Course	Progressive neurologic dysfunction; atrophy and weakness with C-7, T-1 distribution; pain persistent and/or progressive pain; Horner's syndrome	Progressive weakness with C-5, C-6 distribution; variable. Early pain with appearance of weakness	Transient weakness and atrophy affecting C-6, C-7, T-1; complete resolution of motor findings
Computed tomographic scan findings	Circumscribed mass with diffuse infiltration of tissue planes	Diffuse infiltration of tissue planes	Normal
Electromyographic findings	Segmental slowing; low incidence of myokymia	Myokymia present in 67% of patients	Segmental slowing; low incidence of myokymia

TABLE 35-19. Differentiating features of brachial plexopathy induced by tumor infiltration, radiation fibrosis, and reversible radiation injury

Lumbosacral Plexopathy

Direct tumor infiltration from adjacent soft tissues or lymph nodes or by compression from metastases in the adjacent bony pelvis can damage the lumbosacral plexus. Most lumbosacral plexopathy reflects local extension or nodal metastases from colorectal and other pelvic tumors (cervix, uterus, bladder, prostate), sarcomas, and lymphomas, but it may also occur with metastases from breast or lung cancer or melanoma (170). Saphner and colleagues (188) found lumbosacral plexopathy caused by retroperitoneal lymph node metastases the most common neurologic complication in patients with advanced cervical cancer.

The cardinal clinical feature of carcinomatous plexopathy is severe, unrelenting pain (189). The distribution of pain varies and may localize in the pelvis, low back or hip, or refer in a radicular or nonradicular pattern into the leg. The local pain is pressurelike or aching in quality. The referred pain varies with the site of plexus involvement and can be burning, crampy, or lancinating. Weeks to months after pain begins, sensory symptoms of numbness and paresthesias, as well as weakness and leg edema, usually develop. A “hot and dry foot” syndrome may result from lumbosacral plexopathy and may reflect sympathetic fiber dysfunction (190).

Lumbosacral plexopathy may cause different clinical syndromes depending on the level of nerve involvement. Infiltration of the upper plexus occurs in approximately one-third of patients, who present with pain in the back, lower abdomen, flank, iliac crest, or anterolateral thigh. This syndrome has associated L-1 to L-4 distribution neurologic deficits. Involvement of the lower plexus occurs in approximately one-half of patients, and these present with pain in the buttocks and perineum, with referral to the posterolateral leg and thigh. Examination may reveal associated L-4 to S-1 neurologic deficits, leg edema, and bowel or bladder dysfunction. Sacral plexopathy can signal direct bony extension of a bony sacral lesion or a presacral mass. Numbness of the dorsal medial foot and sole with associated weakness of knee flexion, ankle dorsiflexion, and inversion is typical of lumbosacral trunk extension. Involvement of the coccygeal plexus results in sphincter dysfunction and perineal sensory loss. Panplexopathy occurs in one-fifth of patients and pain may refer anywhere in the territory of the plexus. Associated leg edema is relatively common (190).

Jaeckle and colleagues (189) studied 85 cancer patients with lumbosacral plexopathy and documented pelvic tumor by CT or biopsy. They discerned three clinical syndromes: lower (L-4 to S-1), 51%; upper (L-1 to L-4), 31%; and panplexopathy (L-1 to S- 3), 18%. Seventy percent of patients had the insidious onset of pelvic or radicular leg pain, followed weeks to months later by sensory symptoms and weakness. The quintet of leg pain, weakness, edema, rectal mass, and hydronephrosis suggests plexopathy caused by cancer. CT showed pelvic tumor in 96%. On myelography, epidural extension, usually below the conus medullaris, occurs in 45%. With treatment, only 28% of patients had objective responses on CT and 17% on examination.

In previously treated patients, the main differential diagnostic consideration is radiation-induced plexopathy (see following discussion). Taylor et al. (191) found that MRI was more sensitive than CT for diagnosing cancer-induced lumbosacral plexopathy. Thus, MRI is the choice for the diagnostic workup of patients with clinical and electrophysiologic evidence of plexopathy and suspected systemic cancer. Studies should include the L-1 vertebral body through to the true pelvis. Neurologic findings include leg weakness, sensory loss, reflex asymmetry, focal tenderness (in the lumbar region in an upper plexopathy, sciatic notch and sacrum in a lower plexopathy, and lumbosacral region in panplexopathy), rectal mass, decreased sphincter tone, and positive direct and reverse straight- leg-raising signs.

Tumor Infiltration of the Sacrum and Sacral Nerves

Pain in a sacral distribution occurs usually as a result of the spread of bladder, gynecologic, or colon cancer. Dull aching pain occurs in the midline and usually burning or throbbing pain in the soft tissues of the rectal or perineal region. Sitting or lying usually exacerbates the pain. With bilateral involvement, sphincter incontinence and impotence are common. There may be tenderness over the sacrum and in the regions of the sciatic notches. Sometimes limitation of both direct and reverse straight leg raising occurs. Involvement of S-1 and S-2 roots produces weakness of ankle plantar flexion, and the ankle jerks may be absent. Usually, sensory loss occurs in the perianal region and genitalia, and this may be accompanied by hyperpathia.

Spinal and Radicular Pain

Patients perceive radicular pain as arising in a limb or trunk wall. The cause is ectopic activation of nociceptive afferent fibers in a spinal nerve or its roots or other neuropathic mechanisms. The pain is lancinating in quality and travels along a narrow band. It may be episodic, recurrent, or paroxysmal according to the causative lesion or any superimposed aggravating factors. Although patients may experience radicular pain as a deep tissue pain, it also has a cutaneous quality in proportion to the number of cutaneous afferent fibers ectopically activated. Radicular pain differs from nociception in the axons stimulated along their course; their peripheral terminals are not the site of stimulation. Ectopic activation may occur as a result of mechanical deformation of a dorsal root ganglion, mechanical stimulation of previously damaged nerve roots, inflammation of a dorsal root ganglion, and possibly by ischemic damage to the dorsal root ganglia. Acute spine pain may be described as cramping or knifelike, but may also be merely dull or aching. It is worse with movement. Chronic spine pain without a radicular component is generally aching, dull, or burning, or any combination of these three features. It also tends to be made worse with movement.

Central Pain Syndromes Caused by Cancer

Central pain syndromes are relatively infrequent in the cancer population. Although epidural spinal cord compression is almost always painful, central pain is not the predominant symptom; nociceptive input from progressive bony destruction by metastases is the usual cause of pain, with or without concurrent radicular pain from nerve root compression. Radiation myelopathy is a central pain syndrome.

Paraneoplastic Peripheral Neuropathy

Paraneoplastic syndrome refers to a group of disorders (caused by, or associated with, cancers) that are neither direct effects of the primary tumor mass nor metastatic to the involved organs. These disorders can affect virtually any portion of the nervous system. Most paraneoplastic syndromes stem from an autoimmune reaction to an *onconeural* antigen shared by the cancer and the nervous system (192). The immune reaction may retard growth of the cancer, but it also damages the nervous system. Autoantibodies found in individual patients with paraneoplastic syndromes are usually associated with specific tumors. Neurologic disorders, clinically and pathologically identical to paraneoplastic syndromes, may occur in some patients without cancer, but these patients do not have paraneoplastic antibodies. Diagnosis of a paraneoplastic syndrome depends on its increased incidence in patients with cancer, the occasional response of the neurologic syndrome to treatment of the underlying cancer, or the presence of specific autoantibodies.

A subacute sensory neuronopathy or ganglionopathy can cause dysesthesias, paresthesias, and sensory loss in the extremities (193). This represents an inflammatory process involving dorsal root ganglia and may result from antineuronal IgG antibody. The course is usually independent of the primary tumor, which is commonly small cell carcinoma of the lung (194). Sensorimotor peripheral neuropathies presenting with glove and stocking distribution may occur in cancer patients, with production of antibodies against peripheral nerves (195). Paraneoplastic peripheral neuropathies are uncommon (195). They are outnumbered by the more familiar peripheral neuropathies that occur either as a direct result of the cancer (metastases) or its treatment (usually chemotherapy).

Patients with cancer who suffer from a peripheral neuropathy usually do so from causes other than paraneoplastic syndromes. Examples of causes of peripheral

neuropathy in cancer patients are listed in Table 35-20.

Disease	Examples
Neoplastic invasion	Leptomeningeal metastases, neurolymphomatosis
Chemotherapeutic agents	Vinca alkaloids (vincristine), platinum alkaloids (cisplatin), taxoids
Nutritional neuropathies	Cancer cachexia, specific vitamin deficiencies (B_1, B_{12})
Metabolic disorders	Uremia (pelvic tumors), hypothyroidism (postradiation therapy), multiorgan failure (critical illness polyneuropathy)
Unrelated to cancer	Diabetes mellitus

TABLE 35-20. Examples of causes of peripheral neuropathy in cancer patients

Nevertheless, paraneoplastic peripheral neuropathies are important because they may be the first sign of an otherwise occult cancer or because they may substantially disable the patient even when the cancer itself is asymptomatic. Paraneoplastic disorders sometimes involve autoantibodies that react with proteins, both in the underlying cancer and in the nervous system. Their detection may lead to an early diagnosis and potential cure of the underlying cancer.

Four types of polyneuropathies constitute most of the cases of paraneoplastic peripheral neuropathy: motor, sensory, sensorimotor, and autonomic. Motor neuropathies may be acute or chronic, progressive or remitting, demyelinating, axonal, or neuronal. Clinically, they are indistinguishable from the more common nonparaneoplastic motor neuropathies, unless they resolve after treatment of the cancer or are associated with a paraneoplastic antibody. These disorders include the Guillain-Barré syndrome, which occurs more frequently in patients with Hodgkin's disease than in the general population; a remitting and relapsing polyneuropathy resembling relapsing chronic inflammatory demyelinating polyneuropathy; and a subacute motor neuronopathy affecting patients with Hodgkin's disease or other lymphomas. The sensory neuropathies include a subacute pansensory neuropathy and a predominantly distal sensory neuropathy. In approximately 20% of all patients with a subacutely developing pure sensory neuropathy, cancer is the underlying cause. Autonomic neuropathy usually develops in association with encephalomyelitis. However, some patients develop an isolated subacute pan-dysautonomia. Intestinal pseudoobstruction of the bowel is the best-characterized isolated autonomic symptom.

Neuropathic Pain Secondary to Therapeutic Interventions

Many pain syndromes occur in the course of or subsequent to treatment of cancer with surgery, chemotherapy, or radiation therapy. In most cases, injury occurs to the peripheral nervous system or spinal cord, with pain as a major and often presenting complaint. In some cases, these syndromes occur long after the therapy is implemented, resulting in a difficult differential diagnosis between recurrent disease and a complication of therapy.

Postsurgical Neuropathic Pain

Postmastectomy. Pain can be a prominent postsurgical finding in breast cancer patients. It tends to appear in the postmastectomy period, a consequence of the disruption of normal neural pathways, or it may follow the development of lymphedema or the presence of metastases. Chronic neuropathic pain after mastectomy occurs primarily in patients whose surgery included axillary dissection (197), although the problem can occur in women who undergo any surgical procedure on the breast from lumpectomy to radical mastectomy (198). Postaxillary dissection pain is probably a more appropriate name than the usual postmastectomy pain for this syndrome (199). The pain pattern typically involves paroxysms of lancinating pain against a background of burning, aching, tight constriction in the axilla, medial upper arm, chest, or all three areas. Hyperesthesia, dysesthesia, hyperalgesia, allodynia, or hypoesthesia in the intercostobrachial nerve distribution may occur. The etiology appears to be surgical damage to the intercostobrachial nerve (199,200). The intercostobrachial nerve is a cutaneous sensory branch of T-1 and T-2. The nerve is highly variable in size and distribution, making it difficult to avoid in these surgical procedures. Usually, the pain develops shortly after surgery, but it can emerge months after surgery. Late onset should prompt a search for other causes, such as recurrent chest wall disease or bone metastases. The postmastectomy pain syndrome differs from metastatic or radiation-induced brachial plexopathy in which there is a different pattern of sensory loss, lymphedema, and usually, more severe pain.

Neck Dissection. Radical neck dissection for head and neck cancers can result in an iatrogenic syndrome characterized by ipsilateral face and neck pain with associated paresthesias. Pain usually emerges weeks to months after surgery, consequent to injury to the cervical plexus or cervical nerves (156). Sensations of tightness with burning dysesthesias in the area of the sensory loss are its characteristic features. Occasionally, patients report acute lancinating pain in the area of sensory loss. Recurrent tumor can also be a cause of pain that occurs or escalates after neck dissection.

Thoracotomy. Shortly after thoracotomy, a neuropathic pain can develop in the distribution of one or several intercostal nerves near the thoracotomy scar. The pain may remain stable after onset and gradually decrease over a period of months or years. Dajczman and colleagues (201) evaluated the prevalence and functional significance of long-term postthoracotomy pain in 56 patients at least 2 months after surgery. Thirty patients (54%) with a median follow-up of 19.5 months had persistent pain; 26 others were pain free at a median of 30.5 months postthoracotomy. Twenty-four of 44 patients (55%) more than 1 year after surgery, 13 of 29 patients (45%) more than 2 years, 6 of 16 (38%) more than 3 years, and 3 of 10 patients (30%) more than 4 years postthoracotomy reported pain. Pain intensity was low, but 13 patients stated that pain slightly or moderately interfered with their lives. Five of 56 patients had sufficiently severe chronic pain to require daily analgesic use, nerve blocks, relaxation therapy, acupuncture, or referral to a pain clinic. Pain that increases with time, or that first appears more than 3 months after surgery, may signal recurrent tumor and should prompt further investigation.

Phantom Pains. Phantom pain disables a significant number of patients undergoing amputation of different body parts for malignancy (202). It can have continuous or paroxysmal qualities and a burning or shooting character, and it frequently invokes dysesthesias. The incidence of phantom limb pain is greater in cases in which pain was present in the body part before amputation (203). Phantom breast pain occurs in 13% of patients up to 1 year after mastectomy (204). Phantom rectal pain occurs in up to 18% of patients after surgery for rectal carcinoma (205). The reappearance or worsening of pain a long while after amputation can indicate tumor recurrence. The clinician must carefully distinguish among phantom pain, nonpainful phantom sensations, neuropathic stump pain, and nonneuropathic stump pain (see Chapter 21).

Radiation Myelopathy, Plexopathy, and Neuropathy

Radiation treatment may cause pain by damage to peripheral nerves or spinal cord by altering the microvascular of connective tissue surrounding peripheral nerve, via fibrosis and chronic inflammation in connective tissues, or bringing about demyelination and focal necrosis of the white and gray matter in the spinal cord. Typically, these changes occur late in the course of a patient's illness. The differential diagnosis should always include recurrent tumor. In all instances, pain is a component of the clinical picture, but it is rarely as severe as that associated with recurrent tumor.

Subacute radiation myelopathy may occur after radiation treatment of extraspinal tumors; it most commonly appears in the cervical cord after treatment for head and neck cancers and after treatment for Hodgkin's disease (206). The syndrome involves shocklike pains in the neck precipitated by neck flexion (Lhermitte's sign), which can radiate down the spine and into the extremities. The syndrome begins one to several months after treatment and resolves after a few months to a year. Dose levels well below those causing chronic radiation myelopathy may produce it (206). Pathogenesis is probably a transient demyelination.

A bimodal distribution of chronic myelopathy, a late complication of spinal irradiation, suggests the existence of different underlying mechanisms (207). The early delayed type occurs 6 to 8 months after treatment and is related to demyelination and necrosis of the white matter. The delayed type typically occurs 1 to 4 years afterward and relates more to vascular damage. Pain typically precedes development of neurologic signs and follows dermatomes at or below the level of damage. Spinal cord signs consistent with a partial transverse myelopathy eventually appear (208). Some patients develop a Brown-Séquard syndrome. Brown-Séquard

syndrome results in ipsilateral pyramidal deficit and posterior column signs and, contralaterally, loss of spinothalamic function.

Neuropathic syndromes associated with chest wall and axillary radiation therapy include brachial plexopathy, malignant peripheral nerve tumors, nerve entrapment in a lymphedematous shoulder, and ischemia. Both early and late onset brachial plexopathy occurs. Clinically, the plexopathy involves mixed sensory and motor deficits, with or without pain.

Although some authors suggest that pain is rarely a prominent symptom in radiation plexopathy (187,209,210), several studies (211,212,213,214 and 215) suggest the opposite. Zeidman and colleagues (212) estimate that up to 20% of such patients may report severe pain. Typically, however, patients with radiation-induced injury of the brachial plexus present with sensory (paresthesias or dysesthesias) or motor (weakness, paresis) dysfunction in the upper extremity.

Olsen and colleagues (216) described the incidence and latency period of radiation-induced brachial plexopathy in 79 patients with breast cancer. Thirty-five percent of patients developed radiation-induced brachial plexopathy. Fifty percent had involvement of the entire plexus, 18% of the upper plexus alone, 4% of the lower plexus alone, and a definite level of involvement could not be determined in 28% of patients. Radiation-induced brachial plexopathy began in most patients either during or immediately after radiation treatment. Radiation-induced brachial plexopathy was more common in patients who received combination treatment with chemotherapy and radiation than with radiation alone. The likelihood of this lesion is less than 1% when 2-Gy fractions have delivered a total dose of 50 Gy; the incidence is approximately 5% after total doses approaching 60 Gy (211). Mondrup and colleagues (215) noted that the most prominent symptoms for radiation-induced brachial plexopathy were numbness or paresthesia (71%) and pain (41%), whereas the most prominent objective signs were decreased or absent muscle stretch reflexes (93%), closely followed by sensory loss (82%) and weakness (71%). The neurologic deficits are relentlessly progressive and ultimately result in a useless limb. In contrast to malignant infiltration, patients with radiation injury to the plexus tend to have abnormal sensory and normal motor nerve conduction studies and characteristically manifest more fasciculations or myokymia on electromyography than patients with neoplastic disease (217). Electrophysiologic studies reveal evidence of chronic partial denervation with increased mean duration of individual motor unit potentials, and decreased amplitude of compound muscle and sensory action potentials (215).

Harper et al. (209) found that myokymic discharges were the only electromyographic result useful in differentiating radiation induced from neoplastic brachial plexopathy. In addition, these authors noted the highest proportion of myokymic discharges in the pronator teres and abductor pollicis brevis muscles and advised a thorough search of these muscles for myokymic discharges during needle examination in patients with suspected radiation-induced plexopathy. However, myokymic discharges in neoplastic plexopathy, although rare, may exist, and there is a need for caution in using this as an absolute criterion for differentiating radiation induced from neoplastic plexopathy.

Radiation fibrosis of the lumbosacral plexus is relatively rare. It may occur more frequently after intracavitary radium implants for carcinoma of the cervix (218). Paresthesias and distal weakness progressing proximally, but rarely pain, occur in the lower extremities 2 to 3 months after irradiation of the sacral plexus (219). The pathogenesis of this is probably reversible demyelination. The symptoms and signs are usually bilateral on presentation. The weakness commences distally in the L-5 to S-1 segments and slowly progresses (220). Painless, indolent leg weakness occurs early in radiation disease, whereas pain with or without unilateral weakness usually characterizes tumor plexopathy. Radiation disease often results in serious neurologic disability.

Peripheral Neuropathy Caused by Chemotherapy

Antineoplastic drugs associated with neurologic deficits include ifosfamide (soft tissue sarcomas, testicular carcinomas, some lymphomas), cisplatin, vincristine, paclitaxel, cytarabine, interferon-a, and methotrexate.

5-Fluorouracil may produce severe stomatitis and palmar-plantar erythrodysesthesia (hand-foot syndrome). Peripheral neuropathy is rare. 5-Fluorouracil is used to treat breast cancer, colorectal carcinoma, gastric carcinoma, pancreatic carcinoma, and carcinomas of the head and neck.

Cisplatin is highly effective against testicular and ovarian cancer and acts against non-Hodgkin's lymphoma, non–small cell lung cancer, SCLC, and squamous cell carcinomas of the head and neck. Myelosuppression is mild except at high doses. The peripheral neuropathy observed with cisplatin is a distal, symmetric, predominantly larger fiber sensory polyneuropathy with paresthesias, vibratory and proprioceptive loss, relative sparing of pin and temperature sensation, and reduced deep tendon reflexes, and is dose related and cumulative (with a total dose usually more than 300 to 600 mg per m^2). Lhermitte's sign, mild weakness, and autonomic neuropathy may occur. Symptoms may begin or progress even after cisplatin termination (221,222 and 223). Concurrent vincristine or etoposide may exacerbate the neuropathy.

Cytarabine is indicated for leukemia and lymphoma, often in combination with other agents, and it rarely causes peripheral neuropathy. A myelopathy with paraplegia or cauda equina syndrome may occur after intrathecal injection.

Methotrexate is used in choriocarcinoma, epidermal carcinomas of the head and neck, lymphoma, lung cancer, maintenance chemotherapy for childhood leukemia, and in high dose with folinic acid rescue for osteogenic sarcoma. It has little or no neurotoxicity when used orally or intravenously in the usual doses. Intrathecal methotrexate may occasionally produce a myelopathy with paraplegia or a cauda equina syndrome. Because of its relative lack of myelosuppression, oncologists combine vincristine with other chemotherapeutic agents for the treatment of many tumors, including leukemia, lymphoma, primary brain tumors, sarcoma, and breast carcinoma. Peripheral neuropathy is almost universal and is the dose-limiting toxicity (224). This typically begins with loss of deep tendon reflex at the ankle and may progress to complete areflexia, distal symmetric sensory loss (pin and temperature more than vibration and proprioception), motor weakness, footdrop, and muscle atrophy. Autonomic neuropathy with constipation may occur in up to 30% of patients. Muscle pain involving the jaw or legs occasionally develops acutely after an injection. The discomfort may last for several hours or days and sometimes requires a dose reduction or discontinuation. Toxicities are dose related with high variability in individual susceptibility. Patients with a preexisting neuropathy may develop severe postchemotherapy neuropathy.

Interferon-a, active against hairy cell leukemia, has been used alone and with other agents against multiple myeloma, lymphoma, melanoma, and colon and renal cell carcinoma. A mild, distal sensorimotor peripheral neuropathy sometimes occurs.

Paclitaxel treats breast, lung, ovarian, and some head and neck cancers. It produces a dose-limiting distal symmetric polyneuropathy similar to that with vincristine (225). Paclitaxel-induced neuropathy tends to be predominantly sensory in character, although minor motor signs may be present. Paclitaxel-induced neuropathy is a dose-dependent phenomenon, occurring with higher cumulative dose and higher dose per cycle. Using 3-weekly 3-hour infusions of paclitaxel, one would expect dose-limiting neurotoxicity in patients treated with 250 mg per m^2 or more each cycle (226).

Hematopoietic Growth Factors. Although these agents do not typically cause neuropathic pain in cancer patients, they are a significant source of pain, and a brief account is included for completeness. Current options for hematopoietic growth factors include erythropoietin, which stimulates red cell production; granulocyte CSF (filgrastim), which stimulates white blood cell production; and granulocyte macrophage–CSF, which has similar effects. Erythropoietin seldom produces systemic side effects, but the granulocyte CSFs cause low-grade fever, myalgias, and a flulike syndrome, which rapidly resolves. Filgrastim is generally well tolerated. The most frequent adverse reaction is mild to moderate medullary bone pain, reported by approximately 20% of patients (227).

BACK PAIN AND METASTATIC EPIDURAL SPINAL CORD COMPRESSION

Metastatic epidural spinal cord compression is compression of the spinal cord or cauda equina nerve roots from a lesion outside the dura mater (Table 35-21). Epidural spinal cord or cauda equina compression is the second most common neurologic complication of cancer, occurring in up to 10% of patients (228,229). The most common tumors causing metastatic epidural compression are breast, lung, prostate, lymphoma, sarcoma, and kidney.

Signs/Site	Spinal cord	Conus medullaris	Cauda equina
Weakness	Symmetric, profound	Symmetric, variable	Decreased
Deep tendon reflexes	Increased or absent	Increased knee, decreased ankle	Decreased
Plantar response	Extensor	Extensor	Plantar
Sensory	Symmetric sensory level	Symmetric saddle	Asymmetric, radicular
Sphincters	Late onset	Early onset	Spared
Progression	Rapid	Variable	Variable

TABLE 35-21. Signs of spinal compression

Mechanism

Metastatic epidural spinal cord compression presumably occurs by hematogenous arterial spread to bone marrow, which leads to vertebral body collapse and formation of an anterior epidural mass. A second mechanism is spread by direct invasion of tumor through the intervertebral foramina from a paravertebral source. This occurs in 75% of patients with epidural spinal cord compression caused by lymphoma, and 15% of patients with metastatic epidural spinal cord compression from other solid tumors (230,231). It is unusual to find epidural spinal cord compression without bony involvement or direct spread through the bony foramina. Constans and colleagues (232) reviewed 600 cases of spinal cord or nerve root compression and found that vertebral metastases had occurred in 563 patients. The vertebral body was involved in 45% of these patients, the posterior arch in 41%, and the entire vertebra in the remaining 14% of patients. Epidural lesions without vertebral involvement occurred in 30 patients and intradural lesions in seven patients.

Multiple levels of vertebral involvement are particularly common in breast and prostatic carcinoma. The primary compression of the spinal cord from metastatic deposits occurs in the thoracic spine of approximately 70% of patients, the lumbosacral spine in 20%, and the cervical spine in 10% of patients (231,233,234). Multiple sites of metastatic epidural spinal cord compression occur in 17% to 30% of all patients (235). This is particularly common in breast cancer and is uncommon in lung cancer (233).

Most epidural spinal cord compression comes from a solid tumor metastasis to the vertebral body, which spreads posteriorly to the epidural space. Other tumors, such as lymphoma, paragangliomas, and neuroblastomas, invade the epidural space through the intervertebral foramina. Pain from vertebral body destruction usually precedes neurologic signs of cord compression for a prolonged period of time. Epidural metastases, entailing invasion of extrathecal and intrathecal nerve roots by neoplasm, dural infiltration, and generation of reactive fibrosis in the subdural space, may increase pain.

Pattern of Pain

The pattern of pain associated with epidural metastasis may be local, radicular, referred, or funicular. The majority of patients have local pain. Local pain over the involved vertebral body, which results from involvement of the vertebral periosteum, is dull and exacerbated by recumbency. The worsening of pain on recumbency is the most distinctive feature of the pain of epidural spinal cord compression. Many patients with cord compression find they must sleep in a sitting position. Even if pain is absent in the lying position, turning over in bed or rising from a lying position may be particularly painful.

Radicular pain from compressed or damaged nerve roots is usually unilateral in the cervical and lumbosacral regions and bilateral in the thorax, where patients often describe it as a tight band across the chest or abdomen. The pain is experienced in the overlying spine, deep in certain muscles supplied by the compressed root, and in the cutaneous distribution of the injured root. The pain is usually least severe when the patient is in a position that minimizes compression of the root and most severe in positions that compress or stretch the root. Pain is also increased by increasing intraspinal pressure (e.g., coughing, sneezing, and straining). Radicular pain is present in 90% of patients with lumbosacral, 79% of cervical, and 55% of patients with thoracic metastatic spinal cord compression (234). It is frequently bilateral in the thoracic area and unilateral or bilateral in the lumbosacral and cervical areas.

Referred pain in the midscapular region or in both shoulders may accompany cervicothoracic epidural disease and bilateral sacroiliac and iliac crest pain occurs with L-1 vertebral compression. The pain has a deep aching quality and is often associated with tenderness of subcutaneous tissues and muscles at the site of referral. Maneuvers that affect local pain usually have the same effect on referred pain. When pain is referred from pathologic processes in the low back, it is usually appreciated in the buttocks and posterior thighs. Pain from the upper lumbar spine is often referred to the flank, groin, and anterior thigh.

Funicular pain may be an early complaint in patients with cord compression and presumably results from compression of the ascending sensory tracts in the spinal cord. It usually occurs some distance below the site of compression and it has hot or cold qualities in a poorly localized nondermatomal distribution. The pain is less sharp than radicular pain but, like root pain, is usually exacerbated by movements that stretch the compressed structure (neck flexion, straight leg raising) or that increase intraspinal pressure (coughing, sneezing, straining).

Presentation and Physical Findings

The clinical picture of metastatic epidural spinal cord compression is uniformly reported as pain, weakness, sensory loss, and autonomic dysfunction (232,236,237). Although severe back pain is the initial symptom in greater than 95% of patients with epidural spinal cord compression, it may be the only neurologic symptom despite a complete or nearly complete block in 10% of patients (157). The intensity of pain and the extent of neurologic deficit depend on the size of the epidural metastasis and, consequently, the degree of epidural block. Patients with small epidural lesions may have no pain and no neurologic deficits (238).

After weeks of progressive pain, the patient may develop weakness, sensory loss, autonomic dysfunction, and reflex abnormalities. Weakness may be segmental owing to nerve root damage, or pyramidal in distribution if the spinal cord is injured. Once weakness is present, progression is often rapid, and urgent investigations and treatment are essential. Sensory abnormalities include ascending paresthesias, a sensory level, or complete loss of all sensory modalities below the dermatomal level in paraplegic patients. The upper level of sensory findings may correspond to the location of the epidural tumor or be below it by many segments. Bladder and bowel dysfunction is rarely a presenting symptom, but may appear after sensory symptoms have developed. The exception to this generalization occurs with compression of the conus medullaris, which presents as acute urinary retention and constipation without preceding motor or sensory symptoms.

Helweg-Larsen and Sorensen (239) described the frequency and the progression of symptoms in 153 patients with metastatic spinal cord compression. At the time of diagnosis, 88% of patients complained of low back pain. Radicular pain was more frequent in tumors localized in the lumbosacral area (91%) than in tumors localized in the thoracic region (69%), whereas the severity of paresis was more pronounced in patients with metastases in the thoracic region.

Certain spinal tracts appear to be more vulnerable to compression than others (240). The corticospinal tracts and posterior columns are particularly vulnerable, and the spinothalamic tracts and descending autonomic fibers less so. As a result, weakness, spasticity, and reflex hyperactivity tend to be the earliest signs of spinal cord compression, with paresthesias and vibratory and position sense loss occurring soon thereafter. Loss of pain and temperature sensation and of bladder and bowel function usually occurs late in the course of spinal cord compression. The spinocerebellar pathways are also sensitive to compression, and at times ataxia may be the only sign of spinal cord compression.

Reflex abnormalities from spinal cord involvement include loss of superficial cutaneous reflexes, increase in deep cutaneous and deep tendon reflexes at or below the level of compression, and extensor plantar responses. Asymmetric flaccid motor weakness and sensory loss, with absent lower limb reflexes, characterize cauda equina compression. Conus medullaris lesions typically cause a rapidly progressive symmetric perineal pain followed by early autonomic dysfunction, saddle sensory loss, and motor weakness. Limited straight leg raising usually points to an epidural or intradural extramedullary lesion causing root compression, whereas segmental pain and sacral sparing suggest intramedullary disease.

Approximately 1% of patients with epidural compression present initially with ataxia without pain. In patients with back pain and a normal neurologic examination, the

presence of greater than 50% collapse of the vertebral body on plain radiography is associated with an 86% chance of epidural spinal cord compression (238). Back pain in patients with normal radiographic results requires further workup, including bone scan and CT scan.

The diagnosis of epidural spinal cord compression is often delayed 1 week or more (241), even after the onset of other neurologic symptoms. Ventafridda and colleagues (242) reported an association between Lhermitte's sign and epidural spinal cord compression. In their series, the sign appeared at an early stage of compression, particularly with thoracic lesions. Lhermitte's sign, however, lacks specificity and also occurs in patients with radiation myelopathy (206), after cisplatin chemotherapy (243), and in noncancer-related problems such as multiple sclerosis (244) and subacute combined degeneration of the cord (245).

Differential diagnosis for the individual patient with back pain includes intramedullary metastases, herniated disks, epidural hematoma or abscess, transverse myelopathy, and subluxation of the spine from pathologic fractures.

Investigations

Plain radiography is an essential, highly predictive, inexpensive, quick investigation that should be obtained if myelography or MRI scanning is pending. Between 85% and 94% of patients with metastatic epidural spinal cord compression have an abnormal plain film at the time of diagnosis (233). Spinal radiography has a sensitivity of 91% for predicting epidural disease and a specificity of 86% (238). Bone scanning has a similar sensitivity but a specificity of only 53%. Particularly useful radiologic predictors for epidural disease are greater than 50% vertebral collapse and pedicular erosion. CT is valuable in investigating cancer patients with local back pain who have a normal examination and spinal radiography results. Two-thirds of these patients have spinal metastases on CT, but only 17% have metastatic epidural spinal cord compression, and in these cases none has greater than 50% block (246).

When definitive imaging of the epidural space is required, the best approach is MRI. MRI is noninvasive, effectively demonstrates metastatic epidural spinal cord compression, and gives a positive image of the spinal cord to better diagnose intramedullary disease. CT myelography and standard myelography are alternative procedures of choice. Myelography is as sensitive as MRI at identifying extradural or intradural extramedullary lesions and has the added advantage of yielding CSF, which may help exclude or confirm alternative diagnoses. Bone scan and plain radiography provide useful screening tests but are nonspecific and less sensitive than MRI or CT. Electrical studies can also be useful in assessing the level of cord compression (see Chapter 13).

Prognosis

Metastatic spinal cord compression is a disabling complication of malignant disease (247). Effective therapy is necessary to maintain functional integrity for the remainder of life (see Chapter 36). The mean survival time from the diagnosis of epidural compression is 14 months in breast cancer (range, 0.6 to 49.0 months), 12 months in prostate cancer (range, 0.2 to 61.0 months), 6 months (range, 3 weeks to 7 months) in malignant melanoma, and 3 months (range, 0 to 18 months) in lung cancer (248,249). Overall median survival time in patients with epidural compression is 7 months, with a 36% probability of 1-year survival.

The extent of disease and neurologic injury, rather than the primary pathology, determine the outcome of spinal cord compression. The clinical course of spinal cord compression resulting from malignant melanoma is similar to that resulting from breast or prostate cancer. The time from the original diagnosis of melanoma to the development of metastatic spinal disease averages 32 months (range, 0 to 114 months), and the average time from diagnosis of skeletal metastases to spinal cord compression is 27 months (range, 0 to 113 months).

The severity of weakness at presentation is the most significant prognostic variable for recovery of function. Eighty percent of patients who were ambulatory at presentation remain so after treatment (234).

STEPWISE APPROACH TO PAIN ASSESSMENT

Assessing cancer pain is more than quantifying pain with a tool and recording it. A stepwise approach to cancer pain assessment begins with data collection and ends with a clinically relevant diagnosis. It involves determining the etiology of the pain and forecasting its future trajectory. It also involves determining the number of sites from which pain originates and the probable mechanisms involved. Assessment must include evaluation of the effect of pain on sleep, functional capability, activity level, and psychological well-being. In addition, the clinician must determine the nature, course, and effect of the cancer on the patient. A thorough evaluation allows the clinician to obtain a basis for evaluating therapeutic intervention and determining the long-term goals of the patient and the patient's family.

The goals of the pain-related history are listed in Table 35-22. Optimal assessment includes a detailed description of these goals and classification by both pain syndrome and likely underlying mechanisms (see following discussion).

