close to the defect and have high rates of success (62). Tissues can be harvested from a variety of donor sites and are selected based on the defect or reconstructive needs and donor site options. Microsurgical thrombosis is the most dreaded complication in these cases but is fortunately rare (<2%) in most cases. Donor site may also be problematic but are fortunately in most cases infrequent. Patients who undergo these extensive procedures are also at risk for medical complications (e.g., DVT/PE, pneumonia, myocardial infarction), particularly if they have premorbid conditions, therefore consultation and coordination with appropriate support services are necessary to maximally optimize the patients preoperatively and monitor and treat postoperatively.

RADIATION AND RECONSTRUCTION

Postmastectomy radiation therapy (PMRT) is a critical component of breast cancer management in patients with locally advanced breast cancers. Multiple randomized trials have shown that PMRT significantly reduces the risk of local recurrence in the chest wall and regional draining lymphatics (63,64). The 2005 Oxford Overview by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) demonstrated that this decrease in local recurrence translates into a statistically significant improvement in overall survival for women with positive axillary lymph nodes (65). As a result of these studies, an increasing number of patients who undergo mastectomy are treated with radiation therapy. This paradigm shift in breast cancer management has created difficulties in reconstruction because it is sometimes difficult to determine which patients will require PMRT, therefore complicating the preoperative consultation and planning.

Not surprisingly, breast reconstruction in women who will require PMRT is among the most hotly debated topics in plastic surgery. Virtually all aspects of reconstruction in this setting are debated. In addition, the timing of reconstruction (i.e., immediate vs. delayed after completion of radiation), the type of reconstruction that is performed (i.e., implants vs. autogenous tissues), the timing of expander-to-implant exchange (i.e., exchange before or after radiation), even the optimal time to perform reconstruction in a patient who has previously been treated with radiation are all debated. However, despite intense debate there is little consensus and the optimal method remains unknown. All of these approaches have advantages and disadvantages that must be individualized and discussed preoperatively if possible.

The majority of plastic surgeons in the United States recommend delayed reconstruction in patients who will need PMRT (66). The precise reasons for this bias are unknown but are likely multifactorial reflecting risk aversion, medicolegal concerns, and a concern about potential delays to postoperative adjuvant therapy in case of complications related to reconstruction. Risk aversion in these cases is supported by studies demonstrating increased rates of complications, decreased satisfaction, and impaired aesthetics in patients who undergo immediate reconstruction and PMRT.

For example, Carlson et al. (67) and Lee et al. (68) reported that patients who had radiation therapy after autologous tissue reconstruction were two to four times more likely to have complications compared to nonirradiated women. These complications included wound healing issues, partial flap losses, twofold increased rate of clinically significant fat necrosis, and flap shrinkage/fibrosis. Perhaps as a result of these complications, these authors found that patients who underwent autologous reconstruction followed by PMRT were significantly more likely to have impaired aesthetics and decreased satisfaction as compared to nonirradiated patients. These findings were supported by a recent study by Crisera and colleagues reporting their experience with 103 women who underwent immediate autologous breast reconstruction and PMRT (24). In this study, the authors found that nearly 30% of patients experienced fibrosis of their flap, 13% had severe distortion, 7% required an additional flap for reconstruction, and 4% experienced partial flap loss after radiation.

Radiation-induced complications are not unique to patients with autologous reconstructions. Studies of patients who have received PMRT to implant-based reconstructions have also demonstrated that radiation to be an independent risk factor for complications (odds ratio of 3.8 to 4.8), resulting in a two- to threefold increase in the risk of significant capsular contracture (Baker grade III or IV), increased rates of reconstructive failure (three- to fivefold increase), decreased satisfaction, and decreased cosmetic outcomes (69,70).

Some plastic surgeons recommend immediate implant reconstruction in women who will require PMRT but are otherwise good candidates for implant reconstruction. These surgeons argue that the benefits of immediate reconstruction are significant and outweigh the risks in most cases when compared to delayed reconstruction (70). These benefits include preservation of the breast envelope with use of skin-sparing mastectomies, placement of the mastectomy scar at a desired location, decreased number of operations, and psychological benefits of immediate reconstruction. In addition, recent retrospective studies have shown that although the risk of complications in patients treated with PMRT is higher than nonirradiated cohorts, this risk is still relatively low and that most patients successfully complete reconstruction and are satisfied with the results. In a retrospective study of 315 patients treated at Memorial

Sloan-Kettering Cancer Center, Cordeiro et al. found that 90% of patients treated with PMRT successfully completed reconstruction (vs. 99% who did not have PMRT), that the majority of patients (approximately 60%) had acceptable reconstructions with Baker grade I or II capsular contracture, and over 70% were satisfied with their outcome and would recommend the procedure to a friend or family member (7). It is important to note that even if patients were to develop complications following irradiation of an implant necessitating removal, the use of implants at the initial procedure preserves other options (e.g., autologous tissues) for reconstruction at a later date.

Preservation of the breast envelope in reconstructed patients who will require PMRT is also an important consideration when choosing immediate versus delayed reconstruction. Reconstruction after skin-sparing mastectomy is significantly easier and more aesthetic, since the reconstruction is aimed at replacing the breast volume rather than missing breast skin. Consequently, the final breast scars are typically small and more easily concealed with nipple–areola reconstruction. In contrast, in delayed reconstruction after PMRT, a significant portion of the remaining breast skin is damaged and needs to be replaced. The skin below the breast incision is often severely fibrosed and necessitates either partial or complete replacement with healthy skin from a donor site (e.g., TRAM flap or latissimus flap) in order to adequately reconstruct the breast contours. This need results in a large skin paddle on the breast that not only limits the amount of tissues available for reconstruction but also lengthens the breast scars, making them harder to conceal. Based on these differences, it is therefore more valid to compare the aesthetic outcomes of irradiated women who have undergone immediate versus delayed reconstruction, rather than to compare the aesthetic outcomes of reconstructed patients with PMRT to those who have not received PMRT. Prospective studies are needed for more accurate assessment of complication rates and aesthetic outcomes in these patient populations.

The timing of exchange of the expander to the permanent implant relative to radiation has also been a source of debate. Traditionally, most plastic surgeons prefer to wait until the completion of radiation to perform the exchange procedure. This preference is likely due to concerns regarding potential delays to radiation therapy, infections in a fresh surgical field in response to radiation, or desire to perform capsulectomy or capsule releases after radiation. More recently, however, several groups have shown that exchanging the expander to the implant prior to the start of radiation therapy is associated with decreased rates of complications and improved aesthetics. For example, Cordeiro and McCarthy used a retrospective approach with 315 patients comparing implant reconstruction success rates in patients who had undergone immediate expander reconstruction after mastectomy and exchange to final implant prior to radiation with nonirradiated patients and found a high rate of overall success (90%) (7). This rate was significantly less than nonirradiated patients (99% success rate) but was markedly higher than previous reports on implant exchanges following irradiation. In a follow-up study from Memorial Sloan-Kettering, Ho et al. evaluated long-term disease outcomes in a cohort of 151 patients with stage II to III breast cancer who underwent expander/implant reconstruction using the following treatment algorithm: (a) a modified radical mastectomy with immediate placement of expanders, (b) initiation of chemotherapy with expansion performed throughout treatment, (c) exchange of the expander for implant after the completion of chemotherapy, and (d) initiation of PMRT (71). Overall, the 7-year combined permanent implant removal or replacement rate was 29%. The most common causes for permanent implant failure were severe capsular contracture and infection. These findings have more recently been confirmed by a report by Nava et al., who retrospectively demonstrated that their overall rate of success was 94% when implant exchange was performed prior to radiation versus 60% when it was done following radiation (72).

In some cases it is not possible to exchange the expander to a final implant prior to radiation. For example, in patients treated with neoadjuvant chemotherapy, there is often inadequate time to complete expansion, perform exchange, and achieve adequate tissue healing prior to initiating radiation. In these cases, it may be helpful to delay the exchange procedure until the tissues have recovered from radiation injury. This concept is supported by a recent study by Peled and colleagues comparing complication rates in patients treated with PMRT in whom the exchange procedure was performed either early (within 3 months) or late (after 6 months) after radiation. In this study, the failure rate in patients who underwent exchange more than 6 months after completing radiation was nearly threefold lower (7.7% vs. 22.4%) than in patients who underwent surgery less than 6 months following radiation (73). These findings make intuitive sense, since skin changes due to radiation injury (erythema, desquamation, hypersensitivity) often take a significant time to resolve after treatment.

Kronowitz at the MD Anderson Cancer Center has proposed a concept the author terms delayed-immediate reconstruction (71). This concept is also based on the idea that immediate reconstruction has significant merits as compared to delayed approaches and aims to identify patients who will need PMRT before committing to autologous tissue reconstruction. With this approach, patients who are judged to be at high risk for needing PMRT undergo placement of a tissue expander at the time of mastectomy in order to maintain the breast envelope. Over the next several weeks the histology of the breast specimen and lymph nodes are reviewed by a multidisciplinary panel to determine if PMRT is necessary, in which case the expander is left in place until completion of radiation and then definitive reconstruction is performed using autologous tissues. In contrast, if radiation is not needed, then the patient returns to the operating room, the expander is removed, and autologous tissue reconstruction is performed. Long-term studies with validated patient reported outcomes will be helpful in these cases to analyze the efficacy of this approach.

NAR RECONSTRUCTION

Nipple reconstruction is an important adjunct to breast reconstruction helping to restore the normal appearance of the breast and also often helping to cover the mastectomy scar and improve symmetry and increasing patient satisfaction (74). Nipple reconstruction can be safely performed in most patients who have undergone breast reconstruction. Relative contraindications to nipple reconstruction include a history of radiation, very thin skin flaps, or previous failed nipple reconstruction. These patients have higher rates of complications with nipple reconstruction but may be candidates if they understand the risks.

A large number of techniques have been reported for nipple–areola reconstruction. By far, the vast majority of these techniques use local breast skin flaps to reconstruct the nipple (e.g., C-V flap, Skate flap, double opposing tab flaps, etc.). Nipple sharing is a less commonly used approach in which a portion of the normal contralateral nipple is harvested and used as a full-thickness graft to reconstruct the nipple in the reconstructed breast. A theoretical concern in these

procedures, however, is that the transplanted nipple graft may have breast ducts and as such may serve as a nidus of breast cancer recurrence.

By far the most common complication of nipple reconstruction is loss of projection (75). This complication occurs despite the fact that in most instances the size of the reconstructed nipple is overestimated. Minor wound breakdown also occurs on occasion; however, in the vast majority of cases these complications respond nicely to conservative management with dressing changes and antibiotics.

Areola reconstruction is performed using tattoo or with a full-thickness skin graft. Tattoo is simple to perform, requires minimal downtime, and is rarely associated with infection or other complications. However, tattoos can sometimes appear two-dimensional and usually fade over time. In addition, it is often difficult to precisely match the color of a contralateral areola particularly when the color chosen is very light. In contrast, although skin grafts are more invasive and result in a donor site scar, these areola reconstructions often appear more natural because they have both color and texture. The color match of the graft can be improved by harvesting skin from a naturally darker area of the body such as the inner groin crease. This donor site also hides the scar in a relatively inconspicuous area. Complete skin graft loss is rare; however, partial losses do occur and can result in distortion of the areola. In addition, donor site complications may also occur but fortunately are rare and usually heal with conservative management.

MANAGEMENT SUMMARY

- Most patients are candidates for reconstruction.
- Immediate reconstruction after mastectomy has significant advantages.
- Reconstruction is associated with low rates of major complications.
- Obesity, smoking, and hypertension increase the risk complications.
- Implant reconstructions are associated with rapid postoperative recovery but require maintenance and may be complicated by capsular contracture.
- Autogenous tissue reconstructions enable more aesthetic reconstructions but are more invasive and have longer recovery periods.
- Partial breast reconstruction can be performed using local tissue rearrangement or transfer of distant flaps.
- Chest wall irradiation has significant detrimental effects on reconstruction.
- Exchange of expander to implant prior to radiation may decrease infection or implant loss rates.
- Nipple–areola reconstruction is an important adjunct and increases patient satisfaction.

CHAPTER 37

Sentinel Lymph Node Biopsy

Alice P. Chung and Armando E. Giuliano

CHAPTER CONTENTS

INTRODUCTION

Axillary lymph node dissection (ALND) has been an integral component of the staging, prognosis, and treatment of invasive breast cancer and is discussed in Chapter 38. Surgical management of the axilla, however, has undergone a paradigm change since the concept of lymphatic mapping of the breast was introduced at the John Wayne Cancer Institute (JWCI) in 1991, and sentinel lymph node biopsy (SNB) has replaced ALND for axillary staging in clinically node-negative early breast cancer. Although tumor characteristics and molecular markers are increasingly contributing to the understanding of the biology of breast cancer, the status of the axilla remains the most important prognostic indicator for overall survival. The current algorithm for axillary management of invasive breast cancer incorporates outcomes information from SNB, ALND, and axillary irradiation as well as data from the effects of systemic therapies on axillary metastases. This chapter addresses the current understanding of the role of SNB in surgical management of the axilla for breast cancer.

SENTINEL NODE CONCEPT IN CANCER

In the early 1970s, Kett et al. (1) reported that the first regional lymph node, the "Sorgius node," could be identified in breast cancer using direct mammalymphography. This was a cumbersome technique that required a formal ALND to isolate the suspected lymph nodes, radiographic evaluation of the resected nodes to identify the suspicious ones, and determination of concordance through histopathologic confirmation.

Ramon Cabanas (2) coined the term *sentinel node* as a specific lymph node group in penile carcinoma, located in a constant anatomic location in the pelvis. The sentinel node (SN) concept evolved from this observation of specific anatomic nodal drainage and postulates that a primary tumor is drained by an afferent lymphatic channel that courses to the first, "sentinel," lymph node in that specific regional lymphatic basin (3). If the tumor has metastasized, it will do so to this node. The tumor status of the SN reflects the tumor status of the nodal basin. Morton et al. (4) tested the hypothesis that the SN in a given regional basin can be identified

by an indicator dye in a feline model and then validated it in the clinical setting in a group of patients with melanoma.

Identification of a Sentinel Node in Breast Cancer

The feasibility of identifying an SN intraoperatively in breast cancer was first investigated at the JWCI by Giuliano et al. (5). In October 1991, the authors' group began to investigate the feasibility of lymphatic mapping and sentinel lymphadenectomy with isosulfan blue vital dye in breast cancer as a more accurate and less morbid approach to stage breast cancer (Fig. 37-1). This prospective study demonstrated that SNB of the axilla is technically feasible, safe, and without added complications. With a defined technique and experience, a 100% accuracy to predict the status of the axilla was subsequently achieved (5,6). In addition to vital dye-directed lymphatic mapping, three other technical approaches for SN identification in breast cancer with accuracy rates comparable to the blue dye have evolved: radio-guided surgery, radio-guided surgery with preoperative lymphoscintigraphy, and the combination of vital dye and isotope techniques. The most commonly used agents are isosulfan blue dye and filtered technetium sulfur colloid. An increased SN identification rate with the use of the combination of blue dye and radioisotope is well documented. However, there has been only one prospective randomized trial comparing blue dye alone to the combined use of isotope and blue dye, and in this study Morrow et al. showed no difference in SN identification between the two groups (7). The authors found the number of cases performed by an individual surgeon to be the most significant predictor of successful SN identification, demonstrating that surgeon experience impacts SN identification and false-negative rates. Experienced surgeons are extremely successful in accurately identifying the SN regardless of technique. SN identification in breast cancer is technically feasible, safe, and an accurate predictor of the status of the axilla using several different technical approaches.

Proof of Principle

The SN hypothesis for breast cancer has been tested in the clinical setting by several groups of investigators who performed complete histopathologic evaluation of the SN and non-SNs using the same pathologic processing with step sectioning, hematoxylin and eosin (H&E) and immunohistochemistry (IHC) for all H&E negative axillary lymph nodes (8). Turner and colleagues identified 33/103 (32%) patients with a tumor-bearing SN by H&E. IHC evaluation of 157 negative SNs upstaged 10 patients (14.3%). In 60 patients whose SNs were negative by H&E and IHC, 1,087 non-SNs were examined at two levels by IHC and only one additional tumor-positive node was identified. In 57.3% of patients the SN was negative. In the 44 patients with a tumor-positive SN, 56.8% had involvement of the SN alone. Additional studies, including an NCI-sponsored multicenter trial that examined all non-SNs with the same rigorous histopathologic analysis, reported similar findings for cases with negative SN that had further evaluation of non-SN with IHC (9). The SN concept has been validated by these studies enabling widespread clinical application of this technique.

LYMPHATIC ANATOMY OF THE BREAST AND IMPLICATIONS FOR SENTINEL NODE IDENTIFICATION

Anatomy

The axilla is bordered by the latissimus dorsi posteriorly, the axillary vein superiorly, the chest wall medially, the pectoralis muscles anteriorly and extends laterally to where the vein crosses between the lateral edge of the pectoralis major and latissimus dorsi muscles. Level I nodes are located inferior and lateral to the pectoralis minor muscle, level II nodes posterior to the pectoralis minor and below the axillary vein, and level III nodes are medial to the pectoralis minor and below the clavicle. Lymphatic drainage generally follows an orderly sequential pattern from level I to level II nodes and rarely to level III. SNB is a staging procedure that removes one or more lymph nodes from the axillary basin. The SN is found in level I in 83% of cases, level II in 15.6%, in level III in 0.5%, internal mammary in 0.5%, supraclavicular in 0.1%, and elsewhere in 0.3% (10).

Patterns of Regional Nodal Drainage

The axilla is the primary site of drainage in about 95% of breast cancer cases, with isolated internal mammary drainage seen in less than 5% (10). Primary drainage to other nodal pathways, such as supraclavicular, cervical, intercostal, and contralateral lymph nodes, is extremely uncommon. Lymphoscintigrams can accurately identify nodal uptake of radioisotope preoperatively (Fig. 37-2).

Although the axilla is the primary drainage site, with other regions receiving limited lymphatic flow, the prognostic value of the internal mammary nodal status is high, particularly when both axillary and internal mammary nodes are either negative with better survival than with either basin having metastases or with the worst prognosis when both basins are involved (11). In those rare cases, with small tumors and sole drainage to nodal stations other than the axilla, identification of tumor positive regional nodes may be important for adjuvant therapy recommendations or to determine external beam irradiation fields. There have been several groups who have investigated the impact of internal mammary nodal drainage identified by preoperative lymphoscintigraphy on outcome. Kong et al. (12) reviewed their database of 1,172 patients with stage I to III invasive breast cancer who had

FIGURE 37-2 Preoperative lymphoscintigraphy demonstrates a left anterior oblique view of a sentinel node.

preoperative lymphoscintigrams following peritumoral injection of radiocolloid and identified 334 patients with drainage of radiocolloid to the internal mammary nodes. These patients were significantly younger, less likely to have upper outer quadrant tumors, and more likely to have smaller and medial tumors than patients without drainage to the internal mammary nodes. Rates of internal mammary irradiation did not differ between the two groups. With median follow-up time of 7.4 years, internal mammary drainage was significantly associated with a worse distant disease-free survival (DFS)but not locoregional recurrence or overall survival. The data from the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-32 trial demonstrated that the majority of positive SNs came from levels I and II of the ALND, and only 1.2% of the positive SN specimens came from non-axillary locations (13). In general, nodal status is becoming less relevant in determining adjuvant therapy.

Early anatomists studied the lymphatics of the breast by injecting mercury into the lactiferous ducts of female cadavers (14). In 1874, Sappey concluded that all of the lymphatics arising from the breast drained to the axilla via the subareolar plexus. As techniques for visualizing the lymphatics have evolved, our understanding of the lymphatic drainage in the breast has changed (14). Analysis of the superficial and deep lymphatic anatomy of the breast and upper torso from human cadaver studies supports the SN concept. Suami and colleagues (15) studied 24 breasts in 14 human cadavers and found that superficial lymphatic collectors drain into the same first-echelon node close to the lateral edge of the pectoralis minor muscle (Fig. 37-3). In most cases, the drainage was to only one SN. In several cases, however, there was at least one other first-echelon node from a collecting lymphatic that passed directly through the breast. The investigators also found that lymphatics of the nipple–areola complex are different from other areas of the breast and drain only into the first-echelon pectoral node shown in Figure 38-3 in green, but not to the depicted orange node that receives lymphatic drainage that passes through the breast. This study did not identify any direct anastomosis between the superficial collecting system and the collectors associated with internal mammary vessels, an observation consistent with the findings of studies that have used lymphoscintigraphy to study patterns of lymphatic drainage by site of injection (16).

The findings in Suami's anatomic study may explain the clinical experience with lymphatic mapping and the persistence of a false-negative (FN) rate of 8% to 11% (13,16). Dye injected deep into the parenchyma along the purple-colored track (depicted in Fig. 37-3) reaches both the depicted green and orange lymph nodes in the pectoral group, whereas dye injected into the subareolar or intradermal location reached only the depicted green node. SNB using the intraparenchymal injection technique would track to both nodes and suggests that the intraparenchymal route of injection may be more likely to track to both first-echelon nodes and result in a more accurate staging of the axilla. The proof of principle study discussed above was performed with the intraparenchymal injection method and had one FN node (8).

Pan et al. (17) used combined preservation techniques with computed tomographic lymphangiography to obtain a three-dimensional analysis of the lymphatics in the bilateral breasts and anterior upper torso of a human cadaver. They found a predominance of superficial lymphatics with radial drainage to the axilla, and asymmetry between the right and left breasts with high variation in number and size of lymphatic vessels between sides.

Blumgart and colleagues (18) evaluated lymphoscintigraphic data from 2,304 breast cancer patients (2,284 female, 20 male). All patients received four peritumoral injections of technitium 99m sulfur colloid followed by lymphoscintigraphy with documentation of drainage patterns. Unlike Pan, they found that lymphatic drainage and tumor distribution were symmetric between both breasts. There were no differences in drainage patterns between males and females. They also found that among 2,304 patients, axillary (2,263, 98.2%), interpectoral (n = 15, 0.7%), internal mammary (n = 813, 35.5%), infraclavicular (n = 25, 1.1%) and supraclavicular (n = 70, 3.0%) nodal fields directly drain the breasts with variable frequencies, and that patients usually drained to one nodal field (64%) but it was possible for drainage to occur to multiple nodal fields (36%).

Cumulative Experience of Sentinel Node Identification for Staging

Investigators from academic centers and the surgical community worldwide have introduced SNB into clinical practice as a staging procedure. Several multicenter lymphatic mapping trials have confirmed the feasibility of SNB as a staging procedure and reported data on identification and FN rate (Table 37-1) (13,19,20). The identification rate ranges from 86% to 97% with accuracy from 96% to 98% and a FN rate from 4% to 16.7%. Most of the multicenter trials required some formal instruction or validation prior to participation of each institution, however early on most surgeons were self-taught. SN identification rate and accuracy are highly dependent on surgeon experience, more so than technique.

The NSABP B-32 trial randomized patients with clinically node-negative invasive breast cancer to either SNB followed by a level I or II ALND (group 1), or observation of the axilla if the SN was tumor free (group 2) (13). Five thousand six hundred eleven women were randomly assigned to the treatment groups, 3,986 had pathologically negative SN with follow-up information. The study reported an SN identification rate of 97.2%, accuracy rate of 97.1%, and a FN rate of 9.8%. With a mean follow-up of 95.6 months, there was no significant difference between the two groups with respect to overall survival, disease-free survival, and regional control (21).

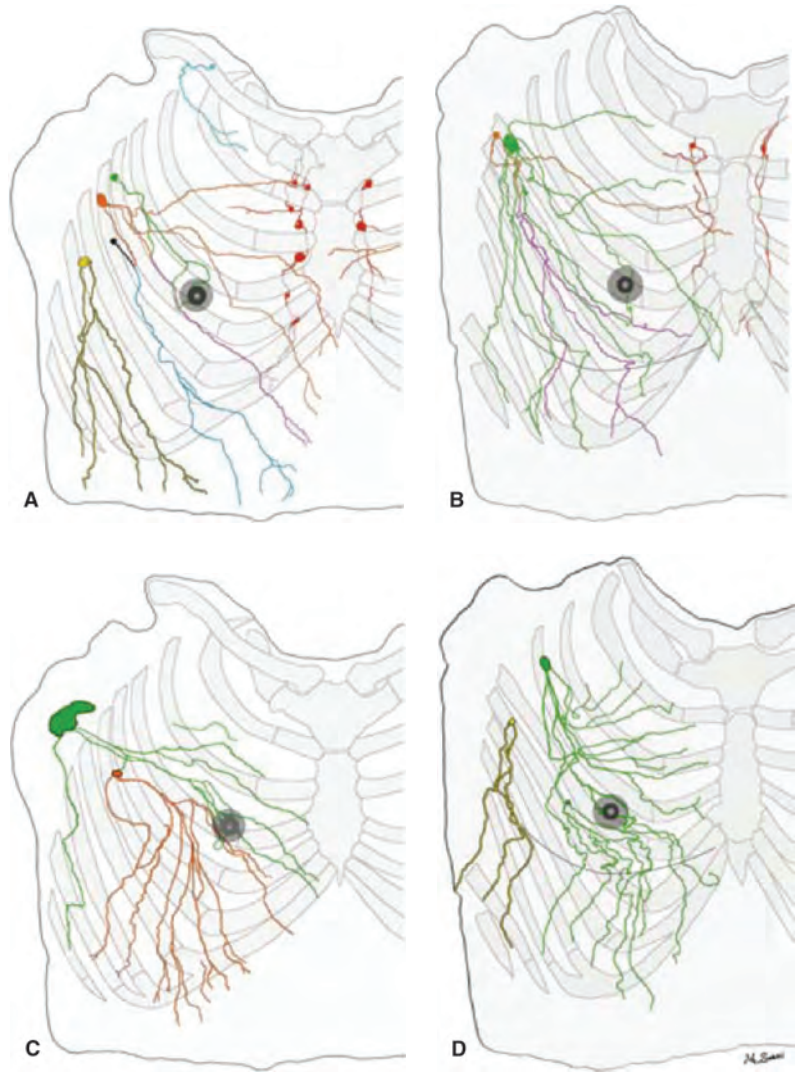

FIGURE 37-3 Tracing distally of lymphatics of both hemi upper torsos (male: **(A)** and **(C)**, female: **(B)** and **(D)**) from each first-tier lymph node color coded: pectoral node (*green, orange, black*, and *yellow*), subclavicular node (*light blue*), and internal mammary node (red). Note: that the lymph collecting vessels from the nipple and areolar region on each specimen drain into the green-colored lymph node; the similar pattern of chest and breast drainage between the male and female studies; the breast lies in the pathway of collecting lymphatics that start peripherally; and although the majority of the breast drains to one sentinel node in **D**, every breast area is drained by more than one first-tier node in each study. (From Suami H, Pan W-R, Mann GB, et al. The lymphatic anatomy of the breast and its implications for sentinal lymph node biopsy: a human cadaver study. *Ann Surg Oncol* 2008;(3):863–871.)

TABLE 37-1

Identification Rate and False-Negative Rate of Selected Multicenter Sentinel Lymph Node Trials That Evaluated the Status of the Axilla with Sentinel Lymph Node Dissection Followed by Completion Axillary Lymph Node Dissection

Study/Author	*No. of Cases*	*SN Identification Rate (%)*	*FN Rate (%)*
Canavese (2009) (109)	202	97.1	6.5
Veronesi (1999) (110)	376	98.7	6.7
Krag (1998) (111)	443	91.0	11.0
Tafra (2001) (71)	529	87.0	13.0
SNAC (19)	1,080	94.5	5.5
NSABP-B32 (21)	5,611	97.1	9.8
ALMANAC (20)	803	96.1	6.7
ACOSOG Z010 (27)	5,283	98.7	0.3 (estimated)
Sentinella/GIVOM (36)	697	95.0	16.7

SNB, sentinel lymph node biopsy; FN, false-negative; SNAC, Sentinel Node Biopsy versus Axillary Clearance; NSABP, National Surgical Adjuvant Breast and Bowel Project; ALMANAC, Axillary Lymphatic Mapping Against Nodal Axillary Clearance; ACOSOG, American College of Surgeons Oncology Group; GIVOM, Gruppo Interdisciplinare Veneto di Oncologia Mammaria.

The Axillary Lymphatic Mapping Against Nodal Axillary Clearance (ALMANAC) trial was a two-phase trial that required surgeons to demonstrate a 90% identification rate and a FN rate of less than 5% prior to proceeding to phase II, which was the two-armed prospective trial that randomized 1,031 patients into SNB followed by ALND (n = 516) or to SNB alone (n = 515) if the SN was tumor free (20). If the SN was positive for tumor cells, the regional treatment was ALND or axillary irradiation. SNB was performed with a 96% success rate with the combined use of blue dye and radioisotope and a 5% FN rate. The investigators reported a significantly lower rate of lymphedema, sensory deficits, and impairment in shoulder function in the SNB arm with patient-recorded quality of life scores statistically significantly better in the SNB arm. A report on long-term outcomes is pending.

The Royal Australian College of Surgeons (RACS) SN versus Axillary Clearance (SNAC) multicenter randomized study was a phase III trial with a two stage design similar to the ALMANAC trial. A sensitivity of 95%, FN rate of 5%, and a negative predictive value of 98% were reported for SN biopsy in stage I. Stage II randomized 1,088 clinically node-negative women with invasive breast cancer less than 3 cm to SNB alone versus axillary clearance to compare rates of axillary morbidity. The average increase in arm volume was 2.8% in the SNB alone group and 4.2% in the axillary clearance group ($p = .002$). Patients in the SNB alone group gave lower ratings for arm swelling ($p < .001$), symptoms ($p < .001$), and dysfunctions ($p = .02$), but not disabilities ($p = .5$) (19).

HISTOPATHOLOGIC PROCESSING

When the authors' group at the JWCI compared ALND alone to SNB followed by completion ALND, axillary metastases were identified in 29% of the ALND-alone group compared to 42% in the SNB group ($p < .03$) (22). H&E analysis of multiple levels of the SN increased the sensitivity to detect micrometastases for SNB versus ALND (9.2% vs. 3.0%, respectively; $p < .004$), and when both H&E and IHC were used, there was increased sensitivity (16.0% vs. 3.0%, respectively; $p < .0005$) (Fig. 37-4). Focused histopathologic analysis of the SN is a more sensitive method to detect micrometastases by both H&E and IHC and leads to improved accuracy of axillary staging for a tumor-positive axillary lymph node. The hope was that ultra-staging of the SN would lead to the identification of H&E node-negative patients who were at higher risk for recurrence.

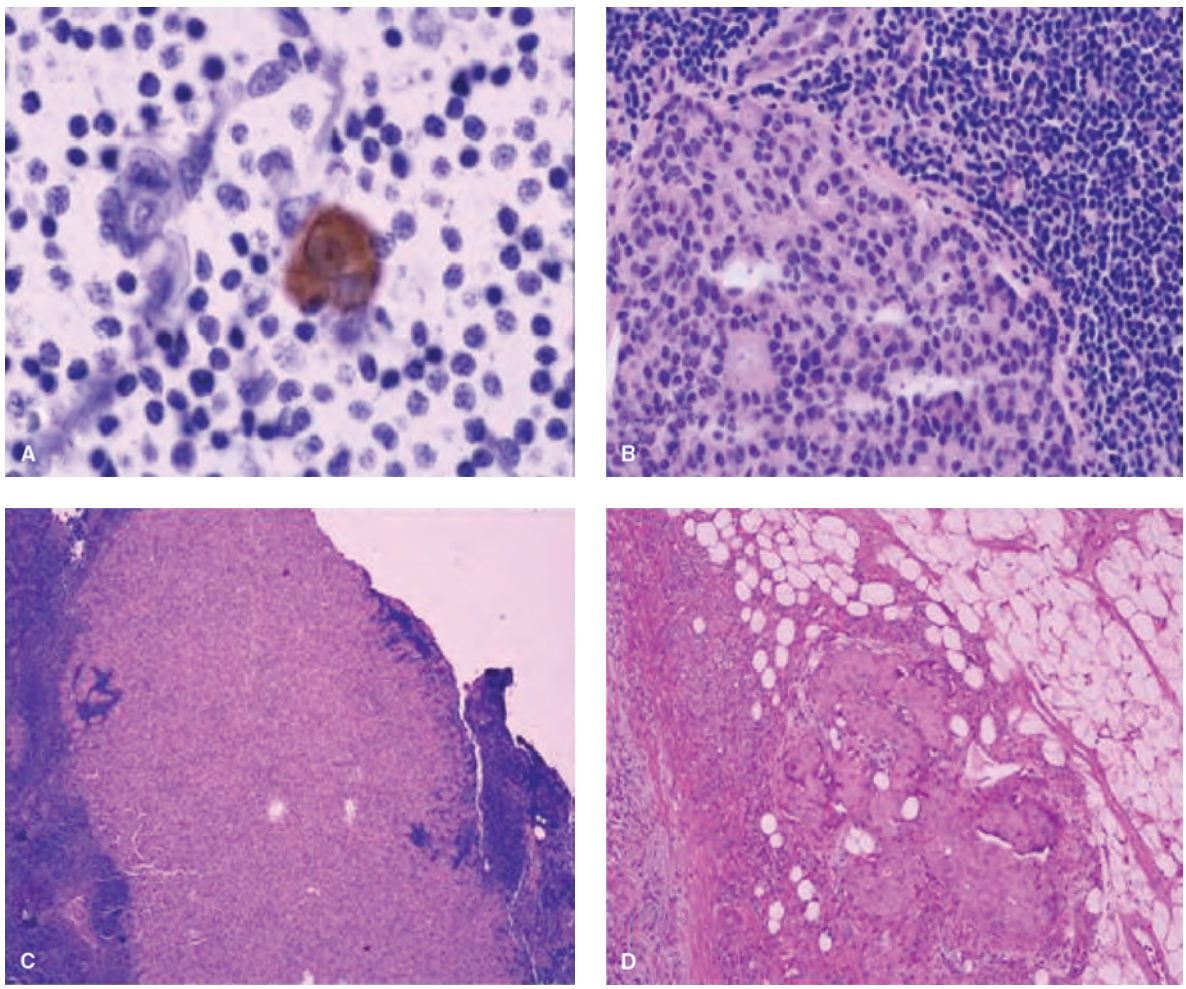

FIGURE 37-4 **Sentinel node metastases. (A)** Demonstrates a single immunohistochemistry-positive cell. **(B)** Demonstrates a high power view of a hematoxylin-eosin metastasis. **(C)** Demonstrates a low power view of a macrometastasis. **(D)** Demonstrates extracapsular extension of a sentinel node micrometastasis.

In view of the identification of small tumors in the SN, the American College of Pathologists established guidelines to process the SN with frozen sections, imprint cytology, or permanent formalin processed specimens (23). The SN is bivalved along the longitudinal axis, serially sectioned at 1.5 to 2.0 mm thickness blocks and each block is sectioned at three levels. If metastases are identified in the SN (see Fig. 37-4), the size of the metastasis is reported as macrometastases (>2.0 mm), micrometastases (>0.2 and ≤2.0 mm), or isolated tumor cells (≤0.2 mm), and the method of detection of the metastasis by H&E, IHC, or reverse transcription-polymerase chain reaction (RT-PCR). In the new American Joint Committee on Cancer (AJCC) guidelines (seventh edition), small clusters of cells not greater than 0.2 mm, or nonconfluent or nearly confluent clusters of cells not exceeding 200 cells in a single histologic cross section of a lymph node are classified as isolated tumor cells.

Molecular analysis of the SN is an area of emerging technology and interest. Some investigators feel that this is a more objective assessment of the tumor burden in the SN, is more reproducible, can be standardized, and evaluates more tissue in a shorter period of time (24). Quantitative RT-PCR (qRT-PCR) evaluation demonstrates a 98% accuracy and can be performed in 40 minutes or less. A prospective trial to evaluate lymph node metastases with a multiplex RT-PCR-based assay detected 98% of metastases greater than 2 mm and 88% of those greater than 0.2 mm, and results were superior to frozen section histology or imprint cytology (24). In a prospective multicenter trial that conducted molecular analysis of SN by qRT-PCR as well as serial sectioning and staining with H&E and with or without IHC in 547 patients, investigators compared the two groups with respect to clinical outcome with mean follow-up of 7 years (25). While molecular staging of SN detected more nodal metastases not seen by standard histologic evaluation, these metastases were not shown to be a significant predictor of disease recurrence. Similar results were observed by Fisher and colleagues (26) who analyzed seven breast cancer associated genes, known to be overexpressed in metastatic breast cancer, in axillary lymph nodes of 501 patients with T1–T3 invasive breast cancer who were followed for 5 years with no impact on clinical outcome. Molecular analysis of SN is unlikely to be of clinical relevance in view of recently reported results of the ACOSOG Z10 and NSABP-B32 trials on micrometastases, discussed later in this chapter. In the absence of participation in a clinical trial, the reasonable management approach should be based on the H&E evaluation of axillary nodes; however, in clinical practice IHC is used in many centers for SNs that are found negative by H&E.

FACTORS INFLUENCING THE SUCCESS AND ACCURACY OF SENTINEL LYMPH NODE DISSECTION

In order to reduce the FN rate of SNB, causes of failure have been sought. Potential explanations for failure include improper surgical technique, lack of surgeon and pathologist experience, lymphatic physiology, aberrant lymphatic patterns, and patient and tumor characteristics.

Effect of Sentinel Lymph Node Dissection Technique on Accuracy

A variety of technical factors, which include type of dye or radioisotope, filtered versus unfiltered isotope, timing of surgery after injection, and site of injection (peritumoral, subdermal, intradermal, subareolar) influence the performance of SNB. A high degree of accuracy and a low FN rate with resection of only one or two lymph nodes is seen in most cases. Differences in the ability to find the SN are reflections of variations in patient characteristics (e.g., obesity, age) and surgeon experience more than technique. Internal mammary nodes are visualized less often with intradermal injection than with peritumoral injection. Subareolar injection of isotope offers some advantages over peritumoral injection; for example, when the tumor is nonpalpable, it increases the distance from the injection site of radioisotope to the axilla for upper outer quadrant lesions, reducing the shine through, and is a good choice for multicentric disease.

In the multi-institutional American College of Surgeons Oncology Group (ACOSOG) Z0010 trial, 198 surgeons enrolled 5,237 patients and used blue dye with radiocolloid in 79.4% of cases, blue dye alone in 14.8%, and radiocolloid alone in 5.7% with a success rate of 98.7%, corresponding to a failure rate of 1.7% (27). The percent of failed SNB with blue dye was 1.4%, radiocolloid 2.3%, and the combination 1.2% (p = .2813). The number of cases (≤50 compared to >50) enrolled was associated with a statistically significant failure rate. Increased body mass index and age were also associated with decreased SN identification in this study. Morrow et al. evaluated isosulfan blue dye alone and compared it to dye with isotope (7). Surgeons achieved equal results with either method. A study from New Zealand confirms this work and reports that identification of the SN is similar with blue dye alone compared to a triple modality approach (lymphoscintigraphy, intraoperative gamma probe, and intraoperative blue dye) (28). The blue dye had an accuracy of 98% and a sensitivity of 96% compared to the triple method accuracy of 95% and sensitivity of 91%. There has been a manufacturing shortage of isosulfan blue in the United States and methylene blue has been used as an alternative vital dye. The success rate of methylene blue with radioisotope is reported to be equivalent to isosulfan blue with isotope (29).

The site of injection of the tracer may influence the outcome of SNB. A prospective randomized trial compared intradermal, intraparenchymal, and subareolar routes of injection and demonstrated a significantly higher rate of localization and more rapid transit by lymphoscintigraphy, and shorter time to surgery with the intradermal injection (16). Another randomized multicenter trial compared periareolar and peritumoral injection of radiotracer and blue dye (30). The intraoperative success was similar for blue dye or gamma detection (99.1%). The detection rate was higher for the periareolar site for each tracer, but this was not statistically significant. The SN was blue in 94.7%, hot in 97.1%, and both in 92.6%. The concordance was 91.5% with the peritumoral injection and 95.6% with the periareolar injection. The blue dye and radiocolloid concordance for the positive SN patients was 94.5% and, when assessed by site of injection, 96.2% in the periareolar group and 92.9% in the peritumoral group.

The SNB procedure has been adopted by surgeons in both academic and community settings throughout the United States as well as internationally. The efficacy of the method, dye, isotope, or both, is more likely a reflection of training and experience than variations in the success of the method itself. The importance of quality control and appropriate training cannot be overemphasized.

Effect of Surgeon Experience: Training and Performance of Sentinel Lymph Node Dissection

Formal lymphatic mapping instruction with hands-on experience leads to a 90% to 95% identification rate and a 3.8% to

4.3% FN rate when more than 30 cases are performed (31). The NSABP B-32 trial required a minimum of five prequalifying cases and reported a technical success rate of 97% (13). Surgical volume impacts identification rates. Surgeons who performed fewer than three cases per month had a success rate of 86.23% ± 8.30%, for three to six cases 88.73% ± 6.36%, and for six or more SN biopsies 97.81% ± 0.44% (31).

The studies just described show individual variation in learning the skills and identify some of the pitfalls in learning the technique. Instruction in SNB is now part of surgical residency training in the United States. For those not trained in the technique during residency, formal instruction, use of dual agents, performance of approximately 20 SNB procedures with a backup ALND, and an adequate volume of cases to maintain skills are all factors that contribute to successful identification of SN and reduced FN rate. In 2005, a consensus statement from the American Society of Breast Surgeons suggests that prior to abandoning ALND for a negative SN, 20 cases of SNB be performed with an identification rate of 85% and a FN rate of 5% or less (32). These should be adapted on an individual basis, with more cases performed by those with lower identification rates and higher FN rates and vice versa. One problem with their application is that most patients are SN negative, making the FN rate more difficult to determine with a high degree of certainty.

Effect of the Number of Sentinel Nodes Removed

Increasing the mean number of SNs removed may improve accuracy (13,33). The number of SNs removed statistically affected the FN rate in the NSABP B-32 trial, where a median of 2 SNs was removed in each treatment arm. The FN rate was 17.7% when one node was removed, 10% for two, 6.9% for three, 5.5% for four, and 1% for five or more nodes removed. In the University of Louisville Breast Cancer Sentinel Lymph Node Study, the mean number of SNs removed per patient was 2.2 and 58% of the patients had multiple SNs removed (33). The overall SN identification rate was 90% with an 8.3% FN rate. If a single node was removed, the FN rate was 14.3% compared to 4.3% when multiple SNs were removed ($p < .0004$). The first two or three SNs removed predict the status of the axilla in about 98% of cases, but additional positive SNs will be identified when four or more nodes are removed, improving the FN rate (13). The removal of all blue, or radioactive, nodes with a count equal to or greater than 10% of the most radioactive node has been shown to decrease the FN rate in these studies. This increase in staging accuracy may be obtained at the cost of an increased rate of complications, especially lymphedema, but the goal is accurate staging for treatment decisions. Fewer nodes may be removed with increasing surgeon experience.

Effect of Patient and Tumor Characteristics

The data from the multi-institutional, randomized prospective NSABP B-32 trial reports a FN rate of 9.8% and an overall accuracy of 97.1% (13). Differences in tumor location (inner and central location vs. lateral and outer), no hot spot identified preoperatively, small tumor size, older age, and type of diagnostic biopsy (excision/incisional biopsy higher than fine-needle aspiration [FNA] or core needle biopsy [CNB]) increased the FN rate. In the ALMANAC study, increased body mass index (BMI), upper outer quadrant location, and nonvisualization on lymphoscintigraphy were significantly associated with failed identification ($p < .001$, $p = .008$, $p < .001$, respectively) (34). None of the following, age, tumor size, tumor histology, tumor grade, or multifocality, affected identification. In the ACOSOG Z0010 trial, a higher failure to identify a SN occurred with increased BMI and age of 70 or older (27).

Impact of Sentinel Lymph Node Dissection on Regional Control and Survival for Sentinel Node–Negative Patients

Results from randomized controlled trials examining local recurrence after SNB alone are summarized in Table 37-2. A meta-analysis of 48 studies that included 14,959 SN-negative patients followed for a median of 34 months demonstrated an axillary failure in 67 patients (0.3%) (35). In the European Institute of Oncology Trial the predicted failure was eight cases, but only one case of overt axillary metastases was seen at 7.2 years of follow-up after surgery. The possibility that the occult metastases in the FN nodes may never become overt has been suggested by several single institution studies, the Swedish multicenter trial, and from the European Institute of Oncology trial at a relatively short follow-up.

One multicenter trial to report results on patients randomized to SNB alone or SNB followed by ALND was the Sentinella/GIVOM trial (36). This study reported a FN rate of 16.7%. Despite this high FN rate, there was only one axillary failure in the SNB-alone group at 55.6 months. The overall survival was 95.5% in the ALND group and 94.8% in the SNB-alone group at 5 years of follow-up.

In the European Institute of Oncology randomized study, women with tumors less than 2 cm were randomized to SNB

No., number; F/U, follow-up; LRR, locoregional recurrence; DFS, disease-free survival; OS, overall survival; SNB, sentinel node biopsy; ALND, axillary lymph node dissection; y, year; GIVOM, Gruppo Interdisciplinare Veneto di Oncologia Mammaria; NSABP, National Surgical Adjuvant Breast and Bowel Project; ACOSOG, American College of Surgeons Oncology Group; *, SN-positive by H&E.

alone if the SN was tumor free or to SNB followed by ALND (37). In the ALND group, 32% had a positive SN and 8 of 174 SN-negative patients had a FN node. The SN was positive in 36% of the SNB-only group with one axillary failure at a median follow-up of 79 months. Because there were eight FNs in the ALND group, there should have been eight FNs in the SNB alone group, but there was only one axillary failure. The overall survival was the same for the ALND group compared to SNB alone (96.4% vs. 98.4%, respectively; $p = .6$). The SNB-alone group had decreased morbidity and cost.

The NSABP-B32 prospective randomized trial of SNB followed by ALND (group 1) versus SNB alone with ALND only in SN-positive patients (group 2) reported outcomes after longer follow-up. Among 5,611 women, there was no difference in regional control between the two groups after median follow-up of 95.6 months (eight regional recurrences in group 1 vs. 14 in group 2, $p = .22$) (21). Eight-year Kaplan-Meier estimates for overall survival were 91.8% (95% CI, 90.4–93.3) in group 1 and 90.3% (88.8–91.8) in group 2, and for disease-free survival were 82.4% (80.5–84.4) in group 1 and 81.5% (79.6–83.4) in group 2. Veronesi et al. conducted a randomized trial at a single institution involving 516 patients with breast tumors of 2 cm or less in size who were randomly assigned to either SNB followed by ALND or SNB with ALND only if the SN contained metastatic disease (38). With a median follow-up of 102 months, there was no difference between the two groups with respect to disease-free survival (89.9% in the SNB arm, vs. 88.8% in the ALND arm) or overall survival (93.5%, compared to the ALND arm, 89.7%, $p = .15$). Of note, there were only two (0.01%) axillary recurrences in this study, both of which occurred in the SNB only group. SNB appears to provide regional nodal control equal to that of ALND when the SN is negative. Standard tangent breast fields may contribute to axillary control in those who undergo breast conservation and receive whole breast irradiation, but several investigators show that they do not encompass all the level I and II lymph nodes (39).

Summary

SNB has met with success in single institution studies and several multicenter trials with credentialed teams. There is a large body of evidence showing that SNB is an accurate staging procedure in expert hands, and it is now the standard of care for staging clinically node-negative invasive breast cancer.

Reliable staging with SNB depends on the success of SN identification, a low FN rate, and histopathologic accuracy. Almost two decades of experience with sentinel lymphadenectomy as the sole axillary treatment at a number of large single institution trials and several randomized trials with long follow-up prove that this is a safe, reliable, and effective procedure for staging.

MANAGEMENT OF THE AXILLA IN THE PATIENT WITH A POSITIVE SENTINEL NODE

ALND has traditionally been the recommended treatment for a positive SN. However, trends to omit ALND in SN-positive patients have been documented over the last 15 years, especially among patients with low tumor burden in the SN. Bilimoria and colleagues (40) identified 97,314 clinically node-negative patients found to have a positive SN from the National Cancer Database from 1998 to 2005. Approximately 20% of SN-positive patients did not have completion ALND and from 1998 to 2005, the proportion of patients with micrometastatic SNs who had SNB alone increased from 25% to 45%. With a median follow-up of 63 months, the authors did not find a difference in regional recurrence or survival between those who had SNB with completion ALND and those who had SNB alone. Similar findings were observed in a review of the Surveillance, Epidemiology, and End Results (SEER) database, where Yi et al. (41) identified 26,986 patients with a positive SN from 1998 to 2004. Approximately 16% of patients had SNB alone without completion ALND. From 1998 to 2004 the proportion of patients with micrometastatic SN who had SNB alone increased from 21% to 38%.

One of the factors influencing a decrease in completion ALND for positive SN may have been the introduction of nomograms that were shown to predict involvement of non-SNs. Van Zee et al. (42) developed a nomogram to help estimate the risk of additional nodal disease when the SN is positive. The nomogram uses pathologic size, tumor type, nuclear grade, lymphovascular invasion, multifocality, estrogen-receptor status, histopathologic method used to detect a positive SN, and the ratio of the number of positive SN removed to the total number of SN removed to predict the likelihood of additional positive non-SNs. Retrospective data were used to create the model, which was tested prospectively at Memorial Sloan-Kettering Cancer Center and found to be predictive of metastases. The receiver operating characteristic (ROC) was 0.76 in the retrospective data set and 0.77 in the prospective group. Several groups have tested the nomogram and found fair to good reliability, but at the same time they have questioned the clinical usefulness (43). Others did not find good correlation, in particular with micrometastatic disease (44,45). Other nomograms have been developed at the Mayo Clinic (45), MD Anderson Cancer Center (46), and Stanford University (47).

There are several studies that have reported the short-term outcomes in SN-positive patients who declined ALND and had no treatment of the axilla (48,49). In these studies, the tumor size was small and the majority of patients had micrometastatic disease. There were no locoregional failures at short follow-up (29 to 32 months). A review from Memorial Sloan-Kettering Cancer Center on SN-positive patients who declined ALND investigated the clinical findings, pathologic features, nomogram scores, and axillary failure rate in 287 SN-positive patients (50). This group of patients was older, had more favorable tumors, had a higher rate of breast conservation, and had a lower estimate of residual nodal disease calculated by a nomogram than the group undergoing axillary dissection. The axillary relapse rate in the untreated group was 2% compared to 0.4% in the group who had a completion ALND ($p = .004$).

The appropriate management of the axilla after a positive SN has been addressed in a number of prospective clinical trials. The ACOSOG Z0011 was a prospective Phase III non-inferiority trial that randomized subjects with clinical T1 or T2N0M0 breast cancer with a tumor-positive SN to completion ALND or observation of the axilla (51,52). Treatment of the breast was breast conservation and whole breast radiotherapy. No third field was given to the axillary lymph nodes. The primary end point of this study was overall survival; morbidity and disease-free survival were secondary end points. A secondary aim was to evaluate surgical morbidity with SNB plus ALND versus SNB alone. The purpose of this study was to determine the therapeutic role of axillary dissection. Unfortunately, this study closed early due to poor accrual and a low event rate.

Results of this study were recently reported and have created a significant amount of controversy in the oncologic community. From May 1999 through December 2004, 891

patients were enrolled from 115 sites: 445 were randomized to ALND, 446 were randomized to no further axillary treatment. There was no significant difference between the two groups with respect to age, tumor size, estrogen-receptor (ER) status, presence of lymphovascular invasion (LVI), grade, or histology. Ninety-seven percent of patients received adjuvant systemic therapy reflecting practice patterns in the United States. The two groups varied naturally by number of LNs removed with the ALND arm averaging 17 nodes and the SNB only arm averaging only two nodes per patient. There was also a difference between the two groups with respect to number of nodes removed and size of metastases with the SNB alone arm having more patients with micrometastatic disease (p = .05). At median follow-up of 6.3 years, there was no difference between the two treatment arms with respect to locoregional recurrence (3.1% with ALND and 1.6% with SNB alone), OS (91.8% with ALND vs. 92.5% with SNB alone), and DFS (82.2% with ALND and 83.9% with SNB alone). Figure 37-5 demonstrates the comparison of outcomes between the SNB only arm and the ALND arm. Non-inferiority between the two arms was achieved with high statistical significance (p < .008). These findings have resulted in considerable controversy with many questioning whether radiation oncologists irradiated the axillary nodes in the SNB alone group, even though axillary irradiation was prohibited in the protocol. Concerns have also been raised regarding the number of patients accrued, length of follow-up, and the applicability of the results to the general population because the majority of patients in the Z011 trial had early metastatic disease. Goal accrual was 1,900, but the actual accrual was 891. However, not only was non-inferiority achieved with high statistical significance (p < .008), total locoregional recurrence, DFS, and OS were in favor of the SNB alone group, suggesting that observed results are not likely to change with an increase in sample size. The excellent locoregional control in the Z011 trial was due to many factors, including whole breast irradiation, routine use of adjuvant systemic therapy, early disease, and low burden of nodal metastases.

Another concern that critics have about this trial is the length of follow-up. Many argue that death from early ER-positive breast cancer tends to occur late and 6.3 years is not enough follow-up. However, axillary recurrences do tend to occur early. There is an abundance of data demonstrating that the median time to axillary recurrence ranges from 14 to 20 months (51,53,54). So 6.3 years should be more than enough time to detect these recurrences. In addition, there have been a number of landmark historical trials evaluating whether axillary treatment, either in the form of surgery or radiation therapy, affects survival (54–59). These are randomized trials on a large number of patients, with long follow-up, with none of them demonstrating a significant difference in breast cancer-specific survival or OS resulting from axillary nodal treatment. ACOSOG Z011 confirms the results of these earlier trials, that axillary treatment does not, in fact, affect survival.

Many argue that the large majority of the study population included older, ER-positive, less aggressive tumors and that the higher risk populations were under-represented in the trial. Therefore, completion ALND should be performed in younger, high-risk, ER-negative populations. In Z011, age ranged from 24 to 92 with 38% of patients under the age of 50. Among the younger patients, there was no difference between the two groups with respect to LRR, and most of the recurrences were in-breast recurrences—not nodal recurrences. In fact, there is no data from clinical trials documenting that younger women are at increased risk for isolated nodal recurrences. So the investigators argue that age should not limit the application of this study to practice. ER/PR-negative patients represented about 16% of the study population. In a subset analysis, there was no difference in survival between the two arms whether they had ER-positive or ER-negative tumors. Another important point is that ER-negative tumors are not more likely to metastasize to the nodes. Wiechmann and colleagues (60) performed immunohistochemical staining to determine subtype on over 6,000 breast tumors that had information on nodal status. They found that the basal subtype, or triple-negative subtype, was less likely than the other subtypes (Luminal A, B, or HER2) to have nodal involvement. Therefore, it is unlikely that patients in this subset would truly benefit from completion ALND any more than low-risk patients.

The other high-risk category is the HER2-overexpressing (Her2+) tumor. ACOSOG Z011 opened in 1999 when routine HER2 testing was not performed, so HER2 data was not consistently reported. While HER2+ tumors are more aggressive, they are not more likely to metastasize to the lymph nodes. Anti-HER2 targeted therapy is likely to reduce the tumor burden in any undissected nodes. Data from the landmark trastuzumab trials shows that trastuzumab significantly

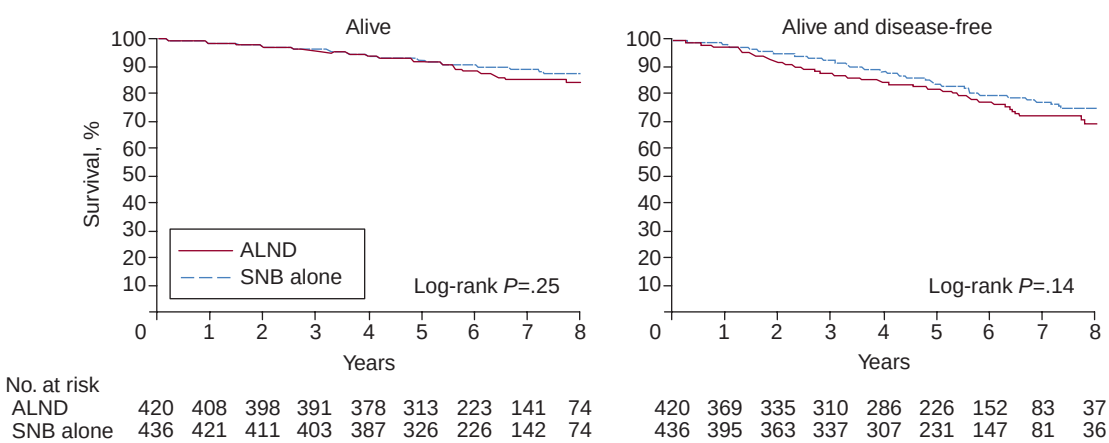

FIGURE 37-5 Comparison of outcomes of patients treated with SNB alone to those treated with SNB plus ALND in the ACOSOG Z011 trial. (A) Disease-free survival. **(B)** Overall survival. (From Giuliano AE, Hunt KK, Ballman KV, et al. Axillary dissection vs no axillary dissection in women with invasive breast cancer and sentinel node metastasis: a randomized clinical trial. *JAMA* 2011;305(6):569–575, with permission.)

reduces the incidence of LRR (NSABP-B31 and N9831) (61,62). Therefore, patients with HER2+ breast cancer should not be excluded from the application of the Z011 trial data.

To address the above mentioned concerns, Dengel and colleagues prospectively assessed the applicability of the Z011 trial in a cohort of 341 consecutive SN-positive patients treated with breast conservative surgery according to a treatment algorithm based on the Z011 eligibility criteria (63). Of 253 patients with ≥1 H&E-positive SN, 212 (84%) had indications for SNB only, and ALND was indicated in 41 (16%) based on Z011 eligibility criteria. Comparison of patient and tumor characteristics did not identify any difference between the two groups with respect to age, hormone-receptor status, or HER2 status. Completion ALND was performed in 34 of the 41 patients where ALND was indicated, and additional tumor-involved nodes were found in 74%. In this study, ALND was avoided in 84% of SN-positive patients, and age, hormone receptor status and HER2 status were not predictive of tumor burden requiring ALND.

In summary, patients with a positive SN that may avoid ALND include those with clinical T1–2, N0 breast cancer with one or two positive SN who plan to undergo lumpectomy with whole breast radiation and systemic therapy. Patients in whom completion ALND should still be recommended include patients who received neoadjuvant therapy, those with a positive SN who are treated with mastectomy, patients with three or more positive SNs, those with significant extra-nodal extension, patients who do not receive adjuvant systemic therapy or whole breast irradiation, and patients with clinically palpable nodes. The results of the Z011 trial represents level I data that should result in practice changes and render nomograms obsolete (64). In addition, although the Z011 trial excluded patients whose SN had micrometastases detected only by IHC, the results can rationally be applied to patients with SN micrometastases. Since the results of ACOSOG Z011 have been reported, the utility of frozen section analysis to evaluate SNs has been questioned. Weber and colleagues (65) evaluated time trends and variation between surgeons in the use of frozen sections for SNB and ALND in over 7,500 patients with clinically node-negative invasive breast cancer. From 1997 through 2006, the use of frozen section analysis of SNs decreased from 100% to 62% ($p < .0001$) and varied widely by surgeon (66% to 95%), demonstrating a diminishing rate of frozen section analysis of SNs over time. While there was no significant trend in ALND with a positive SN detected by frozen section or routine H&E during this time period, the investigators did observe a significant decrease in ALND for those with metastases detected by serial sectioning or IHC. The authors applied the ACOSOG Z011 selection criteria to their cohort of patients and calculated that 66% of SN frozen sections (4,159 of 6,327) and 48% of ALND (939 of 1,953) would have been avoided, sparing 13% of all patients the morbidity of ALND. The American Society of Breast Surgeons released a position statement on the management of axillary lymph nodes following the presentation of ACOSOG Z011 results, stating that intraoperative frozen section analysis of SN can be avoided if clinical suspicion of nodal involvement is low and the patient otherwise meets the entry criteria for the Z011 trial (66). This position includes the use of clinical suspicion; however, this cannot be supported by data.

MANAGEMENT OF MICROMETASTATIC DISEASE IN THE SENTINEL NODE

The ACOSOG Z0010 trial is a prospective observational study of subjects with stage I or II clinically node-negative invasive breast cancer treated with breast conservation, SNB, and bilateral iliac crest bone marrow aspirations. If the SN was free of tumor by H&E examination, no further ALND was undertaken. The aim of this study was to determine the prevalence and significance of IHC-positive micrometastases in lymph nodes, bone marrow metastases identified by immunocytochemistry (ICC), or both, and to determine the risk of regional recurrence. The secondary aim was to determine the morbidity associated with SNB. Blinded analysis of the SN by IHC and bone marrow by ICC was performed in a central processing site on the SNs that were histologically negative by H&E. Adjuvant treatment recommendations were made on the basis of H&E examination of the axillary nodes. Among 5,184 patients with SN, 1,239 (23.9%) had metastases identified by routine H&E. IHC detected an additional 350 (10.5%) with SN metastases. SN metastases detected by IHC did not appear to have a significant impact on 5-year overall survival. Bone marrow micrometastases were identified by IHC in 105/3,491 (3.0%) of cases examined and bone marrow IHC positivity was significantly associated with worse OS. A subset analysis of the NSABP-B32 trial (67) evaluated the prognostic significance of occult metastases in 3,887 tissue blocks from histologically negative sentinel nodes that were re-examined with serial sectioning and IHC, detecting 15.9% with occult metastases. Five-year Kaplan-Meier estimates of overall survival among those with occult metastases, and those without occult metastases, was 94.6% and 95.8%, respectively. The authors concluded that the difference in OS was so small and that there is no added clinical benefit to performing additional sectioning and IHC of H&E negative SN. The IBCSG 23-01 trial was a randomized trial that specifically compared ALND to no ALND in 931 patients with clinical T1N0 invasive breast cancer and at least one micrometastasis in the SN (68). After a median follow up of 5 years, there was no difference between treatment arms with respect to 5-year disease-free survival (87.8% vs. 84.4%, respectively), cumulative incidence of breast cancer related events (10.8% vs. 10.6%) and overall survival (97.6% vs. 97.5%). ALND can be safely avoided in patients with early breast cancer and limited SN involvement. The seventh edition of the AJCC TNM staging system in breast cancer has incorporated changes to reflect the findings on the prognostic significance of micrometastases. Stage I has been subdivided into Stage IA and Stage IB, where Stage IB includes small tumors (T1) with exclusively micrometastases in the lymph nodes (N1mic). Following reports of the ACOSOG Z011 and NSABP-B32 trials, the American Society of Breast Surgeons released a position statement on SN micrometastases in August 2011, stating that SN micrometastases detected only by IHC are clinically insignificant and that routine use of IHC staining of SNs is unnecessary and should be limited to selective use at the discretion of the pathologist. IHC is of value to detect metastases from infiltrating lobular carcinoma which may be difficult to detect with H&E.

SENTINEL LYMPH NODE BIOPSY

Axillary Sentinel Lymph Node Biopsy Technique

If using radioisotope, intradermal, subdermal, or peritumoral injection of a single dose of 0.3 to 1.0 mCi of technetium-99m sulfur colloid is performed 3 to 24 hours prior to incision. Lymphoscintigraphy may be performed after injection to document migration of the radioisotope. Intraoperative subareolar or dermal injection of radioisotope approximately 40 minutes prior to incision has been reported to localize the SN in 98.6% of the cases (419/425) of subareolar

radiotracer alone, 94.8% (326/344) in dual injection, and 100% (6/6) in dermal injection (69). When radioisotope is used, the incision is made directly over the location of a focal site of increased activity and dissection proceeds until the SN is identified by quantitative counts and resected. A radioactive node has been defined as a node with a cumulative 10-second count of greater than 25, the hottest node by absolute counts, a 10 to 1 ratio of SN to background, or a fourfold reduction in counts after the SN is removed (70). Verification is done by *ex vivo* SN counts compared to residual *in vivo* background counts. Additional radioactive SNs are removed until the background is less than one-tenth the value of the hottest node. Lymph nodes with the highest radioactive uptake usually contain the greatest tumor burden, but on occasion tumor replaced nodes may have lymphatic obstruction, and if only the hottest node is removed, a positive SN with lower counts may be missed in 23% of cases (71). If blue dye is employed, 3 to 5 mL is injected approximately 5 to 10 minutes prior to incision. The addition of a post-injection massage has been shown to improve the uptake of blue dye by SNs, further increasing the sensitivity of this procedure (72). After a 2 to 3 cm transverse incision is made in the axillary fossa, a careful search for all blue nodes or lymphatics should be carried out. Palpation of the axillary space for any suspicious nodes will avoid missing a tumor-laden node that has occluded lymphatics and may not be blue or radioactive. All suspicious palpable nodes must be removed at the time of SNB, regardless of technique—isotope or dye.

Complications of Sentinel Lymph Node Biopsy

Dye Complications

Isolated case reports of adverse reactions with blue dye, including allergic urticaria and anaphylaxis, have been reported, but the rate is extremely low. Data from the NSABP B-32 trial shows 0.4% grade 1 and 2 allergic reactions and 0.2% grade 3 and 4 with no deaths (13). The data from ACOSOG Z0010 show 0.1% anaphylaxis with isosulfan blue alone or in combination with radiocolloid (73). Hives covering the trunk and upper extremities, not associated with hypotension, resolve within 24 to 48 hours after administration of methylprednisolone and diphenhydramine. Management of hypotensive anaphylaxis includes discontinuation of anesthetic agents, administration of fluids, epinephrine, diphenhydramine hydrochloride, and corticosteroids. Barthelmes and colleagues (74) reviewed 40 cases of patent vital blue dye associated anaphylaxis in SNB for breast cancer and melanoma documented in the literature. Thirty-one patients did not have a past medical history of allergy. The median interval between blue dye administration and allergic reaction was 15 min (range 1–180 min). Of 20 patients with hypotension, 18 received inotropes. Four patients had a fall in blood pressure as their sole symptom, 23 patients had urticaria or other allergic skin manifestations, 8 had blue wheals, 5 patients had bronchospasm, and 2 patients had a cardiac arrest but were successfully resuscitated. The median dose of blue dye was 2 mL (range 0.5–5 mL). Tryptase levels were elevated in 14 of 26 tested patients. Skin prick testing was positive in 24 of 30 tested patients. Intradermal testing was positive in all 13 tested patients. The authors concluded that the value of formal allergy skin testing for patent blue dye-related allergy lies in excluding other agents as the causative factor to avoid their exposure in the future.

Isosulfan blue can affect pulse oximetry with a pseudodesaturation (75). Surgeons and anesthesiologists must investigate and verify that the partial pressure of oxygen, arterial (PaO_2) is normal. Isosulfan blue can cause transient staining of the epidermis, which can take several weeks to several months to completely fade. There is a transient change in color of the urine and stool to a greenish hue. Although these are temporary events, unless patients are forewarned about what to expect this can cause a great deal of unnecessary distress.

Methylene blue is associated with skin erythema, superficial ulceration, or necrosis with intradermal injections. Partial skin loss usually is treated with topical silver sulfadiazine (Silvadene) therapy and generally does not require surgical debridement. Methylene blue dye appears to be associated with fewer allergic reactions. However, allergy tests in some patients have proven that there is cross-reactivity between isosulfan blue dye and methylene blue dye (76).

Surgical Complications

Axillary complications and adverse side effects are reported with ALND, SNB, and axillary radiation, but to a lesser extent with SNB alone compared to ALND (Table 37-3). The incision is smaller with SNB with less tissue disruption and results in much less morbidity than complete ALND, as reported in the randomized studies (20,37,38,77). There is less pain, less limitation of motion, and fewer neurological sequela. In the randomized European Institute of Oncology trial, axillary pain, numbness and paresthesias, and arm swelling persisted to a significantly greater extent in the ALND than the SNB group (37).

SNB is associated with elimination of an axillary drain, less patient discomfort, and decreased incidence of lymphedema or neurovascular injury. Postmastectomy pain syndrome is significantly reduced with SNB compared to ALND. The incidence of measured lymphedema has been reported to range from 0% to 22%, although the majority of studies report a 3% to 7% incidence (78) of lymphedema after SNB compared to 5%–50% for ALND (79). Risk factors for developing lymphedema include upper outer quadrant lesions, postoperative trauma or infection, axillary radiation, and previous axillary surgery.

The ACOSOG Z0010 trial, previously discussed, was a single arm SNB-only trial when the SN was negative. The secondary aim of the ACOSOG Z0010 trial was to determine morbidity of SNB (73). Anaphylaxis occurred in 0.1%, seroma in 7.1%, and wound infection in 1.4%. Younger age was associated with a higher incidence of paresthesias, while increased BMI was associated with lymphedema. In the ACOSOG Z0011 trial, surgical complications were statistically greater in the SNB plus ALND arm than the SNB-alone arm: wound infections ($p \leq .016$), seromas ($p \leq .0001$), paresthesias ($p \leq .0001$), and subjective lymphedema at 1 year ($p \leq .0001$) (77). Overall quality of life and arm functioning scores were better in the SNB group in the ALMANAC trial (20). The quality of life was improved in the SNB group ($p < .003$) with less use of drains, less lymphedema, fewer days in the hospital, and earlier return to normal activities.

Variations in arm lymphatics contribute to the risk of developing lymphedema. A concept under study to attempt to reduce lymphedema is axillary reverse mapping (ARM) (80). This technique uses 2.5 to 5.0 mL of isosulfan blue injected intradermally or subcutaneously in the tissue of the upper inner arm to map the lymphatics draining the arm. Combined with radioisotope injection for the SNB, ARM attempts to distinguish lymphatics originating from the arm from lymphatics originating in the breast, enabling the surgeon to spare the arm-draining nodes. This concept has been demonstrated in a number of feasibility studies (80–82). However, the data on whether ARM reduces

TABLE 37-3

A Comparison of Morbidity in Five Randomized Controlled Trials of Axillary Lymph Node Dissection Compared to Sentinel Lymph Node Biopsy

Study/Trial	*No. of Patients*	*ALND Morbidity (%)*	*SNB Morbidity (%)*	*P-value*
Veronesi (112)	257	Axillary pain 72%	Axillary pain 14%	
		Paresthesias 85%	Paresthesias 2%	
		Limited ROM 22%	Limited ROM 0%	
		No arm swelling 31%	No arm swelling 89%	
ALMANAC (20)	476	No arm swelling 87%	No arm swelling 95%	<.001
		No paresthesias 69%	No paresthesias 91%	<.001
ACOSOG Z011 (77)	399	Infection 8%	Infection 3%	.0016
		Seroma 14%	Seroma 6%	.0001
		Paresthesias 39%	Paresthesias 9%	<.0001
		Lymphedema 11%	Lymphedema 6%	.0786
SNAC (19)	1080	Increased arm volume 4.2%	Increased arm volume 2.8%	.002
		Limited ROM 4.4%	Limited ROM 2.5%	.02
		Seroma 36%	Seroma 17%	<.001
		Infection 14%	Infection 9%	.02
NSABP B-32 (113)	5611	Limited ROM 9%	Limited ROM 5.7%	<.001
		Arm swelling 14.3%	Arm swelling 7.5%	<.001
		Numbness 31.1%	Numbness 8.1%	<.001
		Tingling 13.5%	Tingling 7.5%	<.001

No., number; ALND, axillary lymph node dissection; SNB, sentinel node biopsy; ROM, range of motion; ALMANAC, Axillary Lymphatic Mapping Against Nodal Axillary Clearance; ACOSOG, American College of Surgeons Oncology Group; SNAC, Sentinel Node Biopsy versus Axillary Clearance; NSABP, National Surgical Adjuvant Breast and Bowel Project.

lymphedema is limited. Boneti et al. (81) enrolled 156 to a prospective study where SNB (114/156) or ALND (42/156) was performed in conjunction with ARM and patients were assessed for lymphedema, defined as an increase in arm volume of over 20% compared to the contralateral side. ARM nodes were preserved in 92.3% (144/156) of cases. With mean follow-up of 14.6 months, 2.9% (4/140) of the patients who had the ARM lymphatics preserved and 18.7% (3/16) who had it transected developed clinical lymphedema. However, a number of studies have found metastatic disease in ARM nodes (83–85), and the SN draining the breast was the same node as the ARM node draining the upper extremity in 13% to 28% of cases. It is clearly unacceptable from an oncologic perspective to preserve metastatic ARM nodes during ALND or to preserve an ARM node that is identified as the SN. Therefore, further investigation of ARM is needed and at present this technique should be considered experimental. The data comparing the morbidity of SNB to axillary dissection are summarized in Table 37-3.

INDICATIONS FOR SENTINEL LYMPH NODE BIOPSY

Guidelines for lymphatic mapping have been put forth by ASCO, National Comprehensive Cancer Network (NCCN) 2012, American Society of Breast Surgeons 2010, and single institution studies and are summarized in Table 37-4.

TABLE 37-4

Indications and Contraindications to Sentinel Lymph Node Biopsy

Routine SNB	*Controversial Applications of SNB*	*Contraindications to SNB*
Clinical stage I–IIIA (for T3 tumors, data is limited and ALND is advised if success of SN mapping is in question)	Prophylactic mastectomy	Inflammatory breast cancer
Clinically node-negative	Previous SNB or ALND	Clinical N2 axillary disease
Unifocal or multicentric disease	DCIS	
Either gender	Suspicious axillary lymph nodes	
All ages	Preoperative chemotherapy	
Previous fine-needle aspiration, core biopsy, or excisional biopsy		

SNB, sentinel lymph node biopsy; ALND, axillary lymph node dissection; DCIS, ductal carcinoma *in situ*.

Acceptable Circumstances

Patient-Related Factors

A variety of factors contribute to the success of SNB, including patient characteristics, tumor features, and technical expertise. SNB has been used successfully in both male and female patients (86) and in all age groups (5). There is no age at which SNB is contraindicated; however, the identification of the SN has been less successful in older patients (27,87). The failed identification rate is 0.3% for age 39 or less and 2.7% for age 70 or older (60). There is also a progressive increase in failure rate as BMI increases above 26 (27,34). Identification in these groups of patients can be improved with isotope and dye combination.

Tumor-Related Factors

SNB has been performed for invasive ductal carcinoma, invasive lobular carcinoma, and other histologic subtypes. SNB for ductal carcinoma *in situ* (DCIS) is recommended for mastectomy patients or in cases where there is suspicion of invasive disease (66). The routine use of SNB for patients with DCIS who are not undergoing mastectomy is not recommended and is discussed in detail in Chapter 23.

Multicentric Disease

Multifocality and multicentricity were initially considered relative contraindications to SNB, but this is no longer the case. There are a number of studies evaluating SNB in multicentric disease using a variety of methods that report an identification rate between 85.7% to 100%, FN rate of 0% to 33.3%, and an accuracy from 77.8% to 100%. A recent meta-analysis was reported evaluating 932 patients with multicentric or multifocal breast cancer who had SNB followed by ALND (88). The authors identified an overall accuracy rate of 96.7% with a FN rate of 7.7%. Among those with a FN SNB, 7/37 had either received neoadjuvant therapy or had tumor size greater than 5 cm. With exclusion of those with a relative contraindication to SNB, the FN rate was decreased to 6.3%. The anatomic studies discussed in the earlier section on Lymphatic Anatomy also support the use of SNB in multifocal or multicentric cancers.

Type of Operative Procedure

The SN can be identified successfully when performing breast-conserving surgery, mastectomy, skin-sparing and nipple-sparing mastectomy for unilateral disease, or synchronous bilateral lesions. When mastectomy with immediate reconstruction is planned, staged SN biopsy may be used before mastectomy, facilitating surgical planning to avoid the complications of discovering a tumor-positive SN after reconstruction, especially when autologous tissue, such as a free-flap, is used. In cases of nipple-preserving mastectomy where viability of the nipple areolar complex is a concern, it may be prudent to avoid injecting dye or isotope directly under the nipple areolar complex which could impair circulation.

The performance of a diagnostic surgical biopsy was considered a contraindication to SNB in some early studies based on the hypothetical premise that the draining lymphatics were transected and mapping would be unreliable (89). This concern was initially refuted by Haigh et al. (90) who demonstrated that biopsy method (FNA, CNB, or excision), excision volume, time from initial biopsy to SNB, tumor size, and tumor location did not affect identification or accuracy by univariate and multivariate analysis. These findings have been confirmed by others. A recent meta-analysis of 18 studies that determined FN rates and 68 studies that determined SN identification rates in head-to-head comparisons of patients with and without history of previous surgical manipulation of the primary breast lesions reported pooled SN detection rates of 91.3% and 92.8% in those with and without prior surgical breast biopsy, respectively (91). The use of SNB in prophylactic mastectomy is advocated by some because of a low but real incidence of occult invasive carcinoma (3.2%–5%) (92). The use of MRI has been evaluated to determine its utility in identifying patients who would benefit from SNB (93,94). In a study of 56 patients who underwent prophylactic mastectomy, 6 occult cancers, 5 DCIS, and 1 invasive ductal carcinoma were identified, all with negative SNBs. The use of MRI in addition to SNB increases costs and, in this study, failed to identify a significant number of patients with occult malignancies. In another study of prophylactic mastectomy, SNB was performed in 393 of 529 patients (74%), 178 of whom underwent MRI. Of these, occult cancer was found in 6 of 178 patients (3%), all of whom had negative SNB. Preoperative MRI was concordant with PM in four of six cases with occult carcinoma. In 136 patients undergoing prophylactic mastectomy with SNB, 57 had preoperative MRI. MRI detected five cancers and prophylactic mastectomy revealed an additional four occult carcinomas not detected by MRI. The authors concluded that MRI accurately ruled out the presence of an invasive cancer in the prophylactic breast, suggesting that MRI can be used to select patients for prophylactic mastectomy without SNB.

In general, high-risk patients who undergo prophylactic mastectomy may be considered for SN biopsy at the time of surgery because identification of an unsuspected cancer in the mastectomy specimen could potentially require an ALND that could have been avoided by the minimally invasive SNB.

CONTROVERSIAL APPLICATIONS OF SENTINEL LYMPH NODE DISSECTION

The greatest amount of information on SNB has been in patients with early stage disease that is clinically node-negative. These are the conditions under which the procedure has been validated. Attempts to incorporate this methodology for other clinical presentations, as listed next, have been reported in small single institution studies and should be considered as not having the same degree of validation.

Previous Axillary Surgery

SNB after prior breast conservation and axillary surgery has been successful at Memorial Sloan-Kettering Cancer Center (95). The SN was identified in 55% (64/117) of the cases that had had previous axillary surgery or a failed sentinel lymphadenectomy. Positive SNs were identified in 16% of the successful cases. The FN rate was 9% for reoperative SNB. The redo SNB was more likely to be successful after a previous SNB rather than an ALND. There was a higher rate of nonaxillary drainage with redo SNB than with primary SNB (30% vs. 6%; $p < .0001$). Reoperative SNB was feasible in this small series of patients, but more information is necessary before this can be recommended routinely. Several smaller studies reported successful reoperative SN mapping in 63% to 97% (96). In the study by Intra et al. (97) the SN identification rate was significantly higher because they excluded patients who had prior ALND for axillary staging. At median follow-up of 45.9 months, no axillary recurrences were observed.

Suspicious Axillary Lymph Nodes

Clinically suspicious axillary nodes have been considered a relative contraindication to SNB. Prior core or excisional breast biopsy for diagnosis can result in inflammatory

changes in lymph nodes that are free of tumor. The correlation of clinical examination and pathologic nodal assessment indicates that the risk of lymph node metastasis is 40.4% if the clinical assessment is negative, 61.5% if the lymph nodes are palpable but not suspicious, and 84.4% if clinically suspicious (98). Clinical examination is subject to false-positive results in 53% of patients with moderately suspicious nodes and 23% of those with highly suspicious nodes (99).

There is no reason to exclude such patients from SNB as long as the clinically suspicious node is resected and analyzed. Alternatively, a suspicious node can be evaluated preoperatively with axillary ultrasound and fine-needle aspiration (FNA) or core needle biopsy. Sensitivity of axillary ultrasound has been reported to range from 21% to 86% with sensitivity rates increasing with increasing size of lymph node metastases. Addition of FNA of lymph nodes that appear abnormal by ultrasound increases the sensitivity of detecting nodal disease to 82% to 89% (100). In patients with clinically suspicious axillary lymph nodes on examination, a negative axillary ultrasound would indicate that the patient is a good candidate for SNB. Any palpable or abnormal lymph nodes detected intraoperatively at the time of SNB should be resected as sentinel nodes, regardless of whether these nodes were mapped by blue dye or radioisotope. It is not clear that patients with a needle biopsy-proven nodal metastasis should be excluded from application of the Z011 data or that the involved node is in reality a SN identified by imaging.

CONTRAINDICATIONS TO SENTINEL LYMPH NODE BIOPSY

Pregnancy and Lactation

The safety of SNB with radioisotope in pregnancy has been studied by Pandit-Taskar et al. (101) at Memorial Sloan-Kettering Cancer Center. Retrospective data from nonpregnant women with breast cancer and SN biopsy was used in a phantom model calculation of the radiation-absorbed dose after a single intradermal dose of 99mTc-sulfur colloid 0.1 mCi on the morning of surgery or 0.5 mCi on the afternoon before surgery. The highest estimated dose received by the fetus was seen with the 2-day protocol, measured at 0.014 mGy, which is less than the National Council on Radiation Protection and Measurements limit to the pregnant woman. The clinical application in pregnancy or lactation has been limited and questioned. Spanheimer and colleagues (102) conducted a prospective study of 14 pregnant breast cancer patients who underwent SNB with lymphatic mapping by technetium sulfur colloid injection where total uterine radiation dose was calculated based on abdominal, perineal, and urinary radiation measurements. The investigators found that the average total uterine radiation dose following radioisotope injection and lymphoscintigraphy for SNB was significantly less than the average daily background radiation (1.14 +/- 0.76 microGy vs. 8.2 microGy, respectively).

Limited data exist for dye usage in pregnancy. Methylene blue dye has been shown to cause intestinal atresia secondary to vasoconstrictive effects of inhibiting nitric oxide, and is considered to be contraindicated in pregnancy (103). However, some argue that the dose of methylene blue delivered for SN mapping is far lower than the levels that could cause harm (104). A pharmacokinetic study of methylene blue dye in 10 non-pregnant women estimated a maximum dose of methylene blue dye to the fetus to be 5% of the administered dose after adjustment for increased volume of distribution, intravascular volume, and renal clearance. Investigators at Lee Moffitt conducted a prospective study where SNB was performed with isosulfan blue dye in eight breast cancer patients (six with technetium sulfur colloid, two with blue dye alone) who were an average of 15.8 weeks pregnant (105). All patients had successful SN mapping, and there were no intra-operative complications associated with use of the blue dye. All patients delivered healthy babies without any reported abnormalities at 1.82 years of follow-up with exception of one who chose to terminate her pregnancy prior to starting chemotherapy.

Although radiolabeled technetium is safe in pregnancy, clinicians are reluctant to use it. The 2012 NCCN guidelines state that radiocolloid appears to be safe for SNB in pregnancy; however, use of blue dye remains contraindicated. Isosulfan blue dye and methylene blue dye are currently considered Class C drugs in pregnancy.

Advanced Disease

Grossly palpable, N2 lymph nodes have been a contraindication for SNB. Axillary evaluation with ultrasound and needle biopsy of suspicious nodes can identify tumor-positive lymph nodes and avoid SNB. If the cytology or histology of the node is negative, staging with SNB is reasonable, as long as the palpable node is also removed. One contraindication to SNB after neoadjuvant chemotherapy is inflammatory breast cancer (106) where studies report SN identification rates of 80%–85% and high FN rates (6%–18%).

While SNB is contraindicated in locally advanced disease, one area of controversy exists in patients that initially present with documented axillary metastases but are converted to clinically node-negative status following a clinical response to neoadjuvant chemotherapy. Shen et al. (107) performed SNB followed by ALND in 69 patients treated with preoperative chemotherapy who had biopsy-proven axillary metastases prior to chemotherapy. SN identification rate was 92.8% but the FN rate was 25%, leading the authors to conclude that SNB is technically feasible but unreliable in this cohort of patients.

This question has been further addressed by the ACOSOG Z1071 trial where patients with clinical T1–4, N1–2 invasive breast cancer at initial diagnosis had SNB followed by ALND after neoadjuvant chemotherapy (108). A Bayesian study design with a noninformative prior was chosen to assess whether the primary endpoint, the FN rate of SNB, would be greater than 10%. The study accrued 756 patients from 136 institutions. Of those who had SNB followed by ALND (n = 643), the SN identification rate was 92.5% with FN rate of 12.6%. The authors concluded that the FN rate of SNB was greater than the pre-specified study endpoint of 10%, and that further analysis of factors associated with FN rates should be performed before performing SNB in these patients.

CONCLUSION

Evaluation of the status of the axilla in invasive breast cancer is important for staging, prognosis, and perhaps survival. Although the status of the axilla was formerly the most important factor for adjuvant treatment recommendations, other factors related to tumor size, tumor features, molecular profiles, and patient age are increasingly entering the algorithm. Axillary treatment by ALND or axillary irradiation achieves excellent regional nodal control. Such treatment is associated with a potentially significant degree of chronic morbidity. SNB has replaced ALND for axillary staging in clinically node-negative patients even in some whose SN is positive. Biologic factors of the primary tumor may prove to play a more significant role in determining prognosis and response to therapy with advances in molecular profiling and whole genome sequencing limiting the role of SNB.

MANAGEMENT SUMMARY

- SNB is a staging procedure that can be performed with vital dyes, radioactive tracers, or a combination of the two.
- SNB alone for a negative SN accurately stages the axilla and is associated with isolated recurrence in the axilla in fewer than 1% of cases.
- SNB alone is appropriate for clinically node-negative women with a tumor positive SN undergoing lumpectomy with radiation.
- The early and late postoperative morbidity of SNB is significantly lower than the morbidity of axillary dissection, but lymphedema occurs in about 5% of patients.
- SNB is contraindicated for inflammatory carcinoma and grossly palpable axillary disease.
- Age, tumor histology, tumor location, and biopsy type are not contraindications to the use of SLND.

CHAPTER 38

Axillary Dissection

Hiram S. Cody III and George Plitas

CHAPTER CONTENTS

INTRODUCTION

For patients with operable breast cancer, axillary node status remains the single most important prognostic factor. The primary goal of axillary surgery is staging to govern the use and type of systemic therapy; secondary goals include local control and the possibility of a small survival benefit. Axillary lymph node dissection (ALND) has been regarded for most of the 20th century as the "gold standard" operation to achieve these goals, but has largely been replaced over the past decade by sentinel lymph node (SLN) biopsy, first reported by Krag et al. in 1993 (1) and Giuliano et al. in 1994 (2). SLN biopsy allows the avoidance of ALND in SLN-negative patients, sparing them the morbidity of a larger operation, and allows the routine performance of additional pathologic studies, potentially increasing the accuracy of staging. Sixty-nine observational series (3) of SLN biopsy validated by a "backup" ALND, three meta-analyses (4–6), and the early results of seven randomized trials (4) comparing ALND with SLN biopsy confirm that the morbidity of SLN biopsy is less than ALND, that staging accuracy is at least equivalent, and (in the single randomized trial reporting long-term results (7) that survival and other disease-related adverse events are comparable at 7 years' follow-up. While the role of ALND in the era of SLN biopsy has been reduced, it has not been eliminated, and this chapter surveys the historic evolution, current indications, operative technique, and morbidity of ALND. Looking ahead, prognostication through rapidly emerging genomic technologies may eventually rival (or even surpass) that of conventional histopathology, and the role of ALND will continue to change.

THE HISTORIC EVOLUTION OF ALND

Jean Louis Petit (1674–1750), director of the French Surgical Academy, was probably the first surgeon to articulate a unified concept for breast cancer surgery (8). He emphasized the importance of an *en bloc* resection of the breast and axillary nodes, but his insight came too early: even by the mid-19th century, breast cancer was widely regarded as incurable by surgery. Halsted's landmark 1894 (9) and 1907 (10) reports of his meticulous technique for "radical mastectomy" (RM, which included removal of the breast and pectoral muscles, with a complete ALND) were the first to demonstrate that coincident with a striking reduction in LR (from 51% to 82% reported by European center to 6%), 31% of patients (a significant proportion at that time) were disease-free at 5 years. This intuitive concept relating local control and survival made RM the standard operation for breast cancer over the next 70 years, despite subsequent reports of techniques that were less radical, including modified radical mastectomy (MRM) (11). In the "Halstedian" era, the goal for ALND (as for mastectomy) was to maximize cure by minimizing local failure.

Coincident with the acceptance of MRM in the 1970s, Fisher (12) proposed that breast cancer survival was largely a function of tumor biology and not surgical technique. The "Fisher hypothesis" was tested in National Surgical Adjuvant Breast and Bowel Project (NSABP) B-04 (1971–1974) (13); patients with clinically node-positive breast cancer were randomized to RM versus total mastectomy/radiotherapy (RT), and patients with clinically node-negative breast cancer were randomized to RM versus total mastectomy/RT

versus total mastectomy alone. At 25 years' follow-up there were no differences in any category of survival (overall, disease-free, distant disease-free) between the patients in the two node-positive arms, or in the three node-negative arms of the trial. B-04 confirmed the overwhelming prognostic significance of axillary node metastasis and for this reason, ALND was incorporated into all subsequent NSABP trials for invasive breast cancer.

With a series of remarkable meta-analyses from the Early Breast Cancer Trialists Collaborative Group (EBCTCG), it has become clear that breast cancer is best viewed as a disease with a wide spectrum of behavior (14), rather than a predominantly local (Halsted) or systemic (Fisher) process. Separate EBCTCG overviews show that local control and survival are related (15) but that there is no survival advantage for more radical versus less radical versions of mastectomy (or for mastectomy vs. breast conservation) (16), and that there is an incremental survival benefit from the addition of systemic adjuvant therapy to local treatment (17). At present, virtually all node-negative patients are staged by SLN biopsy alone and the principal goal of ALND is to maximize local control in patients already proven by SLN biopsy to be node-positive.

ALND VERSUS OTHER METHODS OF STAGING

ALND can be compared with other methods of axillary staging. These are (i) no axillary surgery (with or without axillary RT), (ii) axillary sampling, and (iii) SLN biopsy.

ALND versus No Axillary Surgery

The foremost trial comparing ALND with no axillary surgery is NSABP B-04 (13) (Table 38-1), as described above. Among patients randomized to total mastectomy alone, 18% developed axillary LR as the first sign of treatment failure and required a delayed ALND; 79% of axillary LR occurred within 2 years and 95% within 5 years. Two more recent trials demonstrate far lower rates of axillary LR in older patients treated without ALND. Martelli et al. (18) randomized 219 patients (aged 65 to 80) with T1N0 disease to breast-conservation surgery with or without ALND, and all patients received 5 years of tamoxifen. At 5 years' follow-up there were no differences in disease-free or overall survival, and axillary LR in the no-ALND arm was 1%. Rudenstam et al. (19) randomized 473 patients (aged 60 years or more) to breast surgery with or without ALND; all patients received 5 years of tamoxifen. At 6.6 years' follow-up there were no differences in disease-free or overall survival, and axillary LR in the ALND and no-ALND arms was 1% and 3%, respectively.

The addition of axillary RT improves local control in patients treated without axillary surgery (Table 38-1). In NSABP B-04 (13), locoregional recurrence at 10 years was lower with total mastectomy/RT than with total mastectomy alone (5% vs. 31%), as was axillary LR (3% vs. 19%). In the Cancer Research Campaign (King's/Cambridge) trial (20), 2,268 patients were randomized to total mastectomy/RT (to chest wall and axillary nodes) versus total mastectomy alone; again, crude LR was lower in the RT group (5% vs. 15%), as was axillary LR (2% vs. 13%). In a randomized trial from the Institut Curie, the authors compared the results of ALND and axillary RT in 658 patients; they observed a survival advantage for ALND at 5 years (21), but no survival differences between groups at 10 and 15 years (22). Axillary LR occurred slightly less often after ALND than after axillary RT (1% vs. 3%, $p = .04$). Finally, Veronesi et al. (23) randomized 435 patients, none of whom had ALND, to breast conservation with or without axillary RT. At 5 years' follow-up they found no differences in disease-free survival, and axillary LR in the axillary RT and no-ALND arms was 0.5% and 1.5%, respectively. Three observational studies also report high rates of axillary LR in the untreated axilla and also show that axillary LR is highly dependent on tumor size (Table 38-1) (24–26). Tumor characteristics alone, however, cannot reliably predict axillary node status with greater that 90% to 95% accuracy (27). Bevilacqua et al. (28) have recently developed a multivariate nomogram for the prediction of SLN metastases, using a sophisticated model based on 3,786 SLN biopsy procedures and prospectively validated in 1,545 subsequent procedures. They too find that the prediction of SLN status is imperfect, with only a 75% chance, between two randomly selected individuals (one of whom is node-positive), of correctly identifying the node-positive patient.

Others have asked whether noninvasive imaging can replace surgical staging. Neither CT nor MRI is adequate for lymph node staging. PET lacks the resolution to detect metastases smaller than 5 mm, so is subject to false-negative and false-positive results; in five reports, sensitivity ranges from 27% to 94%, and specificity from 43% to 97% (29–33). The results of axillary ultrasound (US) with fine-needle aspiration (FNA) vary widely, reflecting differences in methodology and case selection, but allow triage of FNA-positive patients directly to ALND (34). US-guided FNA of axillary nodes can spare patients the added time and cost of SLN biopsy, but is insufficiently sensitive to replace surgical staging.

ALND versus Axillary Sampling

As practiced in the United Kingdom, axillary sampling is a limited staging operation in which about four nodes are removed from the low axilla, guided by intraoperative palpation. Two randomized trials from Edinburgh have compared axillary sampling with ALND, for patients having mastectomy (with 11 years' follow-up) (35) or breast conservation (wide excision/breast RT, with 4 years' follow-up) (36) (Table 38-2). Node-positive patients in each trial received axillary RT. Between sampling and ALND, the authors observed a comparable proportion of positive axillae, comparable rates of axillary LR (5.4% vs. 3%), and comparable survival between the two arms of each study, but greater long-term shoulder morbidity for patients who had sampling/RT compared to ALND. Since none of the UK axillary sampling data have been validated by a backup ALND (as has been done for SLN biopsy), one cannot calculate the performance characteristics of this method. In a separate Swedish study by Ahlgen et al. (37), axillary sampling ("five node biopsy") was validated by a planned backup ALND in 415 patients, and sensitivity for cN0 patients was 95.5%.

ALND versus SLN Biopsy

Seven randomized trials compare ALND and SLN biopsy (4), allocating patients to ALND versus SLN biopsy (plus ALND for SLN-positive patients), and collectively confirm that the staging accuracy of ALND and SLN biopsy is comparable, and that the morbidity of SLN biopsy is less. For two of the trials (38,39) patients in the ALND arm also had SLN biopsy, confirming false-negative rates for SLN biopsy of 8.8% and 9.7%, respectively. In the one trial (7) reporting long-term follow-up there were no differences in survival or in any other disease-related adverse events at 7 years, and there was a single case of axillary node recurrence following a negative SLN biopsy.

INDICATIONS FOR ALND

In the simplest sense, ALND would seem to be indicated for any patient with a "contraindication" to SLN biopsy. In fact, most of the putative contraindications to SLN biopsy (including, among others, prior surgical biopsy, nonpalpable lesion, multicentric tumor, and T2 to T3 disease) have been disproved, and SLN biopsy is suitable for virtually all patients with clinical stage T1-3N0 invasive cancers (40). While the role of ALND has diminished in the era of SLN biopsy, there are at least nine clear indications to perform it (Table 38-3).

A Clinically Positive Axilla

Most patients with clinically positive axillae require ALND. However, since clinical axillary examination is equally subject to false-negative and false-positive results (41), the clinically positive axilla is not an absolute indication for ALND and should be validated histologically. In our own experience (42), 25% of patients with highly suspicious axillary nodes on clinical assessment proved to be benign at the time of SLN biopsy. As noted above, there is a role for preoperative axillary US and US- or palpation-guided FNA, allowing patients with proven nodal metastases to avoid SLN biopsy and proceed directly to ALND (34).

TABLE 38-3

Indications for ALND in the Era of SLN Biopsy

Patients outside the ACOSOG Z0011 entry criteria[a]
Prior inadequate ALND
Validation trials of SLN biopsy
Failed SLN biopsy
Clinically suspicious nodes identified at surgery
T4 disease
Unavailability of SLN biopsy
Axillary local recurrence (ipsilateral or contralateral) in previously treated patients

[a]T3, clinically positive axilla and biopsy-proven nodal metastases, positive SLN with disease requiring mastectomy, more than two positive SLN or matted axillary nodes.

Prior Inadequate ALND

What constitutes an "inadequate" (or an "adequate") ALND? In the NSABP B-04 trial, Fisher et al. (41) found that the proportion of cN0 patients with positive axillae was the same whether 3 to 5, 6 to 10, 11 to 15, or 16 to 20 nodes had been removed (i.e., the removal of relatively few nodes was sufficient to establish whether the axilla was positive or negative), but that the proportion with 4 or more nodes positive was highest when 26 or more nodes had been removed (i.e., a more complete node dissection was necessary to correctly determine the *degree* of node involvement). They also observed no cases of subsequent axillary LR when 6 or more nodes had been removed.

The apparent adequacy of ALND is multifactorial. First, while the operative technique is well defined, the performance of ALND in practice varies widely. Second, there is wide variation in the thoroughness with which pathologists examine the ALND specimen. Finally, in a small minority of patients very few nodes will be found despite an anatomically correct ALND and a thorough pathologic assessment. For those patients who have had a recent ALND in which (i) the anatomic extent of surgery cannot be documented, (ii) the gross specimen is not available for reexamination, (iii) few nodes have been removed, and (iv) most are positive (raising concern about residual gross axillary disease), it is quite reasonable to perform a completion ALND, or to consider axillary RT.

A Positive SLN

ALND was considered the standard care for all patients with a positive SLN until recently. The ACOSOG Z11 trial randomized SLN-positive patients to ALND versus no further surgery; all had clinical stage T1-2N0 disease, no more than 2 positive SLN, and were treated with lumpectomy and whole-breast (but not axillary) RT (43,44). Among those randomized to ALND additional positive axillary nodes were found in 27% of patients, but the performance of ALND did not alter systemic therapy and at a median follow-up of 6.3 years there were no significant differences in disease free (82.8% vs. 83.8%) or overall survival (91.9% vs. 92.5%), or in regional node (0.5% vs. 0.9%), breast (3.6% vs. 1.9%), or overall locoregional recurrence (4.1% vs. 2.8%, $p = .53$). Whether these practice-changing results can be extrapolated to women outside the Z0011 entry criteria (for example, those having mastectomy without RT, those with more than 2 positive SLN, or those receving neoadjuvant chemotherapy) remains unproved. A parallel trial, EORTC AMAROS (45), randomized SLN-positive patients to ALND versus axillary RT; the investigators have reported no differences between arms in the usage of local or systemic adjuvant therapy, but have not yet reported longer-term outcomes.

Validation Trials of SLN Biopsy

SLN biopsy is a *diagnostic test* for the presence of axillary node metastases, and is measured by standard test characteristics: sensitivity, specificity, positive predictive value, negative predictive value, and overall accuracy. These do not

require a randomized trial, but do require that SLN biopsy be validated by an immediate planned "backup" ALND. In an overview (1) of 69 observational (nonrandomized) studies of SLN biopsy with planned ALND (comprising 8,059 patients), the success and false-negative rates were 96% and 7%, respectively. The UK ALMANAC trial (46) required each of its initial participant surgeons to do 40 SLN procedures validated by an ALND, with threshold success and false-negative rates of 95% and 5%, respectively, prior to entering the randomization phase; they observed a shorter "learning curve" than expected, with most failed and false-negative results occurring in the very first procedure. This observation is supported by the NASBP B-32 trial (39), in which a false-negative rate of 9.7% did not significantly decline with increasing surgeon experience.

Failed SLN Biopsy

With increasing experience, the success rate of SLN biopsy approaches but does not equal 100%. For that small fraction of failed SLN biopsy procedures, or for an SLN procedure that is technically unsatisfactory in any other way, it is reasonable to perform ALND (47).

Clinically Suspicious Nodes at SLN Biopsy

During SLN biopsy, a small proportion of patients will have a marked reactive adenopathy that is grossly indistinguishable from cancer. In this setting, benign intraoperative assessment (frozen section or imprint cytology) may not be completely reassuring, and it is reasonable on the basis of clinical suspicion alone to proceed with ALND (47).

Neoadjuvant Chemotherapy for Inflammatory Cancer

The suitability of SLN biopsy for T2 and T3 breast cancers is well established, but an overview (48) of 21 small validation studies of SLN biopsy after neoadjuvant chemotherapy (given largely for noninflammatory cancers) observed success and false-negative rates (91% and 12%, respectively) somewhat inferior to those of SLN biopsy in general. In a separate study (49), 56 patients with axillary node metastases proven by FNA had neoadjuvant chemotherapy followed by SLN biopsy with a planned ALND; while 31% had a pathologic complete response, the false-negative rate of SLN biopsy in the remaining patients was unacceptably high (25%). A meta-analysis of 21 published studies, which included 1,273 patients who underwent SLN biopsy with subsequent ALND after preoperative chemotherapy, reports an SLN identification rate of 90% and a false-negative rate of 12% (50). Results from the ACOSOG trial Z1071 that investigated the role of SLN biopsy in clinically node-positive patients undergoing induction chemotherapy were recently published in abstract form (51). In this trial, women with T0-4, N1-2, M0 breast cancers receiving neoadjuvant chemotherapy were enrolled to undergo SLN biopsy followed by ALND at the time of surgery. The SLN correctly identified the nodal status of 84% of all patients and was associated with a false-negative rate of 12.8%. After neoadjuvant chemotherapy, SLN biopsy may be reasonable for patients with T2 and T3 tumors, but ALND should remain standard care for patients with T4 (inflammatory) cancers.

Unavailability of SLN Biopsy

SLN biopsy is not universally available, especially in developing nations where the added logistics and cost may prove to be excessive. Since the potential impact of SLN biopsy worldwide is substantial (a significant proportion of clinically diagnosed breast cancers are still node-negative), the challenge will be to find ways to minimize the cost of SLN biopsy while maintaining accuracy. Where SLN biopsy is not available, ALND should remain standard care.

Isolated Locoregional Recurrence

Axillary local recurrence after a negative SLN biopsy is rare and comparable to that after ALND, occurring in less than 1% of patients (52). Most axillary masses that appear after SLN biopsy are benign, but for those that are proven malignant ALND is indicated. ALND is also indicated for those patients who relapse in the contralateral axilla and do not have other distant sites of disease.

AXILLARY ANATOMY

The axillary contents lie within a complex space best described as an eccentrically shaped pyramid. Viewed through a transverse section (Fig. 38-1), the axilla is a triangular space, bounded by the chest wall medially, the subscapularis posteriorly, the latissimus posterolaterally, and the pectoralis major and minor muscles anteriorly. Viewed from the front through a coronal section (Fig. 38-2), the triangle is bounded by the axillary vein superiorly, the latissimus laterally, and the chest wall medially.

The axillary contents are arbitrarily divided into three "levels": level I lying lateral to, level II lying posterior to, and level III lying medial to the pectoralis minor muscle (Fig. 38-2). Level I comprises the largest volume of axillary tissue and the largest proportion of the axillary nodes (perhaps two-thirds), with level II comprising most of the remainder and level III 10% or less. The anatomic distinction between axillary levels I and II is somewhat arbitrary, while level III is more anatomically distinct. Historically, breast cancer prognosis was related to the "highest level" of axillary node involvement, but since about 1970 the *number* of positive nodes, and not the *level*, has emerged as the prognostically relevant variable.

The extent of ALND is formally classified as level I, level I to II, or level I to III ("complete ALND"); there is no evidence that the morbidity of ALND varies with the extent of the dissection. The historic justification for a complete ALND was the observation of "skip metastases" to levels II or III nodes with level I negative (53–55). Since most "skip metastases" were found in level II (isolated level III disease is rare), many authorities recommended a level I or II ALND as standard care. At present, "skip metastases" are best viewed as level II or III SLN which happen to receive lymphatic drainage *directly from the breast*. These nodes should be readily identified by lymphatic mapping and submitted for pathologic exam as SLN.

In our own practice, ALND is usually a level I to II dissection, but we perform a complete (level I to III) ALND in patients with high-risk (T3 to T4) tumors or with grossly suspicious nodes identified at surgery.

TECHNIQUE OF ALND

ALND is best done under general anesthesia, but for patients with comorbidity is feasible under local anesthesia with sedation. The incision is either separate from or contiguous with the incision used for the breast operation. Separate axillary and breast incisions are cosmetically superior to contiguous ones, but a contiguous incision is reasonable for patients either having mastectomy without reconstruction,

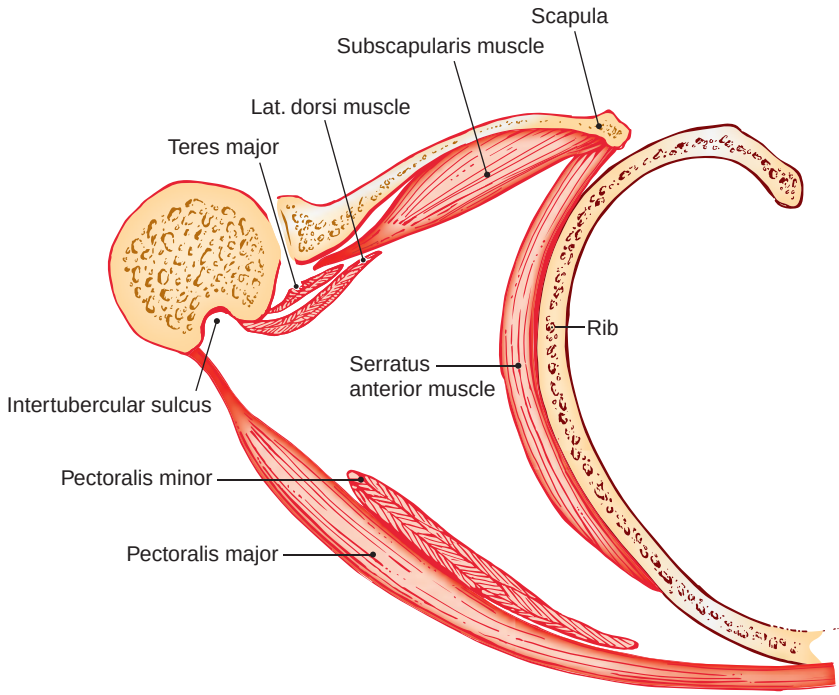

FIGURE 38-1 The anatomic boundaries of ALND, as seen in a transverse section through the midportion of the axilla, showing the pectoralis major and minor anteriorly, the serratus medially, and the latissimus and subscapularis posteriorly.

or having breast conservation for tumors very high in the axillary tail.

The foremost technical element of ALND is to fully dissect the skin flaps to their anatomic limits (the axillary vein superiorly, the pectoralis major superomedially, the serratus inferiorly, and the latissimus laterally) *prior* to entering the axilla; virtually all technical difficulties with ALND stem from inadequate flap elevation at the outset of the procedure. The dissection is carried around the lateral border of the pectoralis major, taking care to avoid injury to the medial pectoral nerve.

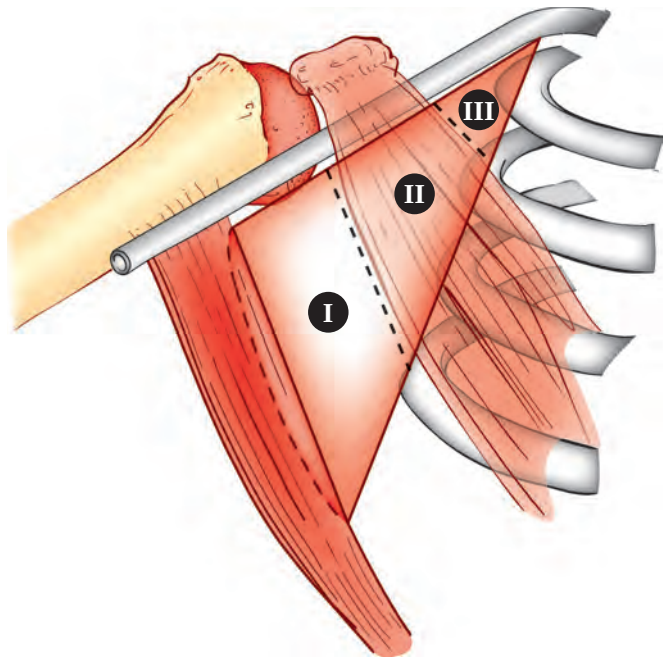

FIGURE 38-2 The anatomic extent of ALND, with "levels" I, II, and III designated as lying lateral to, behind, or medial to the pectoralis minor muscle.

The clavipectoral fascia is incised just anterior to the axillary vein and just lateral to the pectoralis minor, and with this step the axillary contents can be mobilized inferolaterally, completely exposing the axillary vein superiorly and the medial pectoral neurovascular bundle medially as it courses around the lateral border of the muscle. The arm is adducted and the major and minor are retracted medially, exposing level II. If gross axillary disease is palpable in levels II to III, the insertion of the pectoralis minor on the coracoid can be divided to fully expose level III.

The axillary contents are mobilized laterally off the chest wall, ligating side branches of the axillary vein as they are encountered. The long thoracic nerve (innervating the serratus anterior) and thoracodorsal nerve (innervating the latissimus dorsi) are identified and preserved, and the operation is completed by dissecting along the thoracodorsal neurovascular bundle and handing off the operative specimen. A closed suction drain is placed and the skin incision is closed.

Patients having ALND with breast conservation are normally discharged the day of surgery, and with mastectomy on the following day. All patients are instructed in wound care, given a log book to record their wound drainage (the drains are removed when 24-hour drainage is less than 30 cc), and given a program of postoperative shoulder exercises which they can usually begin immediately (except in the setting of breast reconstruction). Patients are encouraged to resume using their arm as soon, and as normally, as possible.

COMPLICATIONS OF ALND

Lymphedema

Lymphedema is the single complication of greatest concern to patients, and is the subject of an extensive but problematic literature. There are no large population-based studies that estimate the incidence of lymphedema, and across the literature there is wide variation in the definition of lymphedema, methods of assessment, patient characteristics,

extent of surgery, extent of RT, and length of follow-up. In a classic 1986 report, Kissin et al. (56) found that (i) lymphedema was more frequent when measured by arm volume (25.5%) than by patient self-assessment (14%); (ii) the frequency of subjective late lymphedema was similar for axillary RT alone (8.3%), axillary sampling plus RT (9.1%), and ALND (7.4%); and (iii) lymphedema occurred far more often after ALND plus RT (38%, $p < .001$). In a comprehensive 2001 overview, Erickson et al. (57) cite 10 more recent studies (1991–2000) in which the incidence of lymphedema ranged from 2% to 43%, and appeared to increase with patient age, body mass index, and length of follow-up.

The most useful current data regarding lymphedema will come from the four randomized trials that compare ALND with SLN biopsy, three of which report less arm swelling with SLN biopsy (38,39,58). In the ALMANAC trial (58), the patient-reported incidence at 12 months of moderate or severe lymphedema was less with SLN biopsy than with ALND (5% vs. 13%) and the relative risk of *any* lymphedema (for SLN biopsy relative to ALND) was 0.37 (95% CI 0.23–0.60). Regarding lymphedema and all of the other side effects of ALND, it is worth noting in the current era of SLN biopsy that the sequelae of ALND are not as severe as patients may expect, and that the sequelae of SLN biopsy may exceed expectations: in a recent report from the prospective ACOSOG Z0010 trial (59) (comprising 5,327 patients), lymphedema developed following SLN biopsy in 6.9% of patients at 6 months.

Standard recommendations to patients for the prevention of lymphedema include the avoidance of (i) trauma or injury, (ii) infection, (iii) arm constriction (especially by blood pressure cuffs), and (iv) heavy lifting or repetitive motions (57). These recommendations are deeply entrenched in the medical and nursing literature, but there is no evidence that any of them are effective in avoiding lymphedema, or that lymphedema *can* be avoided; they may even have the unintended consequence of making a patient feel that the lymphedema is *her fault*, rather than a known side effect of treatment.

Lymphedema cannot be cured but it can be treated. Using various combinations of elastic compression garments, compression pumps, bandaging, exercise, and complex physiotherapy, 15 studies (1989–1991) (57) have reported reductions of 15% to 75% in arm volume or circumference. Large randomized studies are needed to determine the relative efficacy of these treatments and the natural history of lymphedema posttreatment.

Axillary Web Syndrome

Axillary web syndrome (AWS) has been long observed by surgeons but only recently named and described by Moskovitz et al. (60). AWS is a characterized by the appearance 1 to 8 weeks after ALND (or SLN biopsy) of a network ("web") of tender subcutaneous cords running from the lateral axilla down the upper inner aspect of the arm, associated with pain and limitation of arm movement. Among 750 consecutive patients, they observed AWS in 6%. The presumed cause, surgical disruption of veins or lymphatics proximally at the level of the axilla, is supported by the observation of thrombosis in subcutaneous veins and/or lymphatics in four of their patients who underwent biopsy. AWS is a benign and self-limited condition that should not be confused with lymphedema, and which does not require treatment.

Sensory Morbidity

The sensory sequelae of ALND are largely related to the division of sensory nerves, most notably the intercostobrachial nerve (ICBN), a cutaneous sensory branch of T2 that innervates the upper inner arm, axilla, and superolateral breast. Technical modifications of ALND that allow preservation of the ICBN are the subject of an enthusiastic but anecdotal literature. In the single randomized trial comparing ICBN preservation versus division (61,62), ICBN preservation reduced the size of the sensory deficit, but there were otherwise no differences between groups in pain, shoulder movement, arm circumference or presence of neuromas, either at 3 months or at 3 years of follow-up.

Shoulder Function

Restriction in shoulder range of motion (ROM) is a side effect of ALND, and of the four randomized trials, two (38,58) report less limitation in ROM after SLN biopsy than after ALND. In the ALMANAC trial (58), this difference was significant at 1 month, but shoulder ROM (flexion and abduction) improved rapidly in both groups, and at longer follow-up the difference was no longer significant. Exercises to restore shoulder ROM are an essential element of postoperative care following ALND.

Infection

Cellulitis of the arm, chest wall, or breast is a well-recognized but relatively infrequent side effect of ALND and presumably reflects a localized immune impairment from the surgery. The incidence of cellulitis is unknown, but in a careful report by Roses et al. (63) of 200 patients followed 1 or more years after ALND, 5.5% developed cellulitis, and 2% had multiple episodes. Cellulitis can arise following a nonsterile skin break (cut, abrasion, or burn) but often appears without an obvious cause. Patients are routinely advised following ALND to avoid injections, venipunctures, or IVs in the ipsilateral arm, but there is no evidence whatever that *sterile* skin punctures cause cellulitis, or that avoidance prevents either infection or lymphedema (57). Repeated episodes of infection are thought to increase the risk of lymphedema (although it remains unclear in this setting whether infection is a cause or an effect of lymphedema) and prompt treatment with oral or IV antibiotics is recommended.

ALND: FUTURE DIRECTIONS

We have entered a dynamic new era in which genomic technologies (i) suggest a new classification of breast cancer (64); (ii) appear to improve prognostication (65); (iii) may better predict which patients will (or will not) benefit from adjuvant systemic therapy (66); and (iv) promise the identification of new therapeutic targets and more effective drugs. If the prognostic and predictive power of gene expression profiling prove superior to that of conventional histopathology *and* if new classes of drugs with curative potential emerge, then ALND, lymph node staging, and breast cancer surgery in general could become obsolete. The present reality is that surgery remains the single most effective treatment for breast cancer, lymph node staging remains essential for prognostication, and ALND still has a role in achieving local control for select node-positive patients.

MANAGEMENT SUMMARY

1. SLN biopsy has largely replaced ALND as the initial axillary staging procedure of choice for patients with cN0 breast cancers.
2. Staging accuracy, local control, and survival appear to be comparable between SLN biopsy and ALND.
3. ALND is indicated for
   a. SLN-positive patients outside the ACOSOG Z0011 entry criteria, specifically:
      i. T3 disease
      ii. A clinically positive axilla and biopsy-proven node metastasis
      iii. Positive SLN with disease requiring mastectomy
      iv. More than two positive SLN or matted axillary nodes
   b. A recent inadequate ALND
   c. Validation trials of SLN biopsy
   d. A failed SLN biopsy
   e. Clinically suspicious nodes identified at surgery
   f. T4 disease
   g. Unavailability of SLN biopsy
   h. Axillary local recurrence
4. A level I to II ALND is usually sufficient. A level I to III (complete) ALND is indicated for patients with gross axillary disease.
5. Postoperative care after ALND should include shoulder exercises to maintain ROM.
6. There is no evidence post-ALND that other standard recommendations (including the avoidance of trauma or injury, blood pressure cuffs, heavy lifting or repetitive motion) are effective in preventing lymphedema.
7. There is no evidence post-ALND that the avoidance of venipuncture, injections, or IVs in the ipsilateral arm is effective in preventing either infection or lymphedema.

CHAPTER 39

Preserving and Restoring Function after Local Treatment

Andrea L. Cheville

CHAPTER CONTENTS

INTRODUCTION

Primary breast cancer treatment is associated with long-term musculoskeletal problems in up to one third of patients. This is significant because of the favorable survival enjoyed by the majority of women diagnosed with breast cancer. Current estimates suggest that there are 2.9 million breast cancer survivors alive in the United States, and millions more worldwide (1). Physical impairments develop secondary to normal tissue damage inflicted through cancer removal and staging procedures. Nerves, muscles, stroma, and lymphatics fall within surgical and radiation treatment fields leaving them vulnerable to inadvertent injury. Musculoskeletal problems may develop within, adjacent to, or distant from treatment fields, manifesting as impairments in strength, flexibility, and integrated movement patterns (2). Table 39-1 lists impairments associated with breast cancer treatments, some of which may persist for decades following treatment. At all time points, impairments may be associated with disability and diminished health related quality of life (HRQOL) (3–7). The likelihood of long-term disability correlates directly with the intensity and extent of breast cancer treatment. More surgery (e.g., axillary lymph node dissection [ALND] versus sentinel lymph node biopsy [SLNB]) and more radiation (e.g., four-field versus tangent beam configurations) increase the probability that patients will develop musculoskeletal problems (3,8,9).

Empirical data now reinforce theoretical concerns that musculoskeletal pathology at surgical and radiation sites will not spontaneously resolve independent of treatment. (10). Ninety percent of breast cancer survivors report one or more adverse treatment effects 6 months following their diagnoses, with 60% endorsing multiple problems (11). Unfortunately, such problems persist for the 30% of survivors who continue to report adverse sequelae 6 years after their diagnoses (11). Elderly patients and those with elevated body mass indices are at increased risk of developing lasting functional deficits following their breast cancer treatment (12).

Despite the clear correlation between breast cancer treatment and musculoskeletal problems, tissue-level changes remain ill defined. Radiation-induced fibrosis has been implicated on the basis of long-term follow-up studies (13,14). Additional radiation-related problems include shoulder capsule and epimesial contractures, brachial plexopathies, lymphostasis leading to accumulation of inflammatory mediators (15), and muscle hypertonicity secondary to direct or neural irritation. However, no empirical links yet implicate these processes in the development of treatment-related impairments. Surgical procedures, even when limited to local tumor excision and SLNB, can produce maladaptive changes in posture and upper quadrant movement patterns. These changes are thought to be mediated through pain, scarring, and adaptive positioning in the postoperative period. Adjuvant chemotherapy may also contribute to musculoskeletal problems by reducing muscle mass (16) and oxidative capacity (17). The relative contributions of different cancer treatments and pathological processes to functional problems remain poorly characterized despite a growing understanding of treatment-related late toxicities. Manual treatments and therapeutic exercises may effectively address most problems (18), although systematic reviews, noting a paucity of rigorous randomized trials, have remarked the persistent need for better quality evidence (19).

Successful management of musculoskeletal problems depends on a patients' willingness to perform therapeutic exercises. Because treatments are active and must often be continued for extended intervals, its success requires a high level of adherence. Patient "buy in" can be substantially enhanced by the strong endorsement of the entire breast

cancer treatment team. With increasing appreciation of latent treatment toxicities, prophylactic stretching and strengthening activities are now accepted as integral components of comprehensive survivorship care. In the absence of such preventative activities, breast cancer survivors, treated years previously, may become uniquely vulnerable to delayed morbidities that manifest when the musculoskeletal and other systems senesce (20). This chapter will outline the evidence base regarding the epidemiology and management of breast cancer treatment-related musculoskeletal morbidity.

EPIDEMIOLOGY

Upper quadrant disability following breast cancer treatment is primarily due to restricted range of motion (ROM), persistent pain and diminished strength. Reported incidences of these problems vary widely depending on the type of breast cancer treatment, measurement technique, and duration of follow-up. Systematic reviews consistently comment on the heterogeneity of measurement and reporting strategies that characterize the literature on treatment-related morbidity (14,21,22). None-the-less, all concur that late musculoskeletal effects are potentially prevalent and problematic among breast cancer survivors.

Loss of Range of Motion

Survivors who develop ROM deficits are more likely to report pain, reduced HRQOL and difficulty performing activities of daily living (23). Table 39-2 lists shoulder ROM deficits reported at different time points following surgery. Most patients experience an abrupt transient reduction in shoulder ROM after breast cancer surgeries (3,24). Two weeks postoperatively, incidences of restricted ROM as high as 86% have been reported following ALND, and 45% following SLNB (25). However, it should be noted that some surgeons, to reduce the risk of seroma formation, restrict active shoulder abduction to 90° until drain removal which may occur as late as 3 to 4 weeks postoperatively (26).

By 6 weeks the postoperative incidence of restricted shoulder abduction is substantially lessened to 26.5% after ALND, and 24.8% after SLNB (27). Longitudinal studies suggest that restrictions in shoulder ROM gradually resolve to near baseline in a majority of patients (5,28). However, a significant minority of patients do not recover normal shoulder ROM in abduction, forward flexion, and/or external rotation. A history of ALND, modified radical mastectomy, and radiation therapy are associated with more significant and lasting limitations (5,27,29–31). Older age and elevated BMI also increase the risk of persistent ROM deficits (30).

Pain

Recent reports have highlighted the potential for persistent and severe upper quadrant pain following breast cancer treatment (32). The presence of moderate or worse pain among breast cancer survivors is strongly associated with poor mental and physical functioning (29,33). Pain is more common after ALND and axillary/supraclavicular radiation (4,32). Few studies differentiate musculoskeletal pain from neurogenic or lymphedema-related pain. Table 39-3 lists reported pain prevalence. Reports neither specify pain etiologies, nor report consistent outcome measures (e.g., presence/absence of pain versus visual analogue scores [VAS]). The data are therefore challenging to synthesize. However, the table clearly demonstrates that a significant percentage of patients experience persistent pain in the shoulder or arm. A unique study that integrated pain maps from 343 breast cancer survivors established that post-treatment pain may affect the entirety of the upper quadrant, but occurs most commonly in the axilla (34).

Loss of Strength

Strength deficits are less prevalent immediately following breast surgery but become increasingly problematic with time. This pattern has been appreciated for grip strength. In a longitudinal cohort, mean grip strength decreased by 16.9 Nm at 6 weeks and by 41.3 Nm at 24 months after ALND, relative to preoperative values (5,27). A similar pattern was noted after SLNB though the reduction was less pronounced, 5.8 Nm at 6 weeks and 17.2 Nm at 24 months. These reductions agree with high reported prevalence of impaired grip strength, which range from 16% to 40% (23,35). The influence of Lymphedema (LE) on grip strength remain inadequately characterized but may be an important mediating factor (36). Prevalence of reduced shoulder and arm strength are also high with self-reported limitations affecting up to 69% of patients (37). Objective reductions of 10 nM in shoulder abduction strength have been detected at 12 and 24 months following treatment (5,23). Shoulder strength deficits are more common following modified radical mastectomy (38).

Musculoskeletal Syndromes

Axillary web syndrome, Figure 39-1, manifests as taut cords that extend distally along the medial arm from the treated axilla to the cubit and, at times, as far as the wrist. Incidence estimates range from 5.2% to 72%, with completion axillary dissection being a potential inciting factor (25,39,40,41,42). Retrospective studies produced lower incidence estimates (41). Pathological analyses suggest that superficial lymphatic

ALND axillary lymph node dissection, SLNB sentinel lymph node biopsy.

FIGURE 39-1 Axillary web syndrome.

vessels and veins, together with their surrounding connective tissue, comprise the cords (41). The natural history of axillary web syndrome is self-limited with gradual resolution over the first year following surgery without residua (41). However, the cords can be quite painful and may discourage patients from performing needed shoulder ROM activities, thereby contributing to long-term ROM deficits (42).

Since breast cancer treatments may destabilize the balance of shoulder muscles, patients are placed at theoretical risk of secondary musculoskeletal problems (e.g., rotator cuff pathology, premature degenerative disease of the acromioclavicular and glenohumeral joints, and myofascial pain). A prospective cohort study found the incidence of myofascial pain syndrome after ALND to be 44.8% (43), and a second study noted the pectoralis major muscle to be the most commonly affected (44). An additional cohort study serially screened patients for a range of discreet impairments and found that the point prevalence of myofascial pain remained stable at roughly 6.3% over the 12 months following breast cancer treatment, while that of rotator cuff pathology increased from 2.1% at 3 months to 7.1% at 12 months (45). The extent to that breast cancer treatment engenders these common problems must remain speculative until comparisons with age-matched, non-breast cancer populations permit estimation of the attributable risks.

TREATMENT

Shoulder function depends on the coordinated recruitment of multiple muscle groups to perform even basic activities. For this reason, although deficits may initially be discreet, few problems remain isolated. The onset of secondary problems occurs when patients lose flexibility due to pectoral muscle, or generalized shoulder, tightness which causes secondary strength and biomechanical deficits in uninvolved muscles. The anterior deltoid and coracobrachialis muscles, for example, may adopt dysfunctional length-tension relationships and firing patterns which cause weakness and further deviation from normal biomechanics (46). Over time, clusters of related impairments may develop and produce global shoulder dysfunction (47). Addressing problems in isolation will be, at best, limitedly successful. It is more clinically useful and practically relevant to examine generalized shoulder disability arising from multiple, inter-related impairments.

Many exercise and manual treatments benefit musculoskeletal problems provided they are administered in a structured and monitored fashion (6,8,48–50). Regimens tested with randomized, controlled study designs are consistently superior to the common practice of providing patients with illustrated exercise sheets after surgery without formal follow-up. The fact that a variety of therapeutic techniques offer benefit reflects the straightforward treatment goals of restoring normal flexibility, strength, postural alignment, and muscle recruitment patterns to the upper truncal quadrant. Positive results have been reported with therapist-directed programs emphasizing disparate approaches such as general biomechanics and pectoral muscle stretches (49). Although a wide range of structured regimens yield benefit, all therapy programs should have several essential elements that are listed in Table 39-4 and described below.

ROM Activities

ROM activities restore normal flexibility and influence scar formation to prevent restrictions. Distractive forces influence collagen deposition such that fibers align in parallel, rendering the resultant scar supple, distensible, and able to support normal musculoskeletal function. Muscles within surgical and radiation fields are of greatest concern; however, adjacent and even remote muscle groups can also become hypertonic and develop flexibility deficits. Therefore, comprehensive ROM activities should incorporate both treated and "at risk" muscle groups such as the scapular stabilizers (e.g., upper and middle trapezius and rhomboid muscles).

Stretching can be performed in a variety of ways and controlled studies have yet to shed light on which techniques are most effective in breast cancer populations. Several general caveats apply:

1. ROM activities should never be pulsatile, painful, or overly aggressive.
2. Pain or swelling following ROM activities mandates revision of the program.
3. Patients should breath steadily and consciously during ROM activities.
4. ROM activities should continue in an abbreviated fashion long after normal flexibility has been restored to prevent latent fascia contractures.

Active ROM activities can begin 7 days after breast cancer surgeries provided patients have not undergone breast reconstruction. In the latter case, patients should clear all physical rehabilitation activities with their plastic surgeons. Initial stretches include shoulder shrugs; shoulder retraction; wall walking; rowing motions; cervical rotation, extension, and lateral bending; and cane-based overhead stretches. Most institutions have printed sheets illustrating these activities which are provided to patients on hospital dismissal.

For patients who have undergone ALND, once their drains have been removed, a formal physical therapy evaluation will ensure that patients are performing ROM activities correctly and that their recovery is following a

TABLE 39-4

Essential Elements of All Comprehensive Rehabilitation Programs Following Primary Breast Cancer Treatment

Flexibility/range of motion exercises	
Shoulder:	Forward flexion
	Scaption (plane of the scapula; ~20° of cross-abduction)
	Abduction
	Extension at 0° and 90° of abduction
	Internal/external rotation
Thorax:	Abdominal muscles: rectus and obliques
	Pectoral muscles
	Intercostal muscles
Cervical spine	Lateral rotation
	Lateral bending
	Extension
Progressive resistive/strengthening exercises	
Shoulder:	Scapular retractor muscles
Thorax:	Spinal extensor muscles
Cervical spine:	Spinal extensor muscles
Activities for posture and biomechanics	
Education	
Rationale for exercises (e.g., need for continued stretching activities)	
Precautions (e.g., lymphedema)	
Signs of complications strain, infection, seroma	
Tailored home program	
Instructions for tapering over time	
Indefinite maintenance activities as needed	
Emphasis on limited, "essential" exercises	

normal trajectory. The physical therapy visit can be used to demonstrate how patients should advance their ROM activities, to educate patients in the long term protective benefits of regular stretching, and to provide instruction in breathing techniques (e.g., breath stacking to enhance intercostal muscle excursion). Patients should also be alerted to contact a health care provider if they have not recovered full, painless shoulder ROM one month prior to the start of radiation.

The major and minor pectoral muscles merit special attention as they are in proximity to breast surgeries, receive up to 60 Gy with conventional breast tangent beams (51) and may be affected by implant-based breast reconstruction. Pectoral stretching should be a central therapeutic focus since tightness produces well-characterized, maladaptive changes in shoulder biomechanics that may increase survivors' risk of secondary problems (46). Several approaches to pectoral stretching are illustrated in Figures 39-2 through 39-4. The standing corner stretch in (see Figs. 39-2A,B) should be held for at least five deep breaths with the patient leaning forward and allowing her body weight to gently carry her into the stretch. The abdominal muscles should be lightly engaged tilting the pelvis forward to protect the lower back as illustrated by the curved arrow. The positions in Figure 39-3A–D should be passively maintained for as long as 15 minutes on a firm surface. The progression from A to D illustrates increasing shoulder external rotation which places greater traction on the pectoral muscles and intensifies the stretch. At no time should patients experience discomfort. The pectoral stretch can also be increased by placing a pillow, rolled towel or bolster between the scapulae, Figure 39-4, ensuring that the head is adequately supported with a pillow to avoid anterior cervical muscle strain.

Strengthening

Resistive exercises normalize focal strength deficits, ensure adequate strength for normal activities, and prevent periscapular muscle strain. Strength deficits are rarely immediately apparent after surgery in the absence of long thoracic nerve injury. More commonly, evaluations for pain reveal weakness or myofascial dysfunction of the muscles that act on the scapula and upper arm. Strength deficits generally respond to incremental, isotonic resistive activities in all but the rare cases of significant axonal damage. Muscle spasm and pain must be addressed before initiating treatment. A "no pain no gain" approach simply aggravates the problem and may aversively condition the patient. Resistance can be offered by elastic bands, light weights, circuit training equipment, or even soup cans. Activities should target the scapular retractor (middle trapezius, rhomboids), scapular elevator (upper trapezius, levator scapulae), and thoracic spinal extensor muscles. The risk of inciting lymphedema mandates that resistive exercises be initiated at a low level and increased gradually with an emphasis on stamina rather than strength. Patients considered at risk of developing lymphedema should inspect their arms following sessions and consider use of a prophylactic garment. The choice to use a garment should be discussed and supervised by a health care professional familiar with lymphedema.

FIGURE 39-2 Wall stretches for pectoralis major and minor muscles should be performed with the abdominal muscles engaged to protect the low back as indicated by the arrow.

Posture

Effective postural therapy requires restoration of adequate strength and flexibility. Once this essential foundation has been laid, patients can progress to activities designed to enhance truncal and scapular alignment. In the discussion that follows, posture and alignment are used interchangeably. Postural work following breast cancer treatment strives to eliminate exaggerated thoracic kyphosis, scapular protraction, compensatory cervical lordosis, and asymmetry in the shoulder girdle. Postural work can be deceptively subtle and, although not inherently difficult, may be more challenging than ROM and strength-building activities. Most patients recognize "good" posture and can adopt it with little concentrated effort provided they have the requisite strength and flexibility. However, many patients are unable to maintain it once their concentration drifts, as it eventually must, to an alternate focus.

A host of factors operating within muscles and at different levels of the peripheral and central nervous systems determine patients' alignment. Several important factors may be influenced by breast cancer treatment: muscle length–tension relationships, muscle spindle and Golgi tendon organ sensitivity, and afferent proprioceptive input. The dorsal horn of the spinal cord, thalamus and cerebellum receive and process afferent signals to generate efferent signals that maintain patients' default alignment. When an individual deviates too far from her default posture, afferent input triggers subconscious, autorighting mechanisms that restore the default.

Postural therapies refine patients' default alignment to avoid secondary musculoskeletal problems, reduce stress on osseous and articular structures, and support normal biomechanics. Effective therapies spare patients future difficulties including premature osteoarthritis, neural impingement, and rotator cuff dysfunction. Fortunately, the physiological determinants of posture respond predictably to therapies. Once flexibility and strength have been normalized, postural work begins by bringing patients passively into proper alignment. Therapists then work through active assistive techniques to teach patients selective recruitment and relaxation of discrete muscles in order to maintain proper alignment. Work is ideally performed in front of mirrors that provide visual feedback from several planes (e.g., frontal, oblique, etc.). In this way patients can begin to appreciate when they are properly aligned and self-correct when out of alignment. Therapy's ultimate goal is automatic self-correction independent of visual feedback. With due diligence, patients internalize a more functional default alignment sustained through subconscious, autorighting mechanisms. It should be noted that many patients have poor posture when diagnosed with breast cancer and it is not the medical profession's responsibility to eradicate poor posture. However, attention to treatment-related problems that increase patients' vulnerability to future morbidities is an integral part of comprehensive cancer care.

Biomechanics

Biomechanics can be thought of as dynamic posture, or the interrelationship of body parts as patients engage in integrated, multiplanar movements. Restoration of normal upper quadrant biomechanics represents the culmination of successful therapy. Treatments attempt to preserve the

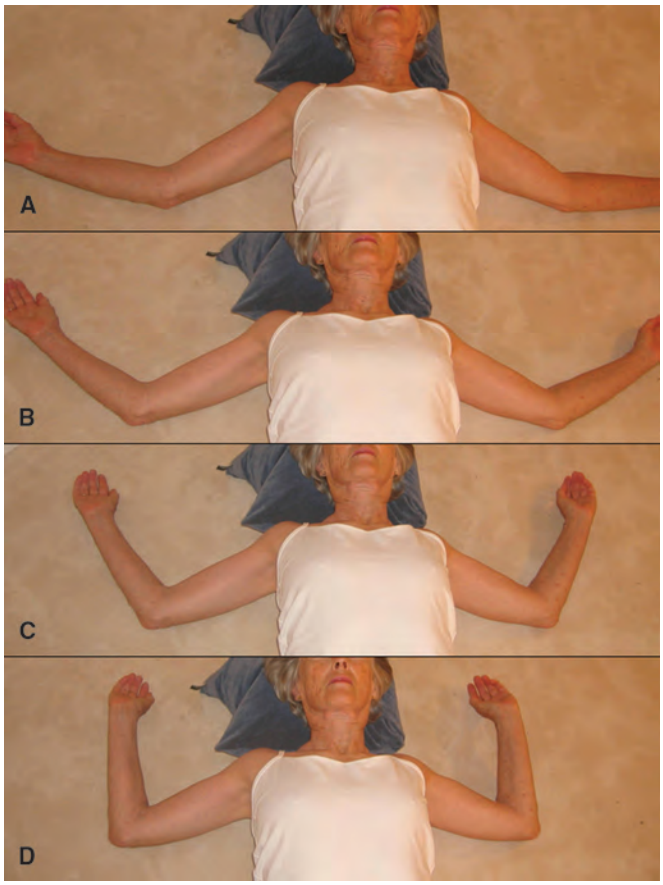

FIGURE 39-3 Sustained anterior chest wall stretch.

optimized static relationships achieved through postural therapies. Initially therapists provide active assistance and tactile cuing to optimize patients' performance of simple motions such as shoulder abduction. Once patients can perform these motions with proper biomechanics, they are encouraged to do so repeatedly with visual feedback from mirrors and verbal cuing. Eventually patients are taught to self-correct independent of feedback while performing increasingly complex activities in multiple planes.

FIGURE 39-4 A rolled pillow, towel or bolster can be placed between the shoulder blades to achieve a more intense pectoral stretch.

Timing

Much research has examined the timing of mobilization and exercise therapies following breast cancer surgery. Early shoulder mobilization within the first week after surgery increases wound drainage and the risk of seroma formation; however, delayed mobilization is associated with decreased shoulder range of motion for 6 months (10,50). By 2 years after surgery, no appreciable difference in flexibility persists between patients undergoing delayed versus early (≤7 days) mobilization (50). A robust evidence base supports the safety and efficacy of gentle postoperative shoulder, neck, and truncal mobilization provided that shoulder forward flexion and abduction are restricted to 90° for the first postoperative week (52). Thereafter, stretching and strengthening activities can be advanced as tolerated, although some surgeons continue to limit abduction and forward flexion until drain removal.

The literature provides far less guidance with respect to the optimal type, intensity, and timing of therapy after the subacute postoperative period. Continuous physiotherapy for 3 months following surgery is beneficial (8) but challenging to justify for all patients in the current era of medical cost containment. A majority of patients remain free of long-term musculoskeletal problems after limited physical therapy visits following removal of their surgical drains (52). Patients with advanced age or lymphedema and those who undergo ALND; chest wall or supraclavicular radiation treatments; or breast reconstruction are at up to 10 times greater risk of developing shoulder disability (3,4,8,9,36,37,48). Empirical data support more extended physical therapy for these patients with the goals of detecting incipient problems, education in self-diagnosis and referral, and provision with long-term prophylactic ROM and strengthening programs (53).

POTENTIAL CONCERNS

Several clinical finding should alert physicians to the possibility that patients require additional attention and care. Lymphedema remains a concern when patients exercise, particularly if they have undergone ALND with or without axillary or supraclavicular irradiation. Patients who have undergone these treatments will generally benefit from a visit with a lymphedema therapist certified by the Lymphology Association of North America (LANA) to review precautions and formulate a safe yet effective rehabilitation program. LANA-certified therapists can be located at http://www.clt-lana.org. The Physical Activity in Lymphedema (PAL) trial established that breast cancer survivors with, and at risk, for lymphedema can safely perform an incremental, resistive exercise program when gradually and systematically initiated and advanced (54,55).

Particular concern attends the rehabilitation of patients who have undergone breast reconstruction with autologous tissues. The range of harvesting and reconstruction techniques coupled with practitioner variability makes it difficult to accurately predict the locations and fragility of vascular anastomoses. Referral to a cancer rehabilitation specialist, or conferral with the plastic surgeon, is advisable prior to initiating physical activity, particularly if reconstruction involved muscle flaps. A comprehensive rehabilitation plan should address potential donor site morbidity, as well as the affected upper quadrant.

INTEGRATED EXERCISE APPROACHES

An ever-expanding array of fitness approaches is available to breast cancer survivors at health clubs and, increasingly, cancer centers. Some approaches such as Feldenkrais movement therapy are long established traditions utilized routinely by physical therapists. Other approaches have only become widely available within the past decade. To name but a few, patients may encounter Pilates, yoga, Alexander technique, Mensendieck exercise therapy, and tai chi. Each approach has unique emphases with the potential to benefit breast cancer survivors beyond enhancing general fitness and body awareness. For example, the Alexander technique focuses on craniocervical alignment, a critical dimension of postural therapy, and tai chi enhances physical functioning in breast cancer survivors (56). Patients should be encouraged to explore different approaches with several caveats. First, most fitness instructors are unaware of lymphedema precautions, hence patients must function as their own self-advocates to protect against inadvertent lymphatic overload. A recent pilot study detected increased arm volumes in breast cancer survivors performing a home-based Pilates program (57). Second, breast cancer patients' fitness regimens should include pectoral muscle stretching, strengthening of scapular retractors, and postural exercises as discussed above. If an integrated exercise approach does not include these elements, patients will need to independently supplement with guidance from a health professional.

A number of exercise regimens have been tailored to breast cancer survivors and marketed through video classes, books, and weekend workshops. The developers of such approaches may or may not have formal clinical training and familiarity with the unique physical vulnerabilities associated with breast cancer treatment. No empiric data supports the efficacy or safety of these tailored approaches. In the authors' opinion, the worth of such media derives from patients' enhanced comfort levels and enthusiasm.

A PROSPECTIVE SURVEILLANCE MODEL

The growing recognition that breast cancer treatments produce adverse upper quadrant sequelae that are common, morbid, and undertreated, particularly among ethnic minorities, has spurred the development of proactive approaches to detect and treat physical impairments. Among these, the prospective surveillance model (PSM) for breast cancer rehabilitation has been most extensively elaborated and studied (58). This model involves a preoperative physical therapy evaluation to characterize patients' baseline status, followed by physical therapy visits at 3, 6, 9, and 12 months post-surgery. The PSM's implementation among a survivor cohort reduced incident lymphedema and improved shoulder function over the first year following diagnosis. A bold initiative, supported by the American Cancer Society, has promoted the adoption of the PSM as a new of standard care (58). However, concern has been raised regarding the PSM's lack of level I supportive evidence, the formidable cost of implementation, and the potential for diverting resources away from the minority of survivors who develop severe and refractory problems (59).

CONCLUSIONS

Musculoskeletal problems involving the shoulder and upper truncal quadrant are common following primary breast cancer treatment, associated with disability, and a source of degraded HRQOL. Many patients recover normal strength and ROM after recovering from transient postoperative deficits, however, a significant proportion develop chronic problems. Modified radical mastectomy (MRM), ALND, breast reconstruction, and axillary or supraclavicular irradiation increase the likelihood that a survivor will develop long-term problems.

All breast cancer patients should receive formal instruction in gentle progressive shoulder and arm ROM following surgery. Forward flexion and abduction should be restricted to 90° until the seventh postoperative day. Patients at increased risk of long-term musculoskeletal problems should receive additional physical therapy with the goal of prevention and education in long-term risk reduction and self-advocacy. Irrespective of risk, all exercise programs should include several essential elements including: anterior chest wall stretching, strengthening of scapular retractor muscles, as well as activities to foster optimal posture and biomechanics. Patients treated with radiation therapy should indefinitely continue a limited ROM program targeting the anterior chest wall and shoulder muscles.

Empiric evidence suggests that musculoskeletal problems can be prevented with routine rehabilitative interventions after primary breast cancer treatment. Simple stretching, strengthening and postural activities may have the capacity to improve breast cancer survivors' HRQOL and represent an integral part of comprehensive care.

CHAPTER 40

Lymphedema

Sarah A. McLaughlin

CHAPTER CONTENTS

Breast cancer–related lymphedema remains a feared complication following breast cancer treatment (1) because it is a chronic process that cannot reliably be prevented. Dramatic modifications to surgical approaches, including less radical breast surgery and widespread adoption of sentinel lymph node biopsy (SLNB) as the standard of care for axillary staging, have contributed to significant decreases in the incidence of lymphedema. However, despite these changes, there remains approximately a 20% risk of lymphedema after axillary dissection (ALND) and a 0% to 7% risk after SLNB. Persistent risk and patient worry result in almost uniform adoption of lifestyle modifications (1). Unfortunately, it is unclear if these modifications reduce the risk for lymphedema, and it is further unclear how these changes impact overall quality of life (QOL).

Women affected by lymphedema have historically had an overall poorer QOL (2). Lymphedema can contribute to musculoskeletal pain and reductions in shoulder range of motion, limiting performance of activities of daily living. Unattended severely lymphedematous limbs can lead to elephantiasis and, in a few cases, to Stewart-Treves Syndrome, a rare but deadly angiosarcoma arising from the lymphedematous tissues. Despite these limitations, most patients with lymphedema do not consider themselves as disabled (3). They do, however, suffer from decreased body image and loss of self-esteem, but further refinement in assessment of all QOL measures has been lacking. Emerging interest supports standardization of QOL assessment in lymphedema patients as a recent meta-analysis demonstrated significant heterogeneity with 17 different instruments used (only two of which were specific to lymphedema patients) in 39 studies to assess health-related QOL outcomes in breast cancer–related lymphedema patients (4). The authors encourage future studies to use high quality lymphedema-specific patient-reported outcome instruments such as the Upper Limb Lymphedema 27 (ULL 27), which had the strongest psychometric properties.

The medical community has devoted little time and attention to lymphedema research and the resources necessary for successful lymphedema treatment. The financial burden placed on patients is frequently a source of anxiety. While Medicare supports consultation and treatment by trained lymphedema specialists, treatment coverage is frequently limited to diagnosis, acute intervention, and establishment of the treatment plan with visits and services covered only as patients demonstrate improvement. Interestingly, federal guidelines exist supporting the coverage of postmastectomy bras and prostheses; however, coverage for lymphedema compression garments and short stretch bandages, both mainstays for in-home maintenance therapy, varies among private insurers and Medicare. Advocating for equality in patient rights, the National Lymphedema Network (NLN) supports the Lymphedema Treatment Act (5,6), a bill before Congress that would help establish and standardize treatment coverage, patient education, development of self-treatment plans, and, ultimately, would reduce healthcare costs. As of July 2011, this bill was referred to the House of Representatives subcommittee on Health and has not been discussed again.

ANATOMY AND PATHOPHYSIOLOGY

The lymphatic system is composed of lymphatic capillaries, transporting vessels, and lymph nodes. The lymphatic system has a low oncotic pressure, allowing diffusion of protein-rich interstitial fluid into lymphatic vessels, which transport it to the venous system. In the upper extremities, the superficial lymphatic system is composed of valveless capillaries located at the dermal–subcutaneous

level that communicate directly with collecting lymphatic vessels coursing through subcutaneous tissues with superficial veins. These collecting vessels, or secondary lymphatics, drain into tertiary lymphatics, which progressively network and ascend to the axilla. On the left, these lymphatic vessels join other thoracic and intercostal lymphatic channels, draining into the thoracic duct, which empties into the left subclavian vein. A smaller right lymphatic duct drains the right upper extremity and neck and enters the right subclavian vein. Secondary and tertiary lymphatic vessels have valves to aid in the unidirectional propulsion of lymph fluid. Lymphatic flow is encouraged by active skeletal muscle contraction, causing intermittent compression of the subcutaneous compartment, and by nearby arterial pulsations. The lymph nodes act as points of filtration throughout the lymphatic drainage process and serve a primarily immunologic function. The vessels of the deep lymphatic system run beneath the muscular fascia near neurovascular bundles. Little communication exists between the superficial and deep systems, and lymphedema generally spares the deep component.

The etiology of lymphedema is incompletely understood, but it likely results from (1) lymphatic obstruction due to obliteration of the lymphatic pathways or removal of the lymph nodes, (2) mechanical insufficiency due to faulty lymphatic pumping or malfunction of the lymphatic valves, or (3) loss of lymphatic vessel integrity. The quantity of fluid within the interstitial space is determined by the delicate balance of hydrostatic and oncotic pressures between the vascular capillaries and the interstitial space. More than 90% of fluid within the interstitial space is removed by the venous capillaries; what remains is normally returned to the vascular system by lymphatics. The combination of the negative oncotic pressure of the lymphatic vessels and their indistinct, virtually nonexistent basement membranes allows larger proteins and macromolecules, such as bacteria and cellular debris, to passively diffuse from the interstitium into the lymphatic system. When the lymphatic system is dysfunctional, fluid transport is disrupted, and interstitial protein accumulates, increasing its oncotic pressure. This draws more fluid into the interstitium. Excessive accumulation of interstitial fluid due to impaired lymphatic transport is called *lymphedema*.

The cycle of lymphedema self-perpetuates as increased lymphatic fluid volume causes stretch in lymphatic vessels, leading to incompetent valves and further failure of lymph transport. Additionally, the stagnant bacteria ignites a chronic inflammatory cascade, recruiting macrophages and neutrophils to the interstitium for wound healing, and leading to collagen deposition and fibrosis, hindering lymphatic contraction. Furthermore, the severity of edema can be exacerbated by episodes of lymphangitis, chronic inflammation, or recurrent cellulitis. It is hoped that the recent development of lymphatic endothelial markers such as LYVE-1, Prox1, and podoplanin will help the study of lymphangiogenesis and regeneration.

CLINICAL EVALUATION OF UPPER EXTREMITY LYMPHEDEMA

To evaluate for lymphedema, the patient sits with arms outstretched and then flexed and rested on the hips. The clinician should pay close attention to subtle differences in symmetry including loss of bony prominences, especially at the olecranon process, styloid process of the ulnar head, and over the extensor tendons of the hand. Other subjective signs of swelling include imprints from tight-fitting shirt sleeves, watches, or jewelry. The physical exam also includes evaluation of skin turgor, firmness, and the presence of pitting or nonpitting edema. Lymphedematous changes may involve the entire upper extremity but can also be isolated to the hand in 61%, the lower arm in 55%, and the upper arm in 72% of patients (7). Table 40-1 lists the clinical stages of lymphedema.

TABLE 40-1

Clinical Stages of Lymphedema

Stage	*Clinical Findings*
0	Subclinical lymphedema Impaired lymphatic transport Swelling not visible by gross evaluation Can be latent for months to years
I	Visibly swollen limb Pitting edema Edema may resolve without treatment
II	Limb is visibly swollen but swelling is nonpitting Onset of tissue fibrosis Chronic condition
III	Lymphostatic elephantiasis Irreversible skin changes, fatty deposits, hyperpigmentation

Metrics

The diagnosis of lymphedema is confirmed by physical exam and a combination of subjective and objective measures (Table 40-2). Unfortunately, the most challenging problems in accurately determining the incidence of lymphedema remain poor standardization in defining lymphedema and the lack of robust data with long-term follow-up. Many studies diagnose lymphedema using subjective measures such as patient questionnaires or survey instruments to directly and indirectly assess symptoms of arm or breast swelling, tightness, tenderness, or edema (7–10). Little correlation between subjective assessment tools and arm measurement changes constituting lymphedema exist; however, it could be argued that it is the patient's perception of lymphedema, not the presence or absence of objective measurement changes, that negatively impacts QOL and contributes to adoption of risk reducing behaviors. A recent study found that, in patients having SLNB, perceptions of lymphedema appear to decline significantly over the first year; however, among ALND patients, perceptions of lymphedema increase between 6 and 12 months after surgery (1). At 5 years' follow-up, a large prospective study found perceived rates of lymphedema to be less than measured after SLNB (3% vs. 5%), while patients undergoing ALND perceived more swelling than was measured (27% vs. 16%) (11). More recently, a retrospective study with 10 years of follow-up documented subjective lymphedema in 10% of SLNB patients and 33% of ALND patients (12). This study did not obtain baseline assessments. Well-documented sensory changes occurring after axillary surgery and the inconsistent practice of sparing the intercostal brachial nerve likely explain the differences between perceptions and measurements of lymphedema (12).

The objective measures of lymphedema that quantify volume differences and volume displacement using water remain the gold standard in assessing lymphedema despite multiple limitations (see Table 40-2). Circumferential arm

TABLE 40-2

Advantages and Disadvantages of Common Lymphedema Diagnostic Tools

Method	*Advantages*	*Limitations*
Patient report (subjective assessment)	• Patient perception of symptoms and their impact on function • Detection of prodromal symptoms of heaviness or subtle arm changes undetected by objective measures	• Recall bias of risk factors • Unclear influence of postoperative sensation sequelae • No standardization in subjective assessment or QOL tools
Water displacement	• Gold standard • Volume calculation of entire limb	• Cumbersome • Infection control limitations (water must be changed between each patient use) • Cannot isolate location of lymphedema (i.e., to hand, forearm, or upper arm)
Circumferential tape measurements	• Portable • Easy to learn • Noninvasive • Cost efficient • Relatively quick to perform	• Intra-rater and inter-rater variability • Nonstandardized process (i.e., inconsistent measurement intervals and diagnostic thresholds) • Requires baseline and bilateral arm measurements
Perometry	• Standardized process • Multiple measurement intervals • Reproducible • Sensitive	• Not portable • Expensive equipment • Cannot reliably measure the upper arm or hand
Bioimpedance spectroscopy (BIS)	• Measures only extracellular fluid compartment • May detect subtle volume changes of <150 mL (prodromal or Stage 0 lymphedema) • Portable • Cost effective • Standardized • FDA approved	• Variable reimbursement • Recommended at baseline and every 3 mo after surgery

measurements with a non-elastic tape measure remain the most commonly reported method for objectively assessing lymphedema. Implementation in clinical practice is relatively straightforward; however, a few guidelines should be followed. First, baseline measurements of the ipsilateral and contralateral arm are essential to control for normal variations between the dominant and nondominant arms at baseline and for any weight gain during follow-up. Second, to minimize intra-rater and inter-rater circumferential arm measurement variability, patients should be measured by the same healthcare professional at all visits and ideally measured multiple times at each point to ensure the most accurate results. Unfortunately, the number of anatomic locations and the number of measurements obtained vary between studies. Some investigators measure at only two points while others obtain 10 to 15 measurements at 3 or 4 cm increments from the nail bed to the axillary fold and then calculate the arm volume according to the volume of a frustrum or truncated cone. When compared to water displacement, multiple measures used to calculate arm volume and patient self-report had the highest specificities (90% and 89%, respectively), while measurement of arm circumferences at 2 points alone had the lowest specificity (73%) (13). Finally, the measurement change constituting lymphedema is not standardized; some consider lymphedema a 2-cm increase in circumference (9), while others consider a volume increase of less than 10% as minimal lymphedema, 10% to 20% moderate, and greater than 20% severe when compared to the baseline (14). The clinician should decide the diagnostic thresholds prior to commencement of screening to ensure consistency in measurements. Figures 40-1 through 40-4 demonstrate mild, moderate, severe, and isolated hand lymphedema. Regardless of the implementation strategy, arm measurements cannot determine the actual volume of extra lymphatic fluid.

Perometry or opto-electric volumetry uses a perometer to emit infrared light beams and to measure changes in the beam angles caused by the shadows of the limb. The frame moves at 3-mm increments along the length of the limb, obtaining circular cross-sectional measures, and then calculates overall total limb volume. The advantages and limitations are listed in Table 40-2. When perometry is used, clinicians consider a change of 3% over baseline measurements to be diagnostic for lymphedema (15).

Another noninvasive measurement option is bioimpedance spectroscopy (BIS), previously known as multifrequency bioelectrical impedance (Table 40-2). BIS uses resistance to electrical current to compare the composition of extracellular fluid compartments within the body and specifically between the affected and unaffected limbs (16). An increase in extracellular fluid results in a decrease in impedance of the affected limb. The most popular device available is the L-Dex marketed by Impedimed. Exploratory studies suggest an increase of 10 L-Dex units from the baseline or

FIGURE 40-1 Mild lymphedema in the left arm.

a value outside of the normal range may aid in the clinical assessment of unilateral arm lymphedema when compared to matched normal controls (17). Smoot et al. compared BIS to circumferential arm measures and found BIS to have the highest Area Under the Curve (AUC) value of 0.88, while using the 2-cm diagnostic cutoff option had an AUC of approximately only 0.60 (18). BIS may be best suited to identify the prodromal early stage of lymphedema as circumferential arm measures or volume calculations may fail to capture subclinical fluid accumulations of less than 150 mL (14). The device is portable and easy to use; however, reimbursement for the procedure varies by state across private insurers and Medicare. Taking all measurement options into account, the NLN recommends circumferential tape measurements made with a flexible non-elastic tape measure at a minimum of six anatomical locations per arm, infrared perometry, or BIS (5); the National Accreditation Program for Breast Centers (NAPBC) strongly recommends the use of BIS or perometry, given their high correlation of results in the assessment of stage 0 lymphedema. The dilemma in

FIGURE 40-2 Moderate lymphedema in the left arm.

FIGURE 40-3 Severe lymphedema in the right arm.

FIGURE 40-4 Moderate lymphedema in the left hand.

diagnosing lymphedema remains that measurement changes alone may not find all patients who are suffering from clinically significant lymphedema and may overdiagnose those who are unaffected by their measurement changes. Imaging techniques including lymphoscintigraphy, CT, and MRI are occasionally discussed to image a lymphedematous limb; however, these imaging techniques are predominantly limited to research, not clinical use.

Early Detection and Progression

An emerging body of literature supports the early detection of breast cancer–related lymphedema. These data cite improvements in functional outcome, resolution of prodromal symptoms, and decreased cost as reasons to support aggressive early detection practices (19). Stout presented data (15) supporting early detection and found intervention at this early stage can reduce or resolve the progression of lymphedema. This study prospectively followed 196 women, measuring arm volumes by perometer at baseline and every three months postoperatively. They controlled interventions, prescribing compression sleeves for 4 weeks to all women with a 3% change from baseline in perometer measurements. After intervention, the investigators found a mean arm volume decrease of 58% that was maintained for nearly 5 months after the compression sleeve was discontinued. Torres-Lacomba also highlights the importance of early intervention and conducted a prospective randomized trial to assess the role of early physical therapy, including manual lymphatic drainage, scar massage, and progressive active shoulder range of motion, on the incidence of lymphedema. After one year of follow-up, those in the intervention group demonstrated significantly less lymphedema (7% vs. 25%, $p = .01$) (20).

Luckily, contemporary estimates find that, among those with lymphedema, the majority have only a mild form (7). However, women with mild lymphedema are more than three times more likely to develop moderate or severe lymphedema compared to women with no lymphedema. Bar et al. reinforces these findings, documenting that 48% of mild lymphedema patients progressed to more severe lymphedema by 5 years follow-up (21). Risk factors for the progression of lymphedema included age more than 65 at diagnosis, morbid obesity, and regional nodal irradiation including posterior axillary boost (22). While studies agree on the importance of early identification and intervention, there is less agreement on what type of intervention should be pursued. Regardless, prospective evaluation and intervention for lymphedema is associated with significant cost savings with a recent study finding the cost to manage early-stage breast cancer–related lymphedema to be $636 annually, while the cost to manage late-stage lymphedema (traditional model) is $3,124 (23).

Risk Factors

Many retrospective studies have reported risk factors for lymphedema, including the extent of axillary surgery, mastectomy, obesity, patient age, radiation, and infection or injury in the ispilateral upper extremity. The strength of association between these treatment and epidemiologic risk factors and lymphedema is inconsistent across studies (24). A meta-analysis reviewed lymphedema risk factors from 98 studies and found a significantly increased incidence of lymphedema after mastectomy compared to lumpectomy (RR, 1.42; CI, 1.15–1.76), ALND compared to no dissection (RR, 3.47; CI, 2.34–5.15), ALND compared to SLNB (RR, 3.07; CI, 2.20–4.29), radiation versus no radiation therapy (RR, 1.92; CI, 1.61–2.28), and for positive versus negative axillary lymph nodes (RR, 1.54; CI, 1.32–1.80). While these data represent a comprehensive, contemporary review of potential risk factors, it should be acknowledged that the 98 studies used 11 different definitions for lymphedema and follow-up ranged between 1 month and 30 years. Finally, the influence of infection and injury must be tempered, as most accounts documenting these occurrences are obtained by patient recall and are therefore subject to significant bias as those affected by lymphedema are more likely to recall infection or injury (1).

The number of nodes removed or the extent of axillary surgery is the most commonly cited risk for lymphedema. However, the relationship between the number of lymph nodes removed and lymphedema risk is unclear, as some retrospective studies find no correlation and others find an increasing risk with more lymph nodes removed (25–29). The prospective randomized trials establishing SLNB as the standard of care for axillary staging support the theory that lymphedema is proportional to the number of nodes removed. They also document the small but definitive risk of lymphedema after SLNB. Although follow-up ranges from 6 to 60 months, these prospective randomized trials comparing SLNB and ALND find SLNB reduces rates of lymphedema to 0% to 7% after SLNB compared to 12–16% after ALND (30–32).

Goldberg et al. questions the role of the number of lymph nodes removed as the sole cause of lymphedema and proposes instead that it may be the relative degree of lymphatic destruction (33). They demonstrated no difference in lymphedema rates among 600 SLNB patients when stratifying the data according to the mean, median, or range of number of nodes excised ($p = .93$). They also found no lymphedema in women having more than 10 lymph nodes excised at SLNB. When this subset was compared to women having 10–17 nodes removed at ALND, they discovered 11% of the ALND patients had lymphedema ($p = .04$) and suggested the etiology of lymphedema is multifactorial and perhaps relative to the amount of lymphatic destruction. In contrast, while patient objective measurements of lymphedema were not correlated with the number of nodes removed, patient perceptions of lymphedema did increase as more nodes were removed (34).

Axillary radiation can also contribute to lymphatic dysfunction. Shah et al. recently retrospectively reviewed 1,861 patients with breast cancer treated by breast conservation surgery and whole breast irradiation. When stratified by regional nodal irradiation technique, they found lymphedema occurred in 9.9% of patients receiving a supraclavicular field, in 14.7% in those receiving a posterior axillary boost, and in 8.3% of patients receiving internal mammary irradiation (35). Bar et al. found similar results, noting that 54% of patients having supraclavicular radiation and posterior axillary boost developed lymphedema within 5 years of treatment compared to 27% of patients with breast irradiation only (22). Additionally, a recent meta-analysis by Shah and Vicini found lymphedema in 9% to 65% of patients after lumpectomy alone (no nodal surgery) and regional nodal radiation and in 58% to 65% of women after mastectomy alone and regional nodal radiation (36). The synergistic effect of surgery and radiation is well documented to result in a 3.5- to 10-fold higher risk of lymphedema when compared with surgery alone (36–38). Although axillary radiation may cause less acute morbidity, long-term complications (such as brachial plexopathy) and decreases in motor and sensory function can occur. The prospective randomized AMAROS (After Mapping of the Axilla: Radiotherapy or Surgery?) trial was presented at the Annual American Society of Clinical Oncology meeting in June 2013. This trial randomized women with clinical T1-2 N0 breast cancer found to have a positive sentinel node to either axillary radiation or ALND. After 5 years of follow up, the investigators reported axillary recurrence rates of less than 1% and found lymphedema to be less after axillary radiation when compared to ALND (14% vs. 28%). As of the completion of this chapter, the final AMAROS manuscript has yet to be published.

Finally, adjuvant chemotherapy, especially anthracycline-based regimens, may also affect lymphatic destruction. Norman et al. (39) conducted a prospective study that followed 631 breast cancer survivors for 5 years and found a hazard ratio of 1.46 (95% CI, 1.04–2.04) for lymphedema among breast cancer patients receiving anthracycline chemotherapy versus no chemotherapy even when the data were controlled for stage at diagnosis or number of positive nodes. Additionally, they found treatment combinations involving ALND or chemotherapy led to four- to fivefold increases in hazard ratios for lymphedema [HR of 4.16 (95% CI, 1.32–12.45) for SLNB/chemotherapy/no radiation] compared with no treatment. Further validation of these findings is needed.

While clinicians widely acknowledge all the risk factors listed above, little effort has been put forth to estimate individual patient risk for developing lymphedema. Prevention and treatment efforts have been historically uniformly applied to all patients at risk. Ideally patient, tumor, and treatment characteristics could be individually weighted to risk stratify each patient. With this goal, Bevilacqua et al. (40) retrospectively evaluated 1,054 women undergoing ALND for breast cancer. Then, using lymphedema risk factors such as age, body mass index, ipsilateral arm chemotherapy infusions, level of ALND, radiation fields, seroma, infection, and early edema, they created a nomogram to predict the risk of lymphedema. The nomogram (available at www.lyphedemarisk.com) was modeled to run at baseline, postoperatively within 6 months of surgery, and postoperatively after 6 months of surgery. The nomogram performed with reasonable certainty in validation with concordance indices of 0.706, 0.729, and 0.736 at each time point, respectively. The authors concluded that the model can help clinicians predict lymphedema and therefore risk stratify patients accordingly.

Incidence

The true incidence of lymphedema has been difficult to determine, and, therefore, wide ranges in incidence are reported from 0% to 75%. The wide ranges may reflect the differences in measurement techniques and the lack of a standardized definition of lymphedema. For example, some studies measure any lymphedema while others measure only moderate or severe lymphedema. Furthermore, the relatively short follow-up of most contemporary studies suggests that the incidence of lymphedema is likely underreported. Although it is clear that 80% to 90% of women who will develop lymphedema do so within 3 years of treatment (7,9), women remain at risk for many years later, as approximately 1% per year will develop lymphedema between years 4 to 20 of follow-up. A recent meta-analysis documents that lymphedema ranges from 0% to 3% after lumpectomy alone to as high as 65% after modified radical mastectomy with radiation to the chest wall and regional lymphatics (41). Otherwise, contemporary estimates of lymphedema appear to range from 0% to 7% after SLNB and 15% to 20% after ALND.