Define the features of the pain.
Outline the anatomic extent of the disease.
Determine responses to previous disease-modifying and analgesic therapies.
Clarify the effect of the pain on activities of daily living, psychological state, and familial and professional function.
Determine the presence of associated symptoms that may modify the perception of pain.

TABLE 35-22. Goals of the pain-related history

Features of Pain History

Table 35-23 lists the key components to assessing the characteristics of the pain complaint.

Location
Intensity
Quality
Timing
Exacerbating/relieving factors
Response to previous analgesic and disease-modifying therapies
Effect of pain
Effect of pain on activities of daily living
Psychological state
Familial and professional function

TABLE 35-23. Key components of pain characteristics

Location

Many patients with advanced disease have multiple pains at different sites. Multiple pain complaints are more common in patients with breast, lung, and prostate cancer compared with gastrointestinal cancers (43). Pain of tumor origin may be characterized by its location. For example, somatic pain resulting from bone metastases tends to be well localized, whereas visceral pain tends to be diffuse and is often referred. Neuropathic pain may be radicular in location (Fig. 35-6).

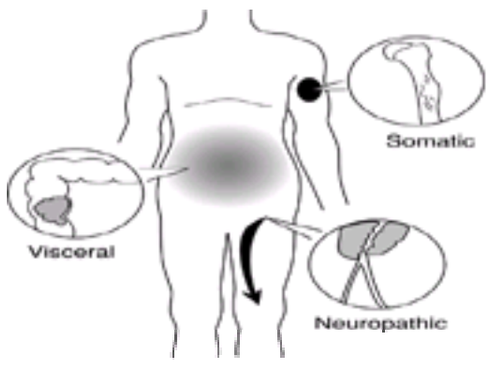

Figure 35-6. Schematic location of nociceptive (somatic, visceral) and neuropathic pain. Pain complaints resulting from somatic sources of pain (e.g., from bone metastasis) tend to be well localized; visceral sources (e.g., tumor infiltration of bowel) more diffuse; and neuropathic sources (e.g., tumor-associated lymphadenopathy infiltrating the femoral neck) radicular in distribution.

Intensity

Guidelines from the Agency for Health Care Policy and Research (250), the American Pain Society (251), and the American Society of Anesthesiologists (252) recommend the regular use of pain rating scales to assess pain severity and relief in all patients who commence or change treatments. These recommendations urge that clinicians teach patients and families to use assessment tools in the home to promote continuity of pain management in all settings. Assessment tools for determining the intensity of pain are discussed previously.

Quality

Tumor-associated pain can be nociceptive (somatic or visceral structures) or neuropathic in origin. Each source of pain has distinguishing qualities. For example, patients tend to describe pain that is neuropathic in origin as burning, shocklike, or shooting in quality, whereas they often describe pain originating from somatic structures as aching, nagging, throbbing, or sharp.

Timing

Cancer patients may have constant or intermittent pain. Constant pain is present continuously and usually fluctuates in intensity. Intermittent pain implies that pain is present for definite periods of time and that the patient is relatively pain free between episodes of pain. Patients and their caregivers need to understand the concept of breakthrough pain, as should health care providers. Breakthrough pain is discussed previously (see Patterns of Cancer Pain).

Exacerbating and Relieving Factors

Cancer patients with pain may experience a worsening of their pain over a wide range of activities. Commonly, patients with metastatic disease to weight-bearing bones experience an increase of their pain on standing or sitting. Patients with breast cancer metastatic to the axillary nodes may have severe pain on abduction of their upper extremity on positioning for external beam radiation therapy. Knowledge of these factors helps clinicians to design an appropriate pain treatment plan.

Responses to Previous Analgesic and Disease-Modifying Therapies

It is important to determine previous opioid use and benefits or side effects encountered during use. Previous unacceptable side effects to a particular opioid may limit successful future titration with the same opioid. Successful tumor shrinkage by chemotherapy or radiation therapy may indicate the need for further evaluation on tumor recurrence.

Effect of Pain

The initial pain assessment should elicit information about changes in activities of daily living, such as work and recreational activities, sleep patterns, mobility, appetite, sexual functioning, and mood. Numerous instruments, including symptom checklists and quality of life measures, may prove useful in this evaluation and are detailed in Chapter 12.

The Memorial Pain Assessment Card is a brief, validated measure that uses Visual Analog Scale scores to characterize pain intensity, pain relief, and mood, and an eight-point verbal rating scale to further characterize pain intensity. The mood scale, which is correlated with measures of global psychological distress, depression, and anxiety, is considered to be a brief measure of global symptom distress. Although this instrument does not provide detailed descriptors of pain, its brevity and simplicity may facilitate the collection of useful information while minimizing patient burden and encouraging compliance.

The Brief Pain Inventory measures both the intensity of pain (sensory dimension) and interference of pain in the patient's life (reactive dimension). It also queries the patient about pain relief, pain quality, and patient perception of the cause of pain. Numeric scales indicate the intensity of pain in general, at its worst, at its least, and right now. An average scale quantifies relief from current therapies. The patient marks a figure representing the body by shading the area corresponding to his or her pain. Seven items determine the degree to which pain interferes with function, mood, and enjoyment of life. Advantages of this questionnaire include that it is self-administered, easy to understand, and available in many languages.

Effects of the Pain on Activities of Daily Living

Many patients function quite effectively with a background level of mild pain that does not seriously impair or distract them (31). As pain severity increases, the pain passes a threshold beyond which it is hard to ignore. At this point, it becomes disruptive to many aspects of the patient's life. Constant daily pain can significantly affect a patient's daily activities. Williamson and Schulz (253) showed that as pain increased over time, restriction in activity occurred, which in turn predicted increases in depressed affect. General measures of functioning should include indicators of physical, psychological, and social functional status. Some factors may include interference on general activity, mood, walking, ability to work, relations with others, and sleep.

Maltoni and colleagues (254) confirmed the importance of certain clinical parameters as prognostic indicators for patients with terminal cancer (clinical experience, physical activity level, and clinical symptoms related to and unrelated to nutritional state). Performance status tables can help the physician assess physical activity levels (Table 35-24). However, the palliative treatment of advanced cancer and the terminally ill requires a broad concept of well-being that goes beyond one based only on physical functioning (255).

Grade	Performance level
0	Fully active, able to carry on all predisease performance without restriction
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature (e.g., light house work, office work)
2	Ambulatory and capable of all self-care but unable to carry out any work activities; up and about more than 50% of waking hours
3	Capable of only limited self-care; confined to bed or chair more than 50% of waking hours
4	Completely disabled; cannot carry on any self-care; totally confined to bed or chair
5	Dead

TABLE 35-24. Eastern Cooperative Oncology Group performance status

Psychological State

Psychological assessment of the cancer patient with pain is imperative and should reflect an understanding of the many factors that modulate distress, such as personality, coping, and both past and present psychiatric disorders. Knowing that the patient has received outpatient or inpatient psychiatric care helps to clarify the psychological risk. Information on how the patient handled previous painful events may provide insight into whether the patient has demonstrated chronic illness behavior.

Familial and Professional Function

The clinician must learn about the patient's familial and social resources, financial situation, and the physical environment in which he or she lives. Knowledge of the patient's and family's previous experience with cancer, or other progressive medical disease, may provide useful insights into the response to physical illness or the genesis of psychological symptoms. Although the influence of social factors on treatment preferences and desire for aggressive cancer therapy is still poorly defined, Yellen and Cella (256) demonstrated that positive social well-being, as well as having children living at home, predicted patient willingness to accept aggressive treatment.

General Assessment

The initial step in the general assessment of the symptomatic cancer patient is a complete medical history that reviews the cancer diagnosis, chronology of significant cancer-related events, previous therapies, and all relevant medical, surgical, and psychiatric problems (Table 35-25). A detailed history of drug therapy should include current and prior use of prescription and nonprescription drugs, drug allergies, and previous adverse drug reactions including side effects. The patient should provide information about prior treatment modalities for each symptom. In the course of this assessment, the interviewer should document the patient's understanding of his or her current disease status. Discussion with other providers involved with the patient's care also helps determine disease status. Table 35-26 lists the different possible categories for a patient's clinical status.

Cancer history	Current medications and past medical history	Psychosocial issues
Diagnosis	Previous medical and surgical illness	Family history
Chronology	Concurrent medical condition	Social resources
Therapeutic interventions including operations and treatments	Drug reactions	Effects of disease and response on patient and family
Patient's knowledge of extent of disease		Patient's and family's goals of care
Current clinical status		

TABLE 35-25. Components of medical history: cancer history, medications, past medical history, and psychosocial factors

Category	Status
I	Active disease; care, palliative and supportive only
II	Active disease; treatment (e.g., chemotherapy, radiation therapy) in progress
III	Active disease; no current treatment, surveillance of tumor status
IV	No active disease; treatment of tumor in progress
V	No active disease; no current treatment, surveillance of tumor status
VI	No active disease; no current treatment, specialized care (e.g., medical oncology) not required

TABLE 35-26. Clinical status of patients defined by disease state and treatment strategy

A careful review of previous laboratory and imaging studies can provide information about the cause of pain and the extent of the underlying disease. Evaluation of concurrent concerns includes other symptoms and related psychosocial problems. Additional investigations are often needed to clarify uncertainties in the provisional assessment. The extent of these investigations must be appropriate to the patient's general status and the overall goals of care (Table 35-27).

Physical examination		
Review of available laboratory and imaging data		
Further diagnostic investigations and specific assessments	Diagnostic investigations, symptom-specific, extent of disease	Other assessments, psychosocial, functional

TABLE 35-27. Components of medical history: physical examination, investigations, and further evaluation

Associated Symptoms

Symptoms interact, and therefore it is important to clarify the degree to which each symptom induces or exacerbates other physical or psychological symptoms. The evaluation should determine whether symptoms are concurrent but unrelated in etiology, concurrent and related to the same pathologic process, concurrent with the one symptom directly or indirectly a consequence of a pathologic process initiated by another symptom, or concurrent with one symptom a consequence or side effect of therapy directed against the other. Fatigue may be the most prevalent symptom reported by cancer patients (257). Disease progression increases the number of factors diminishing quality of life as well as the prevalence and severity of physical and psychological symptoms. In addition to pain, patients with advanced cancer have fatigue, generalized weakness, dyspnea, delirium, nausea, and vomiting. These symptoms may have a major effect on both pain reporting and quality of life.

The Memorial Symptom Assessment Scale is a patient-rated instrument that was developed to provide multidimensional information about a diverse group of common symptoms. The Memorial Symptom Assessment Scale is a reliable and valid instrument for the assessment of symptom prevalence, characteristics, and distress. This approach to comprehensive symptom assessment is helpful for clinical trials that incorporate quality of life measures or studies of symptom epidemiology (258). Portenoy and colleagues (259) evaluated patients with prostate, colon, breast, or ovarian cancer using the Memorial Symptom Assessment Scale and other measures of psychological condition, performance status, symptom distress, and overall quality of life. The Karnofsky Performance Status score was less than or equal to 80 in 49.8%. Across tumor types, 40% to 80% experienced lack of energy, pain, feeling drowsy, dry mouth, insomnia, or symptoms indicative of psychological distress. Although symptom characteristics were variable, the proportion of patients who described a symptom as relatively intense or frequent always exceeded the proportion who reported it as highly distressing. The mean (plus or minus standard deviation range) number of symptoms per patient was 11.5 ± 6.0 (0 to 25).

Laboratory and Imaging Data

Careful review of previous laboratory and imaging studies can provide important additional information. Specific radiologic or laboratory tests may help the clinician understand the pathophysiology of symptoms and their relationships to the disease. This information provides the basis for a provisional pain diagnosis that clarifies both the status of the disease and the nature of other concurrent concerns that may require therapeutic focus.

Some patients require multiple studies to evaluate the pain problem, clarify extent of disease, or assess other symptoms. Assistance from physicians in other disciplines, nurses, social workers, psychologists, or others may prove necessary to evaluate related physical or psychosocial problems identified during the initial assessment. It is appropriate and useful to review the findings of this evaluation with the patient, family, and other appropriate persons, so that they can prioritize problems according to their importance for the patient. It is also useful to identify potential outcomes that would benefit from contingency planning, including the need for advanced medical directives, the evaluation of home care resources, and prebereavement interventions with the family.

Physical Examination

A physical examination, including a neurologic and musculoskeletal examination, is a necessary part of the initial pain assessment. The need for a thorough neurologic assessment is justified by the high prevalence of painful neurologic conditions in the cancer population (260). The physical examination should clarify the underlying causes of the pain problem, detail the extent of the underlying disease, and discern the relation of the pain complaint to the disease.

Diagnosis

The provisional pain diagnosis includes inferences about the pathophysiology of the pain and an assessment of the pain syndrome. Evaluation of concurrent concerns includes other symptoms and related psychosocial problems. Additional investigations can often clarify uncertainties in the provisional assessment.

STAGING SYSTEMS FOR CANCER PAIN

A clinical staging system allows for precise definition of patient characteristics in clinical research trials, resulting in accurate interpretation of data, successful application of therapies, and subsequent formulation of more advanced clinical research studies. The development of clinical staging systems for different tumors marks a major advance in clinical research and treatment. Although pain is a subjective state and therefore more difficult to assess than a tumor, a number of definable features are well known to influence its response to treatment. Several authors have described neuropathic pain, incidental pain, total suffering, and addictive personality as the most intractable pain syndromes (261,262).

Bruera and colleagues (263) developed a clinical staging system (Edmonton staging system) for cancer pain. This system evaluates seven features in a patient's pain: mechanism (visceral, bone and soft tissue, neuropathic, mixed, and unknown), character (nonincidental, incidental), previous exposure to opioids, cognitive function (normal, impaired), psychological distress (without major psychological distress, with major psychological distress), tolerance, and addictive history (alcoholism or drug dependence).

In a prospective study of 56 patients, Bruera and colleagues (263) assessed the effectiveness of a staging system in predicting the outcome of patients with cancer pain. The purpose of the study was not to assess the effectiveness of different treatments but to try to identify prospectively a population with poor prognosis to the best known treatment combination. The authors demonstrated that sensitivity, specificity, and negative predictive value of the system were 0.75, 0.86, and 0.80, respectively. Adequate characteristics of patients allow a better assessment of the effects of different opioids, anesthetic, and neurosurgical procedures in cancer pain. It also allows a better assessment of antineoplastic treatments, such as radiotherapy, chemotherapy, or hormones on cancer pain. In a follow-up prospective multicenter study of 227 patients, Bruera and colleagues (264) proposed a simpler staging system consisting of five categories (mechanism, characteristic, previous opioid dose, tolerance, and addiction) and two stages (good and poor prognosis). The authors conclude that the staging system was highly accurate in predicting patients with good prognosis, but patients with poor prognosis can still achieve good pain control in more than 50% of cases.

SUMMARY

Cancer is one of the medical conditions patients fear most. In addition to anxiety about cancer as a potentially lethal disease, patient and family expectancies that pain is an inevitable and untreatable consequence are major sources of distress. Controlling pain associated with cancer is a major health care problem. Lack of expertise by clinicians in assessing pain is an important cause of poor pain control. A stepwise approach to cancer pain assessment begins with a systemic clinical interview and ends with a clinically relevant diagnosis that outlines the mechanisms and contributing factors to the pain complaint. It involves determining the etiology of the pain and forecasting its future trajectory. It also involves determining the number of sites from which pain originates and the probable mechanisms involved. Assessment must include evaluation of the effect of pain on sleep, functional capability, activity level, and psychological well-being. In addition, the clinician must determine the nature, course, and effect of the cancer on the patient. A thorough evaluation allows the clinician to obtain a basis for evaluating therapeutic intervention and determining the long-term goals of the patient or the patient's family.

Many health care professionals may become involved with the cancer pain patient at any one time. Successful pain management requires that the person or persons responsible for pain management adopt, or at least become familiar with, an interdisciplinary approach to care.

---

*This estimate includes bladder carcinoma in situ only; it excludes skin basal and squamous cell cancer.
*Spurling's maneuver requires the examiner to produce oblique extension of the neck on the affected side with axial compression to the head. By narrowing the affected foramen, pain may be produced in the upper extremity.

CHAPTER 36

Cancer Pain: Management

Dermot R. Fitzgibbon

The number of cancer patients in the world is increasing. Of the estimated 9 million new cancer cases every year, more than one-half occur in developing countries. The majority of the world's cancer patients present with advanced disease, and for such patients, the only realistic treatment options are pain management and palliative care. Some cancer patients need pain relief at all stages of their disease; pain occurs in approximately one-third of patients receiving anticancer treatment. For these, pain relief efforts and anticancer treatment should go hand in hand. Thirty-three percent of patients receiving active treatment for metastatic disease have significant cancer-related pain, and this percentage increases to 60% to 90% in those with advanced disease (1,2 and 3), with the management of pain ultimately becoming the main focus of treatment. Unfortunately, approximately 25% of cancer patients die without adequate pain relief in spite of appropriate tools for adequate pain control being available (4,5).

Undertreatment of chronic cancer pain persists despite decades of efforts to provide clinicians with information about analgesics and pain-relieving techniques. Although the reasons for inadequate treatment of cancer pain are complex, certain barriers to adequate pain relief can be identified. These issues are discussed in Chapter 84 and include factors such as deficiencies in physicians' and nurses' undergraduate and graduate education about pain treatment options (6,7,8,9,10 and 11), concerns of clinicians and patients about the risk of addiction to opioids (12,13), state and federal regulation of the prescribing of opioid analgesics (14), and reimbursement policies for pain-relieving treatments (15).

Several studies demonstrate that many physicians continue to manage cancer pain inadequately (16,17 and 18). Van Roenn and colleagues (9) conducted a survey on cancer pain management within the Eastern Cooperative Oncology Group. The Eastern Cooperative Oncology Group consists of medical oncologists, hematologists, surgeons, and radiation oncologists. Respondents answered questions about the magnitude of their patients' pain, their perceptions of the adequacy of pain management, and whether or not their settings had implemented a management plan for cancer pain. Eighty-six percent of respondents said that pain in their practices was undermedicated. Thirty-one percent said that they would not maximize analgesia unless a patient's life span was less than 6 months. The majority reported not using adjunctive forms of analgesics or having a prophylactic side effect management plan in place.

The Eastern Cooperative Oncology Group survey further identified certain barriers to adequate pain management. The most prevalent single factor (76%) among the respondents was a perceived inability to assess pain appropriately. Sixty-two percent attributed inadequate patient reporting of pain as a significant barrier, and 62% attributed the patients' reluctance to take analgesics as an additional barrier. Sixty-one percent said that the physicians' reluctance to prescribe adequate quantities or doses of opioid analgesics was also a barrier to adequate pain control. In a 1994 follow-up report on the adequacy of outpatient metastatic cancer pain management, Cleeland and colleagues (16) reported that 67% of patients had pain associated with their cancer, of whom 36% had impaired function of activities of daily living associated with their pain. Forty-two percent of these patients said that their pain was inadequately controlled.

Failure to provide adequate cancer pain relief is not unique to the United States. Reports from other modern, industrialized countries reveal varying degrees of success and inadequacy in managing cancer pain (19,20,21,22,23,24,25,26,27,28,29,30 and 31). In 1995, Larue and colleagues (17) reported on cancer pain management in France. Fifty-seven percent of their patients (of a total of 605 patients) had pain associated with cancer, of whom 69% had impairment of function. Thirty percent of the patients consulted had no form of pain medication, and 51% of patients said that despite pain medications, their pain was inadequately relieved. These findings suggest a persistent international pattern of undermedication and suboptimal pain control.

Internationally, many reasons exist why patients receive inadequate cancer pain control (32). Table 36-1 lists some of these reasons. To respond to these issues, the World Health Organization (WHO) advocates a strategy that includes the development of national or state policies that support cancer pain relief through government

endorsement of education and drug availability; educational programs for the public, health care personnel, regulators, and so forth; and modification of laws and regulations to improve the availability of drugs, especially opioid analgesics.

Absence of national policies on cancer pain relief and palliative care
Lack of awareness on the part of health care workers, policy makers, administrators, and the public that most cancer pain can be relieved
Shortage of financial resources and limitations of health care delivery systems and personnel
Concern that medical use of opioids will produce psychological dependence and drug abuse
Legal restrictions on the use and availability of opioid analgesics

From World Health Organization. *Cancer pain relief and palliative care.* Technical report series 804, Geneva, Switzerland, 1990, with permission.

TABLE 36-1. International reasons for inadequate cancer pain control

In the United States, the undertreatment of cancer pain has attracted substantial attention (16,33,34,35,36,37 and 38). The factors contributing to undertreatment of cancer pain appear in Table 36-2.

Factor	Reason
Patient related	Pain underreporting: • Fear of disease progression • Perceived lack of time or inadequate amount of time spent in physician's office discussing pain problems
	Poor compliance with prescribed medications
Physician related	Legal issues regarding overprescription or perceived overprescription of opioids; physician reluctance to prescribe opioid analgesics has multiple causes (49)
	Difficulty assessing pain complaints
	Lack of information or lack of expertise on contemporary strategies for cancer pain management
	Desire to provide the patient with the latest and greatest pain management strategies may pose difficulties with untried or unproven techniques or methods

TABLE 36-2. Factors contributing to undertreatment of cancer pain in the United States

The problem of undertreatment is both complex and multifactorial, and solutions for this problem are not clear-cut. Potential solutions include the following suggestions:

- *Education of patients and health care providers*: Many cancer patients worry that their pain will not be controlled during the course of their disease. Moreover, they report fears of drug addiction, side effects, and tolerance. Educating patients about common barriers to cancer pain treatment can be an effective pain management strategy (39). In addition, each patient should receive a *bill of rights* indicating that the provider is committed to achieving optimal pain control. Health care providers should learn pain assessment techniques and routinely question all patients with cancer for pain prevalence and severity.
- *Establishment of pain management practice plan*: Several guidelines cover cancer pain management from the WHO (40), the American Pain Society (33), the Agency for Health Care Policy and Research (35), and the American Society of Anesthesiologists (38). In addition, each institution should establish and follow a pain management practice plan to anticipate and deal with pain in the cancer patient. Physicians caring for cancer patients should maintain a list of advanced pain management referral sources and protocols, and seek expert consultation when routine management strategies fail.
- *State cancer pain initiatives*: These initiatives are grass roots, multidisciplinary organizations in the United States committed to making optimal cancer pain control a reality. The first initiative began in Wisconsin (41), and they now exist in all states in the United States. A Role Model Education Program has evolved from the Wisconsin Cancer Pain Initiative (34). The key concept in the initiative movement is the provider triad: physician, nurse, and pharmacist. In most states, this program involves attendance of the triad at a day-long course covering all aspects of cancer pain management. In many respects, this program resembles programs currently in practice for Advanced Cardiac Life Support and Advanced Trauma Life Support.

A clinician may achieve pain relief in the cancer patient by several means (Table 36-3). Success requires tailoring treatment to the individual patient: matching drug treatment, anesthetic, neurosurgical, psychological, and behavioral approaches to the patient's needs. Successful management requires that the person or persons responsible for pain management be familiar with all these aspects of care.

Psychological approaches (Chapters 88–94)	Understanding Companionship Cognitive behavioral therapies
Modification of pathologic process (Chapters 36–38)	Radiation therapy Hormone therapy Chemotherapy Surgery
Drugs (Chapters 83–87)	Analgesics Antidepressants Anxiolytics Neuroleptics
Interruption of pain pathways (Chapters 102–106)	Local anesthetics Neurolytics Neurosurgery
Modification of daily activities	
Immobilization (Chapter 95)	Rest Cervical collar or corset Plastic splints or slings Orthopedic surgery

Adapted from World Health Organization. Cancer pain relief and palliative care. Technical report series 804, Geneva, Switzerland, 1990, with permission.

TABLE 36-3. Approaches to pain management in cancer patients

Many pain clinician-educators now believe that traditional medical educational approaches require complementary interventions in health care systems that directly influence the routine behaviors of clinicians and patients (34,42,43,44,45 and 46). This perspective echoes that advocated by the quality improvement movement (47,48). The quality improvement approach to pain treatment is based on the assumption that, although clinicians are concerned with patient comfort, their habits and procedures of practice do not support the achievement of effective pain relief. Although pain has received the most study, some experts believe that many symptoms of medical illness are neglected because patterns of medical practice and accountability have evolved out of a focus on structural disease rather than on patient complaints (49,50). Quality improvement programs designed to enhance treatment of cancer pain should include the following key elements:

- Ensure that a report of unrelieved pain raises a *red flag* that attracts clinicians' attention
- Make information about analgesics available in settings in which physicians write orders
- Promise patients responsive analgesic care and urge them to communicate their pain
- Implement policies and safeguards for the use of modern analgesic technologies
- Coordinate and assess implementation of these measures

The American Pain Society Quality of Care Committee issued guidelines for the treatment of acute pain and cancer pain (33). These guidelines attempted to embody key elements for favorably influencing behaviors of both patients and clinicians. The guidelines addressed settings that used conventional pain relief methods (e.g., intermittent parenteral or oral analgesics) exclusively and those using current technology for pain management. Although the guidelines focused on the assessment of pain and its treatment with analgesic drugs, they also identified that nonpharmacologic measures were an effective therapy.

Bookbinder and colleagues (46) studied the effect of implementing American Pain Society guidelines in a focused program at an academic cancer hospital. The program included routine monitoring of pain, staff education, and focus groups to identify organizational obstacles to effective pain management. During the first year of the program, patient satisfaction increased significantly, but the “worst pain levels over the past 24 hours” remained unchanged. Results from the second and third years suggested further reduction of pain intensity on targeted hospital units. Major change did not occur until pain assessment became routine and the resulting data had convinced physicians to participate in the programs.

Pain Education Programs at a community level have shown mixed results. Elliott and colleagues (51) failed to show a significant reduction in pain prevalence, pain management index, pain intensity scores, patient and family attitude scores, and physicians' and nurses' knowledge and attitude scores. In contrast, de Wit and colleagues (52) reported that patients significantly increased their knowledge of pain and its mechanisms, with a decrease in pain intensity of approximately 20% to 30%.

MANAGEMENT OF THE CANCER PATIENT WITH PAIN

Successful management of the cancer patient with pain depends on the ability of the clinician to assess initial problems, identify and evaluate pain syndromes, and formulate a plan for continuing care that is responsible to the evolving goals and needs of the patient and the patient's family (see Chapter 35). The formulation of an effective therapeutic strategy for the management of cancer pain requires a comprehensive assessment of the patient and the pain complaint. The goals of patient care are often complex, but they broadly comprise prolonged survival and optimizing comfort and function. Adoption of these goals logically leads to a multimodality treatment approach targeted to specific problems (Fig. 36-1).

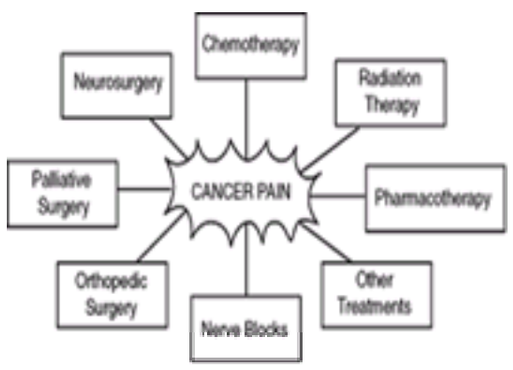

Figure 36-1. Multimodality therapeutic management of cancer pain. Other treatments include psychosocial interventions, nursing care, alternative pain management strategies, and end-of-life issues.

Comprehensive cancer care encompasses a continuum that progresses from disease-oriented, curative, life-prolonging treatment through symptom-oriented, supportive, and palliative care extending to terminal hospice care. Pain management is, and should be, an integral component of comprehensive cancer care (53). Designing an effective pain control strategy for the individual patient requires knowledge of the ways in which a patient's cancer, cancer therapy, and pain therapy can interact. Collaboration with different health care providers (e.g., medical oncologists and radiation oncologists) is essential to successful pain management.

Two important aspects of cancer affect management: (a) the oncologist's ability to treat the cancer and (b) components of the tumor pathophysiology that of themselves do not cause pain (the cancer's *nonpain* pathophysiology) (54). The ability to treat cancer modifies the need for pain management (successful treatment reduces the likelihood of pain) and the appropriateness of invasive pain procedures. Cancer nonpain pathophysiology can interfere with the oral administration of medications, narrow the patient's therapeutic window for analgesic drugs, limit the effectiveness of psychological pain therapies, and complicate or preclude invasive pain-reducing procedures. In addition, cancer therapy can interfere with or enhance pain therapy and vice versa. Antineoplastic treatment can interfere with pain therapy by causing pain or by producing other adverse effects. Cancer treatment can enhance pain therapy by reducing the extent of cancer, acting as an adjuvant analgesic, and providing intravenous access for parenteral drug administration to patients who require it. Pain therapy can sometimes interfere with cancer therapy by increasing or complicating the adverse effects of cancer therapy. It can enhance cancer therapy by improving patient function or sense of well-being, and certain palliative surgical procedures may have the ancillary effect of improving organ function.

The basic principles of tumor-directed pain control include (a) modifying the source of pain by treating the cancer and the inflammatory response of cancer; (b) altering the central perception of pain (e.g., by the use of analgesics, antidepressants, anxiolytics, and psychotherapy); and (c) interfering with nociceptive transmission within the central nervous system (CNS), for example, with anesthetic techniques (e.g., neuraxial analgesia and spinal neurolysis) or neurosurgery procedures (e.g., cordotomy and myelotomy).

The pain experienced by most cancer patients responds to direct and indirect modification of the source of the pain combined with pharmacologic and nonpharmacologic alteration of the central perception of pain (5,55,56).

The guiding principle in developing pain management goals is to individualize the approach to the patient's needs. Part of the process of developing treatment goals is to take into consideration the risks and benefits of different treatment options and the *price* that the patient and family is willing to pay for pain relief. Clinicians may find that patient treatment goals differ from their own, either because patients feel that pain is inevitable, or because patients expect pain to be relieved with minimal effort on their part. Issues that physicians should discuss with patients include expected lifestyle, cost and reimbursement issues, and concerns about opioid tolerance, addiction, and side effects. Discussing these issues in advance may uncover and address potential barriers to treatment. Moreover, treatment goals may change during the course of the patient's illness, and all health care providers interacting with the patient during the course of the illness need to keep abreast of such changes.

Patient life expectancy should influence treatment decisions. For example, if life expectancy exceeds several weeks, then treatment may focus on how to enable the patient to function at the highest possible level. One goal should be to relieve pain and prevent therapy from interfering with normal activities. On the other hand, those likely to die within a few days or weeks require less emphasis on maintaining an active lifestyle and more on tolerance of the side effects associated with pain therapies. The emphasis for these patients should be on treatments that provide immediate relief, rather than those that require a long period of time to become effective. Because maintenance of mental clarity and alertness is always valued, even in the last days or hours of life, patients may be willing to undergo more interventional methods of pain management to achieve better pain control.

Primary Anticancer Treatment

Pain produced by tumor infiltration may respond to antineoplastic treatment with surgery, radiation treatment, or chemotherapy, and pain caused by infections may diminish with antibiotic therapy or drainage procedures (see Chapter 37). Specific analgesic treatments are appropriate adjuncts to the primary therapy. The three major types of antineoplastic treatments are surgery, radiation therapy, and systemic therapy (chemotherapy, hormone therapy, and biotherapy). Surgery and radiation treatment generally attempt to cure localized malignancies, whereas chemotherapy treats disseminated neoplasm. The advantages of combined therapy have become evident, and an increasing number of patients receive combinations of these three therapeutic approaches. The rationale for such combination therapy comes from observations that surgery is most likely to fail locally at the edges of tumor resection (positive surgical margins), radiation therapy is most likely to fail in the center of tumors, and chemotherapy is most likely to fail in the presence of bulk disease.

Radiation Therapy

Radiation therapy is one of the most widely used treatments for cancer (57) (see Chapter 37). Research suggests that DNA is the target of the cytotoxic effects of radiation (58). Radiation therapy has a pivotal role in the treatment of cancer pain caused by bone metastases (see Chapter 37), epidural neoplasm, and cerebral metastases. Especially when combined with cytotoxic chemotherapy, limited surgical excision, or both, radiation can control disease at the primary site and regional nodes without the need for surgical extirpation as was frequently used in past years. New developments in three-dimensional treatment planning and the precise delivery of high-dose radiation promise to increase the benefit of radiation treatment. Table 36-4 lists diseases commonly treated by radiation.

Hodgkin's disease
Non-Hodgkin's lymphoma
Cervical carcinoma
Prostate carcinoma
Head and neck cancers
Seminoma
Tumors of the central nervous system
Retinoblastoma
Choroidal melanoma
Unresectable lung carcinoma
Unresectable pancreatic carcinoma
Unresectable sarcoma

TABLE 36-4. Diseases commonly treated by definitive radiation

Approximately 40% of patients referred for radiation treatment have advanced cancer that does not respond to curative treatment and is accompanied by pain (59). Rutten and colleagues (60) evaluated the pain characteristics that help to predict the pain-relieving efficacy of radiation therapy for cancer pain. In a study of 51 patients, they found a significant relationship between pain characteristics (the presence of radiating pain and a low pain score, i.e., pain scores less than 35, before radiation) and a complete response to palliative radiation treatment. Complete responses to treatment occurred within 21 days of the start of radiation.

Chemotherapy and Biotherapy

Pain relief often occurs after chemotherapy for responsive tumors such as lymphoma, small cell lung cancer, germ cell tumors, and possibly breast cancer. Combination chemotherapy regimens with agents having different modes of action and exhibiting different forms of toxicity are more likely to cure than single-agent therapy, because the chance of double resistance to two drugs is much less than the risk of single-drug resistance. Maximally tolerated drug doses are indicated because the fraction of cells killed is proportional to the dose employed. Single drugs, low doses, and long intervals between chemotherapy cycles encourage the development of resistant tumor cell clones. High-dose chemotherapy with autologous hematopoietic stem cell transplants is currently indicated for the treatment of high-grade non-Hodgkin's lymphoma (relapsed) and acute myelocytic leukemia when an allogeneic donor is not available. Some use this approach for stage IV breast cancer in remission and to complete the adjunctive therapy of high-risk primary breast cancer. Trials are under way in myeloma, ovarian, and testicular cancer, and certain other solid tumors.

Biological response modifiers now play an established role in the treatment of certain cancers (e.g., interleukin-2 in renal carcinoma, interferon as adjunctive therapy in melanoma, bacille Calmette-Guérin as local therapy for bladder tumors). Other modifiers include granulocyte colony-stimulating factor (filgrastim) and granulocyte-macrophage colony-stimulating factor (sargramostim), which stimulate the production of white blood cells. These hematopoietic growth factors facilitate host recovery from severe chemotherapy-induced myelosuppression and permit an increase in the dose intensity of standard chemotherapeutic agents.

Surgery

The surgeon treating a patient with newly diagnosed cancer must meet several responsibilities: biopsy for tissue diagnosis, adequate staging, consultation with medical and radiation oncologists for adjuvant therapy, and surgical resection. Surgery may also play a role in the relief of symptoms caused by specific problems, such as obstruction of a hollow viscus, unstable bone structures, and compression of neural tissues. A variety of surgical disciplines (e.g., general, orthopedic, gynecologic, neurosurgical, plastic, and reconstructive) may participate in the care of the cancer patient. Beginning in the 1960s and 1970s, surgery for certain tumors such as breast, colon, and lung cancer became more conservative. Because surgeons now know that regional lymph node spread often occurs independently from systemic metastasis, many surgeons take a more conservative approach when resecting the primary tumor.