Changes in the surgical management of the axilla, including the adoption of SLNB, limiting ALND even after a positive SLNB, and even questioning the need for SLNB in all patients, aim to further reduce the incidence of lymphedema. In addition, changes in surgical techniques, such as Axillary Reverse Mapping (ARM), have been proposed. Proponents hypothesize that breast and upper extremity lymphatic pathways to the axilla may be separate. ARM uses a combination of blue dye injected into the arm to map the lymphatic channels draining the upper extremity and technetium injected into the breast to map the lymphatic channels draining the breast. The goal is to identify and protect the blue lymphatics during axillary surgery, therefore preventing lymphatic damage and, ultimately, lymphedema. So far, limited data have demonstrated wide variations in ARM identification rates ranging from 40%–90%, salvage of the ARM nodal pathway of approximately only 50%, overlap in the ARM and breast drainage pathways in 20% of patients, especially those with heavy axillary disease burden, and cancer in the ARM node in 9% to 43% of cases (42–45). Most studies have limited follow-up, and the risk of lymphedema after the procedure is unknown.

TREATMENT

The treatment of lymphedema focuses on the chronic nature of the disease and aims to prevent lymphedema progression and recurrent infection and to facilitate return to normal function. Patients and family members must understand the physiologic process of lymphedema and the rationale behind the treatment process. They must also accept life-long active participation in treatment regimens. Certified physical or occupational therapists, physicians, nurses, and even massage therapists can help develop care plans to reduce and maintain fluid volume and provide compression garments and supplies. Early education and intervention remain vital to limiting tissue fibrosis, pain, and decreased function.

Risk-Reducing Strategies

For decades, clinicians have recommended risk-reducing behaviors to prevent lymphedema. Unfortunately, as noted in the risk-reduction guidelines published by the NLN, there remains "little evidence-based literature regarding many of these practices, [as such] the majority of the recommendations must at this time be based on the knowledge of pathophysiology and decades of clinical experience by experts in the field" (5). The overall lack of robust data surrounding this topic has led to the perpetuation of many myths about lymphedema. The primary goals of the risk-reducing practices are to prevent further lymphatic destruction by limiting increases in lymphatic flow, metabolic waste products, and infection, and to avoid lymphatic obstruction. Table 40-3 organizes the commonly recommended behaviors according to the physiologic process they are intended to prevent. In general, many inconsistencies in the application of these behaviors exist, as application of these practices is not differentiated between at-risk and affected individuals nor are at-risk patients stratified by their individual risk. In fact, prospective studies find that most patients having axillary surgery adopt four or five risk reducing behaviors without regard to the type of axillary surgery performed (1,10).

Avoidance of venipuncture, injection, or blood pressure measurement in the ipsilateral arm are the most widely recognized risk-reducing measures. Review of the available literature identifies only one study supporting avoidance of venipuncture or IV catheters as they found skin puncture for intravenous catheter insertion, venipuncture for blood draw, or finger stick for blood glucose testing were associated with an increased risk for lymphedema (RR 2.44, 95% CI 1.33–4.47). However, this was based on only 18 patients recalling skin puncture, of whom 8 had lymphedema at 3 years follow-up, suggesting the possibility that patients with lymphedema are more likely to recall a previous skin puncture (46). Interestingly though, surveys of orthopedic surgeons demonstrate low rates of lymphedema in at-risk patients and nonstatistical rates of infection or progression of lymphedema symptoms in affected patients among women needing carpel tunnel or other ipsilateral orthopedic surgery after breast cancer treatment (47–49). These studies may also be the best assessment of the outcome after planned lymphatic obstruction as surgeons reported

TABLE 40-3

Summary of Frequently Recommended Precautionary Behaviors Categorized by Physiologic Principles and the Cited Evidence Supporting or Refuting the Practice

Supporting Evidence	*Physiologic Principle and Precautionary Behavior*	*Refuting Evidence*
Expert opinion	**Increase lymphatic load** Overuse Trauma Hot weather and sunburn Heating pads Vigorous massage	Showalter (53)—prospective secondary analysis of RCT
Showalter (53)—prospective secondary analysis of RCT	**Increase lymphatic load** Sauna use	none
Casley-Smith (50)—retrospective survey	**Increase lymphatic load** High altitudes	Graham (51)—retrospective survey Kilbreath (52)—prospective but short follow-up
Clarke (46)—retrospective review	**Cause infection** Venipuncture Injections or intravenous catheter placement Acupuncture Cuts and scrapes from gardening Cuticle cutting Shaving with a straight razor	Showalter (53)—prospective secondary analysis of RCT Dawson (47), Hershko (48), Gharbaoui (49); all retrospective, survey, or opinion-based
Expert opinion	**Cause lymphatic obstruction** Blood pressure measurement Tight clothing on upper arm or wrist Tight jewelry Carrying a purse Crossing legs	Showalter (53)—prospective secondary analysis of RCT Dawson (47), Hershko (48), Gharbaoui (49); all retrospective, survey, or opinion-based
Expert opinion	**Increase metabolic waste products** Exercise	Kwan (58), Schmitz (59), Schmitz (60), and Courneya (61): meta-analysis and RCTs
Expert opinion	**Increase metabolic waste products** Heavy lifting Racquet sports	Showalter (53)—prospective secondary analysis of RCT

using tourniquets for exsanguination without evidence of lymphedema postoperatively. This finding may negate the recommendation of avoiding blood pressure measurements as taking a blood pressure requires significantly less time (or lymphatic obstruction) than a surgical tourniquet. These data, however, are anecdotal at best as they are all retrospective with small numbers, complicated by recall bias, and lack any objective measurements.

Another commonly recommended risk-reducing behavior is the use of compression sleeves for air travel. Three studies find conflicting data with one supporting compression garments, citing lowered cabin pressure as the inciting cause for lymphedema (50), while the other two find no difference in lymphedema rates between fliers and non-fliers and no difference according to the length of flight (51,52). In fact, one study found the practice of precautionary behaviors, including using a compression garment when flying, to be associated with an increased risk of lymphedema (OR 6.2, 95% CI 1.2–20.8, $p < .04$). Interestingly, further analysis also found patient use of compression garments did not correlate with other suspected lymphedema risk factors such as nodal disease, number of nodes removed, or radiation (51). Showalter et al. recently reviewed 30 risk-reducing practices with the goal of quantifying the association between these suspected risk factors and the occurrence of incident arm swelling among at-risk breast cancer survivors (53). Overall, 9% of 295 patients developed lymphedema, and sauna use was the only factor predictive of swelling (OR 6.67, 95% CI 1.36–32.56) by multivariate analysis. These findings underscore the discordance in clinician lack of knowledge regarding lymphedema prevention and recommendations made everyday to breast cancer survivors.

TREATMENT COMPONENTS

Complex decongestive therapy (CDT) remains the standard of care for long-term lymphedema treatment. There remain no effective medications to treat or prevent lymphedema. CDT is provided in two phases, the Reductive (Phase I) and the Maintenance (Phase II), and their components are outlined in Table 40-4. Clinicians providing CDT should be certified. Phase I CDT is performed 5 days per week until the reduction in fluid volume plateaus, at which point Phase II begins and a home regimen plan for maintenance therapy is established. Certified therapists also train caregivers to

TABLE 40-4

Goals and Components of Complex or Complete Decongestive Therapy (CDT)

Goals	
• Decrease swelling • Increase lymphatic drainage • Reduce skin fibrosis • Relieve discomfort • Reduce risk of cellulitis • Improve functional status	
Treatment Components	
Phase I: Reductive • Education in self-management • Skin care • Manual Lymphatic Drainage (MLD) • Short stretch bandaging • Lymphatic exercise	*Phase II: Maintenance* • Daily use of compression garments • Custom nighttime compression garments or alternative compression device • Periodic Manual Lymphatic Drainage (MLD), self massage, and lymphatic exercise

assist with the maintenance phase. Individual treatment recommendations and plans may vary according to the expertise of the treating clinician, insurance coverage and patient resources, complexity and duration of the therapy, patient motivation, and ability of patient to perform her own home care. Furthermore, regimens may be modified throughout the treatment process depending on the patient's response to treatment and exacerbations.

Skin Care

Methodical skin care is imperative to prevent infection. Therapists educate patients on daily cleansing routines, cuticle care, shaving, and hydration to minimize skin tears. Patients are also taught to recognize early signs of infection, especially erythematous streaks or increased swelling or fever, and to treat minor wounds with antibiotic ointment and dry gauze. Patients prone to recurrent bouts of cellulitis may carry antibiotics with them for use in case of rapid onset of cellulitis.

Manual Lymphatic Drainage (MLD)

Manual Lymphatic Drainage (MLD) is gentle massage designed to encourage natural drainage of lymphatic fluid away from a blocked lymphatic drainage area toward nearby functioning lymphatic vessels, usually toward the contralateral axilla or inguinal areas. MLD uses light massage strokes in a rhythmic circular fashion distally to proximally to stimulate lymphatic flow. Success of MLD is based on the physiologic principle that massage strokes apply tension to the skin which stimulates peristalsis of the smooth muscle cells in the walls of the superficial lymphatics. In phase I CDT, MLD is provided daily by a trained therapist; in Phase II, the patient practices MLD themselves on an as-needed basis to maintain volume reductions in conjunction with daily daytime and nighttime compression garment regimens.

Several prospective studies have demonstrated MLD to successfully reduce limb volume. Mondry et al. demonstrated a median girth reduction of 1.5 cm (54), while others found a limb reduction of 50% to 60% after MLD and compression bandaging (55,56). In the maintenance phase, increases in limb volume were associated with noncompliance with the bandages and compression garments (RR 1.55, 95% CI 1.3–1.76; and RR1.61, 95% CI 1.25–1.82) but not associated with MLD noncompliance (RR 0.99, 95% CI 0.77–1.2), suggesting the greatest benefit of MLD is seen in the reductive phase of CDT (57). Younger age, greater weight, and higher BMI also contributed to CDT maintenance failure (55).

Multilayer Short Stretch Compression Bandaging

Multilayer short stretch compression bandaging employs multiple layers of material to create low resting pressure but high working pressure gradient compression. Bandages are placed with the limb at rest; muscular contraction within the limited space of the short-stretch bandages creates high working pressure and therefore aids in fluid propulsion from the congested lymphatics to the venous circulation when the arm is in use. Bandage application begins with a bandage lining followed by digital bandage wraps, padding (polyester, cotton, or foam) to protect the fibrotic portions of the limb, then multiple layers of short-stretch bandages with 50% overlap and 50% stretch to cover the entire limb (Fig. 40-5). The goal of these bandages is to promote lymphatic and venous flow return and reduce limb fibrosis. These bandages differ from high-stretch bandages, such as Ace bandages, that can stretch to greater than 100% of their resting length. Compression bandaging is always a part of reductive CDT, and patients with severe forms may require continuation in the maintenance phase. However, success in this phase is variable as the bandages can be difficult for patients to apply and can take up to an hour twice daily to apply and remove. Additionally, insurance coverage is not standardized and bandages must be replaced every 4 to 6 months to maintain optimal stretch. Finally, compliance wanes in warmer climates as these bandages can be bulky and hot.

FIGURE 40-5 Multilayer short stretch compression bandaging.

Exercise

Remedial or lymphatic exercise to reduce arm swelling and promote mobility during lymphedema treatment is beneficial for all patients at risk for and affected by lymphedema. However, aerobic exercise and resistance exercise or weight training have long been discouraged for breast cancer survivors based on the physiologic theory that strenuous exercise would increase metabolic waste products and extracellular fluid causing lymphedema. Recently, these recommendations have been challenged.

Between 2006 and 2010, five randomized control trials found weight lifting is associated with minimal risk of developing or exacerbating lymphedema (58). The physical activity and lymphedema trial (PAL) was the largest study with the longest follow-up; it followed 141 women afflicted with breast cancer–related lymphedema. Patients were randomized to supervised twice weekly weight training wearing a compression sleeve or to the control group who were asked not to alter their exercise level. The authors found no increase in lymphedema in the intervention group and found fewer and less severe lymphedema exacerbations in the weight training group at one year follow-up (59). The researchers then studied weight training in at-risk survivors and similarly found no difference in lymphedema rates between the control and intervention groups (60). Interestingly, at-risk women with more than 5 nodes removed randomized to the intervention weight training group were significantly less likely to develop lymphedema than those in the control (7% vs. 22%, $p = .003$) (60). Based on these data, the NLN guidelines have been modified to reflect the positive benefits of resistance exercise in a controlled fashion, but these guidelines emphasize that patients should start with low weight and a low number of repetitions and progress gradually (5). In general, it is recommended that women wear compression garments during exercise if they are affected by lymphedema and should be considered on an individual basis if they are at-risk for lymphedema.

Less robust data exists on the influence of aerobic exercise; however, it appears to be safe. Kwan et al. reviewed seven studies evaluating aerobic exercise in lymphedema (58). Only three of the trials were randomized, but none found aerobic exercise or the combination of resistance and aerobic exercise to trigger or increase lymphedema. Despite the relative agreement between the studies, the authors expressed caution about the safety of aerobic exercise as the trials were limited by small numbers or poor trial adherence rates (61).

Compression Garments and Alternative Compression Devices

Compression garments are the mainstay of lymphedema maintenance therapy. They effectively reduce edema and can be easier to apply than bandages although their exact mechanism of action is unclear. Some hypothesize that the garments help augment interstitial pressure to maintain interstitial fluid homeostasis and prevent stretching of the patient's skin (62). Once garments are fitted properly, patients may choose fabric, style, and color. Improperly fitting garments lead to noncompliance and decreased efficacy. In general, upper limb garments should be worn with a gauntlet (hand compression glove) to prevent distal limb constriction and fluid build up in the hand. Upper extremity lymphedema compression garments are classified according to the pressure transmitted: class I (20 to 30 mm Hg), class II (30 to 40 mm Hg), or class III (40 to 50 mm Hg). At-risk patients are recommended to start with class I garments.

Compression garments are worn for 12 hours during the day and removed at night as they have higher resting pressures than the multilayer short stretch bandages. Given the difficulties and time needed to correctly place multilayer short stretch compression bandages, custom-made compression sleeves with properties similar to compression bandages (i.e., low resting pressures) have been designed as an alternative. Unfortunately, the cost for some of these custom overnight compression garments can exceed $1,000 and may not be covered by insurance.

Intermittent Pneumatic Compression

Intermittent pneumatic compression pumps (IPC) represent an alternative to multilayer short stretch compression bandaging; however, their incorporation into treatment regimens has been controversial. IPC are made to fit the upper or lower extremity and come equipped with a truncal attachment or vest if necessary (Fig. 40-6). They work

FIGURE 40-6 Intermittent pneumatic compression device.

by delivering sequential pressure through the multiple chambers to force fluid to return to the central venous system in a unidirectional fashion. The primary concern about these devices relates to the potential high pressure applied to the skin, which, in turn, may further damage the subcutaneous tissues and superficial lymphatics (63). However, data suggests IPC may provide better maintenance edema control than self-administered massage and may be a helpful adjunct in maintenance phase treatments (64). Also, Ridner et al. (65) found patients report high satisfaction with the IPC devices and feel they are beneficial to their lymphedema management. The compression process generally takes about an hour and may be used once or twice a day. After IPC, standard compression garments or multilayer short stretch bandages should be applied to maintain the edema reductions. Additional data regarding the role of IPC is needed, as recent studies continue to disagree on how it should be incorporated into treatment regimens (66,67).

Surgery

With advancements in microsurgical techniques, there has been a significant resurgence in the idea of surgery as a treatment for lymphedema. It excites clinicians and patients because it offers a potential cure for an otherwise chronic, incurable condition. In contemporary practice, surgery for lymphedema is either reconstructive—lymphovenous anastomosis (LVA) or free lymph node transfer (FLTS)—or reductive—liposuction.

With modern LVA, the surgeon performs multiple microsurgical anastomoses between 0.3–0.8 mm venules and lymphatics. Although the largest series supporting LVA (68) reports elimination of compression garments in 85% of patients, the data lacks any real patient details, objective measures of subjective improvement, and fails to clearly identify the number of patients with 10 year follow-up. Other series reporting no more than 19 patients find conflicting results of the procedure's benefit, with Lee (69) finding that 47% of patients had worse edema 4 years postoperatively. FLTS harvests healthy lymph nodes from a separate nodal basin (inguinal or contralateral axilla) and transplants them into the affected lymphedematous nodal basin. It fosters lymphatic collateral growth but has the potential risks of donor site morbidity. Overall, studies find only 37% of patients achieved >50% volume reduction, 47% eliminated compression garments, and 0% to 23% experienced donor site morbidity, specifically lymphedema. While these cases of lymphedema were reported as transient, none of the studies have sufficient follow-up or power to detect a small but albeit significant detrimental risk of donor site issues (69,70). Both LVA and FLTS physiologically seem to be more effective in early stages of lymphedema before significant tissue fibrosis exists. Liposuction is the contemporary volume reductive surgery for lymphedema. All series demonstrate >100% limb edema reduction but require lifelong strict adherence to compression garment therapy for maintenance of reduction (71). This technique in no way cures the underlying physiologic process causing lymphedema. Above all else, LVA and FLTS lack data supporting their beneficial impact on overall QOL or improvement in functional capacity. Only Brorson (72) explores these outcomes after liposuction, finding improvement in arm swelling, activities of daily living, and pain but without an improvement in overall QOL. Finally, these highly specialized surgical techniques require significant experience and a dedicated multidisciplinary team. Ideally, lymphedema surgeons would understand and be competent in all techniques for the best results. Until clinicians can assure patients of these standards with rigorously tested data, surgery for lymphedema should be viewed with guarded optimism.

Laser

Low-level laser therapy (LLLT) is a noninvasive laser treatment of damaged tissues. LLLT uses very low-intensity single-wavelength pure light to reduce limb volumes, break down fibrous tissue, and increase range of motion. Theoretically, laser increases lymph flow while reducing the amount of excess tissue fluid protein. LLLT is likely most effective in advanced lymphedema with significant tissue fibrosis, though indications for use are not standardized. A recent meta-analysis reviewed 230 patients in 8 studies and found moderate to strong evidence supporting LLLT but notes further well-designed studies are needed to determine the precise effectiveness (73).

MANAGEMENT SUMMARY

- Lymphedema occurs in 15% to 25% of ALND and 0–7% of SLNB patients.
- There are four stages of lymphedema. Physical exam and a consistent method of arm measurement should be performed on the ipsilateral and contralateral limbs at baseline and in follow-up to accurately diagnose and follow lymphedema.
- Identification of lymphedema at stage 0 and early intervention are the keys to preventing lymphedema progression.
- Common risk factors for lymphedema include ALND, axillary radiation, obesity, and injury or infection in the ipsilateral arm since surgery.
- Treatment focuses on risk reduction, skin care, manual lymphatic drainage, compression garments and devices, and exercise. Surgery remains controversial.
- Compression garments remain essential to lymphedema therapy and represent the most widely used form of compression. Both garments and bandages reduce edema.

CHAPTER 41

Local Management of the Axilla

Monica Morrow and Jay R. Harris

CHAPTER CONTENTS

MANAGEMENT SUMMARY: AXILLA

The management of the axillary lymph nodes changed dramatically with the introduction of sentinel lymph node biopsy (SLNB), and has continued to evolve in parallel with changes in our understanding of breast cancer biology and improvements in systemic therapy. SLNB is now a well-established technique. A sentinel lymph node can be detected in more than 95% of women with breast cancer and predicts the status of the remaining axillary nodes with greater than 90% accuracy, and after a negative SLNB, first failure in the axilla is seen in fewer than 1% of patients. With experience, it has become apparent that there are relatively few contraindications to SLNB. The procedure is contraindicated in inflammatory breast cancer and other T4 tumors. Isosulfan blue dye is not known to be safe in pregnant women, and although the fetal dose with radioisotope mapping is estimated to be safe (1), the procedure has not been widely adopted in pregnant women. With these few exceptions, SLNB is the axillary staging procedure of choice in clinically node-negative women.

In women with clinically positive nodes, a needle biopsy diagnosis of metastases prior to surgery avoids the need for sentinel node biopsy and frozen section, saving OR time and costs by proceeding directly to axillary dissection. Axillary dissection should not be performed without histologic confirmation of nodal metastases because physical exam has a false-positive rate of approximately 20%. If the diagnosis of metastases is not confirmed with a needle biopsy, SLNB is appropriate, but care must be taken to remove any palpably abnormal nodes at surgery even if they are not radioactive or blue, since lymphatics that are blocked with tumor cells may not take up the mapping agents.

Axillary lymph node dissection (ALND) remains standard management for patients with clinical N1 disease, after histologic confirmation, regardless of whether they are undergoing mastectomy or breast-conserving surgery (BCS). ALND also remains standard management for clinically node-negative women found to have sentinel node macrometastases who are undergoing mastectomy.

There is more controversy regarding the management of clinically node-negative women having BCS with whole breast irradiation. The American College of Surgeons Oncology Group (ACOSOG) Z0011 trial (2) indicates that women with metastases in one or two sentinel nodes can be managed with no further axillary treatment after SLNB with no decrease in survival and a rate of first failure in the axilla of less than 1% at 6 years follow-up. SLNB alone is associated with significantly fewer side effects than ALND (3). However, there were concerns that patients randomized into ACOSOG Z0011 were an extremely favorable, highly selected subset of women undergoing BCS, and the results of this study were not generally applicable. This concern was addressed in a study at Memorial Sloan-Kettering Cancer Center which prospectively examined an unselected series of patients meeting ACOSOG Z0011 eligibility criteria to determine how often ALND could be avoided. Of 2,157 T1 and T2, clinically node-negative women undergoing BCS between August 2010 and November 2012, 381 (18%) were found to have hematoxylin and eosin detected sentinel node metastases, and 287 met ACOSOG Z0011 eligibility criteria. ALND was performed for metastases in three or more sentinel nodes or for gross extracapsular extension. Only 45 patients (16%) had such criteria for ALND. Patients requiring ALND did not differ significantly from those who did not by median age, nuclear grade, or estrogen receptor (ER) and HER2 status of the tumor. Tumors were significantly larger in the ALND group (2.2 cm vs. 1.6 cm; $p > .001$) (4). These results indicate that most women undergoing BCS who have metastases to the sentinel nodes have involvement of a limited number of nodes and are candidates for management without ALND. Further follow-up is necessary to determine the incidence of axillary recurrence. However, 72% of women selected for ALND on the basis of involvement of more than two sentinel nodes or the presence of gross extracapsular extension had additional involved lymph nodes, while the Memorial Sloan-Kettering Cancer Center nomogram for predicting the likelihood of additional nodal metastases in breast cancer patients with a positive sentinel node biopsy predicted additional positive nodes in only 34% of patients treated with sentinel node biopsy only, suggesting that the selection criteria used for ALND identifies a population of women at risk for a heavier burden of nodal disease. The findings of the ACOSOG Z0011 trial are supported by the results of the International Breast Cancer Study Group (IBCSG) 23-01 trial, which addressed the need for ALND when micrometastases were present in the sentinel node. In spite of 13% of patients in the ALND arm having additional nodal disease, the 5-year rate of the regional recurrence in this study was 1%, although not all patients received whole breast radiation therapy (RT) (5).

An alternative approach to the patient with positive sentinel nodes was raised in the After Mapping of the Axilla: Radiotherapy or Surgery? (AMAROS) trial, which randomized clinically node-negative, sentinel node–positive patients to ALND or axillary irradiation. At a median follow-up of 6.1 years, 5-year rates of regional control did not differ between the two arms (99.5% vs. 99.0%), but fewer side effects were seen in the RT arm, with 28% of ALND patients having lymphedema compared to 14% in the RT arm ($p < .0001$) (6). However, significant side effects of RT, such as brachial plexopathy, evolve over a more prolonged time course than surgical side effects. Therefore, it is uncertain whether this advantage for RT will persist over time, and provides a note of caution for the widespread adoption of this approach.

In aggregate, ACOSOG Z0011 (2), IBCSG 23-01 (5), and AMAROS (6) all suggest that, in the setting of systemic therapy and limited RT, ALND can be avoided in many patients, decreasing morbidity, and with no decrease in survival. In contrast to these results are the findings of the MA.20 trial (7), which indicate that maximal treatment to the regional nodal areas improves disease-free survival (DFS). In this study, clinically node-negative patients with T1 and T2 tumors undergoing BCS and whole breast irradiation were randomized to ALND or ALND plus RT to the axillary apex, supraclavicular, and internal mammary nodes. Eighty-five percent of patients had one to three positive nodes. After a median follow-up of 5 years, both local-regional and distant metastatic recurrences were significantly reduced from 5.5% to 3.2% ($p = .02$), and from 13.0% to 7.6% ($p = .002$), respectively, with nodal RT, and DFS was significantly improved. A trend toward improved overall survival was also observed. These findings were somewhat surprising because in contrast to findings in the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) overview, the absolute reduction in distant metastases seen with RT was greater than the reduction in local-regional recurrence, and it occurred in the same 5-year time interval. (A similar trial conducted by the EORTC should have results in the near future and will help to clarify the MA.20 results.) How to integrate the findings of these somewhat contradictory trials into a unified approach to the axilla and, more generally, to the regional nodes remains a work in progress. At present, it appears that women with sentinel node micrometastases do not require ALND for local control or survival benefit, although caution should be used in patients having mastectomy who are found to have micrometastases in multiple nodes, as data addressing this scenario are limited. Defining which patients with macrometastases can be managed with no ALND and tangent field RT, and which require both ALND and node field RT, is the challenge for the future, but it is unlikely that a single approach will be appropriate for all node-positive patients.

MANAGEMENT SUMMARY

- Sentinel node biopsy is the axillary staging procedure of choice for clinically node-negative breast cancer patients.
- The only contraindications to sentinel node biopsy are inflammatory and other T4 tumors, and pregnancy.
- In patients with clinically positive nodes, needle biopsy should be used to establish a preoperative diagnosis of metastases. If metastases are not confirmed, sentinel node biopsy is appropriate as long as palpably abnormal nodes are removed.
- ALND remains standard management for clinically node-positive women undergoing mastectomy or BCS, and for clinically node-negative women with sentinel node macrometastases having mastectomy.
- Micrometastases in the sentinel node are not an indication for ALND if BCS and RT are being performed, and evidence is accumulating that ALND is not necessary for micrometastases in the setting of mastectomy.
- At least some patients with macrometastases in one or two sentinel nodes undergoing treatment with BCS and whole breast RT do not require ALND. The largest experience with this approach is in ER-positive, HER2-negative women.
- Subsets of women with one to three positive nodes treated with BCS and whole breast RT requiring nodal field irradiation remain to be defined. Consideration of this approach should be given to women with heavier tumor burdens and high-risk features.

CHAPTER 42

Postmastectomy Radiation Therapy

Atif Khan and Bruce G. Haffty

CHAPTER CONTENTS

INTRODUCTION

The use of postmastectomy radiation therapy (PMRT) is perhaps one of the most intensively studied topics in oncology and yet continues to be a cause of considerable debate. Indeed, some of the first ever prospective randomized trials to be conducted addressed the utility of PMRT. This area has attracted robust scientific inquiry since the initial efforts, and has been the subject of over 20 randomized prospective trials. Despite the scientific scrutiny this area has attracted, important questions still remain to be answered.

This chapter will focus on the topic of PMRT and is divided into four sections:

1. In the section on the Rationale for PMRT, we will review the data supporting the efficacy of PMRT as well as the risks and sequelae of PMRT.
2. Patient selection.
3. Reconstruction and PMRT.
4. Technique of PMRT.

The role of PMRT after neoadjuvant chemotherapy and in locally advanced and inflammatory breast cancer is discussed in Chapters 57, 58, and 59, respectively.

RATIONALE FOR PMRT

The principle that irradiating the chest wall and regional lymph nodes after mastectomy can reduce subsequent local-regional recurrences (LRRs) has been well documented by multiple older trials comparing mastectomy alone to mastectomy with postoperative radiation. These trials typically used unsophisticated radiation techniques coupled with outdated radiation treatment machines that produced orthovoltage x-rays, resulting in less precise delivery of radiation to target tissues and increased doses to nontarget normal structures. Naturally, the relevance of these older trials is limited in the context of modern radiation therapy, but they adequately demonstrated two important facts: first, PMRT can effectively reduce the burden of residual local-regional disease, and second, radiation therapy is more comprehensive and more "radical," in terms of treatment volume, than even the most radical surgery. These trials did not demonstrate improvements in survival; benefits in breast cancer mortality may have been offset by nonbreast cancer–related morbidity and mortality associated with the radiation techniques employed (1).

The potential improvement in local-regional control resulting from adjuvant systemic therapy alone can be studied through the numerous trials of systemic therapy versus nil that have reported patterns of failure (2). Data demonstrating a benefit of systemic cytotoxic chemotherapy on local-regional control are somewhat inconsistent, which may be related to the confounding effects of patient selection, surgery and radiation delivery. However, the most recent Early Breast Cancer Trialists' Collaborative Group (EBCTCG) meta-analysis of systemic therapy trials reported statistically fewer isolated local relapses in patients receiving polychemotherapy (recurrence rate ratio of 0.63 and 0.70 for women younger than 50 and 50–69, respectively) (3). Similarly, adjuvant tamoxifen seems to improve local-regional control as corroborated by the last fully reported EBCTCG meta-analysis, which demonstrated an isolated local recurrence rate ratio of 0.47 with tamoxifen versus without (3). These observations, along with the demonstrable improvement in survival with systemic agents, raise the obvious question of the relative additional benefit of PMRT in patients receiving systemic therapy.

Randomized Trials of Adjuvant Systemic Therapy Alone or in Addition to PMRT

Several trials have studied the efficacy and incremental benefit of PMRT in the presence of systemic therapy (2). The most significant contributions have come from the Danish Breast Cancer Cooperative Group (4,5) and the British Columbia Cancer Agency (BCCA) (6). The trials conducted

by these two groups, together with the updated findings of the EBCTCG meta-analysis of radiation trials discussed later (7), have decisively altered practice and reaffirmed the role of PMRT in current breast oncology.

In protocol 82b, the Danish Breast Cancer Cooperative Group randomized premenopausal women with high-risk breast cancer after modified radical mastectomy (total mastectomy and level I and II axillary dissection) to either nine cycles of cyclophosphamide-methotrexate-fluorouracil (CMF) chemotherapy or to eight cycles of CMF chemotherapy and radiation therapy to the chest wall and regional nodes between the first and second cycles of chemotherapy (4). High-risk status was defined as positive lymph nodes, tumor size greater than 5 cm, or invasion of the skin or pectoralis fascia. Radiation therapy was delivered to a total dose of 50 Gy in 25 fractions or 48 Gy in 22 fractions using anterior electron fields to treat the chest wall and internal mammary nodes (IMNs) and a matched anterior photon field to treat the supraclavicular, infraclavicular, and axillary lymph nodes. A posterior axillary photon field was used in patients with a large anterior-posterior (AP) separation. Over 92% of all patients were treated with megavoltage equipment. The study enrolled 1,708 patients between 1982 and 1989. With a median follow-up of 114 months, the irradiated group demonstrated statistically significant improvements in LRR (32% vs. 9%), disease-free survival (3% vs. 48% at 10 years), and overall survival (45% vs. 54% at 10 years). Over half of all LRRs were on the chest wall.

In the companion trial, protocol 82c (5), postmenopausal women younger than 70 with high-risk breast cancer (defined as in 82b) were randomized after modified radical mastectomy to receive either 30 mg of tamoxifen daily for 1 year beginning 2 to 4 weeks after surgery alone or with concurrent radiation therapy delivered to the chest wall and draining lymph nodes. A total of 1,375 patients were recruited between 1982 and 1990 and followed for a median time of 10 years. As in the 82b study, the irradiated group demonstrated statistically significant improvements in LRR (35% vs. 8%), disease-free survival (24% vs. 36%) and overall survival (36% vs. 45%). As in the 82b study, recurrence at all local-regional subsites was lower with PMRT than without. Although these well-designed efforts by the Danish group are not without flaw (as discussed below) they nonetheless strengthened the theory that, in certain patient subsets, aggressive local-regional control could result in improvements in survival end points.

The smaller British Columbia trial enrolled 318 node-positive premenopausal breast cancer patients and randomized them after modified radical mastectomy to either radiation therapy or no additional local-regional therapy (6). Both groups received adjuvant CMF chemotherapy for 12 (first 80 patients) or 6 months. Radiation therapy was delivered to the chest wall to a dose of 37.5 Gy in 16 daily fractions through opposed tangential photon fields. The supraclavicular and axilla nodes were treated with an AP field and a posterior axillary field, with a target midaxilla dose of 35 Gy. Bilateral IMNs were treated with an additional anterior field to a dose of 37.5 Gy in 16 fractions. All treatments were delivered with cobalt machines, between cycle four and five of chemotherapy. After a median follow-up of 20 years, the 20-year survival free of local-regional disease developing before systemic was 61% in the chemotherapy alone arm and 87% in the irradiated group. The irradiated group had statistically significant improvements in 20-year event-free survival (25% vs. 38%), systemic disease-free survival (31% vs. 48%), breast-cancer specific survival (38% vs. 53%), and overall survival (37% vs. 47%). There were slightly more nonbreast cancer deaths in the irradiated group (9% vs. 4%, $p = 0.11$). There were three cardiac deaths (2%) in the irradiated group versus one (0.6%) in the control group ($p = .62$), and 9% of patients in the irradiated group developed arm edema compared with 3% in the control group ($p = .035$). This study corroborated the Danish experience and again demonstrated some of the most remarkable improvements in survival end points ever reported for any adjuvant therapy.

Taken together, these studies demonstrated that certain patient cohorts have a high risk for LRR that is inadequately addressed by systemic therapy alone. Furthermore, reducing the likelihood of LRR can result in improved survival; presumably, persistent or recurrent local-regional disease can be a source of distant metastases and subsequent death. These studies imply that the benefit of systemic therapy is primarily to lower the competing risk of distant micrometastases, and that adjuvant local-regional therapy and adjuvant systemic therapy independently benefit these patients on the principle of spatial cooperation. There is no definitive randomized data supporting any specific sequencing of systemic therapy and radiation in the postmastectomy setting; for patients receiving both cytotoxic chemotherapy and postmastectomy radiation, the prevailing practice typically sequences the cytotoxic chemotherapy first, followed by radiation. Hormonal therapy, if indicated, may be given concurrently with radiation or following radiation, though some clinicians prefer to sequence tamoxifen after the radiation. Although there is little in the way of long-term follow-up data and additional studies will likely be forthcoming in the next few years, adjuvant systemic therapy with trastuzumab (typically administered for up to 1 year following chemotherapy) appears to be safe and effective given concurrently with radiation (8).

EBCTCG Meta-Analysis

The EBCTCG has collected primary data from every randomized trial of adjuvant radiotherapy in breast cancer and periodically reports the ongoing analyses on the benefits and risks of radiation therapy in these patients. The most recent full report from 2005 reviewed data on 9,933 patients enrolled in 25 trials of PMRT, all of which were unconfounded by the use of systemic therapy (7). Node-positive patients who had axillary clearance and received radiation therapy after mastectomy had a 5-year LRR rate of 6%, compared to 23% for unirradiated controls (15-year rates were 8% vs. 29%). In every large trial of PMRT in node-positive women, radiation therapy produced a similar proportional reduction in local recurrence, powerfully demonstrating the comparable efficacy of radiotherapy in achieving local control across all time periods. Even more significantly, PMRT also produced comparable proportional reductions in local recurrence in all women irrespective of age or tumor characteristics.

Absolute reductions in local recurrence were dependent on the absolute risk in the control arm (i.e., larger reductions were seen in subsets with greater risk). For patients with a control risk of local recurrence greater than 10%, the addition of radiation therapy (RT) improved local recurrence irrespective of systemic therapy. For women with node-positive disease who were irradiated after mastectomy and axillary clearance, a 17% absolute improvement in 5-year local control translated into a highly statistically significant 5.4% absolute improvement in 15-year breast cancer mortality (60.1% vs. 54.7%, $2p = 0.0002$, Fig. 42-1) (7), and a 4.4% absolute improvement in 15-year all-cause mortality (64.2% vs. 59.8%, $2p = 0.0009$) over unirradiated controls.

There was an excess cancer incidence in women studied in the EBCTCG report (including women treated with an intact breast), mainly in contralateral breast cancer and lung

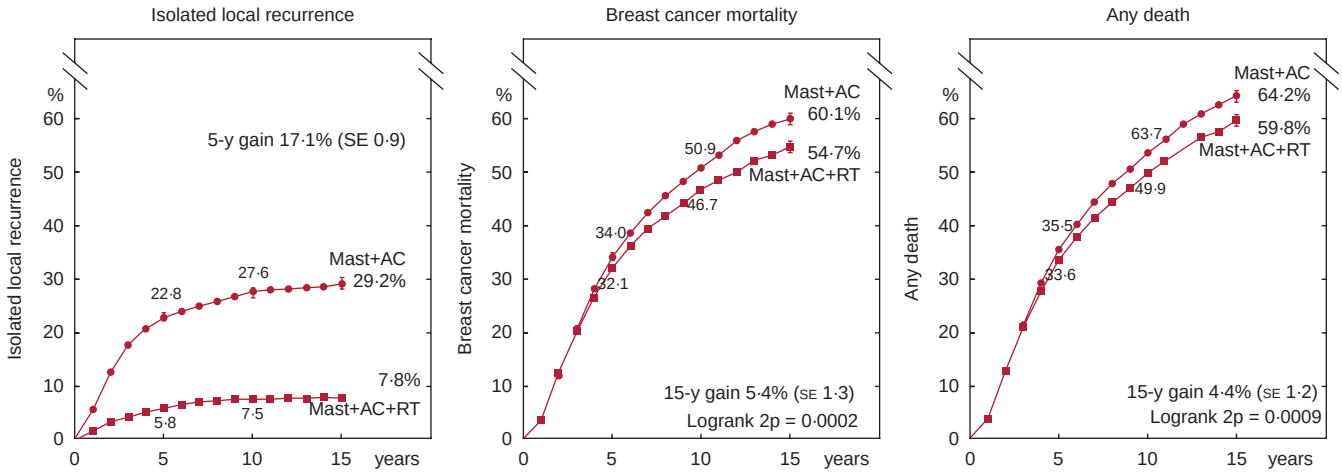

FIGURE 42-1 Probabilities for isolated local recurrence, breast cancer mortality, and any death in node-positive patients treated with postmastectomy radiation therapy after mastectomy and axillary clearance. (Reproduced with permission from Early Breast Cancer Trialists' Collaborative Group. Effects of radiotherapy and differences in the extent of surgery for early breast cancer on local recurrence and 15-year survival: an overview of the randomized trials. *Lancet* 2005;366:2087–2106.)

cancer, and an excess mortality from heart disease and lung cancer. The averaged detrimental effects were modest, with 15-year absolute loss of 1.8% for contralateral breast cancer and 1.3% for nonbreast cancer mortality. Importantly, the proportional excess of nonbreast cancer deaths was greatest 5 to 14 years and more than 15 years after randomization, and the mean dates of randomization for these two groups was 1975 and 1970, respectively. The authors of the EBCTCG correctly point out that the late hazards evident in their report could well be substantially lower for modern radiation therapy technique and regimens.

The EBCTCG data were presented at the 2007 annual meeting of the American Society of Clinical Oncology (9). Since then further analyses have been carried out and prepared for publication (Sarah Darby, personal communication). Although the data are still preliminary, they represent the first detailed analysis of patients stratified both by extent of axillary dissection (at least level II vs. less extensive and by degree of nodal involvement (1–3 vs. 4+), and several pertinent and new findings have been described.

Among women with node positive disease, radiotherapy reduced the rate of any recurrence both for women who had undergone axillary dissection to at least level II (recurrence rate ratio: 0.75, $2p < 0.00001$), and for women who had undergone less extensive axillary dissection (0.59, $2p < 0.00001$), although the proportional reduction was larger in the women who had less extensive axillary dissection ($2p$ for difference = 0.003). In addition, the subgroup of patients with axillary dissection to at least level II and one to three positive lymph nodes had a statistically significant improvement in 15-year breast cancer mortality (death rate ratio irradiated vs. unirradiated: 0.80, 15-year gain 7.9%, 50.2 vs. 42.3%, $2p = 0.01$) with PMRT. This proportional reduction did not differ significantly according to whether or not the trial policy was to give systemic therapy (usually cmf or, for ER+, tamoxifen) in both trial arms.

The cohort of women with axillary dissection to at least level II and four or more positive nodes also enjoyed significant benefits from PMRT in their risk of any recurrence (recurrence rate ratio: 0.79, $2p = 0.0003$) and breast cancer mortality (death rate ratio: 0.87, $2p = 0.04$). In contrast to women with node positive disease, women with node negative disease had no benefit from PMRT either in terms of recurrence (rate ratio: 1.06, $2p > 0.1$) or breast cancer mortality (rate ratio: 1.18 $2p > 0.1$). In summary, the EBCTCG update appears to suggest that women with node positive disease are likely to benefit from PMRT, even when they have had axillary dissection to at least level II and probably also in the presence of systemic therapy.

The EBCTCG overview represents one of the most significant contributions to the study of PMRT. However, the relevance of its findings may be limited by the inclusion of older trials that used fractionation schemes, treatment machines, and treatment volumes that are antiquated by current standards, as well as by the usual limitations of meta-analyses. To address these issues, Van de Steene et al. (10) re-examined the EBCTCG data and identified four factors which selected for significant improvement in the odds ratio (OR) for survival in the irradiated versus control populations: start date of the trial (after 1970 [OR 0.935]), number of patients (>600 patients [OR 0.932]), fractionation (conventional [OR 0.896]), and crude survival on the trial (at least 80% [OR 0.799]). Excluding trials that began before 1970 and trials with small sample sizes produced a significant odds reduction of 12.3% ± 4.3% with irradiation (10). Gebski et al. performed a meta-analysis in which they carefully attempted to control for the quality of radiation delivery in PMRT trials. The authors defined optimal dose as being between 40 and 60 Gy delivered in 2 Gy fractions (nonconventional fractionation schemes were converted to 2-Gy equivalents using bioeffective dose calculations) and appropriate treatment volumes as both chest wall and regional lymphatics (11). The authors reanalyzed data from the EBCTCG applying these criteria. The proportional reduction in local-regional recurrence was greater for trials with optimal dose and volume (80%), compared to those with suboptimal dose (70%) or field design (64%). An improvement in breast cancer mortality was restricted to those trials that used appropriate doses and fields for irradiation (6.4% absolute increase in survival, $p < .001$).

The most concerning risk of PMRT for radiation oncologists is the risk of radiation induced cardiac morbidity. As described above, the EBCTCG meta-analysis as well as other registry data have detected increased risks of cardiac

mortality in irradiated patients (7,12,13). In contrast, an analysis of the Danish postmastectomy trials patients by Hojris et al. (14) found, using a technique of RT that avoided cardiac irradiation, equal rates of ischemic heart disease and acute myocardial infarction in the irradiated and unirradiated group. Approximately 3% of patients in both groups had ischemia-related morbidity at a median follow-up of 117 months and less than 1% of patients in both arms had death due to cardiac causes. There was no difference in this study when comparing left- versus right-sided irradiation. However, these numbers may underestimate the true burden of radiation-related cardiac morbidity due to the competing risk of breast-cancer death in this high-risk population, and also because this study was an unplanned retrospective report on a prospectively studied patient cohort.

Gyenes et al. (15) reviewed 960 patients treated on the first Stockholm Breast Cancer trial (modified radical mastectomy alone vs. preoperative vs. postoperative RT accrued 1971–1976) and reported 58 acute myocardial infarctions (MI) in the study population for a crude rate of 6%. There were no differences in acute MI or death due to cardiovascular disease (n = 63/960) between irradiated and unirradiated patients. Importantly, the authors showed that only patients in the high-dose–volume group had an excess hazard ratio (HR) of cardiovascular death (HR 2, 95% CI, 1.0–3.9, p = .04). A retrospective study by Harris et al. (16) examined cardiac events in a series of 961 women irradiated to the intact breast and reported no interaction between left-sided versus right-sided RT on cardiac mortality or congestive heart disease. A significant interaction was noted between left-sided RT in the subsequent development of coronary artery disease (20-year actuarial risk 25% vs. 10% for right-sided, p <.001) and MI (15% vs. 5%, p <.002). Coexistent hypertension was an independent hazard for the development of coronary artery disease.

A study of the Surveillance, Epidemiology and End Results (SEER) database conducted by Giordano et al. (17) compared 15-year cardiac mortality rates in left- versus right-sided breast cancer as a function of the year of diagnosis in patients who received RT. Presumably, patients with left-sided lesions received more heart irradiation than those with right-sided lesions. Although the authors demonstrated excess cardiac mortality in left-sided breast cancer patients diagnosed between 1973 and 1979 (13% vs. 10%, p = .02), they found no significant difference in patients irradiated in the most recent time periods (~9% for both groups in the 1980–1984 cohort, and 5% to 6% in the 1985–1989 cohort). Beginning in 1979, the hazard of death from ischemic heart disease in left-sided breast cancer patients (vs. right-sided) declined by an average of 6% per year.

In a similar study, Henson et al. (18) evaluated the relative risk (RR) of cardiac disease in women irradiated for left- versus right-sided breast cancer and the relative risk of lung cancer in the ipsilateral versus contralateral lung in women irradiated for breast cancer using the SEER public-use data set. They found that the RR of breast cancer continued to increase, reaching 1.9 (1.52–2.37) 20 years after diagnosis. Similarly, the RR of lung cancer increased continuously in time, peaking at 3.87 (2.19–6.82) for women 20 years after diagnosis. As noted by the study authors, many women in this analysis were treated during an age in which IMN nodal RT was much more common, thus, potentially increasing the toxicity risks compared to contemporary treatment cohorts. Furthermore, current techniques that enhance treatment conformity probably decrease cardiac and lung doses compared to the study cohorts, even when the IMs are treated.

Darby et al. (19) reported a well-executed population-based case-control study of the risks of cardiac irradiation in patients treated for breast cancer. The mean dose to the whole heart was 5 Gy in the control cohort, and each excess Gy in mean dose conferred a 7% RR decrement. Importantly, no threshold dose for risk was detected. Taken together, these data stress the potential for cardiac morbidity and mortality with breast irradiation but are reassuring that routine contouring of the heart and improvements in image-based simulation and treatment delivery can substantially reduce these risks.

Little data exists on the cumulative effects of anthracyclines and radiation therapy on cardiac morbidity and function. Perhaps the best data on this topic comes from Fumoleau et al. (20) who reported long-term cardiac function in 3,577 assessable patients randomized on eight French trials of adjuvant therapy, 2,553 of whom received epirubicin-based chemotherapy. Ninety-seven percent of women on the epirubicin cohort had adjuvant radiation (to the intact breast or postmastectomy) and 94% on the nonepirubicin cohort received RT (with about two-thirds of these receiving RT to the IMNs). The 7-year risk of left-ventricular dysfunction was 1.36% in the epirubicin arm and 0.2% in the nonanthracycline patients. Age 65 or greater and body mass index > 27 kg/m^2 were additional significant risk factors.

Additional nonlife-threatening late risks of postmastectomy irradiation can include arm edema, fibrosis, shoulder stiffness, and brachial plexopathy. In an instructive report, the Danish postmastectomy investigators invited patients irradiated at Aarhus University Hospital who were alive and without evidence of disease to participate in a study of the late effects of PMRT (21). Eighty-four patients accepted the invitation and were eligible for analysis, and these patients were carefully assessed for late toxicity based primarily on LENT-SOMA criteria. More women in the irradiated group had lymphedema (17% vs. 9%) and impaired shoulder movement (16% vs. 2%) that interfered with work or daily activities. Irradiated patients also had more arm parasthesias (21% vs. 7%) and more arm weakness (14% vs. 2%). Only the shoulder function comparison was statistically significant. Symptomatic pulmonary complications were equal in irradiated and unirradiated patients. In a separate report of 161 patients with neurological follow-up who were irradiated on the Danish 82 protocols, 5% of patients had disabling and 8% had mild radiation-induced brachial plexopathies (22). Kuhnt et al. (23) reported acute and chronic reactions in 194 patients receiving PMRT. Twenty-two percent of patients had any incidence of chronic effects, mostly from arm edema (28 of 43). Five patients had telangiectasia and one patient had plexopathy.

In conclusion, randomized trials as well as data from meta-analyses provide a strong rationale for PMRT in patients with a high likelihood of local-regional residual disease, despite the use of systemic therapy in these patients. Additional local-regional therapy in the form of RT reduces LRR rates by a factor of approximately two-thirds, and one breast-cancer death is averted for every four LRR prevented by RT. The risks of PMRT are modest but demonstrable, and cardiac effects may largely be attributable to older technique. The cardiac and pulmonary toxicities of modern day PMRT continue to be evaluated and are likely minimal with careful three-dimensional planning and treatment techniques.

PATIENT SELECTION FOR PMRT

Node-Positive Patients

Node positivity in the axilla is the most significant predictor of LRR after mastectomy. It should be borne in mind, however, that approximately two-third of LRR occur on the

chest wall, and that axillary failures are far less common (24–27). Accordingly, the degree of node positivity should be viewed as an adverse feature that confers a higher risk for overall LRR (i.e., not limited to failure at regional sites).

The Danish and Canadian PMRT trials demonstrated stable relative risk reductions for all events in all groups of node-positive patients. However, the conclusion that all node-positive patients warrant PMRT has been challenged. There are two general criticisms of these studies which limit the generalizing of these findings to all node-positive patients: first, the adequacy of the systemic therapy in the control arms of these studies; and second, the issue of the "background risk" in the relevant study populations.

The most recent EBCTCG meta-analysis of systemic therapy showed a significant but minor improvement for anthracycline containing polychemotherapy regimens over CMF regimens (3). Whether this incremental benefit improves local-regional control as well is unknown and is probably unlikely in patients with high risk for local-regional microscopic residual. Furthermore, neither the addition of taxanes nor increases in the intensity or density of chemotherapy have had demonstrable impacts on local-regional control in node-positive patients, although they do improve survival end points presumably by addressing micrometases (28–33). In sum, it seems unlikely that present-day chemotherapy regimens would significantly alter the findings of the postmastectomy trials. In contrast, the Danish 82c trial treated postmenopausal patients (untested for estrogen-receptor/progesterone-receptor [ER/PR] status) with 1 year of tamoxifen (5), and it is unknown how a longer duration of hormonal therapy in a population known to be hormone-receptor positive would modulate the risk of LRR and thus the benefit of PMRT.

A more significant factor that limits interpretation of the Danish and British Columbia trials is that node-positive patients on the control arm of these trials had higher LRR rates than commonly reported for patients treated in the United States and elsewhere (4–6,24). This difference is especially obvious in patients with one to three positive lymph nodes, who represented about 60% of patients on these studies. In the unirradiated Danish population, the 18-year probability of local-regional recurrence (as first site of failure) was 59% for patients with four or more positive nodes, and 37% for those with one to three positive nodes (34). In the unirradiated Canadian population, the 20-year isolated LRR rate was 41% for patients with four or more positive nodes, and 21% for patients with one to three positive nodes (6). LRR developing any time before distant failure (i.e., cumulative LRR as first failure) was not reported as a function of the number of positive lymph nodes, but was 39% for the entire unirradiated group. In contrast, several large series of patients treated in the United States and elsewhere have reported LRR rates in the range of 6% to 13% for patients with one to three positive nodes (25,26,35,36) (Table 42-1). This seems to indicate that the background risk for LRR in the Danish and BC trials was higher than average, and this may have exaggerated the benefit of PMRT in this population.

Differences in the extent of axillary surgery may partially explain the differences in the risk of LRR in patients with one to three positive nodes. Full level I and II axillary dissections were not performed; a median of seven lymph nodes were removed in the Danish studies and a median of 11 lymph nodes were examined in patients on the Canadian trial (4–6). As such, many of the patients scored as having one to three positive lymph nodes may have actually had four or more positive nodes had full axillary dissections been performed. Tellingly, failure in the axilla either alone or as a component of LRR represented 43% of all LRR in the Danish studies (24), compared to 14% in the data cited above (25).

However, it is important to note that the reports cited above and in Table 42-1 have reported 10-year local-regional control rates. The Danish studies report 18-year recurrence rates, and also document a consistent LRR of about 1% per year between follow-up years 10 and 25 (24). Similarly, in the British Columbia (BC) trial, which has reported 20-year recurrence rates, approximately 20% of LRRs occurred after follow-up year 10 (6). In addition, other identified and unidentified risk factors, such as T4 tumors or pectoral fascia invasion, may have been over-represented in the postmastectomy trials (24), increasing the background risk for local-regional failure. For example, in a combined report of patients with one to three positive axillary nodes treated on the control arm of the British Columbia postmastectomy trial (n = 82) and similar patients treated on prospective systemic therapy trials at the MD Anderson Cancer Center (MDACC) (n = 462), statistically significant differences were detected in patients on the BC trial who were younger (median age 43 vs. 48) and had more lymphovascular invasion (LVI) (52% vs. 33%), in addition to fewer examined nodes (median 10 vs. 16) (37). The resultant 10-year Kaplan-Meier estimates of LRR were 21.5% and 12.6% for the BC and MDACC patients, respectively.

Nonetheless, several reports have demonstrated the prognostic impact of total dissected nodes, nodal ratio (number of involved to uninvolved nodes), and number of total uninvolved nodes on LRR and even overall survival (25,26,35–40). Attempts by Danish investigators to reanalyze their patients to include only those with adequate dissections are limited by the fact that these patients were not stratified by this important risk factor at randomization (41). This issue remains unclear and, because it has complicated the interpretation of the existing postmastectomy trials, can only be addressed in the context of additional large, randomized trials.

Recent reports have demonstrated rather low rates of LRR in patient populations treated with mastectomy and highly active systemic agents alone. These reports challenge the current interpretation of both the PMRT trials and the EBCTCG meta-analysis on the basis of current

improvements in detection, surgical technique, pathological review, and adjuvant therapies. Could the "control" risk for local-regional failure in currently treated patients be much lower than expected from a review of patient data collected decades ago? Sharma et al. (42) at the MDACC reported outcomes in a contemporary cohort of women with T1-2 breast cancer and node-negative or one to three node-positive disease, 1,019 women were treated between 1997 and 2002; 77% of women had adjuvant systemic therapy with a median follow-up of 7.5 years. The local-regional relapse rate was exceptionally low—2.3%. Young age was a significant covariate for LRR on multivariate regression analysis. As with any retrospective analysis, selection biases may have been operant and contributing the low rate of LRR. As pointed out by the study authors, there were few women with three positive lymph nodes in their analysis (<2%) and many women with T1-2N0-1a with adverse features on pathology were likely treated with PMRT, thus selecting for a low-risk group. Nonetheless, the Sharma report offers a tantalizing prospect—perhaps current cumulative improvements in screening, surgery, pathological assessment, and adjuvant systemic therapy combine to significantly reduce the background risk of LR failure. Pointedly, a similar report on identical stage patients treated at MDACC during an earlier time period (1975–1994) had a 10-year LRR of 14% (25).

Still, there is recent evidence that supports an aggressive treatment approach in patients with intermediate-risk presentations. Abdulkarim et al. (43) reported results on a retrospective cohort of triple-negative breast cancer patients (n = 768) and compared outcomes stratified by type of local-regional therapy. Patients who received breast-conserving therapy (BCT) had better local-regional control and better survival than patients who received modified radical mastectomy (MRM) on univariate analysis. On multivariate analysis, initial BCT continued to predict for improved LRR but not overall survival (OS). Interestingly, in the subset of women with T1-T2N0 disease, patients who received BCT had better 5-year local-regional control compared to women who had MRM. Local treatment strategy remained a predictor of LRR on multivariate analysis in this group. One possible explanation is the larger, more comprehensive treatment volume associated with standard radiation fields compared to mastectomy alone. Similarly, Canadian trials have reported preliminary MA.20 results in abstract form. In this trial, high-risk node-negative or node-positive patients were randomly assigned to whole breast irradiation alone or including regional draining lymph nodes after breast-conserving surgery. Results on 1,832 randomized patients were presented at the 2011 annual American Society of Clinical Oncology (ASCO) meeting (44). With a median follow-up of 62 months, the addition of regional nodal RT improved 5-year local-regional control, distant disease control (92.4% vs. 87%, p = .002), and overall survival (92.3% vs. 90.7%, p = .07). Given these data, it appears that a serious discussion of PMRT is *still* warranted in the majority of women with one to three positive lymph nodes on mastectomy.

Both the American Society of Therapeutic Radiology and Oncology (ASTRO) and the ASCO as well as other advisory organizations have endorsed the routine use of PMRT in women with four or more involved nodes and node-positive women with tumors greater than 5 cm, who have a high (>20% to 25%) risk of LRR without RT. Both societies recognize the uncertain benefit of PMRT in patients with T1 or T2 primaries with one to three positive nodes (stage II) in whom the risk of LRR is intermediate (around 10% to 20%) (45,46). The European SUPREMO trial (Selective Use of Postoperative Radiotherapy after Mastectomy) is currently open and will attempt to answer this question. This trial randomizes intermediate risk operable breast cancer (node-positive stage II tumors and node-negative tumors larger than 2 cm with adverse features [high grade or LVI]) to chest wall irradiation or observation after mastectomy.

Several groups have attempted to identify high-risk patients within the one to three positive lymph node group (Table 42-2). Clearly, this group of patients is heterogeneous in terms of various potential clinicopathological factors that may allow differentiation into low- and high-risk cohorts. One of the most significant efforts attempting to identify these risk factors comes from Wallgren et al. (36) who reviewed data on over 5,300 patients enrolled on the first seven trials of the International Breast Cancer Study Group (IBCSG). These trials of systemic therapy required a minimum of eight dissected lymph nodes and negative margins. In patients with one to three involved lymph nodes, premenopausal patients with LVI and grade 3 tumors had cumulative incidence functions (CIFs) exceeding 20% for any LRR. Postmenopausal women with grade 3 tumors and tumors larger than 2 cm had correspondingly high risk. Collapsing this information, premenopausal women with one to three positive lymph nodes had LRR risks ranging from 19% to 27% if they had grade 2 or 3 disease with vascular invasion, but that risk was less than 15% if they had grade 1 disease with no vascular invasion. In a subsequent report, the same group reported results from IBCSG trials 1 through 9 and demonstrated the significant independent impact, in a multivariate model, of the number of uninvolved lymph nodes (38). More specifically, in the group of patients with one to three lymph nodes (n = 2,402), factors that independently predicted a CIF for LRR exceeding 20% included age younger than 40, fewer than 10 uninvolved lymph nodes, and LVI.

The investigators at MDACC have reported results from their cohort of 1,031 patients treated with mastectomy and doxorubicin-based chemotherapy without subsequent radiation therapy on five prospective trials between 1975 and 1994 (25,39,47). Three factors were significant for isolated and total LRR on multivariate analysis of the entire group: T stage, number of involved nodes, and extranodal extension 2 mm or more. Restricting the analysis to patients with T1or T2 disease and one to three axillary nodes (n = 404, overall isolated 10-year LRR risk of 10%), multivariate predictors of LRR were fewer examined nodes, higher T stage, and extracapsular extension (ECE), with isolated 10-year LRR in excess of 25% for patients with gross ECE (33%) and tumor size greater than 4 cm (26%) (25). In a more detailed study of pathologic factors in the same group of patients, Katz et al. (47) reported that close or positive margins and gross multicentric disease were also predictive of LRR on multivariable. However, in the subgroup of patients with one to three positive nodes, invasion of skin and nipple, pectoral fascia invasion, and close or positive margins, but not multicentricity, were significant predictors of higher LRR. In a similar group of patients, Fowble et al. (48) reported that patients with multicentric disease without other strong risk factors for postmastectomy chest wall relapse had a 5-year actuarial risk of an isolated local-regional recurrence of only 8%.

Truong et al. (40) reported on 821 women with T1 and T2 primary lesions with 1 to 3 positive lymph nodes treated with mastectomy and systemic therapy (in 94%) within the BCCA. Twelve putative clinicopathologic factors were examined for their effect on LRR in a multivariate model. Age less than 45, nodal ratio greater than 25%, ER negative status, and medial location independently predicted for isolated and any LRR, with age having the greatest effect (HR = 3.44). The authors suggested using age and nodal ratio as first line discriminants of risk and medial location and ER negative status as secondary factors.

TABLE 42-2

Cofactors Associated with a Greater than 15% LRR after Mastectomy and Chemotherapy in Patients with One to Three Positive Lymph Nodes

Study	*Number of Patients*	*Cofactors*	*End Point*
Wallgren et al. (36)	2,404	• Premenopausal, G2 or G3, LVSI • Postmenopausal, G3 • Postmenopausal, G2, T2 disease	• 10-year LRF ± DF (isolated LRF or with simultaneous DF)
Taghian et al. (35)	2,403	• Age <50, T2 disease	• 10-year LRF ± DF
Recht et al. (26)	1,018	• Premenopausal, T1 disease	• 10-year LRF ± DF (isolated LRF or with simultaneous DF)
Truong et al. (40)	821	• Age <45[a] • 25% of lymph nodes involved[a] • ER negative disease[a] • G3 disease • T2 disease • LVSI • Medial tumor location[a]	• 10-year LRF ± DF (isolated LRF or with simultaneous DF)
Katz et al. (47)	466	• Tumor size >4 cm • Invasion of skin/nipple • Invasion of pectoralis fascia • Close or positive margins	• 10-year LRF ± DF
Cheng et al. (49)	110	• Age <40 • Tumor size ≥3 cm • Presence of LVSI • Adjuvant hormonal therapy	• 4-year LRF ± DF (isolated LRF or with simultaneous DF)

LRF, local-regional failure; DF, distant failure; LVSI, lymphovascular space invasion; ER, estrogen receptor; G2 or 3, grade 2 or 3.
[a]Retain significance on multivariate analysis.

Recht et al. reported on the outcomes of over 2,000 patients enrolled on four randomized Eastern Cooperative Oncology Group (ECOG) studies of systemic therapy. Median follow-up of the entire group was 12 years and 983 patients had tumors 5 cm or less and one to three positive lymph nodes (LNs). In a multivariate analysis of all patients, increasing tumor size, increasing number of positive nodes, ER-negative status and decreasing number of examined nodes were significant independent predictors of LRR (26). Cheng et al. (49) identified 110 patients with one to three positive axillary nodes treated at their institution with modified radical mastectomy and systemic therapy but without radiation, (median number of nodes examined, 17). Sixty-nine patients received adjuvant chemotherapy and 84 received adjuvant hormonal therapy with tamoxifen. On multivariate analysis, only tumor size (<3 cm vs. greater) was significant for LRR. However, the authors found that the four most significant factors on univariate analysis (age < 40 years, tumor ≥ 3 cm, ER-negative disease, and LVI) could segregate patients into a high-risk group (with three or four factors) and a low-risk group (with two or fewer factors). This report had relatively small numbers and short median follow-up (54 months). In a similar Hungarian study, the authors reported on 249 patients with T1 and T2 tumors with one to three positive axillary nodes, half of whom were treated with PMRT (50). Several putative risk factors for LRR were examined in the unirradiated patients on multivariate analysis, and only age (≤ 45 years) and size (T2) emerged as independent predictors of LRR. Finally, Cheng et al. (51) have reported on gene expression profiles that are predictive of LRR after mastectomy, although the number of local-regional events in their patients with 1–3 positive nodes was small. This promising methodology may serve as a valuable tool of risk assessment in the future.

Node-Negative Patients

The most recent EBCTCG overview demonstrated a nominal 5-year local recurrence rate of 6% after mastectomy and axillary clearance in node-negative patients. The addition of PMRT reduced this rate to 2% ($2p = 0.0002$), producing a modest absolute 5-year gain of 4% (7). Given the low overall risk of LRR in node-negative patients, several investigators have attempted to identify subsets within this group with LRR risks high enough to warrant PMRT.

In a multivariate analysis of the IBCSG trial patients discussed above, LVI was a significant risk factor of LRR in node-negative patients, as was size greater than 2 cm in premenopausal node-negative patients (36). Jagsi et al. (52) reported a retrospective analysis of a cohort of 870 node-negative patients (excluding T4 patients) treated with modified radical mastectomy without RT at the Massachusetts General Hospital between 1980 and 2000. A multivariate analysis of several potential risk factors for total LRR revealed four significant independent predictors: margin status (<2 mm), premenopausal status, size (>2 cm), and LVI, with these latter two having the greater hazard ratios (3.8 and 3.2, respectively). Ten-year total LRR rates were approximately 20% with two adverse factors and 40% with three adverse factors. Approximately two-thirds of the patients in this cohort did not received systemic therapy.

Floyd et al. (53) published data on a multicenter effort of 70 patients treated with mastectomy, systemic therapy,

and no radiation for patients with pathological T3N0 disease and reported a 5-year LRR of only 8%. Those who had LVI had a 21% LRR compared to a 4% rate for those without LVI. Taghian et al. (54) reported results on 313 patients with pathological stage T3N0 disease who were treated with mastectomy, systemic treatment, and no radiation on National Surgical Adjuvant Breast and Bowel Project (NSABP) clinical trials. The 10-year LRR for this series was only 7%, with 24 of the 28 LRR developing only on the chest wall.

Truong et al. (55) focused exclusively on patients with T1or T2 node-negative breast cancer treated within the BCCA and extracted clinicopathological data on this cohort from their outcome database. They reported an actuarial 10-year LRR risk of 8% in 1,505 women treated with mastectomy without RT. On logistic regression analysis, grade, LVI, T stage and systemic therapy use were statistically significant independent predictors of LRR. On recursive partitioning analysis, the first split occurred at histologic grade 3 (actuarial 10-year rate of LRR 12% vs. 6%). The concomitant presence of LVI increased the Kaplan-Meier estimate for 10-year LRR to 21% compared to 9% for grade 3 alone. Similarly, Yildirim et al. (56) reported on 502 patients treated with MRM for T1 or T2 node-negative disease in their retrospective study from Ankara Oncology Hospital. With a median follow-up of 77 months, only 3% of patients had LRR. Within these small numbers, multivariate analysis revealed tumor size greater than 2 cm and LVI as predictors for high risk of LRR in women 40 years or younger and tumor size greater than 3 cm, LVI, grade, and HER2 status, and use of tamoxifen in the older women. Ten-year risks of LRR exceeded 30% for younger women with both risk factors, and older women with at least three risk factors.

Margin Status

Margin status is another potential risk factor for LRR in postmastectomy patients. However, information documenting and quantifying the risk of LRR in these patients is scarce because margin issues are uncommon after mastectomy. Furthermore, interpreting the available data is difficult due to the variable definitions of close or positive margins and the small denominators in the handful of existing reports. Perhaps the best effort comes from BCCA who identified 94 women with tumor at the inked margin of resection after mastectomy in their outcomes database (57). Forty-one of these patients received PMRT, while 53 did not, and cumulative crude LRR were 11.3% versus 4.9% in unirradiated and irradiated groups, respectively, with no significant difference between the two groups. Factors that resulted in a cumulative crude LRR of approximately 20% (17% to 23%) without RT were age 50 or younger, T2 tumor size, grade 3 histology, and LVI. The corresponding rates with RT were in the single digits (0% to 9%) but all comparisons were statistically nonsignificant. Also, with a median follow-up time of about 8 years, none of the 22 women with positive margins without these associated features had LRR.

Freedman et al. (58) reviewed 34 patients with close or positive margins after mastectomy whose primary tumor was smaller than 5 cm with zero to three positive axillary nodes and who received no postoperative radiation. Five chest wall recurrences appeared at a median interval of 26 months (range, 7–127 months), resulting in an 8-year cumulative incidence of a chest wall recurrence of 18%. The authors reported a relatively high risk of local relapse among younger women (age 50 or younger) compared to older women (28% vs. 0 at 8 years, $p = .04$). In a multivariable analysis by Katz et al. (47) of factors predictive of LRR in patients treated with mastectomy and chemotherapy without irradiation, close or positive margins were a significant independent predictor of LRR. Although there were only 29 patients available for this analysis, their 10-year LRR was 45%; the risk was 33% for those with pectoralis fascia invasion even when negative margins were achieved.

Childs et al. (59) retrospectively reviewed records on 397 women who were treated at Faulkner Hospital (a Dana Farber affiliate) with mastectomy but without prior induction chemotherapy or PMRT. Fifty-four (14%) of these had positive margins and 68 (17%) had close (<2 mm) margins. The median age was 55 years and the risk profile of the study cohort was quite low. With a median follow-up of 6.7 years, the 5- and 8-year rates of LRR were 2.4% and 4.5%, respectively. The 5-year risk of LRR with a positive margin was 6.2% compared to under 2% for both close and negative margin cases ($p = .04$). Positive-margin status appeared to confer higher risks when combined with other adverse predictors.

Biologic Classifiers and Risk of LRR

Mamounas et al. (60) explored the significance of the Oncotype Dx recurrence score on LRR risk in postlumpectomy and postmastectomy patients enrolled on the NSABP-B-14 and B-20 studies. The Oncotype-Dx assay is a 21-gene expression panel that is a validated discriminator of distant recurrence risk in tamoxifen treated patients. Of 895 tamoxifen treated patients analyzed, 505 were postmastectomy. The LRR rate was 15.8% in patients with a high recurrence score (RS) (95% CI, 10.4–21.2) compared to 4.3% (95% CI, 2.3–6.3). Similar results were noted in the placebo and chemotherapy+tamoxifen cohorts. Multivariate Cox regression analysis confirmed the independent significance of RS. In the subgroup of patients treated with mastectomy ($n = 505$), the LRR rates for low, intermediate and high RS were 2.3, 4.7, and 16.8%, respectively. The RS appeared to consistently discriminate risk in both older (≥50) and younger postmastectomy patients. This hypothesis-generating data is consistent with distant failure validation studies of Oncotype Dx in tamoxifen-treated patients, and demonstrates that LRR rates can even be high in biologically-selected node-negative populations.

Breast cancer can be classified into biologically distinct subtypes (based on gene expression patterns) with varying clinical potential (61). These subtypes can be approximated by assessing expression levels of a handful of markers; prognostic information on metastasis and death is conserved even with these subtype constructs (62). Several groups have examined LRR rates as a function of biologic subtype.

Kyndi et al. (63) retrieved paraffin-embedded tumor blocks for 1,078 patients enrolled on the Danish postmastectomy trials who had at least eight lymph nodes examined. Tissue microarrays were constructed from 1,000 of these patients and then stained with standard immunohistochemical methods for ER, PR, and HER2. Successful IHC for all three markers was achieved in 996 patients. The median follow-up of surviving patients was 17 years. In their multivariate analysis, triple-negative status, and receptor-negative or HER2 positive (HER2 driven) were prognostic for LRR and overall mortality. HER2 driven phenotype was outperformed only by nodal status as a risk for all end points (LRR, DM, and mortality). In the subgroup of patients randomized to observation after mastectomy ($n = 510$), triple-negative tumors were associated with inferior overall mortality, DM rate, and LRR probability. HER2 tumors were associated with mortality and DM but not LRR. In patients who received PMRT ($n = 486$), triple-negative status continued to be

associated with worse LRR, but not survival or metastasis rate. Indeed, in patients who received PMRT, triple-negative status, and HER2 enriched status were the strongest associations with LRR, exceeding even nodal status and tumor size. Perhaps most startlingly, PMRT only appeared to benefit patients with favorable biologic subtypes (constructed Luminal A) with no statistical improvement in mortality for patients with Luminal B, triple-negative, and HER2 subtypes. Although LRR was improved with PMRT in all subgroups, except the HER2 enriched subtype, the relative reductions were higher in the luminal subtypes (HR 0.06–0.09) than in triple-negative subtype (HR 0.33).

The Kyndi report is provocative and requires careful thought and interpretation. Foremost, the subset numbers are limited in their power to detect differences. For example, the Luminal B (HR+, HER2+) curves appear divergent and have an HR of 0.65 (0.40–1.04, $p = .07$). Still, the results of the paper are hard to ignore and counterintuitive—the benefit of PMRT appeared to be somewhat restricted to favorable subtypes. It is plausible that hormone-negative and HER2-driven tumors had preexisting micrometastases that were insufficiently treated with the available systemic therapy and the limitations of the study design (hormonal therapy with tamoxifen was guided by patient age rather than receptor status on trial 82c, trastuzumab was not available, etc.). Additional agents that can be delivered with PMRT may perhaps benefit some of these patients.

Voduc et al. (64) analyzed biologic subtype as a predictor of local-regional recurrence in a cohort of over 4,000 women treated in the BCCA system. Fifty-eight percent of these women (n = 1492) were postmastectomy patients. Basal and HER2 positive subtypes predicted for higher rates of local and regional failure in both postlumpectomy and postmastectomy cohorts. In the postmastectomy patients, all non-luminal A subtypes were found to be independent predictors of chest wall and regional nodal failure on Cox multivariate analysis. The 10-year local relapse-free survival for Luminal A patients was 92% while the regional relapse-free survival was 96%. The corresponding rates were 86% and 88% in Luminal B patients, 83 and 88% for HER2 enriched, and 80% and 81% for basal subtype.

Dominici et al. (65) reported on a cohort of 819 patients who underwent mastectomy at the MDACC. Most of these patients received systemic therapy at the discretion of their treating oncologists—none received PMRT. The majority of patients were either T1 (75%) or N0 (72%). Approximately 27% of patients (219 of 819) had one to three positive lymph nodes. With a median follow-up of 58 months, the 5-year risk of LRR was only 2.5%. Patients with triple-negative tumors had a 10.9% incidence of LRR, which was higher than other phenotype constructs ($p < .01$). On multivariate analysis, having four or more positive lymph nodes and triple-negative status were the strongest predictors of LRR. Triple-negative status and either lymph-vascular space invasion or lymph node positivity increased risk of LRR at 60 months to 30% and 23%, respectively.

Using a three-marker classification, Billar (66) retrospectively analyzed recurrence rates by constructed subtype in a cohort of 1,061 patients of whom 35% were mastectomy patients. Local or regional recurrence developed more frequently in patients with "triple negative" phenotype (5.7%) compared to HER2+ (2.9%) and ER+ (1%), $p = .001$.

Albert et al. (67) also used a three-marker system to assess the prognostic value of molecular subtype for local-regional control in a retrospective cohort of 756 patients treated at the MDACC. Notably, they restricted their cohort to patients with small, node-negative tumors (T1a-b, N0). Approximately 38% of these patients were treated with mastectomy. With a median follow-up of 6 years, the 8-year LRR rates were 5.8% for triple-negative, 3.5% for hormone+/HER2– (Luminal A), 13.4% for hormone+/HER2+ (Luminal B), and 29% for hormone–/HER2+ (HER2 enriched). There were only 26 patients at risk in the hormone–/HER2+ patients. Likewise, there were only eight events in the mastectomy group, making a subgroup analyses impossible.

Finally, Wang et al. (68) successfully completed a multicenter randomized trial in China evaluating the benefit of PMRT in triple-negative breast cancer patients. Six-hundred and eighty-one women were randomly assigned to receive either no further treatment or 50 Gy in 25 fractions to the chest wall or regional lymph nodes after a mastectomy and systemic chemotherapy. With a median follow-up of 86.5 months, patients who received PMRT fared much better than patients randomized to observation in both 5-year relapse-free (74.6% vs. 88.3%) and overall-survival rates (78.7% vs. 90.4%). The Wang trial is notable for its randomized design and its strict inclusion of stage I and II patients. All patients had tumors that were no larger than 5 cm, and over 60% were node negative. Sixty-two percent were 50 or younger.

Taken together, these data strongly suggest that PMRT can reasonably be considered for most women with triple-negative or basal subtype cancers. In our opinion, these data nonetheless do not warrant routine PMRT.

RECONSTRUCTION AND PMRT

Many women desire breast reconstruction after mastectomy, and this presents a commonly encountered challenge in the management of these women should they also require radiation therapy. A multidisciplinary collaboration is warranted in which the surgical oncologist, reconstructive surgeon, and radiation oncologist confer with each other and with the patient to ensure an optimal aesthetic outcome without compromising the proven benefits of timely PMRT.

Breast reconstruction efforts can generally be categorized as either implant-based or autologous tissue reconstructions. In addition, reconstructions can occur at the time of the mastectomy (immediate reconstructions) or at some time after mastectomy, usually after the completion of radiotherapy (delayed reconstructions). Implant-based approaches are simpler to perform, avoid the potential morbidities associated with the donor site, and can be offered to thin women who do not have adequate autologous tissue in potential donor sites. A tissue expander is placed between the chest wall musculature and serially inflated until an appropriate tissue envelope is created, at which time the expander is replaced with a permanent prosthesis. Typically, implant-based reconstructions occur immediately after mastectomy because normal tissues can become less compliant after radiation, making tissue expansion problematic.

Autologous reconstructions are commonly performed using a transverse rectus abdominus myocutaneous (TRAM) flap. Alternatively, a latissimus dorsi flap or a flap based on the deep inferior epigastric perforator (DIEP) artery or gluteal arteries can be used for the reconstruction. These reconstructions can be immediate or delayed. In general, immediate reconstructions are accompanied by a skin-sparing mastectomy, thus preserving sensate skin and a natural inframammary sulcus for the reconstruction. The important advantages of an immediate reconstruction are offset by the potential adverse effects of radiation therapy on the reconstruction, and the negative impact the reconstruction can have on the design and delivery of PMRT.

PMRT can result in high rates of contracture, fibrosis, and poor cosmesis in patients who have immediate implant-based reconstructions. Spear et al. (69) reviewed the data on 40 consecutive patients who had undergone a two-stage saline implant reconstruction followed by RT and compared their outcomes to 40 controls. Fifty-three percent of irradiated reconstructions had complications compared to 10% in controls, including a 33% capsular contracture rate in the irradiated patients compared to zero in the controls (p <.00005). Krueger et al. (70) reviewed data on 19 patients who had expander/implant (E/I) reconstructions and radiation therapy and found that 13 (68%) had complications, compared to 19 of 62 (31%) in unirradiated controls (p = .006). In contrast, the group at Memorial Sloan Kettering Cancer Center (MSKCC) has reported results for their patients treated on an institutional algorithm of E/I reconstructions followed by PMRT and reported excellent disease control, no delays, and good to excellent aesthetic results in 80% of cases (71). Ho et al. (72) recently updated results from 151 patients treated with PMRT at MSKCC after exchange of a tissue expander with a permanent prostheses. With a median follow-up of 86 months, the 7-year rates of implant replacement and removal were 17% and 13%, respectively. Disease-related outcomes were consistent with uncompromised control. Others have demonstrated that immediate autologous reconstructions are associated with somewhat lower complications rates compared to prosthetic reconstructions (73).

Tran et al. (74) compared complication rates in immediate versus delayed TRAM reconstructions in patients who received PMRT. Twenty-four of 32 patients in the immediate reconstruction group had contracture, compared to 0 of 70 in the delayed reconstruction group (p <.0001). Furthermore, 28% of the patients with immediate reconstruction required an additional flap or prosthesis to improve cosmesis. In an attempt to reconcile the benefits of immediate and delayed reconstructions, Kronowitz et al. (75) have published on the "delayed-immediate" breast reconstruction wherein patients have a skin-sparing mastectomy, with preservation of sensate skin, and subpectoral placement of a tissue expander (75). After final pathology is reviewed, those patients not requiring PMRT go on to have an "immediate" (within 2 weeks) autologous reconstruction, while the remainder have a delayed autologous reconstruction after RT. The expander is kept inflated throughout chemotherapy and then deflated before PMRT.

Breast reconstruction can alter the contour of the chest wall in a way that makes delivery of radiation to the necessary target volume much more challenging. In a recent report, Motwani et al. (76) reviewed 112 radiation plans designed to treat postmastectomy breast reconstructions and found that 52% of these required compromises in field design due to geometrical constraints imposed by the reconstruction (33% were scored as moderate compromises and 19% major compromises). Only 7% of similar plans in matched controls had compromises due to patient anatomy (p <.0001). In contrast, the group at MSKCC has demonstrated excellent coverage in a series of 40 patients with E/I reconstructions treated with intensity modulated radiation therapy (IMRT) (77).

TECHNIQUE OF PMRT

Treatment Volume, Dose and Prescription

The volumes at greatest risk for recurrence, the chest wall and the supraclavicular lymph nodes, should always be included. However, a case can be made for omitting the supraclavicular/high axilla lymph nodes in patients with high-risk node-negative breast cancer, due to the low risk of regional failure reported in these patients (52,54). The entire mastectomy flaps, inclusive of the mastectomy scar and drain sites, should be treated. Most commonly, a monoisocentric photon technique is used whereby opposed tangent split beams are employed for chest wall irradiation and are matched at isocenter to a superior AP supraclavicular field. The medial border is typically at midsternum and lateral border is at the mid- or posterior axillary line as clinically indicated. The inferior edge is 2 cm inferior to the level of where the inframammary fold existed. The contralateral breast (if it is intact), can be used to estimate the level of the inframammary fold. The superior border of the chest wall fields serves as the match plane and should be marked at the palpable inferior edge of the clavicular head. The gantry angles on the tangent fields are then designed as is done in conventional intact breast tangents, with half-beam or asymmetric-jaws technique to limit posterior divergence into the lungs. Ultimately, the isocenter should be at mid-separation (SAD technique) along a straight line connecting the medial and lateral wires through the central ray of the symmetrical tangents. Typically, 2 to 3 cm of lung in the tangents is required for adequate coverage of the chest wall. The isocenter is then translated cranially to the match plane, ensuring that the geometry of the tangents remains stable. Collimator rotations on the tangent fields (to correct for the slope of the chest wall) can be avoided by opening the jaws on the lung side of the tangents by 2 to 3 cm and adding a superior lung block to ensure 2 to 3 cm of lung throughout the long axis of the tangent beams-eye view. This eliminates the need to correct for the angulation of the cranial edge and simplifies the isocentric match with the supraclavicular field. If the length of a patient's torso makes coverage of the chest wall impossible with half of the available beam length, the tangent jaws can be opened (symmetrically or asymmetrically) and couch rotations can be performed for each tangent to create a straight nondivergent cranial edge for the tangent fields. Simple trigonometric calculations can be performed to calculate the required couch rotation, or the rod-and-chain technique can be used. All of these steps can be reproduced virtually on image data acquired at the time of a CT simulation, and fields designed as described above. Alternatively, the entire chest wall can be treated with electrons, but variations in patient thickness and slope can make optimal dosimetry difficult with this technique. In particular, transmission into lung has to be carefully accounted for. CT planning should be strongly considered for all left-sided lesions, and dose to the cardiac volume should be tracked and constrained. If the heart is placed anteriorly, the medial chest wall can be treated with an anterior electron field which is matched to shallower chest wall tangents. The target dose to the chest wall is 45 to 50 Gy in conventional 1.8- to 2-Gy fractions. Dose can be prescribed 1.5 cm from the posterior edge of the tangents at midseparation or at one-third of the distance from this point to the anterior skin. Alternatively, dose can be normalized to a treatment isodose line covering the target volume. Ideally, the treatment volume should be homogenous for dose, with acceptable ranges within 95% to 107% of prescription dose. Contributions from 15 MV photons should be minimized and bolus placement should be considered to ensure superficial coverage. Forward-planned IMRT, electronic compensation, and inverse-planned IMRT can be important tools for the radiation oncologist to consider in meeting treatment objectives if the conventional techniques described above result in suboptimal dosimetry. Notably, both the START A and B randomized trials of

hypofractionation allowed PMRT patients, and no special toxicity concerns were noted (including the risk of brachial plexopathy) (78,79). The Cancer Institute of New Jersey and the Huntsman Cancer Institute are accruing patients to a prospective phase II trial of hypofractionated PMRT that is expected to complete enrollment in 2014.

The supraclavicular field is typically an AP photon field with the upper border above the AC joint (or just flashing the skin), medial border at the vertebral pedicles and lateral border at the coracoid process in patients who have had complete axillary dissections. Alternatively, the lateral border can be placed to include the medial two-thirds of the humeral head if the axilla is undissected or inadequately dissected. Strom et al. (80) found that in their population of well-dissected axillae (median number = 17), failures in the low and midaxilla were uncommon (10-year actuarial rate 3%).The AP supraclavicular field is prescribed at a depth of 3 cm by convention, although in the age of the CT planning, an alternate anatomically defined depth can be used provided the superficial entrance dose remains acceptable. Six MV photons are typically used, although higher energies are reasonable to consider. A posterior axillary boost (PAB) can be designed to supplement dose to the axillary apex if the contribution from the AP supraclavicular field to the midplane is inadequate. The depth of the supraclavicular prescription point can be altered to increase the midplane dose; the depth of the supraclavicular and high axilla nodes are often similar (81). Many centers are now routinely contouring axillary nodal stations as well as the supraclavicular nodal target, and this practice can be very helpful in treatment planning. Commonly, 50 Gy prescribed to the supraclavicular volume will result in 40 to 45 Gy to the axillary apex without need for a PAB.

Inclusion of IMNs is widely variable because of the conflicting data on the benefits and risks of irradiating these nodes. Although microscopic involvement of IMNs can be high (82), especially in patients with positive axillary nodes and medial tumors, IMN failures are exceedingly unusual (0.1% in the ECOG experience) (26). Furthermore, the benefit of routinely irradiating (or dissecting) the IMNs has never been proven, although it has not been tested in well-controlled studies. Advocates of IMN irradiation correctly point out that the postmastectomy radiation trials discussed earlier did include the IMNs. This issue will not likely be settled at least until the results of ongoing randomized trials of regional nodal irradiation are mature. If the IMNs are to be included, several techniques have been described, and these were compared by Arthur et al. (83) in a dosimetric study (83) The partially-wide tangents technique, in which the tangents blocks are altered to deepen coverage in the upper three intercostal spaces (Fig. 42-2), resulted in the least amount of incidental heart and lung irradiation. A popular technique not compared in this study is a 5 to 6 cm wide electron patch matched to the entry point of the medial tangent and tilted to a gantry angle 5 to 15 degrees less than the medial tangent (Fig. 42-3). Nine or 12 MeV electrons can be employed to treat at the requisite CT defined depth. At 80 to 90% of prescribed dose, acute skin reactions may necessitate substituting the electron field with a photon field in the same geometry to allow skin sparing. The target dose is 45 to 50 Gy.

The area around the scar is commonly boosted with an additional 8 to 12 Gy with electrons. An electron "cut-out" can be created to treat a 2- to 3-cm margin around the mastectomy scar and/or drain sites. In patients with complex scar geometry or extensive chest wall curvature (especially after reconstruction) a creative way to avoid the uncertainty of matching electron fields is to create a customized thermoplastic surface applicator with embedded afterloading catheters for remote high-dose rate delivery of dose (84).

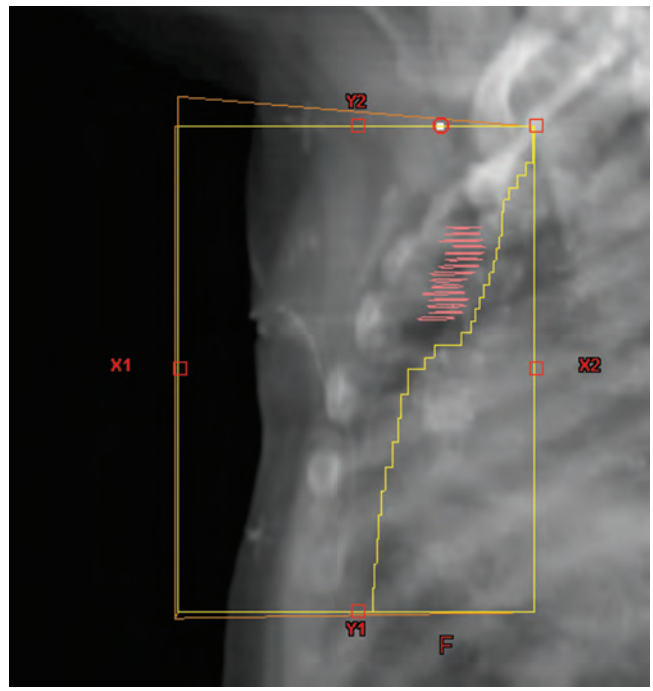

FIGURE 42-2 Beam's eye view reconstruction of a partially wide tangent field.

The quality of radiation treatment plans can be judged by prespecified dose-volume histogram parameters that correlate with disease control and/or tissue toxicity thresholds. The upcoming RTOG1304/NSABP-B51 randomized study of treatment volume after induction chemotherapy calls for 95% of the prescription dose delivered to 95% of the planning target volume (PTV), no greater than 30% of the lung receiving greater than 20 Gy, and no greater than 5% of the heart receiving greater than 25 Gy in left-sided cases. The mean heart dose should not exceed 4 Gy.

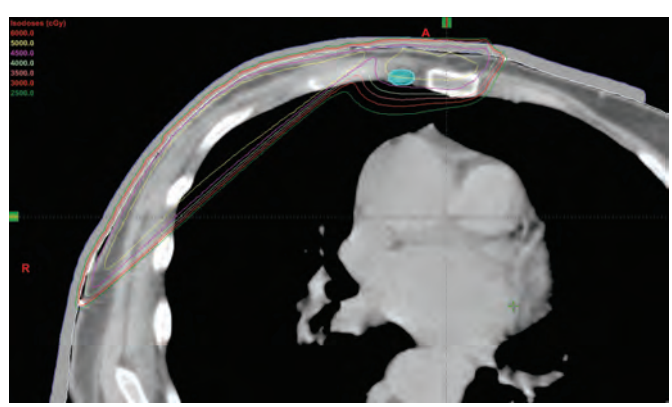

FIGURE 42-3 Axial view of isodose lines produced from a postmastectomy radiation treatment plan employing tangents and a matched electron strip angled toward the medial tangent.

MANAGEMENT SUMMARY

PMRT improves local-regional control, breast cancer-mortality, and all-cause mortality in appropriately selected patients.

In order to improve local-regional control, PMRT should be recommended for all patients who have a projected LRR rate of 20% or greater. This includes patients with four or more involved axillary nodes, patients with one to three involved nodes and a primary tumor larger than 5 cm, and patients with T4 disease (skin involvement, and/or involvement of the chest wall).

Patients with T1 or T2 disease and one to three involved nodes have an intermediate-risk of recurrence (10% to 20%) and should be considered for PMRT if they have less than 10 nodes removed, a nodal ratio greater than 0.20, age less than 45, positive margins, high grade tumors, or LVI. More recent data suggests that these patients might derive the most survival benefit from PMRT.

- Node-negative patients generally have low rates of LRR, including those with T3N0 LVI-negative disease. PMRT can be considered in patients who have at least three of these additional adverse features: young age, histologic grade 3, LVI, and T2 size.
- Adverse tumor biology as indicated by either triple-negative phenotype or high recurrence score on Oncotype Dx assay should be considered, along with other risk factors, as potential indications for PMRT.
- In assessing the survival benefit of PMRT, it is important to consider competing risks of mortality. Patients with a very high risk of DM and older patients derive less benefit from PMRT than patients with fewer competing risks.
- Adjuvant systemic therapy decreases LRR and efforts are underway to assess the survival benefit of PMRT in the context of increasingly-effective systemic therapy.
- In devising radiation fields, CT planning for left-sided cases is very important. The heart should be contoured and the mean cardiac dose limited.
- For patients desirous of reconstruction, a multidisciplinary collaboration is warranted in which the surgical oncologist, reconstructive surgeon, and radiation oncologist confer with each other and with the patient to ensure an optimal aesthetic outcome without compromising the proven benefits of timely PMRT.

CHAPTER 43

Adjuvant Systemic Therapy: Endocrine Therapy

Mothaffar F. Rimawi and C. Kent Osborne

CHAPTER CONTENTS

INTRODUCTION TO ADJUVANT ENDOCRINE THERAPY

Breast cancer causes death because of metastases in distant sites that gradually grow and cause organ dysfunction. In patients with early breast cancer these metastases are not clinically apparent (small numbers of individual or clumps of malignant cells can sometimes be found in the bone marrow or circulating in the blood by research techniques) and are referred to as micrometastases. Since clinicians cannot precisely identify which patients harbor micrometastases and which do not, decisions concerning the administration of systemic therapy, like endocrine therapy or chemotherapy, to kill these occult cells are difficult, and overtreatment with potentially toxic "micrometastatic eradication therapies" is therefore common. Nevertheless the conceptual change in the 1970s that micrometastases were present early on in many patients and that they were ultimately the cause of cancer death when treatment was confined to local treatment alone, led to a large number of clinical trials of adjuvant systemic therapy given either after (adjuvant) or before (neoadjuvant) local therapy. These trials confirmed the idea that micrometastases are present in many patients by the time of diagnosis and that systemic therapy to eradicate them markedly improves disease-free and overall survival of patients. Late recurrences do occur, sometimes decades after treatment of the primary tumor, particularly in patients with ER-positive breast cancer. These very late recurrences are not common but they raise questions about whether ER-positive breast cancer is ever really eradicated. Alternatively, micrometastases may lie dormant only to become reactivated later by some unknown factor(s) or they grow so slowly that it takes decades for them to become apparent.

Widespread use of systemic adjuvant chemotherapy, endocrine therapy, and, most recently, biological therapy has contributed to the continuing reduction in breast cancer mortality rates seen since 1990. Rates have declined 2% per year for the past 20 years and show no hint of stabilizing as further improvements are made in prevention, earlier diagnosis, and treatment.

The first randomized trials of breast cancer adjuvant endocrine therapy were initiated more than 50 years ago and investigated adjuvant ovarian ablation (1). Trials of the antiestrogen tamoxifen were initiated in the mid-1970s. In the late 1990s, trials of aromatase inhibitors were initiated

in postmenopausal patients since they had shown to be slightly more effective than tamoxifen in metastatic breast cancer. The current decade will be recognized for additional trials of aromatase inhibitors (AIs) and tamoxifen combined with other therapies designed to block alternative escape pathways that can cause resistance to ER-targeted therapy. An early example is the combined use of trastuzumab together with endocrine therapy in HER2 (*ERBB2*)-positive, ER-positive tumors. Other inhibitors of growth factor signal transduction molecules such as mTOR inhibitors are just entering adjuvant trials in patients with ER-positive tumors. Finally, this decade will enhance our ability to more accurately predict which patients have micrometastases and need systemic therapy and then to select the best therapy for such patients by comprehensive molecular profiling of both the patient and their tumor.

EARLY BREAST CANCER META-ANALYSES OF ADJUVANT THERAPY

Given the large number of randomized adjuvant therapy trials of different systemic therapies some are likely to be misleadingly promising whereas others misleadingly negative, solely by the play of chance, especially if they are small. One method of overcoming these pitfalls is the overview or meta-analysis technique. This combining of data from multiple trials enables meta-analyses to reliably detect modest advantages for one treatment over another and thereby correct false-negative results produced by small randomized trials. The meta-analyses, undertaken by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) use data from individual patients from all adjuvant trials, thereby allowing detailed and comprehensive analyses on tens of thousands of breast cancer patients.

BIOLOGY OF ENDOCRINE THERAPY

Endocrine therapy of breast cancer represents the first molecularly targeted therapy for cancer. The success of this approach provided a strong rationale for the development and testing of other targeted therapies. All endocrine therapies target the ER protein, which is present in 60% of premenopausal and 75% of postmenopausal breast cancers. The progesterone receptor (PR) has not been utilized as a treatment target itself, but a growing body of evidence suggests an important role for PR signaling in breast cancer development, implicating its potential as a target for prevention and treatment.

Estrogen receptor is a nuclear transcription factor (see Chapter 26). After the binding of estrogen, ER is phosphorylated, homodimerizes with another receptor molecule, recruits coregulatory proteins (CoA), and the receptor complex then binds to target genes at specific estrogen response elements (EREs) in their promoters (2). ER can also be phosphorylated and thereby activated by other signaling pathways in the absence of estrogen, a process called ligand-independent activation (2). Such tumors would not likely respond to estrogen deprivation therapy like aromatase inhibition. There are two estrogen receptors, alpha and beta (2). The function and role of ERβ in breast cancer is not totally defined, although several studies suggest that when it is present in abundance it may signal a tumor more likely to benefit from tamoxifen (3). When ERα (which will be called ER in this chapter) is bound by estrogen, it activates transcription of specific genes and inhibits transcription of others (genomic activity). Some of these induced genes encode proteins important for tumor cell growth and survival and, consequently, therapies designed to block this pathway have therapeutic benefit. Evidence also suggests that in some breast cancer cells, a small pool of ER is located outside the nucleus perhaps tethered to the cell membrane. This nonnuclear ER mediates the so-called nongenomic or rapid effects of estrogen to activate various growth factor pathways, among them epidermal growth factor receptor (EGFR), HER2, and insulin-like growth factor receptor (IGF1-R) (2). Receptor tyrosine kinase pathways, cellular stress, and the microenvironment can modulate ER activity and function by phosphorylation of the receptor and its coregulatory proteins. In this way ER itself can function as a coactivator by binding to other transcription factors such as AP-1 or NFkB or by binding to other sites on DNA to initiate transcription of a different set of genes.

All endocrine therapies target the classical ER pathway in one way or another. Ovarian ablation (surgical or medical) and AIs lower the level of estrogen, thereby reducing the ligand-dependent activation of ER signaling, both genomic and nongenomic. Selective ER modulators, such as tamoxifen and toremifene, bind ER just like estrogen, but they alter ER conformation in a slightly different way than estradiol (4). These drugs demonstrate dual estrogen agonist and antagonist activity depending on the tissue, cell or gene context. Thus, tamoxifen behaves as an estrogen in the endometrium, bone, liver, and even on some genes in the breast, whereas for other genes in the breast, tamoxifen functions as an antagonist to inhibit estrogen-dependent transcription. Growing evidence suggests that this intrinsic agonist activity of tamoxifen and other selective estrogen receptor modulators (SERM) may be higher in some patient's tumors than in others owing to activation of the ER and its coactivators by other cell survival pathways, potentially causing loss of tamoxifen's antagonist activity and resulting in *de novo* or acquired resistance (2,5). Additionally, tamoxifen acts as an agonist on nongenomic ER signaling, which may also be a cause of tamoxifen resistance in some patients.

Pure antagonists or ER downregulators (e.g., fulvestrant) bind ER, but have no intrinsic agonist activity. Furthermore, they induce degradation of ER and theoretically would be effective in tumors in which ligand-independent ER activation is present such as in tumors with active growth factor receptor signaling. This class of agents has not yet been studied in the adjuvant setting, although the steroidal antiestrogen, fulvestrant, when used at a dose of 500 mg monthly, is slightly more effective than the AI anastrozole in metastatic breast cancer (6). ER degraders like fulvestrant deserve clinical trials in the adjuvant setting.

ADJUVANT THERAPY WITH SELECTIVE ESTROGEN RECEPTOR MODULATORS

Tamoxifen is the most commonly prescribed SERM for the treatment of breast cancer. Toremifene, a drug with structural and functional similarities to tamoxifen, appears equally effective to tamoxifen but is prescribed far less frequently (7). Raloxifene is approved for the prevention but not for the treatment of breast cancer. These drugs are nonsteroidal compounds that bind to ER and display both estrogen antagonist and estrogen agonist properties. Although the agonist properties of this class of endocrine therapy may account for resistance in some patients (see above), they also account for the favorable effects in preserving bone mineral density in postmenopausal women and the favorable effect on blood lipid profiles (8,9), both attractive features in postmenopausal women for whom estrogen

replacement therapy is inappropriate. The net result of the binding of tamoxifen to ER in the cancer cell is a blockade of cell cycle transit in G1 phase and modest induction of apoptosis, thereby inhibiting tumor growth (10,11).

Because of its favorable toxicity profile and its activity in advanced breast cancer, tamoxifen entered clinical trials of adjuvant therapy in the mid to late 1970s. More than 70 randomized clinical trials of tamoxifen including 20 trials of 5 years of tamoxifen involving 21,457 patients were included in the most recent meta-analysis (12). The early trials focused on postmenopausal patients, although a few included some premenopausal patients. Most of these studies included both node-positive and node-negative patients, although a large trial from the National Surgical Adjuvant Breast and Bowel Project (NSABP) studied node-negative patients exclusively (13). Both ER-positive and ER-negative patients were included in many of the earlier studies because it was thought by some that tamoxifen might still have a beneficial effect even in tumors lacking ER expression. Nearly all of the early studies found a statistically significant disease-free survival (DFS) advantage for tamoxifen, but only two large studies, the NATO (Nolvadex Adjuvant Trial organization) Trial and the Scottish Trial, showed a significant overall survival (OS) advantage (14,15). A survival trend in favor of tamoxifen was found in most of the other trials.

The 2011 meta-analysis of tamoxifen confirms both a DFS and OS advantage for ER-positive patients treated with tamoxifen for 5 years (Table 43-1) (12). The recurrence rate ratio (RR) of tamoxifen versus control was 0.53 during the first 4 years and 0.68 during years 5 to 9 meaning that tamoxifen reduced the risk of recurrence by about half during the time the patient was taking the drug and by about a third during the first 5 years after stopping tamoxifen. There was no further reduction in recurrence during years 10 to 14. The RR for tamoxifen in patients also receiving chemotherapy was 0.67 while in those treated with tamoxifen alone it was 0.56. Thus, tamoxifen combined with chemotherapy offers significant benefit compared to chemotherapy alone. In contrast to recurrence, mortality was reduced by about a third in all time periods including years 10 to 14. This *carryover* effect of tamoxifen has not yet been explained, but there continues to be significant reductions in recurrence and death for many years after the drug is stopped. It has also been reported in trials of AIs as well and may be owing to a greater proportion of "cured" patients in the endocrine therapy groups. It should also be mentioned that the outcome data from these trials is an underestimate of the true benefit possible with these agents given the high nonadherence rates over the 5-year treatment durations reported in several studies.

Tamoxifen in Premenopausal and Postmenopausal Patients

Earlier meta-analyses suggested that tamoxifen had no benefit in women younger than age 50 (16,17). Because of the inclusion of women with ER-negative tumors, and because the duration of tamoxifen treatment was usually only 1 or 2 years in these early trials, definitive conclusions could not be drawn. Later meta-analyses indicated that more prolonged treatment (approximately 5 years) results in a significant benefit in women younger than 50 years, as well as in older women, so long as their tumors are ER positive (18). The recently updated meta-analyses confirm these results (Table 43-2) (12). Patients younger than 45 years of age, most of whom are premenopausal, benefit in terms of recurrence and mortality from 5 years of tamoxifen nearly as well as those 55 years of age and older. The benefits found with 5 years of tamoxifen in younger women, along with the lack of benefit with the shorter durations used in earlier studies, strongly suggest that longer treatment is very important in this age group. These data also indicate that the tamoxifen dose used in these studies can inhibit breast cancer cells even in the presence of the much higher than normal serum levels of estrogen typically found in premenopausal patients taking the drug.

Thus, with more than 30 years of follow-up from many studies involving thousands of patients, it is certain that if tamoxifen is given for 5 years to patients selected on the basis of ER status, it is effective in both younger and older women. It is also important to emphasize that the differences in outcome between tamoxifen and no tamoxifen observed after 5 years of follow-up grow even larger during the next 5 years, indicating that the benefits of tamoxifen are very durable over time (12).

Tamoxifen in Node-Negative and Node-Positive Patients

No biological reason exists for women with axillary node-negative ER-positive breast cancer to benefit differently from adjuvant tamoxifen therapy than those with positive nodes, and many trials of adjuvant tamoxifen included both node-negative and node-positive patients. Fewer recurrences and deaths overall in the node-negative subset make it more difficult to show significant reductions with tamoxifen, but strong trends were evident early on in the larger studies (14,19). NSABP trial B-14 is by far the largest of the initial

TABLE 43-1

Results of Five Years of Tamoxifen in Patients with ER-Positive Tumors by Years of Follow-Up

Ratios (treatment vs. control) of the Annual Event Rates		
Years	*Recurrence (p-value)*	*Mortality (p-value)*
0–4	0.53 ± 0.03 (<.00001)	0.71 ± 0.05 (<.0001)
5–9	0.68 ± 0.06 (<.00001)	0.66 ± 0.05 (<.0001)
10–14	0.97 ± 0.10 (NS)	0.68 ± 0.08 (<.0001)

trials of adjuvant tamoxifen (2,644 patients), and it focused on patients with histologically negative axillary nodes (19). Both patients younger than 50 years of age (820 patients) and older patients (1,824 patients) were eligible, and all patients had ER-positive disease. Patients were randomly assigned to receive placebo or tamoxifen for 5 years, and those who received tamoxifen were reassigned at 5 years to stop therapy or to continue for 5 additional years.

Women who received tamoxifen had a significantly higher probability of being free of local and distant recurrences (78% vs. 65%, $p < .0001$) and survival (71% vs. 65%, $p = .0008$) than with placebo. Tamoxifen-treated patients also had fewer ipsilateral breast, local-regional, and distant recurrences than placebo-treated patients, and they had a substantial reduction (approximately 50%) in contralateral breast cancer. These benefits persist beyond 15 years of follow-up (19).

The most recent meta-analysis also suggests that the benefit of adjuvant tamoxifen is similar for node-negative and node-positive patients (12). The reductions in the odds of recurrence were 40%, 36%, and 44% for patients with negative nodes, one to three positive nodes, or four or more positive nodes, respectively. The estimated 10-year recurrence rate for node-negative patients was 19% with tamoxifen in the absence of chemotherapy and 35% without tamoxifen, while the recurrence rate for node-positive patients was 42% with and 57% without tamoxifen. Thus, the cumulative data confirm that tamoxifen improves recurrence and survival in both node-negative patients, who have a substantially lower baseline risk of recurrence and death, and in node-positive patients.

Tamoxifen in Different Hormone Receptor Expression Subgroups

Many of the early tamoxifen adjuvant trials included patients with ER-negative or ER-poor as well as ER-positive and ER-unknown tumors. These studies helped assess the potential benefits of tamoxifen in both subsets. The results are difficult to interpret, however, because of varying definitions of *ER-positive* and *ER-negative,* concerns about assay quality, and because only a fraction of the patients in some of these early studies had ER assays performed.

Earlier meta-analyses found a small but statistically significant survival benefit in women with ER-poor tumors treated with adjuvant tamoxifen, but the most recent meta-analyses with longer follow-up and a larger sample size do not (12). Patients with ER-poor tumors, a subset that includes tumors with undetectable or borderline-positive ER (4 to 9 fmol/mg protein by ligand-binding assay), showed no reduction in the annual odds of recurrence or death. For unclear reasons patients with ER-negative first tumors who are treated with adjuvant tamoxifen have no reduction in contralateral breast cancer either. Women with tumors known to be definitely positive for ER had a 39% reduction in the annual odds of recurrence and a 38% reduction in contralateral breast cancer when treated with tamoxifen for 5 years. Interestingly even patients with tumors expressing only low levels of ER (10 to 19 fmol/mg protein) had a significant reduction in recurrence from tamoxifen (Table 43-3). Why tumors with only a small fraction of cells expressing ER by either ligand binding or IHC benefit from adjuvant endocrine therapy remains a mystery. It is possible that other cells in the tumor have low ER levels undetectable by standard assay but still sufficient to affect gene transcription. Alternatively, cells not expressing ER at the time of the biopsy might express it later due to cell cycle variation in expression or other factors. Higher ER levels were associated with a greater risk reduction. The ligand binding assay is no longer used for clinical ER measurements but very low ER levels detected by IHC have also been associated with tamoxifen benefit (20).

TABLE 43-3

Results of Five Years of Tamoxifen by ER Level

	Ratios of the Annual Event Rates ± SE
ER Level (fmol/mg protein)	*Recurrence*
<10	NS
10–19	0.67 ± 0.08
20–29	0.70 ± 0.10
30–49	0.77 ± 0.08
50–99	0.62 ± 0.07
100–199	0.52 ± 0.07
≥200	0.52 ± 0.07

Older studies when ER was measured by ligand binding. The ratio for all ER-positive when ER was measured by other methods mostly IHC is 0.64 ± 0.06. (Adapted from Early Breast Cancer Trialists' Collaborative Group. Relevance of breast cancer hormone receptors and other factors to the efficacy of adjuvant tamoxifen: patient-level meta-analysis of randomized trials. *Lancet* 2011;378:771–784.)

The College of American Pathologists suggests that a cutoff of greater than 1% positively staining cells be used to define ER-positivity by IHC (21). This committee also provided technical guidelines in an attempt to standardize the entire procedure to reduce the high error rate observed in many studies. This procedure should be followed closely to obtain quality results for patient care. The role of PR in predicting benefit from tamoxifen adjuvant therapy or in predicting relative benefit of tamoxifen compared to aromatase inhibitors is more problematic. The assay itself has changed over time from ligand binding to IHC and has not been as well standardized as that for ER. Also PR, as an estrogen-regulated gene product, is affected by the level of estrogen circulating in blood and therefore would be expected to be higher in premenopausal women and postmenopausal women on hormone replacement therapy at the time of breast cancer diagnosis. PR might be negative in women who have been postmenopausal for some time and who are not taking estrogen replacement therapy even if the ER signaling pathway is intact. In the meta-analysis, among women with ER-positive tumors, the efficacy of tamoxifen was independent of the concentration of PR (18). Studies of patients with metastatic disease have shown consistently that patients with ER-negative, PR-positive tumors, although uncommon, benefit from tamoxifen and other endocrine therapies and that those with ER-positive, PR-negative tumors respond less well than those positive for both receptors. There is level-one evidence from a prospective clinical trial in patients with metastatic breast cancer treated with tamoxifen demonstrating the independent predictive role of PR expression (22). And, there are retrospective data from a very large patient cohort with receptor assays done in a single reference laboratory suggesting that PR does predict benefit from tamoxifen adjuvant therapy (23). But this has not been confirmed in the meta-analysis or in the ATAC or BIG 1-98 adjuvant trials (18,24,25). Nor has PR level correlated with selective benefit of either tamoxifen or an aromatase inhibitor in these comparative trials.

Therefore at the present time PR should not be used as a predictive marker for adjuvant endocrine therapy response, although its loss does correlate with a more aggressive luminal B subtype of breast cancer. This issue is discussed in detail in Chapter 26.

It is clear, however, that when the assays are done properly, patients with ER- and PR-negative tumors do not benefit from tamoxifen adjuvant therapy or any endocrine therapy that blocks the ER pathway. Nor do they benefit with a reduction in contralateral breast cancer (see above). On the other hand, patients even with a low but detectable level of ER in their tumors do benefit from tamoxifen and other forms of endocrine therapy, which should be an important component to their treatment.

Tamoxifen for Longer Than Five Years

Because tamoxifen has predominantly antiproliferative effects it was hypothesized early in its use that it might need to be given indefinitely in the adjuvant setting. However, early trials did not show an advantage for continuing tamoxifen beyond 5 years and in fact, two trials showed slightly worse outcome (19,26). This lack of benefit for more prolonged tamoxifen in these two trials persisted at 14 and 15 years of follow-up, respectively. These trials were small and not definitive leading to more recent trials with larger patient accrual. The aTTom trial in the United Kingdom randomized 7,000 patients, many of unknown ER status, to stop or continue tamoxifen to 10 years and recently reported long-term results. Its results a significant benefit for extending tamoxifen beyond 5 years (27). In late 2012 the ATLAS Trial (Adjuvant Tamoxifen: Longer Against Shorter) reported 15-year data (28). This trial randomized 12,894 women between 1996 and 2005 to stop tamoxifen at 5 years or to continue to 10 years; 6,846 of these patients had known ER-positive tumors. Among these patients, continuing tamoxifen to 10 years significantly reduced recurrence (p = .002), breast cancer deaths (p = .01), and overall mortality (p = .01). The relative risk (RR) for continuing tamoxifen was less impressive during years 5 to 9 than after 10 years (0.9 vs. 0.75, respectively) perhaps due to the known carryover effect of just 5 years of tamoxifen during years 5 to 9 (Table 43-4). A reduction in breast cancer mortality for extended tamoxifen was only seen after 10 years (RR = 0.97 vs. 0.71). The cumulative risk for recurrence during years 5 to 14 for extended tamoxifen was 21% compared to 25% for patients stopping at 5 years. The risk of breast cancer death during years 5 to 14 was 12% for continued tamoxifen compared to 15% for the control group.

TABLE 43-4

ATLAS Trial Results

RR (10 years vs. 5 years) of Annual Event Rates		
Years	*Recurrence*	*Mortality*
5–9	0.9 (0.79–1.02)	0.97 (0.79–1.18)
	p = .10	p = .74
10+	0.75 (0.62–0.90)	0.71 (0.58–0.88)
	p = .003	p = .001

Tamoxifen 10 years versus stopping at 5 years.
Adapted from Land LH, Dalton SO, Jensen MB, et al. Influence of comorbidity on the effect of adjuvant treatment and age in patients with early-stage breast cancer. *Br J Cancer* 2012;107(11):1901–1907.

Mortality without breast cancer recurrence overall was not affected by continuing tamoxifen for 10 years. Known tamoxifen side effects were higher in women assigned to 10 years of tamoxifen but these were counterbalanced by favorable effects. Relative risks for pulmonary embolus (1.87) and endometrial cancer (1.74) were higher but mortality was minimally affected. There was no increase in stroke and there was a significant reduction in ischemic heart disease (0.76, p = .02) for continuing tamoxifen. These data offer a new option for ER-positive patients being treated with adjuvant tamoxifen, and appropriately selected ER-positive patients should be considered for 10 rather than 5 years of treatment. Low-risk patients for whom the extra benefit of continuing tamoxifen beyond 5 years would be minimal might stop at 5 years while higher-risk patients should be considered for extended treatment. This strategy would have the greatest appeal for premenopausal patients who are still treated predominantly with tamoxifen. However, given that fewer than 10% of the ATLAS study population was premenopausal raises a small concern about young patients, although there is no legitimate reason why they would not also benefit from more prolonged therapy.

Tamoxifen in Elderly Patients

Adjuvant therapy is more problematic in elderly patients because of comorbidities more common in these patients that can cause death before breast cancer recurrence (29). The meta-analysis demonstrates a significant mortality reduction in patients older than 70 years treated with adjuvant tamoxifen (Table 43-2) (12,18). Furthermore, some individual trials have specifically targeted this population. The Eastern Cooperative Oncology Group (ECOG) study randomized 181 patients 65 years of age or older to tamoxifen or placebo for 2 years (30). The drug was well tolerated, and significant reductions in recurrence and borderline significant reductions in mortality were observed. Tamoxifen also reduced the incidence of contralateral breast cancers. Surprisingly, most of the older patients who died in this study (61%) succumbed to breast cancer, although, as anticipated, a significant number of them (22%) died of competing illnesses not related to cancer. Nonadherence to the prescribed dose and schedule of tamoxifen, which is relatively high overall, is even higher in elderly patients (31).

The ATAC and TEAM trials comparing tamoxifen with an AI evaluated comorbidities and age on death without recurrence (32,33). In the TEAM trial evaluation of disease-specific mortality, as a proportion of all-cause mortality, showed that 78% of deaths in patients less than 65 years of age were due to breast cancer, while in patients between 65 and 74 years or those 75 or greater, 56% and 36% of deaths, respectively, were due to breast cancer (32). Interestingly breast cancer recurrence and disease-specific mortality increased with age but other-cause mortality increased even more dramatically with age with a sevenfold increase in patients 75 years or greater. The increase in disease-specific mortality with age is not explained but could be due to inclusion in the trial of elderly patients with more aggressive disease. Similar findings were observed with longer follow-up in the ATAC trial (33).

Several small, randomized trials have also evaluated the use of tamoxifen as sole treatment without surgery for operable primary breast cancer in elderly patients (34,35). In one study with 20-year follow-up there was no difference in time to distant metastases or overall survival between tamoxifen alone and mastectomy alone as initial treatment despite the fact that the patients were not selected by ER (35). These findings were confirmed in a large Cochrane review of 7 trials

of 1,446 elderly women unselected by ER (36). This analysis found no difference in overall survival between surgery alone without or with tamoxifen, or tamoxifen alone as initial therapy. Hormonal therapy as a single modality with tamoxifen or an aromatase inhibitor might be reserved for elderly patients not suitable for surgery for temporary disease control. Because these patients have a relatively high risk of thromboembolic complications, an AI may be preferable in debilitated elderly patients in need of treatment, although AIs have not been tested in this setting.

Delayed Adjuvant Endocrine Therapy

Although a rare situation today, the question whether patients could still benefit from adjuvant hormonal therapy, even if initiated years after their primary treatment, remains important for a small subset of patients. One study addressed this question and found that patients who had ER- or PR-positive tumors, and whose adjuvant therapy with tamoxifen was started 2 years or more after initial diagnosis, had improved DFS and OS, even when the delay in starting *adjuvant* tamoxifen was more than 5 years (37). Thus, those patients whose tumors are receptor positive and who, for whatever reason, were not started on adjuvant hormonal therapy at the time of diagnosis may still benefit from delayed treatment. It is likely that a similar benefit would be also seen with AIs, although no studies have addressed this topic. However, the remaining risk of recurrence in such patients should be considered. Patients with a low risk at the time of diagnosis may have an extremely low risk of recurrence at the time of initiating endocrine therapy late, not justifying the side effects of therapy if several years have elapsed since diagnosis.

ANCILLARY BENEFITS OF TAMOXIFEN

Although we think of tamoxifen as an antiestrogen because of its antiproliferative properties in the breast, it is more appropriately classified as a SERM because it has estrogen agonist properties in many tissues and on certain genes, while it has estrogen antagonist properties on others. These unique dual activities of tamoxifen provide additional potential benefits for women taking the drug, although the agonist activity may cause other side effects and may also be a cause of resistance.

Serum Lipids and Mortality from Cardiovascular Causes

Side effects and deaths from other causes from tamoxifen have been addressed in meta-analyses of 5 years of tamoxifen treatment and in studies comparing tamoxifen and an aromatase inhibitor. The 2005 meta-analysis showed a reduction in all-cause and in breast cancer mortality with tamoxifen (18). Non–breast cancer mortality was similar for tamoxifen and no tamoxifen. There was a borderline statistically significant increased risk of stroke and a similar reduction in deaths from heart disease, primarily myocardial infarction, with tamoxifen. Long-term follow-up of the Cancer Research UK "Over 50s" trial comparing five with 2 years of tamoxifen showed a striking reduction in cardiovascular disease in women aged 50 to 59 that lessened as patients became older (38). Similar data were observed in a Swedish trial (39). Data from the placebo-controlled NSABP tamoxifen prevention trial (Breast Cancer Prevention Trial [BCPT]) provides additional information regarding cardiovascular mortality (40). At 4 years of follow-up, a shorter time frame compared to the other cancer trials, this study found no differences between tamoxifen and placebo in fatal myocardial infarction, nonfatal myocardial infarction, unstable angina, or severe angina. One possible explanation for differences in cardiovascular mortality might be the variable use of lipid lowering agents for hypercholesterolemia, a hypothesis that can be tested with available data.

Bone Mineral Density

Tamoxifen has estrogen agonist properties in bone. In postmenopausal women, long-term tamoxifen treatment increases the bone density of the axial skeleton and stabilizes the bone density of the peripheral skeleton (8). In premenopausal women, however, tamoxifen may decrease bone mineral density by antagonizing the more potent activity of endogenous estrogen (41). Although evaluating osteoporotic fracture rates in patients with a diagnosis of breast cancer is problematic, prevention trials of tamoxifen do show a significant reduction in fractures with 5 years of treatment (42). There is a marked reduction in fractures in trials comparing tamoxifen with an aromatase inhibitor (43).

Contralateral Breast Cancer

Individual clinical trials in patients with invasive breast cancer, as well as the updated meta-analysis, indicate a nearly 50% reduction in the risk of contralateral breast cancer after approximately 5 years of tamoxifen treatment (18). As described above, there is no reduction in contralateral breast cancer with tamoxifen if the original tumor is ER-negative. Continuing tamoxifen to 10 years compared to 5 years further reduces the risk of contralateral breast cancer, RR 0.88 (0.77–1.00, $p = .05$).

TOXICITY OF TAMOXIFEN

In general, tamoxifen is well tolerated by most patients with breast cancer. In one of the largest randomized, placebo-controlled trials, 7% of tamoxifen-treated patients and 5% of placebo-treated patients withdrew from the study early for reasons that were possibly related to toxicity (42).

Menopausal Symptoms

The most frequently reported side effects in patients taking tamoxifen are menopausal symptoms (44). At least 50% to 60% of these women report some hot flashes, but 40% to 50% of placebo-treated patients report similar episodes. Tamoxifen may cause hot flashes more commonly in premenopausal women than in older women. Approximately 20% of patients report severe hot flashes while taking tamoxifen compared with 3% of patients on placebo. Vaginal discharge and irregular menses are also slightly more common in patients taking tamoxifen than in those receiving placebo. In one study, however, general quality of life scores were similar for tamoxifen and placebo (44). Headaches were reported less frequently with tamoxifen. The incidence of nausea, arthralgias, insomnia, restlessness, depression, and fatigue was similar with tamoxifen and placebo in this study. In the BIG 1-98 trial hot flushes and night sweats were more common with tamoxifen than with letrozole but vaginal dryness was more common with the aromatase inhibitor (Table 43-5) (25,45).

Depression is not increased in randomized, placebo-controlled trials, but this may reflect underreporting of symptoms that may be brought out by more careful and detailed questioning. A nonrandomized, single-institution study suggests that symptoms of depression can be identified in up to 10% of patients taking tamoxifen (46). Symptoms

Cerebrovascular events	1.0	1.0	NS
Venous thromboembolic event	1.5	3.5	<.001

[a]*p*-value not reported. Adapted from Coates AS, Keshaviah A, Thürimann B, et al. Five years of letrozole compared with tamoxifen as initial adjuvant therapy for postmenopausal women with endocrine-responsive early breast cancer: update of study BIG 1-98. *J Clin Oncol* 2007;25(5): 486–492.

are occasionally severe and may require antidepressant medication or even discontinuation of tamoxifen. Failure to identify depression as a side effect in placebo-controlled trials suggests, however, that discontinuation of estrogen replacement therapy or stress from the recent diagnosis of a potentially fatal disease may be causally more important than tamoxifen itself.

The detailed analysis of depression in women on the BCPT adds additional insight on this topic (47), although the women in a prevention trial may not accurately represent breast cancer patients who are diagnosed with a life-threatening disease and have more reason for depression. Nevertheless, no difference was seen in depression by treatment assignment (tamoxifen vs. placebo) in this study, suggesting that tamoxifen itself does not increase the risk of, or exacerbate, existing depression in women.

Although the diagnosis of depression may not be more common in women taking tamoxifen compared with other forms of treatment, depression is still a common and often overlooked condition in breast cancer patients, and the symptoms may be attributed to other causes.

Sexual Dysfunction

Sexual dysfunction is also common in breast cancer survivors, whether they are on endocrine therapy or not. Vaginal dryness, dyspareunia, and decreased sexual desire are common complaints. Vaginal discharge is a common symptom with tamoxifen. In addition to moisturizers, vaginal estrogen cream is often very helpful in women on tamoxifen in whom the systemic absorption of estrogen in these preparations is not of concern. Tamoxifen saturates ER systemically and is effective even in premenopausal patients with high estrogen levels. These problems tend to be much more severe and difficult to treat in women on aromatase inhibitors. Even small amounts of estrogen absorbed systemically could bind and activate ER and, then counteract the beneficial effects of the treatment on breast cancer recurrence. Clearly, more research is needed to evaluate the safety and efficacy of various treatments to improve these non-life-threatening but disabling side effects. Management of menopausal and gynecologic problems in breast cancer patients is also discussed in Chapter 51.

Thromboembolic and Hematologic Toxicities

An increased incidence of thromboembolic events has also been reported from studies of tamoxifen adjuvant therapy in patients with breast cancer as well as from tamoxifen prevention studies in high-risk women (42,48). This complication occurs more frequently when tamoxifen is combined with chemotherapy, and initiating tamoxifen after chemotherapy may decrease this problem. Most patients reported with this complication have superficial phlebitis and do not require hospitalization. Severe thromboembolic phenomena occur in less than 1% of patients given the drug. Deaths caused by thromboembolism have been reported, however, in patients with cancer and in healthy women in the prevention trials. In the ATLAS trial the risk of pulmonary embolism was increased with longer tamoxifen compared to 5 years, but mortality was infrequent and was similar in both groups (28). The risk of thromboembolic events in the BIG 1-98 trial was significantly greater on tamoxifen than letrozole but grades 3 to 5 were uncommon in both, 2.2% versus 1.3%, respectively (25). Nearly identical data were observed in a meta-analysis (43). The thromboembolic risk is especially high in women on tamoxifen having surgery, itself a risk for blood clotting, for an unrelated problem. Perhaps interrupting tamoxifen for a few weeks before surgery and during the surgical recovery period would be prudent. The 7-day half-life of the drug requires a relatively prolonged interruption before surgery. Thrombocytopenia and leucopenia have also been reported with tamoxifen, but are unusual and rarely require cessation of therapy.

Endometrial and Other Cancers

Tamoxifen use, much as with estrogen therapy, is clearly related to an increased incidence of endometrial cancer (18). Even just 1 year of adjuvant tamoxifen is associated with a slightly increased incidence, but the risk rises with more prolonged treatment. Eight-year follow-up of NSABP B-14 in which 2,843 patients were randomly assigned to receive at least 5 years of tamoxifen or placebo indicates that tamoxifen was associated with an annual hazard rate of 1.7 per 1,000, a relative risk of 2.2 compared with population-based rates of endometrial cancer from Surveillance

Epidemiology and End Results (SEER) program data (49). The type of endometrial cancer in patients taking tamoxifen is similar to that in patients not exposed to tamoxifen. Of the 23 cancers in NSABP B14, 18 were of low histologic grade, and most were stage I. Four patients died of uterine cancer, however, indicating the lethal potential of this complication and the need for early identification of symptoms, especially vaginal bleeding. The risk of endometrial cancer with tamoxifen is related to the duration of therapy and is higher in obese women and women who have received prior hormone replacement therapy (50). This was confirmed in the ATLAS trial. The cumulative risk of endometrial cancer was 3.1% with continued tamoxifen and 1.6% for patients treated with 5 years (28). Mortality, however, was very low in both arms, 0.4% versus 0.2%, respectively.

The role of endometrial cancer screening by vaginal ultrasound or endometrial biopsy and the role of progestins in reducing the risk of endometrial cancer have been reported (51,52). Routine transvaginal ultrasound did more harm than good in one study because of its false-positive rates, the requirement for additional tests, and increased iatrogenic morbidity. Neither transvaginal ultrasound nor regular screening endometrial biopsies at 6-month intervals was effective in diagnosing endometrial cancer. These procedures are not justified in asymptomatic patients, but should be considered in women presenting with abnormal bleeding. It is not yet clear whether systemic or intrauterine progestins are beneficial in this setting. An increased incidence of endometrial cancer has also been observed in the BCPT prevention trial in women without breast cancer, but all of the cases reported had a very favorable histology and the one death from endometrial cancer at the time of the report was in the placebo arm (48). Increased endometrial thickness and the incidence of hyperplasia, polyps, and ovarian cysts are increased by tamoxifen.

Tamoxifen is also a potent hepatocarcinogen in the rat, but not in the mouse. Although abnormal liver function tests, fatty liver, and massive liver steatohepatitis, rarely with cirrhosis, have been reported in patients receiving tamoxifen, only a few anecdotal cases of hepatoma have been reported thus far, and the incidence of hepatoma unrelated to hepatitis infection since the introduction of tamoxifen has not increased (53).

Data from individual trials, the meta-analysis and the ATLAS trial indicate that tamoxifen adjuvant therapy has not yet resulted in an increased incidence of other solid tumors (18,28). Specifically only three cases in each arm of liver cancer were seen in the ATLAS trial and there was no increase with prolonged tamoxifen of colorectal or other solid tumors. Long-term follow-up of the ATAC trial showed a higher incidence of death for endometrial cancer, melanoma, and ovarian cancer, but a lower incidence of death for colorectal and lung cancer on the tamoxifen arm (54). All of these events were uncommon. Raloxifene, another SERM with efficacy similar to tamoxifen in breast cancer prevention but less effective in breast cancer treatment, is not associated with an increased risk of endometrial cancer.

Cerebrovascular Disease

There was no increased risk of cerebrovascular disease with prolonged tamoxifen in the ATLAS trial (28). In the meta-analysis of the trials comparing tamoxifen with an aromatase inhibitor this side effect was uncommon, 1.4% on an aromatase inhibitor compared to 1.5% on tamoxifen (43). Finally, the BIG 1-98 and long-term follow-up of the ATAC studies also showed a low incidence of cerebrovascular disease that was not different between tamoxifen and the aromatase inhibitor (25,54).

ADJUVANT THERAPY WITH AROMATASE INHIBITORS

Aromatase inhibitors block the synthesis of estrogen in tissues containing the enzyme. The enzyme is present in breast tumor tissue, fat, muscle, and brain and it converts androgens of adrenal origin to estrogens. There are two classes of aromatase inhibitors that have slightly different mechanisms of action and different mechanisms of resistance leading to incomplete cross-resistance. The nonsteroidal aromatase inhibitors, including anastrozole and letrozole, bind aromatase in a reversible manner (55). Steroidal aromatase inhibitors such as exemestane form an irreversible complex (55,56). Patients with metastatic breast cancer progressing on a nonsteroidal aromatase inhibitor may respond occasionally to treatment with exemestane (56,57).

All of these drugs lower serum and tumor estrogen to very low levels. Although there are modest differences in the degree of aromatase inhibition among these agents, it is not clear whether they translate into differences in clinical benefit (58). Aromatase inhibitors are generally ineffective in premenopausal women. The reduced feedback of estrogen to the hypothalamus and pituitary increases gonadotropin secretion, which stimulates the ovary, leading to an increase in androgen substrate and aromatase (59). Therefore, it is imperative that women who receive aromatase inhibitors are verifiably postmenopausal.

It should probably be avoided in women with chemotherapy-induced amenorrhea as they may still have premenopausal estradiol levels and others may start menstruating again when therapy with an aromatase inhibitor is initiated due to rising gonadotropin levels (FSH and LH), which can stimulate the ovary (60). These women are better off receiving tamoxifen at least initially while they are observed for resumption of menses. Gonadotropins and estradiol levels should be followed as well in such women.

Several large randomized phase III clinical trials incorporating aromatase inhibitors in the adjuvant treatment of breast cancer have been completed (Table 43-6). These studies generally followed one or more of three different strategies: upfront treatment with an aromatase inhibitor compared to upfront tamoxifen; switching to an aromatase inhibitor after initial tamoxifen treatment for 2 to 3 years; or using aromatase inhibitors to extend adjuvant treatment after 5 years of tamoxifen.

Initial Therapy with Aromatase Inhibitors

The ATAC (Arimidex, Tamoxifen, Alone or in Combination) trial was the first large randomized trial to report on the use of an aromatase inhibitor in the adjuvant treatment of breast cancer. In this trial, 9,366 patients were initially randomized after surgery to receive anastrozole, tamoxifen, or their combination. However, the combination arm was discontinued at 33 months of follow-up after this group was found to be equivalent to tamoxifen alone and inferior to anastrozole monotherapy (61). This trial first reported an advantage in DFS for the anastrozole treated group over the tamoxifen-treated group in 2002 and several updates have confirmed this benefit (61,62). At a median follow-up of 100 months, an updated analysis of the ATAC trial of the 6,241 patients randomized to anastrozole versus tamoxifen showed a continued DFS benefit for anastrozole (61). This advantage was observed in all randomized patients (intent-to-treat population) and in the hormone-receptor-positive subgroup, which comprised 84% of all patients on this study. In this subgroup the DFS (HR 0.85, $p = .003$), time-to recurrence (TTR) (HR 0.76, $p = .0001$), and time-to-distant-recurrence (TTDR)

TABLE 43-6

Adjuvant Trials with Aromatase Inhibitors

Study	*Experimental Arm*	*No. of Patients*	*Median Follow-Up (Months)*	*DFS*	*OS*
ATAC	Anastrozole for 5 years	9,366	100	HR = 0.85 p = .003	HR = 0.97 p = .70
BIG 1-98	Letrozole for 5 years Tamoxifen for 2 years → letrozole for 3 years Letrozole for 2 years → tamoxifen for 3 years	8,028	97	HR = 0.86[a] p = .007	HR = 0.87[a] p = .048
IES[b]	Tamoxifen for 2–3 years → exemestane for 2–3 years	4,724	56	HR = 0.76 p = .0001	HR = 0.85 p = .08
ITA[b]	Tamoxifen for 2–3 years → anastrozole for 2–3 years	448	64	HR = 0.57 p = .005	HR = 0.56 p = .10
ARNO95[b]/ ABCSG8	Tamoxifen for 2 years → anastrozole for 3 years	3,224	28	HR = 0.60 p = 0.0009	Not Reported
MA-17[c]	Tamoxifen for 5 years → letrozole for 5 years	5,187	30	HR = 0.58 p < .001	HR = 0.82 p = .30

[a]Upfront letrozole arm was compared to tamoxifen arm. Sequential arms were then compared to the letrozole arm and there was no significant difference in DFS or OS.
[b]Patients were randomized after receiving 2 years of tamoxifen.
[c]In MA-17 patients were randomized after 5 years of tamoxifen to letrozole versus placebo for 5 years.

(HR 0.84, p = .022) were superior for patients in the anastrozole-alone arm compared with tamoxifen alone. Anastrozole also showed a significantly lower ipsilateral and contralateral breast cancer recurrence rate (HR 0.60, p = .004) that was maintained after treatment was completed, especially for the hormone-receptor-positive population where the absolute benefit over tamoxifen was 2.8% (61).

The Breast International Group (BIG) 1-98 study is a large randomized, phase III, double-blind trial that enrolled over 8,000 women comparing the following four options: monotherapy with letrozole or tamoxifen for 5 years, sequential administration of tamoxifen for 2 years followed by letrozole for 3 years, or sequential administration of letrozole for 2 years followed by tamoxifen for 3 years. The trial was conducted in postmenopausal women with hormone-receptor-positive operable invasive breast cancer. This trial was designed to address whether an aromatase inhibitor is more effective as initial adjuvant therapy or as therapy following a few years of adjuvant tamoxifen.

The BIG 1-98 trial employed DFS as its primary end point, using a definition that included local recurrence after breast-conserving treatment, the appearance of metastatic disease, the development of a second primary tumor, or death from any cause. DFS in this trial included secondary non–breast cancers, while DFS in the ATAC study did not. On the other hand, it did not include DCIS in its DFS definition, while the ATAC study did (45,61). Over 8,000 patients were included in the trial, with a median follow-up of 8.1 years. Letrozole monotherapy was significantly better than tamoxifen (disease-free survival HR 0.86, overall survival HR 0.87) (25).

Additionally, the Tamoxifen Exemestane Adjuvant Multinational (TEAM) is another large trial that reported its results (63,64). This trial randomized close to ten thousand patients to 5 years of tamoxifen or exemestane. When results from the IES study were announced, the study protocol was amended and the tamoxifen arm was changed to a sequential arm with initial tamoxifen for 2 to 3 years followed by exemestane. Results from the TEAM trial were initially analyzed at the switching point and therefore the data represented a comparison between upfront exemestane and tamoxifen. The study showed a numerical trend for improved DFS (its primary end point) for upfront exemestane that was not significant (HR 0.85, p = .12) (63). Final results, which compared the upfront exemestane group to the sequential therapy group (after the change in design), showed similar DFS between the two groups (64).

Sequential Adjuvant Therapy with Aromatase Inhibitors following Tamoxifen

The Intergroup Exemestane Study (IES) enrolled 4,742 patients who were on tamoxifen for 2 to 3 years and randomized them to exemestane or continuing tamoxifen therapy for the remainder of the five years of treatment. The primary end point was DFS defined as the time from randomization to recurrence of breast cancer at any site, diagnosis of a second primary breast cancer, or death from any cause. Similar to the ATAC trial, non-breast primary cancers were not included in the definition of DFS.

The most recent update on this study at a median follow-up of 55.7 months reported a hazard ratio of 0.76 (p = .0001) favoring exemestane, with an absolute benefit of 3.3% (65). Fewer deaths occurred in the exemestane group compared to the tamoxifen group, which was statistically significant only after excluding 122 hormone receptor negative patients (HR 0.83, p = .05). In addition, switching from tamoxifen to exemestane demonstrated a significant reduction in contralateral breast cancer (HR 0.56, p = .04) (65).

A combined analysis of the ARNO 95, ABCSG 8, and ITA trials, which included over 4,000 patients, showed that patients who switched to anastrozole had fewer disease recurrences (92 vs. 159) and deaths (66 vs. 90) than did those who remained on tamoxifen, resulting in significant improvements in DFS (HR 0.59, p < .0001) and overall survival (HR 0.71, p = .04) (66).

Despite confirming results from each of the three studies (67–69), this report has the limitations of a meta-analysis. The three trials had different randomization schema; while patients were randomized upfront in ABCSG 8, they were randomized after 2 to 3 years of tamoxifen in the ARNO 95 and ITA trials. There were also differences in the definition of primary end points and in the entry criteria.

The BIG1-98 trial randomized more than three thousand patients to tamoxifen for 2 years followed by letrozole 3 years or letrozole for 2 years followed by tamoxifen for 3 years were compared to patients in the upfront letrozole arm. At a median follow-up of 8.0 years from randomization for the comparison of the sequential groups with letrozole monotherapy, there were no statistically significant differences in disease free or overall survival for either sequence (25). A detailed subset analysis is discussed below.

Extended Adjuvant Therapy with Aromatase Inhibitors

Several trials evaluated extending adjuvant therapy with an aromatase inhibitor after 5 years of tamoxifen. The largest of these is the NCIC-MA17 trial where over 5,000 women who had completed 5 years of tamoxifen were randomly assigned to placebo versus letrozole. The study was terminated early after the first interim analysis demonstrated a significant improvement in DFS in the letrozole group, which was confirmed on longer follow-up (HR 0.58; $p < .0001$) (70). Another analysis of MA.17 demonstrated that the hazard ratio in favor of letrozole continued to improve each year throughout the first 4 years of treatment, suggesting that longer treatment is better (71).

NSABP B-33, which had a similar design using exemestane, was closed to accrual when the results of MA.17 were made public, and patients assigned to placebo were given the option of crossing over to exemestane. At that time, only half of the planned 3,000 patients were enrolled, and more than 40% of patients initially assigned to placebo chose to cross over to receive exemestane. Despite these limitations, a similar trend for improved DFS was observed for the exemestane arm, although it did not reach statistical significance (HR 0.68, $p = .07$) (72). The ABCSG 6a study is a smaller study that showed a significant improvement in DFS (HR 0.64, $p = .048$) for extended adjuvant endocrine therapy. (73). None of these three trials have shown an impact on overall survival.

It should be noted that studies of extended adjuvant therapy using tamoxifen or an aromatase inhibitor were performed in patients who received 5 years of initial tamoxifen therapy, a situation that is less common today in postmenopausal women in the era of aromatase inhibitor therapy. However, just like the ATLAS trial, they support the concept of prolonging endocrine therapy beyond 5 years to prevent late recurrences. Other extended adjuvant studies will help elucidate the optimal duration and regimen of adjuvant endocrine therapy.

LONG-TERM EFFECTS AND TOXICITY OF AROMATASE INHIBITORS

By inhibiting the activity of the enzyme aromatase, aromatase inhibitors markedly suppress plasma estrogen levels in postmenopausal women. In contrast to tamoxifen, these compounds do not bind ER and therefore lack partial agonist activity and are not associated with the adverse effects of tamoxifen on the endometrium and thrombosis. However, they also lack the desirable effects of tamoxifen on bone and serum lipids.

In general and compared to tamoxifen, aromatase inhibitors have a lower incidence of ischemic cerebrovascular events, venous thromboembolic events, hot flashes, and vaginal bleeding. However, lipid disorders, bone fractures, and musculoskeletal pain are more frequent with aromatase inhibitors. Results from individual clinical trials showed no significant difference in the incidence of ischemic cardiovascular events (see Tables 43-5 and 43-7).

However, a meta-analysis of seven trials showed aromatase inhibitors to be associated with a 26% increase in risk of cardiovascular disease (43). Whether this excess in risk is due to a detrimental effect of aromatase inhibitors, a protective effect of tamoxifen, or a combination of the two, is not clear. But these findings are to be taken into consideration together with the patient's other comorbidity when making treatment recommendations for breast cancer patients. Tamoxifen might be preferable in a patient with known cardiovascular disease unless their breast cancer has adverse factors predicting a high risk of early recurrence.

TABLE 43-7

Side Effects of Tamoxifen and Anastrozole in the ATAC Trial

Side Effect	*Anastrozole (%) (n = 3,092)*	*Tamoxifen (%) (n = 3,094)*	*p-Value*
Hot flashes	35.7	40.9	<.0001
Musculoskeletal	35.6	29.4	<.0001

Adapted from Arimidex, Tamoxifen, Alone or in Combination Trialists' Group, Forbes JF, Cuzick J, et al. Effect of anastrozole and tamoxifen as adjuvant treatment for early-stage breast cancer: 100-month analysis of the ATAC trial. *Lancet Oncol* 2008;9(1):45–53; Baum M, Budzar AU, Cuzick J, et al. Anastrozole alone or in combination with tamoxifen versus tamoxifen alone for adjuvant treatment of postmenopausal women with early breast cancer: first results of the ATAC randomised trial. *Lancet* 2002;359(9324): 2131–2139.

Contralateral Breast Cancer and Second Primary Cancer

With 100-month follow-up, the ATAC trial provides the most mature comparison between the side effects and benefits of an aromatase inhibitor with those of tamoxifen (61). It reported a 40% proportional risk reduction of contralateral breast cancers. Since tamoxifen reduces the risk of contralateral breast cancer by about 50%, anastrozole might prevent more than 70% of ER-positive contralateral breast tumors compared to no adjuvant treatment. Additionally, anastrozole had a significantly lower incidence of endometrial carcinoma. There was no significant difference in the occurrence of any other cancer.

Musculoskeletal Symptoms and Effects on Bone

Musculoskeletal symptoms are significantly higher in patients on aromatase inhibitors compared to tamoxifen or no adjuvant therapy. Joint complaints have been reported to range from 20% to 50% in various trials of aromatase inhibitors depending on the definition of this side effect (45,61,65,70) (see Tables 43-5 and 43-7). The incidence of arthralgias, joint stiffness, and musculoskeletal disorders in patients on aromatase inhibitors may be higher than reported by some aromatase inhibitor trials. When patients are questioned carefully, many of them complain of joint stiffness and pain that they attribute to "getting older" and not to the drug.

In contrast to tamoxifen, which has protective effects on bone density of postmenopausal women by virtue of its agonist activity, all aromatase inhibitors are associated with bone loss by lowering endogenous estrogen levels (45,61,65,70,74). In a report of 167 women who received serial bone mineral density (BMD) measurements on the ATAC trial, significant bone loss occurred at the lumbar spine and hip in the anastrozole group (median BMD decrease of 6.1% and 7.2%, respectively) compared to the tamoxifen group (median BMD increase of 2.8% and 0.7%, respectively) (75). Fracture rates were significantly higher in the anastrozole compared to the tamoxifen group (22.6 vs. 15.6 per 1,000 woman-years). Likewise, in the BIG 1-98 trial, fractures were more frequent with letrozole (5.7% vs. 4%) (76). In the MA.17 trial, which compared letrozole to placebo after 5 years of tamoxifen, more modest reductions in bone mineral density were observed (hip = 3.6%, lumbar spine = 5.35%) (74). In the IES trial, loss of bone mineral density also was observed during the 2 to 3 years of treatment with exemestane after initial tamoxifen therapy. However, no patient with a normal bone mineral density at the start of therapy developed osteoporosis during treatment (77). Women receiving an aromatase inhibitor should be assessed for other risk factors for osteoporosis, and bone density should be measured at baseline, and periodically during therapy.

Serum Lipids

All major aromatase inhibitor trials reported a higher incidence of hyperlipidemia in patients receiving aromatase inhibitors. The BIG 1-98 trial showed a significantly higher incidence of hyperlipidemia in the letrozole arm compared to tamoxifen, although most cases were grade 1 (Table 43-5) (76). The ATAC trial reported a 6% incidence of hyperlipidemia in the anastrozole arm compared to 2.2% in the tamoxifen arm ($p < .001$) (61), and the ITA trial showed an 8% incidence of lipid disorders compared to 1.4% with tamoxifen ($p = .01$) at a median follow-up of 64 months.

This higher incidence can be attributed to a cholesterol-raising effect of aromatase inhibitors or to the cholesterol-lowering effects of tamoxifen. The MA.17L substudy reported the effects of letrozole on lipid profiles and showed no overall significant difference from placebo (78). However, treating physicians are generally aggressive in treating hyperlipidemia and the widespread use of lipid-lowering agents like statins may mask the effects of aromatase inhibitors on serum lipids. Women on aromatase inhibitors should be followed with serial serum lipid measurements and appropriate therapy should be initiated when necessary, especially in light of the increased risk of cardiovascular disease with aromatase inhibitors (43).

Cardiac and Cerebrovascular Events

Compared to tamoxifen, aromatase inhibitors were associated with a lower risk of venous thromboembolic and ischemic cerebrovascular events in all aromatase inhibitor trials. However, in some trials, aromatase inhibitors were associated with an increase in the risk of ischemic cardiac disease, although the added risk appears to be small (61,70,79,80).

A recent meta-analysis addressed these issues in seven trials that compared tamoxifen to an aromatase inhibitor (43). This analysis showed a 26% increased risk of cardiovascular disease with an aromatase inhibitor compared to tamoxifen alone. The absolute increase in the risk of cardiovascular disease was small (0.8%), but statistically significant, and the number needed to harm (NNH) was 132. On the other hand, thromboembolic events were significantly more frequent with tamoxifen (RR 0.55), with an absolute increase of 1.2% over aromatase inhibitor treatment, and the NNH was 79 patients.

DECIDING BETWEEN TAMOXIFEN AND AROMATASE INHIBITORS IN POSTMENOPAUSAL PATIENTS

There are two major treatment decisions to be made in patients with ER-positive breast cancer. First, should the patient receive chemotherapy in addition to endocrine therapy? Many patients with ER-positive tumors show little or no benefit from adjuvant chemotherapy. These tumors have high ER, high PR, negative HER2, low Ki-67, and are grades 1 or 2—in other words, well-differentiated or luminal A tumors. Multigene assays such as the 21-gene recurrence score also provide important information on the potential benefits of chemotherapy in such women. Those with low and perhaps many with intermediate scores do not benefit from chemotherapy. These assays and their implications are discussed in Chapters 26, 28, 29, and 44.

The second decision is whether patients should be treated initially with tamoxifen or an AI and, if so, for how long and should a switching strategy be employed? Several studies have addressed this question. First it should be emphasized that aromatase inhibitors overall may not provide a significant survival benefit compared to tamoxifen monotherapy or a switching strategy, and if they do, it must be very small (25,43). In some patient subgroups there might not even be a disease-free-survival benefit. The ATAC and BIG 1-98 trials examined several biomarkers and pathological variables and outcome (24,81). While individual factors like low ER or PR, amplification of *HER2*, high Ki-67, grade 3, positive lymph nodes, and lymphatic invasion predicted early relapse they did not predict a differential benefit for an AI over tamoxifen. In a prospectively planned substudy of the TEAM trial comparing exemestane with tamoxifen followed by exemestane using semiquantitative measurements, ER-rich tumors derived additional benefit

from initial treatment with exemestane while ER and PR low positive tumors did better with sequential therapy (32). In a study of Ki-67 in ABCSG Trial 8 comparing tamoxifen monotherapy with tamoxifen followed by anastrozole the switching arm was superior to tamoxifen in the patients with low Ki-67 (82). A retrospective small subset analysis of the ATAC trial of patients not confounded by the coadministration of chemotherapy showed that a score derived from immunohistochemical determination of ER, PR, *HER2*, and Ki-67 (IHC4 score) was similar to the 21-gene recurrence score in its prognostic utility, but neither these nor clinical variables provided predictive information on the choice of tamoxifen or anastrozole (83). Somewhat discrepant data were reported from the BIG 1-98 trial in a much larger patient subset at 5 years' follow-up (84). While the individual markers alone showed only a nonsignificant trend favoring letrozole monotherapy over the other three arms in patients with higher-risk tumors (lower ER and PR, high Ki-67, and *HER2* amplified), a composite STEPP analysis did discriminate between the arms. Letrozole monotherapy showed an advantage compared to the other arms in the highest risk group. Among patients with the lowest-risk score 5-year DFS was 96%, 94%, 93%, and 94% for the letrozole monotherapy, letrozole followed by tamoxifen, tamoxifen followed by letrozole, and tamoxifen monotherapy arms, respectively. Among patients with an intermediate risk score the DFS percentages were 90%, 91%, 93%, and 86%, and for those with the highest-risk score were 80%, 76%, 74%, and 69%, respectively. These interesting data suggest that patients with ER, PR, HER2, and Ki-67 all falling into the low risk stratum might be treated with any of the treatment arms including monotherapy with tamoxifen while those with high-risk features might be best treated with letrozole monotherapy. However, in view of the inconsistency of data of this type, the fact that the markers were all done in a central laboratory, and the retrospective nature of the studies, these factors should be considered with caution in treatment decisions. These data might, however, provide some comfort that patients given monotherapy with tamoxifen or patients switching to tamoxifen after 2 years because of side effects with an AI, will not have a major reduction in benefit, especially if they have low risk factors.

The role of obesity and breast cancer outcome in patients receiving adjuvant endocrine therapy has also been evaluated. Obesity, especially patients with a body mass index (BMI) greater than 30 kg/m^2, is an independent prognostic factor for recurrence and death (85). Obesity may also have an effect on the relative benefit of tamoxifen or an AI. Although obese patients have a higher risk of recurrence and death from breast cancer and other causes, tamoxifen's beneficial effects on these outcomes are not reduced in such women (86). However, obesity does negatively impact the suppression of plasma estrogens by AIs raising the possibility that they might be less effective in obese patients (87). Two studies, one in premenopausal patients and one in postmenopausal patients, suggest that the relative superiority of AIs compared to tamoxifen is greater in thin women (88,89). In the premenopausal study, ABCSG-12 Trial comparing ovarian suppression plus either anastrozole or tamoxifen, the negative effect of obesity on AI benefit was dramatic (88). Obese patients randomized to anastrozole had a 50% increase in recurrence and a threefold increase in deaths compared to patients treated with tamoxifen. In the BIG 1-98 trial in postmenopausal patients treated with tamoxifen or letrozole, there was no indication that the benefit of letrozole was less in overweight patients (90). The explanation for these differences among trials is not clear although it could be related to menopausal status, the AI used in the study, or other factors. These data do argue that premenopausal women should not be treated with ovarian suppression plus an aromatase inhibitor at this time.

Side effects of AIs versus tamoxifen and patient comorbidities might influence the decision about which drug to choose as initial therapy. Younger, sexually active women with low-risk disease might choose tamoxifen instead of an AI or a switching strategy because tamoxifen is associated with less atrophic vaginitis. This complication, which adversely affects quality of life, is also easy to treat with vaginal estrogens in patients on tamoxifen. Tamoxifen binds to and blocks estrogen receptors and would prevent absorbed estrogen from binding ER and stimulating the tumor. Vaginal estrogens cannot as easily be used in patients on AIs. Tamoxifen might also be preferred in patients with severe cardiac risk factors or those with osteoporosis. In contrast, in patients with high-risk breast cancer or those with a history of thromboembolic phenomenon an AI is an obvious choice. Thus, the characteristics of the tumor and the patient are helpful in making this treatment decision.

ADJUVANT OVARIAN ABLATION

There are three methods of inhibiting ovarian production of estrogen for breast cancer treatment in premenopausal women, ovariectomy, ovarian irradiation, and gonadotropin-releasing hormone (GnRH) agonists. GnRH is made in the hypothalamus and released in a pulsatile fashion. This, in turn, stimulates the pituitary release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), eventually resulting in the production of estrogen from the ovaries. The chronic administration of a GnRH agonist results in internalization of pituitary GnRH receptors, rendering them unresponsive to hypothalamic endogenous GnRH, and thus shutting off the downstream production of estrogen.

Among the first randomized trials of adjuvant therapy in breast cancer were studies of adjuvant ovarian ablation either by surgical oophorectomy or by irradiation (91,92). Some of these trials were not properly randomized by modern standards (93). Many were small, a few included both premenopausal and postmenopausal women, and none included ER analyses, which were not yet available. Most of these trials found a significant DFS advantage for ovarian ablation, and two reported a significant OS advantage (94,95).

The EBCTCG 2005 meta-analysis analyzed almost 8,000 women younger than 50 years of age with ER-positive or ER-unknown disease randomized into trials of ovarian ablation by surgery or irradiation (4,317 women, 63% ER-untested) or of ovarian suppression by treatment with a GnRH agonist (3,408 women, 26% ER-untested).

Overall, a definite effect of ovarian ablation or suppression was evident on both recurrence and breast cancer mortality (see Table 43-8). However, this effect is not as large as it was reported in earlier meta-analyses of these trials, when ovarian ablation was not generally being tested against a background of effective systemic chemotherapy (96).

The absolute effect on 15-year outcomes showed that for recurrence, most of the advantage for ovarian ablation occurs during the first few years and seems to be maintained in later years. This early difference in recurrence translates into a later difference in mortality. The meta-analysis found no indication that the benefits that accrue during the first decade of follow-up are lost during the second decade (96).

All of these women were younger than 50 years of age when randomized, and therefore there have been relatively few non-breast cancer related deaths. However, these

TABLE 43-8

Meta-Analysis of the Effects of Ovarian Ablation (OA), Ovarian Suppression (LHRH), ER Positive or Unknown—Overview 2005

	Reduction (± SE) in Annual Odds	
Group/Age	*Recurrence (%)*	*Breast Cancer Mortality (%)*
OA vs. nil

40–49	5 ± 7	–3 ± 8

Adapted from Early Breast Cancer Trialists' Collaborative Group. Effects of chemotherapy and hormonal therapy for early breast cancer on recurrence and 15-year survival: an overview of the randomised trials. *Lancet* 2005;365(9472):1687–1717.

deaths do not appear to be increased by treatment during either the first or the second decade (96).

Another meta-analysis of the role of medical ovarian suppression in early stage, hormone-receptor-positive breast cancer was reported in 2007 (97). The analysis included data from 11,906 premenopausal women with early breast cancer randomized in 16 trials. This report found that when used as the sole systemic adjuvant treatment, GnRH agonists did not significantly reduce recurrence or death after recurrence in hormone-receptor-positive cancers. However, the number of patients may have been too small to elicit the benefit. When added to other systemic therapy (tamoxifen, chemotherapy, or both), GnRH reduced recurrence in women younger than 40 by 12.7% (p = .02); and death after recurrence by 15.1% (p = .03). When individual therapies were evaluated, adding GnRH agonists to tamoxifen alone did not result in significant benefit (97).

The numbers of patients included in these ovarian ablation studies is still relatively small giving rise to large standard errors in some of the subgroups. These analyses may underestimate the true benefit since they include a large percentage of patients from the early ovarian ablation trials who were ER-unknown. Nevertheless, patients less than 40 years of age and those between 40 and 49 years of age (mostly premenopausal) benefit significantly from ovarian ablation. A benefit is not evident in patients receiving chemotherapy probably because many of those patients already achieve ovarian ablation as a "side effect" of the chemotherapy. There are no major differences between GnRH agonists and other forms of ovarian ablation, although this question has not been well studied directly. Data are insufficient, in any trial or either meta-analysis, to confirm whether like all other adjuvant endocrine therapies, ovarian ablation reduces the incidence of contralateral breast cancer.

The results with ovarian ablation or suppression are comparable to those achieved with chemotherapy or tamoxifen in women younger than 50 years of age. Based on available data, ovarian ablation appears equivalent to chemotherapy alone in premenopausal ER-positive patients (97,98).

Results of several other trials shed additional light on the relative effectiveness of chemotherapy and ovarian ablation. Nearly all of these trials, however, used CMF-based chemotherapy, which may be inferior to more contemporary regimens. The majority of these trials, showed equivalence between ovarian ablation and chemotherapy in ER-positive, premenopausal women (99).

Several other studies have compared ovarian ablation combined with tamoxifen versus chemotherapy. The largest trial, Trial 5 from the Austrian Breast Cancer Group, randomized 1,034 receptor positive patients to 3 years of goserelin plus 5 years of tamoxifen or to six cycles of CMF (100). At 5 years of follow-up there was a significant DFS advantage for the endocrine therapy and a trend for improved OS. Two smaller trials, comparing tamoxifen plus ovarian suppression with chemotherapy showed no difference in DFS and OS between the two groups (101,102).

Therefore, there is a suggestion that the addition of tamoxifen to ovarian ablation may provide superior results. For the moment, ovarian ablation with or without tamoxifen is a reasonable alternative to chemotherapy in patients with ER-positive tumors.

It is still difficult to know where ovarian ablation fits in our current adjuvant therapy options for premenopausal patients. It might be considered in those who refuse other therapies, as an alternative to chemotherapy in certain patients, as an adjunct to chemotherapy in women not achieving chemical ovarian ablation, or for prevention in patients with a hereditary breast cancer syndrome who have a high risk of developing breast and ovarian cancer. Tamoxifen is the better choice in patients needing endocrine adjuvant therapy.

The combination of tamoxifen plus ovarian ablation, and ovarian ablation combined with an aromatase inhibitor are currently being compared to tamoxifen in multiple studies. One of these studies, the ABCSG-12 randomized 1,801 patients according to a 2X2 design to the combination of the LHRH agonist goserelin with anastrozole, or to goserelin with tamoxifen, each with or without zoledronic acid every 6 months for 3 years (103). This study showed no significant difference in DFS between the two endocrine therapy combinations (HR 1.10, 95% CI 0.7–1.53; p = .59). However, overall survival was worse with anastrozole plus goserelin than with tamoxifen plus goserelin (46 vs. 27 deaths; HR 1.75, 95% CI 1.08–2.83; p = .02). The study also showed that the group that received zoledronic acid had a 36% reduction in the risk of recurrence. This benefit was observed in skeletal, visceral and local recurrence rates (103) (see Chapter 47 for further review of the role of bisphosphonates in adjuvant therapy). Results of other large trials, like the SOFT trial, will provide further insight about the role of aromatase inhibitors with ovarian suppression as adjuvant therapy for premenopausal women. Until then, ovarian ablation plus an aromatase inhibitor should not be routinely used as adjuvant endocrine therapy in premenopausal women unless a tamoxifen based regimen is contraindicated.

TOXICITY OF OVARIAN ABLATION

The side effects of ovarian ablation are due to lowering the level of estrogen. Menopausal symptoms and gynecological complaints are common and are similar to those observed with tamoxifen. Premature coronary artery disease and osteoporosis might be expected in some patients.

Even short-term treatment with goserelin in premenopausal women with endometriosis was associated with bone loss (104). The meta-analysis does not yet show increased vascular deaths in women with breast cancer treated by ovarian ablation, but the database is small (91,92,96). Bone loss and premature osteoporosis are likely to be significant in such patients who, therefore, demand close monitoring and the early institution of bisphosphonates when bone loss occurs. Zoledronic acid, administered every 6 months, has been shown to prevent treatment-related bone loss in premenopausal women receiving adjuvant endocrine therapy (105) and showed reduced risk for recurrence and distant metastasis in one study (106). This use of bisphosphonates as adjuvant therapy is discussed in Chapter 47.

COGNITIVE FUNCTION IN PATIENTS ON ENDOCRINE THERAPY

Estrogen regulates emotional responses and cortical activity during cognitive task performance in humans (107) and may have a protective effect on verbal memory (108). These data raise the question of the effects of SERMs or estrogen deprivation therapy such as anastrozole or ovarian ablation on cognitive function. Aromatase is expressed in the brain, although its importance in cognitive function is not known (109). Cognitive function was measured in the Multiple Outcomes of Raloxifene Evaluation (MORE) trial in women with osteoporosis (110). Overall, there was no difference between placebo and raloxifene in several different tests of cognitive function, suggesting that it does not have an adverse effect worse than that in women with postmenopausal estrogen levels. Whether tamoxifen would have a similar effect is not clear, although in a randomized study using magnetic resonance spectroscopy, both estrogen and tamoxifen had a favorable profile (111).

Cognitive assessments that measured a range of memory and attention functions were reported on 94 patients from the ATAC trial and 35 noncancer controls (112). The patient group did not differ from controls on measures of working memory, attention, and visual memory but was significantly impaired compared to the control group on measures of verbal memory ($p = .026$) and processing speed ($p = .032$). Cognitive performance in the patient group was not significantly related to length of time on trial or measures of psychological morbidity (112). Results from this small study suggest that anastrozole, like tamoxifen, may cause a specific deficit in verbal memory. However, a study done on patients from the BIG 1-98 study during their fifth year of therapy showed that patients on tamoxifen had significantly worse cognitive function than patients receiving letrozole (score difference of 28%, $p = .04$) (113). Cognitive function scores were improved for both groups after stopping endocrine therapy (114). Larger studies with longer follow-up are needed to assess the long-term consequences of treatment with endocrine therapy taking into consideration that patients with breast cancer score lower than healthy controls on their cognitive function tests, even before therapy is initiated. These findings indicate that factors other than systemic treatment can also affect cognitive function in women with breast cancer making it difficult to establish causality.

FUTURE DIRECTIONS

Since its introduction almost 40 years ago, significant progress has been made in the systemic adjuvant therapy for breast cancer. The population mortality reductions observed (25%) in most Western countries over the past 20 years have been attributed largely to the widespread use of adjuvant therapy, especially tamoxifen, and to a lesser extent chemotherapy (115). Thus, the hypothesis that many breast cancer patients already have subclinical distant metastases at the time of diagnosis, and that these microscopic foci can be more effectively treated than gross metastatic disease, has been confirmed.

However, several questions regarding adjuvant endocrine therapy remain unanswered, and many of these are now being addressed in ongoing clinical trials.

- Is ovarian ablation combined with tamoxifen or with an aromatase inhibitor, better than tamoxifen alone in premenopausal patients?
- What is the optimal duration of aromatase inhibition, and what are possible long-term sequelae of treatment?
- Are local slow-release vaginal estrogen preparations or other formulations safe to use with aromatase inhibitors and can we find a successful treatment for joint pain and stiffness?
- Do ER degraders like fulvestrant alone or in combination with aromatase inhibitors have a role in the adjuvant setting?
- Do combinations of endocrine therapy with targeted therapies that inhibit growth factor receptors, or downstream pathways like mammalian target of rapamycin (mTOR), the mitogen activated protein kinase pathway, the stress kinase pathway, or the phosphoinositide-3 kinase (PI3K)/Akt pathway improve outcome in the adjuvant treatment of breast cancer?

MANAGEMENT SUMMARY

- Adjuvant endocrine therapy is the most effective systemic treatment modality for hormone-receptor-positive breast cancer; it reduces the risk of recurrence by 50% or more across different tumor characteristics and clinical stages and this may be an underestimation given suboptimal compliance.
- Optimal duration is not yet established for all subgroups. However, all patients should receive at least 5 years of therapy and 10 years of therapy should be considered in certain patients.

Premenopausal Women

- All premenopausal women should be encouraged to enroll in clinical trials of adjuvant hormone therapy.
- For women who do not have access to clinical trials, are not eligible, or choose not to participate, 5 years of tamoxifen is still the most appropriate treatment. At the end of 5 years, in women with higher-risk breast cancer who remain premenopausal, extending treatment to 10 years should be considered.
- Ovarian suppression or ablation (medical or surgical) may be appropriate in selected patients who have a contraindication or do not tolerate tamoxifen. Optimal duration of ovarian suppression (if done medically) is not established, but treating for 3 to 5 years is reasonable.
- Combining tamoxifen and ovarian suppression may be utilized in patients at high risk of recurrence particularly if they are younger than 35 years.
- Aromatase inhibitors are indicated only for postmenopausal patients and should be avoided in women whose menopausal status is not established (60). The use of aromatase inhibitors with ovarian suppression should await results from completed large international trials. They might be useful in patients for whom tamoxifen is contraindicated.

Postmenopausal Women

- Aromatase inhibitors offer a small advantage over tamoxifen and should be at least a part of the adjuvant endocrine therapy of most postmenopausal women with ER-positive breast cancer.
- Upfront treatment with an aromatase inhibitor or sequencing with tamoxifen for 2 to 3 years followed by an aromatase inhibitor for 3 to 5 years or switching from an AI to tamoxifen after 2 to 3 years are considered acceptable options.
- The decision on whether to use upfront aromatase inhibitor therapy or sequential therapy should take into consideration many factors including patient age, years after menopause, risk of recurrence, bone health, history of thromboembolism, cardiac or cerebrovascular disease, menopausal symptoms, and sexual activity of the patient. Patients with more aggressive breast cancers on the basis of high grade, high proliferation, low ER, or *HER2* amplification should be considered for 5 years of an AI.
- Patients whose menopausal status is in question and those who develop amenorrhea after chemotherapy are best started on tamoxifen and hormone profiles followed. If they remain clinically amenorrheic and with postmenopausal hormone profiles for 2 years, they can be switched to an aromatase inhibitor.
- Postmenopausal women (or those who become postmenopausal) completing 5 years of tamoxifen should be considered for extended adjuvant therapy with an aromatase inhibitor. This group of patients is not large as many postmenopausal women now receive aromatase inhibitors initially or after 2 to 3 years of tamoxifen.
- Patients on tamoxifen should not have anything more than a routine annual gynecologic examination unless they present with vaginal spotting or bleeding.
- Patients on aromatase inhibitors should have serial monitoring of bone mineral density and serum lipids.