Although the development of metastatic cancer usually indicates incurable disease, curative surgical resection is possible in rare instances. These instances must meet several criteria before the surgeon can operate: The primary lesion must be controlled; there must be the potential for complete resection of the metastases; there must be no other equally effective or better antitumor therapy available; metastases should involve only one organ; one should anticipate reasonable postoperative function; expected survival should be better than if left untreated; and the patient must be able to tolerate the surgical procedure. Sometimes excision of the primary tumor is indicated in the presence of unresectable metastatic disease. Locally advanced tumor can be painful and unsightly, can interfere with vital functions such as breathing and swallowing, and produce complications such as bleeding and local infection.

Stenting, Drainage Procedures, and Antibiotics

Common complications of advanced cancer include gastrointestinal, hepatobiliary, and ureteric obstructions. Stents and laser treatment have a place in both upper gastrointestinal and rectal obstruction caused by advanced malignancy (61,62 and 63). Endoscopic retrograde placement of ureteric stents under cystoscopic control is the most common urologic approach for the management of malignant ureteric obstruction. Difficult clinical situations may require alternative procedures such as palliative cutaneous ureterostomy, percutaneous anterograde ureteric stent placement, and a combined anterograde and retrograde technique. The insertion of internal biliary stents by endoscopic or percutaneous methods is common practice for the palliative management of obstructive jaundice caused by malignancy, and most surgeons prefer this to the use of external biliary drains (64).

The goals of antibiotic use in terminally ill patients are sometimes to prolong life, and always to relieve symptoms. Treatment for cystitis does not usually prolong life, but may relieve the patient from painful dysuria and troublesome polyuria. Antibiotics may also have pain-relieving effects when the source of pain involves infection, as illustrated by the treatment of pyonephrosis and osteitis pubis.

Symptomatic Cancer Pain Management

The management of the cancer patient with pain is complex and requires interdisciplinary collaboration. Successful management strategies usually require a team approach that focuses not only on the nociceptive processes but also on other factors that influence the final perception of pain. Figure 36-2 outlines tumor pain management strategies directed at the treatment of nociceptive and neuropathic pain at our institution.

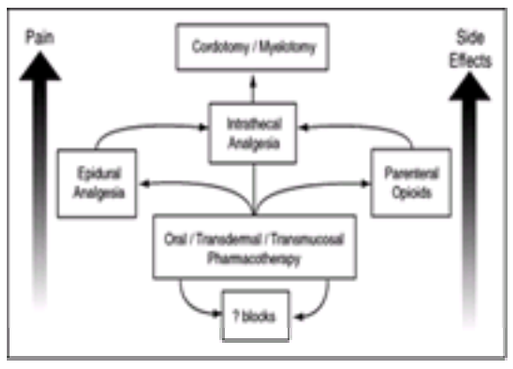

Figure 36-2. Tumor pain management algorithm.

Increasingly severe pain and increasing and intractable side effects determine the appropriate treatment strategy. Most patients respond satisfactorily to relatively simple oral pharmacotherapeutic strategies. When the patient requires drug treatment, therapy should comply with two basic principles: Use oral analgesics and other noninvasive routes of administration (e.g., transdermal and transmucosal) whenever possible, and administer them in accordance with the principles in the WHO analgesic ladder (see World Health Organization Analgesic Ladder). Titrate these analgesics to maximally effective doses or to the appearance of dose-limiting side effects before considering more specialized (and usually) invasive approaches. As an adjunct to medication management, many patients benefit from the use of additional, relatively simple, single-injection anesthetic blocks such as celiac and superior hypogastric plexus blocks, neurolytic subarachnoid and intercostal blocks, and selected peripheral nerve blocks. The intent of these procedures is not to replace medication management, but rather to supplement it.

Severe, uncontrolled pain or intractable side effects require interventional pain management to achieve rapid pain control. Such interventions may include epidural analgesia, parenteral opioid therapy, or both (usually intravenous or subcutaneous administration). As many of these patients have large systemic opioid requirements, it is not unusual to combine epidural and parenteral therapies. A small percentage of patients may fail on these therapies and should then be treated with intrathecal drugs, cordotomy, or myelotomy (see Interventional Pain Management, below).

Occasionally, patients have pain refractory to all interventional measures outlined. For these patients adequate relief may only come at the cost of profound sedation. One can accomplish sedation through the use of benzodiazepines (65), neuroleptics, barbiturates, and (for hospitalized patients) propofol (66). The ethical acceptability of sedation at the end of life depends on informed consent and an acknowledgment of the *principle of double effect*, which distinguishes between the compelling primary therapeutic intent (to relieve suffering) and unavoidable, untoward consequences.

WORLD HEALTH ORGANIZATION ANALGESIC LADDER

In 1986, WHO proposed a method for relief of cancer pain, based on a small number of relatively inexpensive drugs, including morphine (67). This guideline has been translated into 22 languages, and a total of more than 500,000 copies have been sold. A second edition (40) takes into account many of the advances in understanding and practice that have occurred since the mid-1980s. The groundwork for this revision was started in 1989, in the context of the meeting of a WHO Expert Committee on Cancer Pain Relief and Active Supportive Care (32).

The WHO analgesic ladder is a simple and effective method for controlling cancer pain, and the proportion of cancer patients who should receive effective pain relief varies from 75% to 90% (35,68). According to Zech and colleagues (5), 88% of patients with cancer pain should receive good pain control via the guidelines. Similarly, Schug and colleagues (69) estimated that only 11% of cancer pain patients managed with WHO guidelines required alternate methods of pain management. Grond and colleagues (70) found that 75% of terminally ill cancer patients received effective management with these guidelines. Although the effectiveness of the ladder appears to have received widespread approval, some authors have expressed concern on the validity and scientific effectiveness of published data. Jadad and Browman (71) conducted a systematic review of studies (Medline from 1982 to 1995, a hand search of textbooks and meeting proceedings, reference lists, and direct contact with authors) evaluating the effectiveness of the WHO ladder as an intervention for cancer pain management. Although the studies available provide valuable information on the course of cancer pain and its treatment, they fail to estimate confidently the effectiveness of the WHO analgesic ladder. Until results from carefully designed controlled trials become available, it is inappropriate to judge the performance of clinicians, programs, and institutions or to design policies based on such evidence.

Treatment for cancer pain should begin with a straightforward explanation to the patient of the causes of the pain or pains. Many pains respond best to a combination of drug and nondrug measures. Nevertheless, analgesics and a limited number of other drugs are the mainstay of cancer pain management (Table 36-5). Concurrent anticancer treatment and analgesic drug therapy for cancer pain poses no problem. Some pains respond well to a combination of a nonopioid and an opioid drug. Others require combining a corticosteroid and an opioid. Neuropathic pains often respond poorly to nonopioids and opioid analgesics, but tricyclic antidepressants and anticonvulsants may prove effective. Pharmacologic strategies for the control of tumor pain appear in Table 36-6. Table 36-7 lists the principles of pharmacotherapy endorsed by WHO.

Category	Basic drugs	Alternatives
Nonopioids	Acetylsalicylic acid	Choline magnesium trisalicylate
	Acetaminophen	Diflunisal
	Ibuprofen	Naproxen
	Indomethacin	Diclofenac
Opioids for mild to moderate pain	Codeine	Dihydrocodeine
		Dextropropoxyphene
		Standardized opium
		Tramadol
Opioids for moderate to severe pain	Morphine	Methadone
		Hydromorphone
		Oxycodone
		Levorphanol
		Meperidine
		Buprenorphine
Opioid antagonist	Naloxone	—
Antidepressants	Amitriptyline	Imipramine
Anticonvulsants	Carbamazepine	Valproic acid
Corticosteroids	Prednisolone	Prednisone
	Dexamethasone	Betamethasone

TABLE 36-7. Principles of drug therapy for cancer pain

These principles of pharmacotherapy are as follows:

By Mouth

When possible, patients should take analgesic medications by mouth. However, alternative routes such as rectal, transdermal, sublingual, and parenteral (subcutaneous and intravenous) administration may better serve patients with dysphagia, uncontrolled vomiting, or gastrointestinal obstruction.

By the Clock

Patients with continuous pain should take analgesic medications at fixed intervals of time. Titrate the dose of analgesic drug against the patient's pain (i.e., gradually increasing dose until the patient is comfortable). The patient must take the next dose before the effect of the previous dose has fully worn off. Some patients may need to take rescue doses for incident and breakthrough pain, in addition to the regular schedule.

By the Ladder

The WHO analgesic ladder (1996) is based on the premise that most patients throughout the world gain adequate pain relief if health care professionals learn how to use a few effective and relatively inexpensive drugs well (Fig. 36-3). Step 1 of the ladder involves the use of nonopioids. If this step does not relieve pain, add an opioid for mild to moderate pain (step 2). When the opioid for mild to moderate pain in combination with a nonopioid fails to relieve the pain, substitute an opioid for moderate to severe pain (step 3). Use only one drug from each of the groups at the same time. Give adjuvant drugs for specific indications (see Adjuvant Drugs, below).

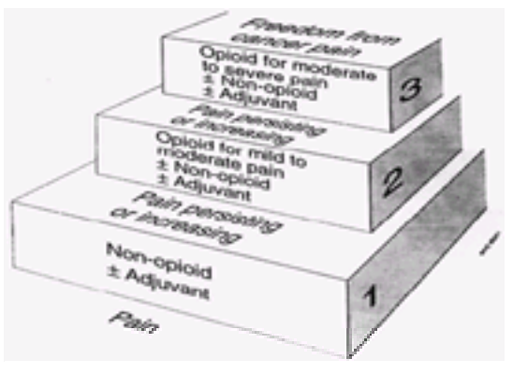

Figure 36-3. World Health Organization analgesic ladder. (From World Health Organization. *Cancer pain relief with a guide to opioid availability*. Geneva, Switzerland: World Heath Organization, 1996.)

For the Individual

No standard doses for opioids exist. The *right* dose is the dose that relieves the patient's pain with the minimum of side effects. Drugs used for mild to moderate pain have a dose limit in practice because of formulation (e.g., combined with acid or acetaminophen, which are toxic at high doses) or because of a disproportionate increase in adverse effects at higher doses (e.g., codeine). Do not use the same opioid if patients had previous unsatisfactory experiences with that drug.

With Attention to Detail

Carefully outline and monitor the patient's analgesic regimen. Follow up regularly with the patient by monitoring compliance, drug efficacy, and side effects. Anticipate adverse effects and, in some situations, treat them prophylactically.

The WHO ladder advocates the use of three classes of analgesics: nonopioid, adjuvant, and opioid. Each of these classes is considered separately.

NONOPIOID ANALGESICS

Because nonopioid analgesic agents and antipyretics are basic drugs for the management of acute and chronic pain, including rheumatic conditions, clinicians should become familiar with the use, efficacy, and adverse effects of these agents. Nonopioid analgesics are important to the successful use of oral pharmacotherapy in the cancer patient with pain. These drugs may function to control pain independently (e.g., in the management of bone pain) or may help reduce the dose of opioid required for pain control (opioid-sparing effect). However, a wide range of drugs with varying effects and side effects are available.

Three groups of nonopioid analgesics exist: acetylsalicyclic acid, acetaminophen, and nonsteroidal antiinflammatory drugs (NSAIDs) (see Chapter 83). Although acetylsalicyclic acid may be considered an NSAID, it merits separate discussion because it is effective, cheap, and widely available.

Aspirin

Aspirin is a salicylate ester of acetic acid. Aspirin irreversibly acetylates and inactivates cyclooxygenase. The antipyretic activity of aspirin probably results from the secondary inhibition of pyrogen-induced release of prostaglandins in the CNS and possibly to centrally mediated peripheral vasodilation. Aspirin acetylates platelet cyclooxygenase and prevents the synthesis of thromboxane A_2, a potent vasoconstrictor and inducer of platelet aggregation.

After oral administration, aspirin has an onset of action in 5 to 30 minutes, peaking after 0.5 to 2.0 hours, and lasting approximately 3 to 7 hours. The standard dose is 500 to 600 mg every 4 to 6 hours. The administration of more than 4 g per day is likely to lead to toxic effects. A review of aspirin's effect on the renal function of experimental animals after acute and chronic administration (72) revealed that although the findings are inconsistent, chronic administration can cause analgesic-associated nephropathy.

Nonacetylated salicylates, such as choline magnesium trisalicylate (CMT) and salsalate, have less ulcer-producing potential than aspirin, and at usual clinical doses do not impair platelet aggregation (73). Kilander and Dotevall (74) compared the effect of aspirin and CMT on gastric and duodenal mucosa by gastroduodenoscopy after 5-day periods of administration in 10 healthy volunteers. Serum salicylate levels were similar in the two groups. All subjects given aspirin developed multiple mucosal lesions, but in only four subjects given CMT were slight mucosal changes noted, suggesting that the risk of developing mucosal lesions is much less during treatment with CMT than with aspirin. Danesh and colleagues (75) measured parameters of platelet thromboxane biosynthesis 24 hours after ingestion of equivalent salicylate doses (500 mg) of aspirin and CMT. In random order, 10 healthy volunteers received these drugs on 2 separate days, 2 weeks apart. Although aspirin significantly prolonged bleeding time, and decreased plasma thromboxane generation and serum thromboxane B_2 levels, CMT failed to produce such effects. CMT has no inhibitory effect on platelet thromboxane biosynthesis, and may therefore be considered safer than aspirin for therapeutic use, when inhibition of platelet function can be hazardous.

Acetaminophen

Acetaminophen, indicated for noninflammatory pain and for fever control, is available in a variety of oral preparations and as a suppository. It has no antiinflammatory action and no antiplatelet activity. I commonly use 650 mg every 6 hours and occasionally prescribe 1,000 mg every 6 hours (particularly if encountering opioid-related side effects). The maximum dose for long-term use is 4 to 6 g per day. This dose may produce adverse effects so if higher doses (more than 4 g per day) are used, it is important to monitor carefully for the occurrence of toxicity. No evidence exists for the development of chronic analgesic nephropathy with acetaminophen alone (76). Epidemiologic studies in healthy individuals have failed to demonstrate a significant correlation between acetaminophen use and chronic renal disease and classic analgesic nephropathy (77). The only reports on this subject suggest that combination therapy with aspirin (78) or ingestion of toxic doses of acetaminophen (79) may induce nephrotoxicity. Hepatotoxicity is predominantly associated with the use of acetaminophen and occurs after single, acute, or short-term exposure to larger (more than 10 g) doses or long-term exposure with lower (less than 4 g) doses, especially in alcoholics (80,81). The majority of acetaminophen- induced fatalities occurs in younger patients after intentional overdose, usually after an acute ingestion of greater than 10 to 15 g of acetaminophen. However, certain subgroups of patients tend to develop acute hepatotoxicity after chronic ingestion of less than 10 g per 24 hours (81,82,83 and 84). These include patients who are fasting or malnourished, and those who have a chronic intake of alcohol or anticonvulsants.

Nonsteroidal Antiinflammatory Drugs

In deciding what is the optimal nonopioid analgesic for a given patient, one must consider the underlying cause of pain, its chronicity and acuity, the patient's concurrent disease states, if any, and the potential for drug interactions with the patient's concomitant medications. It seems prudent to use acetaminophen as the first-line agent for those patients who cannot tolerate aspirin or other NSAIDs. If the relative efficacy of acetaminophen and NSAIDs was similar for a particular patient, then the risk to benefit ratio and economic consequences would favor the use of acetaminophen.

NSAID pain relief is typically characterized both by a ceiling dose, beyond which additional increments fail to yield further pain relief or more severe side effects but no further pain relief, and by a lack of demonstrable physical dependence or tolerance. One cannot predict the minimal effective analgesic dose, the ceiling dose, or the toxic dose in advance for the individual patient with cancer pain, and this dose may be higher or lower than the usual dose range recommended for the drug involved. Standard recommended doses for nonopioid drugs derive from studies performed in populations (generally healthy patients with inflammatory diseases) that may have little in common with cancer patients, the latter often have numerous medical problems and use several other drugs).

The successful use of NSAIDs in the cancer patient necessitates a strategy that involves both low initial doses and dose titration. With gradual dose escalation, one can usually identify the ceiling dose and reduce the risk of significant toxicity. Weekly intervals are usually adequate to evaluate the efficacy of a dose. The potential for dose-dependent toxicity requires the use of an empirical upper limit for dose titration, which is usually in the range of 1.5 to 2.0 times the standard dose of the drug in question. Because failure with one NSAID does not predict a similar outcome with another, the physician may need sequential trials of several NSAIDs to identify a drug with a favorable balance between pain relief and side effects.

In general, the following guidelines for nonopioid dosing may be used:

- An increase in dose generally results in increased side effects.
- There is a questionable ceiling effect in cancer pain; to correctly titrate nonsteroidals or nonopioids in cancer pain patients, limit dosing to 1.5 to 2.0 times the standard recommended dose.
- At this higher dosage, check patients' stools for occult blood, monitor urine for protein, and check plasma creatinine levels bimonthly.
- Titrate doses at weekly intervals and, if there is no response at the higher levels, then decrease the dosage.

Use of Nonsteroidal Antiinflammatory Drugs in Cancer Pain

Studies of cancer pain have involved several NSAIDs. Single- and multiple-dose trials have shown benefit from ibuprofen (85), naproxen (86), ketoprofen (87), and ketorolac (88). Prolonged subcutaneous infusions of naproxen (89), diclofenac (90), and ketorolac (91) have also been reported. NSAIDs are widely believed to be especially helpful for the management of malignant bone pain (92,93). However, specific clinical data about pain-reducing responses to NSAIDs in cancer patients are sparse; many of the assumptions that guide oncologic pain management are based on either clinical impressions or trials in nonmalignant pain. Several authors have questioned the efficacy of NSAIDs for cancer pain (94,95).

Eisenberg and colleagues (94) examined the scientific evidence on efficacy and safety of NSAIDs in the treatment of cancer- related pain. They conducted a metaanalysis of data from 25 randomized controlled trials. The studies provided data on 1,545 cancer patients. Although all 25 trials reported analgesic efficacy, only the single-dose studies were comparable for analgesic efficacy analysis. Single doses of placebo produced a 15% to 36% rate of analgesia, whereas NSAIDs produced roughly twice as much analgesia (31% versus 60%). These results support the WHO position that although placebo produces some pain relief in cancer patients, true nonopioid analgesics have a significantly higher analgesic efficacy in patients with cancer pain (32). The comparative efficacy of one NSAID versus another is somewhat limited. Four studies compared the single-dose efficacy of aspirin with three other NSAIDs (indoprofen, ketoprofen, and naproxen). The results suggested slightly superior pain relief from NSAIDs compared with aspirin, but without statistical significance.

The dose-response analgesic efficacy of NSAIDs in cancer pain is not yet determined and the results of the metaanalysis are still only suggestive. The dose-response relationship was evaluated by comparing the analgesic efficacy of 600 versus 1,000 mg of oral aspirin, 100 versus 200 mg of oral indoprofen, and 10 versus 20 mg of intramuscular ketorolac. The two scores used for analgesic efficacy (peak pain intensity difference and summed pain intensity difference) were approximately 1.3 greater in the high- dose patients than in the low-dose patients, but these differences did not reach statistical significance.

The ceiling analgesic effect was tested by comparing pain scores for recommended and supramaximal single doses of three NSAIDs: ketoprofen, 100 versus 300 mg and 75 versus 225 mg orally; zomepirac, 100 versus 200 orally; and ketorolac, 10 and 30 mg versus 90 mg intramuscularly. The recommended and supramaximal doses showed similar efficacy according to all four scores used (peak pain intensity difference, summed pain intensity difference, peak pain relief, and total pain relief), which indicates a ceiling effect. The authors concluded that the metaanalysis precluded testing the hypothesis that NSAIDs are particularly effective for malignant bone pain because of a lack of comparable studies (95). Well-designed analgesic trials in which bone pain or pain caused by other specific cancer-related syndromes is assessed separately from nonbone pain are required.

Adverse Effects

The ingestion of NSAIDs can produce multiple adverse effects on the kidney (96) and other organ systems (97) (see Chapter 83). Common side effects of NSAIDs include upper gastrointestinal upset, dizziness, and drowsiness. Multiple doses generally produced more side effects than single doses.

NSAIDs may cause bleeding, altered platelet function, or gastric irritation. Gastric mucosal integrity is maintained by the interplay of three protective networks: prostaglandin synthesis, nitric oxide synthesis, and the activity of the enteric nervous system. Patients taking any NSAID require monitoring for gastropathy, renal failure, hepatic dysfunction, and bleeding (94,98,99). Gastric distress should be ameliorated by the use of a histamine H_2 antagonist or sucralfate (100). Misoprostol is a synthetic analog of prostaglandin E_1. It inhibits gastric acid production and has cytoprotective effects on the gastroduodenal mucosa. Misoprostol, in a dose of 200 µg taken orally four times a day, is more effective than 150 mg of ranitidine taken orally twice daily in preventing asymptomatic, NSAID-induced gastric ulceration (101). Side effects include sedation, tremor, abdominal pain, and diarrhea. Mild diarrhea and gastointestinal intolerance may occur in 20% to 40% of patients and may

limit tolerance to the drug (102,103).

All NSAIDs should be used cautiously in patients with renal insufficiency. Although sulindac may have relatively less effect on the kidney (104) and might seem a safer choice when potent antiinflammatory effects are desirable in the cancer patient with renal insufficiency, the clinical relevance for this renal-sparing effect is controversial. Nabumetone may require dose adjustment in the elderly, other patients with active rheumatic disease, and those with hepatic impairment, but not in patients with mild to moderate renal insufficiency (105). The development of cyclooxygenase-2 inhibitors (e.g., celecoxib) as potentially gastro-safe NSAIDs is based on the notion that COX-1 predominates in the stomach, yielding protective prostaglandins, whereas COX-2 is induced in inflammation giving rise to pain, swelling, and stiffness (106). However, the long-term safety and efficacy of selective COX-2 inhibitors have not been studied in the cancer pain population and therefore are not currently recommended over the more commonly available NSAIDs.

ADJUVANT DRUGS

Adjuvant drugs may become necessary in the care of the cancer patient for one of three reasons: (a) to treat the adverse effects of analgesic medications (e.g., antiemetics and laxatives); (b) to enhance pain relief; and (c) to treat concomitant psychological disturbances such as insomnia, anxiety, depression, and psychosis.

Antiemetics

The most widely used of the antiemetic drugs are those that block dopamine receptors, such as metoclopramide, the phenothiazines (prochlorperazine, promethazine), and the butyrophenones (haloperidol, droperidol). Metoclopramide acts both centrally and on gastric motility. Doses greater than 1 to 3 mg per kg act as an antiemetic by antagonizing 5-HT_3 receptors in the gastrointestinal tract and perhaps also in the CNS (107). However, because of its dopamine-receptor antagonism, extrapyramidal side effects appear, limiting usefulness at this dose level. The butyrophenones act by blocking dopamine receptors in the chemoreceptor trigger zone. Similar extrapyramidal side effects may also appear with higher doses. The development of the 5-HT_3 receptor antagonists, such as granisetron, ondansetron, and tropisetron, is an important advance in the treatment of nausea and vomiting. Rung and colleagues (108) demonstrated that intravenous ondansetron is effective for postsurgical opioid-induced nausea and vomiting and has a low incidence of side effects.

If the patient has nausea when beginning an opioid, prescribe a neuroleptic antiemetic concurrently (e.g., haloperidol, 1 to 2 mg once a day, increasing to a maximum of 5 mg). Prochlorperazine is a useful alternative, 5 mg every 8 hours, increasing to a maximum of 10 mg every 4 hours. Some patients receiving morphine develop nausea and vomiting that does not respond to neuroleptics, probably because of drug-induced delayed gastric emptying. In such cases, substitute metoclopramide (10 mg every 8 hours, increasing to a maximum of 20 mg every 4 hours) for the neuroleptic. If vomiting persists, consider changing to a continuous subcutaneous infusion of morphine with metoclopramide, 60 mg per day, for several days. If a patient vomits several times a day, it becomes necessary to give the antiemetic by injection, initially for 2 days. For patients with inoperable bowel obstruction, use an antihistaminic antiemetic, such as cyclizine. To reduce gastrointestinal secretions, an atropinelike drug, such as hyoscine butylbromide, may be necessary (109). Octreotide has proved an effective agent for the palliation of refractory malignant intestinal obstruction. It presumably exerts a proabsorptive effect on the small bowel mucosa, an effect on improving gastrointestinal motility, by a reduction in gastrointestinal hormone levels and by a direct antineoplastic effect on the obstructing tumor (110). Administer octreotide at doses starting with 0.3 up to 0.6 mg (mean, 0.44 mg) a day by subcutaneous continuous infusion (111).

Laxatives

Laxatives should be prescribed whenever starting an opioid drug. The appropriate dose of laxative varies considerably from patient to patient. For most patients, the regular use of a stool softener, such as docusate sodium, and a peristaltic stimulant, such as senna, counteracts opioid-induced constipation. Prescribe stool softeners every 12 hours. Titrate the dose of the stimulant for each patient until a satisfactory result is achieved. One tablet of standardized senna at nighttime is a typical starting dose, increasing to two tablets every 4 hours if necessary. If the patient is already severely constipated when an opioid is first prescribed, consider lactulose, 15 to 30 mL.

Adjuvant Analgesics

An adjuvant analgesic is a medication with primary indication other than pain relief, but it may provide or enhance analgesia in certain circumstances. In the area of cancer pain, the common adjunctive analgesics are corticosteroids, anticonvulsants, and antidepressants. These drugs play an important role for some patients who cannot otherwise attain an acceptable balance between relief and opioid side effects. Adjuvant analgesics divide broadly into general purpose analgesics and those with specific use for neuropathic, bone, or visceral pain.

General Purpose Adjuvants

Corticosteroids are the most widely used general purpose adjuvant analgesics and are available in a wide variety of formats (112). The painful conditions that commonly respond to corticosteroids include increased intracranial pressure, acute spinal cord compression, superior vena cava syndrome, metastatic bone pain, neuropathic pain caused by infiltration or compression, symptomatic lymphedema, and hepatic capsular distension. Patients with advanced cancer who experience pain and other symptoms that may respond to corticosteroids usually receive relatively small doses (e.g., dexamethasone, 1 to 2 mg twice a day). Using a short course of relatively high doses (e.g., dexamethasone, 100 mg intravenously followed initially by 96 mg per day in divided doses) can help manage an acute episode of severe pain related to a neuropathic lesion (e.g., plexopathy or epidural spinal cord compression) or bony metastasis that does not respond to opioids. In all cases, gradually lower the dose after pain reduction to the minimum needed to sustain relief.

Corticosteroids are sometimes indicated for symptoms such as mood elevation, for their antiinflammatory effect, as antiemetics, and as appetite stimulants. For such purposes, one should follow the low-dose regimen outlined previously. However, side effects such as myopathy, hyperglycemia, or psychosis may prove problematic.

Topical local anesthetics, such as EMLA cream (eutectic mixture of lidocaine and prilocaine), have a role in the management of painful cutaneous and mucosal lesions. Apply EMLA cream thickly and cover with an occlusive dressing. Lidocaine viscous can control pain associated with oropharyngeal ulceration.

Neuropathic Pain Adjuvants

The use of adjuvants can contribute substantially to the successful management of neuropathic pain. The drugs used empirically for this indication include selected antidepressants (113), orally administered local anesthetics, anticonvulsants, and others. For the purpose of drug selection, it is useful to distinguish between continuous, lancinating, and sympathetically maintained pain. Given the great interpatient and intrapatient variability in the response to adjuvants in this setting (including those within the same class), many patients require sequential trials (see Chapter 85 and Chapter 86).

The common anticonvulsants are carbamazepine and valproic acid. Carbamazepine causes enzyme induction, thereby enhancing its own metabolism. Consequently, adverse effects (e.g., drowsiness, ataxia) improve with time. Carbamazepine may exacerbate preexisting chemotherapy-induced suppression of bone marrow. Valproic acid has a long plasma half-life and is sedative. Because the drug accumulates in the body, it may be necessary to reduce high doses.

Gabapentin (Neurontin) has been used for the treatment of neuropathic pain. Gabapentin, a cyclohexane amino acid, is related structurally to GABA, yet has neither properties of GABAnergic nor GABA prodrug. It may facilitate GABA release and may act at the *N*- methyl-d-aspartate (NMDA) receptor site. Although developed as an anticonvulsant drug, gabapentin's serendipitous actions in pain relief soon emerged (just as carbamazepine relieves some cases of neuropathic pain). However, no prospective, randomized, double-blind clinical trials are yet available to evaluate the role of gabapentin for malignant neuropathic pain.

Gabapentin appears to have fewer side effects than the other anticonvulsant agents used for the treatment of neuropathic pain, thus facilitating more aggressive dose titration. The initial dose is usually 300 mg twice a day. Increase this dose in frequency to four times a day as tolerated. If symptoms persist, increase the dose strength to an average daily dose of 2,400 mg. The most common side effect encountered is dizziness, then somnolence, ataxia, and nystagmus. These effects usually wane with continued use.

Tricyclic antidepressants can help control pain of a burning nature, depression, and sleep disorders (see Chapter 85). Max and colleagues reported that the character of the pain complaint did not predict response to antidepressants (114). Amitriptyline and imipramine are both widely available. Alternative drugs, available in most

countries, may be more suitable for some patients. Nortriptyline has less sedating properties than amitriptyline; desipramine is relatively nonsedative and has minimal anticholinergic effects. Starting doses depend on the patient's age, weight, previous use of such drugs, and concurrent medications. A dose as low as 10 mg may be appropriate for some patients, but most can take 25 to 50 mg. Increase the dose to 30 to 50 mg as rapidly as tolerated (usually in terms of sedation, postural hypotension, and dry mouth). After that, increase the dose weekly until the pain is relieved or adverse effects preclude further escalation. Pain reduction, independent of changes in mood (115), occurs in many patients after a few days on doses of 50 to 100 mg (116,117).

Bone Pain Adjuvants

The clinical development of bone-seeking radiopharmaceuticals is based on the rationale that medium- to high-energy beta particle radiation, targeted and delivered to skeletal sites involved with tumor, can potentially result in more effective antitumor activity while sparing normal tissues the damaging effects of radiation. Metastatic lesions that produce a significant osteoblastic response in bone will concentrate bone precursors, such as the radiopharmaceuticals.

The most commonly used radiopharmaceutical for the treatment of bone pain caused by metastatic disease is strontium 89. Strontium chloride (^{89}Sr) is a beta particle–emitting calcium analog selectively taken up by osteoblasts. Physiologically, the drug acts as calcium and achieves preferential binding in the inorganic matrix of bone. It is absorbed into areas of high bone turnover and can reduce pain, generally without causing significant bone marrow depression. Because treatment with this agent can compromise marrow reserve and irreversibly lower platelet count, it is contraindicated if significant thrombocytopenia is present.

Robinson and colleagues (118) reviewed findings through December 1994 to evaluate ^{89}Sr therapy for the palliation of pain due to osseous metastases from breast and prostate cancer. Doses of ^{89}Sr ranged from 0.6 MBq per kg (16 µCi per kg) to 400 MBq (10.8 mCi) per patient. Baseline pain assessment and periodic pain estimates as measured by the Karnofsky index, medication diaries, changes in mobility, sleep patterns, and ability to work provided the basis for assessment of response. As many as 80% of selected patients with painful osteoblastic bony metastases from prostate or breast cancer may experience some pain relief after ^{89}Sr administration. In addition, as many as 10% or more may become pain free. Duration of clinical response may average 3 to 6 months in some cases. Hemotoxicity is mild. The nadir of platelet and white blood cell counts appears at approximately 4 to 8 weeks after injection, with a partial return to baseline by 12 weeks. Some patients have received up to 10 injections spaced 3 months apart with repeated palliative effect and without serious hemotoxicity.

Several other radiopharmaceuticals are available for clinical use. These include rhenium 186, phosphorus 32, samarium 153, and gallium nitrate. Prospective clinical studies are needed to evaluate the role of these agents in the cancer patient with painful bone metastases.

Bisphosphonates inhibit bone turnover by decreasing the resorption of bone. They do this both directly, by inhibiting the recruitment and function of osteoclasts, and indirectly, by stimulating osteoblasts. Bisphosphonates may also shorten the life span of osteoclasts. A variety of bisphosphonate compounds are available and include pamidronate, clodronate, etidronate, tiludronate, alendronate, and ibandronate. Although these compounds differ markedly in potency, they share common properties: They are poorly absorbed from the gut and are concentrated in bone, where they remain until the bone is resorbed.

Clinically, bisphosphonates can be strikingly effective in clinical disorders associated with increased bone resorption such as Paget's disease, hypercalcemia of malignancy, myeloma, bone metastases, and osteoporosis. They are now the standard therapy for hypercalcemia after rehydration (119). In malignancy, the clinical effects of bisphosphonates are greatest and most clearly defined in breast cancer and multiple myeloma, but they promise clinical benefit across the entire spectrum of metastatic bone disease (120,121). The efficacy of clodronate is nearly complete in patients with myelomatosis, less complete in solid tumors with hypercalcemia but without skeletal metastases, and intermediate in patients with solid tumors in the presence of skeletal metastases (122).

The choice of therapeutic regimen for bisphosphonates poses interesting questions (e.g., the effect of intermittent dosing versus continuous, intravenous versus oral therapy, the optimal duration of therapy, and the role of individual variability in response). The acute pain-relieving effect, which occurs within days or a week, probably derives from the reduction of various pain-producing substances. Patients with bone metastases and bone pain may obtain benefit from a trial of clodronate, 600 to 1,500 mg intravenously in 500 mL of normal saline over 3 hours given every 1 to 2 weeks, in association with other modalities such as radiotherapy and analgesic medications (119). Oral clodronate or intravenous pamidronate should be given as a preventive measure in patients with established bone metastases from breast cancer (123) and myeloma (124). Although bisphosphonates may delay the emergence of bone metastases in patients with no evidence of bone metastases (125,126), at present this remains under clinical investigation.

The physiologic role of calcitonin is the preservation of osseal integrity through reduced osteoclast activity. As such, the role of calcitonin in the management of tumor pain relates to bone metastases. Repeated doses of calcitonin reduced bone pain in one trial (127), but not in another (128). One can give the drug, salmon calcitonin, 100 IU twice daily subcutaneously or by nasal spray for several weeks. This entails close monitoring, including repeated assessments of calcium and phosphorus. Reports indicate that neuraxial (epidural and intrathecal) administration can reduce metastatic cancer pain (129), but this mode of administration requires further evaluation in controlled randomized clinical trials. Overall, the use of calcitonin for the long-term suppression of osteolysis has proven disappointing, and I do not recommend it as a means of controlling metastatic bone pain.

Bone metastases arise, in general, from blood-borne spread of a primary tumor site. Consequently, even patients with localized bone pain usually have occult sites of metastasis, and many patients develop new pain at new sites. Hemibody irradiation has attracted some interest in this setting. A large randomized trial using hemibody irradiation demonstrated reduced requirements for further bone radiation therapy when patients receive the treatment at the time of presentation of local bone pain (130). However, the role of such prophylactic therapy in clinical practice remains uncertain at this time. Scarantino and colleagues (131) evaluated the effect of fractionated hemibody irradiation in the treatment of osseous metastases. The maximum tolerated dose of fractionated (2.50 Gy) hemibody irradiation was 17.5 Gy, and the major dose limiting toxicity was hematologic (thromboleukopenia).

Visceral Pain Adjuvants

The literature offers little support for the potential efficacy of adjuvant agents for the management of bladder spasm, tenesmoid pain, and colicky intestinal pain. A trial of NSAIDs may help patients with painful bladder spasms (132). Although no well-established pharmacotherapy exists for painful rectal spasms, diltiazem can help in the management of proctalgia fugax (133). The treatment of pain caused by inoperable bowel obstruction has been described previously.

Psychotropic Drugs

Many cancer patients require a psychotropic drug. Some need it for pain relief (e.g., tricyclic antidepressants for nerve injury pain), whereas others need an antiemetic (e.g., haloperidol for opioid-induced nausea). Still others require an anxiolytic, such as clonazepam or alprazolam. Some require a night sedative and others an antidepressant for identifiable depression. The concurrent use of two centrally acting drugs (e.g., opioid with psychotropic drug or two psychotropic drugs together) is more likely to produce sedation in ill and malnourished cancer patients than in others.

OPIOID ANALGESICS

All opioids act by the same mechanisms; therefore, it is seldom advantageous to combine them in significant numbers to treat pain. Such polypharmacy is all too common, probably because of a reluctance to increase the dose of a single opioid to an effective one, which may exceed the usual or recommended dose. In addition, too rapid titration with a single agent causes unacceptable side effects and commonly leads to multiple trials of different agents. When a single drug is used in an adequate dose at an appropriate titration rate, it is less confusing to the patient and may produce more satisfactory pain control.

The use of opioids over time may cause the development of physical dependence and tolerance. In practice, physical dependence and tolerance do not prevent the effective use of these drugs. Patients with stable disease often remain on a stable dose for weeks or months (134). Collin and colleagues (135) demonstrated a relationship between tumor progression and escalation of opioid doses over time such that the development of opioid tolerance as a result of chronic opioid use was unlikely in cancer patients with pain. Furthermore, wide clinical experience has shown that addiction does not occur in cancer patients as a result of receiving opioids for relief of pain (4,136,137).

Several factors must be considered if opioids are to be used effectively. These include (a) previous opioid exposure and preference; (b) severity and nature of disease; (c) age of patient; (d) extent of cancer, particularly hepatic and renal involvement altering normal opioid pharmacokinetics (Table 36-8); and (e) concurrent

disease.

Opioid	Effect
Dihydrocodeine	Decreased clearance
Dextropropoxyphene	Increased norpropoxyphene (toxic metabolite)
Morphine	Increased morphine-6-glucuronide (active metabolite)
Meperidine	Increased normeperidine (toxic metabolite)

TABLE 36-8. Effects of renal failure on opioid pharmacokinetics

The degree of pain relief that a given opioid provides varies both intraindividually and interindividually, and depends on the type and time aspects of the pain experienced, the drug and drug characteristics, and the route of administration. Neuropathic pain and incident pain are among the poor prognostic factors for opioid treatment outcome. The treatment of incident pain is difficult, because the doses of analgesics needed to control the incident pain are often so high that toxicity occurs when the incident pain is absent.

Mixed agonist-antagonists and partial agonist drugs have predominantly agonist actions, but many also have a potentially significant antagonist action. Never change patients currently treated with pure agonists to either mixed agonist-antagonists or partial agonists because this may precipitate a withdrawal reaction. However, it is safe to change patients treated with mixed agonist-antagonists or partial agonists to pure agonists.

It is helpful to consider opioid analgesics as those used for mild to moderate pain and those used for moderate to severe pain. This distinction is arbitrary; it is based on a ceiling effect and on the manner in which these drugs are usually prescribed. Of interest, WHO considers codeine as the basic opioid for mild to moderate pain with dihydrocodeine, dextropropoxyphene, standardized opium, and tramadol as possible alternatives (40). Low-dose (0.2 mg every 8 hours) buprenorphine, a partial agonist, is also considered an alternative drug. For moderate to severe pain, morphine is considered the basic opioid, with methadone, hydromorphone, oxycodone, levorphanol, meperidine, and buprenorphine (high dose up to 1 mg every 8 hours) as possible alternatives (see Table 36-5).

Morphine

Although many compounds produce morphine-like pain relief and other effects, morphine is the standard opioid against which all new analgesics are measured, and it still remains the opioid of choice for the control of moderate to severe cancer pain.

Controlled-release opioid medication facilitates pain relief on a regular around-the-clock rather than on an as-needed basis. A fixed dose schedule has many advantages over as-needed dosing for patients with chronic pain. In particular, scheduled time-release medication allows for a more stable plasma level of drug with fewer *overshoots* (and consequently more adverse effects) and *undershoots* (with inadequate pain control) than short-acting opioids. Additional advantages include less frequent dosing, improved medication compliance, and the ability to relieve pain through the night as the patient sleeps.

The correct dose is that which controls pain but does not cause unacceptable side effects. Titrate the dose against side effects for each patient, and determine the starting dose from previous analgesic treatment. No upper limit exists to morphine dosing. Long-term treatment with 10- to 20-fold increase of oral doses over a period of 6 to 8 months does not seem to change the kinetics of oral morphine (138). Dose requirements may vary 1,000-fold, but relatively few patients need daily doses above 200 to 300 mg (137). Peak plasma concentrations usually occur within the first hour after oral administration of morphine in solution (138) and slightly later with immediate release tablets (139). Both short-acting formulations have a rapid effect, and analgesia lasts for approximately 4 hours. In contrast, controlled-release morphine tablets produce delayed peak plasma concentrations after 2 to 4 hours (140,141), the peak is attenuated, and analgesia usually lasts for 12 hours (142). This means that, with controlled-release morphine, it is more difficult to assess the adequacy of analgesia and to adjust the dose during the dose-finding period and to make rapid changes in dose. Ideally, one should maintain dosing at 12-hourly intervals.

Controlled-release morphine is considered the gold standard for long-acting opioids. In the United States, three preparations of controlled- or sustained-release morphine are available (Table 36-9). Both MS Contin and Oramorph SR are manufactured in a resin matrix that slowly dissolves in the gastrointestinal tract, releasing morphine over approximately a 12-hour period. The controlled- release form of morphine includes macromolecules from two different classes. The proportion of these macromolecules provides gradual, measured release of morphine by dissolution and diffusion. The first type of macromolecule, a polymer, is a highly polar cellulose of variable branching and molecular weight distribution. It passes through the gastrointestinal tract unchanged, except for binding water to allow slow release of the active drug. The second class of macromolecules consists of long-chain aliphatic alcohols. Inclusion of both types is designed to result in both a hydrophilic and a hydrophobic molecular phase during preparation of the granules used to compress the tablets.

Duration of action	Preparation	Dosage formats
Immediate release	Tablet/capsule	15 mg, 30 mg
	Soluble/ sublingual	10 mg
	Solution	Variety, commonly 20 mg/5 mL
	Suppository	5 mg, 10 mg, 20 mg
Controlled/sustained release	MS Contin	15 mg, 30 mg, 60 mg, 100 mg, 200 mg
	Oramorph SR	15 mg, 30 mg, 60 mg, 100 mg
	Kadian	20 mg, 50 mg, 100 mg

TABLE 36-9. Available oral/rectal preparations of morphine in the United States

One advantage of this delivery system is that it permits regulation of a drug's release rate through variation in the proportion of hydrophilic and hydrophobic components. When a tablet reaches an aqueous environment, the drug-containing cellulose matrix is hydrated and swells, reaching a predetermined degree of porosity, but otherwise remaining intact. The absorption of water by the polymer within the tablet matrix, in addition to causing swelling and dissolution, allows the drug to diffuse smoothly and evenly from the surface and from more interior portions of the tablet. The drug release rate is determined by the size of the pores and by the aliphatic alcohol acting as a barrier. The rate of release is primarily determined by the system itself, rather than by pH.

Numerous studies demonstrate the efficacy and safety of MS Contin and Oramorph SR for patients with cancer pain (143,144,145 and 146). However, MS Contin and Oramorph SR tablets have different physical, pharmacokinetic, and clinical characteristics. Results of biopharmaceutical studies indicate that these two products are not bioequivalent. Hunt and Kaiko (147) compared the pharmacokinetic profiles of MS Contin and Oramorph SR by administering a single 60-mg dose to 18 healthy volunteers. Analysis of variance revealed significant differences between the treatments for maximum plasma concentration (p <.001), area under the plasma concentration curve from 0 to 12 hours (p <.01), and apparent elimination half-life (p <.001), indicating that the two morphine preparations were not bioequivalent. Food does not affect the oral bioavailability of MS Contin or Oramorph SR (148,149).

It is particularly important to instruct patients not to chew on or crush these preparations, because this would alter the controlled-release mechanism and cause a potentially toxic dose of medication. Although it is standard practice to prescribe MS Contin and Oramorph SR every 12 hours, it is sometimes necessary to prescribe these medications every 8 hours, particularly when higher doses are required.

Kadian, controlled-release morphine, is available in clear capsules containing small polymer-coated pellets of drug and is currently undergoing clinical trials in the United States. It is intended for 24-hour administration. Each capsule contains multiple pellets (e.g., a 100-mg capsule contains on average 300 pellets), and this has the effect of providing more controlled and uniform release characteristics. Each pellet consists of a morphine sulfate–containing core that acts as a drug reservoir. Three factors, namely, the nature of the core, the nature of the polymer coat, and the thickness of the coat, collectively control the release of morphine from each pellet. A dissolution-containing polymer membrane surrounds the core of each pellet. After ingestion, the outer gelatin capsule dissolves rapidly into the stomach. The polymer coating controls the rate of release of morphine. The coating has three components: an insoluble polymer layer consisting of ethylcellulose, which has an enteric polymer component (methacrylic acid copolymer, which is insoluble and relatively hydrophobic at pH 1.2); a water-soluble component (polyethylene glycol that is soluble and hydrophilic at pH 1.2); and a plasticizer (diethyl phthalate). The core coating is partially soluble at an acidic pH (as in the stomach), and some slow release of morphine occurs in the stomach. At higher pHs, approximating those in the human intestine, the remaining hydrophilic and enteric components of the coating dissolve and absorption occurs in the small and large intestines.

Kadian's pharmacokinetic profile may offer some advantages over the other available controlled-release morphine preparations (150). The pharmacokinetic profile of MS Contin shows a short time to peak plasma concentration and relatively large fluctuations in plasma concentrations at steady state (151). Administration of Kadian every 12 hours is equivalent to the administration of MS Contin every 12 hours with respect to the measured area under the curve. However, the pharmacokinetic profile of Kadian exhibited a significantly higher minimum plasma morphine concentration, less fluctuation in plasma morphine concentration throughout the dosing interval, a longer time associated with the maximum morphine concentration, and a greater time that the plasma morphine concentration was greater than or equal to 75% of an index of the control the formulation exerts over the morphine release rate, compared with that of MS Contin (151).

Broomhead and colleagues (150) compared the efficacy and safety of Kadian administered either 24-hourly or 12-hourly to MS Contin administered 12-hourly. There were no statistically significant differences among the treatments for any morphine-related side effects when adjusted for baseline. Kadian administered 12-hourly had efficacy and safety profiles similar to MS Contin, but had the advantage of 12- or 24-hourly administration. However, patients favored the convenience of 24-hour administration of Kadian (p = .018). Further trials are required to evaluate the 24-hour use of Kadian. Additional potential advantages of Kadian include its use by sprinkling (i.e., breaking the capsule and sprinkling the pellets onto juice or yogurt) because this does not affect the time-release mechanism. This offers a particular advantage for patients with swallowing difficulties.

Hydrocodone

Hydrocodone is the hydrogenated ketone derivative of codeine. The usefulness of hydrocodone has been limited by its preparation in fixed combination with nonopioid analgesics (aspirin, acetaminophen, and ibuprofen). Combination hydrocodone is available in a variety of strengths (2.5, 5.0, 7.5, and 10.0 mg). The strength of the nonopioid component varies in these preparations, and it is important not to exceed toxic doses when prescribing these medications for breakthrough pain, particularly when using acetaminophen combinations. Vicoprofen, consisting of hydrocodone bitartrate, 7.5 mg, and ibuprofen, 200 mg, may be useful as a short-acting opioid in limited doses for patients with preexisting liver disease.

Oxycodone

Oxycodone is a semisynthetic mu-agonist with a pharmacokinetic profile resembling that of morphine (152). Ross and Smith (153) suggest that the intrinsic antinociceptive effects of oxycodone derive from its actions at kappa-opioid receptors, in contrast to morphine, which interacts primarily with mu-opioid receptors.

Pharmacokinetic studies have revealed that after oral administration, oxycodone is rapidly absorbed to produce an initial peak plasma oxycodone in approximately 2 hours (154,155). Once peak plasma concentrations are reached, oxycodone concentrations rapidly decline, with an apparent terminal half-life ranging from 3.0 to 5.7 hours (154,156). Because oxycodone is rapidly absorbed and quickly eliminated after oral administration, frequent dosing is required to maintain plasma concentrations within the therapeutic analgesic range.

Oxycodone is formulated with hydrochloride or pectinate. As the pectinate, oxycodone can be administered rectally, giving a slightly longer duration of action (157). The parenteral (not available in the United States) potency of oxycodone is approximately 0.75 that of parenteral morphine (158). Like morphine, oxycodone has a short elimination half-life (152). Oxycodone, however, has a higher oral bioavailability (60% to 87%) (156,159,160) than morphine (20% to 25%) (161,162), probably because of the methoxy group at carbon 3 (not present in morphine), which protects it from extensive first-pass glucuronidation (158). These bioavailability values for oxycodone are in accord with the higher oral to parenteral efficacy ratio (0.5 to 0.75) (158) for oxycodone compared with that of morphine (0.17). Oxycodone is extensively metabolized to noroxycodone, oxymorphone, and their metabolites. Noroxycodone is a considerably weaker analgesic than oxycodone. Oxymorphone, although possessing analgesic activity, is present in the plasma only in low concentrations.

To alleviate cancer-related pain, less oxycodone than morphine is required orally, but more oxycodone is needed intravenously (155,163). According to Beaver and colleagues (158,164), twice the amount of oxycodone in milligrams is required orally than intramuscularly for equianalgesia; intramuscular oxycodone is two-thirds as potent as intramuscular morphine.

Steady-state pharmacodynamic studies with immediate-release oxycodone have shown it to be well tolerated (156,163,165). The side effects of oxycodone are common to all opioids, with sedation and constipation being most frequent (165). Kalso and Vainio (163) administered morphine and oxycodone hydrochloride in a double-blind crossover study to 20 patients who were experiencing severe cancer pain. Morphine caused more nausea than oxycodone, and hallucinations occurred only during morphine treatment. Otherwise, no major differences in the side effects between the two opioids were observed. Maddocks and colleagues (166) reported an attenuation of morphine-induced delirium in cancer patients when changed to oxycodone.

A controlled-release formulation of oxycodone (Oxycontin) is available in strengths of 10, 20, 40, and 80 mg. A significant advantage of this formulation compared with the immediate-release preparation is the relatively long duration of action of approximately 12 hours.

Mandema and colleagues (167) showed that the controlled-release dosage form has pharmacokinetic characteristics that permit 12- hourly dosing. The absorption profile of Oxycontin is characterized by a rapid absorption component (half-life absorption = 37 minutes) accounting for 38% of the available dose and a slow absorption component (half-life absorption = 6.2 hours) accounting for 62% of the available dose.

Controlled-release oxycodone is a useful alternative to controlled-release morphine (168,169) and to immediate-release oxycodone (170). Reder and colleagues (170) noted that immediate-release oxycodone caused approximately twice as many adverse experiences, several of longer duration, than controlled-release oxycodone. Heiskanen and Kalso (159) compared the steady-state pharmacodynamic profiles of Oxycontin and MS Contin in 27 patients with chronic cancer pain in a double-blind, randomized, crossover design. The total opioid consumption ratio of oxycodone to morphine was 2:3 when oxycodone was administered first, and 3:4 when oxycodone was administered after morphine. The total incidence of adverse experiences reported by patients was similar, but significantly more vomiting occurred with morphine, whereas constipation was more common with oxycodone. The mean daily dose of oxycodone at the end of titration was 123 mg and that of morphine, 180 mg. In this study, the two opioids provided comparable pain relief.

Codeine and Dihydrocodeine

Codeine is commonly prescribed for the management of mild to moderate pain. It is most commonly used in combination with aspirin or acetaminophen. Although some variability exists, its plasma half-life and duration of action are usually in the range of 2 to 4 hours. The value of codeine is limited by the increasing incidence of side effects at doses above 1.5 mg per kg of body weight (55,171). Patients with a deficiency of CYP2D6 enzymes or those taking inhibitors of CYP2D6, such as quinidine, cimetidine, or fluoxetine, may not be able to convert codeine into morphine and therefore may get little or no analgesic effect from codeine (172,173 and 174).

Dihydrocodeine is an equianalgesic codeine analog. In the United States, it is available only in combination with acetaminophen or aspirin.

Hydromorphone

Hydromorphone is a versatile, short-half-life opioid available for administration via several routes. It is a semisynthetic congener of morphine, first synthesized in 1921. Despite its introduction into clinical medicine in 1926, data on the clinical efficacy and safety of hydromorphone are sparse, in part because of the widespread use of morphine in the management of moderate to severe pain. The short elimination half-life of hydromorphone necessitates at least 4-hourly administration of the drug to maintain adequate plasma levels for patients with chronic cancer pain. Hydromorphone is approximately five times as potent as morphine on a milligram per milligram basis. A controlled-release preparation of hydromorphone (Hydromorph Contin) (not currently available in the United States) exists. The primary benefit from this preparation lies in the convenience of the capsule formulation, which allows the patient to sprinkle it onto liquids or food. Preliminary data indicate some benefits and efficacy for cancer pain management (175). Hydromorph Contin is available in strengths of 3, 12, and 24 mg.

Methadone

Methadone is available as methadone hydrochloride powder that can be used for the preparation of oral, rectal, and parenteral solutions and is available commercially in a variety of preparations. Methadone has several advantageous characteristics including excellent oral and rectal absorption (oral bioavailability varies from 41% to 99%), no known active metabolites, high potency, high lipid solubility, low cost, and longer administration intervals. Other advantages include possibly enhanced analgesia from incomplete cross-tolerance with the potential to control pain no longer responsive to other mu-opioid receptor agonist drugs (176,177,178 and 179).

Like morphine, methadone binds preferentially to the mu-type opioid receptor, but differs by non-competitive antagonist activity at the NMDA receptor (180). Activation of NMDA receptors within the spinal cord has been shown to play a crucial role in the development of tolerance to the analgesic effects of morphine (181). Clinically, NMDA appears to be involved in inflammatory pain, neuropathic pain, allodynia, ischemic pain, and other prolonged pain states (182), and the NMDA receptor is involved in the generation and maintenance of spinal states of hypersensitivity. The use of opioids (e.g., methadone) possessing properties of NMDA receptor antagonism may improve pain control by attenuating the development of tolerance to morphine.

A successful conversion from one opioid to another requires an understanding of opioid pharmacokinetics and relative analgesic potency. The latter can be defined as the ratio of the doses of two opioids required to produce the same degree of pain relief. Equianalgesic tables propose a morphine-methadone ratio varying between 4:1 and 1:1 for the oral route and between 1:1 and 2.7:1 for the parenteral route (33,35,36,40). Although one can administer morphine and methadone in a 1:1 ratio for short-term use (183,184), these results do not apply to the management of patients with multiple repeated doses. Major differences exist between the dose of methadone required to control pain in cancer patients and other opioid agonists including morphine and hydromorphone.

Methadone is much more potent than previously recognized, particularly with repeated dose administration (178,179,185,186). The dose ratio between hydromorphone and methadone is also higher than suggested by standard equianalgesic tables (187). Lawlor and colleagues (186) evaluated consecutive rotations involving morphine and methadone using standard selection criteria and identified a total of 20 rotations (14 from morphine to methadone and 6 from methadone to morphine). Median dose ratios (lower upper quartiles) for morphine to methadone and methadone to morphine rotations were 11.36 (range, 5.98 to 16.27) and 8.25 (range, 4.37 to 11.3), respectively (p = .23). Combining all 20 rotations, a unified median dose ratio of 11.2 (range, 5.06 to 13.24) was calculated. Significant differences in pain intensity levels as recorded on a visual analog scale were not observed prerotation and postrotation. Patients receiving more than 1,165 mg per day before methadone rotation demonstrated a median dose ratio of 16.81 (range, 12.25 to 87.95), which was approximately three times higher compared with a median dose ratio of 5.42 (range, 2.95 to 9.09; p = .007) for the 50% of patients receiving lower morphine doses. Ripamonti and colleagues (188) defined the dose ratio between morphine and methadone relative to the previous morphine dose and the number of days needed to achieve equivalent pain relief in 38 patients with advanced cancer. Before the switch, the median oral equivalent daily dose of morphine was 145 mg per day; after the switch, the median equivalent oral dose of methadone was 21 mg per day. A median time of 3 days (range, 1 to 7 days) was necessary to achieve equivalent pain relief with methadone. Dose ratios ranged from 2.5:1 to 14.3:1 (median, 7.75:1), indicating that the dose ratio was much higher than that suggested by published equianalgesic tables. These analyses suggest the need for a highly individualized and cautious approach when rotating from morphine to methadone in patients with cancer pain.

Methadone is characterized by a large interindividual variation in pharmacokinetics and by rapid and extensive distribution phases (half-life alpha = 2 to 3 hours; half-life beta = 15 to 60 hours). Some outpatients have considerably longer elimination half-lives, even extending to 120 hours (189). Repeated doses of methadone at fixed intervals may lead to its accumulation and potential toxic effects. This raises concerns about its use in cancer pain, particularly in situations that require rapid dose escalation (190). Urinary elimination is a minor pathway; fecal excretion accounts for the greater part of the dose elimination. Relatively high daily doses of methadone (40 to 50 mg per day) have been used successively in patients with chronic renal disease (191).

As with other potent opioids, caution must be exercised in elderly patients, in patients with encephalopathy or a major organ failure, in those who are difficult to monitor, and in patients who are noncompliant with treatment regimens. Substantial interindividual variation in the relationship between changes in plasma concentration and pain relief can occur in patients with chronic pain receiving methadone (192). Information about interpatient variation in pain perception has led to the concept of individualization of methadone dosing in the management of cancer pain. Therefore, high individual variation in bioavailability and the long duration of its activity require personalized treatments.

A high individual variation in terminal elimination half-life can result in different rates and extents of drug accumulation, particularly with steady-state levels. To overcome these disadvantages, I suggest an oral dosing titration schedule by patient-administered analgesia (193,194). Patient-administered analgesia with oral methadone appears to be a simple, cheap, and relatively safe technique for controlling cancer pain, permitting self-individualization and potentially avoiding the risk of accumulation. However, during the titration phase, continuous assessment is necessary. The regimen involves self-administered oral methadone at fixed doses and flexible patient-controlled dosage intervals. The original study involved 14 cancer patients (194). Patients hospitalized between days 1 and 6 received a fixed dose of methadone, 10 mg as necessary, at intervals not more than every 4 hours. On the seventh day, patients received a fixed dose at 8 to 12 hourly intervals based on the sixth day average requirements. Generally, on day 1, patients used between 30 and 100 mg of methadone approximately every 3 to 7 hours. On day 7, the average use was 21.5 mg, which then was administered every 8 to 12 hours. Eleven to 14 patients had complete analgesia, and there was only mild sedation in 3 of the 14 patients.

Mercadante and colleagues (193) reported the successful use of this technique in 24 outpatients with advanced disease. During a priming period of 3 days, opioid-naive patients took fixed doses of 3 to 5 mg of methadone three times a day, and those switched from morphine received 50% of the morphine equivalent of methadone. Providers adjusted doses by frequent telephone contact or home visit. After achieving a dose of methadone capable of maintaining acceptable pain relief for more than 6 to 8 hours, patients and relatives learned how to manage pain with rescue doses taken as needed plus a fixed dose at bedtime. During the course of treatment, when patients self-administered methadone more than four times per day, including the nighttime dose, the dose increased. Pain control was deemed satisfactory in the majority of patients. The mean dose number per day was 2.4, including the fixed nighttime dose. Average daily starting dose of methadone per day was 16.5 mg, with an average maximum dose of 30.2 mg. Only one patient on a relatively high dose of methadone presented frequent episodes of confusion. Approximately 20% of patients reported some drowsiness, sweating, and nausea and vomiting.

Morley and colleagues (195) recommend the switch to methadone in all situations in which morphine has ceased to be effective for the control of cancer pain except when the dominant mechanism of pain is neuropathic in origin. The authors recommended using an initial dose of methadone that is one-tenth of the total daily morphine dose, but not greater than 100 mg. Give this dose at intervals determined by the patient as recommended by Sawe and colleagues (194), but not more frequently than 3 hourly. In typical situations, patients may require three to eight doses per day for the first few days, then settle on a lower fixed intake (one to four doses per day) after the first week.

In general, one should reserve methadone as a second-line drug in the treatment of moderate to severe cancer pain. Use methadone if morphine causes intolerable side effects and the patient wishes to continue with noninterventional approaches or if a change in opioid may enhance analgesia because of incomplete cross-tolerance.

Levorphanol

Levorphanol, a morphine congener with a long half-life (12 to 16 hours), is available in both oral and parenteral formulations. It is approximately five times more potent than morphine. The normal starting dose is 2 mg every 6 hours. If given by injection, use half this dose. Like methadone, drug accumulation may follow initiation of

therapy or dose escalation. Guidelines similar to those suggested for methadone may prove helpful for managing the patient requiring high doses of levorphanol.

Fentanyl

Fentanyl is a synthetic phenylpiperidine derivative and a chemical congener of the reversed ester of meperidine. It is an opioid characterized by high potency and lipophilicity. The drug is 75 to 100 times more potent than morphine on a molar basis. It has a short duration of action, 30 to 60 minutes after a single intravenous bolus of 100 µg, mainly because of its large volume of distribution and redistribution and uptake into fatty tissues. It is available in several preparations including transdermal, transmucosal, and parenteral. Parenteral fentanyl is a short-acting analgesic at steady-state conditions, when half-life is primarily determined by redistribution. Because of its low molecular weight and high lipid solubility, fentanyl can be administered transdermally (196).

Transdermal Fentanyl

Transdermal therapeutic system fentanyl (TTS-fentanyl) patches are rectangular transparent units, each comprising a protective liner and four functional layers. These layers consist of a backing layer of polyester film, a drug reservoir of fentanyl and alcohol USP gelled with hydroxyethyl cellulose, an ethylene-vinyl acetate copolymer membrane that controls the rate of fentanyl delivery to the skin surface, and a fentanyl-containing silicone adhesive. The amount of fentanyl released from each system per hour is proportional to the surface area (25 µg per hour per 10 cm^2).

The transdermal system releases fentanyl from the reservoir at a nearly constant amount per unit of time. The concentration gradient existing between the saturated solution of drug in the reservoir and the lower concentration in the skin drives drug release. Fentanyl moves in the direction of the lower concentration at a rate determined by the copolymer release membrane and the diffusion of fentanyl through the skin layers. Although the actual rate of fentanyl delivery to the skin varies over the application period, each system is labeled with a nominal flux, which represents the average amount of drug delivered to the systemic circulation per hour across average skin. Although variation occurs in the dose delivered among patients, the nominal flux of the systems is sufficiently accurate to allow individual titration of dosage for a given patient.

After patch application, the skin under the system absorbs fentanyl, and a depot of fentanyl concentrates in the upper skin layers. Fentanyl then becomes available to the systemic circulation. A lag time of approximately 2 hours occurs before clinically useful systemic levels of drug are achieved after applying the patch (197). Serum fentanyl concentrations increase gradually after application, generally leveling off between 12 and 24 hours. The system delivers fentanyl continuously for up to 72 hours. After sequential 48- or 72-hour applications, patients reach and maintain steady-state serum concentrations that are determined by individual variation in skin permeability and body clearance of fentanyl. A number of studies demonstrate that constant serum levels are maintained with the second transdermal system and that fluctuations of serum levels are small after the first 72 hours (198,199).

After system removal, serum fentanyl concentrations decline gradually, falling approximately 50% in approximately 17 hours (range, 13 to 22). Because of the possibility of temperature-dependent increases in fentanyl release from the system, it is important to advise patients to avoid exposing the application site to direct external heat sources, such as heating pads, heat lamps, and heated waterbeds. Prolonged exposure to heat can cause a toxic overdose.

TTS-fentanyl offers the advantage of providing continuous administration of a potent opioid in the absence of needles and expensive drug-infusion pumps for the treatment of cancer pain. Several studies have investigated the management of cancer pain with TTS-fentanyl (200,201,202,203,204,205,206,207 and 208). Some authors have expressed concerns about using the manufacturer's dose conversions and dosing intervals, believing that these recommendations are too conservative (203,204,209). The manufacturer's recommended doses for opioid-tolerant patients derive from the incorrect oral to parenteral morphine dose ratio of 6:1 (or a ratio of oral morphine to TTS- fentanyl of 150:1).

Patients receiving doses of TTS-fentanyl believed to be equianalgesic to the patients' previous opioids based on the package labeling conversions may experience markedly increased pain because of the fentanyl equivalent dose being as little as one-half that required for equianalgesia. Grond and colleagues (202) (Table 36-10) have indicated from intravenous fentanyl patient-controlled analgesia (PCA) studies that higher initial doses of TTS-fentanyl may be required. Transdermal administration of opioids provides a simple and noninvasive alternative producing stable blood concentrations comparable with continuous intravenous infusion.

Patient-controlled analgesia fentanyl (intravenous) dose (mg/day)	Transdermal therapeutic system fentanyl delivery rate (mg/day)	Size (cm^2)
0.2–0.6	0.6[a]	10
0.6–1.0	1.2	20
1.0–1.4	1.8	30
1.4–1.8	2.4	40
Every additional 0.4	Additional 0.6	Additional 10

[a]Fentanyl delivery rate of 0.6 mg/day corresponds to a rate of 25 µg per hour.
From Grond S, Zech D, Lehmann KA, et al. Transdermal fentanyl in the long-term treatment of cancer pain: a prospective study of 50 patients with advanced cancer of the gastrointestinal tract or the head and neck region. Pain 1997;69: 191–196, with permission.

TABLE 36-10. Conversion table for parenteral fentanyl dose to initial transdermal therapeutic system fentanyl

In a pilot study of 20 cancer patients, Zech and colleagues (207) demonstrated that intravenous PCA with fentanyl allowed effective, safe, and rapid dose finding for transdermal treatment. However, the conversion ratio used of 1:1 from intravenous to transdermal was considered too low. In a follow-up study (202) of 50 patients, the conversion ratio was increased by 50% to a ratio of 1.0:1.5. In spite of these increases, the authors considered the conversion ratio still too low in the majority of patients as the delivery rate of the second patch needed to be increased markedly, on average increasing by 100% at the end of the first week. Despite this, the authors noted that three patients had a low respiratory rate during the titration period and recommended a conversion ratio of 1:1.

Donner and colleagues (200) studied the direct conversion from long-acting oral morphine to TTS-fentanyl with a ratio of 100:1 in 98 cancer patients with constant pain relief under oral opioids. During the prestudy phase of 6 days, they stabilized patients on long- acting morphine. After this phase, patients shifted to TTS-fentanyl using a conversion ratio of 100:1, changing the fentanyl patches every 3 days. The initial fentanyl dose proved satisfactory in 42% of patients, but a significant percentage of patients (58%) required a further dose escalation of at least 100%. On completion of the study after 15 days, Donner and colleagues estimated the conversion ratio for oral morphine to TTS-fentanyl at 70:1. Of interest, none of the patients required a dose reduction during the fentanyl phase of the study.

Pharmacokinetic studies indicate a relative steady state (pseudo-steady state) 15 hours (210) and 16 to 20 hours after application of the patch (211), suggesting the possibility of early titration with TTS-fentanyl at 24-hour intervals. Korte and colleagues (203) investigated the conversion doses of oral morphine to TTS-fentanyl according to the clinical experiences of Zech and colleagues (212) and dose finding requirements by day-to-day titration with TTS-fentanyl in 39 cancer patients. The investigators assumed satisfactory pain relief when the mean daily visual analog score (VAS) value was less than 35 mm as previously defined by Miser and colleagues (213). If pain relief was inadequate after 24 hours, they added further TTS-fentanyl if no toxicity or intolerable side effects were present. Patients repeated titration every day with an additional 25 µg per hour until they achieved adequate pain control. Patients changed patches every 3 days unless pain profiles suggested changes at 2-day intervals. Mean VAS scores improved significantly from day to day during week 1. Both dose increases of TTS-fentanyl and the use of rescue medication were necessary to maintain pain control. Forty-nine percent of patients needed one or more dose increases during days 1 to 3; 38% needed two or more increases during days 1 to 6; and 26% needed three or more dose increases during days 1 to 9 of treatment. The goals of pain control with day-to-day titration were almost reached by day 2 and were completed by day 5. No compliant outpatient experienced severe side effects. The authors demonstrated a way to titrate TTS-fentanyl effectively and safely on a day-to-day basis with an increased initial dose and adequate patient monitoring. Note, however, that it took a relatively long time to optimize pain control.

In another study, the long-term efficacy of TTS-fentanyl was evaluated in 51 cancer patients by Donner and colleagues (201). Seventy-five percent of patients had metastases. Patients used TTS-fentanyl for an average of 158 days (range, 15 to 855 days). Seventy-three percent of patients received treatment for a period of 3 to 12 months. The investigators discontinued TTS-fentanyl in 16% of patients because of insufficient pain relief. In these patients, the last TTS-fentanyl dosage was a

mean of 233.3 µg per hour (range, 25 to 700 µg per hour). In addition, four patients returned to oral morphine therapy. At the start of therapy, patients needed 69.5 µg per hour of TTS-fentanyl (25 to 250 µg per hour). At the end of therapy, the dosage was 167.7 µg per hour (25 to 1,000 µg per hour). Most patients changed patches every 3 days, but 24% of patients required more frequent changing (varying from 48 to 60 hours). Pain relief was good throughout the study. The seventy-fifth percentile of the VAS scores ranged between 2.5 and 3.4. Only 15% of patients did not require additional oral opioid (liquid morphine). Constipation decreased during the transdermal therapy. At the end of the study, 70% of therapy days were free of constipation. In addition, the need for laxatives decreased during therapy.

Payne and colleagues (206) compared pain-related treatment satisfaction, patient-perceived side effects, functioning, and well- being in 504 patients with advanced cancer who received either TTS-fentanyl or sustained-release oral forms of morphine. The mean dose of fentanyl was 84.4 µg per hour (range, 25 to 400 µg per hour). For those who received morphine, the mean 24-hour dose was 195 mg (range, 15 to 3,000 mg). There were no significant differences between measures of pain intensity and sleep adequacy. However, patients who received TTS-fentanyl were more satisfied with their pain medication than those who received oral morphine. Patients receiving fentanyl also experienced a significantly lower frequency and effect of pain medication side effects. However, because assessment of side effects was global in nature, the investigators could not distinguish between the frequency, effect, or both of individual, particular side effects.