CHAPTER 44

Adjuvant Systemic Chemotherapy in Early Breast Cancer

Chau Dang and Clifford A. Hudis

CHAPTER CONTENTS

INTRODUCTION

In women, breast cancer is the most common life-threatening malignancy, but the second leading cause of cancer mortality with a falling mortality rate in the United States over the past few decades (1). This trend has been attributed to both large-scale screening leading to the identification of earlier stage disease with lower risk and to an improvement in systemic treatment strategies that reduce the likelihood of recurrence. Individual large-scale, randomized, controlled clinical trials have generally indicated modest improvements in disease-free survival (DFS) and overall survival (OS) but translated into a large population the public health impact can be substantial. Worldwide overviews conducted by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) have confirmed the scale of these improvements. Based on these meta-analyses, the combination of chemotherapy and hormonal therapy would be expected to halve the rate of breast cancer mortality in patients with estrogen receptor (ER)-positive disease during the first 15 years after diagnosis (2). Similarly, polychemotherapy significantly improve outcomes in patients with ER-poor breast cancer (3). Recently, the EBCTCG reported long-term outcomes of various polychemotherapy regimens for early breast cancer, including trials that contained the taxanes (4). This chapter will focus on the evolution, and current status of adjuvant chemotherapy in the treatment of early breast cancer.

DEVELOPMENT OF COMBINATION CHEMOTHERAPY

First-Generation Trials with Alkylating Agents and Cyclophosphamide-, Methotrexate-, and Fluorouracil-Based Chemotherapy

The first trial of adjuvant chemotherapy for breast cancer was performed by the National Breast Cancer Bowel and Breast Project (NSABP) in 1958 (5). This study was based on the premise that cancer cells were sometimes dislodged at the time of surgery. Two days of perioperative thiotepa was compared to placebo in over 800 women undergoing radical mastectomy and showed a benefit in premenopausal patients. In an attempt to improve upon these results, the NSABP studied 2 years of postoperative adjuvant therapy with melphalan and again showed a more pronounced benefit in premenopausal, node-positive patients (6).

The observed activity of combination chemotherapy consisting of cyclophosphamide, methotrexate, and fluorouracil or 5-FU (CMF) for metastatic breast cancer led to its incorporation as adjuvant therapy. In 1975 Bonadonna et al. reported that 12 cycles of cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) resulted in a 19% advantage in 5-year DFS compared with no adjuvant chemotherapy ($p < .002$) and a 14% improvement in OS ($p < .04$) (7). This combination eventually became known as "oral" or classical CMF because the cyclophosphamide (100 mg/m^2) was administered orally for 14 days of the 28-day regimen.

Methotrexate (40 mg/m^2) and 5-fluorouracil (600 mg/m^2) were both administered intravenously (IV) on days 1 and 8. A follow-up study, comparing 6 months of therapy to 12 months, demonstrated an equivalent outcome (8). Bonadonna et al. reported the 30-year follow-up on randomized studies of adjuvant CMF and showed the enduring benefit of this regimen in the adjuvant setting (9). Similarly, the Cancer and Leukemia Group B (CALGB) conducted several trials of CMF-based therapies and demonstrated that the clinical benefit of chemotherapy was maintained with over 20 years of follow-up (10).

A joint analysis of two studies conducted by the International Breast Cancer Study Group and German Breast Cancer Study Group compared 6 months of CMF to 3 months (11). There was a trend toward a benefit for 6 months of therapy in women 40 years or younger (p = .22) and in those with hormone-receptor-negative breast cancer (p = .37). In the German Adjuvant Breast Cancer Group comparison of 6 months to 3 months of adjuvant treatment with CMF in 789 women there was no difference in outcome (12). The Southwest Oncology Group (SWOG) found that a 2-year duration of CMF with vincristine and prednisone (CMFVP) in patients with axillary-node-positive, hormone-receptor-negative breast cancer was no better than 1 year in terms of OS (p = .33) or DFS (p = .24) (13). The Ludwig Trial Group found that one peri-operative cycle of CMF chemotherapy was superior to surgery without any chemotherapy (p = .04) (14). However, a follow-up study was done by the Ludwig group compared one perioperative cycle of CMF to 6 cycles in node-positive breast cancer, and they concluded that CMF for 6 cycles was superior in terms of DFS (p < .0001) and OS (p = .011) (15). Based on the results of these earlier trials of CMF with 6 months of CMF adjuvant therapy being equivalent to longer durations of therapy, this has become the most popular duration of therapy for the three-drug combination. Furthermore, studies utilizing adjuvant CMF in combination with other agents (i.e., prednisone, vincristine) failed to demonstrate a consistent an impact on DFS or OS (10,16–18).

Most of the earlier trials were performed in the node-positive population. The trial NSABP B-13 evaluated no chemotherapy versus methotrexate/5-flourouracil (MF) in 760 patients with hormone-receptor-negative, node-negative disease and showed a benefit of MF through 16 years of follow-up in terms of relapse-free survival (RFS) (hazard ratio [HR] = 0.59, p < .001; OS: HR = 0.75, 95% CI = 0.58–0.98, p = .03) (19). In a subsequent trial (NSABP B-19), 1,095 patients with ER-negative, node-negative tumors were assigned to MF versus CMF, and through 13 years of follow-up, an overall benefit was seen in favor of CMF (RFS: HR = 0.59, p < .001; OS: HR = 0.71, p = .01), especially in patients 49 years or younger (19). The NSABP B-20 enrolled patients with hormone-receptor-positive, node-negative disease and with a median follow-up of 8 years, it demonstrated that the addition of chemotherapy (MF or CMF) to tamoxifen was superior to tamoxifen alone in both DFS (84% vs. 77%, p = .001) and OS (92% vs. 88%, p = .018) (20). Based on the results of these node-negative trials, the 2000 National Institutes of Health (NIH) Consensus Conference recommended that all patients with tumors of greater than 1 cm or positive lymph nodes should be offered adjuvant chemotherapy, regardless nodal status, menopausal status, and hormonal receptor status (21).

Adjuvant Anthracyclines

Doxorubicin

The anthracyclines were introduced in the adjuvant setting, mainly doxorubicin or epirubicin, in the 1980s. In 1981, NSABP B-11 added doxorubicin (A) to melphalan and fluorouracil (PAF) versus melphalan and fluorouracil (PF) in over 700 ER-poor patients (22). The study demonstrated that the addition of doxorubin conferred a DFS (p = .003) and OS (p = .05) benefit. The CALGB 8082 compared a prolonged regimen of cyclophosphamide, methotrexate, fluorouracil, vincristine, and prednisone (CMFVP) with CMFVP followed by anthracycline-based vinblastine, doxorubicin, thiotepa, and fluoxymesterone (VATH) in over 900 patients. At a median follow-up of 11.5 years, the incorporation of VATH led to significant improvements in DFS (p = .004) and OS (p = .043) (23). Bonadonna et al. conducted two trials involving doxorubicin given sequentially with CMF. The first trial compared CMF IV × 12 versus CMF IV × 8 followed by doxorubicin × 4 (CMF → A) in over 550 women with one to three positive nodes. The second study enrolled over 400 patients with four or more involved nodes and evaluated doxorubicin × 4 followed by CMF × 8 (A → CMF) versus alternating 2 courses of CMF with 1 cycle of doxorubicin (CMF/A) (24). There was a benefit in DFS and OS when sequential doxorubicin was given all before CMF in the second trial. This may be due to the importance of maintaining dose density which will be discussed later in this chapter. However, there was no benefit in DFS or OS with the addition of doxorubicin in the first trial, and perhaps this could be due to the inclusion of a lower-risk population in this study (one to three positive nodes).

The US Intergroup conducted a study (INT-0102) comparing CAF × 6 cycles (100 mg/m^2 orally days 1 to 14, 30 mg/m^2 IV days 1 and 8, 500 mg/m^2 IV days 1 and 8) against classical CMF in over 3,900 patients with high-risk (tumor size greater than 2 cm, ER-negative, or high S-phase fraction), node-negative disease, with or without tamoxifen. The study showed that CAF was associated with a marginal improvement in OS (85% vs. 83%, HR = 1.19 for CMF vs. CAF, p = .03) (25). The Grupo Espanol de Investigacion en Cancer de Mama (GEICAM) group enrolled over 980 patients with stages I to III breast cancer and compared FAC (500/50/500 mg/m^2) IV versus CMF (600/60/600 mg/m^2) IV, all given every 3 weeks × 6, and showed superiority in favor of FAC in DFS (RR 1.2, p = .03) and OS (RR 1.3, p = .05) (26).

The NSABP conducted study B-15 that enrolled over 2,100 patients with node-positive disease to a shorter course of an anthracycline-based treatment with the omission of fluorouracil. In this study patients were randomized to AC (60/600 mg/m^2) IV every 3 weeks × 4 versus classical CMF × 6 versus AC × 4 followed by 6 months of rest period followed by CMF IV every 28 days × 3 (750 mg/m^2 days 1 and 8, 40 mg/m^2 days 1 and 8, 600 mg/m^2 days 1 and 8) (AC → rest → CMF) and found no significant DFS or OS in all three arms (27). Next, the NSABP conducted trial B-16 and showed the benefit of the addition of AC therapy with tamoxifen over endocrine therapy alone in node-positive patients (28). Moving forward, the NSABP conducted study B-23 and randomized over 2,000 node-negative patients to classical CMF × 6 versus AC × 4, with or without tamoxifen. Similar to B-15, there was no difference in RFS or OS between the two regimens (18,29). Unlike other anthracycline-based regimens (CAF or FAC) and epirubicin-based therapies (discussed below), all given either as 6 cycles or over 6 months, AC was not better than classical CMF. There are several reasons to explain the lack of benefit of AC over classical CMF, and they include the short duration of this therapy, the omission of 5-fluorouracil, and the use of intravenous cyclophosphamide. However, the AC regimen was considered to be preferable to the classical CMF regimen due to ease of administration and its convenience, and it was incorporated into several subsequent sequential anthracycline-taxane combinations (Table 44-1).

NSABP B-23 (29)	2,008	AC +/− Tam = CMF +/− Tam	NS	NS

DFS, disease-free survival; RFS, relapse-free survival; EFS, event-free survival; OS, overall survival; NS, not statistically significant; NSABP, National Surgical Adjuvant Breast and Bowel Project; CALGB = Cancer and Leukemia Group B; INT-0102, US Intergroup Study 0102; GEICAM, Grupo Espanol de Investigacion en Cancer de Mama; P, melphalan; A, doxorubicin; F, fluorouracil; C, cyclophosphamide; M, methotrexate; V, vincristine; P, prednisone; VATH, vinblastine, doxorubicin, thiotepa, and fluoxymesterone; Tam, tamoxifen.

Epirubicin

The National Cancer Institute of Canada (NCIC) conducted trial MA.5 and enrolled over 700 node-positive patients to cyclophosphamide, epirubicin, and fluorouracil (CEF) (100 mg/m^2 orally days 1 to 14, 60 mg/m^2 IV days 1 and 8, 600 mg/m^2 IV days 1 and 8) versus classical CMF (30). Now at 10 years, results showed a statistically significant improvement in relapse-free survival (RFS) (52% vs. 45%; p = .007) and a trend in OS (62% vs. 58%, p = .085) in patients in the epirubicin-containing arm. Treatment with CEF was accompanied by more toxicities than CMF, including hospitalizations for febrile neutropenia (8.5% vs. 1.1%). Nevertheless, CEF became the standard chemotherapy in Canada for treating high-risk patients.

The French Adjuvant Study Group (FASG) conducted study FASG 05 and randomized 565 patients to FEC 100 (500/100/500 mg/m^2) versus FEC 50 (500/50/500 mg/m^2), all administered IV every 3 weeks × 6 cycles (31). At a median follow-up of 10 years, results were in favor of FEC 100 in DFS (50.7% vs. 45.3%, p = .036) and OS (54.8% vs. 50.0%, p = .05). Delayed cardiac toxicity after relapse occurred in 4.3% and 4.1% of patients in FEC 50 and FEC 100 arms, respectively. Thus, the survival advantage of FEC 100 was not offset by a higher incidence of cardiac toxicities. At that time FEC 100 then became a standard adjuvant treatment option in Europe.

Poole et al. reported on the combined results of two trials investigating the efficacy of epirubicin in the National Epirubicin Adjuvant Trial (NEAT) and the Scottish trial BR9601 in over 2,300 women (32). In the NEAT study, patients were randomized to E (100 mg/m^2) IV × 4 followed by classical CMF × 4 (E → CMF) versus classical CMF × 6. In BR9601, patients were randomized to E (100 m/m^2) × 4 followed by modified CMF (750/50/600 mg/m^2) IV every 3 weeks × 4 versus modified CMF × 8. Overall, results were in favor of the addition of epirubicin with 5-year RFS rates of 76% versus 69% and 5-year OS of 82% versus 75% (p < .001 for all comparisons). This study confirmed the benefit of an anthracycline-based regimen over CMF alone. Thus, E → CMF regimen, similar to the original Bonadonna regimen, became another standard option as adjuvant therapy in Europe (24) (Table 44-2).

The EBCTCG evaluated 14,000 patients in trials comparing CMF with an anthracycline-based regimen and demonstrated a modest, but statistically significant, benefit favoring the anthracyclines, with absolute benefits of 3.4% for recurrence and 3.3% for mortality at 15 years of follow-up, irrespective of age or hormone receptor status (2). Epirubicin-based regimens are commonly used in Europe and Canada. Epirubicin has almost half of the cardiotoxicity than seen doxorubicin, on a milligram by milligram basis (33). However, the cumulative doses of epirubicin in the adjuvant regimens are higher than those for doxorubicin, and thus, the cardiac toxicity of epirubicin-based regimens are quite similar to that with doxorubicin-containing therapies.

The anthracyclines have been a mainstay of breast cancer treatment for the past 30 years. The use of the anthracyclines has been declining due to various reasons, as specific treatments for different subgroups of women are being defined. However, the data are unclear on which subsets of patients may have the anthracyclines omitted. The literature on response to the anthracyclines, or not, based TOPO II gene aberrations or *HER2* overexpression or amplification is still unclear (34). Thus, given the established benefit of the anthracyclines, any decision to eliminate doxorubicin or epirubicin, especially in high-risk patient, should be based on the results of adequately powered, prospective randomized trials.

Despite the use of the anthracyclines, the risk of relapse remains significant, especially in those with poor risk features (35). Inherent or acquired drug resistance could result in disease relapse and variable drug sensitivity among subclones could also contribute to resistance (36). To overcome the limitations of chemotherapy, various strategies have been investigated, which include the manipulations of dose and schedule and the use of non-cross-resistant drugs, such as the taxanes.

Adjuvant Taxanes

Paclitaxel

The CALGB 9344 trial enrolled more than 3,100 node-positive women to receive AC versus AC → paclitaxel (P), and three different doses of doxorubicin were evaluated (60 mg/m^2, 75 mg/m^2, or 95 mg/m^2) (37). There was no benefit with the higher doses of A beyond the standard dose of 60 mg/m^2. At a follow-up at 5 years, the hazard reductions from adding paclitaxel to AC were 17% for recurrence (p = .0023) and 18% for death (p = .0064). The DFS was 65% for AC alone versus 70% for AC → P; OS was 77% for AC and 80% for AC→ P. The effects of adding paclitaxel were not significantly different in subsets defined by protocol. However, in an unplanned subset analysis, the hazard ratio (HR) of AC → P versus AC

TABLE 44-2

NEAT/BR9601 (32)	2,391	E → CMF > CMF	<.001	<.001

DFS, disease-free survival; RFS, relapse-free survival; EFS, event-free survival; OS, overall survival; NS, not statistically significant; NCIC, National Cancer Institute of Canada; FASG, French Adjuvant Study Group; NEAT, National Epirubicin Adjuvant Trial; C, cyclophosphamide; E, epirubicin; F, fluorouracil; M, methotrexate.

alone was 0.72 for those with ER-negative tumors and only 0.91 for those with ER-positive tumors. The additional toxicities of P were modest.

Similarly, the NSABP B-28 also randomized over 3,000 women with node-positive breast cancer to AC × 4 versus AC × 4 followed by P × 4 (38). The 5-year results were reported showing the benefit in the addition of P to AC in all node-positive breast cancer patients, regardless of ER status, use of tamoxifen, age, number of positive nodes, type of surgery, tumor grade, and histologic type. The 5-year DFS was 72% versus 76% (p = .008) in favor of addition of P. The 5-year OS was 85% in both groups. The lack of OS benefit with P in this study, unlike CALGB 9344, may be attributed to a better prognosis group (70% in NSABP B-28 vs. 46% of patients in CALGB 9344 with one to three positive nodes) and the concurrent use of tamoxifen with chemotherapy in NSABP B-28.

With the results of CALGB 9344 and NSABP B-28, every 3 weeks AC → P became the standard option for the treatment of high-risk breast cancer and became the standard arm in the next trial led by Eastern Cooperative Oncology Group (ECOG) in study E 1199 (39). This study randomized over 5,000 node-positive and high-risk node-negative patients to AC → P every 3 weeks versus AC → weekly P × 12 (80 mg/m^2) versus AC → docetaxel (D) (100 mg/m^2) every 3 weeks versus AC → weekly D × 12 (35 mg/m^2). Overall, when compared to control, AC → weekly P was superior in terms of DFS (81.5% vs. 76.9%, p = .006) and OS (89.7% vs. 86.5%, p = .01), and AC → D was better only in DFS (81.2%, p = .02). The result of this trial confirmed the benefit of the weekly paclitaxel over the every 3 weekly schedule as demonstrated in the metastatic setting (40). In an exploratory analysis, the addition of weekly paclitaxel was beneficial regardless of hormone receptor or *HER2* status. As AC → weekly P was better in both endpoints and there were higher rates of febrile neutropenia and infection with AC → D than in other groups, AC → weekly P emerged as the best option from this trial. A direct comparison of weekly versus dose-dense (every 2 weekly) adjuvant paclitaxel was performed by SWOG (0221) and results are anticipated in 2013.

Another trial demonstrating the benefit of weekly paclitaxel was conducted by the GEICAM group in study 9906 (41). In this study over 1,200 patients were randomized to standard 6 cycles of FEC (600/90/600 mg/m^2) IV every 3 weeks or FEC × 4 → P (100 mg/m^2) weekly × 8. The 5-year DFS was superior for the FEC → P arm (78.5% vs. 72.1%, p = .006). The FEC → P was associated with a 23% reduction in relapse (p = .022) and 22% decrease in death but this was not statistically significant (p = .110). This translated into a 37% risk reduction in recurrence (p = .0008) in all subsets. There was no significant interaction hormone receptor or *HER2* status and paclitaxel treatment. Toxicities were acceptable for both arms. Thus, this was another study strongly confirming the benefit of a taxane in the adjuvant treatment of breast cancer. Recently, the GEICAM group also showed the benefit with the addition of weekly paclitaxel to an anthracycline backbone in a node-negative population (42). In this trial patients were randomized to FAC (500/50/500 mg/m^2) every 3 weeks × 6 versus FAC × 4 → weekly P (100 mg/m^2) × 8. Overall, the 5-year DFS was in favor with the addition of P (93% vs. 90%, p = .043). Although the result of this study was consistent with most other anthracycline-taxane trials, 58% of the patients had T1 tumors and 73% had hormone-receptor-positive disease. In the era of precision medicine most of these patients should undergo genomic profiling (i.e., ONCOTYPE) to determine if they truly need chemotherapy. This will be discussed later in this chapter.

In terms of administering paclitaxel concurrently with an anthracycline, the European Cooperative Trial in Operable Breast Cancer (ECTO) randomized over 1,350 patients to control of sequential A (75 mg/m^2)→ CMF versus concurrent A/P (60/200 mg/m^2) → CMF preoperatively or postoperatively (43). The addition of paclitaxel significantly improved RFS over control (HR = 0.73, p = .03), and RFS outcomes were the same whether chemotherapy was given preoperatively or postoperatively. Another trial of concurrent P with A was conducted by the Loesch et al. comparing every 3 week AC → P against concurrent A/P (50/200 mg/m^2) → weekly P (80 mg/m^2) (44). This study did not show a benefit of concurrent A/P → weekly P. This may be attributed to the higher percentage of patients requiring dose reduction (14% vs. 3%) and delays (14% vs. 5%) in the A/P → weekly P arm. Thus, unlike the result in E1199 showing the benefit of AC → weekly P, the specific regimen (A/P → weekly P) cannot be considered a standard option (Table 44-3).

Docetaxel

Docetaxel is active in the adjuvant treatment of breast cancer. Docetaxel has no pharmacologic interaction with the anthracyclines, thus allowing its coadministration with an anthracycline in an effort to achieve a (theoretical) synergistic response, or to minimize treatment duration. However, toxicity generally means that such a combination will utilize lower doses of these active agents, especially when agents are combined concurrently. One such concurrent combination trial with docetaxel was conducted by the Breast Cancer International Research Group (BCIRG) 001 was a randomized phase III trial comparing FAC with docetaxel plus AC (DAC) in node-positive breast cancer patients (45–46). In this study almost 1,500 patients were randomly assigned to treatment with DAC (75/50/500 mg/m^2) or FAC (500/50/500 mg/m^2), all given every 3 weeks × 6 cycles. Now at a long-term follow-up of 10 years, the benefit of DAC was maintained for DFS (62% vs. 55%, p = .004) and OS (76% vs. 69%, p = .002) (46). In terms of toxicity, the febrile neutropenia rate was 10-fold

DFS, disease-free survival; RFS, relapse-free survival; EFS, event-free survival; OS, overall survival; NS, not statistically significant; NR, not reported; NSABP, National Surgical Adjuvant Breast and Bowel Project; CALGB, Cancer and Leukemia Group B; INT-0102, US Intergroup Study 0102; GEICAM, Grupo Espanol de Investigacion en Cancer de Mama; ECOG, Eastern Cooperative Oncology Group; ECTO, European Cooperative Trial in Operable Breast Cancer; NCIC, National Cancer Institute of Canada; A, doxorubicin; C, cyclophosphamide; P, paclitaxel; F, fluorouracil; D, docetaxel; M, methotrexate; E, epirubicin; w, weekly; DD, dose dense.

higher with DAC over FAC (25% vs. 2.5%) and thus, granulocyte colony stimulating factor (GCSF) should be used when administering DAC. The GEICAM group evaluated the efficacy of DAC against FAC in over 1,000 patients with node-negative disease in study 9805 (47). At a median follow-up of 77 months, DFS in favor of DAC (87.8% vs. 81.8%, $p = .01$), but and OS was not statistically different between the 2 arms. In this study about half of the patients had T1 tumors and two-thirds had hormone-receptor-positive breast cancer. Once again, in the modern era most of these patients should undergo genomic profiling to help determine if they are likely to benefit from chemotherapy.

Another trial of concurrent docetaxel and doxorubicin was conducted by the North American Breast Cancer Intergroup led by the Eastern Cooperative Oncology Group (Trial E 2197). In this study over 2,800 women with zero to three involved nodes were randomized to control of AC versus AD (60/60 mg/m^2) (48). Overall, there was no difference in DFS (85% in both arms) or OS (91% vs. 92%) at 5 years. Toxicities were higher with AD. Thus, there is no role for AD in the treatment of breast cancer.

A trial that evaluated the role concurrent versus sequential docetaxel with an anthracycline-based treatment was the BIG 02-98 in which over 2,800 patients with node-positive breast cancer were randomized to controls of A (75 mg/m^2) → CMF or AC (60/600 mg/m^2) → CMF versus the experimental arms of A (75 mg/m^2) → D (100 mg/m^2) → CMF or AD (50/75 mg/m^2) → CMF. The CMF was given in the classical schedule (49). At a median follow-up of 5 years, there was an improvement in DFS with the addition of docetaxel, regardless of its schedule (HR = 0.86, $p = .05$). Secondary comparisons showed that the sequential docetaxel was better than the concurrent taxane schedule (HR = 0.83). The superiority of sequential docetaxel arm was likely due to the ability to give higher doses of A and D. This trial confirmed the benefit of a taxane addition.

In terms of trials on sequential anthracyclines and taxanes, several studies were designed and NSABP B-27 was an add-on study of docetaxel preoperatively or postoperatively to 4 cycles of preoperative AC (50). In this study more than 2,400 patients were assigned to receive AC → surgery or AC → D → surgery or AC → surgery → D. There was a doubling of pathologic complete response (pCR) in those who received preoperative AC → docetaxel versus AC alone (26.1% vs. 13.7%, $p < .001$). However, in NSABP B-27, despite a doubling of pCR rates in patients who received AC → docetaxel over those given AC alone, there was no statistically significant difference in terms of DFS or OS. However, there was a trend in improvement in RFS in those who received docetaxel preoperatively (HR = 0.85, $p = .08$). This finding may be attributable to the maintenance of dose density leading to maximal cell kill. Pathologic complete response was a significant predictor of DFS and OS, regardless of treatment types. These results were updated and at a longer follow-up, the 5- and 8-year DFS and OS outcomes were the same across all 3 arms (51). Although the results of this trial were disappointing on the effect of docetaxel, there were many other trials in favor of the addition of the taxanes. Of note, NSABP B-27 is a preoperative trial and there are sufficient data demonstrating that DFS and OS outcomes are not affected when the same systemic therapy is given preoperatively or postoperatively. These data are discussed in detail in another chapter.

Yet another study that evaluated the sequential anthracycline and docetaxel schedule was the Programme Action Concerte Sein (PACS) 01 trial (52). Here, patients were randomized to receive standard FEC 100 × 6 versus FEC 100 × 3 → D (100 mg/m^2) × 3, all given IV every 3 weeks. Now at a median follow-up of 8 years, DFS rates were 70.2% versus 65.8% in favor of FEC → D (HR = 0.85, $p = .036$) and OS rates of 82.2% versus 78.0 % (HR = 0.75, $p = .007$). For many years FEC 100 was the standard option as treatment for high-risk patients in Europe. With the result of PACS 01, this was then supplanted by FEC → D as the new option. Similarly, the West German Study (WGS) group reported the result of sequential epirubicin-docetaxel regimen against the control regimens which consisted of FEC 100. In this study patients with 1–3 positive nodes were randomized to control, FEC 100 (500/100/500 mg/m^2) × 6 or CMF, and experimental EC

(90/600 mg/m^2) × 4 → D (100 mg/m^2) × 4 (47,53). Of note over 90% patients who were randomized to the control arm received FEC 100. At a median of 5 years, the event-free survival (EFS) (89.8% vs 87.3%, p = .03) and OS (94.5% vs. 92.8%, p = .035) were in favor of the docetaxel containing arm. Certainly, the result of this trial was consistent with the literature, and EC → D may be added to the list of anthracycline-taxane options as a standard adjuvant therapy.

Like the NSABP B-27 study, there was another sequential anthracycline-taxane that did not show benefit with the addition of docetaxel. The Taxotere as Adjuvant Chemotherapy Trial (TACT) randomized over 4100 patients to a control regimen [either FEC (600/60/600 mg/m^2) × 8 or E (100 mg/m^2) × 4 → CMF × 4] versus the experimental arm of FEC × 4 → D (100 mg/m^2) × 4 (54). At a median follow-up of 5 years, there was no benefit with the addition of docetaxel. An exploration of biomarker-defined subgroups may help to identify which group may still benefit from the addition of D in this study.

The NSABP reported the data on study B-30 which randomized over 5300 node-positive patients to standard AC → D (100 mg/m^2) versus DAC (60/60/600 mg/m^2 and amended to 75/50/500 mg/m^2) × 4 versus AD (60/60 mg/m^2 and then amended to 50/75 mg/m^2) × 4 (55). At a median follow-up of 6 years in terms of OS, AC → D was superior to AD (HR = 0.83, p = .034) and marginally better than DAC × 4 (HR = 0.86, p = .086). In terms of DFS, AC → D was better than DAC × 4 (HR = 0.83, p = .006) and AD (HR = 0.80, p = .001). Thus, AC → D remained the standard option in the treatment of high-risk breast cancer from this trial.

The BCIRG sought to determine whether sequential or concurrent use of anthracycline-taxane regimens differed in risks and benefits and conducted BCIRG 005, which compared two standard options of AC → D and DAC × 6 in almost 3300 node-positive women (56). At a median follow-up of 5 years, the DFS rates were 79% for both groups (p = .98) and OS rates were 88% and 89% (p = .37). Toxicities differed with more febrile neutropenia seen with DAC and more sensory neuropathy and nail changes reported with AC → D. The authors concluded that these two regimens were equivalent in efficacy. However, they could not address the issue of sequential versus concurrent therapy due to the various confounders (dose sizes and number of cycles).

In exploring the omission of an anthracycline, the US Oncology group conducted trial 9735, comparing DC (75/600 mg/m^2) × 4 against standard AC over 1,000 patients with stage I, II, or operable III breast cancer (57). Almost half of the patients in each arm had node-negative disease. At a median follow-up of 7 years, there was statistically significant improvement in DFS in those receiving DC over AC (81% vs. 75%, HR = 0.74, p = .033 and OS (87% vs. 82%, HR = 0.69, p = .032). However, it is still unclear when DC may be appropriate. First, half of the patients in this trial had node-positive disease, and the AC comparator was an obsolete regimen for the treatment of patients with high-risk disease in the modern era (37–38). Second, DAC × 4 was inferior to standard AC → D in NSABP B-30. The DC regimen was similar to DAC × 4 (without A), and thus it would be suboptimal as a treatment for high-risk patients. Third, since the other half of the patients in trial 9735 had node-negative breast cancer, with the majority having hormone-receptor-positive disease, genomic signatures would now be used to determine if they would even benefit from chemotherapy. Perhaps DC may be considered in those with hormone-receptor-positive, *HER2*-negative, node-negative disease with an intermediate recurrence score based on the 21-gene recurrence score (which will be discussed later in this chapter). However, this is also where another non-anthracycline-based therapy (i.e., CMF) may also be considered as a treatment option (Table 44-4).

Dose Intensity

Another way to improve the benefit of adjuvant chemotherapy is to increase the dose intensity formulated as body-size adjusted dose (mg/m^2) divided by time (per week) (58). One method of increasing dose intensity is dose-escalation, which is supported by preclinical models demonstrating that some forms of resistance to cytotoxic drugs can be overcome by increasing the dose size (59). Based on this hypothesis, a variety of clinical trials have tested dose-escalation to improve outcomes. CALGB 8541 evaluated three doses of CAF chemotherapy in 1,550 patients (low, moderate, and high dose intensity). At 9 years of follow-up, DFS and OS were superior for the moderate and higher dose arms when compared with the lower dose arm (60). Similarly as discussed previously FASG 05 demonstrated that FEC 100 was better than FEC 50 (31).

However, other trials have failed to demonstrate improved outcomes with supranormal levels of chemotherapy beyond the standard dose (61–62). NSABP B-22 and B-25 evaluated dose-escalation of the cyclophosphamide doses from the standard 600 mg/m^2 up to 2,400 mg/m^2. There was no improvement in outcomes in both trials, but there was a significant increase in cases of myeloproliferative disorders, including acute leukemia, observed in B-25. As mentioned previously CALGB 9344 did not demonstrate any benefit with the higher doses of doxorubicin over the standard dose (37). Thus, simple dose-escalation beyond standard dose levels at conventional dosing intervals may not be sufficient to improve outcome.

A number of trials have evaluated the role of myeloablative adjuvant regimens requiring autologous bone marrow or peripheral stem cell rescue. Despite promising phase II results, randomized trials have failed to demonstrate a clear benefit in disease-free or overall survival for the use of high-dose chemotherapy with stem cell transplant (HDC-SCT). An overview of 15 randomized trials of more than 6,200 patients demonstrated that HDC-SCT led to an improved RFS but not OS. Due to these findings, along with the much higher toxicities inherent with HDC-SCT, as well as lack of data on its comparison with modern taxane-based therapies or trastuzumab-based therapy (for *HER2*-positive patients), there is no role for this type of therapy in breast cancer treatment (63).

Dose Density

The Norton-Simon model predicts that the optimal treatment of a heterogeneous mix of cells (in terms of chemotherapy sensitivity) is to eradicate the numerically dominant, faster-growing cells first, followed by eradication of the more slowly growing, resistant cells (64). This is termed sequential therapy and was found to be superior to alternating therapy in a randomized clinical trial reported by Bonadonna et al. (24). Sequential therapy may be more effective because it increases the frequency ("density") of treatments as compared to alternating therapy, thereby minimizing the time during which sensitive cells can regrow before retreatment. When filgrastim (granulocyte colony-stimulating factor, G-CSF) became available, several pilot studies testing increased dose density at Memorial Sloan-Kettering Cancer Center (65–67). These studies led to a randomized trial led by the CALGB (C 9741) for the Intergroup in over 2,000 patients which compared every-2-week to every-3-week cycling of chemotherapy, given sequentially (A→ P→ C) or concurrently (AC → P) (68–69). This trial used a 2 × 2 factorial design to answer two questions: (1) Is dose dense (DD) superior to conventional chemotherapy? (2) Is sequential superior to concurrent combination chemotherapy? At a median follow-up of 36 months, outcomes were significantly

DFS, disease-free survival; RFS, relapse-free survival; EFS, event-free survival; OS, overall survival; NS, not significant; NR, not reported; BCIRG, Breast Cancer International Research Group; GEICAM, Grupo Espanol de Investigacion en Cancer de Mama; ECOG, Eastern Cooperative Oncology Group; BIG, Breast International Group; NSABP, National Surgical Adjuvant Breast and Bowel Project; PACS, Programme Action Concerte Sein; WGS, West German Study; TACT, Taxotere as Adjuvant Chemotherapy Trial; D, docetaxel; A, doxorubicin; C, cyclophosphamide; F, fluorouracil; M, methotrexate; E, epirubicin.

better in favor of the DD arms (risk ratio [RR] 0.74, p = .010) and OS (RR 0.69, p = .013) (Table 44-3). There was no difference in either DFS or OS between sequential and concurrent chemotherapy schedules. There was no interaction between dose density and sequence. These results were maintained with a longer follow-up of 6.5 years (69). This trial was a pure test of dose density with no confounders, as the dose size, the number of cycles per chemotherapy, and the number of agents were consistent across all arms. Thus, based on the results of C9741, DD AC → P became a popular and commonly used standard option in the United States.

SWOG is conducting a large phase III trial comparing two anthracycline schedules and two optimal schedules of paclitaxel (weekly vs. dose dense) as mentioned above. Trial S0221 has randomized over 2,700 patients in a 2 × 2 factorial design to experimental AC + granulocyte colony-stimulating factor (GCSF) versus DD AC and then to weekly P (80 mg/m^2) × 12 versus DD P (175 mg/m^2) × 6. In the AC + GCSF arm, A was given as 24 mg/m^2/week × 15 and C was administered as 60 mg/m^2/day orally, with GCSF daily (except on days of A administration). It has been reported that AC + GCSF is not superior to DD AC (70) and a comparison of the two paclitaxel schedules is expected in 2013. CALGB 40101, recently reported by Shulman et al., is a related trial in lower-risk disease. Here, over 3100 patients with zero to three positive nodes were randomized to AC × 4 or 6 or P × 4 or × 6 (71). After 2003 when CALGB 9741 showed the superiority of DD chemotherapy, all treatments were given in DD schedule. At a median follow-up of 5 years, the 4-year RFS (90.9% vs. 91.8%) and OS (95.3% vs. 96.3%) were the same with 6 versus 4 cycles of therapy. The result of C40101 on the comparison between A versus P is expected in 2013.

Another trial that tested dose density was led by the National Cancer Institute of Canada. Trial MA.21 randomized patients to DD EC (120/830 mg/m^2) × 6 →P (175 mg/m^2) × 4 every 3 weeks against two control arms (CEF and every 3 week AC → P). At a median follow-up of 30 months, the RFS was inferior with every 3 week AC → P when compared to both CEF (HR = 1.49, p = .005) and DD EC → P (HR = 1.68, p = .0006). Notably, in DD EC → P, the paclitaxel was given every 3 weeks so the additional gain of this regimen was attributable to the DD schedule of EC and possibly the higher number of cycles of this chemotherapy regimen as compared to what was given in AC → P. Although the study is not a pure test of the dose-dense hypothesis, the results support the concept that DD regimens have a role in adjuvant treatment (72) (Table 44-3).

Not all DD trials confirmed benefit. An Italian phase III study randomized over 1,200 patients to FEC (600/60/600 mg/m^2) × 6 every 3 weeks versus every 2 weeks (dose dense). At a median follow-up of 10 years, there was no improvement in EFS or OS with DD FEC (73). Cameron and colleagues recently reported the result of UK TACT 2 trial comparing standard versus DD epirubicin (74). This was a 2 × 2 factorial design in which patients were randomized to E (100) mg/m^2 × 4 every 3 weeks versus every 2 weeks and then to classical CMF versus capecitabine. In the first analysis of this study, there was no benefit with DD E. The reason for this is unclear and we await the final analysis. The comparison of CMF versus capecitabine will be reported later.

Moebus et al. tested the question of dose intensity and density in the AGO phase III study in which over 1,200 patients with four or more positive nodes were randomized to "intense dose dense" (IDD) E (150 mg/m^2) × 3 → P

(225 mg/m^2) × 3 → C (2,500 mg/m^2) × 3, all administered every 2 weeks with GCSF versus EC (90/600 mg/m^2) × 4 → P (175 mg/m^2) × 4 every 3 weeks (75). At a median follow-up of 5 years, the EFS (70% vs. 62%, $p < .001$) and OS (88% vs. 77%, $p = .0285$) were in favor of IDD chemotherapy. Not surprisingly, there were more nonhematologic and hematologic toxicities with the IDD regimen, including four cases of acute leukemia and myelodysplastic syndrome observed. With a longer follow-up of 10 years, these benefits were still maintained for both RFS and OS, regardless of subgroups (76) (Table 44-3). Unlike CALGB 9741, this trial was not a pure study of dose density as there were variations in dose size (dose intensity), cumulative dose, and number of cycles of each chemotherapy agent. Because NSABP B-25 (and B-22 before) showed the lack of benefit for dose-escalation of cyclophosphamide to 2,400 mg/m^2, the AGO study is relevant supporting for DD scheduling, but the high-dose regimen is not considered standard.

THE EARLY BREAST CANCER TRIALISTS' COLLABORATIVE GROUP PROCESS AND RESULTS

The Early Breast Cancer Trialists' Collaborative Group was formed in the mid-1980s to perform a meta-analysis of randomized trials in the adjuvant setting with updated reports published approximately every 5 years. The EBCTCG overview contains individual data from thousands of patients and has substantial power to detect relatively small differences in outcome with long-term follow-up. Data on hormone receptor status of the primary tumor were not available in many of the older trials, and most trials did not test for human epidermal growth factor receptor 2 (*HER2*). Both of these markers are now critically important for the decision making on adjuvant treatment. The EBCTCG meta-analyses demonstrated that single-agent chemotherapy was better than none and that polychemotherapy was superior to no therapy in improving recurrence, breast cancer mortality, and overall mortality. In 2005 the EBCTCG showed that 6 months of an anthracycline-based polychemotherapy reduced the annual breast cancer death by 38% for those younger than 50 years of age and 20% for those at 50 to 69 years at diagnosis. These regimens were superior to CMF chemotherapy ($2p = 0.0001$ for recurrence, $2p < 0.00001$ for breast cancer mortality) (2). The reduction in the risk of recurrence with chemotherapy was noted within the first 5 years after randomization and was maintained at the 10- and 15-year time points. Most notably, the improvement in survival continued to improve with the absolute decrease in the risk of death doubling between 5 years and 15 years of follow-up. The EBCTCG demonstrated that in women with ER-poor disease, polychemotherapy, compared to no chemotherapy, significantly reduced recurrence, breast cancer mortality, and death from any cause in those younger than 50 years and those at 50 to 69 years (3). In patients younger than 50 years, the 10-year risks of recurrence, breast cancer mortality, and death from any cause were 33% versus 45% (relative risk [RR] 0.73, $2p < 0.00001$), 24% versus 32% (RR 0.73, $2p = 0.0002$), and 25% versus 33% (RR 0.75, $2p = 0.003$), respectively. For the older group at 50 to 69 years of age, the 10-year risks of recurrence, breast cancer mortality, and death from any cause were 42% versus 52% (RR 0.82, $2p < 0.00001$), 36% versus 42% (RR 0.86, $2p = 0.0004$), and 39% versus 45% (RR 0.87, $2p = 0.0009$), respectively.

Recently, the EBCTCG updated the meta-analyses of long-term outcomes comparing different polychemotherapy regimens for early breast cancer among 100,000 women in 123 randomized trials (4). This overview included taxane-containing trials. The overview demonstrated that add a median follow-up of 8 years, adding four cycles of a taxane to a fixed dose of an anthracycline-based regimen led to an improvement to recurrence (30.2% vs. 34.8%, RR 0.84, $2p < 0.00001$), breast cancer mortality (21.1% vs. 23.9%, RR 0.86, $2p = 0.0005$), and overall mortality (16.3% vs. 18.2%, RR 0.86, $2p = 0.0002$). In the confounded taxane trials in which the effects of the taxanes were counterbalanced by the control arms with more (nonfixed) anthracycline treatment, at a short median follow-up of 5 years there were small, but significant, reductions in recurrence, breast cancer specific mortality, and overall mortality.

Clearly, the results from the EBCTCG meta-analyses confirm the essential role of adjuvant chemotherapy in breast cancer from single-agent chemotherapy and polychemotherapy versus none, to anthracycline-based treatments as superior therapy over CMF, and to the incremental gain with the addition of a taxane to an anthracycline. Yet, the absolute benefits vary with age, nodal status, and hormone receptor status of the tumor, meaning that clinicians still have to exercise judgment and investigators must develop and refine tools to enable more precise selection of patients for treatment.

NEWER AGENTS

New Chemotherapy Agents

With incremental benefits observed from the use of the anthracyclines and taxanes, new drugs were added to see if small additional gains could be attained. Gemcitabine (G) was tested in the tAnGo trial which randomized over 3,100 patients to EC (90/600 mg/m^2) × 4 → P (175mg/m^2) × 4 or EC → PG (1250 mg/m^2) while the doses of other agents were the same (77). Overall, the 3-year DFS and OS were the same in both arms. Likewise, the NSABP also tested the efficacy of gemcitabine in B-38 and found no benefit. This study compared two standard arms of DAC × 6 and DD AC → P against DD AC → PG (2,000 mg/m^2) in over 4,800 patients (78). Overall, there was no difference in the 5-year DFS and OS with the addition of gemcitabine when compared to each control arm. Additionally there was no difference in efficacy outcomes between DAC and DD AC → P, but febrile neutropenia and more deaths occurred on treatment with DAC. Based on these data, DD AC → P remains a preferred standard.

Two studies tested the efficacy of adding capecitabine (X) to the anthracycline–taxane combinations showing no benefit (79–80). FinXX compared standard D → CEF against DX → CEX in 1,500 patients and at a median follow-up of 59 months, there was no difference in RFS or OS (79). US Oncology conducted trial 01062 randomized over 2,600 patients to AC → D versus AC → DX. At a median follow-up of 5 years, again there was no difference in DFS or OS with the addition of capecitabine (80). Other agents that are being evaluated currently are the platinums, particularly in patients with triple-negative breast cancer. We have reached the end of an era of conducting large adjuvant chemotherapy trials and should move forward to designing trials of using less or no chemotherapy (based on genomic signatures) and incorporating more effective biologic or targeted agents.

Antiangiogenic Agents Added to Chemotherapy

One of the greatest advances in adjuvant therapy has been the addition of trastuzumab to chemotherapy in the treatment of patients with human epidermal growth factor

receptor 2 (*HER2*)-positive breast cancer. This is discussed in detail in another chapter. In the *HER2*-negative population there are several trials evaluating the efficacy of bevacizumab (B), a humanized monoclonal antibody against vascular endothelial growth factor. One such trial is ECOG 2104, a pilot study demonstrating the feasibility of bevacizumab combined with DD AC → P in the adjuvant setting (81). This has led to the design of ECOG 5103, a three-arm, phase III trial randomizing about 5,000 node-positive or high-risk, node-negative women to either AC → weekly P/placebo versus AC → weekly P/B versus AC → weekly P/B → B. This trial has completed accrual and results are forth coming. Recently the results of the BEATRICE trial were reported, demonstrating no benefit with the addition of bevacizumab added to standard adjuvant chemotherapy when compared to chemotherapy alone in the patients with triple-negative breast cancer (82). In light of the mixed and modest results in metastatic disease, the available data suggests a limited role for bevacizumab in early stage breast cancer.

THE ELDERLY POPULATION

Older women have been historically underrepresented in adjuvant clinical trials. A review of four CALGB studies demonstrated that older women derive clear benefits from the use of adjuvant chemotherapy, but the toxicity profiles differed by age, with more hematologic toxicity and greater risk of treatment-related death in the older population (83). Treatment decisions in older women should be individualized based on tumor characteristics as well as comorbid conditions and potential life expectancy. Muss et al. reported the result of CALGB 49907 trial, the largest prospective trial in the older population (84). In this study, 633 women at 65 years of age or older were randomized to receive standard chemotherapy with either AC × 4 or classical CMF × 6 (at the discretion of the physician and patient) versus experimental capecitabine therapy. Capecitabine was chosen as it was felt to be a less toxic chemotherapy than the control regimens. In contrast, this study demonstrated that capecitabine was relatively toxic in this setting. More importantly, patients on capecitabine were twice as likely to relapse (68% vs. 85%, $p < .001$) and die (86% vs. 91%, $p = .02$). The inferior outcome with capecitabine was particularly dramatic in patients with ER-negative disease (84). Thus, once the decision is made to treat older women with cytotoxic therapy, standard combination chemotherapy should be used.

THE TAXANE BENEFIT

In recent years, there had been considerable debate about the identification of the appropriate populations for taxane treatment. The CALGB analysis identified the ER-negative subset as deriving substantially more benefit from adjuvant paclitaxel than the ER-positive group (85). However, this relationship had not been consistent across various trials. De Laurentiis performed a meta-analysis of the 14 randomized taxane trials and demonstrated equivalent benefits regardless of ER status, number of involved nodes, age, or menopausal status (86). Although the subgroup analyses based on hormone receptor status were inconsistent, overall the taxanes appeared to provide benefit in patients with both ER-positive and -negative disease. The EBCTCG in 2012 also showed that in meta-analyses of anthracycline/taxane-based against anthracycline-based treatments, risk reductions were little affected by hormone receptor status as well as tamoxifen use, age, nodal status, size, or tumor differentiation (4). Thus, when the decision to treat high-risk patients with chemotherapy is made, the use or omission of the taxanes should not be based on hormone receptor status. The differential benefit from chemotherapy (in absolute terms), based on hormone-receptor-negative versus receptor-positive disease, underscores the need to develop more robust predictors of chemotherapy benefit, particularly in patients with hormone-receptor-positive breast cancer. The use of genomic signatures to aid in chemotherapy decision-making in patients with hormone-receptor-positive breast cancer is discussed below.

TOOLS TO AID IN DECISIONS ON ADJUVANT CHEMOTHERAPY

After surgical resection adjuvant chemotherapy should be considered for most patients with high-risk disease, based on histological parameters (i.e., nodal involvement, tumor size) and poor-risk biology (i.e., triple-negative or *HER2*-positive breast cancer). However, chemotherapy may not be suitable for all patients with hormone-receptor-positive/*HER2*-negative disease and is controversial for many with node-negative disease. There are guidelines set forth by the National Comprehensive Cancer Network and the St. Gallen International Breast Cancer Consensus that may be used in making decisions on when to recommend chemotherapy (87–88). There are also tools that can aid clinicians in objectively assessing the absolute benefits from systemic chemotherapy after local treatment. One such too is Adjuvant! Online, developed by Ravdin et al., which is a validated computer-based model that determines the risk of recurrence based on age, comorbidities, tumor size and grade, hormone receptor status, and nodal status to estimate the contribution of chemotherapy and hormonal therapy in risk reduction (89). However, several limitations of Adjuvant! Online exist, including the omission of *HER2* status and the incorporation of wide ranges of tumor sizes and numbers of involved nodes. Furthermore, it is based primarily on the anatomic spread, rather than molecular biology, and it uses average estimates of treatment effects.

The next step in assessing risk, and more importantly, response to chemotherapy is genomic analysis. These tools have made it possible to further characterize tumors based on the risk of recurrence after hormonal therapy in defined subsets based on expression profiles. In the NSABP B-14 trial, the OncotypeDX (Genomic Health, Redwood City, CA) assay provides individual, quantitative assessments of the likelihood of breast cancer recurrence after 5 years of treatment with tamoxifen in patients with node-negative disease. It is an RT-PCR assay that measures the expression of 21 genes, consisting of 16 cancer-related genes and 5 reference genes. The expression of these genes is used to calculate a recurrence score (RS) that predicts the likelihood of recurrence at 10 years (90). Patients are classified into three different categories based on the RS, namely low (RS <18), intermediate (RS 18–30) and high (RS ≥31) with associated 10-year distant recurrence rates of 6.8%, 14.3%, and 30.5%, respectively. More important than its accuracy as a prognostic tool is its role as a predictive one. Indeed, retrospectively applied to the NSABP B-20 study, the OncotypeDX was not only prognostic but also predicted the likelihood of chemotherapy benefit in patients with node-negative ER-positive cancer. Those with a low RS derived minimal benefit with adjuvant chemotherapy, whereas those with higher scores gained more significant improvements in disease free survival. Based on this, one would predict that those with low scores would be sufficiently treated with hormonal therapy

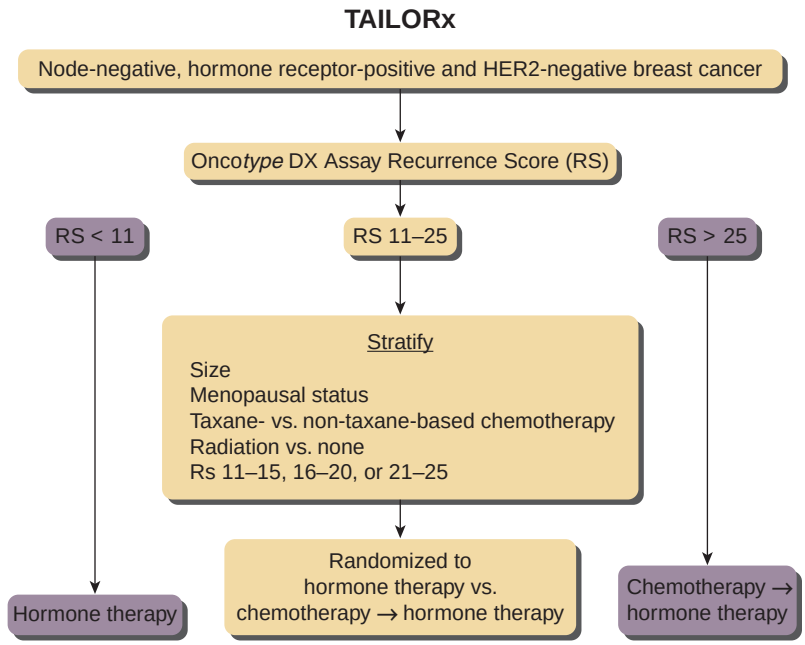

FIGURE 44-1 TAILORx (Trial Assigning Individualized Options for Treatment). RS, recurrence score.

alone (91). The Breast Cancer Intergroup of North America has concluded the Trial Assigning Individualized Options for Treatment (TAILORx) trial to evaluate the benefit, or not, of chemotherapy combined to hormonal therapy in patients with intermediate RS (Fig. 44-1). This study has reached its target accrual and the results are awaited (92).

The SWOG 8814 study demonstrated the efficacy of anthracycline-based chemotherapy plus tamoxifen when administered sequentially in patients with node-positive, ER-positive disease with a high RS. Here again a retrospective analysis from this study showed little benefit with the addition of anthracycline-based chemotherapy in women with node-positive disease with a low RS (93). Recently SWOG has activated a phase III trial, namely Rx for Positive Node, Endocrine Responsive Breast Cancer (RxPONDER) study focusing on patients with one to three involved nodes with low to intermediate RS (Fig. 44-2). These patients are randomized to chemotherapy followed by hormone therapy or hormone therapy alone (94). The result of this study will be critical as it may help us to identify the proper patient group with ER-positive, node-positive disease whom we may spare from chemotherapy exposure. Taken together, these results predict a future in which biology, in the form of a genomic assessment, is the dominant factor in determining the need for adjuvant chemotherapy.

The only Food and Drug Administration (FDA) approved microarray-based assay is the MammaPrint which uses a similar approach to explore a larger number of genes for prognostic purposes. MammaPrint is a 70-gene signature (also referred to as the Amsterdam signature) developed at the Netherlands Cancer Institute. It categorizes patients into two groups, good prognosis and poor prognosis,

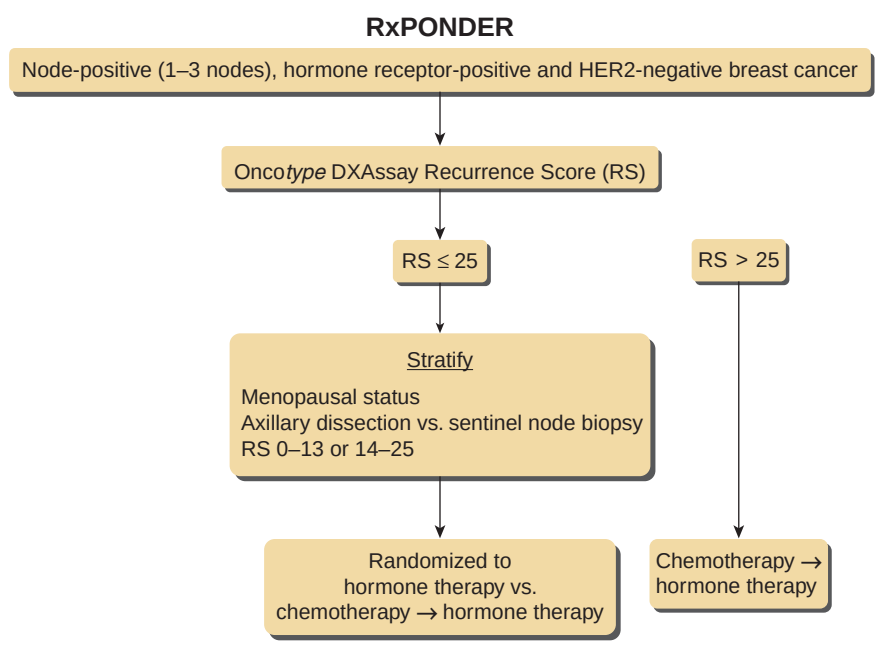

FIGURE 44-2 RxPONDER (Rx for Node-Positive, Endocrine Responsive Breast Cancer). RS, recurrence score.

irrespective of their ER status. The signature largely consists of genes regulating proliferation, plus those involved in invasion, metastasis, stromal integrity, and angiogenesis. Initial validation studies were done by the Translational Breast International Group (TRANSBIG) and this formed the basis of its use in the ongoing Microarray In Node-Negative Disease may Avoid ChemoTherapy (MINDACT) study that evaluates which patients can be spared chemotherapy (95). However, there are a few differences with this test from OncotypeDX, such as its clinical utility in ER-negative patients, where 0% to 4% are classified as good prognosis, and in *HER2*-positive patients, where up to 22% are classified as having good prognosis and not requiring therapy.

The use of these clinical tests of gene expression raises questions regarding the clinical utility of the five intrinsic molecular subtypes defined by gene profiling studies. The subtypes do not precisely reproduce the results of conventional immunohistochemistry testing. For example, there is discordance between tumors identified to have the *HER2*-positive molecular subtype and those identified by immunohistochemistry or fluorescence *in situ* hybridization. Other limitations of gene expression profiling for intrinsic subtypes include the requirement (at least until recently) for fresh frozen tissue for microarray-based signatures. To address this issue, an intrinsic 50-gene set has been used to develop an RT-PCR based predictor called PAM50 (96). The PAM50 gene assay identifies the five intrinsic subtypes (luminal A and B, *HER2*-enriched, basal-like, and normal-like) and provides a continuous risk score based on the similarity of an individual sample to prototypic subtypes. Recent data suggest that when the OncotyopeDX assay and PAM50 are compared, there is a large overlap in the ability of these tests to determine the recurrence risk in ER-positive breast cancer (97). In fact, 51% of the patients, classified to have an intermediate RS by OncotypeDX, have been recategorized as low-risk luminal A using PAM50. Although these results are encouraging, the prognostic utility of PAM50 is currently restricted to ER-positive, node-negative disease and its predictive utility has not been established (98). Please refer to Chapter 30 for more details on molecular prognostic and predictive factors.

SUMMARY

With an abundance of data over several decades, there are now several chemotherapy options to choose from when treating patients with high-risk disease (defined biologically or histologically). In terms of regimens containing paclitaxel, dose-dense AC → paclitaxel or dose-dense A → paclitaxel → C (CALGB 9741), AC-weekly paclitaxel (ECOG 1199), FEC-weekly paclitaxel (GEICAM 9906), dose-dense EC → paclitaxel (MA.21), and A/P → CMF (ECTO) (39,41,43,68–69,72) are acceptable. For regimens that contain docetaxel, they are DAC (BCIRG 001), AC → docetaxel (ECOG 1199, NSABP B-30, BCIRG 005), A → docetaxel → CMF (BIG 02-98), FEC → docetaxel (PACS 01), and EC → docetaxel (WGS) (39,45–46,49,52–53,55–56). Anthracycline-containing regimens without a taxane may also be considered such as CEF (MA.5 and MA.21) and E → CMF (NEAT/BR9601) for patients with contraindications to paclitaxel and docetaxel (30,32,72). When choosing a regimen, it is important to factor in the toxicity differences across these options as discussed earlier.

CONCLUSION AND FUTURE DIRECTIONS

Adjuvant chemotherapy for early breast cancer has been studied for nearly 50 years and has contributed to improved outcomes worldwide. This is an area where clinical trials have been highly successful and influential in establishing standards and benchmarks against which we can measure future progress. As a result of these studies and our communities' efforts, we have identified the value of specific agents, dosing, and scheduling, and have begun to apply advances in molecular biology to the problem of patient and tumor selection for treatment. At the moment, the best results in terms of OS and DFS are achieved in most patients through the use of sequential combination chemotherapy containing the anthracyclines, alkylating agents, and the taxanes. The absolute benefit from the addition of taxanes is most notable in patients with hormone-receptor-negative tumors but some patients with hormone sensitive disease also benefit. As we develop more sophisticated ways to characterize tumors using techniques such as gene array analysis, we are reminded that breast cancer is a heterogeneous disease. Rather than designing trials that segregate patients based on historically standard clinical criteria such as estrogen receptor status, we can now investigate the role of adjuvant therapy on patients stratified by risk based on specific genetic signatures of their tumors in both the node-negative (TAILORx) and node-positive (RxPONDER) groups. With the ongoing implementation of well-designed clinical trials incorporating new therapeutic agents in a rational way, we hope to continue to see a trend toward improved DFS and OS in patients presenting with early breast cancer.

CHAPTER 45

Adjuvant Chemo Endocrine Therapy

Vered Stearns and Nancy E. Davidson

CHAPTER CONTENTS

INTRODUCTION

Adjuvant systemic therapy is associated with significant improvements in disease-free and overall survival benefits and is recommended to most women with stage I–III breast cancer. Adjuvant systemic therapy may include endocrine manipulation, cytotoxic therapy, anti-HER2 agents, or a combination of more than one of these approaches. The benefits and adverse effects associated with each of the individual treatments are discussed elsewhere in this textbook. As described in Chapter 43, endocrine therapies are recommended to most women with a tumor expressing the estrogen receptor α (ER) and/or progesterone receptor (PgR) proteins. The main challenge facing healthcare providers and women with newly diagnosed hormone receptor-positive tumors is to further determine who would benefit from the administration of chemotherapy in addition to endocrine manipulations, designated chemo endocrine therapy. Other questions pertain to the type, duration, and sequence of therapy that should be considered in this population. Notably, some women with hormone receptor–positive tumors are relatively resistant to endocrine manipulations, yet might not derive benefit from chemotherapy either. Identification of mechanisms and biomarkers of endocrine resistance will help in development of novel therapies that could be administered either with or instead of endocrine therapy. In this chapter, we review current considerations for administration of chemo endocrine therapy in properly selected women.

WHO IS A CANDIDATE FOR CHEMO ENDOCRINE THERAPY?

The presence of the hormone receptors ER and/or PgR is required for response to endocrine manipulations. However, not every woman whose tumor expresses the hormone receptors benefits from endocrine manipulations. Over the last two decades several analyses have helped provide guidance in the difficult task of separating women who would benefit from endocrine therapy alone from those for whom additional or alternative therapy is required.

Main Results from the Early Breast Cancer Trialists' Collaborative Group Overview

The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) Overview of patient-level data from prospective randomized trials continues to provide the largest data set estimating impact of single or multi-agent adjuvant endocrine and chemotherapy regimens on survival outcomes in women with early breast cancer. The 2005 publication of the 2000 Overview included 194 studies of combination chemotherapy including CMF (cyclophosphamide, methotrexate, fluorouracil), FAC or CAF (fluorouracil, doxorubicin, cyclophosphamide), or FEC (fluorouracil, epirubicin, cyclophosphamide), and the endocrine therapies tamoxifen or ovarian ablation/suppression. Treatment with approximately 6 months of anthracycline-based polychemotherapy was significantly more effective than CMF in reducing breast cancer recurrence ($2p = 0.0001$) and mortality ($2p = 0.00001$) (1). The benefit was more substantial in women younger than 50 years of age, with a 38% (Standard Error [SE] 5%) reduction in annual breast cancer death rate compared to about 20% (SE 4%) for those ages 50 to 69. The differences were irrespective of ER status, use of tamoxifen, nodal status, or other tumor characteristics. The number of women older than age 70 who were included in the prospective studies was too small to allow for meaningful conclusions for this subgroup. In women whose tumors were ER-positive, 5 years of tamoxifen was associated with a substantial reduction in annual breast cancer recurrence and death irrespective of the use of chemotherapy, age, PgR status, or other tumor characteristics.

The Overview suggested that allocation to ovarian ablation or suppression (n = 8,000) also significantly reduced breast cancer recurrence and mortality. However, the benefit was seen primarily in women who have not received other systemic treatments (1).

The most recent EBCTCG updates of relevant randomized trials shed further light on tamoxifen as well as newer chemotherapy regimens. In an overview of data from 20 trials (n = 21,457) in early breast cancer of about 5 years of tamoxifen versus no adjuvant tamoxifen, tamoxifen was associated with a substantial reduction of recurrence rates at 5 years (26.1% and 15.4% in control- and tamoxifen-treated women, respectively) and 10 years (37.7% and 24.8% in control- and tamoxifen-treated women, respectively) (2). Although women were allocated to tamoxifen for only 5 years, the benefits were observed up to 15 years from the initial assignment, well beyond the duration of administration and emphasizing the importance of this agent.

In the most recent analysis of 123 randomized trials addressing chemotherapy questions, the trialists compared results with polychemotherapy versus no chemotherapy (n = 32,000), different anthracycline-containing regimens (n = 7,000), CMF-containing regimens (n = 18,000), or any taxane plus anthracycline-based combinations to regimens of nontaxane chemotherapy (n = 44,000) (3). A comparison of CMF for six cycles with the standard combination of doxorubicin 60 mg/m^2 and cyclophosphamide 600 mg/m^2 (AC) for four cycles revealed equivalent breast cancer mortality rates (relative risk [RR] 0.98, SE 0.05; $2p$ = 0.67). However, the administration of anthracycline-based regimens that included a higher cumulative dose than standard AC, such as CAF or CEF, were superior to standard CMF (RR 0.78, SE 0.06; $2p$ = 0.0004). When comparing polychemotherapy to no chemotherapy, greater breast cancer mortality reductions were observed with CAF (RR 0.64, SE 0.09; $2p < 0.0001$) compared to standard AC (RR 0.78, SE 0.09; $2p = 0.01$) or CMF (RR 0.76, SE 0.05; $2p < 0.0001$). Finally, the administration of four cycles of a taxane following an anthracycline-based regimen was associated with significant reduction in breast cancer mortality (absolute gain 2.8%, SE 0.9; RR 0.86, SE 0.04; $2p$ = 0.0005) when compared with the anthracycline-based regimen alone. In contrast, when taxanes added to anthracycline-based therapy without changing the duration of treatment in the investigational arms were compared to roughly doubling nontaxane agents' dose in control arms, a significant difference in breast cancer mortality was not observed (RR 0.94, SE 0.06; $2p$ = 0.33). For all comparisons of taxane-based or anthracycline-based regimens, the EBCTCG noted that proportional risk reductions were independent of age, nodal status, tumor size, tumor differentiation, ER expression, or tamoxifen use. Subgroup analysis by ER status and subset analysis by expression, age, and differentiation in ER-positive tumors are presented in Table 45-1A–C.

While the EBCTCG provides substantial information regarding the value of specific therapies in reducing recurrence and mortality rates in women with early breast cancer, it is associated with several limitations. The Overview has not yet evaluated the role of newer agents such as third-generation aromatase inhibitors or trastuzumab or dose-dense anthracycline- and taxane-based regimens. Evidence regarding the benefit or harms of these newer agents or approaches is derived mostly from smaller meta-analyses or from large prospective randomized trials. Overview data regarding tumor or patient characteristics provide important information regarding odds of benefiting from endocrine strategies alone or whether additional agents should be considered. However, the Overview cannot provide data regarding benefits that an individual woman should expect from specific types of treatment or agents. Finally, there was no central review of ER, PgR, or other tumor characteristics in the Overview and results of new molecular analyses such as HER2 status or multigene assay results are not yet a part of the Overview. Nonetheless, the EBCTCG analyses have been pivotal in defining the benefits of adjuvant tamoxifen and chemotherapy for the population at large.

Meta-Analyses of Randomized Trials of Aromatase Inhibitors

A recent meta-analysis of randomized trials of aromatase inhibitors (AIs) compared with tamoxifen either as initial monotherapy (Cohort 1) or after 2 to 3 years of tamoxifen

EBCTCG, Early Breast Cancer Trialists' Cooperative Group; NS, not significant; ER, estrogen receptor; O–E, observed minus expected.
Data from Peto R, Davies C, Godwin J, et al. Comparisons between different polychemotherapy regimens for early breast cancer: meta-analyses of long-term outcome among 100,000 women in 123 randomised trials. *Lancet* 2012;379(9814):432–444.

Cohort 2 consisted of four trials including German Adjuvant Breast Cancer Group/Arimidex-Nolvadex, Intergroup Exemestane Study/BIG 02-97, Italian Tamoxifen Anastrozole Trial (ITA), and Austrian Breast & Colorectal Cancer Study Group (ABCSG) 8, with a total of 9,015 women and a mean of 3.9 years of follow-up. At 3 years from treatment separation, AI therapy was associated with an absolute decrease in recurrence of 3.1% (SE 0.6%, 5.0% for AI vs. 8.1% for tamoxifen; $2p < 0.00001$) and in breast cancer mortality of 0.7% (SE 0.3%, 1.7% for AI vs. 2.4% for tamoxifen; $2p = 0.02$). The use of chemotherapy was not described in this analysis; however, review of the individual studies reveals that approximately 20% to 30% of participants received chemo endocrine therapy and these results are reviewed below. This meta-analysis confirms that use of an AI, administered instead of or in sequence with tamoxifen, is superior to use of tamoxifen alone in most postmenopausal women. This analysis helps to evaluate the role of AI instead of or in addition to tamoxifen, but unfortunately it does not provide specific guidance regarding the use of chemo endocrine therapy.

Prognostic and Predictive Markers

Clinicians use important tools, such as Adjuvant! Online, derived from and based on results from the Overview and other data sets, to provide estimates of recurrence and death and to predict response to specific treatments for their patients (5). However, increasing understanding of the molecular characteristics of individual tumors is expected to aid further in personalized treatment recommendations. The EBCTCG and AI meta-analyses have examined the role of prognostic and predictive markers that can be used to determine who would benefit from endocrine therapy alone, and who should be recommended chemo endocrine therapy. Prognostic factors reflect the natural biology of the tumor in the absence of systemic therapy and are used to estimate risk of recurrence (6–8). In contrast, predictive factors reflect likelihood of benefit from specific treatments or agents. Most factors are both prognostic and predictive as reviewed in Chapter 28. Although initial investigations concentrated on single biomarkers such as ER, PgR, or markers of proliferation or differentiation, newer analyses are assessing the role of multiple markers simultaneously.

ER and PgR Status

The EBCTCG assessed benefit from tamoxifen versus not based on level of ER expression and PgR status. In 7,378 women with ER- and PgR-positive tumors, tamoxifen use led to a relative risk of recurrence at 10 years of 0.63 (95% Confidence Interval [CI], 0.58–0.68; Log-rank $2p < 0.00001$) (1). A similar substantial benefit was observed in 2,310 women with ER-positive and PgR-poor tumors (RR 0.60, 95% CI, 0.52–0.69; Log-rank $2p < 0.00001$) (Table 45-2A), and in women whose tumors were marginally ER-positive. No benefit was seen in those women whose tumors were ER-poor.

In Cohort 1 of the AI meta-analysis, a difference in outcome was observed with respect to PgR status in the 8,745 patients (89%) with a known PgR status. The proportional reduction in recurrence in AI compared to tamoxifen was 40% (SE 9%) in the 22% of women with ER-positive, PgR-poor tumors and 17% (SE 6%) in those with ER-positive, PgR-positive tumors (Table 45-2B). The authors noted, however, that the results could be attributed to chance alone given that the global test of heterogeneity was nonsignificant, the total number of subgroups was large, and the PgR-associated effect was seen only in one of the two trials (ATAC) (4). In Cohort 2, PgR status was known in 8,184 patients (91%), and was associated with a similar proportional reduction in recurrence in women with ER-positive, PgR-poor disease (37%, SE 12%) and those with ER-positive, PgR-positive disease (21%, SE 8%) (Table 45-2B). No significant difference was seen between the groups, regardless of PgR status, age, nodal status, and tumor grade, and the global test of heterogeneity for the subgroup analyses was negative.

The role of PgR in determining response to endocrine therapy alone was also examined in several studies that have consistently demonstrated superior benefit for women whose tumors contain both ER and PgR compared to those with ER-positive, PgR-poor tumors (9–11). One of the largest cohorts included two databases, the first consisting of 3,739 patients who did not receive adjuvant systemic therapy and 1,688 patients who received adjuvant endocrine therapy alone, and the second consisting of 10,444 patients who received adjuvant endocrine therapy alone and whose tumors were subjected to central biochemical ER and PgR testing. The majority of women (>95%) received tamoxifen. PgR status was associated with disease-free and overall

EBCTCG, Early Breast Cancer Trialists' Cooperative Group; NS, not significant; ER, estrogen receptor; PgR, progesterone receptor; AI, aromatase inhibitor; O–E, observed minus expected.
Data from Early Breast Cancer Trialists' Collaborative Group (EBCTCG). Effects of chemotherapy and hormonal therapy for early breast cancer on recurrence and 15-year survival: an overview of the randomised trials. *Lancet* 2005;365(9472):1687–1717; Dowsett M, Cuzick J, Ingle J, et al. Meta-analysis of breast cancer outcomes in adjuvant trials of aromatase inhibitors versus tamoxifen. *J Clin Oncol* 2010;28(3):509–518.

survival in endocrine therapy–treated patients, and was independent of nodal status, tumor size, and age. Compared to women with ER- and PgR-negative tumors as a baseline, the relative risk of recurrence and death was reduced more substantially in women with ER-positive, PgR-positive tumors than in those with ER-positive, PgR-negative tumors ($p < .0001$), suggesting that women whose tumors express both hormone receptors derive more benefit from endocrine therapy, primarily tamoxifen (9). Since these data sets excluded women who received chemotherapy, this study cannot answer whether women whose tumors are PgR-negative derive preferential benefit from chemo endocrine therapy compared to those whose tumors are PgR-positive. However, given a reduced benefit from endocrine therapy alone compared to women whose tumors contain both hormone receptors, women with ER-positive, PgR-negative tumors may be candidates for chemo endocrine therapy.

A comprehensive review of the role of ER and PgR in breast cancer is provided in Chapter 27. In aggregate, available data provide a strong rationale for the consideration of endocrine therapy in every woman with an invasive cancer that contains ER or PgR expression at any level. Indeed, the American Society of Clinical Oncology (ASCO) and the College of American Pathologists (CAP) International Expert Panel recommended that ER and PgR immunohistochemistry (IHC) assays should be considered positive if there are at least 1% positive tumor nuclei in the sample on testing in the presence of proper internal and external controls (12). This would then trigger a discussion about the value of adjuvant endocrine therapy.

ER and PgR assessment by IHC alone, however, may not be useful in determining who should also be advised to receive chemotherapy. Overall the data suggest that women with tumors lacking PgR may suffer inferior benefit with endocrine therapy alone compared to women whose tumors express both hormone receptors, and for those women additional evaluation of the tumor may be considered prior to making recommendations regarding chemotherapy use. Newer methods may enable better determination of quantitative ER and PgR expression. Assessment of the functional status of the ER, optimal balance of coactivators and corepressors, and crosstalk between ER and growth factor signaling may be available in the future and could perhaps allow prediction of response to endocrine therapy or requirement for alternative or additional therapies. It is likely, however, that the presence and strength of hormone receptor expression correlates with intrinsic tumor subtypes, as described below, and that newer, more comprehensive assays may be more informative in selecting women who should consider chemo endocrine therapy.

Tumor Differentiation and Markers of Proliferation

Historically, poor differentiation or a high tumor grade or proliferative index has been associated with inferior prognosis in the absence of treatment, an improved response to cytotoxic therapy, and a poor response to endocrine therapy. In the Overview, information regarding tumor differentiation and outcome was available from approximately 47% of all tumors. The proportional risk reductions produced by chemotherapy in each of the differentiation categories were statistically similar (Table 45-3A) (3). In the AI meta-analysis, subgroup analyses of the recurrence results based on grade showed no significant difference (Table 45-3B) (4). However, as is the case with hormone receptor status, central review of grade was not conducted in either the EBCTCG or the AI meta-analyses.

Most other evaluations assessing grade, differentiation, or other proliferation factors are also retrospective in nature, but collectively they suggest that highly proliferative tumors are associated with a relative endocrine resistance and enhanced sensitivity to cytotoxic therapy, thus supporting chemo endocrine approaches. As is the case with other individual biomarkers, the use of assays that allow for multi-gene assessment may be more informative than tumor grade in determining relative responsiveness or resistance to endocrine therapy.

Growth Factors and Other Tyrosine Kinase Receptors

As we noted previously, chemo endocrine therapy has been recommended to women with ER-positive tumors that are associated with biomarkers predictive of endocrine resistance. Suggested mechanisms of endocrine resistance include activation of downstream regulatory molecules in other growth factor signaling pathways such as epidermal growth factor (EGFR, HER1) and human epidermal growth factor receptor 2 (HER2), expression of other tyrosine kinase receptors, and alterations in the balance of coregulators (13).

Cross-talk between the ER and HER1 and HER2 has been implicated as a predictor of relative resistance to endocrine manipulations in several preclinical and clinical

TABLE 45-3A

investigations (14). In addition, ER-positive, PgR-negative tumors are often associated with overexpression of HER1 or HER2 compared to tumors expressing both ER and PgR. The expression of HER1 and overexpression of HER2 in ER-positive, PgR-negative but not in ER-positive, PgR-positive tumors predicted tamoxifen resistance and a high risk of recurrence (15). Recent results from studies in advanced breast cancer clearly demonstrate that the addition of an anti-HER2 agent to an AI is associated with improved progression-free survival (PFS) and provide rationale for studies in the adjuvant setting. In TAnDEM, postmenopausal women with hormone receptor–positive, HER2-positive metastatic breast cancer were randomly assigned to first-line anastrozole with or without trastuzumab. The combination was associated with improved PFS compared to anastrozole alone (Hazard Ratio [HR] 0.63; 95% CI, 0.47–0.84; median PFS 4.8 vs. 2.4 months; Log-rank p = .0016) (16). In a second study in a similar population, women were randomly assigned to letrozole with or without lapatinib. The combination was associated with superior PFS (HR 0.71; 95% CI, 0.53–0.96; p = .019; median PFS 8.2 vs. 3.0 months) (17). Small underpowered studies have provided conflicting results regarding the role of AI and EGFR tyrosine kinase inhibitors. PFS was longer in patients receiving the combination of anastrozole and the EGFR inhibitor gefitinib compared to those receiving anastrozole plus placebo (HR 0.55; 95% CI, 0.32–0.94; median PFS 14.7 vs. 8.4 months) (18), but other studies suggested that the likely benefit from EGFR inhibition added to AI or fulvestrant is small and not likely to outweigh increased toxicity (19).

Activation of other tyrosine kinase receptors may also predict for a more aggressive tumor phenotype and relative resistance to endocrine therapy. In these situations, although the estrogen-dependent growth is inhibited via endocrine manipulations, other growth signals stimulate proliferation and lead to relative endocrine resistance. Activation of other growth signals is usually associated with higher grade tumors and those women have traditionally been offered chemo endocrine therapy (20,21). Emerging results in the advanced, acquired endocrine-resistance disease setting provide strong support for prospective studies of novel targeted agents in the adjuvant setting in tumors with de novo endocrine resistance and are summarized in the "Future Directions" section of this chapter.

Molecularly Defined Tumor Subtypes

In the last decade emphasis has been given to designating tumors not only by their ER and PgR status but also by using a more careful determination of their intrinsic subtype. Initial gene expression analysis led to the recognition that several tumor subtypes exist and these carry differential prognostic and predictive implications (22). Tumors that

express ER or PgR may be Luminal A or B, or fall into the HER2 subtype. Luminal A tumors are generally associated with a high expression of ER, expression of PgR, and a low proliferation profile. Women with this tumor subtype are expected to derive benefit from endocrine manipulations. In contrast, Luminal B tumors, although ER-positive, are more likely to lack PgR and are associated with high proliferation indices. Luminal B tumors are more likely to be resistant to endocrine manipulations alone and women with this tumor subtype may benefit from chemo endocrine therapy.

In the clinic, several assays can aid in classification of individual tumors to intrinsic subtypes and thus in treatment recommendations. A more comprehensive overview of the role of molecular prognostic and predictive markers is provided in Chapter 30. The most commonly used commercial assay is Onco*type* DX. The assay includes 21 prospectively selected genes (16 cancer-related genes and 5 housekeeping genes) that are performed via reverse-transcriptase-polymerase-chain-reaction (RT-PCR) on paraffin-embedded tumor tissue in a central laboratory. The expression of each of the genes is evaluated and tabulated using a proprietary formula and reduced to a single Recurrence Score. The assay was initially developed and validated in trials that included women with T1-2, node-negative, hormone receptor–positive tumors and is commercially available for women meeting these general criteria (23,24). Although the Recurrence Score is continuous, it is further categorized as low, intermediate, or high. Tumors with low Recurrence Score are likely hormone-sensitive and chemotherapy does not appear to offer significant benefit. In contrast, tumors with high Recurrence Scores are relatively hormone-resistant and chemotherapy should be strongly considered. The initial studies suggest that women with tumors scoring in the intermediate range are also not likely to benefit from chemotherapy but were constrained by small sample size. It is anticipated that the prospective study, **T**rial **A**ssigning **I**ndividua**L**ized **O**ptions for Treatment (**Rx**), or TAILORx, which has recently completed accrual, will help provide true estimates of risk with endocrine therapy alone or in combination with chemotherapy.

The predictive role of the Recurrence Score was also evaluated in node-negative or -positive postmenopausal women receiving anastrozole or tamoxifen in ATAC. Reportable Recurrence Scores were available from 1,231 evaluable patients. Recurrence Score was significantly associated with time-to-recurrence in both node-negative and -positive patients (25). Importantly, the prognostic value of the Recurrence Score was similar in both anastrozole- and tamoxifen-treated patients.

Additional studies suggest that Onco*type* DX is also a prognostic and predictive factor in women with node-positive disease. Southwest Oncology Group (SWOG) investigators analyzed samples from node-positive, hormone receptor–positive, postmenopausal women who enrolled in Trial S8814 (Intergroup 0100). The women were randomly assigned to tamoxifen alone or CAF with either concurrent or sequential tamoxifen (CAF-T). Compared to tamoxifen alone, CAF-T was associated with superior disease-free and overall survival (26). Specimens from approximately 40% of the participants were evaluable for the biomarker study (tamoxifen: n = 148, CAF-T: n = 219). The investigators reported that the Recurrence Score provided prognostic information in the tamoxifen arm (p = .006). CAF did not provide significant additional benefit in women with low Recurrence Score tumors (HR 1.02, 95% CI, 0.54–1.93; Log-rank p = .97), but was associated with a significant improvement in disease-free survival in women with a high Recurrence Score (HR 0.59, 95% CI, 0.35–1.01; Log-rank p = .03) (27). Similarly, Eastern Cooperative Oncology Group (ECOG) investigators evaluated the role of Onco*type* DX in women with 0-3 positive nodes who received the combination of AC or doxorubicin and docetaxel (AT) in Trial E2197. Disease-free and overall survival rates were identical in the two arms in the parent trial (28). The investigators compared Recurrence Score in a subset of the participants with hormone receptor–positive disease who received chemo endocrine therapy and suffered a recurrence (n = 99) versus a similar subset who did not suffer a recurrence (n = 366). Recurrence Score was a significant predictor of recurrence both in node-negative (p = .0007) and node-positive (p = .0004) patients, all of whom received adjuvant chemotherapy (29).

More recently, National Surgical Adjuvant Breast and Bowel Project (NSABP) investigators evaluated the role of Onco*type* DX as a prognostic and predictive factor in 3,060 node-positive women who received AC with or without paclitaxel in Trial B-28. In the entire trial population, the addition of paclitaxel to AC was associated with a significantly reduced annual hazard for disease-free survival event by 17% (HR 0.83, 95% CI, 0.72–0.95; p = .006). In the 2,007 women with ER-positive disease, the annual hazard for a disease-free survival event was reduced by 24% (HR 0.76, 95% CI, 0.63–0.91, p = .003). Tissue blocks were available and evaluable from 1,065 participants (AC: n = 519, AC followed by paclitaxel: n = 546). The group included in the biomarker analysis had slightly inferior breast cancer–related outcomes compared to the entire study population. Approximately 36%, 34%, and 30% of the specimens were associated with low, intermediate, and high Recurrence Scores, respectively. Women who were older and those with smaller tumors were more likely to have low Recurrence Score tumors. Preliminary data suggest that Recurrence Score was predictive of outcomes of women with node-positive, ER-positive tumors treated with adjuvant chemo endocrine therapy, including disease-free survival, distant recurrence-free survival, breast cancer–specific free survival and overall survival (30). In addition, in the subset available for analysis, Recurrence Score did not significantly predict benefit from the addition of paclitaxel to AC. Overall, however, the number of subjects available for each analysis was small and the power to detect differences among the groups was low (31).