As a rough guide for conversion, consider the 8-hourly dose of MS Contin equal to the µg per hour dose of TTS-fentanyl. For example, if a patient is receiving MS Contin, 75 mg three times a day, then the TTS-fentanyl conversion dose is 75 µg.

The TTS-fentanyl system may be considered a first-line treatment modality for moderate to severe cancer pain. Appropriately used and titrated, pain control appears satisfactory with apparent high levels of patient satisfaction. In situations in which compliance may be a problem, the system may have particular advantages. In addition, the system may be used for patients who are unable to take medications by mouth.

Oral Transmucosal Fentanyl

Oral transmucosal fentanyl citrate (OTFC) units consist of a lozenge with a handle and are of uniform size and shape. Product manufacture involves dissolving fentanyl in a sucrose solution, pouring it into a mold, and allowing it to harden on a handle. Fentanyl is compounded in a hardened matrix form on a stick. The lozenge is available in a variety of strengths, from 200 to 1,600 µg. In the mouth, the unit dissolves in saliva: A portion of the fentanyl diffuses across the oral mucosa, and the patient swallows the rest, which is partially absorbed in the stomach and intestine. Patients must smear the lozenge on either the buccal mucosa or under the tongue and not swallow. Smearing avoids first-pass metabolism in the liver, whereas swallowing does not. Ideally, the lozenge should be consumed within a 15-minute period. Onset of action is rapid (5 to 15 minutes). Peak analgesic effect is 20 to 30 minutes, and duration is approximately 2 hours. Of the total available dose, 25% is absorbed transmucosally over a 15-minute period, and an additional 25% is absorbed through the gastric mucosa during the next 90 minutes (214). Potential advantages of this drug delivery system include rapid-onset analgesia, transmucosal absorption (i.e., no need to swallow), ease of titration, and ease of use.

Farrar and colleagues (215) evaluated the effect of OTFC for breakthrough pain in a double-blind, randomized trial of 130 patients. All subjects were started on the lowest dose of OTFC (200 µg) and then titrated to an effective dose for breakthrough pain up to the maximum available dose (1,600 µg) over a 2-week period. All subjects who were able to achieve adequate relief with OTFC advanced to the double-blind phase, which was designed as a 10-period crossover. In this phase, each subject received a box of 10 sequentially numbered units. Of the 10 units, seven contained fentanyl at the same dose found effective for that patient during the titration phase, and three were placebo units. Instructions told patients to consume the total dose in 15 minutes and to take rescue medication after 30 minutes for inadequate pain relief. The pain types treated in the study included somatic (53%), visceral (31%), neuropathic (15%), and unknown (1%). Of the original 130 patients, 93 completed the open-label titration phase and 37 did not. Twenty patients did not complete the full 10 doses of the double-blind phase. Eighty-six patients were included for efficacy comparisons, and six were not because of protocol violations. In these patients, patients receiving placebo required significantly more additional rescue medication than those treated with active drug (34% versus 15%). OTFC produced significantly larger changes in pain intensity and better pain relief than placebo at all time points (two-sided $p < .0001$). The most frequent opioid-related adverse events reported as possibly related to OTFC were dizziness (17%), nausea (14%), somnolence (8%), constipation (5%), asthenia (5%), confusion (4%), vomiting (3%), and pruritus (3%). The authors concluded that the OTFC drug-delivery system is highly efficacious for the treatment of cancer-related breakthrough pain with a large margin of safety in patients on chronic opioid therapy. Of interest, the dose of OTFC required to control breakthrough pain is not predicted by the around-the-clock opioid dose (216). Each patient should be titrated to a dose that is effective for control of breakthrough pain.

The Food and Drug Administration has approved the use of transmucosal fentanyl for the management of procedure-associated pain and for the management of breakthrough pain in cancer patients. The main clinical application for this preparation may be for breakthrough and incident pain in the cancer patient (217), but further clinical evaluation is under way. The concurrent use of TTS- fentanyl patches with OTFC units appears attractive and merits future study.

Tramadol

Tramadol is a synthetic 4-phenyl-piperidine analog of codeine. It is a central analgesic with a low affinity for opioid receptors (218,219,220 and 221). There are few reports of the use of tramadol in cancer pain. Wilder-Smith and colleagues (222) compared the analgesic efficacy of tramadol and morphine in 20 cancer patients. After 4 days, the mean daily doses were 101 ± 58 mg of morphine and 375 ± 135 mg of tramadol, indicating a relative potency of 4:1 with oral dosing. Side effects such as nausea and constipation were fewer with tramadol, but pain control was less satisfactory. Patients with cancer who are most likely to benefit from tramadol are those with mild to moderate pain not relieved by acetaminophen who cannot tolerate NSAIDs and wish to avoid taking opioids.

Opioids Not Recommended for Routine Use in Cancer Pain Control

I recommend avoiding several opioids for the control of moderate to severe cancer pain. These are meperidine, buprenorphine, pentazocine, butorphanol, dezocine, and nalbuphine. Meperidine has a short half-life, and its metabolite, normeperidine, is toxic (223). Partial agonists such as buprenorphine are of limited benefit because of their low maximal efficacy. Above a certain dose, toxicity without additional analgesia is observed. Mixed agonist-antagonists such as pentazocine, butorphanol, dezocine, and nalbuphine present other problems. Although these agonist-antagonists are often classified as a kappa-receptor agonist and a mu-receptor antagonist, they are more accurately described as a partial agonist at both kappa and mu receptors. These agents have a low maximal efficacy and have the potential to reverse mu-receptor analgesia, and even precipitate a physical withdrawal syndrome when taken by patients already receiving full agonists such as morphine (224). In addition, agonist-antagonist opioids have a ceiling effect (218,224). Propoxyphene is a poor choice for routine use because of its long half-life and the risk of accumulation of norpropoxyphene, a toxic metabolite (219).

Selection and Dosing of Oral Opioids

It has become common practice in the United States to initiate opioid therapy with a commercial product that contains an opioid combined with aspirin or acetaminophen. If pain worsens, the dose of these products can be increased only until the safe maximum level of the nonopioid component is reached. The value of codeine is limited by the increasing incidence of side effects at doses above 1.5 mg per kg. Patients who fail to obtain adequate analgesia at the maximum doses of a combination product typically change to opioids commonly used for the management of moderate to severe pain (see Table 36-5).

For moderate to severe pain, morphine is the opioid of first choice. Because great intraindividual variability exists in the patient response to the different opioids, any of the other opioids may yield a more favorable balance between pain relief and side effects. Sometimes sequential trials are necessary to identify the optimal drug. One can calculate equivalent doses of other opioids from the relative potencies listed in Table 36-11. When using morphine, employ an oral-to-parenteral relative potency ratio of 3:1 for these calculations. Patients already receiving regular opioid doses and switching to another opioid should receive 50% to 75% of the equianalgesic dose initially because cross-tolerance is incomplete. It is wise to plan a dose reduction of approximately 25% for the elderly or medically frail patient. When switching to methadone particularly, when the patient is requiring high doses of opioids, exercise extreme care. Titration of the opioid dose usually is necessary at the start of therapy and repeatedly during the patient's course. At all times, address inadequate pain relief through gradual escalation of the dose until adequate pain relief is reported or intolerable and unmanageable side effects limit further dose escalation. Titration in this fashion requires repeated assessment and the ongoing management of side effects.

Drug	Equianalgesic dose (mg)[a]	
	Oral	Parenteral
Morphine	30	10
Hydromorphone	6	2
Oxycodone	20–30	NA
Methadone	10[b]	10[b]
Levorphanol	2–3[b]	2[b]
Codeine	130[c]	75

NA, not available in the United States
[a]Suggested doses are guidelines only. Doses are based on chronic opioid use.
[b]Particular care with titration is recommended as doses may need to be reduced significantly when steady-state levels are reached after 2 to 3 days.
[c]Codeine doses greater than 65 mg may be associated with significant constipation.

TABLE 36-11. Opioids used orally or parenterally to treat cancer pain

Doses can become extremely large during titration for cancer pain relief. The absolute dose is not important as long as therapy is not compromised by dose-limiting toxicity, cost, or excessive inconvenience produced by the number of pills. The rate of titration depends on the severity of pain, appearance of side effects, or both. Patients who present with severe pain may be best managed initially by repeated intravenous boluses of opioid until pain is partially relieved. In contrast, patients with relatively moderate pain can undergo dose increments of 30% at intervals greater than those required to approach steady state after each change—for example, every 24 to 48 hours for morphine, every 72 hours for methadone, and every 48 hours for TTS-fentanyl.

Most patients have constant or frequently recurring pain and respond best to a fixed dosing schedule (around-the-clock dosing). As- needed dosing alone may prove helpful, however, in selected circumstances, such as the start of opioid therapy in the opioid-naive patient (see Methadone, previously in this chapter), during periods of rapidly declining pain (such as may follow radiation treatment), and in the treatment of patients with intermittent pain.

The following rules provide a guide to dose titration with controlled-release morphine:

- If the every-12-hour interval dose is less than 60 mg, then titrate upward by 15 mg.
- If the every-12-hour interval dose is between 60 and 120 mg, titrate up by 30 mg.
- If the every-12-hour interval dose is between 120 and 300 mg, titrate up by 60 mg.
- If the every-12-hour interval dose is more than 300 mg, titrate up by 100 mg.

Another useful approach to dose titration involves the concurrent use of a regularly scheduled dose and a rescue dose. The rescue dose is a supplemental dose provided as needed to treat breakthrough pain. The ideal drug for breakthrough pain should be short-acting, identical to the regularly scheduled drug, and the dose may be equivalent to approximately 10% to 20% of the total daily dose, offered every 2 hours as needed. The number of rescue doses required daily could then guide the size of the increment in the regularly scheduled dose as it is titrated upward.

Patients should be advised to follow a 1:2:3 regimen (i.e., take one tablet initially, and if ineffective in 2 hours, take two tablets, and if ineffective in 2 hours, then take three tablets). Repeat this dose every 2 hours until either the pain is controlled or side effects are encountered. Alternatively, if three tablets every 2 hours control pain but cause side effects, the patient may reduce the number of tablets by one tablet every 2 hours until the side effects become tolerable. Once pain is controlled on the short-acting medication, increase the dose of the controlled-release preparation appropriately. This regimen has been effective for the majority of situations in which rescue medication is required. It is easy for both patients and family members to remember.

Opioid-Related Side Effects

The side effects or toxicities associated with opioids can significantly distress the patient and impair normal functioning. Effective opioid intervention requires careful dose titration targeted at an optimal pain relief to side effect ratio. Table 36-12 lists the major side effects and indicates the frequency with which they occur. Most patients report more than one side effect, although a few report only constipation.

Side effect	Frequency with oral long-acting opioids	Does toxicity diminish with tolerance?
Constipation	Very common	No
Sedation	Common	Yes
Nausea	Common	Yes
Cognitive impairment	Occasional	Yes
Pruritus	Occasional	Yes
Dysphoria	Occasional	Yes
Hypnogogic imagery	Rare	Yes
Myoclonus	Rare with oral route	No
Respiratory depression	Very rare	Yes

TABLE 36-12. Opioid-related side effects

The distress imposed by one or more side effects typically determines the upper limit or the rate of dose titration. Patients with similar pain problems differ markedly in side-effect burden even when they receive similar dosages of a single opioid drug. For a given patient, a specific drug may cause a heavy side-effect burden, whereas an alternative drug delivered at equianalgesic concentrations may produce a mild side-effect burden. For this reason, adept prescribers often ask about patients' previous experiences with opioid drugs in an attempt to avoid trial-and-error drug selection.

Because marked interindividual differences exist among patients, the best predictor of patient response to an opioid is the patient's past experience with that drug. Although the side-effect burden depends in part on the idiosyncratic fit between the patient and the drug administered, it depends primarily on dose magnitude and the rate of dose increase. With increments in drug dosage or rapid rates of titration, the probability of a particular side effect occurring typically increases and the severity of any existing side effect increases as well.

The severity of the side-effect burden also depends on the duration of drug use. Fortunately, patients develop tolerance to most side effects more rapidly than to pain relief (220). Consequently, the longer a patient uses an opioid, the fewer the side effects and the less severe persisting side effects become.

Assessment and treatment of side effects are basic aspects of opioid therapy. When side effects are strong and poorly controlled, patients are likely to report poor pain relief as well. Patients tend to take opioids on an as-needed rather than an around-the- clock basis. Often, they use drugs only when the pain becomes unbearable. Moreover, intermittent drug use prevents patients from developing tolerance to side effects, so bothersome side effects never abate. Side effects are also a significant source of discomfort and suffering in their own right. The extremely nauseated patient feels miserable, tends to avoid comforting social interactions, and cannot engage in productive activity. The cognitively impaired patient cannot cope effectively with the simple mental demands of everyday life and becomes increasingly dependent on others. In these and other ways, untreated side effects compromise the quality of life in patients using opioids for pain relief.

Opioid-related side effects occur because of opioid receptor pharmacodynamics, the production of toxic metabolites, or both. Activation of mu $_2$-receptors appear to cause certain side effects, such as sedation and respiratory depression, but other side effects are linked to other receptor types or subtypes (221). Evidence suggests that kappa-receptor agonism contributes to dysphoria as well as to pain relief (218). Sigma-receptor agonism produces purely negative effects: dysphoria, depersonalization, and psychotomimetic experiences such as hypnogogic imagery (225). The sigma receptor is a naloxone-inaccessible opioid receptor, so standard

opioid receptor antagonism does not relieve these side effects. However, this receptor has a high affinity for haloperidol, and this may antagonize negative side effects (226).

Some side effects result from the toxic metabolites associated with a particular drug. The side effects associated with the accumulation of normeperidine and norpropoxyphene are well recognized (219,223). The role of M3G, a metabolite of morphine, is less clear because it does not bind to opioid receptors and yet it seems to exert antagonist effects (227,228). Some authors speculate that the antagonist effects of M3G are responsible for some of morphine's side effects, including myoclonus (227).

Preventing or Minimizing Opioid-Related Side Effects

Appropriate dosing of opioids requires minimizing or preventing opioid-related side effects (see Dosing of Oral Opioids, earlier in this chapter). For patients with constant pain, the early use of a long-acting in preference to short-acting opioids as soon as dose titration permits may help to attenuate side effects. If side effects are significant, the clinician should allow time for tolerance to develop. This may require a period of 3 to 7 days. Protecting the patient from severe side effects during this period is appropriate and does not prevent tolerance development. For example, a patient with nausea could benefit from a 1-week course of antiemetic medication at the outset of opioid therapy.

If side effects do not diminish satisfactorily over time, there are two alternatives: changing drugs and introducing supplementary medications that control the side effects. Changing from one opioid to another may enhance pain relief and reduce opioid-related side effects, particularly if incomplete cross-tolerance to opioid effect is experienced (185,229,230,231 and 232). In some cases, changing the route of administration for a particular drug, such as morphine, may eliminate certain difficult side effects (233). It is possible to alleviate many of the most difficult side effects pharmacologically when necessary. For example, administering methylphenidate can help protect the cognitive functioning of patients using high doses of opioids (234,235). Table 36-13 lists side effects and their treatments.

Side effect	Treatment
Constipation	Stool softener, laxative
Sedation	Methylphenidate
Pruritus	Diphenhydramine, hydroxyzine
Nausea	Prochlorperazine, haloperidol, metoclopramide, ondansetron, antihistamine
Dysphoria	Haloperidol
Hypnogogic imagery	Haloperidol
Cognitive impairment	Methylphenidate
Respiratory depression	Naloxone
Myoclonus	Clonazepam, dose reduction, opioid rotation

TABLE 36-13. Pharmacologic treatments for opioid-related side effects

In cancer patients, certain pathophysiologic conditions commonly contribute to side-effect problems or masquerade as side-effect problems. For example, renal insufficiency in patients using morphine can lead to accumulation of M6G, which in turn can exacerbate side effects. Nausea is a frequent opioid toxicity, but it has other potential causes: gastric irritation, constipation, or other changes in gut motility, chemotherapy, or hypercalcemia induced by bone metastases. Similarly, sedation and confusion may accompany opioid use, but other potential causes in the cancer patient such as raised intracranial pressure, metabolic disturbances (e.g., hypercalcemia), sepsis, or concomitant drug use merit consideration. Opioid-induced changes in mental status become less probable when the patient has been on a stable dose without recent significant dose escalation.

Opioid-induced gastrointestinal problems may manifest as nausea and vomiting, mild abdominal discomfort, constipation, gaseous abdominal distension, and functional colonic obstruction. Kaufman and colleagues (236) suggest that opioids may cause constipation in part by slowing colonic transit in the proximal colon and by inhibiting defecation. Opioids also affect the gut by increasing electrolyte and water absorption in the small intestine and colon and by increasing tone in the ileocecal and anal sphincters. This results in delayed passage of increasingly viscous stool.

Opioid receptors exist on gut smooth muscle and at all levels of nervous input to the intestine; mu- and delta-receptors appear to be the most important in gut motility. In animals, opioid effects on the gut involve central and peripheral receptors (237,238). Oral and parenterally administered opioids produce constipation; subcutaneous morphine reduces stool frequency and slows transit (236). Undoubtedly, opioid receptors in the gut wall are accessible not only to opioids in the lumen but also to those in the circulation.

The constipating effects of morphine probably result mainly from its action on colonic motility. Morphine stimulates colonic motility in humans by action on both central and peripheral sites (239). This increase in colonic motility and the delay in colonic transit are associated with a reinforcement of tonic contractions and reduced propulsive waves. Opioid peptides participate in the colonic motor response to eating in humans and animals (239).

When healthy volunteers take opioids in single doses, opioid analgesics impair reaction time, muscle coordination, attention, and short-term memory sufficiently to affect driving and other skilled activities. However, such studies do not correspond to the situation of cancer patients who develop tolerance to side effects. Psychomotor and cognitive dysfunction in cancer patients falls into two main categories according to etiology: disease-induced factors (metabolic disturbances, brain metastasis, pain, and so forth) and treatment-related factors (drugs, antineoplastic therapy, and so forth) (240). Bruera and colleagues found that cancer patients receiving chronic oral opioid therapy had prolonged continuous reaction times, and opioids seemed to be mainly responsible for the prolongation (223). Significant dose escalations of short-acting opioids (more than 30%) over a short period of time (3 days) transiently impaired psychomotor and cognitive functions in cancer patients. The impairment disappeared 1 week after the increase.

Clemons and colleagues (241) studied the effects of morphine on alertness and cognition in patients with advanced cancer. Twenty-nine subjects were recruited into three groups: healthy volunteers (16 subjects without cancer and not on opioids), inpatients and outpatients with advanced cancer not taking any opioids (six subjects), and inpatients and outpatients with advanced cancer on a stable and regular dose of oral morphine (seven subjects). Subjects were tested with a battery of tests designed to test the global effects of alertness on cognitive function on either five or six occasions. The New Adult Reading Test, Reaction Time, and Stroop Colour-Word tests failed to show any difference between the two cancer groups, whereas they did show a difference between the healthy control subjects and the cancer patients, suggesting that the tests were sensitive to the effects of cancer but not to the effects of morphine. The Stroop Colour-Word test is a complex measure of cognitive function, and the difference between healthy volunteers and cancer patients receiving no morphine suggests that advanced cancer itself may be impairing performance. The authors noted that the cancer with morphine patients subjectively felt less generally well, less alert, less active, more depressed, had poorer concentration, and were more anxious than either of the other groups.

Vainio and colleagues (242) examined the effects of continuous morphine medication on the driving ability of cancer patients. They conducted psychological and neurologic tests, originally designed for professional motor vehicle drivers, in two groups of cancer patients who were similar apart from their experience of pain. Twenty-four patients received continuous morphine (mean, 209 mg of oral morphine daily) for cancer pain, and 25 were pain free without regular analgesics. Although the results were a little worse in the patients taking morphine, there were no significant differences between the groups in intelligence, vigilance, concentration, fluency of motor reactions, or division of attention. Of the neural function tests, reaction times (auditory, visual, associative), thermal discrimination, and body sway with eyes open were similar in the two groups; only balancing ability with closed eyes was worse in the morphine group. These results indicate that in cancer patients receiving long-term morphine treatment with stable doses, morphine has only a slight and selective effect on functions related to driving.

Opioids can cause or exacerbate confusion, and these effects may range from mild impairment in concentration to frank delirium with disorientation, disorganized thinking, perceptual distortions, and hallucinations. Hallucinations are the product of sigma receptor activation, and they can occur in the context of intact cognitive function (243). Obviously, when this problem occurs it is important to consider other causes of altered mental status. When a confusional state is caused by opioids, it generally follows a recent increase in dose and usually resolves with tolerance or as the dose is reduced. Rapid discontinuation of the opioid results in severe pain, withdrawal symptoms, and possible exacerbation of confusion; it should be avoided. Dysphoria is probably more common than euphoria after opioid administration in

patients with cancer.

Opioid Tolerance in Cancer Pain

The development of tolerance to opioids and its effect on analgesia is a controversial area in cancer pain management (134). Tolerance is a complex pharmacologic phenomenon characterized by the need for higher opioid doses to maintain constant effects. It represents the accommodation of the CNS to the presence of drugs that look like the brain's own endogenous ligands. The interaction of opioid systems with many neurotransmitters [serotonin, dopamine, noradrenaline, glutamate, gamma-aminobutyric acid (GABA), and so forth] or neuromodulators (cholecystokinin, neuropeptide FF, and so forth) may change during the development of morphine tolerance, dependence, or both. The central activation of NMDA receptors is involved in the development of morphine tolerance (180). Noncompetitive NMDA receptor antagonists can attenuate the development of tolerance to the analgesic effect of morphine without affecting acute morphine analgesia (244). Intracellular events (increase in Ca^{++} concentration, production of nitric oxide, and possibly regulation of gene expression) initiated by NMDA receptor activation may initiate neuronal plastic changes in the CNS and thus mediate morphine tolerance (181). With chronic morphine use, a functional uncoupling of opioid receptors from guanosine triphosphate–binding proteins (G proteins) occurs and the acute effects of the drug decrease. As a result, triggering the second messenger response requires higher doses of opioid (245).

Any patient who requires dose escalation for pain relief, or who has experienced an opioid side effect (e.g., sedation) that has disappeared with repetitive dosing, is showing tolerance. Progression of malignancy with increased nociception, a modification in pain mechanisms not well controlled by opioids (e.g., neuropathic pain resulting from tumor invasion of nerve plexuses), or both may lead to opioid dose escalation and thus complicate identification of true opioid tolerance. Several authors believe that escalation of doses in cancer patients results from disease progression rather than from development of tolerance (246,247). Although tolerance to the different opioid effects develops at different rates, it is usually possible to titrate the opioid dose to the amount that works for the individual patient without encountering any dose-limiting side effects. Tolerance to respiratory depression develops rapidly. Tolerance to the constipating effects of opioids, a largely peripheral effect, does not usually develop. Tolerance to nausea, vomiting, or both typically appears within 2 to 3 days. Opioid-induced sedation is usually transient (223). Dysphoria, confusion, and hallucinations generally occur with rapid opioid dose escalation and resolve with either dose stabilization or reduction.

Intrathecal Morphine and Tolerance

Repeated intrathecal or epidural morphine administration has produced conflicting results. Ventafridda and colleagues (248) observed a rapid loss of effectiveness of 1 mg of morphine during a 3- to 5-day sequence of once-daily intrathecal injections in cancer patients. Greenberg and colleagues (249) reported one case of tolerance to continuous intrathecal infusion of morphine via an Infusaid pump for a patient with painful metastatic lumbosacral plexopathy. The effective dose increased from 1 mg during the trial period to 10 mg per day 1 week later and 150 mg per day 3 months later. In a retrospective study of the doses of morphine administered intrathecally by chronic infusion in a population of 163 patients treated by 19 physicians, Yaksh and Onofrio (246) reported a marked time- dependent increase from 4.8 ± 0.4 mg per day at week 1 (n = 130), to 16 ± 4 mg at 24 weeks (n = 33), and to 21 ± 9 mg at 52 weeks (n = 10). In a series of 35 patients treated with continuous intrathecal morphine (mean, 5.4 months) for intractable cancer pain, Penn and Paice (250) reported that the occurrences of tolerance can be managed effectively. Sallerin-Caute and colleagues (251) retrospectively examined the records of 159 patients with refractory cancer pain treated with intrathecal morphine for the development of opioid tolerance. The mean follow-up period was 95 days (range, 5 to 909 days), the mean starting dose of intrathecal morphine was 2.69 mg (range, 1.0 to 7.5 mg), and the mean terminal dose was 7.82 mg (range, 1 to 80 mg). Only a moderate increase in daily dose of intrathecal morphine was required during the course of treatment (a two- to threefold increase for a 3-month period). The dose increment was similar for patients followed up for more or less than 60 days. These studies suggest that, although tolerance to the effect of spinal morphine may develop in the cancer patient, tumor progression is much more likely to increase opioid requirements.

Opioid Rotation in Cancer Pain

A change in drug, which is known as *opioid rotation* or *sequential opioid trials*, has become an accepted strategy to address an initially poor response to a specific opioid. The approach derives from the observation that there is large interindividual variation in the pattern of adverse effects produced by different opioids, and that the balance between analgesia and adverse effects improves after a switch to an alternative drug. The equianalgesic dose ratios largely represent average data from controlled single-dose studies in selected populations. These values are approximations in the setting of long-term administration of the drugs to medically ill patients. The ratios also fail to account for the possibility of incomplete cross-tolerance, which would render the new drug more potent than anticipated and the effect on administration of either unrelieved pain or a predisposition to opioid toxicity. Guidelines for the use of the equianalgesic dose table include a standard reduction in the calculated equianalgesic dose, which requires further adjustment based on the clinical characteristics of the patient. The new dose becomes the starting point for the process of dose titration.

These guidelines require further adaptation for two special cases: a switch to methadone (which yields a potency much greater than expected) and conversions that involve the TTS-fentanyl system. Morphine's side effects, particularly sedation, cognitive impairment, and myoclonus at high doses, have provoked the use of opioid rotation to alternatives such as methadone and hydromorphone. This involves equianalgesic dose tables. These tables generally propose a dose ratio of 5:1 between morphine and hydromorphone. In the case of a change from subcutaneous hydromorphone to methadone, the tables indicate dose ratios ranging from 1:6 to 1:10. Morphine and hydromorphone are commonly used opioid analgesics for cancer pain. Lawlor and colleagues (252) suggest that hydromorphone is five times more potent than morphine when given second, but is only 3.7 times more potent when given first. Bruera and colleagues (185) showed that the hydromorphone to methadone ratio correlated with total opioid dose (correlation coefficient = 0.41, $p < .001$) and was 1.6 (range, 0.3 to 14.4) in patients receiving more than 330 mg of hydromorphone per day before the change, versus 0.95 (range, 0.2 to 12.3) in patients receiving an average of 330 mg of hydromorphone per day ($p = .023$).

The process of switching from a high-dose opioid agonist to methadone is complex and should only be attempted by physicians with experience in cancer pain management. Even among experienced physicians, occasional serious toxicity can occur during the administration of methadone (253). Contrary to expectations, toxicity occurs more frequently in patients previously exposed to high doses of opioids than in patients receiving low doses. Manfredi and colleagues (178) described the conversion of four patients receiving high continuous infusions of either morphine or hydromorphone to methadone. All four patients had excellent pain relief without significant side effects at a dose that, according to the conversion charts, was approximately 3% of the calculated equianalgesic dose of hydromorphone. When converting from continuous intravenous hydromorphone to continuous intravenous methadone, use much lower doses than those suggested by the opioid conversion charts as starting doses. This author reported on the conversion of a patient receiving approximately 2,000 mg per day of morphine intravenously by PCA and continuous infusion to methadone by the same treatment modalities (179). Although the patient required 1,800 mg of methadone on the first day of conversion, the total daily dose decreased by one-tenth the initial dose on day 3 once the patient reached steady-state plasma levels.

Bruera and colleagues (185) provide some guidelines for the conversion of patients from high-dose oral opioids to oral methadone. They recommend decreasing the previous opioid dose by one-third over the first 24 hours and replacing it with methadone using an equianalgesic dose ratio. One milligram of oral methadone is equal to 10 mg of oral morphine (i.e., a patient receiving 1,000 mg of oral morphine per day will switch to 660 mg of oral morphine per day plus 33 mg of oral methadone during the first day). Administer methadone every 8 hours by the oral route. During the second day, if pain control is adequate, the patient requires a further one-third decrease in the dose of the previous opioid. The dose of the methadone should only increase if the patient experiences moderate to severe pain. Manage transient episodes of pain with intermittent rescue doses of short-acting opioids. During day 3, discontinue the final one-third of the previous opioid and maintain the patient on regular methadone every 8 hours, plus approximately 10% of the daily methadone dose as an extra dose orally for breakthrough pain. Assess pain and methadone requirements frequently until a stable methadone dose is reached. Until the equianalgesic dose ratio of parenteral and oral opioids to methadone is clearly established, patients receiving high doses of oral or parenteral opioids who require conversion to methadone should undergo this conversion only under close supervision and preferably in an inpatient environment. In general, the safe use of methadone to control cancer pain requires meticulous follow-up care and anticipatory downward dose titration.

INTERVENTIONAL PAIN MANAGEMENT

Physicians managing terminally ill cancer patients with pain generally turn to interventional pain management only after medication management has failed. Failure of therapy exists when the patient considers the pain relief inadequate and cannot obtain further relief without unacceptable side effects. In some situations, the use of interventional modality can be less invasive and troublesome to the patient than continued aggressive medication management. Interventional strategies comprise two categories: ablative and augmentative modalities.

Ablative Modalities

These modalities involve blocking nociceptive transmission by neurolytic injections or surgical lesions. The goal is to use chemicals (e.g., phenol, alcohol), heat, cold, or a scalpel to destroy nociceptive pathways and thereby achieve pain relief. Surgical sectioning of nervous tissue and radiofrequency denervation may provide more complete or longer lasting pain relief than chemicals.

Neurosurgical Procedures

The common ablative neurosurgical procedures available for the management of cancer pain are discussed in detail in Chapter 105, Chapter 106, Chapter 107 and Chapter 108. The aggressive use of opoids has dramatically reduced the role of ablative procedures since 1980.

pinal Neurolysis

Both intradural (especially in the cauda equina) or extradural (at the spinal foramina) blocks or denervations introduce lesions at the nerve root level (see Chapter 104). Techniques used include injections of phenol or alcohol, electrodes for radiofrequency or cryoablation destruction, or open surgical section of nerves.

Spinal neurolysis may be an effective method for pain control in cancer patients with limited life expectancy, who have nociceptive pain covering two or three dermatomes (especially in sacral, perineal, and thoracic areas), and in patients who are severely compromised or who have absent bladder, bowel, or bladder and bowel function. Intrathecal neurolysis with small volumes of alcohol or phenol requires careful positioning to place the affected sensory nerve root uppermost (for alcohol) or in the most dependent position (for phenol). Patient movement during or shortly after injection can spread the drug to other dermatomes or to motor roots. The popularity of spinal neurolysis has waned with the increasing use of neuraxial infusional therapy. Randomized, prospective studies on the effects of spinal neurolysis on pain relief are lacking. Indeed, much of the published data in this area lack uniform patient selection, inadequately report preblock analgesic therapy, or inconsistently evaluate outcome and inadequately follow up with patients in the long term. Based on the studies available, good pain relief may be anticipated in approximately 51% of appropriately selected patients, moderate pain relief in 23%, and poor relief in 26% (254,255). Gerbershagen (256) showed that the success rate of intrathecal alcohol neurolysis declined with repeated injections, with approximately 60% of patients obtaining some relief with the first block, 30% with a second block, 8% with a third block, and 3% with more than three blocks. Papo and Visca (254) reported on the use of phenol for subarachnoid rhizotomy in 290 cancer patients. They reported good results (pain free until death) in 40%, and fair results (reduced analgesic requirements or temporary complete relief) in 35%. Patients with pain localized to sacral dermatomes had the best results. Swerdlow (255) reviewed 13 reports of the results of phenol and alcohol rhizotomies and found good relief of pain in approximately 60% of patients. In reviewing results of his own patients, he found that pain relief lasted less than 2 months in one-half the patients and less than 1 month in 25%. Complications lasting longer than 1 week occurred in 15%.

Other Procedures

Autonomic nervous system blocks for visceral pain, although often overlooked, can prove quite effective. In general, these blocks should be considered as analgesic adjuvants and not definitive pain relief treatment. These procedures should allow patients to lower drug dosages and thereby reduce side effects, or to experience better pain relief from current dosages to improve their quality of life. It is inappropriate to promise patients permanent relief, because their disease may progress and spread.

Celiac Plexus Block

The celiac plexus, originating from the sympathetic fibers of the thoracic splanchnic nerves, contains preganglionic splanchnic afferent fibers, parasympathetic preganglionic fibers from the phrenic and vagus nerves, and postganglionic sympathetic fibers, both efferent and afferent (see Chapter 104). It is the main target in abdominal visceral nociceptive innervation. Nociceptive impulses originating from all the abdominal viscera (pancreas, liver, stomach, intestine proximal to transverse colon, renal pelvis, proximal ureter, and gallbladder) are carried by visceral nerve fibers that pass through the celiac plexus and thoracic splanchnic nerves. The celiac plexus surrounds the axis of the celiac artery and overlaps the aorta at this level. The plexus varies anatomically in relation to the vertebral column from the bottom of T-12 to the middle of L-2 (257). The plexus is not a separate and distinct structure, but rather a dense network of ganglia around the aorta between the celiac and superior mesenteric arteries. It has a more consistent anatomic relationship with the celiac artery. It lies in areolar tissue behind the stomach, pancreas, and omental bursa; retroperitoneal in front of the aorta and crura of the diaphragm, and between the adrenal glands.

Interruption of nociceptive input at the level of either the celiac plexus or the thoracic splanchnic nerves is a potentially effective means of visceral pain control. Preblock computed tomographic (CT) scanning is useful to define the retroperitoneal anatomy and the vertebral relationship for the origin of the celiac artery.

De Cicco and colleagues (258) suggest that, when the celiac area is free from anatomic distortions, and the single-needle neurolytic celiac plexus block (NCPB) technique is used, the needle tip should be positioned cephalad to the celiac artery to achieve a wider neurolytic spread. It appears that only a complete (four-quadrant) neurolytic spread in the celiac area can guarantee long-lasting analgesia. When the celiac area is free from anatomic alterations and a single-needle precrural approach is chosen, the needle tip position in relation to the celiac artery may be critical.

Eisenberg and colleagues (259) performed a metaanalysis of the efficacy and safety of NCPB for cancer pain. Twenty-one studies were retrospective, one was prospective, and two were randomized and controlled. Sixty-three percent of cancer types were pancreatic in origin, and 37% were nonpancreatic. A bilateral posterior approach with volumes varying from 15 to 50 mL of 50% to 100% alcohol was the most common technique. Nonradiologically guided NCPB was performed in 32%; guidance was by CT in 28%, radiography in 34%, fluoroscopy in 5%, or ultrasound in less than 1%. Good to excellent pain relief resulted in 89% during the first 2 weeks after NCPB. Long-term follow-up beyond 3 months revealed persistent benefit. Partial to complete pain relief continued in approximately 90% of patients alive at 3 months post-NCPB and in 70% to 90% until death even if beyond 3 months post-NCPB. Patients with pancreatic cancer responded similarly to those with other intraabdominal malignancies. Common adverse effects were transient, including local pain (96%), diarrhea (44%), and hypotension (38%); complications occurred in 2%. This analysis suggests that NCPB has long-lasting benefit for 70% to 90% of patients with pancreatic and other intraabdominal cancers, regardless of the technique used, that adverse effects are common but transient and mild, and that severe adverse effects are uncommon.