Together, these retrospective analyses in women with node-positive disease suggest that, as with women with node-negative tumors, the Recurrence Score, consisting of multiple estrogen responsiveness, proliferation-associated, and other genes, may predict the sensitivity to endocrine interventions and may be a useful tool to separate women who can be prescribed endocrine therapy alone from those requiring chemo endocrine therapy. In the ongoing SWOG RxPONDER (**Rx** for **Po**sitive **Nod**e, **E**ndocrine **R**esponsive Breast Cancer, S1007) trial, 4,000 women with hormone receptor–positive, HER2-negative tumors involving 1-3 positive nodes are being recruited to evaluate the benefit of chemotherapy in those with low or intermediate Recurrence Score. Those with a Recurrence Score of ≤25 are randomized to endocrine therapy with or without chemotherapy, while those with Recurrence Score >25 will be recommended to receive chemo endocrine therapy.

Other assays that combine assessment of more than one factor have been proposed. For example, a combination of standard IHC measurements of four factors, including ER, PgR, HER2, and Ki-67, designated IHC4 Score is a prognostic model that uses classical variables. It was developed in a study that included 1,125 ER-positive specimens from ATAC participants who did not receive adjuvant chemotherapy and who had a Recurrence Score analysis and then assessed in a separate cohort of 786 patients. The investigators demonstrated that all four IHC markers provided independent

prognostic information and that the IHC4 Score provided prognostic value similar to that provided by the Recurrence Score; this was further validated in the second separate cohort (32). One noteworthy aspect of the IHC4 score is that it is not assessed in a central laboratory. This decentralized approach enhances its potential utilization but also mandates that individual laboratories will need to validate the assay prior to implementation in practice. Another multigene assay is PAM50, a quantitative RT-PCR assay for 50 genes identifying intrinsic breast cancer subtypes. Its value has been assessed in 786 specimens with IHC analysis of ER, PgR, and Ki-67 and linkage to clinical data. PAM50 signatures for proliferation genes were more prognostic than clinical assays for hormone receptors or Ki-67 (33). The assay is validated in formalin-fixed, paraffin-embedded blocks and is commercially available in the United States. This assay may allow for accurate subtyping without the need to obtain fresh tissue for analysis and for estimates of recurrence.

Other multiparameter assays are also in development. For example, the MammaPrint® assay, which includes a panel of 70 genes that predicts prognosis of primary breast cancer, may help select patients who should receive adjuvant therapy (34). The assay is currently under investigation in the large international MINDACT (**M**icroarray **I**n **N**ode negative and 1–3 positive lymph node **D**isease may **A**void **C**hemo**T**herapy) Breast Cancer Clinical Trial. In this study, the use of MammaPrint® is compared to Adjuvant! Online in selecting patients with 0–3 positive nodes for adjuvant chemotherapy in breast cancer. Another assay is the RT-PCR-based assay that includes a ratio of 2-genes (HOXB13 and IL17BR), and is designated H/I (35). The H/I ratio may also predict outcomes in tamoxifen-treated women (36). Another commercially available assay is Mammostrat®, a panel that provides an assessment of risk of recurrence that is independent of proliferation and grade (37). It is anticipated that samples obtained through TAILORx, RxPONDER, MINDACT, and other studies will be available for analysis using emerging assays and technologies.

A key question is how these assays will assist in adjuvant treatment decisions, especially in decisions about chemo endocrine therapy. The 2013 St. Gallen Expert Panel recommended that clinical-pathological features continue to be used to classify intrinsic biological breast tumor subtypes to assist in treatment recommendations. Members of the panel recognized that several multi-gene molecular assays provide accurate and reproducible prognostic information or prediction of response to chemotherapy. However, it was also recognized that the assays cannot be applied globally due to cost constraints. Therefore, when access to molecular assays is not possible, biomarkers obtained through IHC for ER, PgR, Ki-67, and IHC or *in situ* hybridization for HER2 continue to provide strong support for approximate stratification to tumor subtypes. "Luminal A" tumors are generally ER-positive and HER2-negative, with high PgR expression, and with a low Ki-67. In contrast, "Luminal B" tumors are ER-positive and HER2-negative, with either low PgR expression or a high Ki-67. "HER2-positive" subtypes are associated with overexpression or amplification of HER2, whereas "basal-like" tumors do not express ER, PgR, and are HER2 negative. Women with tumors consistent with the "Luminal A" subtype should be offered endocrine therapy alone, whereas those with the "Luminal B" tumor subtype should be recommended chemo endocrine therapy. Trastuzumab-based therapy should be added to women with the "HER2-positive" subtype, regardless of hormone receptor status (38,39). Ongoing clinical trials will also help assess whether treatment strategies should be considered based on tumor characteristics, disease stage, or both.

Other Tumor and Host Factors

Additional factors that are potentially predictive of relative endocrine resistance include factors in the microenvironment such as angiogenesis, modifications in epigenetic regulation, and other tumor and host genetics (13). A comprehensive discussion regarding the role of these markers is beyond the scope of this chapter except to state that emerging data suggest that combinations of endocrine agents with anti-angiogenic agents or epigenetic modulators are under study.

Whether host factors modulate benefit from endocrine therapy is under debate. While there is strong rationale to hypothesize that genetic variants in genes encoding for drug target or metabolizing enzymes may influence drug efficacy and safety, clinical data have been mostly retrospective and results are mixed. For example, the presence of variant alleles in the cytochrome P450 2D6 gene (*CYP2D6*) leads to an inactive or low-activity enzyme and thus to a reduced conversion of tamoxifen to its active metabolite, endoxifen (40–42). Several small studies suggested that women with *CYP2D6* variants may have reduced benefit from tamoxifen (43), but more recent data from ATAC and BIG 1-98 fail to show a correlation (44,45). Similarly single-nucleotide polymorphisms (SNPs) in the gene-encoding aromatase (CYP19A1) have been shown to influence AI-associated benefits (46,47). If indeed genetic variants influence response to endocrine strategies, these data can be used to inform treatment decisions and are discussed in more detail in Chapter 48.

In summary, chemo endocrine therapy is generally recommended to women with ER-positive tumors that are associated with individual biomarkers predictive of endocrine resistance such as lack of PgR expression, high histological grade, or HER2 overepression or amplification. Assays that provide information regarding multiple gene products performed in dedicated laboratories, such as Onco*type* Dx, can be utilized to determine with more accuracy endocrine sensitivity or resistance as well as the utility of chemotherapy in addition to endocrine therapy. Until other data are available regarding use of multiple endocrine agents, the addition of novel therapies, or elimination of endocrine agents, women with tumors that are classified as endocrine resistant should be considered for chemo endocrine therapy. Other known and emerging tumor and host characteristics may also influence endocrine responsiveness but are not sufficiently validated for use in routine clinical decision making. It is expected that a better understanding of the molecular heterogeneity of breast tumors will ultimately yield an individualized risk stratification and treatment approach.

CHEMO ENDOCRINE THERAPY: SELECTION OF ENDOCRINE TREATMENT

Once a decision is made to recommend chemo endocrine therapy, the selection of endocrine agents must be considered. General factors regarding the choice and duration of adjuvant endocrine therapies for women whose tumors express hormone receptors are described in detail in Chapter 43. Until validated evidence is available to inform clinicians which specific tumors are endocrine resistant, every woman whose invasive tumor expresses ER or PgR should be considered for endocrine therapy. Below we review the evidence that may guide the selection of endocrine therapy when a decision is made to also administer chemotherapy.

Tamoxifen

At least 5 years of tamoxifen continues to be the endocrine treatment of choice in premenopausal women.

In postmenopausal women, tamoxifen may be used in sequence with AIs for a total of 5 to 10 years, or administered as single agent to those with a contraindication or intolerance to AIs. Whether tamoxifen should be administered for 10 years in women who have received chemotherapy has not been specifically reported (48).

The EBCTCG results suggested that chemo endocrine therapy is superior to either modality alone, regardless of factors such as age, nodal status, or tumor grade. The most recent EBCTCG specifically evaluated the use of tamoxifen with or without chemotherapy. The addition of chemotherapy to tamoxifen provided substantial additional reduction in 10-year recurrence risk compared to the use of tamoxifen alone in both node-negative and node-positive women. Specifically, in the absence of chemotherapy, relative risk of recurrence was superior in women taking tamoxifen versus no therapy (Node negative: RR 0.57, 95% CI, 0.51–0.63; Log-rank 2p < 0.00001. Node positive: RR 0.63, 95% CI, 0.52–0.76; Log-rank 2p <0.00001), and, in the presence of chemotherapy, relative risk of recurrence was superior in women receiving chemotherapy and tamoxifen versus chemotherapy alone (Node negative: RR 0.74, 95% CI, 0.60–0.92; Log-rank 2p = 0.005. Node positive: RR 0.66, 95% CI, 0.60–0.74; Log-rank 2p < 0.00001) (2). The recurrence reductions were significant both in trials with no chemotherapy (6 trials) or those with chemotherapy plus tamoxifen versus the same chemotherapy alone (14 trials) (Table 45-4). In both instances, the effect of tamoxifen was greater in women with tumors expressing higher degrees of ER. Women who received chemotherapy benefited equally whether it was administered in a concurrent or sequential manner (Table 45-4).

A review of key pivotal trials that contributed to the EBCTCG is illustrative. NSABP investigators analyzed outcomes of node-negative hormone receptor–positive women who were randomized in B-14 to placebo (n = 1,453) or tamoxifen (n = 1,439), and in B-20 to tamoxifen alone (n = 788) or in combination with six cycles of CMF (CMFT, n = 789) or MF. In B-14, recurrence-free survival was significantly improved in tamoxifen-treated women compared to placebo irrespective of age, menopausal status, or tumor ER concentration (49,50). In B-20, CMFT was associated with improved 5-year disease-free and overall survival compared to tamoxifen alone (50,51). In the combined analysis, the investigators reevaluated outcomes by age (<50 years, 50 to 59 years, >60 years) and menopausal status. In B-14, tamoxifen provided a substantial benefit compared to placebo, regardless of age, menopausal status, or tumor ER concentration. In B-20, CMFT was associated with greater benefit compared to tamoxifen alone. By indirect comparison, compared to placebo, CMFT was associated with a 65% reduction in treatment failure, regardless of age. These results suggest that neither age nor menopausal status is sufficient to dictate recommendations for the addition of chemotherapy to tamoxifen. Rather, recommendations for tamoxifen versus chemo endocrine therapy should rely more strongly on tumor characteristics for patients whose general health is such that they would have qualified for these trials.

Additional studies of chemotherapy and tamoxifen have specifically enrolled women who were only postmenopausal or premenopausal. Postmenopausal node-negative women were randomized to three cycles of CMFT or tamoxifen alone in International Breast Cancer Study Group (IBCSG) Trial IX. Whereas disease-free and overall survival were superior in CMFT-treated ER-negative participants, those with ER-positive tumors benefited equally from tamoxifen or CMFT (52). Given the brevity of the chemotherapy, which is likely suboptimal by today's standards, it cannot be assumed that women with similar characteristics would not benefit from more established regimens such as six cycles of CMF chemotherapy or an anthracycline or taxane-based regimen added to tamoxifen.

In Intergroup Trial 0100 (SWOG 8814), postmenopausal women with node-positive, hormone receptor–positive breast cancer were randomly assigned to tamoxifen alone or six cycles of CAF followed by T (CAF-T) or concurrent CAF and tamoxifen (CAFT-T). CAF-T was associated with superior disease-free and overall survival compared with tamoxifen alone (26).

The use of tamoxifen in premenopausal women became prevalent only after the 1995 EBCTCG analysis showing that hormone receptor–positive women <50 years, who were presumably mostly premenopausal, gained substantial benefit from the use of tamoxifen, regardless of chemotherapy administration. More recent analyses of the Overview

ER, estrogen receptor; O–E, observed minus expected, with variance.
Data from Davies C, Godwin J, Gray R, et al. Relevance of breast cancer hormone receptors and other factors to the efficacy of adjuvant tamoxifen: patient-level meta-analysis of randomised trials. *Lancet* 2011;378(9793):771–784. PMCID: 3163848.

indeed confirmed that women age 45 or younger and those ages 45 to 54 years enjoy similar benefits from tamoxifen compared to older women (2).

Only a few individual studies provide data regarding the role of chemotherapy and tamoxifen in premenopausal women. In IBCSG Trial 13-93, node-positive premenopausal women received three cycles of anthracycline-based chemotherapy followed by three cycles of CMF with or without 5 years of tamoxifen (53). Disease-free survival, but not overall survival, was superior in women receiving chemo endocrine therapy, and this result was observed in women younger than age 40 as well as those age 40 or older.

Together, the Overview data and older prospective trials demonstrate that the addition of chemotherapy to tamoxifen is overall associated with superior survival outcomes in premenopausal and postmenopausal women with hormone receptor–positive disease. With the recent improvement in understanding of the importance of biological tumor characteristics as predictors of benefit from chemotherapy versus endocrine therapy, it is not possible to use a specific age cutoff or menopausal status to recommend chemo endocrine therapy. Rather, it appears prudent to evaluate a woman's tumor carefully using assays such as Onco*type* DX or IHC4 to identify those patients whose tumors suggest they are likely to benefit from chemotherapy in addition to endocrine therapy.

Aromatase Inhibitors

Following the recognition that AIs were superior to tamoxifen in the setting of metastatic postmenopausal breast cancer, the AIs were evaluated in adjuvant clinical trials using several different approaches—AI compared with tamoxifen for a total of 5 years of each (upfront), administered in sequence with tamoxifen for a total of 5 years of endocrine therapy (sequential), or administered for 5 additional years following 5 years of tamoxifen versus placebo (extended). Several of these pivotal studies allowed adjuvant chemotherapy prior to initiating endocrine therapy and reported outcomes by chemotherapy use or not, although the AI meta-analysis investigators have not reported outcomes based on chemotherapy use versus not.

In ATAC, approximately 20% of women received adjuvant chemotherapy. No difference between assignment to tamoxifen or anastrozole was observed in this subgroup (HR 0.89, 95% CI, 0.70–1.13); however, the number of observed events was small (54,55). Similarly, only 25% of participants in BIG 1-98 received chemotherapy. Disease-free survival was superior in the letrozole- compared to tamoxifen-treated women, regardless of chemotherapy use (Women who received chemotherapy: HR 0.74, 95% CI, 0.56–0.97; $p = .03$. No chemotherapy: HR 0.86, 95% CI, 0.73–1.01; $p = .07$) (56). Although these two large studies comparing AI monotherapy to tamoxifen provide conflicting results, the subgroups are small and cannot be regarded as conclusive. Therefore, the assignment to specific endocrine therapy should be made based on other factors such as menopausal status and bone health and irrespective of the decision whether to administer chemotherapy or not.

Likewise, small proportions of women included in the studies comparing sequential AI administration after tamoxifen to tamoxifen monotherapy received adjuvant chemotherapy. Approximately 32% of IES participants received adjuvant chemotherapy, and similar disease-free survival benefits were observed in AI-treated women, regardless of chemotherapy use (57). Neither ABCSG 8 nor ARNO 95 allowed adjuvant chemotherapy, and only a small proportion of ITA participants received adjuvant chemotherapy. In a combined analysis of the three studies, 8% of the patients received adjuvant chemotherapy, and anastrozole was superior to tamoxifen irrespective of adjuvant chemotherapy use (Women who received chemotherapy: HR 0.33, 95% CI, 0.18–0.61. No chemotherapy: HR 0.67, 95% CI, 0.53–0.85) (58).

Finally, in National Cancer Institute of Canada (NCIC) Trial MA.17, outcomes were compared among women receiving 5 years of tamoxifen followed by 5 years of letrozole or placebo. In this study, 45% of participants received adjuvant chemotherapy. Disease-free survival was identical, regardless of chemotherapy use (Women who received chemotherapy: HR 0.58, 95% CI, 0.40–0.83. No chemotherapy: HR 0.58, 95% CI, 0.40–0.84) (59).

With the exception of ATAC, studies of AIs in the upfront, sequential, and extended setting demonstrated that women benefit from assignment to AI or tamoxifen, regardless of adjuvant chemotherapy administration. More recent studies compared outcomes in women receiving different AIs. For example, in NCIC MA.27, in which women were randomly assigned 5 years of anastrozole or exemestane, 31% of participants received adjuvant chemotherapy. Event-free survival was identical among the groups, and regardless of chemotherapy use (Women who received chemotherapy: HR 1.02, 95% CI, 0.80–1.29; $p = .89$. No chemotherapy: HR 1.01, 95% CI, 0.84–1.23; $p = .89$) (60). Future analyses may provide additional guidance regarding the use of AI versus other endocrine interventions in chemotherapy-treated women. Importantly, the women enrolled in the AI studies were relatively older and the majority died without a breast cancer recurrence, suggesting that chemotherapy played a minor role. Overall, tumor characteristics predictive of endocrine sensitivity appear to apply equally to tamoxifen and to AIs. At this time there is no reason to recommend AI over tamoxifen or vice versa based on specific tumor or host characteristics. AIs should be administered as monotherapy or in sequence with tamoxifen to women without regard for the use of chemotherapy (61,62).

Given the substantial benefit observed in postmenopausal women, the role of AI is under investigation with ovarian suppression or ablation in hormone receptor–positive premenopausal women. AIs should not be used as monotherapy in premenopausal women because suppression of peripheral aromatase may cause a reduced feedback to the hypothalamus and a resulting surge in ovarian stimulation (63). A confounding factor is that many pre- and perimenopausal women will experience chemotherapy-induced amenorrhea or ovarian failure. Due to lack of good predictors of chemotherapy-induced ovarian failure, whose likelihood varies greatly based on patient age and type and duration of chemotherapy, and the knowledge that hormone levels immediately following chemotherapy may not accurately predict ovarian function, tamoxifen should be the initial agent of choice in those women (64). AI use is associated with an increase in circulating estrogens in younger women and may stimulate ovarian function; indeed, pregnancies have been reported in this group (65,66). In premenopausal women for whom tamoxifen is contraindicated or for those participating in clinical trials, AIs may be used with ovarian ablation or suppression. In those women with chemotherapy-induced ovarian failure who have received tamoxifen for 2 to 3 years, a transition to an AI should be considered with extreme caution and with serial determinations of high-sensitivity estradiol concentrations (65,67,68).

The use of AI with ovarian suppression in premenopausal women is still under investigation. Results of pivotal clinical trials such as **S**uppression of **O**varian **F**unction **T**rial (SOFT) and **T**amoxifen and **E**xemestane **T**rial (TEXT) are expected in the next few years and will clarify the role of routine use of ovarian ablation in addition to tamoxifen or AI.

Ovarian Ablation

The role of ovarian suppression or ablation for premenopausal women with hormone receptor–positive breast cancer has been recognized for many more decades than tamoxifen's. Ovarian ablation can be achieved directly either by surgery or radiotherapy (ovarian ablation), medically by suppression with luteinizing hormone-releasing hormone (LHRH) agonists (ovarian suppression), or indirectly by chemotherapy.

The 2000 EBCTCG Overview included studies in which approximately 8,000 women younger than age 50 with tumors that were ER-positive or unknown were allocated to chemotherapy plus ovarian ablation (15 studies) or suppression (six studies) versus chemotherapy alone. Ovarian ablation/suppression was associated with a substantial reduction in both risk of breast cancer recurrence ($2p < 0.00001$) and mortality ($2p = 0.004$) in the absence of other therapy (1). There was no apparent difference between ovarian ablation and suppression approaches and the risk reductions among women younger than 40 years were similar to those seen in women ages 40 to 49. When both groups received chemotherapy, the absolute benefit from ovarian treatment was smaller compared to trials that did not employ chemotherapy. It is not clear whether the reduced benefit from the use of ovarian ablation/suppression and chemotherapy is due to the concurrent use of the endocrine and cytotoxic interventions or due to chemotherapy-induced ovarian suppression that led to an indirect endocrine intervention in women who received chemotherapy alone.

The LHRH agonists in the Early Breast Cancer Overview group reported a separate meta-analysis that included individual patients from 11,906 premenopausal breast cancer patients in 16 trials who were randomized to LHRH agonists versus other treatments. Administration of LHRH agonists, as the only systemic adjuvant treatment to women with hormone receptor–positive cancer, was not associated with significant improvements in relative reduction in risk of recurrence ($p = .08$) or death after recurrence ($p = .49$), although the numbers were small. When LHRH agonists were added to tamoxifen, chemotherapy, or both, recurrence and death were substantially reduced ($p = .02$ and $p = .03$, respectively) (69). When compared to chemotherapy, LHRH agonists provided similar risk-reduction benefits. Unfortunately, there were no comparisons of LHRH agonists and tamoxifen to chemotherapy and tamoxifen because these trials predated the recognition of tamoxifen's benefit in premenopausal women.

A Cochrane Analysis reported in 2009 included 14 randomized trials assessing LHRH agonists as adjuvant treatment in 13,000 premenopausal women with early-stage, mostly ER-positive, breast cancer. The investigators noted that, for most comparisons, there were too few trials, too few randomized patients, and/or too little follow-up to draw meaningful conclusions regarding the relative effects of different treatments. In addition, most of the chemotherapy regimens included in the comparison were older and may be viewed as suboptimal by today's standards. Four main comparisons were conducted (70). (i) LHRH agonists versus another treatment: In ER-positive patients LHRH monotherapy provided similar recurrence-free and overall survival benefits compared with first-generation chemotherapy regimens such as CMF. There were insufficient data to compare LHRH agonist monotherapy to tamoxifen alone, but these treatments appeared comparable in terms of recurrence-free survival. (ii) LHRH agonists plus anti-estrogen versus another treatment: Data were insufficient to compare LHRH agonists plus tamoxifen to tamoxifen alone, but results suggested that the combination of LHRH agonists plus tamoxifen may be superior to an LHRH agonist alone or to chemotherapy alone. The data comparing LHRH agonists plus AI to LHRH agonists plus tamoxifen were inconclusive. (iii) LHRH agonists plus chemotherapy versus another treatment: There were insufficient data to compare the LHRH agonists plus chemotherapy combination to LHRH agonists alone, but one study suggested the two provided identical outcomes in ER-positive patients. In comparison to chemotherapy alone, LHRH agonists plus chemotherapy combination was associated with a trend toward improved recurrence-free and overall survival. (iv) LHRH agonists plus anti-estrogen plus chemotherapy versus another treatment: compared to chemotherapy alone, LHRH agonists plus tamoxifen plus chemotherapy provided a trend toward improved recurrence-free and overall survival.

Together, results of several meta-analyses suggest that ovarian ablation or suppression provided an effective endocrine intervention to premenopausal women with hormone receptor-positive breast cancer. Individual studies may help further define who may be appropriate for treatment with ovarian ablation/suppression.

In E5188/Intergroup 0101, 1,503 premenopausal women with hormone receptor–positive, node-positive tumors were randomly assigned to CAF chemotherapy alone or CAF followed by goserelin or CAF followed by goserelin and tamoxifen. Although 5 years of goserelin added to CAF did not provide significant additional benefits compared to chemotherapy alone for the entire study population, women younger than age 40 derived substantial benefit from the combination (71). In IBCSG Trial 13-93, node-positive premenopausal women received three cycles of anthracycline-based chemotherapy followed by three cycles of CMF with or without 5 years of tamoxifen (53). The combined therapy was associated with a significant improvement in disease-free but not in overall survival, and was observed both in women age 40 or older (HR 0.60, 95% CI, 0.44–0.81; $p = .0009$), and in those younger than 40 (HR 0.57, 95% CI, 0.38–0.86; $p = .008$). Importantly, the investigators observed that the women with ER-positive tumors who achieved chemotherapy-induced amenorrhea had a significantly improved outcome (amenorrhea vs. no amenorrhea HR 0.61, 95% CI, 0.44–0.86; $p = .004$) (53). These studies suggest that chemotherapy-induced amenorrhea predicts improved outcomes in premenopausal women with hormone receptor–positive tumors. Therefore, the addition of ovarian suppression may provide survival benefit to young women who resume menstruation following chemotherapy.

In NSABP B-30, 5,351 women with node-positive breast cancer were randomly assigned to four cycles of doxorubicin and cyclophosphamide followed by four cycles of docetaxel (sequential ACT); four cycles of doxorubicin and docetaxel; or four cycles of doxorubicin, cyclophosphamide, and docetaxel (concurrent ACT). Disease-free and overall survival were superior in the sequential-ACT group compared with the doxorubicin and docetaxel and concurrent-ACT groups. Overall survival was improved in patients with amenorrhea for 6 months or more across all treatment groups; a landmark analysis showed that this was seen for women with hormone receptor–positive but not –negative disease (72,73).

Two other relevant studies were not included in the meta-analyses: Adjuvant Breast Cancer Trials Collaborative Group Ovarian Ablation Or Suppression Trial and IBCSG Trial 11-93. The collaborative study included 2,144 pre- or perimenopausal women with ER-positive or unknown tumors who received tamoxifen for 5 years with or without ovarian suppression. Chemotherapy was administered to those at high risk. No difference was observed between women who

received ovarian suppression and tamoxifen and those who received tamoxifen alone (74). In 11-93, 174 premenopausal women with node-positive, hormone receptor–positive tumors were randomly assigned to 5 years of ovarian suppression and tamoxifen with or without four cycles of adjuvant anthracycline-based chemotherapy. Although disease-free and overall survival were identical in the two arms, this study closed early due to low accrual rate and underpowered analysis.

In aggregate, neither the individual studies reported to date nor the completed meta-analyses provide us with the knowledge required to select with certainty premenopausal women who should receive ovarian suppression in addition to optimal chemotherapy, when appropriate, or to tamoxifen. It seems unlikely that women who receive modern chemotherapy and tamoxifen will obtain more than a modest benefit, if any, from the addition of ovarian ablation/suppression. One exception may be a group of women younger than age 40 whose menstrual cycles resume following adjuvant chemotherapy. Women older than age 40 are more likely to undergo chemotherapy-induced ovarian failure and may not obtain additional benefits from ovarian ablation/suppression. Given that few studies evaluated the role of ovarian ablation/suppression with modern chemotherapy and 5 years of tamoxifen, and fewer still have evaluated the role of AIs in premenopausal women, results from the SOFT trial will be instrumental in defining the role of ovarian suppression plus tamoxifen compared to tamoxifen alone with or without prior chemotherapy. The study will also identify the role of ovarian suppression and AIs compared to tamoxifen. For individuals where ovarian suppression is considered, initial results from the ABCSG 12 study comparing ovarian suppression with goserelin plus tamoxifen or anastrozole demonstrated that the disease-free and overall survival rates were equivalent between the two endocrine treatment–assigned groups (75). More recently, a 62-month follow-up revealed that there was no significant difference in disease-free survival between patients receiving tamoxifen alone or anastrozole alone (HR 1.08, 95% CI, 0.81–1.44; $p = .591$), but overall survival was worse in anastrozole-treated women compared to those receiving tamoxifen (HR 1.75, 95% CI, 1.08–2.83; $p = .02$) (76). Other studies such as TEXT will further assist in assessing the role of ovarian suppression and tamoxifen versus ovarian suppression and AI. Other studies evaluating the role of chemotherapy in premenopausal women receiving endocrine therapy were unfortunately closed prematurely due to poor accrual; these include Premenopausal Endocrine Responsive Chemotherapy Trial (PERCHE) and Premenopausal Optimal Management IS Endocrine therapy (PROMISE), meaning that this critical question is not likely to be addressed in a prospective randomized fashion.

At present single-agent tamoxifen is the standard approach for premenopausal women with hormone receptor–positive breast cancer. Ovarian suppression can be discussed with individual women with high-risk hormone receptor–positive breast cancer who retain or regain ovarian function after chemotherapy, especially those younger than age 40.

CHEMO ENDOCRINE THERAPY: CHEMOTHERAPY CONSIDERATIONS

Once a decision has been made that a woman with hormone receptor–positive breast cancer will receive chemotherapy, another question is whether a preferred chemotherapy agent or regimen should be considered. The EBCTCG demonstrated that polychemotherapy consistently continues to outperform single-agent therapy and that anthracycline-based therapy is superior to CMF-based regimens (1). In the 14 trials of chemotherapy plus tamoxifen versus the same chemotherapy alone, the EBCTCG reported a substantial reduction in risk of recurrence and death in those receiving chemo endocrine therapy, suggesting a benefit for the addition of tamoxifen to first- or second-generation chemotherapy regimens in women with hormone receptor–positive tumors (2). Furthermore, regimens that contain a higher cumulative anthracycline dose than in standard AC are superior to CMF, and sequential taxane following anthracycline-based therapy is superior to anthracycline-based therapy alone (3). As reviewed in Table 45-1, the superiority of each generation of treatment regimens is independent of hormone receptor status.

We have previously discussed the role of ER and HER2 as predictors of response to endocrine therapy. Others have evaluated the role of these markers as predictors of benefit from specific chemotherapy agents in women with ER-positive tumors. Cancer and Leukemia Group B (CALGB) investigators evaluated ER and HER2 status and benefit from adjuvant chemotherapy in 6,644 women included in three studies. In C8541, women received one of three CAF regimens, in C9344 participants received four doses of combination AC, with or without sequential paclitaxel, and in C9741 women received sequential doxorubicin, paclitaxel, and cyclophosphamide or AC followed by paclitaxel, administered every 2 or 3 weeks. Endocrine therapy was recommended but not mandated for hormone receptor–positive women enrolled in these trials. Overall, women with ER-negative tumors enjoyed greater benefits from chemotherapy compared with ER-positive tumors. The investigators then compared outcomes of women who received the most intense regimen in C9741 (chemotherapy administered every 2 weeks) to the low-dose CAF in C8541. They reported that 22.8% more ER-negative patients were disease-free at 5 years compared to 7.0% for ER-positive patients (77). ER-negative women also had an enhanced overall survival benefit at 5 years compared to ER-positive patients (improvement by 16.7% and 4.0%, respectively). Every 2 weeks AC followed by paclitaxel in C9741 lowered the rate of recurrence and death in ER-negative breast cancer by more than 50% compared to low-dose CAF used in C8541. The magnitude of benefit in ER-positive patients was more modest, with a 26% and 23% reduction in recurrence and death, respectively, compared to the benefits observed for patients with ER-negative disease.

The CALGB investigators have also evaluated whether hormone receptor and HER2 status predicted benefit from adjuvant doxorubicin doses higher than standard levels, or from the addition of paclitaxel to AC, or from both using tumor blocks from 1,322 of 1,500 women that were randomly selected from those previously enrolled in C9344. HER2 status was not predictive of response to doxorubicin in doses above 60 mg/m^2, but women with HER2-positive tumors were more likely to benefit from paclitaxel compared to those with HER2-negative disease (HR for recurrence of 0.59; $p = .01$), regardless of ER status (78). In contrast, women with HER2-negative, ER-positive tumors did not gain benefit from the addition of paclitaxel. These results suggest that patients with HER2-negative, ER-positive, node-positive breast cancer gained little value from the administration of paclitaxel following combination AC; however, since all women received AC, it is not clear whether the tumor phenotype is predictive of little benefit from chemotherapy in general. In addition, women with HER2-positive tumors are currently expected to receive anti-HER2 agents in addition to chemo endocrine therapy.

Several studies conducted in the 1990s evaluated the role of taxane administered either in combination with or following anthracycline-based regimens in the adjuvant setting. In E2197, 2,882 women with high-risk node-negative or 1-3 node-positive disease were randomized to AC or to AT. Disease-free and overall survival were identical. In an exploratory analysis of prespecified stratification factors by hormone receptor expression, the investigators observed a trend toward improved disease-free survival in women with hormone receptor–negative disease receiving AT (28). Other studies have not confirmed differences in outcomes by hormone report status. In Breast Cancer International Research Group (BCIRG) 001, the docetaxel, doxorubicin, and cyclophosphamide (TAC) combination was superior to FAC both in hormone receptor–negative and –positive women (79,80). In Spanish Breast Cancer Research Group GEICAM Study 9805, high-risk node-negative women were randomly assigned to six cycles of TAC or FAC. TAC was associated with improved disease-free (HR 0.68, 95% CI, 0.49–0.93; $p = .01$), regardless of hormone receptor status (81).

Other studies evaluated the role of taxane following anthracycline-based therapy. In B-28, NSABP investigators randomly assigned node-positive women to AC with or without sequential paclitaxel. AC followed by paclitaxel was associated with superior disease-free survival (RR 0.83, 95% CI, 0.72–0.95; $p = .006$), and a non-significant overall survival benefit (RR 0.93, 95% CI, 0.78–1.12; $p = .46$) (82). The benefit of paclitaxel was observed, regardless of hormone receptor status or tamoxifen administration. In GEICAM 9906, women with node-positive disease were randomly assigned to FEC or FEC followed by weekly paclitaxel; disease-free and overall survival were superior in the FEC followed by paclitaxel arm (83). Tumor samples from approximately 75% of participants were assessed for hormone receptor expression and HER2 amplification testing at a central laboratory; no statistically significant interaction between hormone receptor status or HER2 status and/or paclitaxel administration was observed.

Newer studies comparing anthracycline- and taxane-based regimens tested different combination or sequences. In NSABP B-30, disease-free and overall survival were superior in women receiving sequential-ACT compared with the doxorubicin and docetaxel and/or concurrent-ACT groups. The benefits were observed both in ER-negative and in ER-positive patients, regardless of hormone therapy use (72). BCIRG 005 investigators compared TAC versus AC followed sequentially by docetaxel in women with node-positive breast cancer. The two regimens provided similar disease-free and overall survival benefits, regardless of hormone receptor status (84). In a preliminary report of B-38, no differences in survival outcomes were observed among women receiving TAC versus dose-dense AC followed by dose-dense paclitaxel or dose-dense doxorubicin and cyclophosphamide followed by dose-dense paclitaxel and gemcitabine (85). Whether outcomes differ by hormone receptor status is not yet known.

In E1199, ECOG investigators evaluated optimal taxane use following four cycles of AC in women with node-positive or high-risk node-negative breast cancer. The women were randomly assigned to either paclitaxel or docetaxel administered either every 3 weeks for four cycles or weekly for 12 cycles. Disease-free survival and overall survival were improved with weekly paclitaxel compared to paclitaxel every 3 weeks. Docetaxel administered every 3 weeks was also associated with improved disease-free survival compared to every 3-week paclitaxel, but not overall survival. In an exploratory analysis of the influence of hormone receptor status and HER2 expression, improvements in disease-free and overall survival were observed with weekly paclitaxel in women with HER2-negative disease, regardless of the hormone receptor status (86). In C9741, an exploratory analysis suggested that women with hormone receptor–positive disease were not likely to gain additional benefit from a dose-dense schedule compared to women who received the same regimen on an every 3-week schedule (87).

Finally, newer studies compared outcomes of women treated with taxane-based therapy with or without an anthracycline. In a study of node-negative women who received four cycles of AC or docetaxel and cyclophosphamide (TC), TC was slightly superior to AC both in women with hormone receptor–positive and –negative tumors (88). Ongoing studies in women with node-positive or high-risk node-negative invasive breast cancer such as NSABP B-49 compare the TC combination to anthracycline-based chemotherapy regimens in HER2-negative disease.

Although not completely consistent, the data presented to date support the use of the same chemotherapy regimens for women at high risk of recurrence based on tumor characteristics or nodal status, regardless of hormone receptor status. Thus decisions about type of chemotherapy should continue to be made based on estimates of risk of recurrence and death without consideration of hormone receptor status.

Importantly, current and future studies will be likely enriched for women who are expected to benefit from chemo endocrine therapy compared to those included in older studies because of a more careful determination of tumor characteristics in addition to anatomical features. Therefore new studies may provide additional answers regarding optimal cytotoxic agents, regimens, and duration in women with hormone receptor–positive disease.

The role of hormone receptor status was also investigated in pivotal trials comparing outcomes following the administration of chemotherapy with or without trastuzumab. In the combined analysis of NSABP Trial B-31 and North Central Cancer Treatment Group (NCCTG) Trial N9831, women with HER2-positive tumors were randomly assigned AC followed by paclitaxel with or without trastuzumab. Trastuzumab was administered for a total of 52 weeks. Women randomized to trastuzumab had a significant improvement in disease-free and overall survival. The benefits were independent of hormone receptor status (89). In the Herceptin Adjuvant (HERA) (BIG 01-01) Trial, women with HER2-positive tumors were randomized to a minimum of four courses of (neo)adjuvant chemotherapy with or without 1 or 2 years of sequential trastuzumab. Adjuvant endocrine therapy was given after chemotherapy to the 52% of women with hormone receptor–positive disease. The magnitude of benefit was most significant in the hormone receptor–negative cohort; however, the investigators cautioned that survival benefits may emerge with further follow-up (90,91). Finally, in the BCIRG 006 study, women with HER2-positive early-stage breast cancer were randomly assigned to AC followed by docetaxel every 3 weeks with or without trastuzumab, or docetaxel and carboplatin with 52 weeks of trastuzumab. Disease-free survival and overall survival were improved in the trastuzumab-containing arms compared to the non-trastuzumab-containing arm. The two trastuzumab-containing regimens provided similar benefits. The improvement seen with trastuzumab was independent of the hormone-receptor status (92).

Together, these studies provide strong evidence that women with HER2-positive tumors benefit from trastuzumab-based regimens, regardless of hormone receptor status. As is the case with HER2-negative tumors, clinicians should consider the use of the same chemotherapy regimens for women at high risk of recurrence based on

tumor characteristics or nodal status without consideration of hormone receptor status.

DOSE, DURATION, AND SCHEDULE OF CHEMO ENDOCRINE THERAPY

Since data available to date have not specifically addressed dose and duration of either endocrine agents or chemotherapy regimens specifically in women prescribed chemo endocrine therapy, the optimal dose and duration of specific endocrine and chemotherapy regimens should be made based on the principles presented in Chapters 43 and 44, respectively. In brief, 5 years of tamoxifen is recommended to pre- or postmenopausal women who cannot take or tolerate AIs. Five additional years of tamoxifen may also be considered in select women (48). AIs should be administered as monotherapy for a total of 5 years or in sequence with tamoxifen for a total of 5 to 10 years of endocrine therapy for most postmenopausal women (61,62). Ovarian ablation/suppression may be considered in select young women with high-risk tumors or in premenopausal women who cannot take tamoxifen. The value of a first-, second-, or third-generation chemotherapy regimen should be discussed with an individual woman based on her tumor characteristics, estimates of recurrence, value added, and potential side effect profile with each type of regimen. There are no conclusive data suggesting that specific regimens or agents should or should not be recommended preferentially to women with hormone receptor–positive tumors.

Several studies investigated the question of sequential versus concurrent administration of chemo endocrine therapy, mainly using tamoxifen. The EBCTCG reported that the administration of chemotherapy and tamoxifen was superior to tamoxifen alone, whether administered concurrently (RR 0.62, SE 0.06) or sequentially (RR 0.71, SE 0.05, Table 45-4) (2). While concurrent use of chemotherapy and tamoxifen appears to be slightly better than sequential administration, the comparisons are indirect and do not represent results from prospective data trials.

The largest single study that has assessed the concurrent versus sequential use of tamoxifen and chemotherapy is Intergroup Trial 0100 in which concurrent CAF and tamoxifen (CAFT-T) was associated with inferior outcomes compared to CAF followed by tamoxifen (CAF-T). Disease-free survival at 8 years was 67% for CAF-T, 62% for CAFT-T, and 55% for tamoxifen alone (26). This direct comparison generated sufficient concern about concurrent chemo endocrine therapy that most modern studies have required that tamoxifen, and by extrapolation other endocrine therapies, would be administered after completion of adjuvant chemotherapy. Whether other endocrine therapies such as AIs or ovarian ablation/suppression should also be administered sequentially has not been investigated prospectively and it is unlikely that large randomized prospective data will become available. While it is possible that smaller studies in the neoadjuvant setting will address sequence questions prospectively, sequential administration appears to be the most cautious strategy in the absence of other randomized data. As we move toward a better identification of women with hormone receptor–positive disease who require chemotherapy, it is likely that women with truly hormone-sensitive disease will receive hormonal therapy earlier in the course of adjuvant therapy.

In summary, the selection of dose and duration of endocrine agents and chemotherapy regimens should be made independent of the decision to prescribe chemo endocrine therapy. Until other prospective data are available, chemotherapy should generally precede endocrine treatment.

TOXICITY OF ADJUVANT CHEMO ENDOCRINE THERAPY

Each endocrine agent and chemotherapy regimen is associated with specific toxicities that are reviewed in detail in other chapters. Women receiving both treatments will likely receive chemotherapy followed by the endocrine agent and will be subjected to the possible side effects of each. Whether the sequential administration of the treatments will lead to a different or greater side effect profile has not been evaluated in detail. It is noteworthy that the concomitant administration of endocrine therapies and chemotherapy, in particular tamoxifen, can be associated with increased risk of thromboembolic events compared to each modality given alone—another argument against concurrent chemo endocrine therapy.

Premenopausal women who receive chemotherapy who suffer treatment-related amenorrhea or ovarian failure may be more likely to report high prevalence and severity of menopausal symptoms compared to postmenopausal women or to their counterparts who have not received chemotherapy. Early menopause may also result in greater bone loss. Ovarian suppression following CAF (CAF-Z) was associated with a slightly higher risk for weight gain, hypertension, diabetes, anemia, and hot flashes. The addition of tamoxifen to CAF-Z slightly increases the incidence of diabetes, hot flashes, and anemia (71). Whether chemo endocrine therapy will have a detrimental effect on cognitive function compared to either approach alone is not known.

One concern is that women treated with chemotherapy agents that are associated with specific toxicities will have a prolonged or worsening symptomatology once the endocrine treatment is initiated. For example, anthracycline or trastuzumab-based therapy is associated with increased risk for cardiac toxicity and AIs may lead to a slight increase in cardiac events (89,90,92,93). Whether the administration of AIs following anthracycline or trastuzumab-based therapy will lead to a higher risk of cardiac events is not known. Likewise, women who receive chemotherapy, in particular taxane-based, may be more likely to report AI-associated musculoskeletal complaints (94–96). It is not known whether women who have suffered taxane-associated neurotoxicity are more likely to develop AI-associated neurotoxicity or musculoskeletal complaints.

SUMMARY AND FUTURE DIRECTIONS

Results from dozens of randomized clinical trials conducted over four decades have shaped the adjuvant treatment approaches used in our clinics every day. A greater understanding of tumor biology coupled with sophisticated assays allows us to make increasingly better informed recommendations to individual women. We now recognize that the decision to prescribe each individual type of treatment, including endocrine, chemotherapy, and anti-HER2 agents, or a combination, continues to be highly dependent on tumor size, nodal status, age, and menopausal status, but relies ever more heavily on intrinsic tumor subtype and other characteristics. Results from ongoing studies in women with hormone receptor–expressing tumors such as TAILORx, MINDACT, and RxPONDER will provide us with an even greater ability to prescribe a more individualized treatment. Likewise, a better understanding of host factors such as pharmacogenetics, and environmental factors such as diet or activity level, will lead to even better understanding of endocrine resistance and new methods to overcome it. Prospective studies should help generate a better

understanding whether specific regimens are more suitable to women with hormone receptor–positive disease who will also be receiving endocrine therapy.

Questions include not only whether specific chemotherapy regimens, dose, duration, or sequence are important, but also whether there is a group of women with tumors that are endocrine-resistant despite the expression of hormone receptors and who may not benefit from endocrine therapy either. Activation of tyrosine kinase receptors, for example, may predict for a more aggressive tumor phenotype and relative resistance to endocrine therapy. In these situations, although the estrogen-dependent growth is inhibited via endocrine manipulations, other growth signals stimulate proliferation and lead to relative endocrine resistance. Activation of other growth signals is usually associated with higher-grade tumors and those women have traditionally been offered cytotoxic-based therapy in addition to the endocrine manipulation. Data regarding combination approaches to target the estrogen-signaling pathways using multiple agents such as AIs and antiestrogens have been mixed and it is unlikely that other signaling pathways will be successfully blocked by this approach alone (20,21). Emerging results in the advanced, acquired endocrine-resistance setting provide strong support for prospective studies of novel targeted agents in the adjuvant setting in tumors with de novo endocrine resistance.

While studies in the metastatic setting support an improved benefit with the combination of agents that target ER and HER2, studies in the adjuvant setting using such combinations have not been conducted. Therefore, we cannot recommend the use of combinations of endocrine and anti-HER2 agents to women with early disease outside of clinical trials. However, given the strong evidence that the coexpression of hormone receptors and HER2 is associated with relative endocrine resistance, women in good health with hormone receptor–positive and HER2-positive tumors should be offered trastuzumab-based chemotherapy, as recommended in Chapter 47, followed by endocrine therapy.

Activation of the mammalian target of rapamycin (mTOR) intracellular signaling pathway contributes to endocrine resistance. A study of letrozole with or without temsirolimus in AI-naive patients with metastatic disease demonstrated no improvement in PFS (97). The recent BOLERO-2 study, however, revealed that women with hormone receptor–positive advanced breast cancer who have received a prior nonsteroidal AI had superior PFS with the combination of everolimus and exemestane compared to exemestane and placebo (10.6 and 4.1 months, respectively, by central assessment, HR = 0.36, 95% CI, 0.27–0.47; $p < .001$) (98). Everolimus is currently under study in the adjuvant setting. Activated protein kinases may also contribute to endocrine resistance. The CDK 4/6 inhibitor (PD0332991) was recently reported to provide a substantial improvement in PFS in combination with letrozole, over letrozole alone, in a randomized phase 2 clinical trial (99). Agents that reverse epigenetic modification may also overcome endocrine resistance (100). Preliminary data suggests that the addition of the histone deacetylase inhibitor entinostat to an AI may provide superior survival benefits and definitive studies are planned (101). Finally, studies evaluating the role of genetic variants in predicting differential response to endocrine therapies may also lead to identification of a subgroup of women that may benefit from modification of endocrine therapy (102).

In closing, given the substantial benefits observed from both chemotherapy and endocrine therapy, it is likely that in the next decade almost every woman with hormone receptor–positive tumors will receive endocrine agents, and those with predictors of endocrine resistance will receive chemo endocrine therapy. However, enhanced understanding of tumor biology and mechanisms of endocrine resistance has already led the way into new trial designs in which targeted treatments are investigated. Studies in the adjuvant or neoadjuvant settings will not only investigate early predictors of response and resistance, but will also attempt to integrate new targeted therapies or agents that enhance sensitivity or reverse resistance. Indeed, new generations of clinical trials will incorporate tumor-intrinsic subtype and host factors more commonly than ever before.

MANAGEMENT SUMMARY

- Every woman with an invasive primary tumor that expresses estrogen or progesterone receptor protein should be considered for endocrine therapy.
  - Selection of the type of endocrine manipulation varies by menopausal status and is discussed in detail in Chapter 43.
- The recommendation for endocrine therapy should be made, regardless of the decision whether or not to administer chemotherapy. Use of chemotherapy should be based on the guidelines discussed in detail in Chapter 44.
  - At present, data suggest that the addition of chemotherapy should be considered for women with high risk of recurrence based on anatomic stage and specific tumor characteristics. For example, the absence of the progesterone receptor and/or the overexpression of the HER2 receptor or a high Recurrence Score may indicate a relative endocrine resistance and drive a decision to use chemotherapy.
  - The decision regarding type and duration of chemotherapy should be independent of the hormone receptor status. Data today suggest that polychemotherapy with anthracycline and/or taxane-based regimen is superior to other therapies. The available data support the use of the same regimen for women at high risk for a systemic recurrence, regardless of hormone receptor status.
- When chemo endocrine therapy is recommended, sequential rather than concurrent administration appears to be the most prudent strategy.

CHAPTER 46

Adjuvant and Preoperative Systemic Therapy for HER2-Positive Breast Cancer

Ian E. Krop and Eric P. Winer

CHAPTER CONTENTS

INTRODUCTION

HER2/neu is a member of the ErbB family of transmembrane tyrosine kinases. The family includes the epidermal growth factor receptor (EGFR), HER2, HER3, and HER4. HER2 is activated through dimerization, either with other HER2 proteins (homodimerization) or with other HER family members (heterodimerization). Once activated, HER2 potently initiates downstream signaling, including signaling through the PI3-kinase and MAP kinase pathways. As a result, HER2 activation produces an array of cellular changes leading to increased proliferation, invasiveness, angiogenesis, and enhanced survival.

Amplification of the HER2 gene occurs in approximately 20% of breast cancers (1,2). This amplification causes marked overexpression of HER2 protein on the cell surface—typically over a million HER2 proteins per cell (3)—and leads to constitutive activation of HER2 signaling. HER2 amplified breast cancers are typically highly proliferative and are associated with adverse clinical behavior. In the absence of systemic adjuvant therapy, HER2 amplification is independently associated with a greater risk of disease recurrence in both node negative and node positive cancers (4–7). Several studies have also demonstrated that HER2 amplification is a negative prognostic feature for cancers ≤1 cm (8,9).

Despite its negative prognostic effects, HER2 amplification and/or overexpression predicts sensitivity to several classes of chemotherapy. In Cancer and Leukemia Group B 9344, a phase III adjuvant study in patients with node positive disease in which patients were randomized to four cycles of AC (doxorubicin/cyclophosphamide) alone or AC followed by four cycles of paclitaxel, HER2 overexpression was associated with a significant benefit from the addition of the paclitaxel (10). Similar findings were observed in a phase III metastatic trial comparing epirubicin/paclitaxel (ET) with epirubicin/cyclophosphamide (EC). In that study, patients with HER2-positive cancers who received ET had improved progression-free survival and overall survival relative to the patients with HER2-positive cancers who received EC (11).

HER2-positive cancers also demonstrate specific sensitivity to anthracyclines. In MA.5, a randomized phase III adjuvant study in patients with node positive disease in which patients received either cyclophosphamide/methotrexate/fluorouracil (CMF) or cyclophosphamide/epirubicin/fluorouracil (CEF), patients with HER2-positive cancers had improved relapse-free survival (hazard ratio [HR] = 0.52, 95% CI, 0.34–0.80; p = .003) and overall survival (HR = 0.65, 95% CI, 0.42–1.02; p = .06) with the anthracycline regimen (12). Patients with HER2 negative cancers did not have an improvement in outcome with the anthracycline (interaction p value p = .01) (12). A meta-analysis of eight randomized studies comparing anthracycline-based regimens to non-anthracycline regimens (total n = 6564) also demonstrated that anthracyclines were superior to non-anthracycline regimens in HER2-positive cancers (HR of death from any cause = 0.73, 95% CI, 0.62–0.85; p < .001), while no benefit was observed in HER2-negative cancers (HR of death from any cause = 1.03, 95% CI, 0.92–1.16; p = .6) (13). The interaction

between HER2 status and anthracycline benefit was significant (chi-square statistic for overall survival = 12.6; $p < .001$) (13).

The preclinical data pointing to the importance of HER2 signaling together with the clinical data demonstrating the poor prognostic effect of HER2 amplification sparked interest in utilizing HER2 as a therapeutic target. This idea led to the development of trastuzumab, a humanized monoclonal antibody specific for the extracellular domain of HER2. In preclinical studies, trastuzumab demonstrated multiple potential mechanisms of action, including inhibition of HER2 signal transduction, induction of antibody-dependent cell-mediated cytotoxicity (ADCC), and inhibition of shedding of the HER2 extracellular domain (reviewed in [14]). The clinical effectiveness of trastuzumab was evaluated in a pivotal phase III study in patients with HER2-positive metastatic breast cancer who were randomized to chemotherapy with or without trastuzumab. The chemotherapy backbone was either paclitaxel or AC, depending on whether patients had previously been exposed to anthracycline treatment. The addition of trastuzumab to chemotherapy markedly improved outcomes, with a longer time to disease progression (median, 7.4 months vs. 4.6 months; $p < .001$) and overall survival (25.1 months vs. 20.3 months; $p = .01$) compared to chemotherapy alone. (15) The benefits of trastuzumab were associated with minimal increases in toxicity, with one notable exception—the addition of trastuzumab to the anthracycline regimen caused a high incidence of symptomatic cardiomyopathy (16% had New York Heart Association class III or IV cardiac dysfunction) (15). Patients who received trastuzumab with paclitaxel (all of whom had previously received an anthracycline) had a much lower rate of severe cardiac toxicity (2%). The unequivocal benefits of trastuzumab in combination with a taxane led to the widespread use of taxane–trastuzumab combinations for patients with HER2-positive metastatic breast cancer. The synergistic benefits of trastuzumab with chemotherapy were subsequently shown to extend across a wide range of regimens. In addition, two randomized clinical trials demonstrated that continuation of trastuzumab after disease progression on a prior trastuzumab regimen is beneficial (16,17). These studies have far reaching clinical and biologic significance, and as a result, trastuzumab based combinations are widely used in multiple lines of therapy for HER2-positive metastatic breast cancer.

The clinical benefits of trastuzumab observed in these trials provided definitive proof that targeting HER2 was an effective approach in HER2-positive breast cancer. This demonstration led to the successful development of other HER2-targeted agents, such as the EGFR/HER2 tyrosine kinase inhibitor lapatinib, the HER2 specific monoclonal antibody pertuzumab, and the antibody drug conjugate trastuzumab emtansine. All three of these agents have significant activity in patients with HER2-positive metastatic breast cancer, either combined with chemotherapy or hormonal therapy (in the case of lapatinib), combined with trastuzumab and chemotherapy (in the case of pertuzumab), or as monotherapy with trastuzumab emtansine.

The benefits of trastuzumab seen in patients with metastatic disease also provided the rationale to evaluate this agent in the adjuvant and neoadjuvant settings. In 2005, initial results from the first three phase III adjuvant trials of trastuzumab were reported, demonstrating significant improvements in disease-free survival, and ultimately overall survival, with the addition of trastuzumab to chemotherapy in the adjuvant setting. The improvements in outcome were so impressive that adjuvant trastuzumab became the standard of care within weeks after the trial results were presented. This chapter will review these adjuvant studies and subsequent randomized adjuvant trials of HER2 directed therapy. In addition, the chapter will discuss the results of smaller neoadjuvant trials as well as future directions in the treatment of early stage HER2-positive breast cancer.

BENEFIT OF TRASTUZUMAB IN THE ADJUVANT TREATMENT OF HER2-POSITIVE BREAST CANCER

Six randomized phase III studies have evaluated the addition of trastuzumab to chemotherapy in the adjuvant setting. The details of these studies are summarized in Tables 46-1 and 46-2. All of the studies were restricted to patients with HER2-positive cancers, although the definition of HER2 positivity and the requirement for central testing differed across the trials. All the studies focused on a relatively high-risk population (node positive or high-risk node negative) and all except FinHer included at least one year of trastuzumab.

The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-31 and North Central Cancer Treatment Group (NCCTG) N9831 were both conducted in North America and shared similar designs. The chemotherapy backbone consisted of four cycles of AC followed by paclitaxel. In B-31, the paclitaxel was given as 175 mg/m^2 every 3 weeks × 4 cycles, and in N9831 it was administered weekly for 12 weeks. Trastuzumab was administered concurrently with paclitaxel and was continued for a total of one year. In N9831, a third arm was included in which the year of trastuzumab was delayed until the completion of all chemotherapy. Because of the similarities of the trial designs, the investigators performed a pooled analysis of the two trials, combining the two control arms and the two investigational arms that involved concurrent administration of trastuzumab and paclitaxel. Patients from N9831 who received sequential paclitaxel followed by trastuzumab were excluded from this analysis. A total of 3,351 patients (1,679 in combined control group and 1,672 in combined trastuzumab group) were included. Both studies initially excluded node negative patients, but ultimately the N9831 trial was amended to include high-risk node negative patients (defined as a tumor >2 cm for hormone receptor positive cancers and tumor >1 cm for hormone receptor negative cancers), but less than 6% of the patients in the combined analysis had node negative disease.

The results from this analysis were initially presented after 2.0 years median follow-up because the results had crossed an early-stopping boundary. At that time, there were 261 DFS events in the control group and 133 in the trastuzumab group. This difference translated to a hazard ratio of 0.48 (95% CI, 0.39 to 0.59; $p < .0001$) (18). The addition of trastuzumab was also associated with a 33% reduction in the risk of death ($p = .015$) (18). The improvement in outcome seen with the addition of trastuzumab led to the approval of trastuzumab by the United States Food and Drug Administration (FDA) in 2006.

More recently, the final results from the pooled analysis of N9831/B31 were presented with 8.4 years median follow-up. With this additional follow-up, the relative benefits of trastuzumab remain robust with a 40% reduction in DFS events (HR = 0.60, 95% CI, 0.53–0.68; $p < .0001$) (19). The absolute improvement in DFS is 11.5%, and the majority of the events (8.2%) were distant recurrences. Overall survival was also meaningfully improved with the addition of trastuzumab with a HR = 0.63, 95% CI, 0.54–0.73; $p < .0001$, corresponding to an increase from 74.2% in the control arm to 82.0% in the trastuzumab arm (19). Because of the clear benefit of trastuzumab observed in the first pooled analysis in 2005, patients on the control arm of the study were offered treatment with one year of trastuzumab. A total of 413 women (20.4%) in the combined control arm elected to receive trastuzumab. These patients are included in this final analysis according to intention to treat, and if anything, this crossover would lead to an underestimation of the true benefit of trastuzumab.

AC, doxorubicin; BCIRG, Breast Cancer International Research Group; Cb, carboplatin; CI, confidence interval; D, docetaxel; DFS, disease-free survival; ED, epirubicin, docetaxel; FEC, 5-fluorouracil, epirubicin, cyclophosphamide; HERA, HERceptin Adjuvant; HR, hazard ratio; NSABP, National Surgical Adjuvant Breast and Bowel Project; PACS, Protocole Adjuvant dans le cancer du sein; OS, overall survival; P, paclitaxel; RFS, relapse-free survival; T, trastuzumab; V, Vinorelbine. NS, not significant.
[a]N9831 included a small percentage of node negative patients (5.7% overall).
[b]In B31 the paclitaxel was given every 3 weeks for four cycles. In N9831, paclitaxel was weekly × 12.
Adapted from de Azambuja E, Piccart M. Adjuvant treatment of ERBB2 positive breast cancer. In: Morrow M, Harris JR, Lippman ME, Osborne CK, eds. *Diseases of the Breast*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2011. (Ref. 90.)

The largest adjuvant trastuzumab trial was HERA (Herceptin Adjuvant), a global, but non-U.S. trial that included a total of 5,081 evaluable patients. Like the joint analysis of N9831/B31, initial results from HERA were also reported in 2005.The study population of HERA was more heterogeneous than N9831/B31. The eligibility criteria were relatively broad, allowing both node positive and node negative patients as long as tumor size was at least 1 cm. Overall, approximately 32% of patients on the trial had negative nodes. The chemotherapy backbone in HERA was not specified apart from requiring that patients receive at least four cycles of treatment. Ninety-four percent received an anthracycline-based regimen and 26% also received a taxane. The HERA study design differed from the pooled analysis of N9831/B31 in that trastuzumab therapy was initiated after completion of all chemotherapy. The trastuzumab, which was given every 3 weeks, was mandated to begin no more than 7 weeks from day 1 of the conclusion of chemotherapy or 6 weeks from the completion of radiation or definitive surgery, whichever was last. Unlike the North American trials, HERA asked a duration question, with participants randomized to 1 or 2 years of trastuzumab, or observation.

The initial publication of HERA in 2005 reported the results of 1 year of trastuzumab versus the observation group. This first interim analysis crossed the prespecified early stopping boundary with a median follow-up of only 1 year. In that analysis, there were 127 DFS events in the 1 year of trastuzumab arm compared to 220 events in the observation arm (20). The hazard ratio for DFS events was 0.54 (95% CI, 0.43–0.67; $p < .0001$) (20). There was no significant effect on survival with the short follow-up time. A subsequent analysis with 8 years median follow-up continued to demonstrate improved DFS associated with 1 year of trastuzumab therapy (HR = 0.76; $p < .0001$) as well as a significant survival benefit (HR = 0.76; $p = .0005$) (21). As was the case with the North American trials, patients on the observation group were offered 1 year of trastuzumab; fully 52% crossed over, which presumably had an effect on the observed benefit of trastuzumab.

The Breast Cancer International Research Group (BCIRG) conducted the fourth large randomized trial evaluating trastuzumab in the adjuvant setting. This global study was unique in that it included an arm with a non-anthracycline regimen. Participants were randomized to a control arm of four cycles of AC followed by four cycles of docetaxel (100 mg/m^2) every 3 weeks, or the same regimen with 1 year of trastuzumab starting with the first dose of docetaxel. There was also a third arm on which patients received docetaxel (100 mg/m^2) and carboplatin (area under the curve of 6 mg/mL/min) given every 3 weeks for six cycles

TABLE 46-2

Study Design and Demographic Characteristics of the Trastuzumab Adjuvant Trials

[a]N9831 had a sequential arm but this was not included in the joint analysis.
[b]Only if tumor size >1cm.
[c]Only if at least one concomitant risk factor (grade >1, hormone receptor negative, tumor >2 cm, age <35y).
[d]Only if size >20 mm and PR negative.
[e]ER positive only.
[f]Initially local *HER2* testing was permitted, but the protocols were amended to require centralized testing.
Adapted from de Azambuja E, Piccart M. Adjuvant treatment of ERBB2 positive breast cancer. In: Morrow M, Harris JR, Lippman ME, Osborne CK, eds. *Diseases of the Breast*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2011. (Ref. 90.)

concurrently with trastuzumab (TCH). For both of the trastuzumab arms, the trastuzumab was given weekly during the chemotherapy and then every 3 weeks to complete 1 year. The trial had broad entry criteria and included both node positive and high-risk node negative (defined as having at least one of the following criteria: tumor size >2 cm, ER and PR negative, histologic and/or nuclear grade 2–3, or age <35 years) patients. A total of 3,222 patients were enrolled, of whom approximately 29% were node negative.

The primary endpoint of BCIRG- 006 was disease free survival. Recently, a protocol-specified analysis of the study was reported after 656 DFS events had occurred. Both trastuzumab containing arms demonstrated significantly improved DFS and overall survival relative to the AC/docetaxel control arm of the study. The 5-year disease-free survival rate was 75% for AC/docetaxel, 81% for TCH, and 84% for AC/docetaxel/trastuzumab (22). This corresponds to a hazard ratio for the comparison of TCH and ACTH with AC/docetaxel of 0.75; $p = .04$, and 0.64; $p < .001$ respectively. The 5-year overall survival rate was 87% for AC/docetaxel, 91% for TCH, and 92% for AC/docetaxel/trastuzumab. This corresponds to a hazard ratio for the comparison of TCH with AC/docetaxel of 0.77; $p = .04$, and AC/docetaxel/trastuzumab with AC/docetaxel of 0.63; $p < .001$ (22). Unlike the N9831/B31 and HERA studies, very few patients (1.6%) on the control arm of BCIRG 006 crossed over to receive trastuzumab, so this issue did not significantly affect the impact of trastuzumab on outcomes in this study. The differences in DFS and overall survival between TCH and AC/docetaxel/trastuzumab were not significant. The study had only limited power to detect large differences in outcome between the two trastuzumab-containing arms. While both trastuzumab-containing arms were better than the control, the anthracycline containing arm has a numeric advantage in terms of both DFS and OS. Importantly, the results do not prove equivalence of TCH to ACTH.

Two smaller randomized trials have also evaluated the adjuvant use of trastuzumab. Both the FinHer study and FNCLCC-PACS 04 study evaluated trastuzumab in the subset of patients with HER2-positive cancers (232 patients in FinHer, 528 in PACS 04) as part of larger studies comparing different chemotherapy regimens. FinHer was noteworthy for two reasons. First, the chemotherapy backbone consisted of a randomization to either vinorelbine (25 mg/m^2 weekly for 9 weeks) or docetaxel (100 mg/m^2 every 21 days), both followed by three cycles of FEC (fluorouracil 600 mg/m^2, epirubicin 60 mg/m^2, and cyclophosphamide 600 mg/m^2 every 21 days). Second, patients with HER2-positive cancers randomized to trastuzumab received weekly therapy for only 9 weeks, concurrent with either the vinorelbine or docetaxel. Despite the short duration, patients who received trastuzumab had an improved recurrence-free survival (RFS) at 3 years compared to those who were randomized to chemotherapy alone (89% vs. 78%; HR = 0.42; 95% CI, 0.21–0.83; $p = .01$) (23).

In PACS04, patients with node positive, HER2-positive cancers received either six cycles of FEC (fluorouracil 500 mg/m^2, epirubicin 100 mg/m^2, and cyclophosphamide 500 mg/m^2) or ED (epirubicin 75 mg/m^2 and docetaxel 75 mg/m^2)

every 3 weeks. A second randomization was to either observation or a year of trastuzumab (given every 3 weeks) starting after completion of the chemotherapy. In this study, the addition of trastuzumab was associated with only a minimal improvement in DFS (HR = 0.86, 95% CI, 0.61–1.22), which was not statistically significant (p = .41) (24).

BENEFIT OF TRASTUZUMAB IN THE NEOADJUVANT TREATMENT OF HER2-POSITIVE EARLY-STAGE BREAST CANCER

The clear benefit of trastuzumab in patients with metastatic disease sparked interest in evaluating trastuzumab in the neoadjuvant setting. While several small, single-arm studies demonstrated that preoperative treatment with the combination of trastuzumab and chemotherapy was feasible and active (25,26), the first randomized trial to show a benefit to trastuzumab was conducted by the MD Anderson Cancer Center. Buzdar and colleagues randomized patients with operable stage II–IIIA HER2-positive cancers to either four cycles of paclitaxel (225 mg/m^2 as a 24-hour infusion every 3 weeks) followed by four cycles of FEC (500 mg/m^2 fluorouracil on days 1 and 4, 500 mg/m^2 IV cyclophosphamide and 75 mg/m^2 epirubicin on day 1 only of a 3-week cycle) or the same chemotherapy regimen combined with weekly trastuzumab. The trastuzumab was started concurrent with the taxane and continued throughout the chemotherapy (24 weeks). The primary objective of the study was to compare the rate of pathological complete response (pCR, defined as no residual invasive cancer in the breast or axillary nodes) between the two arms. Although the study planned to enroll 164 patients, accrual was terminated after 42 patients were randomized because a large difference in pCR rates was observed. 26.3% of patients who received chemotherapy alone had a pCR compared to 65.2% of patients who received chemotherapy with trastuzumab (27). Despite the small sample size, this difference in pCR rates was significant (p = .016). A cohort of 22 patients was subsequently enrolled and treated in a uniform fashion with the same chemotherapy and trastuzumab regimen. The pCR of this cohort was 54.5% (28). After a median follow-up of 36 months, the 3-year disease-free survival for those patients randomized to chemotherapy alone was 85.3% while no patients randomized to the trastuzumab arm had recurred (p = .041 for the comparison between arms) (28).

The benefit of neoadjuvant trastuzumab was confirmed in the larger phase III NOAH (Neoadjuvant Herceptin) trial. In this study, 235 patients with HER2-positive locally advanced (T3N1 or T4 or N2/N3, or ipsilateral supraclavicular node involvement) breast cancer received a multiagent chemotherapy regimen consisting of doxorubicin 60 mg/m^2 and paclitaxel 150 mg/m^2 every 3 weeks for three cycles, followed by paclitaxel 175 mg/m^2 administered every 3 weeks for four cycles. Cyclophosphamide (600 mg/m^2), methotrexate (40 mg/m^2), and fluorouracil (600 mg/m^2) were then given on days 1 and 8 every 4 weeks for three cycles. Those patients randomized to the trastuzumab arm received the antibody every 3 weeks concurrent with the entire chemotherapy regimen. They also received trastuzumab postoperatively to complete a total of 1 year of trastuzumab therapy.

Similar to the results from the MD Anderson study, the addition of trastuzumab in NOAH led to a marked improvement in pCR rates—19% for patients who received chemotherapy alone compared to 38% for those who received chemotherapy and trastuzumab (29). With a median follow-up of 3.2 years, long-term outcomes were also improved with trastuzumab. Three-year event-free survival (defined as disease recurrence or progression, or death from any cause) was 71% (95% CI, 61–78; n = 36 events) among patients randomized to trastuzumab, vs. 56% (46–65; n = 51 events) for the patients who received chemotherapy alone (29). This difference was statistically significant with a hazard ratio of 0.59 (95% CI, 0.38–0.90; p = .013). Because of the clear benefit of trastuzumab demonstrated in the MD Anderson and NOAH neoadjuvant studies, as well as similar benefits seen in the adjuvant trials discussed earlier, all subsequent neoadjuvant trials included HER2-directed in all arms.

CARDIAC TOXICITY OF TRASTUZUMAB

In general, trastuzumab is well tolerated. In the randomized studies, rates of adverse events were similar in patients assigned to receive trastuzumab relative to that of the control group (18,20,22). However, as previously discussed, the pivotal metastatic study demonstrated significant evidence of cardiac toxicity with trastuzumab, particularly when combined with an anthracycline. Because of this observation, all of the adjuvant studies and many of the early neoadjuvant studies avoided concurrent use of trastuzumab with an anthracycline and required confirmation of an adequate left ventricular ejection fraction (LVEF) prior to a patient's initiating the trastuzumab. In addition, all of these trials included extensive cardiac monitoring. The data from these randomized studies thus provide valuable information regarding the cardiac effects of trastuzumab in patients with early-stage disease, including quantification of the absolute risk of cardiac toxicity, identification of treatment regimens that are more likely to be associated with cardiac effects, and characterization of risk factors that predict a higher likelihood of cardiac toxicity.

There is no question that trastuzumab, particularly when given in conjunction with an anthracycline-based regimen, does have the potential to cause cardiac toxicity in the adjuvant setting (summarized in Table 46-3), but the absolute incidence of significant toxicity is low and the rates vary substantially across the trials. While cross-trial comparisons are complicated by the varied definition of cardiac events used in the individual studies and possible differences in the patient populations, the highest rate of symptomatic cardiac events (NYHA class III/IV CHF) was generally seen in studies in which patients received an anthracycline within weeks of initiation of trastuzumab. In N9831, NSABP B31, and the BCIRG trial, the rates of significant cardiac toxicity when a taxane–trastuzumab regimen was administered immediately following AC were 2.9%, 4.1%, and 2.0% respectively (18,22). Patients on the TCH arm of BCIRG 006 had the lowest rate of cardiac toxicity (0.4%) (22). Interestingly, the rate of symptomatic cardiac events in patients randomized to trastuzumab in HERA (0.5%) appeared lower than that of the other trials despite the fact that 94% of patients on HERA received an anthracycline prior to the trastuzumab (20). There are several possible explanations for this observation. Of note, HERA required a LVEF of ≥55% to begin trastuzumab whereas most of the other studies required an LVEF of >50%. This difference may be particularly relevant given that several studies suggest that a baseline LVEF <55% increases the risk of trastuzumab-induced cardiotoxicity (30–32). Another difference is that because HERA required participants to complete chemotherapy and radiotherapy before randomization, there was a longer delay between completing chemotherapy and initiation of trastuzumab relative to the other studies. The majority of patients in HERA did not

receive a taxane, in contrast to the other large studies in which taxanes were given to all patients. There are however, no data that clearly implicate prior receipt of a taxane as a risk factor for trastuzumab induced cardiac toxicity. Lastly, it has been postulated that HERA's purely sequential design may have contributed to its low cardiac toxicity rate by extending the time interval between the anthracycline and initiation of trastuzumab. However, given the similar rates of significant cardiac events in the sequential (2.8%) and concurrent (3.3%) arms of N9831 (30), the only randomized comparison of the two approaches, it seems unlikely that the sequential design of HERA was the primary reason for its relative lack of serious cardiac toxicity.

Several studies have sought to identify patient characteristics that predict an increased likelihood of developing trastuzumab-induced cardiotoxicity. In a univariate analysis of data from the N9831 study, age ≥60, prior or current use of antihypertensive medications, and baseline LVEF <55% were all associated with increased risk of cardiac events within 3 years. (30) A similar analysis from the NSABP B-31 data again found age (50–59 years, HR = 2.43, ≥60, HR = 2.73), use of hypertension medications (HR = 2.1), baseline LVEF 50%–54% (HR = 6.7), and post-AC LVEF (55%–64% HR = 3.6, 50%–54% HR = 11.8) associated with increased cardiac risk. (31) A multivariate analysis has also been performed in the combined N9831/B-31 database with age >50 years and baseline LVEF identified as independent predictors of cardiac events. (32)

A recent report with extended follow-up (7 years) of NSABP B-31 provides insight into the timing and long-term outcomes of trastuzumab-induced cardiotoxicity. In this analysis, a total of 37 (4.0%) of 944 patients treated on the trastuzumab arm of the study experienced a significant cardiac event (defined as cardiac death or CHF with a decrease LVEF of greater than 10% to a value <55% or a decrease of greater than 5% to a value below the lower limit of normal) compared to 1.3% of patients who received chemotherapy alone (31). There was one cardiac death in each arm. The vast majority of cardiac events occurred during the first year of trastuzumab therapy, and only two events occurred more than 2 years from the initiation of trastuzumab. Thus, at this time, there is no clear evidence to suggest that trastuzumab therapy is associated with delayed-onset cardiotoxicity. In patients who do develop cardiotoxicity while on trastuzumab, it appears to be reversible in most cases. Of the 37 trastuzumab-treated patients who developed a significant cardiac event on B-31, 33 were no longer symptomatic when assessed 6 months after the event, although most remained on cardiac medications (31). When assessed at least 6 months after the cardiac event, 25 of the 37 patients had an LVEF that was lower than their initial baseline, all but 21 of these patients had recovered to at least 50% (31).

As discussed previously, all of the large randomized trials included extensive cardiac monitoring, typically with LVEF evaluations at baseline and approximately every 3 months while patients were receiving trastuzumab. The studies also employed strict stopping rules for trastuzumab therapy based on defined decreases in LVEF. This approach was developed before the benefits of trastuzumab in the adjuvant setting had been demonstrated. Given the low absolute rates of clinically significant cardiac toxicity, particularly in patients without risk factors for this toxicity, the substantial benefits of adjuvant trastuzumab, and the reversibility of most cardiac toxicity, it is not clear that such extensive cardiac monitoring and strict trastuzumab stopping rules are necessary. One can argue that the cardiac safety of adjuvant trastuzumab was established in the context of strict monitoring and dose interruption, but in the absence of symptoms, it is not clear that the best interests of patients are served by dose interruption for minor changes in the ejection fraction. Unfortunately, it is unlikely that this question will ever be answered in a randomized trial. In our view, cardiac function should be evaluated prior to initiating trastuzumab and at some regular intervals during therapy. Physicians should carefully consider the potential benefits of trastuzumab in the individual patient before discontinuing it in patients who are asymptomatic and do not have major reductions in their cardiac function. Patients with risk factors for trastuzumab-induced cardiac toxicity need more extensive monitoring.

It is intriguing that despite data from the pivotal metastatic trial demonstrating that concurrent therapy with an anthracycline and trastuzumab is associated with significant cardiotoxicity, several neoadjuvant studies treated patients with concurrent anthracycline and trastuzumab without substantial cardiac toxicity. In NOAH, participants received a total of 180 mg per square meter of doxorubicin, while in the MD Anderson study, a total of 300 mg per square meter of epirubicin was given. Two of the 117 patients treated with trastuzumab and anthracycline on the NOAH study and none of the 45 patients treated on the MD Anderson study

developed clinically significant cardiac toxicity (28,29). More recently, in the GeparQuattro and GeparQuinto studies, each of which included an arm that received a total of 360 mg per square meter of epirubicin with concurrent trastuzumab, only two of 752 (0.3%) patients and one of 307 (0.3%) patients developed clinical CHF, respectively (33,34). It is unknown if the relatively low rate of cardiotoxicity observed in these trials despite the delivery of concurrent anthracycline and trastuzumab is due to the use of epirubicin or <4 cycles of doxorubicin, the requirement of baseline EF ≥55% in most of the trials, or some other unknown factor. However, it does suggest that an absolute prohibition on concurrent anthracyclines and trastuzumab is not necessary and that in the appropriate circumstances this is a reasonable approach.

OPTIMIZING ADJUVANT TRASTUZUMAB THERAPY

Ultimately, a wide range of factors may influence the choice of adjuvant therapy for the patient with early stage HER2-positive breast cancer. One can imagine a time when there will be a number of anti-HER2 regimens that combine various targeted therapies, chemotherapy, and/or hormonal therapy. Decisions about treatment may depend on disease burden, biologic characteristics of the tumor, and patient preference. At this time, however, trastuzumab is the only anti-HER2 agent with demonstrated efficacy in the adjuvant setting, and once a decision has been made to administer trastuzumab, the questions remaining are: (i) should the administration be concurrent with chemotherapy; (ii) how long should trastuzumab be administered; and (iii) what is the most appropriate chemotherapy regimen to use in a given patient, taking into account effectiveness and toxicity.

Concurrent versus Sequential Trastuzumab Therapy

The study designs of the adjuvant trastuzumab trials varied as to whether the trastuzumab was given concurrent with chemotherapy or initiated only after the chemotherapy regimen was completed (see Table 46-2). Only one of the studies, N9831, included a randomized comparison of sequential versus concurrent therapy. When the study was initially reported (as part of the joint analysis with NSABP B-31), an unplanned interim analysis was performed when the number of DFS events observed on the sequential and concurrent arms was small. This initial analysis demonstrated a DFS benefit for concurrent trastuzumab relative to sequential therapy (HR = 0.64, 95% CI, 0.46–0.91; p = .00114) (35). In many ways, the result was perplexing given the robust benefit of sequential trastuzumab seen in the HERA trial.

More recently, an updated analysis of the concurrent versus sequential arms of N9831 was reported with a 6-year median follow-up. In this analysis, the 5-year DFS for the sequential arm was estimated at 80.1% (95% CI, 77.4%–82.9%) compared to 71.8% (95% CI, 68.6%–75.1%) for the control arm treated with chemotherapy alone (HR = 0.69; p < .001) (36). Although the concurrent arm had a numerically superior DFS compared to the sequential arm (84.4% vs. 80.1%, HR = 0.77; p = .02), this difference did not meet predefined criteria for statistical significance at this interim analysis (36). There were an insufficient number of deaths at the time of the analysis to compare survival between the arms.

In clinical practice, there seems to be little reason not to embrace a concurrent approach. While the only randomized comparison between sequential and concurrent trastuzumab therapy has failed to show an unequivocal benefit for the sequential approach, the trial (as noted above) did reveal a strong trend in that direction. Given this result, and the observation that concurrent therapy is not associated with any excess toxicity compared to sequential therapy, a strong case can be made that concurrent trastuzumab and chemotherapy should be the preferred approach.

Optimal Duration of Trastuzumab Therapy

All of the large randomized studies of adjuvant trastuzumab included at least 1 year of trastuzumab therapy. One year was arbitrary, but was made possible by the lack of significant chronic toxicities of trastuzumab. The small FinHer trial randomized patients to chemotherapy alone or with 9 weeks of trastuzumab, concurrent with the chemotherapy (docetaxel or vinorelbine). Despite this short duration of therapy, the benefits of trastuzumab initially observed in this study, RFS HR = 0.42 (p = .01) (23), were similar to that seen in the trials in which trastuzumab was given for 1 year. Although the subsequent report, at a median follow-up of approximately 5 years, was less promising (HR = 0.65, 95% CI, 0.38–1.12; p = .12) (37), the early results from FinHer called into question assumptions about the necessity of a year of trastuzumab treatment.

At the 2012 European Society for Medical Oncology (ESMO) Congress, results from the first randomized studies comparing different durations of trastuzumab therapy were presented. The HERA study included a randomization of 1 versus 2 years of trastuzumab therapy, and with approximately 1,550 patients in each arm and a median of 8 years of follow-up, there was absolutely no difference between the two arms; DFS of 75.8% and 76.0%, respectively (HR = 0.99, 95% CI, 0.85–1.14; p = .86) (38). Overall survival for the two arms was also essentially the same (HR = 1.05, 95% CI, 0.86–1.28; p = .63) (38). Of interest, the additional year of trastuzumab was associated with a modest increase in mild or asymptomatic cardiac toxicity, which was 4.1% in the 1-year arm and 7.2% in the 2-year arm, but no difference was seen in severe cardiac toxicity (0.8% vs. 1.0%) (38).

Initial data from the PHARE study shed further light on the question of duration of therapy. In this study, 3,384 patients who had received 6 months of trastuzumab were randomized to receive an additional 6 months of trastuzumab (total of 12 months) or no further therapy. The study included a heterogeneous population; 55% of the patients had node negative disease and 73% received both an anthracycline and a taxane. 58% of the patients started the trastuzumab concurrently with the chemotherapy and 42% received a sequential regimen (39). The trial was designed to test the non-inferiority of 6 versus 12 months of trastuzumab, and with a median follow-up of 42.5 months, the hazard ratio for DFS was 1.28 (95% CI, 1.05–1.56; p = .29) in favor of the 12-month arm (39). Although the results did not allow the investigators to conclude that 12 months was superior, non-inferiority of the 6-month regimen, which would have required that the upper boundary of the 95% confidence interval be no higher than a HR of 1.15, could not be established.

With the results of the HERA and PHARE studies, there is now fairly clear guidance on the optimal duration of trastuzumab therapy. HERA shows that extending trastuzumab therapy beyond a year is not beneficial. Although the PHARE study did not definitely demonstrate that 12 months was superior, the trend unquestionably favors 12 months. These data, coupled with the significant disease-free and overall survival benefit of 12 months of trastuzumab observed in the BCIRG006 and B31/N9831 studies, dictates that 12 months of trastuzumab is the standard of care. It is fortunate that the

decision to use 1 year of therapy in the initial randomized trials, which was completely arbitrary, has been borne out as likely the optimal approach.