Polati and colleagues (260) compared the efficacy of NCPB with pharmacologic management in a randomized, prospective, double-blind trial of 24 patients with pancreatic cancer. Immediately after the block, patients reported significant pain relief compared with those who received only pharmacologic management ($p < .05$), but long-term results did not differ between the two groups. NCPB was associated with a reduction in analgesic drug administration and drug-related adverse effects and was considered an effective tool in the treatment of pancreatic cancer pain.

Unfortunately, NCPB is associated with both minor and major complications. Documented side effects and complications from celiac plexus block include myofascial back pain (259), hypotension (259,260), intravascular injection (261), damage to the artery of Adamkiewicz (262,263) with a subsequent anterior spinal artery syndrome (264), paraplegia (265,266) secondary to either a spinal with a neurolytic solution or the spinal artery syndrome (267), retroperitoneal pain (268), reversible paraplegia (269), infection (270), loss of anal and bladder sphincter function (266), mild or persistent diarrhea (259,271), retroperitoneal fibrosis (272), pleural effusion (273), chylothorax (274), neurologic injury (footdrop) (275), intradiskal injection (276), and aortic pseudoaneurysm (270). Other possible problems include diskogenic backache, spinal or epidural spread of injected solution, postdural puncture headache, piercing of renal parenchymal tissue, pneumothorax, L-1 and L-2 neuralgia, lumbar plexus block, psoas muscle injection, spasm or damage to the celiac artery, intrabowel injection, bleeding into the peritoneal cavity or retroperitoneum, and thrombosis of any pierced vessels.

Davies (266) determined the incidence of major complications after NCPB. In 2,730 neurolytic blocks performed from 1986 to 1990, the overall incidence of major complications (paraplegia, bladder and bowel dysfunction) was 1 per 683 procedures. A number of other authors suggest that the incidence of a catastrophic sequela after NCPB to be in the region of 1 to 2% (259,277,278). Eisenberg and colleagues (259) quote a 1% incidence of neurologic complications, defined as lower extremity weakness, paresthesia, epidural anesthesia, and lumbar puncture, although it is difficult to determine the incidence for any particular complication. Unilateral paralysis caused by spread of neurolytic solution to the lumbar plexus (279) and bilateral paresis caused by subarachnoid injection have been reported (280). Galizia and Lahiri (281) presented a case of total bilateral sensory and motor loss in an L-1 to L-5 distribution immediately after celiac plexus block. Cherry and Lamberty (265) also reported paraplegia 2 hours after an alcohol injection. They speculated that the cause of the paraplegia was an anterior spinal artery syndrome caused by lumbar artery ischemia caused by spasm. Anterior spinal artery syndrome caused by anterior spinal artery ischemia results in a predominantly motor lesion, because the anterior two-thirds of the spinal cord, including the anterior horn cells, is supplied almost exclusively by the anterior spinal artery. Loss of pain and temperature sense, intact fine touch and position sense, and lower extremity paralysis are characteristic.

Transcrural and transaortic techniques attempt to minimize the neurologic complications occasionally reported with the retrocrural approach. Singler (282) and Hilgier and Rykowski (283) reported using the transcrural approach in 41 patients, with transient diarrhea as a side effect in some patients. In 148 patients who received the transaortic approach (284,285 and 286), transient orthostatic hypotension and diarrhea occurred as the main side effects in some. However, Kaplan and colleagues (287) reported on a case of aortic dissection as a complication of transaortic celiac plexus block. Sett and Taylor (270) reported the development of a traumatic pseudoaneurysm after the procedure. Naveira and colleagues (288) described the presence of an atheromatous plaque as a cause of resistance to needle passage during a transaortic celiac plexus block under CT guidance. Although the incidence of major vascular complications following this approach is largely undetermined, note that translumbar aortography, which punctures the lumbar aorta, has a mortality of 0.05%, with 27% of fatalities resulting from aortic dissection and aneurysm rupture (289), yielding an incidence of 1.35 per 10,000 procedures.

Some authors have recommended the use of CT scanning, guided by a radiologist, as a method of reducing or eliminating the morbidity associated with celiac neurolysis (290). However, one can surmise that not all adverse events from celiac plexus blocks were reported, regardless of the approach used. The only truly accurate determination of complication rates associated with celiac plexus blocks will be through a mandatory central registry of all procedures.

Superior Hypogastric Plexus Block

Pelvic pain associated with cancer arises from visceral involvement, from tumor extension to the muscles and bones of the pelvic wall, and from nerve involvement. Visceral pain may be a significant feature of advanced stage cancers of the pelvis such as cervical, bladder, prostate, and rectum. Relief of pain from pelvic organ nociception is possible because afferent fibers innervating these structures travel in the sympathetic nerves, trunks, ganglia, and rami. The superior hypogastric plexus is situated in the retroperitoneum, bilaterally extending from the lower third of the fifth lumbar vertebral body to the upper third of the first sacral vertebral body. The plexus innervates the pelvic viscera via the hypogastric nerves and inferior hypogastric plexuses.

The surgeon can divide the superior hypogastric plexus (presacral neurectomy) either at laparotomy (291) or at laparoscopy (292). Various nonsurgical approaches to the plexus are also possible. Plancarte and colleagues (293) used a bilateral percutaneous phenol nerve block approach for the management of intractable pelvic visceral pain. The block offers a practical, minimally invasive alternative for controlling cancer pain associated with tumor extension into the pelvic viscera. An incomplete block may occur in patients with retroperitoneal disease caused by limited spread of phenol (294). Despite the use of a unilateral needle insertion under CT guidance (295), the results are sometimes less favorable than those obtained with bilateral needle placement because of the bilateral distribution of pelvic pain (296). Ina and colleagues (297) advocated the deliberate passage of needles through the L-5 to S-1 disk (transdiskal approach) for patients with difficult anatomy and reported on the safe and successful use of this technique in eight patients. I have used this approach successfully on a patient with intractable pelvic visceral pain where a decubitus ulcer overlying the right posterior iliac crest prevented a bilateral percutaneous needle approach.

A study by de Leon-Casasola and colleagues (294) evaluated the efficacy and safety of the block in 26 patients with extensive gynecologic, colorectal, or genitourinary cancer who suffered uncontrolled, incapacitating pelvic pain. Neurolysis was carried out under fluoroscopy with bilateral needle placement and injection of 8 mL of 10% phenol on each side. Criteria for success of the block were (a) a decrease in VAS of at least 70%, or (b) pain intensity of less than $^{3}/_{10}$ during the first 2 weeks after the block, and (c) a decrease in oral opioid requirements of at least 30% with disappearance of bothersome side effects 2 weeks after the block. All patients reported a VAS of $^{10}/_{10}$ before the block, despite oral opioid therapy. Mean use of morphine before the first neurolytic block in all patients was 953 ± 722 mg per day with a median of 780 mg per day (range, 80 to 2,780 mg per day). Postprocedure patients in the success group demonstrated significantly less daily oral intake of morphine than patients in the failure group (736 ± 633 versus 1,443 ± 703 mg per day, $p = .02$; Table 36-14) Sixty-nine percent of patients had satisfactory pain relief (VAS less than $^{4}/_{10}$). Fifty-seven percent of these patients had satisfactory relief after one block, the remaining 12% after a second block. Thirty- one percent had moderate pain control (VAS $^{4}/_{10}$ to $^{7}/_{10}$) after two blocks and received supplementary neuraxial analgesia therapy. Both groups of patients experienced significant reductions in oral opioid therapy after the neurolytic blocks. Patients who had a good response during a 6-month follow-up period required no additional blocks. No intraoperative complications such as bladder puncture or retroperitoneal hematomas occurred. Two patients had transvascular neurolytic blocks without problems. There were no long-term complications such as urinary or fecal incontinence.

	Success	Failure	p Value
Preblock	736 ± 633	1,443 ± 703	.02
Postblock	251 ± 191	800 ± 345	.001
% Reduction in use	67	45	–
p Value	.001	.01	–

Values expressed as mean ± standard deviation.

TABLE 36-14. Comparison of oral doses of morphine before and after neurolytic blocks between the success and failure groups (mg/ day)

Neurolytic superior hypogastric plexus blocks are useful for patients with intractable visceral pelvic pain and have a low incidence of side effects or complications.

Augmentative Modalities

Augmentative modalities comprise infusional and electrical stimulation techniques (see Chapter 99, Chapter 100, Chapter 101, Chapter 102 and Chapter 103). Medication infusion has emerged as a major resource in cancer pain management, whereas electrical stimulation plays a relatively minor role. Much of the growing interest in infusion therapy results from improved technology for continuous infusion, using epidural, intrathecal, or intracerebroventricular (ICV) catheters connected to external infusion pumps, subcutaneous injection reservoirs, or implanted programmable infusion pumps. The use of infusion techniques can be cumbersome, labor intensive, and technically demanding. Most modalities require initial inpatient care and screening with a temporary device. After successful implantation and adequate pain control, domiciliary care requires the aid of a home infusion service with regular monitoring and adjustments by the managing physician.

Intravenous Opioid Therapy

Parenteral routes should be considered for patients who require rapid onset of analgesia, and for highly tolerant patients who require doses that cannot otherwise be conveniently administered (298). Intravenous opioids allow for rapid control of pain. Ideally, patients with severe, uncontrolled pain who require intravenous therapy should start treatment in a monitored inpatient setting. High doses of intravenous opioids via PCA or continuous infusion offer a means of rapidly controlling increasing severe pain. Because of high interindividual variation in opioid requirements, ascertain previous opioid exposure and consider the patient's tolerance. Flexibility for individual titration and the PCA modality are important considerations for patients requiring intravenous opioid therapy. Once patients begin opioid therapy for tumor pain control, titrate doses according to patient comfort or the appearance of intolerable side effects. For severe pain, employ a minimum lockout interval of 6 minutes. However, for patients with inadequate pain control and minimal opioid-related side effects, increase incremental doses by 50% every 4 hours. Order additional nurse-administered loading doses to achieve pain control. Once pain is under control, it is possible to continue therapy safely at home with the aid of a home infusion service (299,300and301).

Intravenous therapy can use any of several opioids: morphine, hydromorphone, fentanyl, sufentanil, and methadone. The use of opioids (e.g., methadone) with properties of NMDA receptor antagonism may improve pain control by attenuating the development of tolerance to morphine (181). This degree of incomplete cross-tolerance is probably unique to methadone (185) and may stem from isomers of methadone interacting with the NMDA receptor to reverse tolerance, and thereby reduce dose requirements (180).

Postoperative pain studies comparing opioid-related side effects failed to show a difference between morphine and hydromorphone (302) and morphine, meperidine,

and fentanyl (303). Coda and colleagues (304) found differences in efficacy and side effects for morphine, hydromorphone, and sufentanil in bone marrow transplantation patients with severe oral mucositis pain. The pain relief achieved in all three opioid groups was nearly equivalent, whereas measures of side effects, especially for the combination of sedation, sleep, and mood disturbances, were statistically lower in the morphine group than in the hydromorphone or sufentanil groups. Daily opioid consumption patterns showed continual dose escalation during the first week of therapy for all three opioids, coincident with worsening mucositis. Morphine consumption reached a plateau by day 5, whereas hydromorphone and sufentanil consumption continued to increase until days 7 and 9, respectively. Sufentanil dose requirement increased by approximately tenfold compared with morphine and hydromorphone, whose requirements increased only fivefold, suggesting the possibility of development of acute pharmacologic tolerance in some patients with this phenylpiperidine opioid.

Knowledge of intravenous opioid pharmacokinetics and pharmacodynamics helps guide opioid selection for the management of severe cancer pain. Coda and colleagues (305) defined the intravenous dose-effect characteristics of hydromorphone. Bolus doses of 10, 20, and 40 µg per kg of hydromorphone in human subject volunteers produced log linear dose-dependent analgesia. Onset of analgesia after an intravenous bolus was rapid, within 5 minutes, and the maximum analgesic effect was seen between 10 and 20 minutes after maximum plasma concentrations with analgesia lasting approximately 2 hours after a bolus injection. Hydromorphone is approximately three to five times as potent as morphine on a milligram basis (305,306). Peak CNS effects of methadone coincide with peak plasma concentrations, thus corresponding well to the observed early onset of action of 3 to 5 minutes after intravenous administration (192).

Morphine, on the other hand, has a slower onset of action, probably related to its relatively poorer lipid solubility. Hug and colleagues (307) administered an intravenous bolus of morphine to dogs and showed that the peak concentration in CSF did not occur for approximately 15 to 30 minutes. Fentanyl, a highly lipophilic opioid, has a rapid analgesic onset and time to peak effect (less than 6 minutes) (308). Intermittent boluses of opioids (such as fentanyl) with rapid onset and early peak effect offer advantages for patients whose predominant pain stems from activity or weight-bearing and occurs intermittently. Patients with constant, severe, intractable cancer pain and large opioid requirements may benefit from the use of intravenous methadone by PCA and continuous infusion. This approach offers some advantages over the more hydrophobic drugs such morphine and hydromorphone. The more rapid peak analgesic effect and longer elimination half-life of methadone foster earlier intense analgesia with prolonged analgesic effect, particularly after patients reach steady-state plasma levels with repeat administration.

Systemic opioid therapy has limitations: Most commonly, drowsiness and sedation are dose limiting; in such situations consider alternate therapies (e.g., neuraxial analgesia). Less frequently, CNS side effects of high-dose opioids occur. These effects include hyperexcitability, myoclonus, confusion, and hyperalgesia (309). Myoclonus, the most common problem for patients receiving high-dose opioid infusion therapy, appears localized, but it can spread and eventually progress to grand mal seizures. These effects can occur with opioids administered via different routes (oral, parenteral, and neuraxial). The cause of opioid- induced myoclonus is still unknown. Some speculate that the active metabolite of morphine, M3G, may be responsible for the hyperalgesia and myoclonus seen with high-dose morphine therapy (227). Intravenous hydromorphone in doses of more than 60 mg per day has resulted in hyperalgesia and myoclonus. Doses of intravenous morphine greater than 60 mg per hour have resulted in similar problems. Although treatments including phenobarbital loading and clonazepam have occasionally proved helpful (310), definitive treatment for myoclonus usually involves either dose reduction, a change in opioid, or both (231). Switching to intravenous methadone therapy may also prove helpful. If these strategies fail, consider alternative pain management techniques (311).

Subcutaneous Opioid Therapy

Continuous subcutaneous infusion of opioids is both an efficacious and safe method to control the chronic pain of the home-bound and hospitalized patient (301,312,313 and 314). Hypothetically, absorption of opioid from the subcutaneous compartment into the systemic circulation should be slow, but it is not, even for morphine (315). Moulin and colleagues (316) reported equianalgesic responses in a comparison of intravenous versus subcutaneous infusions of hydromorphone. Breakthrough pain control was equal in both groups and only occasionally did patients experience undue dermal irritation or recurrent infection. A wide variety of opioids are suitable for subcutaneous infusion: morphine, hydromorphone, methadone, fentanyl, and sufentanil.

Hydromorphone's solubility, its high bioavailability by continuous subcutaneous infusion (78%) (316), and the availability of a high-concentration preparation (10 mg per mL) make it a good choice for subcutaneous infusion. Parenteral hydromorphone is six times as soluble in aqueous solutions as morphine and five times as potent, allowing for smaller injection or infusion volumes in patients who require parenteral opioids (168).

Continuous subcutaneous infusions offer a safe, simple, effective alternative to intravenous infusion when patients cannot take medications orally. Moulin and colleagues (316) compared the safety and efficacy of subcutaneous versus intravenous infusion of hydromorphone in cancer patients. Pain intensity, pain relief, mood, and sedation did not differ between the two techniques. The mean bioavailability of hydromorphone from subcutaneous infusion was 78% of that with intravenous infusion. Simplicity, technical advantages, and cost-effectiveness are clear advantages of continuous subcutaneous opioid infusion into the chest wall or trunk. Paix and colleagues (317) described the successful use of subcutaneous fentanyl and sufentanil for morphine, noting the effective substitution of sufentanil for fentanyl when the patient needs higher doses of a lipophilic opioid.

Most patients require a weekly change of the site of subcutaneous infusion (313). The usual initial concentrations of morphine and hydromorphone are 5 mg per mL and 1 mg per mL, respectively, calculated according to the hourly infusion rate. Ideally, the subcutaneous rate should not exceed 2 mL per hour although some have established considerably higher rates (rates of 20 to 80 mL per hour by adding hyaluronidase to the infusion to promote hypodermoclysis) (318). One might expect a longer time to peak plasma levels after bolus injection with subcutaneous use than with intravenous use and consequently the subcutaneous route requires a longer lockout interval (10 to 15 minutes compared with 6 to 8 minutes for the intravenous). PCA doses may equal 25% to 50% of the hourly infusion rate every 10 to 15 minutes as needed. Subcutaneous administration of opioids may prove impractical in patients with generalized edema, who develop erythema, soreness, or sterile abscesses with subcutaneous administration, in patients with coagulation disorders, and in patients with poor peripheral circulation.

Intracerebroventricular Opioids

After neurosurgical consultation, it becomes possible to deliver opioids directly into cerebral ventricles through ICV catheters from subcutaneous reservoirs. Morphine sulfate, the usual agent, gains a marked increase in potency when delivered ICV as compared with intrathecal or epidural infusion routes, and the ICV route appears to affect supraspinal pathways for analgesia (319). Daily morphine doses for ICV delivery range from 50 to 700 µg per day (320,321). Generally, an implanted infusion pump, placed subcutaneously in the anterior abdominal wall and connected by subcutaneous tubing to an implanted ventricular catheter, delivers the drug. The duration of pain relief after ICV injections appears to be significantly longer than with intraspinal, and some patients gain adequate relief via an implanted ventricular catheter connected to a subcutaneous Ommaya reservoir-type device with one to two injections per day (322). This form of drug delivery is indicated for head and neck cancer pain, or, rarely, for patients with a good initial response to intraspinal infusions of opioids and subsequent development of apparent tolerance, but with limited (1 to 3 months) remaining survival time. The safety and side effects of ICV injections or infusions resemble those for intraspinal infusions, except that an increased risk of respiratory depression exists the first 3 days of therapy (322).

Some refractory head and neck pain responds only to ICV opioids, but pain below the waist may be most amenable to spinal treatment. In a metaanalysis of 1,587 cancer patients, Ballantyne and colleagues (323) compared ICV with the more common epidural and intrathecal opioid treatments in an attempt to establish the utility and safety of ICV therapy. All patients considered had intractable cancer pain that proved resistant to systemic treatment. Sedation and confusion occurred in 4% to 5% of patients receiving ICV therapy. Persistent nausea, urinary retention, and pruritus occurred more frequently with the two spinal treatments than with ICV therapy. Initial doses for ICV trial patients were in the range of 0.25 to 2.0 mg. Onset of effect was 2 to 30 minutes, and average duration of pain relief after a single dose was 12 to 48 hours. Tolerance proved less of a problem than with epidural or intrathecal therapy because the dose escalation was gradual (the average increase in daily dosage was 0.375 mg per month). However, because most of the studies that Ballantyne and colleagues reviewed were uncontrolled trials, she and her colleagues could not reach definitive conclusions on the comparative analgesic efficacy, side effects, and complication rate of the different treatments. No studies to date directly compare ICV therapy with epidural or intrathecal opioids. None of the trials that Ballantyne and colleagues reviewed quantified pain relief with a formal measure of pain, such as a pain scale.

Intraspinal Opioids

The intraspinal (epidural or intrathecal) infusion of opioids has been well established for the treatment of cancer pain for more than two decades (see Chapter 103). Initial reports of the efficacy and lack of complications associated with intrathecal and epidural morphine for cancer pain relief led many to believe that the solution to intractable pain awaited the development of satisfactory long-term neuraxial delivery systems (324). Epidural or intrathecal infusions can involve externalized spinal catheters, subcutaneous reservoirs for intermittent injection, or implanted infusion pumps, with either a constant rate or a programmable rate (325). Although such delivery systems have come into widespread use, particularly for the management of chronic nonmalignant pain, the overall success of long-term intrathecal and

epidural opioid administration is somewhat lower than initially anticipated for cancer pain.

Choice of Spinal Delivery System. Table 36-15 lists the spinal opioid delivery systems available (325). Ever since Behar and colleagues (326) first reported the use of epidural morphine for the treatment of cancer pain, anesthesiologists have been looking for a means to overcome the technical problems that can arise during chronic treatment with epidural opioids. These complications include catheter dislodgment, infection, pain on injection, leakage, and occlusion. Options to reduce these problems included tunneling the catheter to the flank or the anterior abdominal wall or implantation of a subcutaneous injection port located on the patient's anterior chest wall.

Type	System
I	Percutaneous epidural or intrathecal catheter
II	Percutaneous epidural or intrathecal catheter with subcutaneous tunneling
III	Totally implanted epidural or intrathecal catheter with subcutaneous injection port
IV	Totally implanted epidural or intrathecal catheter with implanted reservoir and manually activated pump
V	Totally implanted epidural or intrathecal catheter with implanted externally programmable infusion system

TABLE 36-15. Spinal delivery systems

Many reviews of epidural treatment of cancer pain have reported technical complications (Table 36-16). The use of percutaneous catheters (not tunneled or tunneled) is somewhat limited. Advantages include ease of placement and ability to attach to an external pump. Disadvantages include the risk of infection with long-term use, a high incidence of displacement of the catheter, and fibrosis around the catheter tip resulting in pain on injection. A three-piece silicone-rubber exteriorized epidural catheter system described by DuPen and colleagues (327) allows for specific spinal level location of the catheter tip from a lumbar entry site and may help reduce the incidence of displacement and pain on injection. Disadvantages include a relatively high incidence of infection (both subcutaneous and epidural space) associated with long-term use. The rate of epidural and deep track catheter-related infections was 1 in every 1,702 days of Silastic catheter use (328). Tunneled epidural catheters with subcutaneous injection ports reduce the complication rate of simple percutaneous and tunneled epidural catheters, particularly for catheter dislodgment and early infections (329). Plummer and colleagues (330) noted in a series of 313 patients that the most frequent complications of subcutaneous injection ports were pain on injection (12.0% incidence), occlusion of the portal system (10.9%), infection (8.1%), and leakage of administered morphine such that it did not all reach the epidural space (2.1%). Possible disadvantages of these systems include the need for skin puncture with each delivery system use and the increased cost of the system. No direct comparison studies of Silastic tunneled exteriorized epidural catheters and subcutaneous ports are available.

TABLE 36-16. Technical complications of epidural catheters: review of the literature

The intrathecal route is sometimes more efficient and less expensive than epidural delivery for the treatment of refractory cancer pain (331). Potential advantages of intrathecal administration include better distribution of medication to the target site and enhanced pain relief (332). However, the intrathecal route is less frequently used than the epidural route (333). Concerns about externalized intrathecal catheters focus around potentially higher risks of complications (particularly meningitis, CSF fistula, and CSF hygroma) than an epidural catheter. Therefore, physicians who use the intrathecal route tend to avoid percutaneously inserted, subcutaneously tunneled, *open* or externalized catheters, preferring a totally implanted system that, it is hoped, will reduce or abolish these complications. However, such concerns appear to be largely unfounded (334). Implanted systems, especially if programmable, are the most convenient for long-term treatment with intrathecal opioids. Use of infusion technology is not without problems, and complication rates varying from 5% to 15% appear in the literature (248,322,330,335,336). They appear to offer a lower risk of certain complications (infection, displacement, and pain on injection) than other systems, but may also introduce specific delivery system problems (battery failure, pump torsion, overfilling of reservoir, programming errors, and so forth) (337). In addition, the high cost of the devices, which can be used in only one patient, and the relatively low capacity of the implanted infusion reservoir limit both the choice of drugs or further treatment options and necessitate restriction of use of these devices in cancer patients with pain.

According to cost-benefit analysis, an implanted infusion pump is more favorable when survival times exceed 3 months (338). With a median follow-up of 7.1 months, long-term epidural infusions of morphine sulfate have produced satisfactory pain relief in over 80% of patients. Mean pain ratings decreased from 8.6 before pump placement to 3.8 at 1 month after pump placement and remained relatively stable thereafter. Mean systemic morphine equivalents likewise decreased from 77.7 mg per day preimplantation to 27.9 mg per day at 1 month postimplantation with stable doses thereafter, but with increasing mean spinal infusion rates from 20.7 mg per day at 1 month after pump placement to 49.3 mg per day at 9 months (339). The experience with long-term intrathecal infusions reveals still greater efficacy with intrathecal infusion rates increasing from 3.8 mg per day (1 month postimplantation) to 9.5 mg per day (4 months postimplantation) and daily systemic analgesic doses decreasing significantly to 1 month postimplantation and remaining relatively stable thereafter (340).

The best application for this technique appears to be for patients with nociceptive or visceral pain localized in the lower body who have experienced some pain relief with systemic opioids. The intraspinal infusions usually are used in patients who either cannot tolerate systemic opioids because of intolerable side effects, such as nausea, vomiting, or sedation, or in patients who require large systemic opioid doses (e.g., greater than 20 mg per hour morphine systemic equivalents).

Issues relating to the use of such delivery systems include determining when in the course of treatment to initiate spinal opioids, which patients are suitable candidates, and what types of pain respond reliably and well to this method. Although no one would recommend indiscriminate or widespread use of spinal opioids, many clinicians experienced in cancer pain management remain convinced of the efficacy and safety of spinal opioids. Potential indications for use may include patients treated by systemic opioids with effective pain relief but unacceptable and refractory opioid-related side effects or patients unsuccessfully treated with opioid rotation. However, we must recognize the limitations of the technique (in terms of efficacy and potential side effects or complications).

It is difficult to determine the long-term benefits of epidural and intrathecal opioid therapy for cancer pain for the following reasons: (a) The criteria for treatment success are usually vague and vary between reports, and (b) the selection criteria for initiation of neuraxial opioid administration vary tremendously. In some centers, neurologists or oncologists manage pain, and they may be more aggressive with systemic analgesics and more conservative with invasive measures than anesthesiologists. They tend to refer patients for neuraxial therapy late in the course of the illness, when metastases are widespread, nociceptive inputs are high, and tolerance is a substantial problem. Frequently, such patients require supplementary local anesthetics for pain control. Alternatively, other centers may initiate spinal therapy at an early stage, possibly when systemic therapy may be equally if not more effective.

Hogan and colleagues (341) determined that in a population of 1,205 cancer patients, the aggressive use of systemic opioids limited the trial of epidural analgesia to only 16 cases. Successful analgesia was obtained with epidural morphine alone in 6 of these 16 cases after systemic opioid failure. Complications occurred in 11 of the 16 cases of epidural analgesia and included dislodged or broken catheters, pain on injection, hyperesthesia from epidural morphine, and bleeding or infection related to the epidural catheter.

Hassenbusch and colleagues (339) evaluated the efficacy and safety of continuous epidural morphine infusions in 69 patients with refractory midline, bilateral, or both kinds of lower body cancer pain unresponsive to systemic opioid therapy. Sixty percent of these patients gained adequate pain relief during a pretrial assessment and underwent subsequent implantation with an epidural Infusaid infusion pump. Preinfusion VAS scores were 8.6 ± 0.3, and postimplantation values at 1 month were 3.8 ± 0.4 (p <.001). Eighty percent of these patients continued to experience satisfactory pain relief (based on a minimum of 30% decrease in VAS compared with preinfusion values) at 3- and 6-month follow-up. Over the first month, requirements of systemic morphine equivalents decreased by 79% compared with preinfusion requirements. At 9 months, systemic opioid requirements remained 64% lower than preinfusion requirements. The mean epidural dose after 1 month of infusion was 20.7 ± 2.6 mg per day, increasing to 49.3 ± 9.9 mg per day after 9 months of infusion. There were no instances of epidural scarring, respiratory depression, epidural infections, meningitis, or catheter blockage. The study suggests that chronic epidural morphine infusion can yield significant reductions in cancer pain with few complications and a low morphine tolerance rate, although this report omitted specifics relating to the pain characteristics.

Clearly, certain patients who experience inadequate analgesia, intolerable side effects from systemic opioids, or both may have an excellent response to spinal or epidural administration of the same drugs. However, some patients never experience adequate analgesia from neuraxial opioids (so-called treatment failures; see Intrathecal Administration, later in this chapter). Pain characterization is important in providing optimal spinal opioid analgesia for cancer pain (342). Arner and Arner (343) examined the differential effects of epidural morphine on cancer pain. They provided intermittent bolus doses of morphine to 55 patients with different types of cancer pain (daily dose range, 4 to 480 mg; dose interval range, 3 to 12 hours). Twenty-eight of the 55 patients became pain free. Twenty-one of the remaining patients were completely relieved from one or two pain types, whereas other coexisting pain types were either unaffected or partially relieved. In six cases the treatment proved ineffective. The best response to epidural morphine occurred when pain was continuous and originated from deep somatic structures. In coexisting continuous visceral pain or intermittent somatic pain originating from a pathologic fracture, for example, the outcome of treatment was variable. Cutaneous pain, neuropathic pain, and intermittent pain caused by intestinal obstruction responded only occasionally. Ten of the patients had coexisting pain that was nonmalignant in origin, and none gained relief. This study and others (344) suggest that one can, to some extent, predict outcome of treatment with epidural morphine from the character of the pain requiring relief.

Development of tolerance and opioid resistance to some types of pain may limit the effectiveness of spinal opioids for intractable cancer pain. Gourlay and colleagues (345) found a significantly greater degree of dose escalation in patients receiving a continuous infusion of morphine compared with patients receiving repeated bolus doses, whereas Hassenbusch and colleagues (339) reported a low morphine tolerance rate using chronic epidural morphine infusions.

Selection of Opioid for Neuraxial Administration

Epidural Administration. The objective of epidural administration is to restrict the drug to analgesic sites in the spinal cord. Nonetheless, all epidurally administered drugs reach the systemic circulation to some extent. Thus, to determine whether epidural administration of a drug is appropriate, we need to know for each drug whether the observed analgesia is the result of a selective spinal action, the result of systemic uptake and redistribution to extraspinal sites, or some combination of these actions. Morphine was the first spinally active analgesic administered into the epidural space. It clearly produces analgesia by actions in the spinal cord (346) and it is the standard of comparison for all other epidural opioids. Several clinical studies of postoperative patients have clearly shown that the dose of fentanyl consumed, the plasma concentration at equivalent analgesia, or both are no different when the drug is given epidurally or intravenously (347,348 and 349). Miguel and colleagues (350) used a randomized double-blind study design to compare epidural versus intravenous sufentanil for analgesia after abdominal surgery. They found no difference in sufentanil dose, plasma concentration, pain score, or sedation between the two routes of administration. Coda and colleagues (351) demonstrated that at clinically equivalent degrees of analgesia the plasma concentration of alfentanil was the same whether the subjects received alfentanil intravenously or in the lumbar epidural space. These studies suggest that little or no value exists in administering highly lipophilic drugs such as fentanyl, sufentanil, or alfentanil into the lumbar epidural space. Meperidine may yield greater efficacy with epidural versus intravenous administration. Paech and colleagues (352) demonstrated that patients using lumbar epidural meperidine PCA required less drug and generated lower plasma meperidine concentrations while reporting better pain relief, less sedation, and better satisfaction than others using intravenous PCA meperidine. Presumably, this reflects a spinal mu-receptor site of action for meperidine. However, the drug's well-known local anesthetic effects could also explain the greater efficacy of epidural meperidine. Approximately 30 times more meperidine than morphine is required for epidural analgesia (353). Epidural methadone is only one-half as potent as epidural morphine (353). In summary, although a variety of opioids are administered epidurally, morphine appears to be the drug of choice for epidural administration.

Intrathecal Administration. Implanted drug administration devices can deliver any of several opioids for the management of chronic noncancer and cancer-related pain. These opioids include morphine, hydromorphone, sufentanil, fentanyl, meperidine, and methadone. The intrathecal use of opioids for cancer pain has been studied in numerous reports (246,248,249 and 250,322,339,340,354,355,356,357,358,359 and 360). Although many of these reports imply significant benefit from the use of intrathecal opioid therapy, few have accurately quantitated pain relief. An additional problem noted in many series is treatment failure; these were patients who received intrathecal catheter implants but reported no significant pain relief, despite escalation of opioid doses to sometimes enormous proportions (356,360,361 and 362). The true incidence of treatment failure with implantable intrathecal infusion systems is unknown. Paice and colleagues (358) evaluated the efficacy of intraspinal opioid therapy for cancer and noncancer pain. Patients with cancer pain of somatic origin had greater relief with intrathecal opioid infusions than patients with other types of pain. Compared with those with noncancer pain, cancer pain patients had a higher average initial dose of opioid. The average dose used by cancer patients escalated quickly and then stabilized, whereas the average doses used by noncancer pain patients exhibited a more gradual, linear increase in dose. Yaksh and Onofrio (246) analyzed changes in continuous infusion doses of morphine over time in 130 cancer pain patients and found a prominent time-dependent increase from 4.8 ± 0.4 mg per day to 21 ± 9 mg per day at 52 weeks. Plummer and colleagues (330) reported that patients with implantable subcutaneous intrathecal catheters receiving continuous infusions of morphine exhibited wide variations in dose requirements to control cancer pain. This suggests that the response to intrathecal opioid therapy may depend more on pain characteristics (similar to those defined for epidural opioid therapy outlined previously) than on the specific opioid used. Curiously, intrathecal methadone produces analgesia of inferior quality even in dosages 10 times higher than morphine (363).

Side Effects of Neuraxial Opioid Therapy. The side effects of systemic morphine are well described in the medical literature. The spinal administration of this drug results in a similar range of side effects, despite the more limited distribution of the drug in the body. Some of these side effects are temporary, normally lasting for the first several days after initiation of therapy and then resolving; others are more enduring (364). In a retrospective study of 82 patients receiving long-term opioid therapy for noncancer pain, Winkelmuller and Winkelmuller (365) reported the most frequent side effects were constipation (50%), disturbance of micturition (42.7%), and nausea (36.6%). These occurred early in the course of therapy and responded to appropriate medication. Some patients experienced a loss of libido or amenorrhea for the first 6 to 8 months of therapy, but these side effects proved self-limiting to most patients and disappeared after 12 to 14 months of therapy. Escalating doses of intrathecal morphine may prove problematic because of increased risk for hyperalgesia and myoclonus (356). To avoid this problem, intrathecal doses of morphine should not exceed 15 mg per day.

Current knowledge on spinal opioids in tumor pain permits the following generalizations:

- A slow increase occurs in mean daily opioid dose requirements in many series, generally at a rate that doubles every few months. Some individuals escalate their dose requirements more rapidly, particularly in the terminal phase of their disease.
- Dose escalation tends to be slower with intrathecal administration systems. This may relate to the tendency for fibrosis to occur around epidural catheters (335).
- The escalation of dose over time tends to be slower in patients receiving continuous infusions as opposed to intermittent bolus injections (366). This may be related to the more rapid development of tolerance when spinal opioid receptors are exposed intermittently to high opioid doses.
- Higher spinal opioid doses are required for pain that is neuropathic in origin than for somatogenic pain (343). Opioid requirements for visceral pain are intermediate between neuropathic and somatic.
- Incident pain (occurring with activity) is difficult to control with either neuraxial or systemic opioids.
- Higher systemic opioid requirements predict higher neuraxial requirements.

Many patients who do not obtain pain relief with systemic opioids eventually demonstrate no benefit from epidural or intrathecal opioids. Although pain relief is excellent in 45% to 90% of patients with initiation of intraspinal opioid therapy, dose escalation and increased need for supplemental oral opioid therapy occur commonly over 2 to 4 months of therapy (246,248,340,343,366). Van Dongen and colleagues (367) noted that 33% of patients failed intrathecal morphine therapy (after intrathecal therapy started because of failure of epidural therapy) and required the addition of bupivacaine for pain control.

OTHER CONSIDERATIONS FOR INTRASPINAL ANALGESIA

Intraspinal opioid analgesia combined with local anesthetic agents is a well-established method of pain relief for postoperative pain control (368,369,370,371 and 372). Ambulatory epidural analgesia is now relatively commonplace for the control of labor pain (373). Concern over toxicity and adaptation to sympathetic block associated with the chronic use of spinal local anesthetics has limited the consideration of this technique for home care of cancer patients with intractable pain or opioid-related side effects. DuPen and colleagues (374) demonstrated the safety and efficacy of long-term epidural bupivacaine-opioid infusion in 68 patients with cancer pain refractory to epidural opioids alone. The majority of patients experienced pain relief with little or no sympathetic or sensorimotor impairment after the first 24 hours at bupivacaine concentrations of 0.125% to 0.25% and could receive management at home or in chronic care settings without the need for rehospitalization. Transient postural hypotension during the first 24 hours occurred in only 9% of patients, and this supports the requirement for close monitoring and fluid therapy during initiation of therapy.

Segmental limitations of epidural analgesia with local anesthetic agents mandate placement of the tip of the catheter at a site adjacent to the dermatome covering the field of pain. Failure to do so limits the effectiveness of the technique. In general, if a pain complaint merits an epidural trial, first place a site-specific, percutaneous epidural catheter. Titrate epidural bupivacaine-opioid combinations according to the guidelines listed in Table 36-17.

Patient rating of pain management	Response[a]
Unsatisfied	Increase opioid by 50%
	Increase bupivacaine by a concentration factor of 0.03% (e.g., 0.12% to 0.15%)
Uncomfortable/ functional	Increase opioid by 25%
	Increase bupivacaine by a concentration factor of 0.02% (e.g., 0.12% to 0.14%)
Uncomfortable/ function impaired	Increase opioid by 25%
	Decrease bupivacaine by a concentration factor of 0.1%
Uncomfortable/ nausea + sedated	Increase bupivacaine by a concentration factor of 0.02%
	Decrease opioid by 10%
Comfortable	No change

[a]Range of bupivacaine changes, 0.01% to 0.03%. Range of opioid changes, 10% to 50%.

TABLE 36-17. Guidelines for titration of epidural bupivacaine- opioid combinations

The space-occupying role of epidural metastases may reduce the efficacy of epidural pain management (375) (see Implications of Epidural Metastasis and Spinal Canal Occlusion for Intraspinal Drug Treatment , later in this chapter). Advancement or progression of disease may result in multiple sites of pain complaint, some of which may resist epidural therapy. In such situations consider alternative routes, drugs, or strategies.

DuPen and colleagues (328) have issued guidelines for the management of epidural catheter–related infections. Infection of epidural catheter systems usually begins at the exit site. The bacteria cultured from the space are most frequently from skin flora contamination (*Staphylococcus aureus*, *Staphylococcus epidermidis*), but occasionally include *Escherichia coli*. Patients who are immunosuppressed may yield a wider variety of organisms. Catheter infections involve *S. aureus* more than 90% of the time. If organisms such as *Campylobacter* appear, suspect a contaminated infusion solution. Track infections may also occur. Suspect a deep catheter or epidural infection on clinical grounds (pain during epidural injection, soft fluctuant mass under incision, decreasing epidural analgesia even with increasing dose, constant and nonspecific back pain). Thorough daily cleaning with povidone-iodine treats superficial track and exit site infections. Use topical, oral, or both kinds of antibiotics depending on the extent of involvement and the response to treatment. All deep catheter track and epidural infections require catheter removal and treatment with parenteral antibiotic therapy. The duration of treatment depends on the organism cultured. Replace catheters after completion of antibiotics and a magnetic resonance imaging scan indicates no further epidural involvement or inflammation. Deep catheter infections require inpatient management. Flush the catheter with 1 mL of saline. Aspirate and, if positive, send for culture. Continue aspirating until clear. Wait for the culture results and treat systemically. Leave the catheter until no further aspirate is visible (acts to decompress) and then remove the catheter. Treat with antibiotics (usually vancomycin) for 10 days, then replace the catheter if indicated.

Clonidine

Several reasons exist to consider spinal clonidine for intractable cancer pain. Clonidine is a centrally acting a_2-adrenergic agonist with established analgesic effects (376,377) and has synergistic effects with both spinal opioids (378,379) and spinal local anesthetics (380,381). Like opioid receptors, a high density of a_2-adrenoreceptors occurs in the superficial dorsal horn of the spinal cord (382). a_2-Adrenoreceptor activation blocks transmission of noxious sensory information at the level of the spinal cord by both presynaptic and postsynaptic mechanisms (383,384,385). Epidural clonidine produces analgesia by a spinal mechanism in patients after surgery and in those with cancer pain (386), and it appears to be an effective treatment for severe cancer pain in patients in whom other treatments fail (387). For this reason, clonidine is an effective analgesic when administered intraspinally but a poor analgesic when administered systemically (388). Also, because clonidine does not interact with opioid receptors, it fails to cause treatment-limiting side effects common to opioids.

Clinical experience with spinal clonidine largely consists of postoperative analgesia studies, although Eisenach (387) has reported on its long-term use in cancer pain. This and other clinical studies (389,390 and 391) suggest that intrathecal and epidural clonidine in combination with other agents such as opioids or local anesthetics is a suitable treatment for intractable cancer pain. Eisenach and colleagues (387) investigated the efficacy of epidural clonidine in 85 patients with cancer who continued to have either severe pain despite large systemic or epidural doses of opioids or who were experiencing therapy-limiting side effects from opioids. Patients were randomized to receive either epidural clonidine, 30 µg per hour, or a placebo in a double-blind, multicenter study. All patients received rescue medication (epidural morphine) by PCA. patients' primary pain was considered neuropathic in nature in 42% and nonneuropathic in 58%. Successful analgesia (defined as a decrease in either morphine use or VAS scores) was more common with epidural clonidine (45%) than with placebo (21%) and was particularly prominent in those patients with neuropathic pain (56% versus 5%). The onset of side effects from epidural clonidine occurred early in treatment, without any delayed- onset effects. Clonidine decreases blood pressure after epidural administration by actions in the spinal cord (392,393), brainstem (394), and periphery (395). Blood pressures remained approximately the same level as baseline in the placebo group but decreased by approximately 10 mm Hg in the clonidine group. This was a serious complication in two patients. Of interest, the hypotensive action of clonidine is counteracted at larger doses by a peripheral vasoconstrictive action. For patients in the nonneuropathic pain groups, the likelihood of success was similar for each treatment group regardless of whether the pain was characterized as visceral or somatic, which suggests that the addition of clonidine in the treatment of such conditions does not confer additional benefit over epidural opioids.

Good reason exists to believe from laboratory and clinical experience that intrathecal clonidine may also be effective in the treatment of neuropathic pain. Intrathecal injection of clonidine reduces autotomy behavior in an animal model of neuropathic pain (396). A number of clinical reports document the efficacy of intrathecal clonidine for intractable cancer pain (390,391,397). Clinical investigators have administered intrathecal clonidine in bolus doses of 30 to 150 µg and in continuous infusions of 8 to 400 µg per day, usually in combination with morphine. The analgesia dose requirements for drugs with moderate to high lipophilicity, such as fentanyl or sufentanil, may diminish with epidural versus systemic administration (348,350) because of rapid systemic absorption after epidural injection and nonspecific binding to epidural fat. In contrast, significant dose sparing compared with systemic administration occurs with intrathecal fentanyl or sufentanil (398,399). Given clonidine's lipophilicity (similar to fentanyl), one would expect its spinal effects to be more pronounced and selective after intrathecal rather than epidural administration.

Neostigmine

Cholinergic mechanisms are involved in the control of nociceptive input in the CNS. Human studies have confirmed the analgesic action of the anticholinesterase physostigmine given intravenously (400,401), but the duration of analgesic action is short. In contrast, the longer-acting anticholinesterase neostigmine lacks antinociceptive properties after systemic administration in laboratory animals, probably because of its inability to cross blood–brain barriers. Because neostigmine is water soluble, chemically stable, and commercially prepared without preservative, it is possible to give it by the subarachnoid route. Unfortunately, the sole manufacturer of the preservative-free neostigmine solution used in the initial clinical studies no longer markets this preparation. Although solutions containing preservatives are generally avoided for intrathecal injection, methyl- and propylparabens have not proven toxic. Eisenach and colleagues (402) performed a phase I

tolerability and safety study of the commercially available neostigmine formulation in human volunteers and found no evidence of toxicity. Studies in human volunteers have shown that intrathecal neostigmine lacks neurotoxicity and produces low plasma concentrations (403), in contrast to a long-lasting, measurable CSF concentration. Klamt and colleagues (404) reported on the successful use of bolus injection of neostigmine in two patients with cancer pain. The pain-relieving effect of neostigmine was of slow onset and long duration in both patients. Gastrointestinal discomfort occurred in both cases, even with dose reduction.

Intrathecal Therapy with Bupivacaine and Morphine

Some types of tumor-associated pain are less likely to respond to epidural analgesia. These include mucocutaneous ulcers, pain caused by body movements as a result of fracture, edematous swelling or ischemia of an extremity, and neuropathic pain from plexus infiltration (332). The administration of intrathecal morphine does not appear to offer any significant advantages (see previous discussion). However, the combination of intrathecal bupivacaine with morphine may be more efficacious than epidural administration when given for cancer pain relief. These two agents may act synergistically through different mechanisms at the spinal cord level. Local anesthetics given intrathecally even at subanesthetic concentrations can reduce the maximum firing rates of nociceptive fibers with opioids that reduce the sensitivity of wide dynamic range neurons. The mechanism may involve specific neurons in the dorsal horn that process high threshold nociceptive input (405). Intrathecal bupivacaine with its predilection for unmyelinated axons could contribute to the clinical efficacy by blocking slow, burning pains (406), which may not respond to bupivacaine alone. In addition, this approach probably delays the occurrence of tolerance to intrathecal morphine because of the smaller doses and the added analgesic effects of bupivacaine.

Nitescu and colleagues (331) compared the efficacy of epidural and intrathecal pain treatment with morphine and bupivacaine in 25 patients with severe, multifocal cancer pain, in whom epidural administration of morphine and bupivacaine failed to provide acceptable pain relief. Both epidural and intrathecal catheter systems consisted of open, subcutaneously tunneled catheters. Fifteen patients had infradiaphragmatic pain, and 10 had both infradiaphragmatic and supradiaphragmatic pain. The investigators assessed consecutive epidural and intrathecal periods (2 to 174 days, median, 50 days; and 1 to 305 days, median, 37 days, respectively) in terms of daily analgesic dosages giving acceptable pain relief and quality of life expressed as sleeping hours and walking and daily activities. They placed both epidural and intrathecal catheters using a midline approach from T-11 to T-12 or between T-12 and L-5. Eleven patients received preservative-free morphine solutions 0.2 to 2.0 mg per mL, and the other 14 received morphine with preservatives in solutions of 10 mg per mL. Bupivacaine 2.5 to 5.0 mg per mL, diluted or not with isotonic saline, was added to morphine until concentrations judged to be suitable with respect to the daily dosages and volumes were obtained. Epidural solutions were administered as intermittent injections two to six times per day, for a total of 1,242 treatment days (range per patient, 2 to 174 days; median, 50 days). All patients receiving intrathecal treatment began with intermittent injections given 1 to 15 times per day (mean, 3; median, 2) and continued in 18 patients. In seven patients, the initial, intermittent administration continued until termination of treatment by continuous infusion of morphine, with or without bupivacaine. The combined, intermittent and continuous treatment ranged from 1 to 305 days (median, 37 days). Eleven patients received treatment at home for 7 to 125 days (median, 46 days). With intrathecal treatment, the total opioid consumption and the daily doses of spinal morphine and bupivacaine decreased significantly both at the start of treatment and for the 6-month follow-up period. Intrathecal treatment provided more satisfactory pain relief, and because of lower daily doses and volume, proved to be more suitable for treatment at home than epidural treatment.

Since this report was published a number of different studies have confirmed the efficacy of intrathecal morphine and bupivacaine combinations for the treatment of severe, refractory cancer pain (332,367,407,408,409,410 and 411). Sjoberg and colleagues (332) reported on the applicability of long-term (1 to 305 days; median, 23 days) intrathecal bupivacaine and morphine in 52 patients with complex *refractory* cancer pain. Particular consideration was given to the dosages, concentrations, volumes and proportions of the drugs, and side effects and complications that they could attribute to the long-term administration of bupivacaine. The investigators estimated efficacy from the daily dosage (intraspinal and total opioids, and intraspinal bupivacaine), scores of nonopioid analgesic and sedative consumption, gait and daily activities, and amount and pattern of sleep. Intrathecal treatment began with a test dose of 1 to 6 mg of morphine (median, 2) and 1.0 to 12.5 mg of bupivacaine (median, 4.5), given in a volume of 1.0 to 8.0 mL (median, 4). Intrathecal daily volumes ranged from 1 to 114 mL and increased with the duration of the intrathecal treatment, the median values being approximately three times higher at 6 months (30 mL) than at 2 days after the start (9 mL).

Eighty-five percent of patients obtained continuous and acceptable pain relief (VAS 0 to 2 versus pretrial values of 7 to 10 out of 10), 60% of them with daily doses of intrathecal bupivacaine of 30 mg per day (1.5 mg per hour). Temporary, moderate, or severe breakthrough pain (VAS of 3 to 8), not always relieved by escalating intrathecal treatment, was experienced in eight patients (15%). Higher intrathecal bupivacaine doses (more than 60 to 305 mg per day), not always giving acceptable pain relief, were necessary in 13 patients (25%) with deafferentation pain spinal cord, plexus (brachial, lumbosacral), or celiac plexus, or from large, ulcerated mucocutaneous tumors. By combining intrathecal bupivacaine with intrathecal morphine, it was possible to use relatively low intrathecal morphine doses (10 to 25 mg per day during the first 2 months of treatment) in more than one-half of the patients. The intrathecal treatment significantly decreased the total (all routes) opioid consumption and significantly improved sleep, gait, and daily activities. For the whole period of observation (6 months), the intrathecal treatment was assessed as adequate in 3.8%, good in 23.1%, very good in 59.6%, and excellent in 13.5% of the cases. Adverse effects of the intrathecal bupivacaine (paresthesia, paresis, gait impairment, urinary retention, anal sphincter disturbances, and orthostatic hypotension) did not occur with doses of 2.5 to 3.0 mg per hour (approximately 60 to 70 mg per day). Paresthesia in patients at bolus doses exceeding 1.25 mg was sometimes experienced as very unpleasant. Two patients who experienced paresthesia refused to continue intrathecal bupivacaine therapy for fear of becoming paralyzed. Because of this, the authors suggested an upper limit of the incremental dose of intrathecal bupivacaine per demand of 1.25 mg. With intrathecal bupivacaine infusion, most of the patients did not complain of unpleasant paresthesias at doses up to 3 mg per hour. Paresis and gait impairment usually did not occur with infusion doses (3 mg per hour). This was particularly true for patients whose skeleton, muscles, and nervous system were not impaired by the basic disease, radiation therapies, or both. The incidence of early urinary retention was 27%. Late urinary retention appeared consistently at daily dose of bupivacaine equal to or greater than 60 mg per day.

In a follow-up study, Sjoberg and colleagues (411) tested the clinical efficacy of a constant infusion of 0.5 mg per mL of morphine plus 4.75 mg per mL of bupivacaine (morphine to bupivacaine ratio approximately 1:10), given through open intrathecal catheters to 53 patients. They obtained satisfactory pain relief, defined as VAS scores of 0 to 2 versus 6 to 10 in the preintrathecal stage, with relatively low daily doses of intrathecal morphine (median, 6 mg). Daily intrathecal volumes (median, 10 mL) were low, whereas the daily dose of intrathecal bupivacaine was relatively high (median, 50 mg). Side effects attributable to intrathecal bupivacaine occurred in the forms of late urinary retention (33%), paresthesias (41%), paresis and gait impairment (33%), and occasional episodes of orthostatic arterial hypotension (1.8%).

The importance of intrathecal volumes, versus that of the concentrations and doses, for the intensity and spread of spinal analgesia during chronic infusions of intrathecal morphine and bupivacaine is still unclear. Kroin and colleagues (412) could not demonstrate any advantage in placing the catheter tip at more rostral locations, such as at the midthoracic or cervical cord when using hydrophilic drugs for pain relief. Van Zundert and colleagues (413) demonstrated that a constant 70-mg dose of subarachnoid lidocaine produced the same pinprick level of analgesia, degree of motor block, and duration of spinal anesthesia. Wagemans and colleagues (360) measured the pH of CSF in a patient receiving high doses of intrathecal morphine who failed to demonstrate either motor or sensory block after injection of 75 mg of lidocaine, 5%. This patient's CSF pH fell outside the physiologic range at 7.19 (normal range, 7.27 to 7.37), suggesting a possible explanation for the decreased activity of the local anesthetic. Kroin and colleagues (414) noted an absence of ataxia at intrathecal bupivacaine doses of 0.4 to 0.5 mg per hour in dogs. The human CSF volume is approximately 10 times that of a dog. Therefore, one might reasonably assume that doses up to 3 mg per hour are safe in patients without evidence of neurologic deficit. When patients have neurologic deficits caused by nerve damage or polyneuropathies, it is appropriate to reduce doses substantially (0.5 to 1.0 mg per hour) to avoid causing motor disturbances.

The intrathecal route offers distinct pain relief advantages for cancer pain compared with the epidural route: enhanced pain relief efficacy; ease of insertion; aspiration of CSF provides a definite end-point for placement; after placement, correct placement may easily be confirmed by CSF aspiration; absence of systemic effects of drugs; uniform drug distribution to the target area within CSF; and low reported incidence of complications.

Sjoberg and colleagues (332) offered guidelines for starting intrathecal therapy for morphine and bupivacaine in patients with refractory cancer pain.

1. Place intrathecal catheter tips in the center of segments of maximum pain (particularly with thoracic and cervical pain).
2. Titrate intrathecal dosage individually:
   a. Start with low morphine (0.5 to 1.0 mg per mL) and relatively high bupivacaine (4.75 to 4.5 mg per mL) concentrations and low volumes (3 to 4 mL per day).
   b. Gradually increase the volumes until the patient reports adequate pain relief (VAS of 0 to 2 of 10).
   c. Set the incremental dose per demand below 1.25 mg of intrathecal bupivacaine.
3. Be prepared to use higher intrathecal bupivacaine doses (per hour, and on demand) in patients with deafferentation pain from the spinal cord, brachial or lumbosacral plexus, pain from celiac plexus, ischemic and colicky pain, and smarting pain from large, ulcerated mucocutaneous tumors.
4. Limit the daily dose of intrathecal morphine to less than 15 mg to avoid the possibility of opioid-induced myoclonus and hyperalgesia.
5. Most patients do not experience side effects from intrathecal bupivacaine if the daily dose is less than 60 mg. Patients may start at doses of 30 mg per day. Some patients may require doses as high as 300 mg per day.

6. Treat opioid withdrawal independently of intrathecal morphine doses.
7. Decrease, but do not interrupt, administration of sedatives.
8. Contact the patient every day and adjust the dosages as necessary.

The safety of externalized tunneled intrathecal catheters, particularly in relation to the development of meningitis and epidural abscess, has come under question (330,333,336,338). Crul and Delhaas (335) reported on the type and incidence of technical complications (e.g., obstruction and dislocation of the catheter and infection) in long-term (10 to 366 days) spinal morphine administration in terminally ill cancer patients by means of an epidural or intrathecal catheter. During the first 20 days of treatment, a significant difference ($p = .02$) in the incidence of complications differentiated the epidural group (8%) from the subarachnoid group (25%). During the remainder of the treatment period, the complication rate rose to 55% in patients receiving epidural morphine and declined to 5% in the subarachnoid group, a significant difference ($p = .001$). The most frequent complication in the epidural group was obstruction and dislocation of the catheter, probably because of the development of epidural fibrosis. This problem became apparent in 50% of patients during the treatment period from day 20 to 366. In patients receiving intrathecal morphine, the prevalent complication was CSF leakage, which was observed only during the first 2 weeks of treatment. Crul and Delhaas concluded that the intrathecal route is the route of choice for patients expected to live longer than 1 month, and for patients with a shorter life expectancy, epidural administration can yield acceptable results. In contrast, Bedder and colleagues (338) recommended against using intrathecal catheters for long- term pain control because of the potential risks of meningitis and spinal headache.

To correctly define the role of externalized intrathecal catheters in the treatment of intractable cancer pain, Nitescu and colleagues (334) compared the rates of postinsertion complications of externalized intrathecal catheters with the rates reported in the literature for externalized epidural and intrathecal catheters, as well as implanted epidural and intrathecal catheters connected to subcutaneously implanted ports, reservoirs, or pumps. The authors studied 200 patients with refractory cancer pain treated for 1 to 575 days (median, 33; total, 14,485). Seventy-nine patients received treatment at home for 2 to 226 days (median, 36; total, 4,711). Standardized care after insertion included daily telephone contact with the patients, their families, or the nurse in charge; weekly dressing changes at the tunnel outlet by the nurses; refilling of the infusion containers by the nurses; and exchange of the infusion systems when empty (within 1 month) and of the antibacterial filter once a month by nurses. Providers carefully avoided all contact between the connections of the syringes, cassettes, and needles with the operator's hands during filling and refilling of the infusion containers and exchange of the antibacterial filters. However, they took no further aseptic precautions. Table 36-18 lists the rates (as a percentage of the number of patients) of perfect function and complications of the systems in Nitescu and colleagues' series versus the range of rates reported in the literature (334).

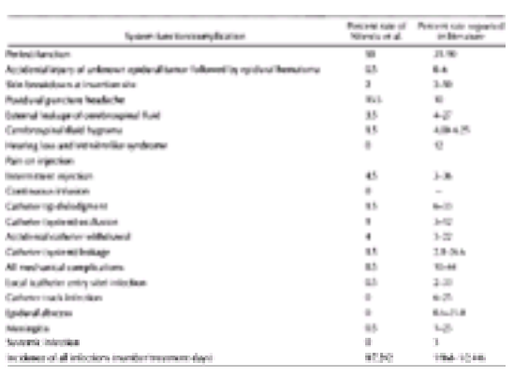

TABLE 36-18. Rates (as a percentage of the number of patients) of perfect function and complications of the systems in the series by Nitescu et al. versus the range of rates reported in the literature (334)

Of interest, infectious complications such as tunnel exit and deep catheter track infections did not occur in this study. No epidural abscess was recorded, and meningitis occurred in only one patient. The authors speculated that the most important factor in preventing local infection was the secure fixation of the catheter with the externalized systems to prevent to-and-fro movements of the catheter and the transport of skin bacteria into the subcutaneous reactive passage formed around the catheter. The fear of meningitis has presented a major obstacle to the use of intrathecal pain treatment. However, the few reports presented do not support such fears (415). Nitescu and colleagues attributed the low rate of meningitis in their study to the technique of insertion and care of the intrathecal catheters, as well as to the use of mixtures of morphine with preservatives and bupivacaine as analgesic solutions. Both preservatives (sodium pyrosulfite and sodium edetate) from morphine solution and bupivacaine have bacteriostatic effects (416,417).

Novel Techniques with Intrathecal Therapy

Continuous Intracisternal and High Cervical Intrathecal Bupivacaine

Progressive tumor growth in the head and neck often leads to various types of pain localized to the distribution of both the cervical nerve roots and cranial nerves. The upper cervical components of the spinomesencephalic tract cells and cranial nerves V, VII, IX, and X are involved in mechanisms of pain from head, face, and neck structures. The pain is seldom limited to one side or confined to the distribution of one nerve. In patients with diffuse upper neck and head pain, the source of pain often involves multiple nerves. Cranial nerves and peripheral somatic nerves often provide nociceptive afferent input. In addition to somatic pain, burning discomfort may result from nociceptive pathways within the sympathetic chain. These circumstances restrict the usefulness of nerve blocks and neuroablative procedures.

Appelgren and colleagues (407) reported on 13 patients with complex, refractory pain who received continuous intracisternal or high cervical subarachnoid infusions of bupivacaine as a method to control pain in the head, face, mouth, neck, and upper extremities. Patients received bupivacaine continuously at rates of 1 to 7 (median, 1.5) mg per hour, with optional bolus doses of 0.5 to 2.0 mg two to four times per hour. They assessed efficacy from VAS scores, daily dose of intracisternal bupivacaine and total opioid, amount of nocturnal sleep, and rates of adverse effects. Patients were treated from 3 to 182 days (median, 37; total, 712 days).

The investigators could not evaluate one patient because of the patient's advanced senility. For most patients (11 of the remaining 12), infusions of bupivacaine provided satisfactory pain relief, decreased systemic opioid consumption, improved nocturnal sleep patterns, and improved overall function. Daily doses of intracisternal bupivacaine ranged from 20 to 118 mg (median, 37 mg). Average VAS scores decreased from 7 to 2. Total daily opioid dose decreased from median values of 53 to 36 mg of parenteral morphine equivalents. Nocturnal sleep increased from median values of 2 to more than 6 hours. In patients with refractory pain from the shoulders and upper extremities, the intracisternal administration of bupivacaine gave less pain relief than intrathecal administration of the same bupivacaine doses at the midcervical (C-4–C-5) levels.

Associated side effects generally were dose related and similar to those described with lower sites of infusion. Signs of motor impairment of the cranial nerves occurred for the somatic fibers of the vagal nerve, expressed as hoarseness after intrathecal injection of 5.0 mg of bupivacaine, in all intracisternal tests, and of the glossopharyngeal nerve (dysphagia) after a bolus dose of 7.5 mg of bupivacaine. No signs of motor impairment from the other cranial nerves appeared at therapeutic doses. Paresis of the upper extremities occurred in two patients at intracisternal doses of bupivacaine of 1.5 and 5.0 mg per hour, respectively. No patient experienced gross impairment of phrenic nerve activity. The absence of obvious phrenic nerve paralysis is notable, and it probably reflects the greater resistance of the large motor fibers of the phrenic to the effects of local anesthetic agents (418).

Novel side effects included one patient experiencing severe tiredness, faintness, and malaise and one experiencing somnolence and sleep. These side effects emerged transiently with relatively high infusion rates or large bolus doses and resolved after decreasing the infusion rate or withholding the bolus dose. These symptoms occurred at doses equal to or greater than 3 mg per hour. They may derive from a decrease of skeletal muscle tone, inhibition of the tonic activity of the reticular substance by reduction of signals from the peripheral receptors, and loss of control of fairly specific motor tasks, such as rhythmic locomotor movements and of eye, head, and body movements in response to optic and vestibular stimuli. No persistent neurologic deficit or death could be attributed to the intracisternal pain treatment.

Appelgren and colleagues concluded that long-term intracisternal administration of bupivacaine might help the rare, well- selected patient with refractory pain from the

head, face, and neck structures to obtain adequate pain relief when alternate methods have failed. Although the actual mechanism of pain relief is unknown, Carpenter and Rauck (419) contend that the low doses of bupivacaine used in the study suggest the possibility of a central neuronal analgesic effect, and they advocated further research to explore this possibility.

Intrathecal Adrenal Medullary Transplants

Adrenal medullary chromaffin cells secrete both catecholamines and opioid peptides, endogenous substances that independently and possibly synergistically reduce pain when injected locally into the spinal subarachnoid space (420,421 and 422). An advantage of this transplant approach for the alleviation of pain is that it acts as a living biological pump that can serve as a local endogenous source of pain-reducing, neuroactive substances on a long-term basis, reducing or even eliminating the need for repetitive exogenous opioid administration. Inserting a source for substances that act via conventional spinal receptors to alter nociceptive transmission is attractive.

The technique is relatively straightforward and involves a simple approach. Winnie and colleagues (423) introduced 2 mL of human adrenal medullary tissue via lumbar puncture into the subarachnoid space in five patients with cancer pain. They assessed VAS scores, functional activity, and opioid intake before and after the transplantation procedure. Four of the five patients demonstrated progressive decreases in pain scores after the procedure, with concomitant reductions in opioid intake. Three of these four patients remained pain free, two for over 10 months. Although the results of this study are encouraging, they merit caution in interpretation because the study lacked a parallel control group of patients.

Foley and Yaksh (424) contend that evolution of transplant therapy requires the same systematic characterization as any novel therapy. In particular, the functional and biochemical characteristics of each implant (i.e., cell type, content, and viability at the time of delivery) require accurate definition. Until this appears in the literature, these authors called for a moratorium on further transplant injections.

Patient-Controlled Intrathecal Analgesia

A variety of medications, including morphine, bupivacaine, and clonidine, may be used both intrathecally and by PCA for the control of cancer pain. One aspect of the efficacy and high acceptance of PCA is the higher degree of satisfaction of patients who are involved in self-administration of drugs and self-monitoring of pain and side effects (425,426). Ferrante and colleagues (427) demonstrated a significant reduction of the total bupivacaine requirement without any change in pain relief when comparing epidural PCA and continuous epidural infusion. Rundshagen and colleagues (428) described intrathecal PCA using bupivacaine for the control of postoperative pain, and Hardy and Wells (429) described using intrathecal PCA morphine for cancer pain. Further reports are needed with a variety of different agents including morphine, bupivacaine, and clonidine by intrathecal PCA.

IMPLICATIONS OF EPIDURAL METASTASIS AND SPINAL CANAL OCCLUSION FOR INTRASPINAL DRUG TREATMENT

The onset of back pain accompanies epidural metastasis in more than 60% of cancer patients and 80% to 95% of patients with confirmed epidural metastasis experience pain at some time during the course of the disease (430,431). The intensity of pain and the associated neurologic deficit depends on the size of the epidural metastasis and consequently determine the degree of epidural block. Patients with small epidural lesions may have no pain and no neurologic deficit (432). The occurrence and severity of complications during insertion of epidural and intrathecal catheters may depend on the location of the epidural tumor in relation to the puncture site, to the inserted catheter length in relation to the location of the epidural tumor, and to the degree (total or partial) of spinal canal stenosis.

Epidural metastasis with invasion of extrathecal and intrathecal nerve roots by neoplasm, dural infiltration, and generation of reactive fibrosis in the subdural space may increase the intensity of nociceptive stimulation and hinder diffusion of drugs to the nerve roots and spinal cord, thereby reducing the effectiveness of intraspinal pain treatment. Significant interpatient variation in daily doses of analgesics may occur for both epidural and intrathecal pain treatments. Epidural morphine doses varying from 6 to 120 mg per day at the start of treatment (331), 16 to 600 mg per day at steady state, and 28 to 600 mg per day at the final stage of treatment have been reported (334). Similar wide variations in epidural bupivacaine doses of 96 to 2,100 mg per day also occur (374). For intrathecal treatment, morphine doses have varied from 0.8 to 200 mg per day and bupivacaine doses from 15 to 305 mg per day (332).

Appelgren and colleagues (375) retrospectively reviewed 201 consecutive patients with cancer pain who received intrathecal pain treatment between 1985 and 1993. These patients participated in a study undertaken to test the hypothesis that epidural metastasis is a common cause of *refractory* cancer pain and that its presence may affect the efficacy and the complication rates of intraspinal pain treatment. Epidural metastases occurred in 40 (70%) and spinal stenosis in 33 (58%); 7 patients had total and 26 partial occlusion of the spinal canal. The presence of epidural metastasis affected catheter insertion complications, daily dosages, and complications of the intrathecal pain treatment only when it was associated with spinal canal stenosis (partial or total). During the period of intrathecal treatment, patients with confirmed epidural metastasis and total spinal canal stenosis needed significantly ($p < .05$) higher daily doses of morphine (means, 77 ± 103 versus 22 ± 29 mg) and intrathecal bupivacaine (means, 65 ± 44 versus 33 ± 20 mg) and had significantly ($p < .05$) higher rates (14% versus 0%) of radicular pain at injection and poorer distribution of analgesia than those without epidural metastasis and spinal canal stenosis. Unexpected paraplegia occurred in four patients caused by accidental injury during attempted dural puncture (n = 1) and collapse [caused by CSF leakage leading to *medullary coning* of an unknown epidural metastasis (n = 3)].

Because most pathologic changes are limited to the epidural space, and the prevalence of intrathecal metastasis is 1% to 4% (433) compared with approximately 70% for epidural metastasis, epidural pain treatment is more often affected than intrathecal therapy by the presence of spinal metastasis. The presence of epidural metastasis with invasion of the extrathecal and intrathecal nerve roots, infiltration of the dura, and generation of reactive fibrosis in the subdural space may increase the intensity of nociceptive stimulation and hinder diffusion of drugs to nerve roots and the dorsal horn of the spinal cord, thereby reducing the efficacy of intraspinal treatment. The risk of rapid neurologic deterioration after lumbar puncture removal of CSF below the level of a subarachnoid block has been known since 1940 (434). In such situations, it is possible that lumbar puncture may remove CSF that has acted as a critical buffer between the spinal cord and the extramedullary tumor. Hollis and colleagues (435) recommend avoiding lumbar puncture and intrathecal catheterization below the level of a suspected mass causing complete block, estimating the risk of neurologic deterioration at approximately 14% after lumbar puncture in patients with complete spinal block.

MANAGEMENT OF SPINAL CORD AND CAUDA EQUINA COMPRESSION

The management of spinal cord or cauda equina compression must delicately balance the need to deliver a sufficient dose of radiation to kill the tumor and the need to avoid further injuring the spinal cord. The restrictions imposed by the radiation tolerance of the cord can limit the success of therapy. The ceiling of response, defined as maintaining pretherapeutic levels of ambulation and motor function, is 80% with radiation therapy alone (436). This is particularly true in extensive tumor burdens, such as spinal cord compression associated with a paravertebral mass, which require high doses of radiation to achieve local control. Lung cancers, specifically apical tumors, account for 60% of the presentations of epidural spinal cord compression associated with a paravertebral mass. Combining surgery with radiation treatment may help improve therapeutic outcome. In some cases, surgical decompression by vertebrectomy or laminectomy can promptly reduce pain and improve neurologic status. These clinical improvements follow promptly on relieving the mechanical compression produced by collapse of a vertebral body and improving spinal stability. A statistically significant increase in functional outcome occurred with laminectomy and radiation treatment of epidural spinal cord compression versus either modality alone (437,438).