Anthracycline vs. Non-Anthracycline Regimens

While ambiguity regarding optimal scheduling and duration of trastuzumab have been largely resolved by the recent clinical trial results discussed in the preceding sections, there is still substantial controversy regarding the optimal chemotherapy backbone to use with trastuzumab in the adjuvant setting. The central question is whether to include an anthracycline in the treatment regimen. The argument to exclude an anthracycline relates to the toxicity of this approach. Although the incidence of clinically significant cardiac toxicity is quite low with the use of an anthracycline followed by trastuzumab, it is higher than is seen with non-anthracycline-containing regimens. The absolute risk is particularly low in individuals who have no risk factors for cardiomyopathy. In addition, there is a small increase in the risk of acute leukemia or myelodysplasia in individuals treated with anthracyclines, though this risk appears to be less than 0.5% in almost all studies (40–42). Ultimately, it may be possible to eliminate anthracyclines from the treatment of most or all women, but at this time there are compelling reasons to include an anthracycline for the majority of patients with HER2-positive disease. First, as described previously, it is known that the anthracyclines are particularly active in HER2-positive disease. Second, almost all of the adjuvant regimens that have demonstrated a benefit from the addition of trastuzumab have included an anthracycline. Third, and perhaps most importantly, the one study that compared an anthracycline-containing regimen (AC-TH) to a regimen devoid of anthracycline therapy (TCH), demonstrated a nonsignificant trend in favor of the AC-TH regimen (22). While the study does not allow us to conclude that AC-TH is superior to TCH, it certainly does not provide sufficient evidence to conclude the two regimens are equivalent. Even if one includes all of the serious cardiac events and cases of leukemia/myelodysplasia along with the disease recurrences and deaths in each arm, AC-TH has fewer absolute events than TCH. At this time, the optimal approach seems straightforward. In a patient with a moderate to high risk of disease recurrence where one wants to optimize the adjuvant regimen, we favor an anthracycline-based regimen as long as the patient does not have risk factors for the development of cardiac toxicity. If she does, or if her risk of disease recurrence is relatively low, a very reasonable approach is to substitute TCH for AC-TH. We fully expect that adjuvant regimens for HER2-positive disease will change over the next 5 to 10 years, and as part of this evolution, it is likely that there will be fewer women receiving anthracyclines. For some or many women, it may be possible to eliminate chemotherapy altogether and use HER2-directed approaches alone; however, at this time, it is not possible to select women for such a treatment approach.

NOVEL AGENTS UNDER EVALUATION IN THE ADJUVANT AND NEOADJUVANT SETTING

The introduction of trastuzumab in the adjuvant and neoadjuvant setting has substantially improved outcomes for women with HER2-positive early breast cancer. A recent Monte Carlo simulation using SEER data estimates that the widespread use of adjuvant trastuzumab in the United States will decrease the number of patients with HER2-positive cancers who develop disease recurrence by approximately 38% or 2,800 patients per year (43). However, trastuzumab is not perfect—recurrences still occur despite treatment with an optimal trastuzumab regimen. The same Monte Carlo simulation estimates at least 4,500 patients still develop recurrence each year (43). In an effort to further reduce the number of women who develop metastatic disease, several novel HER2-targeted agents are being evaluated in combination with standard therapies in patients with early-stage HER2-positive cancers.

Lapatinib

Lapatinib, an oral small molecule inhibitor of the HER2 and EGFR tyrosine kinases, improves DFS when combined with capecitabine in patients with metastatic disease who have previously received trastuzumab-based therapy (86). Preclinical studies, as well as clinical data, suggest that the combination of lapatinib with trastuzumab has synergistic anti-tumor effects. In the adjuvant setting, lapatinib was first evaluated as monotherapy in the phase III TEACH trial in which trastuzumab naïve women who had previously received an adjuvant chemotherapy regimen were randomized to one year of lapatinib (1,500 mg daily) or placebo. Enrollment on this study closed in 2008 with a total of 3,147 patients randomized (44). Because the study did not place any restrictions on the time between completion of adjuvant chemotherapy and entry on the study, the trial population was heterogeneous with approximately 29% of patients enrolling more than 4 years after their initial diagnosis. After a median follow-up of approximately 48 months, there were 210 (13%) DFS events in the patients who received lapatinib and 264 (17%) in patients who received placebo (HR = 0.83, 95% CI, 0.7–1.0; p = .053) (44). Given the widespread use of trastuzumab in the adjuvant setting, the clinical relevance of this study is limited.

In the neoadjuvant setting, lapatinib has been directly compared to trastuzumab, and has also been evaluated in combination with trastuzumab. The phase III GeparQuinto study, led by the German Breast Group, randomized 620 patients to four cycles of EC (epirubicin [90 mg/m^2] and cyclophosphamide [600 mg/m^2] every 3 weeks), followed by four cycles of docetaxel (100 mg/m^2 every 3 weeks) with either trastuzumab or lapatinib (1,000–1,250 mg daily) (33). The trastuzumab and lapatinib were given throughout the entire chemotherapy course. Patients on this study had either clinical T3/4 tumors and/or clinically node positive disease with at least T2 tumors. Patients with sentinel node positive cancers were also eligible. The primary endpoint was pCR defined as no residual invasive or *in situ* cancer in the breasts or nodes. The pCR rate was 30.3% in patients who received trastuzumab-based therapy and 22.7% in those patients who received lapatinib (odds ratio [OR] 0·68 [95% CI, 0.47–0.97]; p = ·04) (33). Trastuzumab was also better tolerated with more rash, diarrhea, and treatment discontinuation (14% vs. 33.1%) in patients randomized to lapatinib.

NeoALTTO randomized 455 patients with T2 or larger HER2-positive cancers to a 6-week run-in of lapatinib (1,500 mg daily), trastuzumab (weekly), or the combination (lapatinib given at 1,000 mg daily) (45). After 6 weeks of that therapy, all patients received 12 weekly doses of paclitaxel (80 mg/m^2) with continuation of the same HER2-targeted regimen, followed by definitive surgery. The primary endpoint was pCR, defined in this study as no residual invasive cancer in the breast. Those patients randomized to the combination of lapatinib and trastuzumab had a significantly higher rate of pCR than those who received trastuzumab alone 51.3% versus 29.5%

(absolute difference 21·1%, 9·1–34·2, p = ·0001) (45). The pCR rate for patients in the lapatinib arm (24.7%) was numerically lower than that of the trastuzumab arm (29.5%), but unlike the GeparQuinto study, this difference was not statistically significant (absolute difference –4·8%, –17·6 to 8·2, p = ·34) (45).

A third neoadjuvant study, NSABP B-41, also compared trastuzumab and lapatinib regimens. In this study, women with operable HER2-positive breast cancer were randomized to four cycles of AC, followed by four cycles of paclitaxel (80 mg/m^2 on days 1, 8, and 15 of 28-day cycle) with either trastuzumab, lapatinib (1250 mg daily), or the combination (with lapatinib at 750 mg daily). In 519 evaluable patients, the rate of pCR (defined as absence of invasive disease in the breast) was similar for patients randomized to trastuzumab (52.5%) or lapatinib (53.2%) (46). Patients who received the combination had a somewhat higher rate of pCR (62%), but this did not meet statistical significance (p = .075 for the comparison with trastuzumab) (46). Higher rates of diarrhea were observed in the lapatinib-containing arms.

Together, the results of GeparQuinto, NeoALTTO, and NSABP B-41 are consistent with data from the metastatic setting that suggest that lapatinib based therapy is not superior to trastuzumab and may be inferior (47). More importantly, these data, which are consistent with what has been seen in the metastatic setting (48,49), indicate that combining two HER2 inhibitors with different mechanisms of action, an approach termed "dual-blockade," is associated with improved short-term efficacy. These observations will be tested definitively in the ALTTO study, a global phase III adjuvant study comparing 1 year of trastuzumab, lapatinib, and combinations of the two in conjunction with chemotherapy.

In addition to lapatinib, other small molecule tyrosine kinase inhibitors are being evaluated in the treatment of HER2-positive breast cancer. Neratinib, an inhibitor of the HER2, EGFR, and HER4 kinases, differs from lapatinib in that neratinib binds irreversibly to the target kinase. In preclinical studies, neratinib appears more potent than lapatinib (50), and in studies in the metastatic setting, neratinib has substantial single agent activity (51). Presumably because of its greater potency, neratinib has relatively high rates of moderate to severe diarrhea, which requires aggressive management (51).

Neratinib is currently being studied in a randomized phase III adjuvant trial, the ExteNET study, in which patients with HER2-positive early stage cancers who completed a year of trastuzumab-based therapy are randomized to an additional year of neratinib or placebo. Accrual to this study has been completed, and the analysis is ongoing.

Pertuzumab

Another approach to the "dual-blockade" paradigm of utilizing two anti-HER2 agents with nonoverlapping mechanisms of action is to combine trastuzumab with pertuzumab. Pertuzumab, like trastuzumab, is a humanized monoclonal antibody specific for the extracellular domain of HER2. Data from the phase III CLEOPATRA study in the first-line metastatic setting demonstrates that the addition of pertuzumab to a trastuzumab-taxane regimen markedly improves progression-free and overall survival in patients with HER2-positive cancers (52,53). In addition, a small phase II study showed the combination of pertuzumab and trastuzumab has clinical activity in patients whose cancer had progressed on a previous trastuzumab regimen (54).

These findings were extended to the early disease setting by the NeoSphere study, a phase II randomized neoadjuvant trial in which 417 women with HER2-positive cancers received four cycles of docetaxel (75 mg/m^2, escalating, if tolerated, to 100 mg/m^2) every 3 weeks, combined with trastuzumab (8 mg/kg loading dose, followed by 6 mg/kg every 3 weeks) or pertuzumab (840 mg loading dose, followed by 420 mg every 3 weeks), or the combination of the two antibodies. Patients in a fourth arm of the study received the combination of pertuzumab and trastuzumab without chemotherapy. The primary endpoint was pCR in the breast. Consistent with what was observed in the metastatic setting, the pCR rate in NeoSphere was significantly higher in patients receiving docetaxel with the combination of trastuzumab and pertuzumab (45·8% [95% CI, 36.1–55.7]) than in those patients who received docetaxel with either trastuzumab (29·0% [20.6–38.5]; p = .0141) or pertuzumab alone (24.0% [15.8–33.7]) (55). The addition of pertuzumab to trastuzumab and chemotherapy was not associated with any significant increase in toxicity (55).

Interestingly, while women randomized to pertuzumab and trastuzumab without the docetaxel had a lower rate of pCR (16.8% [10.3–25.3]) than any of the chemotherapy groups, one-sixth of the patients achieved a pathologic complete response with 12 weeks of combined antibody therapy alone (55). This observation suggests that there is a subset of patients with HER2-positive cancers that are exquisitely sensitive to HER2-directed agents and that such patients, if identified, might be treated with targeted therapy alone and spared the toxicity of chemotherapy. Why is there enhanced clinical activity with dual blockade? In the case of pertuzumab and trastuzumab, preclinical data suggest that synergism may result from the ability of pertuzumab, which binds to the dimerization arm of HER2 (domain II), to inhibit ligand-induced heterodimerization of HER2 with HER3 (56). In contrast, trastuzumab, which binds to the juxtamembrane region (domain IV) of HER2, is able to inhibit ligand-independent HER2/HER3 interactions (57).

Pertuzumab's ability to augment the effectiveness of trastuzumab in the metastatic and neoadjuvant settings, without substantially increasing toxicity, has led to interest in exploring the role of pertuzumab in adjuvant therapy. The APHINITY study, a phase III trial of patients with high risk HER2-positive early breast cancer randomizes patients to 1 year of pertuzumab or placebo in addition to a standard chemotherapy/trastuzumab regimen. This study completed accrual in 2013 and is awaiting maturation and analysis.

Based on the substantial improvement in pCR seen with the addition of neoadjuvant pertuzumab in the NeoSphere study, and in view of the survival benefit seen with pertuzumab in the CLEOPATRA trial, the United States FDA granted accelerated approval for the neoadjuvant use of pertuzumab in combination with chemotherapy and trastuzumab in September, 2013 (58,59). The indication is limited to patients with locally advanced, inflammatory, or early breast cancer greater than 2 cm in diameter and/or node positive. The FDA guidance suggests that based on the study design and safety data from NeoSphere and another neoadjuvant pertuzumab study, TRYPHENA (60), appropriate regimens to use with pertuzumab include 1) four preoperative cycles of pertuzumab in combination with trastuzumab and docetaxel followed by 3 postoperative cycles of FEC, 2) three preoperative cycles of FEC alone followed by 3 preoperative cycles of pertuzumab in combination with docetaxel and trastuzumab, or 3) six preoperative cycles of pertuzumab in combination with TCH.

It should be noted that at the current time, there are no data indicating that the use of pertuzumab in the early disease setting is associated with improvements in long term outcome measures such as DFS or OS. Thus, the conversion to full FDA approval of pertuzumab is contingent upon confirmatory data from the adjuvant APHINITY study described above. Given the current lack of proven long term benefit

for the use of neoadjuvant pertuzumab, it may be prudent to reserve the use of this agent for patients at high risk for disease recurrence.

Trastuzumab Emtansine

The most recent HER2-directed agent to be evaluated in the early disease setting is trastuzumab emtansine (T-DM1). T-DM1 is an antibody drug conjugate consisting of the potent anti-microtubule molecule DM1 (up to 270-fold more potent than paclitaxel) (61) conjugated via a non-cleavable linker to the trastuzumab monoclonal antibody. On average, there are 3.5 DM1 molecules per antibody. Even with the conjugation, the trastuzumab retains its affinity for HER2 and its effector functions including activation of ADCC. T-DM1 is thus able to deliver the cytotoxic DM1 selectively to the HER2-positive cancer cell, and also retain the anti-tumor functions of trastuzumab. In patients with metastatic HER2-positive breast cancer who were previously treated with trastuzumab, the phase III EMILIA study demonstrated that T-DM1 improved PFS and survival compared to capecitabine and lapatinib, and did so with significantly less toxicity. T-DM1's combination of potent activity and favorable toxicity profile has led to interest in evaluating this agent in the (neo)adjuvant setting. To date, only a pilot safety study with T-DM1 has been conducted in the (neo)adjuvant setting, and this revealed that the use of T-DM1 after standard anthracycline based chemotherapy was well tolerated (62). This study paves the way for a large, randomized adjuvant trial as well as randomized neoadjuvant studies to evaluate the role of T-DM1 in the early disease setting.

Although there is much interest in the pending adjuvant trial results with the new agents described above, the relatively favorable outlook for most patients with operable HER2-positive breast cancer may make it difficult for these novel therapies to demonstrate a clinically meaningful benefit. This issue is particularly important because most of these adjuvant studies used "add-on" designs in which the investigational agent was given in addition to standard therapy, rather than replacing it. This approach makes it especially important to show a substantial improvement in outcome to justify the extra toxicity from the additional therapy. It is also quite possible that several of these new HER2-targeted agents will show improvements in outcome when added to the current standard of care. Identification of molecular predictors of response to these individual agents will be critical to rationally select among these different options to optimize outcomes for an individual patient.

PREDICTIVE MARKERS OF TRASTUZUMAB BENEFIT AND RESISTANCE

Although the introduction of trastuzumab has improved outcomes of patients with HER2-positive early breast cancers, trastuzumab is not uniformly effective—recurrences still occur despite treatment with an optimal trastuzumab regimen, and only a subset of patients treated with neoadjuvant trastuzumab-based regimens achieve a pCR. These observations reflect some degree of either inherent or acquired resistance to trastuzumab-based therapy. If molecular markers could be identified that predict which patients' cancers are not fully sensitive to trastuzumab-based therapy, those patients could be provided additional or alternative therapies to overcome this resistance. Biomarkers are also needed to help select which alternative anti-HER2 agents would be most active for a given cancer. As noted above, this question is becoming increasingly important as the number of novel HER2-directed agents increases. Unfortunately, it has proven difficult to identify markers that definitively predict which patients will or will not benefit from trastuzumab or who might benefit from an alternative approach.

In the initial analyses of the large randomized adjuvant studies evaluating trastuzumab, it was clear that trastuzumab had similar benefits across the subgroups of breast cancer defined using standard clinical or histological criteria (e.g., hormone receptor status, nodal status, tumor size, patient age, or menopausal status) (18,20,22). Most of the recent efforts to identify predictive markers of trastuzumab benefit in the (neo)adjuvant setting have focused on individual components of the HER2 signaling pathway. Preclinical studies demonstrate that the transforming activity of HER2 is critically dependent on signaling through the PI3-kinase pathway, and that resistance to trastuzumab can be induced by constitutive activation of PI3-kinase (63,64). It was therefore hypothesized that activating mutations in *PIK3CA*, the gene coding for the catalytic subunit of PI3-kinase, or loss of PTEN, the suppressor of the PI3-kinase pathway, would be associated with resistance to trastuzumab. Consistent with this hypothesis, in retrospective analyses of small preoperative studies, and some metastatic datasets, alterations in the PI3-kinase pathway were associated with inferior outcomes in trastuzumab-treated patients (64–66). However, analysis of the N9831 and NSABP B31 studies failed to show an association between alterations in either PIK3CA or PTEN and benefit of trastuzumab (Reference (67) and Soon Paik, personal communication, 2012). Similarly, a comprehensive biomarker analysis focused on HER family members and the PI3-kinase pathway failed to show any significant association between a specific biomarker and differential benefit from trastuzumab or pertuzumab in the Neo-Sphere Study (68).

There has also been interest in evaluating the role of p95 as a predictor of trastuzumab benefit. p95, which is expressed in a subset of HER2-positive cancers, is a truncated form of the HER2 protein which lacks the extracellular domain, but retains kinase activity. p95 can be formed by proteolytic cleavage or synthesis of the protein from an internal translation initiation site. Because p95 lacks the extracellular portion of HER2, trastuzumab is unable to bind to it, and many therefore hypothesized that the subset of HER2-positive cancers with significant expression of p95 would exhibit resistance to trastuzumab. Consistent with this hypothesis, retrospective analyses of small series of archival primary HER2-positive cancers from patients treated with trastuzumab-based therapy in the metastatic setting found inferior outcomes in patients with p95 expressing cancers (69,70). However, a recent analysis of pretreatment tumor samples from 134 patients treated with trastuzumab-based neoadjuvant chemotherapy on the GeparQuattro study found that patients with p95 positive cancers actually had higher pCR rates than those with p95 negative cancers (59% vs 24%, $p < .001$) (71). A similar analysis of tumor samples from patients treated with neoadjuvant chemotherapy and trastuzumab on the CHER-LOB study also failed to demonstrate an inverse association between p95 expression and pCR; however, this study included only 29 evaluable patients (72). Given the small sample sizes and questions regarding the optimal method to assess p95 expression, these results do not definitively disprove the hypothesis that p95 expression is a clinically important mediator of trastuzumab resistance. Additional data, perhaps with alternative assays for p95 expression, are needed to address the role of p95 in resistance to trastuzumab.

In cancers that are both HER2-positive and express estrogen and/or progesterone receptors, resistance to HER2-directed therapy has been postulated to occur due to cross-talk between the HER2 signaling pathway and hormone receptors. Preclinical studies demonstrate that the estrogen receptor can interact with the HER2 signaling pathway through both genomic and nongenomic mechanisms (73,74). Consistent with these observations, tamoxifen or estrogen deprivation improves the effectiveness of HER2-targeted therapy in xenograft models (75). This interaction between the HER2 and estrogen receptor signaling pathways could be playing a role in the lower rates of pCR consistently observed in hormone receptor positive compared to hormone receptor negative HER2-positive cancers treated with preoperative HER2-directed therapy in the absence of endocrine treatment (e.g., reference 45,55). A recent neoadjuvant study of 12 weeks of trastuzumab and lapatinib, combined with hormonal therapy in hormone receptor positive, HER2-positive breast cancers demonstrated that this combination is feasible and was associated with a substantial rate of pCR (21%) (76). Randomized trials are needed to definitely evaluate whether there is a role for antiestrogens in overcoming resistance to HER2-directed therapy.

In preclinical models, trastuzumab is able to activate ADCC, and it has been suggested that this immune effect plays a significant role in mediating trastuzumab's clinical benefit. Because activation of ADCC requires binding of trastuzumab's Fc component to Fcγ receptors (FcγR) on the surface of immune effector cells, it has been hypothesized that polymorphisms in the FcγR gene that affect antibody binding affinity would influence the benefit of trastuzumab. Supporting this hypothesis, studies have demonstrated associations between higher affinity FcγR genotypes and better outcome in patients with lymphoma who received the CD20 specific monoclonal antibody rituximab and in patients with colorectal cancer treated with the EGFR targeted antibody cetuximab (77,78). In addition, a small retrospective study of 54 patients with metastatic HER2-positive breast cancer treated with trastuzumab found a significant association between FcγR genotype and improved patient outcomes (79). However, when FcγR polymorphisms were evaluated in approximately 1,200 patients from the BCIRG006 study, there was no correlation between FcγR genotype and DFS (80).

Thus, despite a number of potential mechanisms of resistance to trastuzumab identified in preclinical studies, none have been conclusively validated in the adjuvant or neoadjuvant setting. As we move forward, it may be more productive to use more comprehensive analytic approaches, rather than testing serial candidates. The ability to assess tumors comprehensively at the genomic level, using next generation sequencing platforms to perform whole genome or whole exome sequencing and/or RNA sequencing analyses may be illuminating. These approaches are currently being applied to the tissue samples from recent large preoperative studies.

Even in the absence of well-validated mechanisms of resistance to HER2-directed agents, one approach that has been successful in overcoming therapeutic resistance has been the strategy of combining two HER2-directed agents. As discussed previously, combining trastuzumab with lapatinib or with pertuzumab improves progression free and overall survival in the metastatic setting and pathologic complete response rates in neoadjuvant trials compared to the use of a single HER2-directed agent (16,45,68,81). The benefits of this dual-blockade approach may be attributable to the ability of these combinations to inhibit more comprehensively signaling from HER2 homodimers and heterodimers of HER2 with other HER family receptors.

MANAGEMENT OF SPECIAL POPULATIONS

Adjuvant Therapy in Patients with Small (<2 cm) Node Negative HER2-Positive Cancers

Although HER2 positivity is associated with more advanced stage disease at diagnosis, a sizable proportion of patients present with stage I disease (T1N0). The optimal management strategy for patients with this subset of cancers is not clear, particularly for patients with node negative cancers that are one centimeter and smaller. All of the large studies evaluating trastuzumab in the adjuvant setting were restricted to patients with high-risk cancers, typically defined as node positive or node negative with higher risk features. Small, node negative cancers were generally not included in these studies, and as a result, we lack data from randomized trials on the outcomes of patients with small HER2-positive cancers treated with trastuzumab-based regimens. The chemotherapy backbone of most of the adjuvant studies was designed for patients at high risk of recurrence and typically included regimens with multiple agents and prolonged duration of therapy (e.g., ACTH, TCH). These regimens are clearly effective, but are also associated with a significant side effect burden. They may well represent excessive treatment for patients with a low burden of disease, yet until recently, there were not data available for less intensive chemotherapy regimens.

A critical question relates to the natural history of small HER2-positive cancers in the absence of treatment, or with hormonal therapy alone (for those with hormone receptor positive disease). If the recurrence risk is low enough—for example as low as most HER2 negative T1a,bNO cancers—then perhaps chemotherapy, with or without HER2-targeted therapy, may not be needed for many of these cancers.

Several recent retrospective studies have provided data to address this question. The MD Anderson group analyzed 965 patients with T1a,bN0 cancers who did not receive adjuvant chemotherapy or trastuzumab. With 74 months' median follow-up, there were significantly more recurrences in patients with HER2-positive cancers than those with HER2-negative cancers (5-year RFS 77.1% vs. 93.7%; $p < .001$) and HER2 status was a significant independent risk for distant recurrence in a multivariable analysis (HR = 5.3, 2.23–12.62, $p < .001$) (8). An Italian study evaluated 150 patients with HER2-positive T1a,bN0 cancers as well as matched patients with HER2-negative cancers. In this study, a subset of the patients received adjuvant chemotherapy, but no patient received trastuzumab. Overall, the 5-year DFS rates (92% for HER2-positive vs. 99% for HER2-negative) were higher than those seen in the MDACC study, but in multivariable analysis there was a trend for worse outcomes in the HER2-positive group (HR = 2.4, 0.9 to 6.5; $p = .09$) (9). An analysis of a tissue microarray dataset from British Columbia included 117 patients with T1N0 HER2-positive cancers, only a small minority of whom received systemic adjuvant chemotherapy. In these patients, with a median follow-up of 12.4 years, the 10-year RFS was 71.6%, and breast cancer–specific survival (BCSS) was 81.3% (82). Looking specifically at patients with T1b (0.6–1.0 cm) HER2-positive cancers who did not receive systemic adjuvant therapy, the 10-year RFS was 68.4%, but this was in a very small population (82). In a Finnish study of patients with HER2-positive T1N0 cancers; the 9-year RFS was approximately 72% (83).

These data show a relatively broad range of outcomes for patients with small node negative HER2-positive cancers, and the studies are limited by small sample sizes and heterogeneous treatment. However, it does seem clear

that there is at least a modest risk of recurrence associated with these cancers (at least those that are greater than 0.5 cm), and therefore some type of adjuvant therapy is appropriate for most patients. Currently, there is no universally accepted standard for the adjuvant treatment of these patients. Although node negative cancers <1 cm were not included in the randomized adjuvant trials, data from the trials suggests that the benefits of trastuzumab are independent of tumor size or nodal status (20,22). For example, in HERA, approximately 15% of the trial population had T1c (between 1.1 and 2.0 cm), node negative cancers. In this subset, the benefit of trastuzumab (HR = 0.53, 0.26–1.07) was similar to that of the entire population (HR = 0.64, 0.54–0.76) (84). Given these observations, and the highly favorable toxicity profile of trastuzumab, it would seem logical to incorporate trastuzumab into the treatment regimen for this population. However, it also seems reasonable to try to reduce the chemotherapy component of the regimen in view of the lower overall recurrence risk of these patients.

It has been postulated that one approach to providing an effective regimen for this population while minimizing the toxicity of therapy would be to utilize HER2-targeted therapy without chemotherapy (85). It is clear from data in the preoperative setting that treatment with dual-blockade targeted therapy regimens such as trastuzumab/pertuzumab (55) and trastuzumab/lapatinib (76) without chemotherapy are extremely active (as evidenced by pCRs in neoadjuvant studies) in a subset of HER2-positive cancers. The main limitation of this approach is that currently there are no established biomarkers to identify which HER2-positive cancers are likely to be sensitive to this approach.

Another approach has been taken by investigators from the Dana-Farber Cancer Institute. They hypothesized that utilizing a relatively well-tolerated single agent chemotherapy regimen in combination with trastuzumab would exploit the synergy observed when trastuzumab is given concurrently with chemotherapy, while avoiding the toxicity associated with combination chemotherapy regimens. To test this hypothesis, they initiated a single-arm phase II study, the APT trial, in which a planned 400 patients with node negative HER2-positive cancers less than 3 cm in size received 12 weekly infusions of paclitaxel (80 mg/m^2) and 1 year of trastuzumab with the trastuzumab starting concurrent with paclitaxel. Because a randomized study in this population is difficult due to the expected low event rate, a single-arm design was utilized with the goal of demonstrating a very low recurrence rate in patients who received this regimen. The design has a high probability (95%) of declaring the regimen worthy of further study if the true 3-year failure rate is 5% or less.

The initial results of the APT study were presented at the 2013 San Antonio Breast Cancer Symposium (86). A total of 406 patients were enrolled; 9% of patients had T2 cancers, 42% had T1c cancers, 31% had T1b cancers, and 19% had T1a cancers. With a median follow-up of 3.6 years, there were 10 disease free survival events, of which only 2 were distant recurrences. The overall 3-year DFS was 98.7% (95% CI: 97.6% to 99.8%) (86). The favorable outcome was seen regardless of tumor size (95% CI: 96.0% to >99.9% for tumors >1cm and 98.4% to >99.9% for tumors ≤ 1cm) or hormone receptor (HR) status (95% CI: 97.0% to >99.9% for HR-positive cancers and 97.7% to >99.9% for HR-negative cancers). The paclitaxel/trastuzumab regimen was generally well tolerated with 2 cases (0.5%) of symptomatic CHF and 13 patients (3.2%) with an asymptomatic LVEF decline that led to an interruption of trastuzumab. 11 of these patients were able to resume trastuzumab without further complications. 14 patients (3.4%) had grade 3 neuropathy.

Outside of a trial, treatment of patients with T1 lesions with negative lymph nodes needs to be individualized. Consideration of a trastuzumab-based regimen is reasonable for most patients with T1b and T1c cancers. In general, it is prudent to avoid an anthracycline-based regimen in these "low risk" patients, and some clinicians use TCH in this setting. Unfortunately, TCH is associated with substantial short-term toxicity. Given the recent data from the APT study, which demonstrated an extremely low rate of distant recurrence and a favorable tolerability profile (86), the paclitaxel/trastuzumab regimen can be considered an appropriate standard of care for such patients. For T1a tumors, particularly those that are hormone receptor positive, the prognosis is quite favorable in the absence of systemic chemotherapy and it is appropriate to consider using hormonal therapy alone for patients with HR expressing cancers and no therapy for very small HR-negative cancers.

Adjuvant Therapy of HER2-Positive Cancers in the Elderly

While the incidence of HER2-Positive breast cancer in older populations is not well studied, an Italian study of 1,085 women with early-stage breast cancer found that 16% of the cancers were HER2-positive (3+ by IHC), suggesting that the percentage of HER2-positive cancers in this age group is similar to that of the general population (87). The optimal treatment for this group is not well established. A study of patients with stage I–III, HER2-positive disease aged ≥60 treated at academic centers within the National Comprehensive Cancer Network (NCCN) found that the rates of initiation of trastuzumab-based adjuvant chemotherapy were 79% for women in the 60–69 age group and 54% for women ≥70 (88). These data suggest that in practice, there appears to be reduced utilization of trastuzumab in this population. It is worth exploring the basis for this reduced utilization. One factor may be concerns over a lack of data on trastuzumab's effectiveness in this population. It is clear that the elderly were underrepresented in the randomized adjuvant trials of trastuzumab. Only approximately 16% of patients participating in HERA and NSABP B31/N9831 were aged ≥60. PACS 04 and FinHer excluded patients >65 years, and BCIRG 006 only characterized patients as younger or older than 50 years. However, despite the underrepresentation, there is fairly clear evidence that trastuzumab is effective in older patients. In the B31/N9831 combined analysis, the addition of trastuzumab was associated with a significant improvement in DFS in patients aged ≥60 (HR = 0.41, 0.24–0.68). In a recent pooled analysis of the available data from the randomized trials of patients aged ≥60, a significant reduction in DFS events was observed with the addition of trastuzumab (HR = 0.53, 0.36–0.77) (89). These data suggest that trastuzumab has similar benefits in older patients as it does in the general population. A second concern with the use of trastuzumab is possible toxicity, specifically cardiac effects. As detailed previously (see the Cardiac Toxicity of Trastuzumab section), multivariable analysis of data from the B31/N9831 dataset identified age >50 years as an independent predictor of cardiac events (32). The absolute incidence of serious cardiac events in patients aged ≥60 who received trastuzumab was 5.3% in NSABP B-31 and 6.6% in N9831 (89). A third concern is increased prevalence of comorbidities in older women that influence their competing risks of mortality, which has to be considered on a case-by-case basis.

Given the available data, it is appears that women over the age of 60 derive as much benefit from trastuzumab as younger patients, but are subject to modestly higher risks (in absolute

terms) of cardiac toxicity from this agent. These factors need to be considered, along with the patient's comorbidities, when planning adjuvant therapy for the older patient with HER2-positive disease. Availability of lower toxicity regimens with single agent chemotherapy or targeted therapy alone, as discussed above for patients with small HER2-positive cancers, would be appealing for older patients as well.

MANAGEMENT SUMMARY

- Patients with moderate to high risk HER2-positive breast cancer (node positive, or node negative with high-risk features) should generally receive chemotherapy and 1 year of trastuzumab.
  - Appropriate chemotherapy regimens include an anthracycline/taxane/trastuzumab regimen or TCH.
  - Current data support initiating trastuzumab concurrently with taxane chemotherapy.
- There is no standard of care for patients with small (<2 cm) node negative cancers, as these patients were not well represented in the randomized trials. Treatment needs to be individualized for these lower-risk patients.
  - The combination of weekly paclitaxel and trastuzumab is associated with an extremely low recurrence rate in a large single arm study. This regimen represents a reasonable standard for many, if not most, patients with T1b/T1c cancers.
  - T1a cancers, particularly those that are hormone receptor positive, have a favorable prognosis in the absence of chemotherapy and it is appropriate to consider using hormonal therapy alone for such patients with hormone receptor expressing cancers and no therapy for very small hormone receptor negative cancers. If a chemotherapy and trastuzumab regimen is administered, the weekly paclitaxel and trastuzumab approach is optimal.
- Randomized long-term data on the optimal neoadjuvant regimen are limited. A pertuzumab/trastuzumab/chemotherapy regimen is associated with a high pCR rate and is recommended for the neoadjuvant treatment of patients with higher risk disease. For the neoadjuvant treatment of lower risk patients, and in situations in which pertuzumab is not available, it is reasonable to use one of the standard regimens used in the adjuvant setting (e.g., anthracycline/taxane/trastuzumab or TCH).
  - In general, unless a patient demonstrates progressive disease or unacceptable toxicity during neoadjuvant therapy, one should complete the full planned course of therapy prior to surgery.
- Trastuzumab and pertuzumab, in combination with one of several chemotherapy regimens, is an effective approach in patients with locally advanced HER2-positive breast cancer.
- Patients receiving trastuzumab based therapy should have LVEF evaluated prior to initiating trastuzumab and then at regular intervals during trastuzumab therapy.

CHAPTER 47

Adjuvant Systemic Therapy: Bone-Targeted Treatments

Robert E. Coleman

CHAPTER CONTENTS

Bone is the most common site for distant recurrence in breast cancer and is the first location for recurrence in about one-third of patients who relapse. The incidence of bone metastases in metastatic breast cancer is 60% to 80% (1). The development of skeletal metastases involves complex interactions between cancer cells, osteoblasts, and osteoclasts and both hematopoietic and endothelial stem cells within the bone microenvironment. The presence of tumor in bone ultimately results in activation of osteoclasts, leading to an increased rate of bone resorption. Additionally, bone marrow derived stem cells are of fundamental importance in the development of metastases at other sites, preparing the environment for tumor cells to establish a metastasis (2). Drug that are able to target bone, notably the bisphosphonates but also inhibitors of receptor activator of nuclear factor kappa-B ligand (RANKL), a key regulator of bone cell function, provide an additional strategy to prevent metastasis within bone and, potentially, at extraskeletal sites.

Bisphosphonates are potent inhibitors of osteoclastic bone resorption, with proven efficacy in reducing tumor-associated skeletal complications in advanced cancer (3). More recently, clinical studies have investigated the adjuvant use of these drugs in breast cancer, with evaluation of their impact on bone density, metastases, and survival. Additionally, numerous preclinical experiments have shown that the development of bone metastases can be inhibited by either the bisphosphonates or RANKL inhibition, through both bone-mediated and possible direct antitumor mechanisms (4). Synergy between potent aminobisphosphonates such as zoledronic acid with chemotherapy has been demonstrated in mouse models, although the clinical relevance of these observations remains uncertain (5).

The data available to date suggest an increasing role for adjuvant bisphosphonates in the treatment of early-stage breast cancer although, as is discussed below, benefits appear to be confined to the postmenopausal setting (6). A strong need exists for continued clinical and laboratory investigation of these drugs in the adjuvant breast cancer setting.

RATIONALE: THE BIOLOGY OF BONE METASTASES

Healthy bone is in a constant state of remodeling, a process that is essential to preserve the structural integrity of bone and to minimize the risk of fragility fractures. Bone-derived osteoblasts and osteoclasts work together through the influence of cytokines and other humoral fractors to couple formation and resorption. Osteoblasts, derived from fibroblast precursors, produce collagen matrix and contribute to bone formation. Osteoclasts are multinucleated giant cells derived from the macrophage-monocyte lineage, and are the major mediator of bone degradation or resorption. In normal health and bone remodeling, the relationship between osteoblastic bone formation and osteoclastic bone resorption are balanced. However, bone diseases including malignancy disturb this delicate balance and result in a loss of the normal structural integrity of the skeleton.

The process of breast cancer metastasis includes tumor cell seeding, tumor dormancy, and subsequent metastatic growth. The primary tumor releases cells that pass through the extracellular matrix, penetrate the basement membrane of angiolymphatic vessels, and then are transported to distant organs via the circulatory system. Circulating breast cancer cells have a particular affinity for bone. These circulating cells can adhere to the vessels and sinusoids of the bone marrow, invading into the marrow and intertrabecular spaces with the help of adhesion molecules. Tumor cells have been shown to exhibit chemotactic responses to areas of bone undergoing resorption (7). Disseminated tumor cells have been reported in the bone marrow of 30% to 40% of early-stage breast cancer patients at the time of diagnosis (8). Most disseminated tumor cells die, but the bone marrow microenvironment may act as a reservoir for malignant cells and the site for dormant tumor cells that only result in relapse many years after the diagnosis of early breast cancer. Tumor cells have the capacity to produce a wide range of cytokines and growth factors that may increase the production of RANKL and macrophage colony-stimulating factor (M-CSF) from osteoblasts leading to activation of osteoclasts and disturbance of the balance of new bone formation and bone resorption. These

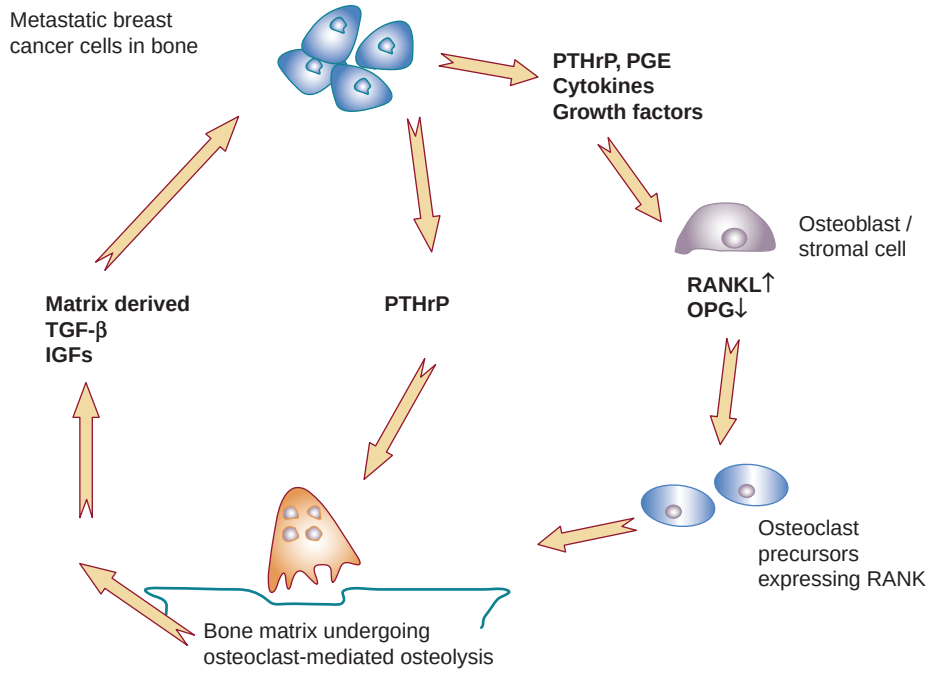

FIGURE 47-1 **This illustration highlights the interaction between breast cancer cells and the bone microenvironment.** A variety of cancer-derived growth factors, including parathyroid hormone-related protein (PTHrP), prostaglandins (PGE), and cytoikines, stimulate osteoclastic activity. Other osteoclast-stimulating cytokines, such as receptor activator of NF-κB ligand (RANKL) and macrophage colony-stimulating factor (M-CSF), are indirectly released through interactions between cancer cells and osteoblasts, macrophages, and other cells within the bone environment. Bone provides a favorable niche for the cancer cell because it is a repository for tumor-stimulating growth factors, such as transforming growth factor β (TGFβ) and insulin-like growth factor (IGF-1), which are released with bone resorption.

multiple interactions between metastatic tumor cells and the bone microenvironment may contribute to the development of metastases both within and outside bone.

Käkönen and Mundy (9) have described a "vicious cycle" that occurs when cancer cells are present adjacent to the bone matrix (Fig. 47-1). Products produced by the tumor induce breakdown of bone, causing release of factors into the local environment that may cause stimulation and further growth of malignant cells, which in turn leads to yet further bone resorption. At the microscopic level, osteoclasts are visible between cancer cells and the bone surface that is being destroyed (10). Osteoclasts are activated by cytokines produced directly or indirectly by the tumor cell, including parathyroid hormone related peptide (PTHrP), prostaglandins, and interleukins (11). As bone matrix is broken down, a rich supply of mitogenic factors is released, including insulin-like growth factor (IGF-1), platelet-derived growth factor (PDGF), and transforming growth factor β (TGFβ). These factors can lead to increased growth and proliferation of the breast cancer metastases (6,11). The overall effect is the creation of a self-sustaining vicious cycle with multidirectional interactions between cancer cells, osteoclasts, osteoblasts, and the bone microenvironment.

BISPHOSPHONATES: AGENTS AND MECHANISM OF ACTION

Bisphosphonates are effective in treating conditions in which there is excessive bone resorption and osteoclast activity, including Paget's disease of bone, osteoporosis, fibrous dysplasia, and hypercalcemia of malignancy. Bisphosphonates have a proven role in reducing skeletal complications in breast cancer patients with bone involvement, and a potential emerging role in the prevention of breast cancer metastases.

Bisphosphonates are analogs of endogenous pyrophosphate, in which a carbon atom replaces the central oxygen atom (Fig. 47-2). As with pyrophosphate, bisphosphonates bind strongly to hydroxyapatite on the bone surface. Unlike pyrophosphate however, which is rapidly split

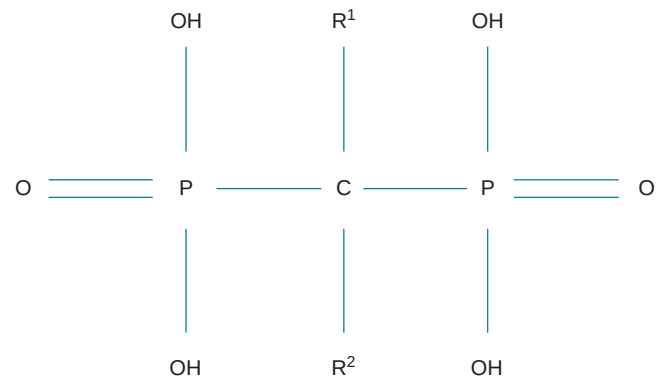

FIGURE 47-2 **The basic chemical structure of bisphosphonates includes a central carbon and two variable side chains (R).** Variations in the side chains alter the potency and side effects of the drugs.

by the hydrolytic enzymes of osteoclasts, bisphosphonates are stable owing to the central carbon substitution that makes them resistant to hydrolysis. This substitution also allows two additional side chains of variable structure that affect the pharmacologic properties of these agents. One of the side chains usually contains a hydroxyl moiety, which allows high affinity for calcium and bone mineral. The structural variation in the other side chain produces differences in the antiresorptive properties and toxicities (12).

Within the family of bisphosphonates, there are more similarities in pharmacologic effects than differences, although side effect profiles, rates of oral absorption, and potency do differ. Although differences in their molecular mechanism of action exist, all therapeutic bisphosphonates have a final inhibitory effect on osteoclast function. Bisphosphonates have a powerful affinity for bone; 40% to 70% of an intravenous administration binds rapidly to the bone surface, preferentially at sites of increased bone formation or resorption with the remainder excreted in the urine. The half-life of bisphosphonates in circulation is less than an hour (13). However, the half-life in bone is very long with biological effects of the most potent agents such as zoledronic acid still evident years after administration of a single dose (14). Once deposited on the bone surface, bisphosphonates are ingested by osteoclasts engaged in bone resorption. These agents interfere with bone resorption by producing a direct toxic apoptotic effect on osteoclasts, and by inhibiting their differentiation and maturation.

Bisphosphonates fall into two classes, based on whether this second side chain is nitrogen-containing or not. First-generation bisphosphonates, such as clodronate and etidronate, do not contain nitrogen. These agents substitute into the production of adenosine triphosphate, which then becomes a toxic adenosine triphosphate analogue that poisons the osteoclast (12). Nitrogen-containing bisphosphonates, such as pamidronate, alendronate, risedronate, ibandronate, and zoledronic acid, interfere with cell signaling and block the prenylation of small signaling proteins that are essential for osteoclast function and survival (12).

Several bisphosphonates are available worldwide for various conditions, with variable antiresorptive potency and route of administration (Table 47-1). The clinical impact of the differences in relative potency between bisphosphonates is not well documented, because only a few direct clinical trial comparisons have been conducted. Although all bisphosphonates can theoretically be administered either orally or intravenously, the oral bioavailability of any bisphosphonate is extremely limited and so for some only intravenous formulations have been developed. The dose and frequency of administration varies depending on the clinical indication, with doses used to treat bone metastases being about 10-fold higher than those used to treat osteoporosis. For example, the zoledronic acid dose approved for treating bone metastases is 4 mg intravenously every 3 to 4 weeks. When used in the treatment of osteoporosis, it is approved as a 5-mg dose once yearly. Ibandronate, available in both oral and intravenous forms, is given 50 mg orally daily or 6 mg intravenously monthly for bone metastases, compared with 150 mg orally monthly or 3 mg intravenously every 3 months for osteoporosis. In the United States, ibandronate is approved only for the osteoporosis indication. Doses of bisphosphonates under investigation in the adjuvant breast cancer setting for prevention of metastases have ranged from full bone metastasis treatment doses to somewhat lower doses or less frequent administrations more similar to the osteoporosis treatment schedules.

TABLE 47-1

Bisphosphonates: Antiresorptive Potency and Route of Administration

Bisphosphonate	*Relative Antiresorptive Potency*	*Route of Administration*
Etidronate	1	Oral, IV
Clodronate	10	Oral
Tiludronate	10	Oral
Pamidronate	100	IV
Alendronate	1,000	Oral
Risedronate	5,000	Oral
Ibandronate	10,000	Oral, IV
Zoledronic acid	100,000	IV

IV, intravenously.

BISPHOSPHONATES AS ADJUVANT THERAPY IN EARLY-STAGE BREAST CANCER

Preclinical data have provided biologic plausibility for a role of bisphosphonates in inhibiting the development of bone metastases. *In vitro* studies have demonstrated that bisphosphonates can inhibit critical steps in development of metastases in the bone, including adhesion and invasion (15). Animal tumor model systems have shown that bisphosphonates can inhibit development of bone metastases, reduce tumor burden in the bones, and improve survival in nude mice injected with human breast cancer cells (5,16,17). Although most animal models suggest that the primary antitumor effect of bisphosphonates is manifested in the bone, some data indicate also an effect of bisphosphonates on extraskeletal metastases. The potential mechanisms involved are summarized in Figure 47-3A. Laboratory experiments have shown also that bisphosphonates can have an impact on cancer cells through antiangiogenic, anti-invasive, and immunomodulatory mechanisms (18–20). Additionally, nitrogen-containing bisphosphonates can directly induce tumor cell apoptosis, inhibit tumor cell proliferation, and synergistically with cytotoxic chemotherapy agents commonly used in breast cancer treatment (5,16,21). The high doses of bisphosphonates that have been used in many laboratory studies suggesting direct anticancer activities are incompatible with the clinical doses and schedules approved for the treatment of cancer patients. Whether a direct antitumor effect of bisphosphonates plays a clinically significant role in the treatment or prevention of cancer in humans remains unproved.

Although bone-targeted treatments have had a profound effect on skeletal morbidity and quality of life in advanced breast cancer, clear improvements in survival of advanced cancer patients have not been seen. The studies may have been underpowered to detect survival advantages or, more likely, reflect the futility of modifying the bone microenvironment to influence the large burden of disease present with overt metastases. However, in the adjuvant setting, where the disease burden is microscopic and potentially more receptive to cellular changes in the bone marrow, the anticancer effects of bone-targeted treatments seen in the preclinical models are more likely to be mirrored in patients.

Phase II exploratory studies in women with early-stage, high-risk breast cancer have reported that monthly

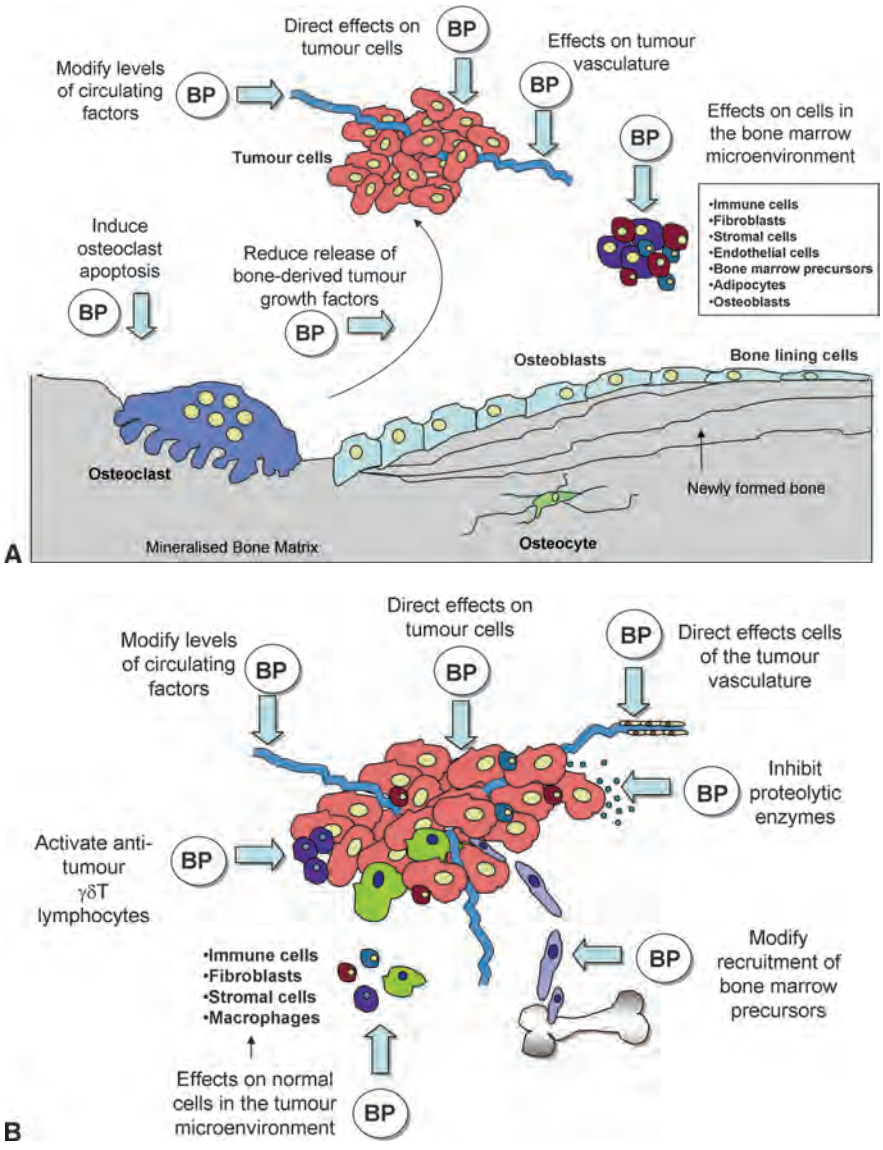

FIGURE 47-3 Potential antitumor effects of bisphosphonates within **(A)** and outside **(B)** bone. BP, bisphosphonates.

zoledronic acid, in combination with standard anticancer therapy, was able to increase the clearance of disseminated tumor cells (DTC) and reduce the number and persistence of DTC in bone marrow compared with standard therapy alone (22–24). The zoledronic acid-mediated reduction in DTC persistence might be one of the mechanisms underlying the observed clinical benefits in the studies described below. However, further studies are needed to determine whether the disease-modifying benefits seen in some patient subsets correlate with decreases in DTC levels.

The early adjuvant clinical trials evaluated oral bisphosphonates with three using daily oral clodronate (25–27) and a fourth daily oral pamidronate (28). Clodronate is approved for the treatment of metastatic bone disease in many parts of the world (except the United States) while the development of oral pamidronate was abandoned due to poor absorption and gastrointestinal toxicity at the high doses required for effects on bone metabolism.

The adjuvant trials evaluating oral clodronate provided promising but conflicting results (25–27). In the first study, 302 women with breast cancer and DTC detected using immunocytochemistry in a bone marrow aspirate (but no overt metastases) taken at the time of diagnosis were randomized to receive either clodronate (1,600 mg/day) or no bisphosphonate for 2 years. Additionally, patients received standard adjuvant systemic therapy (25). Patients who received clodronate had a lower incidence of bone metastases ($p = .003$), and a significantly longer bone metastasis-free survival ($p < .001$). A final analysis at 8.5 years of follow-up continued to show a significant improvement in overall survival for patients given clodronate, although the significance in disease-free survival (DFS) no longer persisted (29).

A larger, randomized, placebo-controlled, multinational trial was conducted in which 1,079 patients with early-stage breast cancer were randomized to receive either clodronate (1,600 mg/day) or placebo for 2 years in addition to standard systemic therapy (26). Patients were assessed for bone metastases at 2 and 5 years, and as clinically indicated. The final analysis showed that oral clodronate significantly reduced the risk of bone metastases at 2 years (hazard ratio [HR] 0.546; $p = .03$) and 5 years (HR 0.692; $p = .04$). A significant reduction was also seen in mortality (HR 0.768, $p = .048$). Follow-up showed a continued separation of the survival curves between years 5 and 10 (26). This reduction

was largely restricted to patients who were postmenopausal at diagnosis of breast cancer.

The third study of oral clodronate was a randomized, open-label study investigating 3 years of adjuvant clodronate therapy (1,600 mg/day) in 299 patients with lymph node–positive breast cancer (27). This study showed no reduction in bone metastases in the clodronate treated arm, and, at least at the time of the initial report, a worrisome increase in visceral metastases and a reduction in overall survival at 5 years for patients receiving clodronate. At the final analysis after 10 years, survival was similar in both groups (30). This small study also had some imbalances in important prognostic factors that may explain the apparent adverse effects with clodronate. Nevertheless, this study had a disproportionate effect on the perception of adjuvant clodronate as an adjuvant treatment and regulatory approval based on the other two positive studies was not achieved. The Danish study with oral pamidronate also failed to show any significant effect on disease outcomes, perhaps due to the poor absorption and patient adherence to treatment (28).

It was not until the first published results of the Austrian Breast and Colorectal Cancer Study Group (ABCSG) 12 trial in 2009 (31) that the potential role of adjuvant bisphosphonates was really appreciated by the breast cancer community and the old "seed and soil" theory of metastasis described in the 19th century by Sir Stephen Paget (32) regained influence in the search for further improvements in the outcome of patients with early breast cancer. The ABCSG 12 trial enrolled 1,803 premenopausal women with estrogen-receptor-(ER-) positive breast cancer. All patients received ovarian suppression for 3 years with goserelin. Patients were randomized in a 2 × 2 design to receive tamoxifen versus anastrozole, and zoledronic acid (4 mg every 6 months) or not.

At the first efficacy analysis, reported after 137 events (70 distant relapses) with approximately 60 months of follow-up, no difference was seen in outcome with respect to the endocrine therapy randomization. There was, however, a statistically significant improvement in DFS for the patients who received zoledronic acid (HR 0.64; $p = .01$). Patients who received zoledronic acid had fewer recurrences at all sites including visceral metastases. Additionally, locoregional recurrence was also less frequent with zoledronic acid. These results were maintained at a later analysis after a median follow-up of 62 months (33). Moreover, after further follow-up (median = 84 months) a persistent benefit in DFS more than 3 years after completion of treatment (HR = 0.71, $p = .011$) suggested a sustained "carryover" benefit from adding zoledronic acid to endocrine therapy (34). In addition at this most recent analysis, there were sufficient deaths in this generally good prognosis population of patients to show that treatment with zoledronic acid also significantly improved overall survival (OS) compared with the control group (HR = 0.61, $p = .033$). Interestingly, and of relevance when the results of the other adjuvant studies are discussed later, this most recent analysis of ABCSG-12 showed that the benefits of zoledronic acid appeared to be confined to women over the age of 40 at diagnosis in whom ovarian suppression with goserelin can be expected to reliably fully suppress estrogen and other reproductive hormone production. In women aged 40 years or younger ($n = 413$), no statistically significant difference in DFS was observed between the zoledronic acid-treated and control groups (HR = 0.87, $p = .53$). However, among women aged 40 years or more at study entry ($n = 1,390$), zoledronic acid resulted in a 34% reduction in the risk of DFS events compared with the control group of patients (HR = 0.66, $p = .013$). Zoledronic acid was also associated with a statistically significant improvement in OS in this older subset of patients (HR = 0.57, $p = .042$) (34).

The ZOledronic acid and FemarA Synergy Trials (European ZO-FAST, North American Z-FAST, and worldwide EZO-FAST) were designed to investigate the effects of zoledronic acid on bone mineral density (BMD) during adjuvant therapy with aromatase inhibitors (35–37). Postmenopausal women with ER+ early breast cancer were treated with letrozole and either immediate zoledronic acid 4 mg every 6 months, or delayed zoledronic acid mandated following a low-trauma fracture or significant decline in BMD. The effects of zoledronic acid on DFS and OS were secondary end points. In ZO-FAST ($n = 1,065$), the immediate zoledronic acid group had a statistically significant 34% reduction in the risk of DFS events versus the delayed zoledronic acid group (HR = 0.66, $p = .038$), with a reduction in breast cancer recurrence both within and outside bone (35). Disease modifying effects in Z-FAST and EZO-FAST were less clear. These studies are smaller and the number of DFS events few. However, in Z-FAST a nonsignificant improvement in DFS was seen (36), while in EZO-FAST, early information on recurrence, showed a nonsignificant disadvantage from treatment with zoledronic acid (37). Taken together the three studies would suggest an approximate 25% improvement in DFS with use of immediate 6 monthly zoledronic acid alongside an aromatase inhibitor for ER+ postmenopausal breast cancer.

The trial titled Does Adjuvant Zoledronic Acid Reduce Recurrence in Stage II/III Breast Cancer? (AZURE) is the largest adjuvant trial of zoledronic acid, and included a broad population of patients with stage II or III breast cancer, unrestricted by menopausal status or ER status. Patients received standard chemotherapy and endocrine therapy and were randomly assigned to receive an intensive regimen of zoledronic acid or a control group. Patients allocated to the zoledronic acid arm received 4 mg intravenously every 3 to 4 weeks for 6 doses to exploit any possible synergy with chemotherapy, and then every 3 to 6 months until 5 years or first evidence of distant metastases (38).

In the overall population, zoledronic acid did not significantly increase DFS compared with standard therapy alone (HR = 0.98, $p = .79$). However, preplanned subgroup analyses identified that menopausal status of the patients at study entry was an important modifier of zoledronic acid treatment effects. For pre- or perimenopausal patients, there was no appreciable difference in DFS (HR = 1.15, $p = .11$) or OS (HR = 0.97, $p = .81$) with zoledronic acid treatment versus standard therapy alone. However, in patients who were postmenopausal for at least 5 years before study entry, zoledronic acid significantly reduced the risk of DFS events by 25% (HR = 0.75, $p = .02$) and the risk of death by 26% (HR = 0.74, $p = .04$). Interestingly, although the effects of ZOL on distant skeletal recurrence did not differ significantly by menopausal groups (heterogeneity test $\chi^2_1 = 0.14$, $p = .70$), for the other components of invasive DFS there was a statistically significant large difference in treatment effect according to menopausal status, with benefit in postmenopausal women and harm in all other women (heterogeneity test $\chi^2_1 = 14.00$, $p \leq .001$). Treatment effects in AZURE were not influenced by ER status.

Recently, the National Surgical Adjuvant Breast and Bowel Project (NSABP) study B-34 has reported results of a placebo-controlled trial of oral clodronate 1,600 mg daily (39). In the total study population after a median follow-up of 8.4 years, oral clodronate had no significant effect on DFS or OS. However, similar to the findings in AZURE, a significant reduction in distant metastasis was seen in patients over age 50 (a surrogate for postmenopausal status) treated with clodronate (HR = 0.62; $p = .003$). Again the benefit was greatest in preventing recurrence at extraskeletal sites.

TABLE 47-2

Summary of Populations, Treatment Schedules, and Primary Outcomes in Key Trials Evaluating the Adjuvant Use of Clodronate or Ibandronate in Early-Stage (Stages I–III) Breast Cancer

	Trial (reference)		
Characteristic	*CLODROPLAC (26)*	*NSABP B-34 (39)*	*GAIN (40)*
Population	1,069 women pre- and postmenopausal women with stage I–III early breast cancer receiving standard chemotherapy and/or hormonal therapy.	3,323 women pre- and postmenopausal women with stage I–III early breast cancer receiving standard chemotherapy and/or hormonal therapy.	3,023 women pre- and postmenopausal women with stage II–III early breast cancer receiving one of two intensive chemotherapy regimens.
Treatment	Patients were randomly assigned to receive standard adjuvant treatment with or without oral clodronate (160 mg daily) for 2 years.	Patients were randomly assigned to receive standard adjuvant treatment with oral clodronate (1,600 mg daily) or placebo for 3 years.	Patients were randomly assigned to receive adjuvant chemotherapy with or without oral ibandronate (50 mg daily) for 2 years.
Primary outcomes	Clodronate group had a reduced risk of bone metastases (HR = 0.692, p = .043) and improved OS (HR = 0.768, p = .048).	DFS did not differ between ITT groups: HR 0.91, 95% CI 0.78-1.07; p = .27. In women aged 50 years or older on study entry clodronate improved RFI (0.75, 0.57–0.99; p = .045), BMFI (0.62, 0.40–0.95; p = .027), and NBMFI (0.63, 0.43–0.91; p = .014), but not OS (0.80, 0.61–1.04, p = .094).	No differences in DFS or OS in ITT population. In patients who were aged 60 or older a trend for improved disease outcomes was observed.

CLODROPLAC, Royal Marsden trial of oral clodronate versus placebo in stage I–III early breast cancer; NSABP B-34, National Surgical Adjuvant Breast and Bowel Project—Breast protocol 34; GAIN, German adjuvant ibandronate study: All p values quoted are two-sided; HR, hazard ratio; CI, confidence intervals; DFS, disease-free survival; OS, overall survival; RFI, relapse-free interval; BMFI, bone metastasis-free interval; NBMFI, nonbone metastases-free interval; ITT, intention to treat.

Finally, the German adjuvant ibandronate study (GAIN) randomized 3,023 women with breast cancer and involved axillary lymph nodes to one of two chemotherapy regimens plus either oral ibandronate 150 mg daily or a control group. With a short median follow up of 31 months, no significant differences in DFS (HR = 0.94, p = .59) or OS (HR = 1.04, p = .80) between the ibandronate and placebo treated groups were seen (40). There was a trend in favor of ibandronate in postmenopausal women or those over the age of 60, but insufficient events have occurred for reliable subgroup analyses.

A summary of the major randomized trials of adjuvant bisphosphonates reported to date is provided in Tables 47-2 and 47-3. The results from NSABP B-34 (39) and the previous clodronate study by Powles et al. (26) suggest that the beneficial effects of bisphosphonates in solid tumors may be less dependent on the type of agent chosen and more on the hormonal status of the patient. The ongoing South West Oncology Group (SWOG) clinical trial SWOG-0307 (NCT00127205) comparing zoledronic acid, ibandronate, and clodronate has recently completed accrual and will address the relative efficacy of oral clodronate (1,600 mg daily) versus oral ibandronate (50 mg daily) versus zoledronic acid (4 mg intravenously monthly for 6 months, then every 3 months), all for 3 years in both pre- and postmenopausal women.

There are also ongoing adjuvant studies with denosumab, a monoclonal antibody with high specificity for RANKL that has been shown to be more effective than zoledronic acid in preventing skeletal morbidity from bone metastases in advanced breast cancer (41). ABCSG-18 (NCT00556374) is a placebo-controlled study of denosumab 60 mg 6 monthly in postmenopausal women receiving an aromatase inhibitor, while the D-CARE study (NCT01077154) is evaluating a more intensive schedule of denosumab 120 mg, administered initially monthly for 6 months and then every 3 months thereafter in both pre- and postmenopausal women with stage II or III breast cancer. Accrual to D-CARE completed in 2012, but results are not anticipated before 2016.

The interactions between reproductive hormones and the paracrine TGFβ growth factors may provide an explanation for the differences seen according to ovarian function in the response to bisphosphonates. At menopause, serum oestradiol and inhibin decline over several years and follicle-stimulating hormone (FSH) levels rise. In the absence of inhibin, the TGFß ligand activin becomes the dominant signaling molecule in bone. Inhibin binds to the activin type II receptor and activates the SMAD family of proteins that are known to have important effects on both bone and cancer cell functions. Both activin and TGFβ will support homing of disseminated tumor cells to bone by increasing the chemokine CXCL4, and stimulating osteoclastic bone resorption leading

TABLE 47-3

Summary of Populations, Treatment Schedules, and Primary Outcomes in Key Trials Evaluating the Adjuvant Use of Zoledronic Acid in Early-Stage (Stages I–III) Breast Cancer

	Trial (reference)		
Characteristic	*ABCSG-12 (31,33,34)*	*ZO-FAST (35)*	*AZURE (38)*
Population	1,803 premenopausal women with endocrine-receptor-positive early-stage breast cancer receiving goserelin to induce menopause (3.6 mg every 28 days).	1,065 postmenopausal women with early-stage breast cancer receiving letrozole (2.5 mg per day for 5 years).	3,360 pre- and postmenopausal women with early-stage breast cancer receiving standard chemotherapy and/or hormonal therapy.
Treatment	Patients were randomly assigned to receive anastrozole (1 mg per day) or tamoxifen (20 mg per day) with or without zoledronic acid (4 mg every 6 months) for 3 years.	Patients were randomly assigned to receive immediate zoledronic acid (4 mg every 6 months) or delayed zoledronic acid (initiated only for fracture or high risk thereof).	Patients were randomly assigned to receive zoledronic acid 4 mg every 4 weeks × 6, then every 3 months × 8, then every 6 months until 5 years or until first evidence of distant metastases.
Primary outcomes	Zoledronic acid group had a 29% relative risk reduction for DFS (HR DFS event = 0.71, 95% CI = 0.55–0.92; p = .011) (54). Benefit largely restricted to women aged 40 years or older at study entry.	Immediate zoledronic acid group had a 34% relative risk reduction for DFS (HR of DFS event = 0.66, 95% CI = 0.44–0.97; p = .038) (57)	No differences in DFS or OS in ITT population. In patients who were postmenopausal for at least 5 years before study entry, zoledronic acid group had a 25% relative risk reduction for invasive DFS (HR of DFS event = 0.75, 95% CI = 0.59–0.96; p = .02) and the risk of death by 26% (HR of death = 0.74, 95% CI = 0.55–0.98; p = .04).

All p values quoted are two-sided. ABCSG-12, Austrian Breast and Colorectal Study Group-12; ZO-FAST, Zoledronic acid and FemarA Synergy Trial; AZURE, Does Adjuvant Zoledronic Acid Reduce Recurrence in Stage II/III Breast Cancer?; HR, hazard ratio; CI, confidence intervals; DFS, disease-free survival; OS, overall survival; ITT, intention to treat.

to greater availability of bone derived growth factors. In premenopausal women, the cycling endocrine effect of estrogen, progesterone, and inhibin has the potential to inhibit activin and TGFß signaling. In a postmenopausal woman, the loss of inhibin, estrogen, and progesterone will reduce inhibition of the TGFß superfamily, and thus the relative biological activity of activin and TGFß will increase (42,43).

Quite how the variable effects of reproductive hormones on the bone microenvironment explain the differential effects on extraskeletal recurrence according to menopausal status remains unclear. However, elegant experiments have demonstrated the ability of breast cancer cells to reseed from bone to other distant sites and back to the breast (44), perhaps suggesting that the bone microenvironment is the key coordinator in the metastatic process, determining the fate of cancer cells not only within bone but also at other distant sites.

Whether doses used in metastatic disease are required for prevention or alternatively that lower doses will suffice is unknown. It is unclear whether adjuvant bisphosphonates should be given continuously and orally, whether intravenous therapy is preferable, and whether less intensive intravenous regimens will turn out to be as effective as more intensive regimens. The optimal duration of adjuvant bisphosphonate therapy is also unknown.

BONE HEALTH IN PATIENTS WITH BREAST CANCER

Most women with breast cancer are at risk for osteoporosis, owing to either their breast cancer therapy or their age (45). The use of bone-targeted agents in preventing bone loss is a subject of increasing clinical importance in breast cancer patients. Aromatase inhibitors, increasingly used in postmenopausal breast cancer patients, have a detrimental impact on bone mineral density and increase fracture rates (46,47). In the premenopausal setting, ovarian suppression and chemotherapy-induced ovarian failure can lead to rapid, profound loss of bone density (48). Accelerated bone loss brings with it an increased fracture risk, which affects quality of life, treatment costs, and potentially survival (46,48). The American Society of Clinical Oncology (ASCO) 2003 update on the role of bisphosphonates and bone health issues in women with breast cancer stated that oncology specialists need to take an expanded role in managing bone health in breast cancer patients (49).

Women with early-stage breast cancer should be evaluated for fracture risk. Counseling on nutrition and lifestyle for bone health is advised for all patients, and appropriate calcium and vitamin D supplementation is recommended. Vitamin D supplementation is particularly important as

only a minority of women with breast cancer have sufficient levels of vitamin D (50). Pharmacological therapy to prevent bone loss should be considered on an individualized basis based on bone mineral density and other fracture risk factors (including age, body mass index, personal and family history of fracture, smoking, alcohol consumption, and corticosteroid use). Evidence from randomized trials indicates that several intravenous and oral bisphosphonates can be effective in preventing bone loss and accelerated bone turnover in breast cancer patients receiving endocrine or chemotherapy (35–37,51–59). The comparative efficacy of these bisphosphonates has not been defined.

In premenopausal women, studies have shown that clodronate (53), risedronate (54), alendronate (55), and zoledronic acid (51) prevent and reduce bone loss caused by chemotherapy-induced menopause, ovarian suppression with LHRH analogues, and tamoxifen (which has a net negative effect on bone in the premenopausal setting in contrast to its positive effect in the postmenopausal setting).

The ABCSG-12 study prospectively examined the effects on bone density caused by ovarian suppression combined with tamoxifen or anastrozole, with or without zoledronic acid (4 mg every 6 months) in premenopausal women (51). In addition to the improvement in DFS described above (31,33,34), the addition of zoledronic acid inhibited loss of bone mineral density in both the tamoxifen and anastrozole arms and stabilized it at baseline levels. Without zoledronic acid, significant bone loss occurred; the mean reductions in bone mineral density at 3 years were 8% and 16%, with tamoxifen and anastrozole, respectively.

The Cancer and Leukemia Group B (CALGB) recently reported first results of C79809, a randomized trial of zoledronic acid (4 mg every 3 months) in premenopausal women who developed ovarian failure owing to adjuvant chemotherapy (58). The mean percentage change in lumbar spine bone mineral density at 12 months was +2.6% in the group receiving zoledronic acid, and –6.4% in the control group ($p<.0001$). Zoledronic acid added minimal toxicity and prevented the accelerated bone loss occurring in young women who developed ovarian failure from adjuvant chemotherapy.

In postmenopausal women receiving aromatase inhibitor therapy, studies have evaluated the impact of risedronate (57) and zoledronic acid on bone density (35–37). In the Z-FAST and ZO-FAST studies, comparing immediate versus delayed zoledronic acid (4 mg every 6 months), the powerful bone protective effects of twice yearly treatment on BMD were clearly demonstrated. In both of these studies, the differences in lumbar spine and total hip BMD at 5 years between patients receiving immediate or delayed treatment were approximately 9% and 6%. Less than 20% of patients on the delayed treatment arm met the protocol-specified criteria for starting zoledronic acid for T-score changes or fractures, however, and no significant differences in fracture rates were seen. Early reports of smaller randomized trials of risedronate and ibandronate in postmenopausal women receiving aromatase inhibitor therapy have also shown favorable impacts on bone mineral density (57,59).

A recent trial reported results for the RANK ligand inhibitor denosumab (60 mg subcutaneously every 6 months) versus placebo given to women receiving aromatase inhibitors in early-stage breast cancer (60). Rapid and significant gains in BMD at both the axial (spine and hip) and peripheral (wrist) sites were seen with denosumab, compared with slight bone loss in the placebo-treated patients.

As in the setting of postmenopausal bone loss and osteoporosis, bisphosphonates and denosumab are effective in preventing cancer treatment-associated loss of bone mineral density. Many issues need to be clarified to determine optimal management of bone loss in women with breast cancer. Whether early implementation of bisphosphonates will have an impact on long-term fracture rates remains a critical question. Is there harm incurred in delaying therapy until patients meet criteria for significant increased fracture risk? That very much depends on whether the benefits of bisphosphonates on disease recurrence are accepted. If they are, an argument can be made for all postmenopausal women to receive a bisphosphonate, irrespective of fracture risk. If not, treatment should be restricted to those at a relatively high absolute risk of fracture (46,48). To date we have no direct comparison of agents or delivery routes to guide in drug selection. It will also be important to determine which early-stage breast cancer patients are at most risk of clinically significant bone loss, and who will benefit most from early addition of bisphosphonates for preservation of bone mineral density.

SAFETY AND ADVERSE EFFECTS OF BISPHOSPHONATES

As a group, bisphosphonates are generally well tolerated at both osteoporosis and bone metastases treatment doses. Few serious adverse effects have been reported in clinical trials when given either orally or intravenously. Gastrointestinal toxicity in the form of dyspepsia is the most common side effect for oral agents. Esophageal inflammation and ulceration are described as rare but serious adverse effects (61). The efficacy of oral bisphosphonates is compromised by poor absorption. Generally, only a low percentage of an oral dose is absorbed from the gastrointestinal tract and intake of any food or beverage further diminishes absorption to negligible levels. Patients are therefore advised to take their oral medication in the morning on an empty stomach and wait 30 to 60 minutes before eating to maximize absorption.

Intravenous bisphosphonate administration can be associated with acute-phase reactions, which include flu-like symptoms, such as bone pain, transient arthralgia and myalgia, nausea, and fever. These reactions typically occur only after the first or second infusion, and symptoms usually resolve within 48 hours. The symptoms typically respond well to antipyretic and nonsteroidal anti-inflammatory drugs, and are not an indication to discontinue treatment. Hypocalcemia is another reported complication of bisphosphonate therapy. Clinically relevant hypocalcemia is rare, and generally may be prevented with the addition of supplemental calcium and vitamin D. FDA-approved labeling for pamidronate and zoledronic acid recommends periodic monitoring of serum calcium, electrolytes, phosphate, and magnesium. Hypocalcemia is also an important potential adverse effect of denosumab. However, denosumab has the advantage that acute phase responses are much less frequent and renal monitoring is not required.

Bisphosphonates have a potential for renal toxicity. The pharmacokinetics vary from agent to agent, and between oral and intravenous formulations, but all bisphosphonates are excreted via the kidneys. Clinical trials with pamidronate and zoledronic acid have shown renal toxicity, especially in patients with preexisting renal impairment (62). Increased dose, frequency, and speed of infusion are all related to the risk of renal toxicity; reducing the dose and slowing the infusion decrease toxicity. It is recommended that serum creatinine be monitored before each dose of these drugs. For patients with renal impairment or reduced creatinine clearance, it is recommended that the dose be reduced.

Osteonecrosis of the jaw (ONJ) has been reported to occur in cancer patients treated with intravenous bisphosphonates

(63,64). This entity is defined as an area of exposed, nonhealing bone in the maxillofacial region. The most common predisposing factors appear to be the type and total dose of bisphosphonate, a history of dental surgery (such as tooth extraction), and dental trauma (65). The true incidence of this problem is still not known, especially in the adjuvant setting. It appears to be most commonly associated with zoledronic acid when used at bone metastasis treatment doses, and is rarely seen with oral bisphosphonates used at osteoporosis treatment doses. It is recommended that before initiating bisphosphonate therapy, particularly intravenous administration, patients should receive a dental examination and appropriate preventive dentistry (66). While on therapy, patients should maintain excellent oral hygiene and avoid, if possible, invasive dental procedures. In the AZURE adjuvant breast cancer trial, with a median follow-up of 73.9 months, 26 cases of ONJ were reported, all in the zoledronic acid treated patients, representing a cumulative incidence of 2.1% (95% CI 0.9–3.3%). The median number of zoledronic acid administrations before onset of ONJ was 13 (range 1–19) and median time from randomization to onset was 863 days (range 21–2,767) (67). With the 6 monthly administration used in ABCSG 12 and ZO-FAST, the cumulative incidence of ONJ appears to be lower at less that 1%.

CONCLUSIONS

Bisphosphonates are a promising group of compounds in the adjuvant breast cancer setting. This class of drugs has two potential roles in the treatment of early-stage breast cancer patients: prevention of metastasis with resultant improved disease-free and overall survival, and prevention and treatment of osteoporosis.

Preclinical studies provide good proof of principle for the role of bisphosphonates in preventing the growth and development of bone metastases. There is also increasing evidence of clinically relevant anticancer response to bisphosphonates in disease outside the skeleton. Recent adjuvant studies in breast cancer patients have shown efficacy in a low-estrogen environment (postmenopausal women, and premenopausal women treated with GnRH agonists), with improvements in both local and distant DFS. Ultimately, we would like to determine which adjuvant breast cancer patients might benefit most from the addition of bisphosphonates to maximize benefit and minimize costs and risk. Tumor or patient characteristics, biomarkers, and bone marrow micrometastases may predict who is at highest risk for bone recurrence.

Breast cancer patients can have an added benefit from bisphosphonates, unrelated to the reduction of bone metastases, in the form of preservation of bone density. Several recent trials in early-stage breast cancer patients have demonstrated that bisphosphonates (and denosumab) are effective in treating and preventing bone loss associated with cancer treatment. Optimal timing of initiation of bisphosphonates to suppress loss of bone density, whether early in the treatment course or after bone loss has occurred, has not been established. The major studies of bisphosphonates in cancer treatment-induced bone loss have not yet shown clinically significant differences in fracture rates.

In addition to bisphosphonates and densoumab, several new classes of agents with antiosteoclastic activity are in various stages of investigation for treatment of bone metastases, prevention of bone metastases, and prevention and treatment of osteoporosis. These include radium-223, src kinase inhibitors, and cathepsin-k inhibitors. The relative efficacy and toxicity profiles of these agents compared with bisphosphonates and denosumab will be of great future interest.

MANAGEMENT SUMMARY

- The use of bisphosphonates or denosumab in the adjuvant setting has not been approved by the regulatory agencies. However, the use of bisphosphonates in women with early-stage breast cancer with the intention of reducing bone metastases is currently supported by the available clinical data for women who have passed through menopause or who are receiving ovarian suppression therapy.
- Adjuvant bisphosphonates are not recommended in women with ongoing ovarian function. Treatment in the presence of premenopausal levels of reproductive hormones may increase the risk of recurrence.
- Before initiating bisphosphonates, baseline dental examinations should be performed, to identify and treat oral problems that could lead to the need for dental surgery. It is important that patients maintain good oral hygiene, undergo regular dental examination, and be advised on appropriate measures for reducing the risk of osteonecrosis of the jaw.
- When giving intravenous bisphosphonates, it is advised that serum creatinine be checked before infusion. The dose of bisphosphonate may need to be adapted to renal function.
- All breast cancer patients on high-dose bisphosphonates or denosumab should be advised to take calcium and vitamin D supplementation to avoid the risk of hypocalcemia. Periodic monitoring of serum calcium, electrolytes, phosphate, and magnesium should be performed.
- Women with early-stage breast cancer should be evaluated for their bone density and risk of fracture. Nutritional vitamin D supplementation and lifestyle interventions should be advised for all women. Early-stage cancer patients at risk of developing cancer treatment-induced bone loss should be monitored by bone mineral density and considered for bisphosphonate treatment.

DISCLOSURES

Robert Coleman has received consultancy and speaker fees from Amgen and Bayer and given expert testimony on behalf of Novartis.

CHAPTER 48

Pharmacogenomics of Systemic Therapy

James M. Rae

CHAPTER CONTENTS

INTRODUCTION TO PHARMACOGENETICS AND PHARMACOGENOMICS

Over the past half century, a large number of studies on the genetic diversity of human drug response have shown that a person's unique genetic makeup is a major determinant of idiosyncratic adverse drug reactions and therapeutic failure (1). This field, designated pharmacogenetics or pharmacogenomics, is defined as the study of inherited genetic polymorphisms (mostly single nucleotide polymorphisms [SNPs]) in genes that code for proteins responsible for a drug's pharmacokinetic (absorption, distribution, metabolism, and excretion) and pharmacodynamic (target interaction and signaling alterations) properties. The first groundbreaking pharmacogenetic studies identified gene variants that had profound effects on gene function and these variants had major effects on patient drug response. The advent of high throughput and cost effective DNA sequencing technologies have ushered in the new era of "pharmacogenomic" investigations which use a multi-gene or whole genome approach to identify the germline genetic causes of inter-patient variable drug response.

Pharmacogenetics and pharmacogenomics are shaping the future of personalized medicine, the concept of tailoring the type and dose of drug based on a patient's unique genetic makeup. This approach promises to have a significant impact in the field of oncology, in which the currently available drugs exhibit substantial variability in their pharmacokinetics and pharmacodynamics and only a limited number of generic therapeutic strategies are employed for all patients. The concept of personalized medicine embraces the goal of "finding the right drug at the right dose for the right patient."

For the most part, the practice of personalized medicine in breast cancer treatment has been based on using the somatic changes acquired by the cancer during the malignant process to select a therapeutic strategy most likely to be of benefit. Perhaps the two best examples of this approach are the use of estrogen receptor (ER) over-expression and HER-2 over-expression for the selection of anti-estrogen and anti-HER-2 therapies, respectively. A superior understanding of the estrogen-sensitive biology of the tumor (2) has meant that the treatment of breast cancer has led the treatment of many other cancers. The use of tumor-based markers such as the estrogen and progesterone receptors to guide endocrine therapy, first with tamoxifen worldwide and now with the aromatase inhibitor class of drugs, is the standard of care worldwide (3). These advances have been supplemented by the advent of HER2 based therapy in the form of trastuzumab aimed at tumors that express the HER2 receptor (4). The targeting of therapy based on tumor estrogen, progesterone, and human epidermal growth factor receptor 2 expression has recently been supplemented by the use of RNA expression-based biomarkers that can be used to predict the benefits of chemotherapy with the best example being the clinically used Oncotype Dx™ 21 gene array assay (5).

While approaches based on tumor biology have clearly resulted in improvements in recurrence free survival, the morbidity and mortality associated with breast cancer remain unacceptably high, and the toxicity of current therapies results in unacceptably low levels of compliance. As a result, the need for further improvements in targeting and treatment remains high, and the possibility that inherited variants in genes that control the metabolism, distribution and elimination of drugs, and that code for their targeted receptors and signaling pathways might be important predictors of drug effects and toxicity in breast cancer. The availability of high throughput genomic technologies that are able to screen for hundreds of thousands of individual variants at once has provided insights into the pathogenesis of breast cancer (6), and is now poised to identify inherited genetic associations with responses to specific therapies.

It seems particularly important to explore the inherited germline for clues to therapeutic response, when it is clear

that the treatments now available have been tested and validated in primarily Caucasian populations. Our ability to treat breast cancer in African-Americans, in whom the incidence of breast cancer is 20% lower than that in Caucasians, but the mortality is 20% higher, would appear more limited. Similarly, the notably increasing rates of lethal breast cancer in Asian populations (7) demands serious attention to the question of whether we can ignore differences in response to therapy that might be based not on tumor biology, but on the inheritance of factors that might alter drug efficacy and toxicity. There is widespread precedent for the concept of pharmacogenomics in other fields of medicine where, for example, it is recognized that 7% of the population experience little analgesic benefit from codeine because they lack the ability to metabolize codeine to morphine via the CYP2D6 enzyme (8), or experience an increased risk of intracranial bleeding while being treated with warfarin due to variants in the *CYP2C9* or *VKCOR* genes (9). In addition, a number of pharmacogenomic tests are already available in other areas of cancer treatment.

PHARMACOGENOMICS IN MEDICAL ONCOLOGY

Thiopurine S-methyltransferase and the Metabolism of Mercaptopurines

Perhaps one of the best studied examples for the application of pharmacogenomic strategies to prevent adverse drug reactions is the polymorphism of the thiopurine S-methyltransferase (*TPMT*) gene (9). *TPMT* catalyses the S-methylation of thiopurine drugs such as mercaptopurine and its prodrug azathioprine. These drugs are successfully used to treat acute lymphoblastic leukemia (ALL), and gastroenterologists prescribe thiopurine drugs as second-line (off-label) therapy for Crohn's disease and ulcerative colitis. Because methylation by *TPMT* is the predominant pathway for inactivation of thiopurines, patients with *TPMT* deficiency accumulate active thioguanine nucleotides and this can lead to severe and life-threatening hematological toxicity. *TPMT* activity in erythrocytes is trimodally distributed among Europeans, European-Americans, and African-Americans and this distribution corresponds well to the genotypes or the respective presence of 2, 1, or 0 functional *TPMT* alleles. Twenty mutant alleles of *TPMT* have been associated with low *TPMT* activity and 3 of these variants (*TPMT*2, TPMT*3A* and *TPMT*3C*) account for approximately 95 % of low *TPMT* activity phenotypes. Approximately 1 in 150–300 individuals is homozygous for inactive *TPMT* alleles, approximately 10% of patients are heterozygous and have intermediate activity and approximately 90% are normal or high methylators in a Northern European Caucasian population (10).

Because of the strong genotype–phenotype concordance and the severe toxicity associated with high concentrations of thioguanine nucleotides, several cancer centers routinely genotype patients for *TPMT* mutant alleles and use genotype-derived algorithms for dosing. Intermediate metabolizers receive approximately 65% and poor metabolizers 5% to 10% of standard doses of mercaptopurine (11). Dose reductions in patients with variant *TPMT* alleles lead to similar or superior survival compared to patients with wild-type alleles.

Of major concern is a report of an increased incidence of secondary brain tumors after radiotherapy in children with decreased *TPMT* activity phenotypes and/or high concentrations of thioguanine nucleotides in blood cells (12). The implications for therapeutic decisions regarding prophylactic radiotherapy in ALL, therefore, must be further investigated.

Uridine Diphosphate glucuronosyltransferase (*UGT*) 1A1 and the Metabolism of Irinotecan

Results from several recently published trials suggest that patients who are homozygous for a *UGT* gene variant known as *UGT1A1*28* (the "7/7" genotype) are at greater risk for irinotecan-induced severe diarrhea or neutropenia (13). Irinotecan is a camptothecin analogue and acts on cancer via inhibition of topoisomerase. The disposition of irinotecan is complex and involves numerous metabolic enzymes and transport proteins. SN-38 is the active metabolite of irinotecan and is eliminated via *UGT1A1* conversion to SN-38G, an inactive glucuronide cleared via biliary excretion. Reduced activity of *UGT1A1* is linked to an approximately four fold increased risk of severe toxicity, including dose-limiting diarrhea and neutropenia. Significant correlations between patients carrying one or two copies of the *UGT1A1*28* allele and reduced *UGT1A1* expression and reduced SN-38 glucuronidation are now been well documented.

More than 50 mutations in *UGT1A1* have been reported, many of which are found in patients with Gilbert's syndrome, a form of mild nonhemolytic unconjugated hyperbilirubinemia. The most common mutant gene is *UGT1A1*28*, which contains 7 dinucleotide repeats in the TATA box of the promoter ($A(TA)_7TAA$) instead of the normally 6 repeats, and leads to approximately 70% reduction of transcriptional activity. Many rare mutations also lead to Gilbert's syndrome, and individuals with this syndrome are predisposed to SN-38 initiated toxicity. Although, as always, a number of additional factors influence the toxicity of SN-38 in the intestine and bone narrow, assessment of the presence of the *UGT1A1*28* allele in patients prior to irinotecan treatment may allow lower starting doses or change to alternative therapies. Although there are pharmacogenetic studies that support this position, it is also clear the association of this toxicity with *UGT1A1* genotype is irinotecan dose-dependent (14). As a result, many oncologists prefer to simply adjust the irinotecan dose and avoid *UGT1A1* genotyping.

PHARMACOGENOMICS STUDIES IN BREAST CANCER

The study of pharmacogenomics in breast and other cancers has been impaired in part by the lack of availability of germline DNA from properly consented patients in the majority of large prospective clinical cancer trials. This is in contrast to other medical disciplines, where the collection of blood, buccal swabs, or saliva to allow extraction of germline DNA has been routine for many years. This obstacle in cancer trials has been overcome, in part, by the key demonstration that effective germline genotyping can be carried out on DNA extracted from paraffin blocks (15). The technical ability to genotype germline DNA from paraffin opens up the possibility of testing pharmacogenomic hypotheses in a large number of clinical studies that have available archived paraffin-embedded specimens with associated well annotated clinical outcomes data. As a result, significant progress has been made in studies designed to examine germline genetic associations with both the efficacy and toxicity of treatments for breast cancer (16).

Genetic Variants Associated with Toxicity of Agents Used to Treat Breast Cancer

Cyclophosphamide Activation by Cytochrome P450 Enzymes

A majority of chemotherapeutic regimens that have been used to treat all stages of breast cancer have used cyclophosphamide as an integral component. Cyclophosphamide

is a prodrug that requires metabolic activation by cytochrome P450 (CYP) enzymes to 4-hydroxycyclophosphamide. Multiple CYPs have been implicated in this activation, including CYP2A6, 2B6, 2C19, 2C9, 3A4, and 3A5 (17). Interestingly, CYP2C19 appears to be the predominant enzyme responsible for cyclophosphamide activation, particularly at low drug concentrations. CYP2C19 is a genetically polymorphic enzyme that is expressed primarily in the liver and that has been shown to be responsible for the metabolism of a wide range of important therapeutic agents (18). The genetic variants in *CYP2C19*, which have now been studied in a wide range of human populations, results in complete absence of enzyme activity in 3% to 5% of Caucasians and in 15% to 25% of Asian populations. In addition, the *CYP2C19*17* allele, which is present in 18% of Caucasians and Africans, and 4% of Asians, codes for a significantly more active enzyme, and interestingly, has been associated with a decreased risk for breast cancer (19). It is reasonable to hypothesize that those individuals who do not carry active *CYP2C19* alleles may experience less prodrug activation and, therefore, decreased cyclophosphamide efficacy and treatment related side effects. Furthermore, those individuals who carry the more active *CYP2C19*17* allele may experience exaggerated drug response at standard doses.

Thus, in a study conducted in lupus nephritis patients taking cyclophosphamide monotherapy, it was found that *CYP2C19*2* is a predictor of premature ovarian failure and progression to end-stage renal disease (20). These findings have been validated by other investigators; however, not all studies to date have been able to reproduce the association (21). While the precise mechanism of this effect is unclear, these observations suggest that a line of *in vitro* and clinical investigations are necessary to determine the cause of ovarian toxicity, and thus to prevent it in women at risk, an example of "reverse" translational research. Although these studies suggest that there is clinical relevance to the role of *CYP2C19* in the use of cyclophosphamide in other settings, studies to test whether these variants in *CYP2C19* or variants in other candidate genes are associated with cyclophosphamide outcomes in breast cancer are not available at present.

Vincristine Inactivation by Cytochrome P450 Enzymes

While cyclophosphamide is used in a large number of adjuvant regimes used in breast cancer, the use of vincristine is confined to the metastatic setting. After many years during which the metabolism of vincristine was poorly understood, it has recently been shown that vincristine is primarily metabolized by a highly genetically polymorphic enzyme: *CYP3A5* (22). This enzyme has two common polymorphisms (*CYP3A5*3* and *CYP3A5*6*) that cause alternative splicing and protein truncation resulting in the absence of functional *CYP3A5* enzyme production in patients with the homozygous variant genotype. Interestingly, *CYP3A5* is more frequently expressed in livers of African-Americans (60%) than in Caucasians (33%) due to ethnic differences in the *CYP3A5*3* and **6* alleles frequencies (23). In a clear demonstration of the potential clinical relevance of this variability, Caucasians recently have been shown to be notably more vulnerable to vincristine-related neurotoxicity than African-Americans (24). Four percent of total doses administered to Caucasian patients were reduced due to vincristine-related neurotoxicity compared to 0.1% given to African-Americans ($p < .0001$), and 1.2% of all protocol-indicated doses for Caucasians were held due to severe vincristine-associated toxicity compared to 0.1% of doses for African-Americans ($p < .01$). The association between vincristine-induced neurotoxicity and *CYP3A5* genotype was confirmed in a prospective study of children with precursor B cell acute lymphoblastic leukemia (25). Together, these studies suggest that the unpredictable neurotoxicity that patients experience with vincristine may actually be predictable, and that *CYP3A5* genotype may contribute. However, further studies are required to determine whether *CYP3A5* genotype will have clinical utility for predicting side effects associated with vincristine and other chemotherapeutic agents metabolized by the *CYP3A5* drug metabolism pathway.

Tamoxifen Pharmacogenomics

Mortality from breast cancer has been declining over the last two decades. Much of this decline is due to the widespread application of endocrine therapy, of which there are two major types: (i) selective estrogen receptor modulators (SERMs) including tamoxifen; and (ii) aromatase inhibitors (AI) including anastrozole, letrozole, and exemestane. These drugs have clearly played a substantial role in decreasing breast cancer mortality rates, especially when used in the adjuvant setting (26). Tamoxifen has also been shown to prevent breast cancer (27). Approximately 60% to 70% of newly diagnosed breast cancers are estrogen receptor (ER)-positive, but only 60% of these will respond to therapy. It is not currently possible to identify which patients with ER-positive cancers will respond to endocrine therapy nor is it possible to determine whether a specific treatment (tamoxifen or an AI) will be more effective for an individual patient. Currently, a great deal of research has been focusing on using pharmacogenomic strategies to personalize breast cancer endocrine therapy. It has been proposed that variants in genes that encode proteins involved in drug and steroid metabolism, and in genes that code for components of the estrogen signaling pathways can predict response to, and side effects from, endocrine therapy.

Tamoxifen is the most widely studied breast cancer drug from a pharmacogenomic perspective. It is an essential part of standard adjuvant and palliative systemic therapy for patients with ER-positive breast cancers. Adjuvant tamoxifen significantly decreases relapse rates and mortality in pre- and postmenopausal patients, and the therapeutic benefit resulting from 5 years of adjuvant tamoxifen is maintained for more than 10 years after diagnosis (28). Tamoxifen is a valid therapeutic option next to AIs in postmenopausal patients with endocrine responsive disease; it is considered the standard care for premenopausal patients, for prevention of invasive breast cancer in women at high risk including those who have had ductal carcinoma *in situ*, and for the treatment of male breast cancer. It is important to note that, although the clinical benefit of tamoxifen has been evident for more than three decades, up to 50% of patients receiving adjuvant tamoxifen relapse or die due to tumor resistance or lack of response to the drug. In addition, while tamoxifen is a very effective drug, as with all potent medications, it also has side effects. Because the difference in efficacy between tamoxifen and the aromatase inhibitor class of drugs is in the 2 to 4% range, we are in great need of biomarkers that are able to predict the efficacy of specific endocrine treatments, and that help identify individual patients who are most likely to experience specific side effects that are not predictable *a priori*.

Efforts to identify genomic biomarkers for tamoxifen effects have been significantly aided by improved understanding of tamoxifen metabolism that has helped identify candidate genes involved in the actions of the drug. Tamoxifen itself has weak anti-estrogen properties and is converted into much more potent anti-estrogenic metabolites. It has, therefore, been proposed that tamoxifen, like cyclophosphamide, is a prodrug and that inherited variations in drug metabolizing enzymes (mainly CYP450s) might alter tamoxifen's anticancer activity and side effects.

Data on the metabolism of tamoxifen carried out in the 1980s in rats indicated that the drug is extensively metabolized by the cytochrome P450 system and that it is primarily demethylated to *N*-desmethyl tamoxifen or hydroxylated (29). It was shown that the 4-hydroxylated metabolite was approximately 100 times more potent as an anti-estrogen than the parent tamoxifen and its primary metabolite *N*-desmethyltamoxifen, and it was subsequently believed that 4-hydroxy-tamoxifen was *the* active metabolite. As a result, this metabolite was synthesized by a number of companies and remains the most widely used substitute for tamoxifen in many laboratory studies. Another hydroxylated metabolite, 4-hydroxy-*N*-desmethyl tamoxifen is created in humans, but not in mice (30) by the hydroxylation of *N*-desmethyl tamoxifen, and this has more recently been clearly documented to be the most abundant species in human serum at steady state (31). Stearns et al. reported that the serum concentrations of this metabolite, now designated endoxifen, were notably lower in patients who were co-prescribed paroxetine, a potent *CYP2D6* inhibitor, and in patients with *CYP2D6* gene variants that result in no functional enzyme production (32).

CYP2D6 is one of the most intensively studied human drug metabolizing enzymes with known genetic variants (33). *CYP2D6* is the key metabolic route for over 20% of clinically used drugs including many antidepressants, neuroleptics, antiarrhythmics and other commonly used drugs. It is absent in 7% of Caucasians as the result of genetic variants that do not code for active enzyme. Patients who are homozygous for two null *CYP2D6* alleles are considered poor metabolizers (PM) compared to patients with one or more wild-type *CYP2D6* alleles (intermediate metabolizers [IM] and extensive metabolizers [EM], respectively). A high prevalence of IM in Asian populations results in lower average *CYP2D6* activity in these patients, and the presence of multiple copies of the *CYP2D6* gene results in high or ultrarapid metabolizers (UM) in approximately 5% of Caucasians, but more than 20% of East African populations in Ethiopia and Saudi Arabia (33).

To confirm a clinically important involvement of the *CYP2D6* enzyme in tamoxifen metabolism, Desta et al. (34), conducted a comprehensive evaluation of the metabolism by the cytochrome P450 system, and demonstrated that the metabolism of *N*-desmethyltamoxifen to endoxifen is carried out almost exclusively by *CYP2D6*. The human metabolism of tamoxifen is now well understood. It involves the conversion of the parent drug to two well documented active metabolites: 4-hydroxy-tamoxifen, which is formed directly from tamoxifen by 4-hydroxylation catalyzed by at least three enzymes, and the independent conversion of tamoxifen to *N*-desmethyl tamoxifen by cytochrome P450 3A, followed by secondary metabolism to endoxifen catalyzed exclusively by *CYP2D6* (34).

Endoxifen is believed to be tamoxifen's clinically active metabolite because it binds to ER with 100-fold greater affinity than tamoxifen and *N*-desmethyl-tamoxifen, and its serum concentration is 6 to 10-fold higher than 4-hydroxy-tamoxifen (31). *CYP2D6* is the primary and rate-limiting enzyme responsible for the formation of endoxifen and patient *CYP2D6* genotype correlates with endoxifen serum concentrations (32). These studies were the basis for the hypothesis that *CYP2D6* genotype may predict response to tamoxifen.

In an examination of a randomized, controlled prospective trial, Goetz et al. successfully isolated intact DNA from paraffin blocks from 223 of 256 eligible patients, and found that women with the *CYP2D6 *4/*4* genotype (the most common null variant found in Caucasians) had worse relapse-free time (RF-time; $p = .023$) and disease-free survival (DFS; $p = .012$), but not overall survival ($p = .169$) and did not experience moderate to severe hot flashes relative to women heterozygous or homozygous for the wild-type allele (35). In the multivariate analysis, women with the *CYP2D6 *4/*4* genotype still tended to have worse RFS (hazard ratio [HR], 1.85; $p = .176$) and DFS (HR, 1.86; $p = .089$). It was concluded that breast cancer patients with estrogen receptor-positive disease and who have the *CYP2D6 *4/*4* genotype tend to have a higher risk of disease relapse and a lower incidence of hot flashes, consistent with the previous observation that *CYP2D6* is responsible for the metabolic activation of tamoxifen to endoxifen.

The initial tamoxifen/*CYP2D6* publication spurred a growing number of studies evaluating the possible association between *CYP2D6* genotype and response to tamoxifen therapy (reviewed by Hertz [36]). These studies have generated a great deal of controversy over whether *CYP2D6* genotyping should be used clinically to identify patients less likely to respond to tamoxifen (36). Most of the studies conducted thus far have been confounded by relatively small numbers of patients, lack of comprehensive genotype data, lack of detailed clinical outcome data, and patient selection biases. Furthermore, no studies have controlled for differences in rates of adherence to tamoxifen therapy which may, in fact, be lower in patients with the highest endoxifen levels (37). A large study combined two previously published patient cohorts with additional patients from a registry study and concluded that *CYP2D6* genotype does predict response to tamoxifen (38). This was considered by many the definitive study establishing the value of CYP2D6 status. However, evidence against the clinical use of *CYP2D6* testing was generated recently from two prospective-retrospective studies published from the Breast International Group (BIG) 1-98 and Arimidex, Tamoxifen, Alone or in Combination (ATAC) clinical trials, which failed to show an association between *CYP2D6* genotype and clinical outcomes in tamoxifen-treated patients (39,40) The strengths of these two studies include the large number of patients analyzed, the long-term and detailed clinical follow-up set within registration clinical trials, and the inclusion of control groups (patients receiving AI). To date, these two studies provide the highest level evidence available, suggesting that *CYP2D6* genotype does not influence tamoxifen activity and that genetic testing is not indicated for women with ER-positive breast cancer considering adjuvant tamoxifen therapy.

The interaction between antidepressants and tamoxifen has also received considerable attention as a result of this work, as it is clear that *CYP2D6*-inhibiting SSRIs such as paroxetine and fluoxetine lower endoxifen concentrations (31,32). It has been demonstrated that venlafaxine, a weak inhibitor of *CYP2D6*, does not appreciably lower the concentrations of active tamoxifen metabolites, affording women with breast cancer the possibility of taking an effective antidepressant that is also able to treat hot flashes, and has little chance of altering the risk of recurrence.

Post-menopausal women being treated with endocrine therapy for breast cancer clearly now have a number of alternative therapies available to them. These include tamoxifen and the aromatase inhibitors anastrozole, letrozole, and exemestane. The choice of which therapy should be used in which woman should obviously be guided by the potential benefits for each woman and the attendant risks of specific therapies in each woman, but also by the tolerability of specific therapies, as it is clear that compliance with tamoxifen or the aromatase inhibitor class of drugs can influence outcomes. While it was hoped that *CYP2D6* genotype would have clinical utility for determining whether a patient should be prescribed tamoxifen, the data are not yet conclusive. However, it is recommended that, if possible, women taking tamoxifen should avoid *CYP2D6*-inhibiting drugs (a list of common *CYP2D6* inhibitors is provided in

TABLE 48-1

Common Drugs That Inhibit CYP2D6

Strong Inhibitors
Paroxetine (Paxil®)
Fluoxetine (Prozac®)
Bupropion (Wellbutrin®)
Quinidine (Cardioquin®)

Moderate Inhibitors
Duloxetine (Cymbalta®)
Diphenhydramine (Benadryl®)
Thioridazine (Mellaril®)
Amiodarone (Cordarone®)
Cimetidine (Tagamet®)

Weak or Noninhibitors
Venlafaxine (Effexor®)
Citalopram (Celexa®)
Escitalopram (Lexapro®)
Sertraline (Zoloft®)

Table 48-1). In situations where women are committed to a *CYP2D6*-inhibiting antidepressant by years of effective treatment that is not easily substituted for by another drug, then it is recommended that they stay on the effective antidepressants. Of note, these recommendations do *not* apply to women in the premenopausal setting, in whom the aromatase inhibitors are not effective alternatives to tamoxifen, and for whom there is only limited data on the clinical consequences of *CYP2D6* genomics.

Pharmacogenomics in the Use of Anti-angiogenic Agents in Breast Cancer

The possibility that host genomics might influence outcome is perhaps greatest in situations where the host response to the tumor might be modified. This is obviously the case in the physiology of tumor angiogenesis, where the host's ability to confer a sustaining blood supply to a solid tumor is widely recognized as variable, and a target of therapy. This has most recently been made clear by the approval of bevacizumab, an anti-vascular endothelial growth factor antibody to treat breast cancer. Bevacizumab was approved as the result of the data from a number of trials, including a trial designated as E2100, in which women with metastatic breast cancer were treated with either paclitaxel alone, or paclitaxel with bevacizumab. The results of this trial indicated that bevacizumab prolonged disease-free survival from 5.9 to 11.8 months, but did not alter overall survival. Using techniques similar to those developed for CYP pharmacogenetics testing, researchers were able to obtain sufficient high quality DNA to conduct germline genetic testing from paraffin blocks to allow genotyping for candidate gene that are in the angiogenesis response pathway. When these techniques were applied to paraffin blocks obtained during the E2100 trial, they were able to show that women who carried either of two promoter single nucleotide polymorphisms in the *VEGF* gene experienced notably longer overall survival (41). Women who carried the –2578 *AA* variant experienced a 10 month increase in median overall survival (p = .023), relative to the control arm, while women who carried the –1154 *AA* variant survived for 20 months longer (p = .001) than those in the control, paclitaxel alone arm. While these data require validation, the size of the effects is large, and the cost of bevacizumab therapy argues that it may make not only clinical sense, but economic sense to conduct pharmacogenetics testing before treatment with bevacizumab in this setting and many others.

FUTURE IMPACT OF PHARMACOGENOMICS IN BREAST CANCER

The pioneering studies in the field of pharmacogenetics investigated clear-cut genotype–phenotype relationships, and were, therefore, possible with relatively small numbers of patients. In contrast, predicting response to breast cancer therapy is much more complex, and much larger studies are required to dissect the more subtle effects that some genetic polymorphisms may have in cancer pharmacology. Furthermore, the relevant treatment outcomes may take many years to become manifest in this context. Although the science of pharmacogenomics is more than 50 years old, it is only recently that pharmacogenetics variants have been tested as possible biomarkers of response to therapy in breast cancer. Women with breast cancer have benefited tremendously from improved understanding of tumor biology and we now routinely stratify therapy based on the presence of estrogen, progesterone, HER2 and expression array data. There is great potential for similar stratification of therapy using germline pharmacogenomics, and ongoing studies in the areas of chemotherapy, endocrine therapy, and anti-angiogenic therapy make clear that this is now not only an active area of investigation, but one in which there is great potential to identify women most likely to respond to very expensive biologic therapies as well as treatments that have become more routine. This is now clear to many investigators, and so the pace of presentation of pharmacogenetic studies in breast cancer is accelerating rapidly.

MANAGEMENT SUMMARY

At present, we are in the early stages of determining whether any of the pharmacogenomic tests currently being evaluated will aid in therapeutic decision-making in breast cancer. While there has been a great deal of excitement about the potential use of *CYP2D6* genotype for determining tamoxifen therapy, to date the available clinical data argues against the use of *CYP2D6* genotyping. Until higher levels of evidence become available for *CYP2D6* and the other genetic tests discussed earlier, they should all be considered as pharmacogenomics research hypotheses that require further validation in studies providing the high level of evidence required in order to show the markers' clinical utility. Current specific recommendations are:

- *CYP2D6* genotype in the premenopausal setting. Women with hormone receptor-positive breast cancer do not have multiple alternative therapies for endocrine therapy beyond tamoxifen as neither raloxifene nor the aromatase inhibitors are effective in this context. *CYP2D6* genotyping is *not* recommended in this setting given the lack of clinical data supporting the test. Similarly, in the breast cancer prevention setting, *CYP2D6* genotyping is *not* recommended.

- *CYP2D6* genotype in the postmenopausal setting. Women with hormone receptor-positive breast cancer have multiple potential alternative therapies that include tamoxifen and three aromatase inhibitors. While the ideal sequence and duration of these therapies in individual women is still a subject of research, *CYP2D6* genotyping is *not* recommended in this setting given the lack of clinical data supporting the test.
- Avoiding *CYP2D6* inhibitors in women prescribed tamoxifen. Given the high level of evidence provided by the BIG 1-98 and ATAC studies which failed to detect an association between *CYP2D6* genotype and benefit from tamoxifen, it stands to reason that concomitant use of *CYP2D6* inhibitors will not influence tamoxifen efficacy. However, from a clinical drug-drug interaction standpoint, it is recommended that *CYP2D6* inhibitors be avoided whenever possible because the *CYP2D6* drug metabolism pathway is involved in the metabolism of approximately 25% of all drugs.
- In terms of anti-angiogenic therapy, we have one large prospective trial in women with metastatic breast cancer (E2100) to rely upon for pharmacogenomic data, so it remains premature to make firm recommendations at this time. If data from this trial are validated, then we will be able to quickly identify a group of women who stand to derive considerable benefit from this effective but expensive treatment, and another group who do not and who should, therefore, not be treated.

CHAPTER 49

Implications of Obesity in Breast Cancer

Ayca Gucalp, Patrick G. Morris, Clifford A. Hudis, and Andrew J. Dannenberg

CHAPTER CONTENTS

INTRODUCTION

Obesity is a major risk factor for the development of some of the leading preventable causes of death in the United States including cardiovascular disease, diabetes mellitus, and stroke. In addition, epidemiologic studies link obesity with an increased incidence of common epithelial malignancies including postmenopausal hormone-receptor-positive and triple-negative breast cancers (TNBC). Obesity is also recognized as a poor prognostic factor among survivors of breast cancer irrespective of menopausal status and breast cancer subtype. The underlying mechanisms for these phenomena remain incompletely understood. Growing evidence suggests that complex interactions between multiple pathways regulating estrogen synthesis, insulin resistance, adipokine and cytokine production, and chronic systemic inflammation may collectively explain the link between obesity and breast cancer pathogenesis. Increasing adiposity also poses additional technical challenges in the detection of breast cancer and in its effective local and systemic treatment. This chapter reviews the epidemiologic data linking obesity and breast cancer, the underlying biological mechanisms, and the important practical implications of this condition on the diagnosis and management of this disease. Finally, we examine potential interventions and strategies to reduce the unfavorable impact of obesity on the diagnosis and treatment of breast cancer.

EPIDEMIOLOGY OF OBESITY

Obesity has been classified by the World Health Organization as a global epidemic (1). The number of overweight and obese individuals in the United States has doubled since 1990, and it is projected that the prevalence of obesity will be greater than 50% in 39 states by the year 2030 (Fig. 49-1) (2).

One commonly used measure of extent of body fat is body mass index (BMI), calculated by dividing an individual's weight in kilograms by the square of his or her height in meters (1). For adults, BMI is categorized into the following four standard groups: underweight less than 18.5 kg/m^2, normal 18.5 to 24.9 kg/m^2, overweight 25.0 to 29.9 kg/m^2, and obese 30 kg/m^2 or more (1). Although BMI is reproducible, inexpensive, and easy to measure and calculate, it is nonetheless only a surrogate measure of body fat. The correlation between BMI and percentage of body fat varies by age, ethnicity, gender, and muscle mass. For example, BMI routinely overestimates the adiposity of trained athletes and underestimates the true percentage of body fat of older individuals with less lean muscle mass (1).

EPIDEMIOLOGIC LINK BETWEEN OBESITY AND BREAST CANCER

Postmenopause

Many observational studies have demonstrated that increasing BMI is a risk factor for postmenopausal hormone-receptor-positive breast cancer. This is the most common subtype of breast cancer. Of note, breast cancers are considered "hormone sensitive" when they expresses the estrogen receptor (ER) and/or progesterone receptor (PR). However, gene expression profiling has allowed us to subdivide hormone-receptor-positive breast cancers into those that are likely sensitive to hormone therapies ("luminal A") and those that are usually not ("luminal B"). Hence, hormone receptor status is an imperfect surrogate for hormone sensitivity. Of course, the absence of these receptors is very predictive of hormone insensitivity.

In a meta-analysis of eight prospective cohort studies, increasing BMI was directly correlated with breast cancer risk in postmenopausal women (3). Compared to those with a BMI less than 22.5 kg/m^2, women with a BMI in the overweight to obese range had an increased relative risk (RR) of 1.36 to 1.62 of developing breast cancer (Table 49-1) (3).

Premenopause

The effect of overweight and obesity on breast cancer risk in premenopausal women is less clearly defined. More precisely, it appears likely that the influence of weight may differ based on an individual patient's underlying risk. Cecchini et al. reported the pooled analysis of two large, randomized breast cancer prevention trials (Breast Cancer Prevention Trial [P1] and the Study of Tamoxifen and Raloxifene [STAR]), which included nearly 32,000 women at high risk of developing the disease. In comparison to premenopausal women with normal BMI, overweight (hazard ratio [HR] 1.59, 95% CI 1.05–2.42) and obese women (HR 1.70, 95% CI 1.10–2.63) had an increased risk of developing invasive breast cancer (4).

Several studies have also suggested an association between adult obesity and the development of TNBC, which lacks expression of the ER, PR, and human epidermal growth factor receptor 2 (*HER2*). In the Women's Health Initiative (WHI), a longitudinal study of postmenopausal women, in which over 5,000 invasive breast cancers were diagnosed, the highest quartile of BMI (31.5 or higher) was associated with a 1.39-fold (95% CI 1.22–1.58) increase in the risk of ER-positive breast cancer when compared to women with a BMI in the lowest quartile (less than 23.75) but a similar magnitude of risk of TNBC was also seen (HR 1.35, 95% CI 0.92–1.99), although this latter result was not statistically significant (5).

Impact on Treatment Outcomes

Studies examining the prognostic effect of overweight or obesity after a breast cancer diagnosis have consistently demonstrated poorer clinical outcomes for women with

TABLE 49-1

Relative Risk of Breast Cancer Development by Body Mass Index

Body Mass Index Category (kg/m^2)	*Relative Risk*	*95% Confidence Interval*
<22.5	Reference	Reference
25.0–27.4	1.45	1.08–1.95
27.5–29.9	1.62	1.17–2.24
≥30	1.36	1.00–1.85

Data from Key TJ, Appleby PN, Reeves GK, et al. Body mass index, serum sex hormones, and breast cancer risk in postmenopausal women. *J Natl Cancer Inst* 2003;95:1218–1226.

an elevated BMI. In a recent meta-analysis, Protani and colleagues examined 43 studies with sample sizes ranging from 100 to more than 420,000, and included women diagnosed with breast cancer from 1963 to 2005. The authors demonstrated that obese women consistently experienced higher breast cancer–specific (HR 1.33, 95% CI 1.19–1.50) and all-cause mortality (HR 1.33, 95% CI 1.21–1.47) in comparison to their nonobese counterparts (6). Obesity has also been associated with several other poor clinical outcomes including increased risk of contralateral breast cancer and second primary breast cancers (7).

OBESITY-RELATED PATHWAYS AND BREAST CANCER PATHOGENESIS

Several lines of evidence suggest that obesity-induced tumor development, invasion, and progression are mediated by a complex interplay between both estrogen dependent and independent pathways (Fig. 49-2). Following the decline of ovarian function at menopause, estrogen production predominantly occurs by the peripheral conversion of androgen precursors to estrogens in extragonadal sites such as adipose tissue. The rate-limiting step in this process is catalyzed by the enzyme aromatase, encoded by the *CYP19* gene. Breast cancer incidence increases with age and it is in the setting of lowered circulating estrogen levels that the highest rates of hormone sensitive breast cancer are diagnosed. This seemingly paradoxical phenomenon is thought to be partially due to two related factors: increased adipose tissue and elevated aromatase expression in adipose tissue (8).

In addition to peripheral fat stores, the majority of the normal female breast is composed of white adipose tissue (WAT). WAT is an active endocrine organ producing various hormones, growth factors, and cytokines. Complex interactions between adipocytes and immune cells, such as activated macrophages, have been shown to promote chronic inflammation in the tumor microenvironment as well as insulin resistance. Through multiple interactive pathways involved in energy metabolism and immune function, adipose tissue is thought to contribute to breast cancer development and progression (Fig. 49-2).

Insulin Resistance

Obesity is associated with insulin resistance, characterized by impaired glucose tolerance and elevated systemic levels of insulin and insulin-like growth factor-1 (IGF-1), which have both been associated with breast cancer risk and worse prognosis (9). In a cohort of 512 patients with early-stage breast cancer, elevated fasting insulin levels were associated with both distant recurrence (HR 2.0, 95%

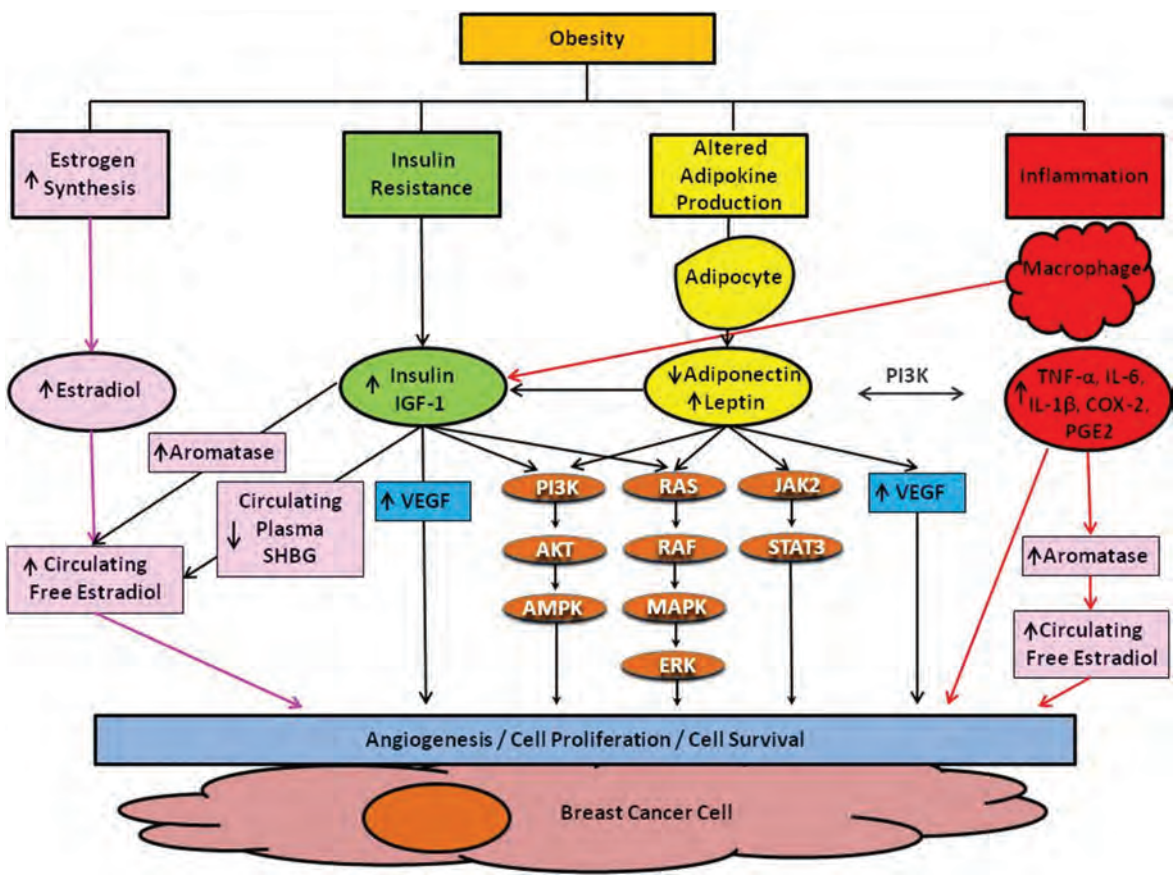

FIGURE 49-2 Pathways linking obesity with breast cancer. SHBG, sex hormone-binding globulin; IGF-1, insulin-like growth factor 1; VEGF, vascular endothelial growth factor; PI3K, phosphatidylinositol 3-kinase; ERK, extracellular signal-regulated kinase; MAPK, mitogen-activated protein kinase; JAK2, Janus kinase 2; STAT3, signal transducer and activator of transcription 3; AMPK, 5' adenosine monophosphate-activated protein kinase; TNF-α, tumor necrosis factor alpha; IL-6, interleukin-6; IL-1β, interleukin-1β; COX-2, cyclooxygenase-2; PGE2, prostaglandin E2.

CI 1.2–3.3) and all-cause mortality (HR 3.1, 95% CI 1.7–5.7) (9). It is theorized that insulin mediates breast carcinogenesis by stimulating signaling through activation of insulin/IGF-1 receptors that can be overexpressed on human breast cancer cells. Downstream activation of the Ras-Raf-MAPK and PI3K/Akt pathways ultimately leads to tumor cell proliferation and inhibition of apoptosis. Additionally, IGF-1 and insulin have been shown to stimulate aromatase activity in adipose tissue. Moreover, increasing insulin levels can affect sex hormone biosynthesis leading to increased androgen production by the ovaries and decreased hepatic production of sex hormone-binding globulin (SHBG) that normally antagonizes some negative effects of circulating estrogens.

Altered Adipokine Production

Adipokines, a group of proteins synthesized and secreted from adipose tissue, are also implicated in the interaction between obesity and breast cancer. Decreased serum adiponectin and elevated leptin levels have been associated with obesity and type 2 diabetes mellitus. Similar disturbances in these adipokines have also been associated with increased breast cancer risk (10) and worse prognosis (11). Although the mechanisms underlying these phenomena are incompletely understood, adiponectin is thought to exert its effects through the activation of multiple downstream signaling pathways including AMPK, PI3K/mTOR, and the transcription factor, nuclear factor-kappaB (NF-κB), which have also been implicated in breast cancer development (12). In addition, adiponectin has been shown to inhibit the growth of multiple breast cancer cell lines (13).

In contrast, leptin is thought to affect different aspects of breast tumorigenesis such as cell growth, angiogenesis, and metastasis and is to known to act mainly through activation of the JAK/STAT, MAPK/ERK, and PI3K/Akt signaling pathways leading to increased cell migration, invasion, and cell survival. Leptin-induced proliferation has been associated with overexpression of c-myc and cyclin D1which are important in cell cycle regulation (12). Finally, leptin has also been reported to have both proinflammatory and angiogenic properties, which may be important for breast carcinogenesis.

Obesity-Induced Chronic Systemic Inflammation: The Obesity-Inflammation-Aromatase Axis

Obesity causes chronic subclinical inflammation in adipose tissue (14). In obese women, increased levels of proinflammatory mediators such as tumor necrosis factor alpha (TNF-α) and interleukin-6 (IL-6) are commonly found in the circulation and may contribute to breast cancer progression and mortality. Interactions between adipocytes and immune cells promote this proinflammatory response through toll-like receptor- (TLR)-mediated signaling pathways and the activation of NF-κB. In mouse models of obesity and in overweight and obese humans, macrophages infiltrate visceral and subcutaneous adipose tissue and form characteristic crown-like structures (CLS) around dead adipocytes. In both dietary and genetic models of obesity, CLS occur in the adipose tissue of the mouse mammary gland as well as in visceral fat (15). Similarly, in women undergoing mastectomy, the presence of CLS of the breast (CLS-B) was associated with increased BMI. Importantly, the presence of CLS-B is associated with NF-κB-dependent upregulation of multiple proinflammatory mediators such as interleukin-1β (IL-1β), cyclooxygenase-2 (COX-2), prostaglandin E2 (PGE2), and TNF-α, which leads to increased transcription of *CYP19,* the gene encoding aromatase (16,17). These elevated levels of proinflammatory molecules and aromatase expression and activity are paralleled by upregulation of PR, an ER target gene. Aromatase activity correlates more strongly with the CLS-B index ($\rho = .88$, $p < .001$), a marker of extent of inflammation, than with BMI ($\rho = .5$, $p = .02$). This finding underscores the fact that obesity-related inflammatory mediators are critical for the induction of aromatase. Collectively, these results establish the existence of an obesity-inflammation-aromatase axis in breast tissue, which is likely to be one mechanism by which obesity influences breast carcinogenesis.

CLINICAL IMPLICATIONS

Obesity poses several practical challenges in regard to diagnosis, surgical management, and systemic treatment for breast cancer. In addition to the physical limitations that are associated with an elevated BMI, there may be psychosocial barriers to providing optimal care for the obese patient. Several studies have shown that obese patients are more likely to delay seeking medical care and are also less likely to receive preventive testing such as breast examinations and mammography when they do present for routine health maintenance (18). Consistent with these observations, overweight and obese women often present with tumors that are higher stage (larger size and higher number of involved lymph nodes) than lean women (19).

DIAGNOSTIC IMAGING

Obesity poses challenges for screening mammography and other imaging modalities (20). In mammography, increasing BMI has been associated with a higher false-positive rate (the detection of radiographic abnormalities that subsequently turn out to be benign). In reviewing over 100,000 screening mammograms, Elmore and colleagues demonstrated that obese women had an increased risk of having a false-positive mammogram result compared to nonobese women (odds ratio [OR] 0.79, 95% CI 0.74–0.84) (21). This study, as well as others, also demonstrated increased rates of recall for additional imaging for obese women compared with underweight and normal-weight women, as well as increased biopsy rates (21).

SURGERY

Although obesity may not have a negative impact on less invasive breast procedures such as lumpectomy, it has been associated with higher rates of complications after more invasive procedures such as mastectomy and breast reconstruction surgery. The National Surgical Quality Improvement Program Patient Safety in Surgery prospectively collected postoperative morbidity and mortality data on 1,660 and 1,447 women undergoing mastectomy and axillary procedures respectively. In this study, obesity was a significant independent predictor of wound infection, the most common adverse event, on multivariate analysis ($p < .001$).

Furthermore, the risk of postoperative lymphedema has been shown in several large cohort studies to be higher among women who were obese (22). With respect to breast reconstruction, increasing BMI is an independent risk factor for the development of surgery-related complications. In a retrospective series of nearly 1,200 breast reconstructions, Mehrara and colleagues reported that obesity was a major predictor of postoperative complications overall in both univariate and multivariate analysis and across all complication types (minor, major, early, and late) (23). Chang et al. reported similar findings among women who underwent free transverse rectus abdominis myocutaneous (TRAM) flap breast reconstruction (24). Finally, in women undergoing tissue expander

and implant reconstruction a BMI greater than 30 kg/m^2 was associated with nearly a twofold increase in perioperative complications (OR 1.8, 95% CI 1.1–3.0, p = .02) (25).

RADIATION

Obesity has important implications for the delivery of adjuvant radiotherapy following breast surgery. As a practical matter, increasing BMI may preclude the use of radiation therapy for the morbidly obese patient as standard equipment used in the planning and delivery of radiation has established weight limitations. Additionally, increased toxicity after radiation therapy has been observed in obese women. In a case control study of 200 patients who received adjuvant radiotherapy after lumpectomy or mastectomy, Allen and colleagues identified BMI as an independent predictor of radiation pneumonitis in multivariate analysis (p < .01) (26). It is hypothesized that this association may be due, in part, to increased dose delivery to the lung based on body habitus, an increased incidence of comorbid pulmonary conditions among overweight and obese patients, and elevations in circulating proinflammatory mediators, which have been documented in both obese individuals and those at risk for pneumonitis. Obesity is an independent risk factor for the development of ipsilateral arm edema following radiation therapy (27). Factors related to patient size, such as breast volume, are also strongly associated with poor cosmetic outcomes (28) and skin toxicity (29).

SYSTEMIC THERAPY

Obesity can also interfere with the effective delivery of systemic therapy. Investigators have identified many contributing factors to explain the suboptimal outcomes observed with chemotherapy and endocrine interventions in overweight and obese women which fall into two main categories: inadequate dosing and reduced efficacy.

CHEMOTHERAPY

Historically, cytotoxic chemotherapeutic agents have been dosed based on body surface area (BSA). Unfortunately, for drugs with fat solubility and consequently a higher volume of distribution, the use of BSA may result in relative underdosing of overweight and obese patients. Additionally many physicians "cap" the total administered dose for some drugs in obese patients by using a maximum weight in order to minimize toxicity. On average, overweight and obese women are at an increased risk for dose reductions or treatment delays. In a study of 20,799 early-stage breast cancer patients, BSA greater than 2 m^2, which approximates to an obese BMI, was an independent risk factor for the delivery of relative dose intensity less than 85%, a threshold that has been associated with decreased clinical benefit (30).

Adjuvant Chemotherapy

Less favorable outcomes following adjuvant chemotherapy have been reported among overweight and obese women. Several studies including a pooled analysis of three large, randomized trials coordinated by the Eastern Cooperative Oncology Group evaluating various adjuvant therapy regimens have demonstrated that obesity is associated with inferior outcomes (7). In one of these three studies (E1199) obesity was strongly associated with decreased disease-free survival (HR 1.24, 95% CI 1.06–1.46, p = .0079), overall survival (HR 1.37, 95% CI 1.13–1.67, p = .0015), and breast cancer–specific survival (HR 1.40, 95% CI 1.11–1.76, p = .0042) in multivariate analyses. Importantly, this negative prognostic effect of obesity was demonstrated despite the use of modern anthracycline and taxane-based chemotherapy regimens in this study. This suggests that despite advances in systemic therapy, obese patients remain at risk of worse clinical outcomes.

Neoadjuvant Responses

In the preoperative or "neoadjuvant" setting, an inverse relationship between BMI and the efficacy of cytotoxic chemotherapy has been reported in several studies. In a large cohort of nearly 1,200 patients who received preoperative chemotherapy, overweight and obese individuals were less likely to achieve a pathological complete response than nonobese patients (OR 0.67, 95% CI 0.45–0.99) (31). However, actual administered doses were not verified in this study and thus it is unclear whether the decreased response to chemotherapy was a result of some degree of inadequate dosing in this setting. As mentioned earlier, concern over increased toxicity has led many clinicians to adopt a practice of limiting doses in overweight and obese patients and, consistent with this practice, several studies have demonstrated lower rates of toxicity in obese women compared to patients of normal weight, including fewer hospital admissions (BMI over 35; OR 0.61, 95% CI 0.38–0.97) and fewer neutropenic events overall (BMI over 25; OR 0.49, 95 % CI 0.37–0.66) (32). Conversely, low body mass index (BMI) (less than 23 kg/m^2) was associated with a higher risk of febrile neutropenia (OR 4.4, 95% CI 1.65–12.01). All of these observations could reflect the impact of unreported dose-capping by clinicians or the routine use of hematopoietic growth factor support in obese patients receiving adjuvant chemotherapy.

Practical Considerations for Chemotherapy

With increasing attention being paid to the impact of obesity on chemotherapy dosing and its influence on treatment efficacy and toxicity, the American Society of Clinical Oncology issued clinical practice guidelines for the optimal dosing of obese patients (33) (Table 49-2).

TABLE 49-2

Adapted from the American Society of Clinical Oncology Clinical Practice Guidelines for Chemotherapy Dosing for Obese Adult Patients with Cancer

- Actual body weight should be used when dosing both oral and intravenous cytotoxic chemotherapy doses for all patients including those who are overweight and obese particularly in the curative setting.
- For morbidly obese patients (BMI of 35 kg/m^2 or more), full weight-based dosing is also recommended.
- Dose reduction for adverse events should be consistent for all patients and full weight-based doses for subsequent cycles should be attempted provided the toxicity has resolved.
- The use of fixed-dose cytotoxic chemotherapy should be limited to specific agents with established maximum doses secondary to toxicity such as vincristine, bleomycin, and carboplatin.

Data from Griggs JJ, Mangu PB, Anderson H, et al. Appropriate chemotherapy dosing for obese adult patients with cancer: American Society of Clinical Oncology clinical practice guideline. *J Clin Oncol* 2012;30:1553–1561.

These recommendations state that actual body weight should be used when dosing both oral and intravenous cytotoxic chemotherapy for almost all patients, including those who are overweight and obese particularly in the curative setting.

ENDOCRINE THERAPY

Traditionally, endocrine therapies such as tamoxifen and aromatase inhibitors have not been dosed according to weight or BSA. However, a post hoc analysis of the Arimidex, Tamoxifen Alone or in Combination (ATAC) study demonstrated a higher rate of distant plus local recurrences (HR 1.39, 95% CI 1.06–1.82) in women with high BMI (over 35 kg/m^2) versus BMI less than 23 kg/m^2 at baseline. In the multivariate analysis, treatment with anastrozole was shown to be significantly less effective in postmenopausal women in the highest BMI quintile when compared to women in the lowest quintile (HR 1.53, 95% CI 1.01–2.32, p = .001) (34). In contrast, in this study (34) and others tamoxifen was equally effective across all BMI groupings. One possible explanation for the reduced efficacy of certain endocrine therapies in obese women is the inadequate suppression of elevated estrogen levels, commonly seen in overweight and obese patients, by aromatase inhibitors like anastrozole. This hypothesis is supported by work by Folkerd and colleagues which demonstrated a direct correlation between circulating estradiol levels and increasing BMI (ρ = .57, p < .001) (35). Results of this study are consistent with another report by Ewertz et al. which suggested a difference (not statistically significant in this report) in survival outcomes for obese versus normal-weight patients treated with either letrozole or tamoxifen (HR = 1.22; 95% CI 0.93–1.60 and HR = 1.18; 95% CI 0.91–1.52, respectively) (36). Randomized prospective trials are warranted in this setting to further elucidate whether dose adjustments or the preferential use of more potent aromatase inhibitors can improve outcomes for overweight and obese patients. If obesity is found to activate ER signaling by both ligand-independent and ligand-dependent mechanisms, higher doses of aromatase inhibitor or more potent agents may not yield added clinical benefit. If so, alternate treatments may be required.

OBESITY-DIRECTED INTERVENTIONS

Obesity is a modifiable risk factor. Therefore, interventions such as lifestyle changes and the development of agents that target obesity-related pathophysiological pathways have the potential to have an impact on breast cancer incidence, morbidity and mortality.

BEHAVIORAL INTERVENTIONS

Weight Loss and Exercise

The maintenance of a BMI less than 25—either through physical activity, diet modification, or a combination of the two—has been associated with improved outcomes for women diagnosed with breast cancer in multiple observational studies. For example, in the Nurses' Health Study approximately 3,000 women with early stage breast cancer were followed for a median of 8 years and serially surveyed to assess the relationship between reported activity levels and breast cancer–related outcomes. Women who reported engaging in at least 3 to 5 hours of physical activity per week, equivalent to walking at an average pace (2.0–2.9 mph), derived the greatest benefit in terms of breast cancer–related morality (RR 0.50, 95% CI 0.31–0.82) (37).

The effect of dietary modifications on breast cancer–related outcomes is an area of active research. The Women's Intervention Nutrition (WINS) Study randomized 2,437 women between 1994 and 2001 to evaluate the influence of dietary fat reduction on relapse-free survival in patients with early stage breast cancer. The dietary fat intake in the investigational arm (involving registered dietitians implementing a low-fat eating plan with individual goals and regular counseling sessions) was significantly lower than in the control arm at one year (33.3 fat grams/day (95% CI 32.3–34.5) versus 51.3 fat grams/day (95% CI 50.0–52.7, p < .001) and this difference was maintained over the course of 5 years of follow-up. On average, women in the intervention arm lost approximately 6 pounds and, at a median follow up of 60 months, had a lower risk of relapse than those in the control arm (HR 0.76, 95% CI 0.60–0.98). Interestingly, the dietary modifications had the greatest effect on relapse-free survival in the ER-negative subset (HR 0.58, 95% CI 0.37–0.91) suggesting that obesity may promote breast cancer pathogenesis via estrogen independent mechanisms, in addition to estrogen-dependent pathways (38). Because the lower-fat diet was associated with weight loss, the WINS is not able to resolve the contribution of a particular diet as opposed to calorie restriction and weight loss specifically. In contrast, the Women's Healthy Eating and Living (WHEL) study failed to demonstrate a lower risk of recurrence among breast cancer survivors randomized to a low-fat, high-fiber, high intake of fruits and vegetables diet (39). Notably, unlike the WINS study, the women randomized to the intervention diet did not have similar resultant weight loss. Hence, one possible explanation for the difference in effect on breast cancer outcomes observed in these two studies may be that weight loss may be more important than the type of dietary intervention strategy.

In an effort to better characterize the causal relationships between obesity and breast carcinogenesis, many studies have evaluated the effect of diet and weight loss on circulating biomarkers implicated in obesity-related pathways. Campbell and colleagues reported the results of a randomized controlled trial examining the effect of aerobic exercise versus calorie reduced diet either alone or in combination on sex hormone levels in postmenopausal women with a BMI over 25 kg/m^2. Women randomized to the combination arm of exercise and reduced calorie diet demonstrated a reduction in circulating estradiol levels by 20.3% (p < .001) and an increase in SHBG by 25.8% (p < .001) (40). Statistically significant reductions in serum levels of insulin, highly sensitive CRP, and leptin were also observed with diet-induced weight loss as was increased adiponectin levels. Several studies have reported similar favorable changes after weight loss in these, as well as other, inflammatory biomarkers that have been implicated in breast cancer development and progression. These results have established the association between weight loss and improved breast cancer outcomes and circulating biomarker levels and confirmed the feasibility of effecting durable lifestyle changes and weight loss through dietary and exercise interventions. Collectively, these findings can serve as the blueprint for future prospective trials focused on evaluating the effect of lifestyle changes on breast cancer outcomes and the parallel development of predictive biomarkers of benefit.

Pharmacologic Agents

As our understanding of the biological underpinnings linking obesity with breast carcinogenesis evolves, so does research to develop novel therapeutic agents to target metabolic

and inflammatory pathways known to be dysregulated in overweight and obese women with breast cancer.

Metformin

Retrospective data suggest that metformin, an oral antidiabetic agent, is associated with reduced cancer incidence and mortality. A meta-analysis of 11 studies demonstrated that metformin was associated with a reduction in all cancer incidence or mortality, reported as a summary relative risk (SRR), in comparison to other antidiabetic agents (SRR 0.69, 95% CI 0.61–0.79). A nonsignificant decrease in breast cancer risk was observed (41). It is hypothesized that in the setting of obesity, metformin may act indirectly to reduce cancer risk or progression via AMPK-mediated inhibition of hepatic gluconeogenesis resulting in lower levels of circulating insulin, a hormone suggested to play a role in carcinogenesis. A second more direct effect is also postulated whereby metformin activates AMPK in tumor cells. This causes downstream inhibition of mammalian target of rapamycin (mTOR) resulting in decreased protein synthesis, tumor cell proliferation, and increased apoptosis. Prospective neoadjuvant "window of opportunity studies" in which patients are administered metformin from the time of their diagnostic core biopsy up until their surgical resection have demonstrated a reduction in circulating insulin levels as well as alterations in gene expression, decreased proliferative index, and increased apoptosis (42). Currently, several prospective phase II and III trials are accruing patients to further investigate the anticancer effects of metformin.

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit the cyclooxygenase activity of COX-1 and 2, important enzymes in the biosynthesis of prostaglandins which play an important role in carcinogenesis. Although both epidemiologic studies and prospective randomized clinical trials have demonstrated that use of NSAIDs is associated with risk reduction for colorectal cancer, the data for breast cancer remain inconsistent. Recently, Zhang and colleagues explored the relationship between NSAID use and breast cancer risk within the Nurses' Health Study, which includes detailed and routinely updated information about NSAID use. In this cohort, approximately 4,700 invasive breast cancers were diagnosed over a period of 28 years and no significant difference in breast cancer incidence was demonstrated between regular aspirin users and nonusers. This lack of benefit was also reported both among users of nonaspirin NSAIDs and acetaminophen and did not vary based on either baseline patient or tumor characteristics or drug administration schedule (43). However, given the emerging data regarding the role of inflammation in the pathogenesis of breast cancer, the use of NSAIDs in more highly selected populations, such as the obese, remains an attractive area of active research (8).

Statins

Preclinical data suggest that statins (HMG-CoA reductase inhibitors) may have an antineoplastic role based on their pleiotropic effects on various cells and tissue. However, clinical data regarding the association between the use of statins and breast cancer risk are inconsistent. A meta-analysis of 24 observational studies failed to demonstrate a significant benefit in terms of breast cancer risk reduction for either short-term or chronic statin use (44). This may in part be due to the observational nature of these studies and the inherent biases associated with this type of analysis as well as difficulties acquiring complete and accurate cancer-related outcome data, since these studies were largely designed with primary cardiac and vascular endpoints. Moreover, preclinical studies suggest that only lipophilic statins are able to traverse the cell membrane and affect cell proliferation, invasion, and apoptosis. Therefore, well-planned randomized prospective trials are necessary to more clearly evaluate the role of these agents in breast cancer prevention and treatment.

Docosahexaenoic Acid (DHA)

Docosahexaenoic acid (DHA), an omega-3 fatty acid in fish oil, can suppress inflammation by multiple mechanisms including inhibition of TLR4-activated signaling pathways that induce TNF-α and COX-2. Diets rich in fish oil have been associated with a reduced risk of a number of malignancies including breast cancer. Consistent with other targeted therapies, specific dietary factors including omega-3 fatty acids may be beneficial only in subsets of patients. Therefore, trials to evaluate the anti-inflammatory and potentially antineoplastic effects of DHA are currently underway in multiple cancers including breast cancer, with a focus on higher risk cohorts where the impact may be demonstrable.

CONCLUSION

The effect of obesity on breast cancer development and natural history is complex and is becoming increasingly important, as a larger proportion of the population has elevated BMIs. Overweight and obesity are associated with an increased risk of ER-positive breast cancer in postmenopausal women, and may be associated with increased risk for other subtypes of the disease, specifically the triple-negative phenotype. Following a diagnosis of breast cancer, increasing BMI is associated with worsened breast cancer specific outcomes. Increasing adiposity presents a series of challenges for the optimal clinical management of breast cancer in terms of detection, local therapy (surgery and radiotherapy), and systemic treatment. Diet and exercise may attenuate the adverse prognostic impact of obesity to some degree, but novel therapeutic strategies are urgently needed to combat the complex interaction between the obesity epidemic and breast cancer. These strategies will need to focus on the specific pathophysiology of obesity, as it relates to breast cancer, rather than simply on BMI alone. Hence, as prospective clinical trials are designed and developed in this arena we must consider, similar to other targeted therapies, that the efficacy of these novel agents may be patient specific in identifiable ways. In the future, a more individualized approach to obesity may allow us to both prevent breast cancer and treat it more effectively, despite the special challenges presented by obesity and overweight.

MANAGEMENT SUMMARY

- Obesity is associated with an increased risk of ER-positive breast cancer in postmenopausal women and possibly triple-negative disease.
- Increasing body mass index (BMI), a commonly used metric of obesity, is associated with a series of challenges for the optimum detection and management of breast cancer, including increased surgical complications, and difficulties in the delivery of safe and effective radiotherapy and systemic therapy.

- Guidelines from the American Society of Clinical Oncology suggest that clinicians should generally use actual body weight when calculating both oral and intravenous cytotoxic chemotherapy doses, including for patients who are overweight and obese.
- Clinicians and other health care professionals should encourage regular physical activity, adherence to a healthy balanced diet, and weight management during all phases of breast cancer care.
- Novel approaches based on the underlying pathophysiology of overweight and obesity are urgently needed and clinical trial participation should be encouraged.

CHAPTER 50

Lifestyle Issues in Breast Cancer Survivors

Jennifer A. Ligibel and Rowan T. Chlebowski

CHAPTER CONTENTS

Evidence increasingly suggests that lifestyle factors such as diet, physical activity, and body weight may play an important role in breast cancer survivors. Observational studies suggest that obesity, inactivity, and possibly differences in dietary intake may influence breast cancer prognosis (1,3). Studies have also demonstrated that interventions targeting weight, diet, and physical activity lead to better quality of life and fewer disease and treatment-related side effects in breast cancer survivors (4,5). Preliminary evidence suggests that lifestyle change may also improve prognosis in early stage breast cancer (6), but much work still needs to be done to validate this and to determine which types of lifestyle change are most important. This chapter outlines the observational evidence regarding lifestyle and breast cancer outcomes, with emphasis on recent reports, and presents an overview of lifestyle intervention studies in breast cancer survivors.

BODY WEIGHT AND BREAST CANCER

More than 50 observational studies have looked at the relationship between weight at the time of breast cancer diagnosis and clinical outcomes (1,7–10). Studies have focused on different populations, used different weight measures, and have been conducted in different eras. Despite these differences, the majority of these studies have demonstrated an increased risk of breast cancer recurrence and mortality in individuals who are obese at the time of breast cancer diagnosis as compared to leaner individuals. A recent meta-analysis by Protani et al. (1) included 43 studies looking at the relationship between weight at diagnosis and outcomes; the report demonstrated a 33% increase in breast cancer–specific and overall mortality in individuals who were obese (body mass index [BMI] 30 kg/m^2 or over) at the time of breast cancer diagnosis compared to individuals who were not obese (BMI less than 30 kg/m^2). The relationship between poor prognosis and obesity was seen in both pre- and postmenopausal women, and was also independent of type of weight measurement (BMI vs. other measure), year of report, and type of study (observational cohort vs. treatment trial).

Potential Influence of Treatment Factors

Although the Protani meta-analysis showed a relationship between poor prognosis and obesity both in the setting of clinical trials and observational cohort studies, it is notable that only 7 of the 45 reports included in the analysis collected data in the setting of a clinical trial, and few other reports included in the analysis adequately controlled for systemic adjuvant therapy (1). Recent attention has focused on optimizing adjuvant therapy for obese cancer patients, as concerns regarding toxicity have led many oncologists to cap or otherwise adjust chemotherapy doses in obese patients. Studies have shown that these a priori dose reductions in obese patients lead to inferior outcomes (11,12). For example, in Cancer and Leukemia Group B 8541 (12), a randomized trial of adjuvant anthracycline-based chemotherapy in women with node-positive breast cancer, obese women who received less than 95% of expected weight-based doses of chemotherapy for their first cycle of therapy had an increased risk of cancer recurrence as compared to obese women who received full weight-based chemotherapy (adjusted risk ratio [ARR] 0.73, 95% confidence interval [CI] 0.53–1.00). Obese women treated with full weight-based doses of chemotherapy had a similar risk of recurrence as compared to leaner women (ARR 1.02, 95% CI 0.83–1.26). Findings such as these prompted the American Society of Clinical Oncology to issue guidelines for the treatment of obese patients (13), which recommended full weight-based dosing of chemotherapy for all patients, regardless of body weight.

Body Weight and Breast Cancer Outcome (in Cooperative Group Trials)

Given the potential influence of treatment factors on the relationship between obesity and poor breast cancer prognosis, data from clinical trials, where treatments are uniform, doses are recorded, and outcomes are well documented, are especially relevant. A number of recent reports (Table 50-1) examine the relationship between obesity and breast cancer prognosis in the setting of modern adjuvant therapy trials. These studies continue to show a fairly consistent relationship between obesity at the time of breast cancer diagnosis and increased risk of recurrence and death in women with early-stage breast cancer treated with aromatase inhibitors (10,14,15) and modern anthracycline- and taxane-based chemotherapy regimens (7–9).

The relationship between BMI at the time of breast cancer diagnosis and outcomes has been evaluated in three large adjuvant aromatase inhibitor trials. In each of these, the Anastrozole, Tamoxifen, Alone or in Combination (ATAC) trial, the Breast International Group (BIG) 1-98 trial, and the Austrian Breast Cancer Study Group (ABCSG) 12 trial, obesity was associated with a significantly higher risk of breast cancer recurrence. However, in the ATAC and ABCSG 12 studies, obesity was associated with poor outcomes only in patients treated with anastrozole and not in patients treated with tamoxifen. In contrast, the BIG 1-98 trial, which randomized women to letrozole or tamoxifen, demonstrated a modest relationship between obesity and worse overall survival in the study population as a whole (OR 1.19, 95% CI 0.99–1.44), but did not see a difference in the relationship between etiology of obesity and poor outcomes in women treated with letrozole versus those treated with tamoxifen (p = .74). The difference in outcomes in obese aromatase inhibitor-treated women in these studies is not clear, but could potentially be a reflection of the relative potencies of the drugs (16). One report from the ALIQUOT study suggested that suppression of estradiol was more complete in obese women treated with letrozole as compared to anastrozole, although it is not clear whether these differences are clinically meaningful (17,18).

Obesity at diagnosis has also been linked to a higher risk of recurrence in individuals treated in the context of recent adjuvant chemotherapy trials. Three recent trials—the Eastern Cooperative Oncology Group (ECOG) 1199 trial, the ADEBAR study, and CALGB 9741—have all evaluated the relationship between BMI at diagnosis and outcomes in women treated with adjuvant anthracyclines and taxanes. In all three studies, individuals who were obese at the time of breast cancer diagnosis had an increased risk of breast cancer recurrence and/or mortality as compared to leaner women. In E1199, this finding was seen only in women with hormone-receptor-positive tumors, whereas in CALGB 9741, obesity was a poor prognostic factor in both estrogen-receptor-positive and estrogen-receptor-negative tumors. These reports provide provocative information regarding

Obesity and Breast Cancer Prognosis in Recent Adjuvant Chemotherapy and Hormonal Therapy Randomized Trials

Study	*N*	*Study Treatment*	*Patient Population*	*Results*
ABCSG 12 (15)	1,684	Ovarian suppression + tamoxifen or anastrozole	Premenopausal women	-Anastrozole: BMI ≥25 kg/m^2 vs. <25 kg/m^2: • HR recurrence 1.60 (95% CI 1.06–2.41) • HR death 2.14 (95% CI 1.17–3.92) -Tamoxifen: No increased risk of recurrence or death seen in overweight women
ATAC (14)	4,939	Tamoxifen, anastrozole, or combination	Postmenopausal women	-BMI ≥35 kg/m^2 vs. <23 kg/m^2: • HR for recurrence 1.39 (95% CI 1.06–1.82) -Anastrozole significantly less effective in women with BMI >30 kg/m^2 vs. <28 kg/m^2 (p = .01)
BIG 1-98 (10)	4,760	Letrozole or tamoxifen	Postmenopausal women	-BMI ≥30 kg/m^2 vs. BMI <25 kg/m^2: • HR OS 1.19 (95% CI 0.99–1.44) -Efficacy of letrozole not dependent on BMI
ADEBAR (8)	1,500	5-FU, Epirubicin, cyclo-phosphamide vs. epirubicin, cytoxan-docetaxel	Pre and postmeno-pausal women	BMI ≥30kg/m2 vs. BMI > 25 and <30 kg/m^2: -Significantly worse DFS (p = .0075)
E1199 (7)	3,484	Doxorubicin, cyclo-phosphamide and taxane	Pre- and postmeno-pausal women	-HR positive tumors: BMI ≥30 vs. <30 kg/m^2 • HR recurrence 1.24 (95% CI 1.06–1.46) • HR death 1.37 (95% CI 1.13–1.67) -HR negative and HER-2 positive tumors: No association between obesity and prognosis
C9741 (9)	1,909	Doxorubicin, cyclophosphamide and paclitaxel	Pre- and postmeno-pausal women	-In multivariate analyses, each unit increase in BMI associated with 1.5% increase risk of recurrence and death • BMI 32 vs 22: HR for RFS 1.22 (p = .01) -No interaction between HR status and relationship between BMI and outcomes

the potential role of obesity in altering breast cancer outcomes even in patients receiving contemporary anticancer adjuvant treatment.

Weight Gain after Diagnosis and Breast Cancer Outcome

The association between obesity and poor prognosis in early-stage breast cancer is especially worrisome given the weight gain seen in many women following diagnosis where, even with anthracycline-based adjuvant regimens, weight gain of 2 to 6 kg is commonly reported (19). A number of older studies suggest that weight gain after breast cancer diagnosis is associated with poor prognosis, but recent reports have been less consistent. A report from the Nurses' Health Study found that nonsmoking women with early-stage breast cancer who gained 2.0 kg/m^2 or more (median weight gain of 17 pounds) had higher risk of breast cancer recurrence, breast cancer death, and all-cause mortality than did women who did not gain weight (20). Other recent reports, including an analysis of the Life After Cancer Epidemiology Study Cohort (21), have not shown a relationship between weight gain and breast cancer prognosis.

Weight-Loss Studies in Breast Cancer Survivors

Despite the consistent evidence that obesity at the time of breast cancer diagnosis is a poor prognostic factor, there are no data from randomized trials demonstrating that purposeful weight loss after diagnosis will lead to improvements in prognosis. Many experts have speculated that the difference in findings of two large-scale dietary intervention trials (6,22) (see description below in dietary section), one of which induced weight loss and the other of which did not, provides evidence that weight change after diagnosis will lower the risk of cancer recurrence and related mortality, but large-scale trials are needed to test this hypothesis.

A number of smaller-scale trials have been performed in breast cancer populations demonstrating the feasibility and benefits of weight-loss interventions (23). The largest weight-loss study in breast cancer survivors to date, the Lifestyle Intervention Study for Adjuvant Treatment of Early Breast Cancer (LISA) trial, randomized 338 postmenopausal women with hormone-receptor-positive breast cancer to an educational control group or to a 2-year, telephone-based weight-loss intervention focused on calorie restriction, a low-fat diet, and increased physical activity. Intervention participants lost approximately 4.5 kg more than the control group at 6, 12, 18, and 24 months and reported a significant improvement in physical functioning scores as compared to control participants (5). A number of other weight-loss studies, including the ENERGY, SUCCESS-C, DIANA-5, and CHOICE trials, will provide additional information regarding the efficacy and benefits of weight-loss interventions in breast cancer survivors.

PHYSICAL ACTIVITY AND BREAST CANCER

A number of reports over the last several years have examined the relationship between physical activity and breast cancer outcomes (2). A recent systematic review identified 17 studies evaluating the association between physical activity patterns before and/or after cancer diagnosis and breast cancer–specific and overall mortality (2). Studies largely focused on recreational physical activity, although a few evaluated occupational and household activity as well. Most of the data were collected from prospective cohorts of healthy individuals who subsequently developed cancer or from cohorts of cancer survivors. Physical activity was assessed using a variety of interviewer-administered or questionnaire-based instruments; all of the data were self-reported. Only a few of the studies accounted for BMI, tumor stage, or treatment variables.

The review found consistent evidence that higher levels of physical activity both before and after breast cancer diagnosis were associated with a lower risk of breast cancer–specific and overall mortality (Fig. 50-1). No study reported

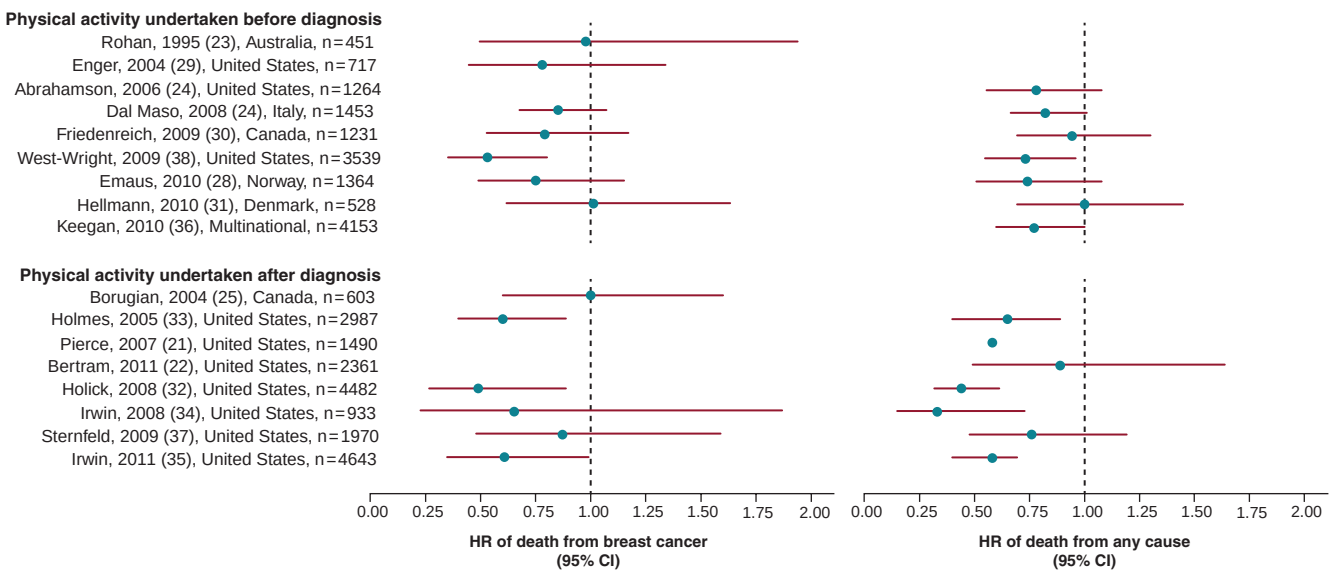

FIGURE 50-1 Forest plot of risk estimates from observational studies of physical activity and mortality outcomes in breast cancer survivors. (Redrawn from Ballard-Barbash R, Friedenreich CM, Courneya KS, et al. Physical activity, biomarkers, and disease outcomes in cancer survivors: a systematic review. *J Natl Cancer Inst* 2012;104[11]:815–840. doi:10.1093/jnci/djs207.)

an increased risk of cancer-specific or overall mortality with increased levels of physical activity. Thirteen of 16 reports evaluating the relationship between physical activity and breast cancer–specific mortality demonstrated a 13% to 51% lower risk of mortality in physically active individuals. Similarly, 12 of 14 studies evaluating the relationship between physical activity and all-cause mortality found lower rates of mortality in individuals who reported higher levels of physical activity.

Of note, although some reports suggested a dose–response relationship between increasing physical activity and improved outcomes, many reports demonstrated an improvement in prognosis with relatively modest levels of physical activity. For example, the NHS investigators prospectively examined relationships between physical activity and clinical outcomes in a cohort of 2,987 women diagnosed with stage I to IIIA breast cancer (24). Women who reported 9 to 14.9 MET hours of physical activity per week, equivalent to 3 to 5 hours per week of moderate pace walking, had a 50% lower risk of breast cancer mortality as compared to women who completed less than 3 MET hours per week of physical activity. A similar relationship between performance of relatively modest levels of physical activity after diagnosis and improved outcomes was reported in the Collaborative Women's Longevity Study (25), in which long-term breast cancer survivors who reported at least 2.8 MET hours per week of physical activity had significantly lower breast cancer mortality when compared to women with lower levels of activity. Taken together, the results are consistent with a modest increase in physical activity being associated with substantial improvement in clinical outcome for patients with early-stage breast cancer.

Physical Activity Interventions in Breast Cancer Survivors

Despite the observational data suggesting better outcomes in women who engage in modest levels of physical activity after cancer diagnosis, there are no randomized trials testing the impact of increased physical activity after diagnosis upon prognosis in women with early-stage breast cancer. Observational studies have demonstrated that a breast cancer diagnosis often is associated with a substantial decrease in physical activity (26), further underscoring the need for interventions designed to increase physical activity in breast cancer survivors.

Dozens of studies have tested the feasibility and potential benefits of physical activity interventions in breast cancer patients receiving adjuvant therapy and in the posttreatment setting (4). Studies have implemented both supervised and home-based intervention programs and have focused on a variety of exercise modalities including walking, cycling, yoga, strength training, and rowing. The American College of Sports Medicine recently published a comprehensive review of exercise intervention studies in cancer populations which included data from 54 randomized controlled trials of exercise in breast cancer survivors deemed to have high internal validity, based upon low rates of attrition, high rates of adherence, and standardization of the intervention (4). In both the adjuvant and posttreatment settings, there was consistent evidence to suggest that physical activity interventions were safe and led to increased aerobic fitness and strength. A modest level of evidence also suggested that individuals who participated in physical activity interventions experienced improvements in quality of life, anxiety, depression, fatigue, body image, body size, and body composition, although not all studies were consistent in these findings. Large-scale, randomized clinical trials are needed to determine whether increasing physical activity after breast cancer diagnosis will not only help women feel better, but also lead to improvements in prognosis.

DIETARY INTAKES AND BREAST CANCER OUTCOME

Studying the relationship between postdiagnosis dietary intakes and breast cancer prognosis represents an especially challenging area for observational studies, with methodologic issues related to the optimal timing of data collection, difficulty in accurately measuring the dietary exposure, and the modest range of intake for nutrients of interest in a general population (27).

The relationship between dietary fat intake and breast cancer outcome has been examined in more than a dozen observational studies (3). Although recent analyses suggest that commonly used instruments may have difficulty in accurately measuring this parameter, seven reports demonstrated a significant association between lower fat intakes and lower recurrence risk (3,19). These reports did not adjust for BMI or total energy intake, however, making interpretation problematic. Reports relating vegetable and related nutrient intake to breast cancer prognosis presents a similarly mixed picture with three of eight reports describing significant associations between higher intake and lower recurrence risk (3). Recently, two randomized clinical trials have provided a higher level of evidence on the question of the influence of nutrient intake on breast cancer outcomes.

Dietary Intervention Studies and Breast Cancer Outcomes

Two full-scale randomized clinical trials have evaluated lifestyle interventions targeting dietary change in the adjuvant breast cancer setting. The Women's Intervention Nutrition Study (WINS) (6) and Women's Healthy Eating and Living (WHEL) study (22) enrolled slightly different populations and studied different dietary patterns, but both aimed to reduce dietary fat intake. These trials are compared and contrasted below (Table 50-2).

The WINS was a randomized, prospective multicenter clinical trial evaluating the impact of a dietary intervention on disease-free survival (DFS) in women with early-stage breast cancer receiving conventional cancer management (6). The dietary intervention was designed to reduce fat intake with eight every-other-week visits during the intensive intervention period followed by every-3-month contacts during the maintenance period, implemented by centrally trained, registered dietitians using a previously developed low-fat eating plan. After 5.6 years' median follow-up, a sustained statistically significant reduction in dietary fat intake, in terms of both fat grams and percent calories from fat, was seen in intervention participants (Table 50-2). Although weight loss was not a specific intervention target, significantly lower body weight was also seen in the intervention group throughout. More relapse events occurred in the control (181 of 1,462, 12.4%) compared with the intervention group (96 of 975, 9.8%, HR 0.76, 95% CI 0.60–0.98, $p = .034$). Preliminary analyses from an additional 3 years of follow-up provided similar results (relapse-free survival HR 0.79, 95% CI 0.62–1.00), but the difference was no longer statistically significant (28). In exploratory analyses, substantially greater influence was seen in women with ER-negative, PR-negative breast cancer (overall survival HR 0.34, 95% CI 0.16–0.70) (28).

TABLE 50-2

Dietary Intervention Studies with Breast Cancer Outcomes

	WINS	*WHEL*
Eligibility		
Stage	I–III A	I–III A
Time from surgery	≤12 mo	≤48 mo
Age	48–79 yr	18–70 yr
Diet at baseline	≥20% calories from fat	Any
Dietary intervention	Individual sessions with dietitian	Telephone-based sessions
Number of patients	2,437 (3:2 randomization)	3,088 (1:1 randomization)
Intervention target		
Fat	↓ to 15% calories from fat	↓ to <20% calories from fat
Vegetable	Increase (no target)	Increase to 5 servings and 16 oz vegetable juice/day
Fruit	Increase (no target)	Increase to 3 servings/day
Follow-up interval	5 yr	7.3 yr
Change in dietary intakes (intervention vs. control)		
Fat	–33%	–13%
Vegetables	Not reported	+65%
Fruit	Not reported	+25%
Weight change (intervention vs. control)	–2.7 kg	None
End-point events (*n*)	277	518
Primary breast cancer outcome	HR 0.76 (95% CI 0.60–0.98, $p = .034$)	0.96 (95% CI 0.80–1.14, $p = .63$)

WINS, Women's Interventional Nutrition Study; WHEL, Women's Healthy Eating and Living Study.

The WHEL study was a multicenter, randomized prospective trial of a dietary intervention program in 3,088 women with early-stage breast cancer designed to determine whether a diet focused on increasing intakes of vegetables, fruit, and fiber intake and decreasing fat, would influence breast cancer recurrence risk and all-cause mortality (22). Intervention participants received a telephone counseling program involving 18 calls during the first year with a subsequent decrease in intensity. Significant changes were achieved in the nutrition targets: vegetables plus 65%, fruit plus 25%, fiber plus 30%, and energy intake from fat minus 13%. Over the 7.3-year mean follow-up, no difference emerged in invasive breast cancer events (HR 0.96, 95% CI 0.80–1.14, $p = .63$) or overall survival (HR 0.91, 95% CI 0.72–1.15; $p = .43$) (22).

Although both WINS and WHEL included dietary fat intake reduction as an objective and entered early-stage breast cancer patients, substantial differences between these trials exist. The WHEL intervention resulted in a substantial and sustained increase in vegetable, fruit, and fiber intake and a relatively short duration, moderate reduction in fat intake. The WINS intervention did not report increased vegetable, fruit, or fiber intake, but resulted in a substantial, sustained reduction in fat intake, which was associated with significant weight loss that may account for the apparent differences in influence on clinical outcome seen.

POTENTIAL MEDIATORS OF LIFESTYLE CHANGE

The biologic mechanisms underlying the relationship between lifestyle factors and cancer prognosis are not well understood. Current hypotheses suggest these effects may be mediated through metabolic and inflammatory pathways that have been linked to cancer risk and prognosis (29–34). Inflammatory and metabolic pathways are interconnected and dysregulation of this system contributes to the development of many common diseases, including cancer (35). Of the many mediators that have been purported to link lifestyle factors and cancer, evidence is strongest to support a significant role of insulin in this process (30,36). Hyperinsulinemia has been linked to poor outcomes in patients with early-stage breast cancer in several studies (Table 50-3). For example, Goodwin and colleagues demonstrated a twofold increase in the risk of cancer recurrence and a threefold risk of death in newly diagnosed breast cancer patients with the highest quartile of fasting insulin levels compared to the lowest (31).