Surgical intervention is an alternative for patients presenting with a high-grade epidural lesion, particularly a lesion caused by a radiation-insensitive tumor. Surgery often is the only available option for therapy because previously administered radiation may preclude further radiation in the area of compression. This is often the case in lung cancer, because over 70% of spinal cord involvement in lung cancer is located in the thoracic spine, and many of these patients have received mediastinal radiation. Surgical intervention may provide significant benefit in specific groups with spinal cord or cauda equina compression. Patient selection should depend on prognostic factors, so far as possible. For example, median survival in breast cancer patients with epidural metastases is significantly less if visceral metastases are evident (439). Even patients with advanced malignancies may benefit from surgical intervention if it is possible to maintain neurologic integrity (440).

Complete response to radiation treatment is achieved in 30% of all tumor types, including breast cancer and malignant melanoma (436). Radiosensitive tumors, such as lymphoproliferative malignancies, multiple myeloma, and germ cell tumors, have a better outcome, with 77% of these tumors achieving a complete response to radiation alone.

Measures of response involve pain and functional status. With radiation treatment alone, back pain resolves in 60% to 80% of patients (441,442,443 and 444). Improvement in motor and autonomic dysfunction occurs in 40% to 60% of cases (441,442). Pretreatment functional status is maintained at 3 years in follow-up after

radiation treatment in more than 90% of surviving patients.

HOME INFUSION THERAPY

Home care is a dynamic component of the health care system. In the United States, several factors have contributed toward change as well as growth in the home care industry. Since the 1990s, the use of home care and home infusion therapy continues to expand and grow. Several areas may account for this growth. Prospective payment for hospital services and diagnosis-related groups for Medicare patients, implemented in the mid-1980s, resulted in earlier discharge from hospital. An aging population and improved survival rates for chronic illnesses, including cancer, have led to an increased use of home care. In addition, marketplace regulation has forced the delivery of health care from its traditionally hospital-based center of services into alternative settings. Advances in pain management technology, such as ambulatory PCAs and the use of silicone subcutaneously tunneled neuraxial catheters, have expanded the scope and success of interventional pain management beyond the hospital to the home.

Ambulatory infusion pumps are either designed to be therapy specific or are multipurpose, enabling treatments such as chemotherapy, systemic antibiotics, total parenteral nutrition, hydration therapy, and opioid pain control. Developments in pump design include remote access capability by modem with the ability to change pump settings and download data.

Home-based PCA therapy provides select patients with the ability to deliver analgesia based on their own perception of need. PCA therapy may be superior to oral analgesia, especially in the treatment of severe oscillating pain. Patient selection criteria include intact cognition and proper supervision from a family member or health professional. A collaborative interdisciplinary approach is necessary for effective pain control for the cancer patient receiving interventional pain management at home. Collaboration between the patient, the patient's family, the home care nurse and home care agency, and the patient's physician is necessary. The physician remains responsible for determining the appropriate drug, bolus dose, background infusion rate, and lockout interval.

Potential benefits of home infusion therapy include decreased health care costs, patient and caregiver convenience, and less time spent in hospital, with the ability to extend interventional pain management strategies into the patient's home. A possible disadvantage to home infusion therapy may include the additional burden placed on the patient or caregiver in terms of role responsibilities and schedules. Home care agencies must have explicitly defined policies and procedures consistent with regulatory bodies and national and regional standards of practice.

PCA is increasingly more commonly used in the home setting as an effective option in pain management. As discussed previously, the subcutaneous and intravenous routes are the primary methods of administration. The availability of a central vascular access device such as a tunneled or peripherally inserted central catheter offers advantages over peripheral access to ensure safe and consistent administration of intravenous analgesia.

The safety and efficacy of home-based PCA opioid therapy has not been extensively reported as in-hospital use. One study (299), however, reported on the use of morphine PCA in the home environment of 143 preterminally and terminally ill tumor patients suffering either from excruciating chronic pain or severe chronic or acute complex pain that could not be relieved adequately by oral analgesia. After initial dose adjustment, which lasted 2 to 3 days, the median morphine dosage was 93 mg per day (range, 12 to 464 mg per day). This median was 28% lower than the median dose administered orally before PCA therapy. During the course of treatment, morphine requirements increased by a median of 2.3 mg per day (range, –29 to 52 mg per day). Most patients were treated continuously in the home care setting until death, the median duration of treatment was 27 days (range, 1 to 437 days). Terminal morphine demands reached a median of 188 mg per day (range, 15 to 1,008 mg per day). The authors concluded that PCA was both safe and effective in the home environment, attaining excellent results in 95 (66%) patients and satisfactory pain relief in 43 (30%). PCA was considered insufficient in five (4%) cases. Side effects, in general, were considered mild: the most common being constipation, fatigue, and nausea.

Although further study is warranted, safe provision of domiciliary interventional pain management probably requires selection of appropriate patients, effective patient and caregiver education, well-defined policies, and use of experienced and knowledgeable home care agencies.

MANAGEMENT OF PAINFUL BONE METASTASES

Metastasis to bone is a significant problem for a large number of cancer patients; up to 85% of patients dying breast, prostate, or lung cancer primary tumors demonstrate bone involvement at autopsy (445). The morbidity of bone metastases can become significant because of pain and pathologic fracture. Radiation therapy for bone metastases is discussed in detail in Chapter 37.

Bone metastasis represents systemic spread of disease, and oncologists often treat bone metastases with systemic therapies, such as chemotherapy and hormonal therapy (446,447). Chemotherapeutic options can provide excellent pain relief, especially in breast or prostate cancer patients. Physiologic bone turnover maintains normal skeletal integrity through a coupled process of bone resorption, mediated by osteoclasts, followed by new bone formation. Major features of the pathogenesis of tumor-associated skeletal destruction are enhanced osteoclast-mediated bone resorption and disruption of normal bone formation. Bisphosphonates, by inhibiting bone turnover and decreasing the resorption of bone, benefit the management of bone metastases. Their role is most clearly defined in breast cancer and multiple myeloma, but clinical benefit may extend to the entire spectrum of metastatic bone disease (120,121).

Surgery

Structural weakness secondary to extensive bone loss is not acutely reversed with medical or radiation treatment. The local effects of chemotherapy and radiation depress the rate of bone regeneration in compromised areas. In such cases, an approach that supports the bone during recovery is often necessary. Long bone fractures most commonly occur in the femur and humerus and are typically internally fixed by intramedullary devices that control impaction, distraction, and torque stresses by the use of proximal and distal interlocking fixation. Orthotic devices can often protect upper extremity lesions. The lower extremity is less tolerant, largely because of the high stress experienced during ambulation. Impending fractures of the lower extremity generally require surgical stabilization with fracture fixation devices or prosthetic reconstruction. The indications for prophylactic fixation of impending fractures remain poorly defined. Table 36-19 lists guidelines for indications for prophylactic fixation of impending long bone fractures.

Cortical bone destruction of more than 50%

Lesion of more than 2.5 cm in the proximal femur

Pathologic avulsion fracture of the lesser trochanter

Persisting stress pain despite irradiation

From Harrington KD. Orthopaedic management of metastatic bone disease. St. Louis: Mosby, 1988, with permission.

TABLE 36-19. Indications for prophylactic fixation of impending long bone fractures

One of the problems with plain roentgenography is that bone loss must approach 30% to 50% before it becomes apparent. In addition, in metastatic lesions characterized by bone production (e.g., prostate), clear evidence of bone destruction can be difficult to assess roentgenographically. Once a pathologic fracture has occurred, aggressive surgical treatment is normally in order. Patients who are unstable medically or who have a life expectancy of less than 4 weeks are not surgical candidates. Habermann and colleagues (448) found that 97% of patients had good to excellent pain relief after internal fixation or prosthetic replacement. Harrington (449) reported a success rate of 95% in returning patients to prefracture ambulatory status with surgical intervention. Current fracture fixation methods have led to improved patient survival (24.6 months versus 11.6 months) after pathologic fracture (449).

The spine is the most common site for skeletal metastasis. Oncologists can manage most spinal metastases conservatively. CT and magnetic resonance imaging of the spine are reserved for patients who present with vertebral body compression of more than 50% or who present with neurologic involvement. Once the workup is complete, patients fall into five categories, depending on the extent of neurologic involvement or bone destruction (Table 36-20).

Class	Degree of involvement
I	No major neurologic involvement
II	Involvement of bone without collapse and instability
III	Major neurologic involvement (sensory or motor) without significant bone involvement
IV	Vertebral collapse with pain caused by mechanical causes or instability but without significant neurologic impairment
V	Vertebral collapse or instability combined with major neurologic impairment

Data from Harrington KD. Metastatic disease of the spine. *J Bone Joint Surg Am* 1986;68:1110–1115.

TABLE 36-20. Categories of skeletal spinal metastasis

The majority of patients fall into categories I, II, or III, and if they are candidates for nonoperative treatment with either chemotherapy, hormonal manipulation, or radiation therapy. Operative intervention is reserved for patients in categories IV or V. The treatment of choice is anterior resection of the diseased vertebral body and reconstruction with bone graft or methylmethacrylate and spinal instrumentation as needed. Advances in spinal instrumentation have resulted in better methods for the stabilization of vertebral body collapse secondary to metastatic disease.

MANAGEMENT OF DEPRESSION IN CANCER PATIENTS WITH PAIN

Treatment decisions for depression in the cancer patient presume that a thorough medical and psychiatric assessment has led to an accurate diagnosis that will allow specific and effective intervention. Patients with severe depression, suicidal ideation or intent, or both require psychiatric consultation. Before planning an intervention, the physician should consider a history of previous depressive episodes and substance (including alcohol) abuse, family history of depression and suicide, concurrent life stresses, losses secondary to cancer (e.g., financial, social, and occupational) in addition to loss of good health, and the availability of social support. Once it becomes clear that the patient is depressed, one must consider coexisting organic factors before starting treatment.

Standard therapeutic approaches, such as the use of corticosteroids (450), chemotherapeutic agents [tamoxifen (451), asparaginase (452), interferon (453), and interleukin (454)], whole brain radiation (455), and amphotericin (456) can cause or exacerbate depressive symptoms in cancer patients. Likewise, the presence of brain metastases or tumors (457), metabolic and endocrine complications (458), and paraneoplastic syndromes (459) often contribute to the presence of depressive symptoms.

Depressed patients with cancer should be treated with a combination of psychological treatments (cognitive behavioral and supportive psychotherapy) and psychopharmacologic interventions (antidepressants and psychostimulants). For patients with cancer pain, interventions that help diminish mood disturbance also help reduce pain (460). Reducing severe pain often relieves depression.

Psychotherapy

The goals of psychotherapy are to reduce emotional distress and to improve morale, coping ability, self-esteem, sense of control, and resolution of problems. It consists of four basic components: social support, emotional expression, cognitive restructuring, and coping skills training. These are discussed in Chapter 88, Chapter 89, Chapter 90, Chapter 91, Chapter 92 and Chapter 93.

Antidepressant Medications

The antidepressant agents appropriate for use in the cancer patient include the tricyclic antidepressants, atypical antidepressants, selective serotonin reuptake inhibitors, psychostimulants, and the anxiolytics (see Chapter 85). Although a number of studies report on the efficacy of antidepressants in depressed patients with cancer, there are only two double-blind, placebo-controlled studies demonstrating efficacy (461,462).

Tricyclic Antidepressants

These agents are particularly helpful for cancer patients with insomnia, pain, and depression and can be effective in relatively low doses (see Chapter 26 and Chapter 85). The literature supports the use of tricyclic antidepressants in the treatment of a wide variety of chronic pain syndromes (115). Studies show potent direct analgesic effects of tricyclic antidepressants, as well as enhancement of morphine analgesia (463). Dosing may be initiated at 10 to 25 mg at bedtime and the dose increased every 2 to 3 days until benefit is achieved. The effects on appetite and sleep are frequently rapid; the effects on mood may be delayed or not clinically apparent. The choice of tricyclic antidepressant depends on the nature of the depressive symptoms, medical problems present, and side effects of the particular drug. The depressed patient who has insomnia may benefit from the use of a tricyclic antidepressant that has sedating properties, such as amitriptyline or doxepin. Patients with psychomotor slowing benefit from agents with the least sedating properties, such as desipramine. Patients with stomatitis secondary to chemotherapy or radiation therapy, or who have slow intestinal motility should receive agents with the least anticholinergic effects, such as desipramine or nortriptyline.

Patients who cannot swallow pills may be able to take an antidepressant in a liquid suspension (amitriptyline, nortriptyline, or doxepin) or in intramuscular form (amitriptyline or imipramine). Consider parenteral administration of tricyclic antidepressants for the cancer patient unable to tolerate oral administration (absence of swallowing reflex, presence of intestinal drainage tubes, or intestinal obstruction). Three tricyclic antidepressants are available in injectable form: amitriptyline, imipramine, and clomipramine. All three have been given intravenously; however, only imipramine and amitriptyline are available for intramuscular injection.

Imipramine, doxepin, amitriptyline, desipramine, and nortriptyline are commonly used in the management of neuropathic pain in cancer patients. Dosing is similar to the treatment of depression, and analgesic efficacy, if it occurs, is usually observed at a dose of 50 to 150 mg daily; higher doses are sometimes necessary.

Atypical Antidepressants

The atypical antidepressants are generally considered to be less cardiotoxic than the tricyclic antidepressants (464). Consider bupropion if patients have a poor response to a reasonable trial of other antidepressants. It may be somewhat activating in medically ill patients and is contraindicated for patients with seizure disorders and brain tumors and in those who are malnourished. Trazodone is strongly sedating and in low doses (100 mg at bedtime) is helpful in the treatment of the depressed cancer patient with insomnia. Effective antidepressant doses are often greater than 300 mg per day. Trazodone may produce priapism.

Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors and new agents help depressed patients with medical illnesses because the drugs lack the significant adverse anticholinergic and cardiovascular effects of tricyclic antidepressants and other classes of antidepressants. Commonly selected agents in this category include fluoxetine (Prozac), sertraline (Zoloft), and paroxetine (Paxil). These drugs have fewer sedative and autonomic effects than tricyclic antidepressants. The more common side effects are mild nausea, insomnia, headache, somnolence, and a brief period of increased anxiety. These drugs can cause appetite suppression that usually lasts for a period of several weeks. Typical onset of action occurs within 2 to 6 weeks after initiation of antidepressant therapy. Thus, 6 weeks of treatment at therapeutic doses

constitutes an adequate antidepressant trial.

The energizing properties of fluoxetine help in cancer patients who are persistently fatigued. Nausea, a common side effect with fluoxetine, usually diminishes after several weeks of treatment (465). Its relatively long half-life and its active metabolite nofluoxetine can be problematic in the medically ill patient in whom the ability to clear the drug is impaired. Razavi and colleagues (466) failed to demonstrate any benefit with fluoxetine for cancer patients with symptoms of anxiety and depression.

Paroxetine and sertraline have shorter half-lives and inactive metabolites and may be more useful in a medically ill population. Therapeutic daily dosage for paroxetine is 10 to 50 mg and for sertraline is 25 to 200 mg daily. The starting dose of sertraline, 50 mg per day, is the usually effective therapeutic dose, and the optimal dose when considering both efficacy and tolerability for most patients. For patients who do not show an adequate therapeutic response, the dose of sertraline can be increased in 50-mg-per-day increments at no less than weekly intervals to a maximum of 200 mg per day (467).

The development of newer antidepressants has focused on those that have low affinities for muscarinic cholinergic, histaminergic, and a_1-adrenergic receptors. Drugs that have low affinities for muscarinic receptors are associated with decreased likelihood of anticholinergic effects (dry mouth, constipation). Those possessing low affinities for histaminergic receptors would be expected to produce less sedation and weight gain, and those that have less affinity for a_1-adrenergic receptors would produce fewer cardiac effects (e.g., orthostatic hypotension).

Psychostimulants

Psychostimulants such as dextroamphetamine, methylphenidate, and pemoline help diminish sedation secondary to opioid analgesics and are useful antidepressants in the medically ill. Dextroamphetamine has been reported to have additive analgesic effects when used with opioids (235). Treatment with dextroamphetamine or methylphenidate usually begins with a dose of 2.5 mg on awakening and at noon. The dosage is slowly increased over several days until a desired effect is achieved or side effects (overstimulation, anxiety, insomnia, paranoia, and confusion) become apparent. Occasional doses of 60 mg per day are required, but doses of not more than 30 mg per day are more typical.

A strategy for treating depression associated with cancer pain is to start the patient on a stimulant and then add a tricyclic antidepressant after several days to help prolong and potentiate the effects of the stimulant (468). Psychostimulants used for the treatment of depression may result in a rapid response, usually within the first 2 days of treatment (469). Pemoline may be useful as both an antidepressant and adjuvant analgesic in cancer patients (470). Pemoline can be started at a dose of 18.75 mg in the morning and at noon, which is gradually increased over several days. Typically patients require 75 mg per day or less. Liver function tests should be monitored periodically with long-term treatment (471).

Anxiolytics

Several types of anxiety syndromes can appear in cancer patients with and without pain. These include reactive anxiety related to the stress of cancer and its treatment, anxiety that is a manifestation of a medical or physiologic problem related to cancer such as uncontrolled pain, and chronic anxiety disorders that predate the cancer diagnosis but are exacerbated during illness. The pharmacotherapy of anxiety in cancer patients involves the judicious use of a variety of agents, including the benzodiazepines, antihistamines, and antidepressants.

Hydroxyzine, an antihistamine, is a mild anxiolytic with sedative and analgesic properties that are useful in the mildly anxious cancer patient with pain. The addition of 25 to 50 mg of hydroxyzine every 6 hours to a regimen of opioids often helps relieve anxiety as well as provides adjuvant analgesia.

The main actions of benzodiazepines (hypnotic, anxiolytic, anticonvulsant, myorelaxant, and amnesic) confer a therapeutic value in a wide range of conditions. In general, use benzodiazepines in conjunction with other interventions (psychological treatments, antidepressants, other drugs), although such interventions have a slower onset of action. Indications for benzodiazepines include acute stress reactions, episodic anxiety, and fluctuations in generalized anxiety, and and as initial treatment for severe panic and agoraphobia.

The major clinical advantages of benzodiazepines are high efficacy and rapid onset of action. Adverse effects include psychomotor impairment, especially in the elderly, and occasionally paradoxical excitement. The high-potency benzodiazepines (e.g., clonazepam, alprazolam, lorazepam) are indicated for the treatment of panic disorder and mania. Benzodiazepines have so many uses in cancer patients that the physician may target more than one advantage as he or she considers choice of drug and dose. It is possible to treat nausea, pain, and anxiety simultaneously. These drugs treat reactive anxiety, insomnia, claustrophobia, and panic disorder. As they ameliorate anticipatory anxiety and phobia, they mitigate anticipatory nausea and a component of posttreatment nausea. With chemotherapy itself, they cause sedation, suppress recall of treatment, and limit vomiting, and most patients find them desirable. They suppress the restlessness associated with metoclopramide and other dopamine-antagonist antiemetics.

Although benzodiazepines relieve acute anxiety, they are relatively ineffective for chronic anxiety (472). Drugs such as antidepressants and anxiolytics such as buspirone, which combine anxiolytic and antidepressant actions, are more effective for the management of chronic anxiety. The starting dose of buspirone is 5 mg three times a day. Dosage may be increased by 5 mg per day until the desired effect is achieved. The usual daily maximum dose is 60 mg. Onset of anxiolysis is delayed relative to benzodiazepine and it is not uncommon for onset of effect to occur after 5 to 10 days.

The apparent efficacy of benzodiazepines in patients with major depressive disorder may depend on the patient's level of anxiety. In patients with chronic anxiety who are either unresponsive to or unable to tolerate antidepressants, triazolo-benzodiazepines or nonbenzodiazepine anxiolytics such as buspirone are preferable to other benzodiazepines as first-line drugs.

Because drug interactions and decreased clearance are often factors in treating cancer pain patients, benzodiazepines with shorter half-lives are desirable. Alprazolam is a benzodiazepine that produces dose-related sedation and relief of anxiety. Compared with other benzodiazepines, alprazolam has particular efficacy in the treatment of panic disorders and may have antidepressant effects. It may help cancer patients who have mixed symptoms of anxiety and depression, or serve as an adjuvant analgesic for certain types of neuropathic pain secondary to tumor growth (473). A typical starting dose is 0.25 mg three times a day. Therapeutic effects may require 4 to 6 mg daily (474).

Clonazepam also produces dose-related sedation and relief of anxiety. Its relatively long duration of action of 6 to 10 hours is attractive, particularly for long-term use. The usual dose range is 0.5 to 4.0 mg three times a day. Clonazepam, more than any other benzodiazepine, is used alone or with other drugs as an anticonvulsant. It may also be useful in the management of lancinating pains in the cancer setting and may possibly be an effective analgesic for patients with trigeminal neuralgia and postherpetic neuralgia (475,476).

SUMMARY

The goals of cancer therapy include cure, symptom palliation, psychological support, and research. Comprehensive cancer care encompasses a continuum that progresses from disease-oriented, curative, life-prolonging treatment through symptom-oriented, supportive, and palliative care extending, for some patients, to terminal hospice care. Pain relief must be a priority in cancer patients. Pain is the most common symptom experienced by cancer patients, and it requires aggressive treatment to maximize both quality and quantity of the patient's life.

Interdisciplinary collaboration is essential for comprehensive care of the cancer patient. Disciplines and specialties involved in care commonly include anesthesiologists, oncologists, surgeons, psychiatrists, psychologists, physical therapists, pharmacists, nurses, and social workers.

Detailed assessment of pain and other quality-of-life concerns is the foundation for successful pain management in the cancer patient. Typically, the pain experience is multidimensional, and treatment must address both the physical and emotional components. Aggressive therapy of both cancer and pain are mutually beneficial and are best done by skilled, interdisciplinary teams.

Most patients can attain adequate symptomatic relief of cancer pain using appropriate oral pharmacotherapy. The concurrent use of adjunctive or specialized therapies is sometimes necessary, however, and referral for specialized surgical, anesthetic, or psychological intervention benefits a significant number of patients. In

addition, the growth of the home care industry has broadened the possibilities of extending interventional pain management strategies into the home.

CHAPTER 37

Part A: Radiotherapeutic Management of Symptomatic Disease

Nora A. Janjan

BASIC CONSIDERATIONS

In the 1990s 11 million cases of cancer were diagnosed, and 5 million people died from cancer. Approximately one-half of patients diagnosed with cancer develop metastatic disease. More than 70% of all cancer patients develop symptoms from either their primary or metastatic disease (1,2,3 and 4). Although any site can be involved, 64% of the palliative therapy administered in the United States is prescribed to relieve symptoms from bone metastases. Reflecting the systemic spread of disease, metastatic involvement of a solitary bony site or of only the bones is rare and occurs in fewer than 10% of patients. Prognosis is influenced by the overall metastatic burden and the number and location of the sites involved by disease. When metastases are found also in the lung, liver, or central nervous system, the prognosis is especially poor.

Palliation represents a large component of cancer treatment and includes the use of therapeutic and supportive care measures. Unlike other aspects of cancer therapy, tumor control and survival are not the end points of therapeutic success in palliative care. The goal of palliative care is to effectively and efficiently relieve symptoms and maintain the maximum quality of life for the duration of the patient's life (2,3,4,5,6,7,8 and 9). Effective palliation of cancer-related pain can enhance quality of life by improving functional and emotional well-being. The factors that determine the effectiveness of palliative radiation include the percentage of patients who experience persistent and recurrent symptoms in the radiated area, whether reirradiation is possible, and if persistent and recurrent symptoms can be relieved with reirradiation or other therapeutic modalities (9,10 and 11).

Bone metastases are the most common cause of cancer-related pain, and more than 70% of patients with bone metastases are symptomatic. Among hospitalized patients, severe pain was experienced by more than 50% of patients with bone metastases (4). One of the most important goals in the treatment of bone metastases is to relieve suffering and return the patient to independent function (12,13). The location of the metastasis, however, can influence the degree of pain relief achieved with palliative interventions. Metastatic involvement of weight-bearing bones, and bones responsible for ambulation and activities of daily living are often less likely to respond completely to palliative interventions. Pain relief is achieved in 73% of spine metastases, 88% of limb lesions, 67% of pelvic metastases, and 75% of metastases to other parts of the skeleton (10).

The debility that results from cancer and its treatment is a significant issue on a socioeconomic level. Cancer was diagnosed in sites other than the skin in 1,647 of 9,745 (17%) elderly community-based Medicare beneficiaries. Cancer patients had poorer health, more limitations of the activities of daily living, and greater levels of health care use (14). Limitations in activities included difficulty walking (38%), getting out of a chair (21%), completing heavy housework (34%), and shopping (17%). Poorer health was observed more frequently in lung, breast, prostate, and colon cancer patients. Lung cancer most frequently limited the activities of daily living. Lung, bladder, and prostate cancers predicted for increased health care use, and the mean annual Medicare reimbursement for lung cancer was more than twice that for colon, breast, and prostate cancers. Even though the decrease in functional capacity for cancer patients was not as great as with other chronic diseases, such as arthritis, stroke, and emphysema, the health care costs for cancer patients were greater than those for other chronic diseases (15). This most likely results from the inability to determine how many of the cancer patients evaluated had active disease at the time of the evaluation. If this assumption is true, then an even greater percentage of cancer patients with active disease are functionally impaired and use more health care resources. Quality of life measurements have been shown to predict for survival and add to the prognostic information derived from the Karnofsky Performance Status (KPS) and extent of disease. Physical symptoms that include pain, dry mouth, constipation, change in taste, lack of appetite and energy, feeling bloated, nausea, vomiting, weight loss, and feeling drowsy or dizzy portend a poorer prognosis (16).

DEMOGRAPHICS

The three most common cancers, lung, breast, and prostate cancers, have high rates of metastatic spread to bone and visceral structures (17,18 and 19). Occasionally, musculoskeletal pain is an indicator of an undiagnosed malignancy. Among 491 patients with new or recurrent complaints of bone pain and no known underlying malignancy, 4% of the entire group and 9% of patients 50 years of age or older had definite evidence of metastases (20). Of the group that had any abnormality noted on bone scan, 20% had evidence of metastatic disease, and all of these occurred among patients 50 years of age or older. For all patients, 52% of pain localized in the back, 16% in the hips or pelvis, and 15% in the extremities. Among cancer patients, diffuse pain was identified in 57%, 18% had neck or upper T-spine pain, and 18% had pain in the hips, pelvis, or the extremities. Malignancies were subsequently diagnosed in the lung (32%) and prostate (16%).

Because of an aging population, the incidence of prostate cancer is increasing significantly. Prostate cancer represents the second leading cause of death from cancer among men (21). Each year between 1995 and 1999, more than 1 million men older than age 50 in the United States died of prostate cancer (22). The clinical presentation of prostate cancer has changed with routine use of digital rectal examination and prostate-specific antigen (PSA) screening. In the 1970s, only 50% of cancers were confined to the prostate gland, and metastases were present in 30% of cases at diagnosis. When patients were referred to a urologist for symptoms, 70% of cases had disease confined to the prostate gland; but pathologic confirmation of disease confined to the prostate gland occured in only 50% of patients undergoing prostatectomy. However, with routine screening using digital rectal examination and PSA more than 90% of cases have disease confined to the gland, and 70% of these are pathologically confirmed.

The natural history of prostate cancer based on a therapeutic approach that does not include routine screening and is limited to palliative intervention showed a statistically significant relationship between disease-specific death, stage of disease, and tumor differentiation. Of 719 new cases, 45% were diagnosed incidentally and 31% had organ-confined disease (23). Symptoms at diagnosis included prostatism (42%), bone pain (12%), and fatigue (9%). The median age of diagnosis was 75 years. Age at diagnosis, however, did not influence disease-specific survival rates. Prostate cancer was the cause of death in 62% of patients and the disease-specific survival rates at 1, 5, and 10 years were 80%, 38%, and 17%, respectively (Table 37A-1).

TABLE 37A-1. Disease-specific survival rates at 5 and 10 years based on stage of disease and tumor differentiation among 623 prostate cancer patients treated only with palliative intent

The risk for the subsequent development of distant metastases is significantly lower when the primary tumor is controlled. Survival rates after an isolated recurrence of disease in prostate cancer are influenced by the initial stage of the disease and the disease-free interval from initial treatment (24,25). In over 70% of cases of locally recurrent prostate cancer, radiation can control symptoms that include hematuria, urinary outflow obstruction, ureteral obstruction, and lower extremity edema (24). With or without local recurrence, the survival rate is most compromised by the presence of distant metastases. The survival rates at 5 and 10 years after pelvic recurrence alone equal 50% and 22%, respectively. With distant metastases, the survival rate at 5 years is 20% and less than 5% at 10 years (25).

Bone metastases are evident in 30% to 40% of prostate cancer patients at diagnosis, but pain is the presenting symptom in only 11% of these newly diagnosed patients (23,26). However, pain develops in 75% of prostate cancer patients during the course of their disease (27). Radiographically detectable bone metastases develop in 20% of patients with stage A_2 (T_{Ib}) and B (T_2) disease, 40% of patients with stage C (T_3), and 62% of patients with stage D1 (T_4) disease presentations (23,25,28).

Bone scans are the most sensitive and specific method of detecting bone metastases, but magnetic resonance imaging (MRI) is the best available technique for evaluating the bone marrow, neoplastic invasion of the vertebrae, central nervous system, and peripheral nerves (29,30,31 and 32). Bone or other metastases rarely fail to be detected when radiographic diagnosis is pursued. When radiographic confirmation of malignancy is equivocal, bone biopsy should be considered (33,34 and 35).

After bone metastases are diagnosed, the median survivals are 12 months for breast cancer, 6 months for prostate cancer, and 3 months for lung cancer. In breast cancer, the median survival rate is 48 months when metastases are confined to the skeletal system, but it decreases to only 9 months if visceral metastases are also present (18,19). In prostate cancer, the distribution of bone metastases on scintigraphy also has prognostic significance. The rate of survival is significantly longer when the metastases are restricted to the pelvis and lumbar spine, and among patients who respond to salvage hormone therapy (25,28,29). Any metastatic involvement outside the pelvis and lumbar spine results in lower rates of survival irrespective of response to salvage hormone therapy. The median length of survival is critical to evaluating response to and determining the appropriate recommendations for palliative therapy.

Although the length of survival can vary significantly after the development of bone metastases, two factors are constant. First, the presence of bone metastases predicts for progression of disease to other sites, and second, bone metastases are the most common cause of cancer-related pain (1,7,8,9,10,11,12,13,14,15,16,17,18 and 19,23,24 and 25,28,29). Factors that influence prognosis among patients with metastatic disease include the site of the primary disease, metastatic burden, interval between primary diagnosis, symptoms of disease, and KPS. The KPS has been shown to consistently predict survival after palliative irradiation. The site of the primary disease and the presence of a solitary metastatic site are predictive of a more prolonged survival (16,36,37,38 and 39).

Bone metastases in prostate and breast cancers involve the axial skeleton more than 80% of the time because of the predilection of these tumors to involve the red marrow. Metastatic invasion of the bone cortex rarely happens without red marrow involvement (30,31,32,33,34 and 35,40,41,42,43,44,45 and 46). For this reason, the spine, pelvis, and ribs are generally involved before metastases become evident in the skull, femora, humeri, scapula, and sternum. The mechanisms involved in the metastatic spread of cancer to the bone are complex. The predilection of specific types of tumors, such as prostate cancer, that metastasize to bone is not well understood.

Bone is unique because it is continuously remodeled by local and systemic growth factors. The process involved in bone remodeling includes an increase in osteoclast activity followed by an increased attraction and proliferation of osteoblast precursors, which mature and lay down new bone (34,35,40,41,42 and 43,45,46). Tumors can release osteoclastic stimulatory factors either locally or systematically including parathyroid hormone-related protein, transforming growth factor-a, transforming growth factor-b, prostaglandins, and cytokines. Tumors can also indirectly stimulate bone loss through the activation of immune mechanisms that release cytokines including tumor necrosis factor and interleukin-1. Metastases to bone result from a synergistic relationship between the cancer cell and the bone that results in increased bone resorption because of release of mediators from the cancer cells or leukocytes. Factors released during bone resorption promote growth of the cancer through activation of proliferation-associated oncogenes. The relationship between bone invasion and bone pain is unknown. Pain may result from the stimulation of nerve endings from the release of factors such as prostaglandins, bradykinin, histamine, or substance P in areas of bone involvement (43). Mass effect from stretching of the periosteum, pathologic fracture, or direct tumor growth into adjacent nerves and tissues may be the mechanisms for pain in larger metastatic deposits.

ROLE OF RADIOTHERAPY

Although palliation constitutes a large part of radiotherapeutic practice, radiation is underused in palliative care. At the M. D. Anderson Cancer Center in Houston, approximately 25% of all radiation treatments were administered with palliative intent. This pattern of practice has been consistent for over 35 years, and it has specifically been the same through the 1990s. When compared with a course of curative radiation, 30% fewer radiation treatments are given during a course of palliative radiation. Because of this, over 40% of the total number of patients who had radiation at the M. D. Anderson Cancer Center were treated with palliative intent (13).

Consistent with radiotherapeutic practice in the United States, palliative radiotherapy for bone metastases was administered to approximately 25% of all radiotherapy patients in Sweden. However, this corresponded to only 10% of all Swedish cancer patients (47). It is considered that palliative radiotherapy for bone metastases is underused in Sweden because metastatic disease occurs in more than 10% of cancer patients. It is also unclear if the other therapeutic options used to treat bone metastases are providing pain relief that is comparable with radiation. In 1993, approximately 800,000 patients were estimated to have metastatic disease, and bone metastases were the most frequent symptomatic site (48). Approximately 300,000 patients nationwide receive palliative radiation costing $900 million per year. Approximately 100,000 patients receive curative radiation therapy costing a total of $1.1 billion per year (49). Although more abbreviated radiation courses may result in cost savings, the response to therapy must be critically analyzed to ensure that treatment efficacy is not compromised. Ineffective therapy may prove more costly than a more prolonged and effective radiation schedule because of the continued need for analgesics and the functional limitations caused by unrelieved pain and disability (50,51).

Multidisciplinary evaluation of patients with metastatic disease to the bone allows comprehensive management of the associated symptoms, determines the risk for pathologic fracture, and helps coordinate administration of a wide range of available antineoplastic therapies (9). Bone metastases can be treated with localized, systemic, or both kinds of therapies (12,34,43,44,45,46,47,48,49,50,51,52,53,54,55 and 56). Because radiation provides treatment only to a localized symptomatic site of disease, it is frequently used in coordination with systemic therapies such as chemotherapy, hormonal therapy, and bisphosphonates. Radiopharmaceuticals are another systemic option that treats diffuse symptomatic bone metastases. Because the radiation is deposited directly at the involved area in the bone, radiopharmaceuticals, such as strontium 89, can also be used to treat bone metastases when symptoms recur in a previously irradiated site (57,58,59,60,61,62,63,64,65,66,67,68,69,70,71 and 72). Radiopharmaceuticals can also act as an adjuvant to localized external beam irradiation and reduce the development of other symptomatic sites of disease.

Control of cancer-related pain with the use of analgesics is imperative to allow comfort during and while awaiting response to therapeutic interventions. Pain

represents a sensitive measure of disease activity. Close follow-up should be performed to ensure control of cancer and treatment-related pain, and to initiate diagnostic studies to identify progressive or recurrent disease. Pain, risk for pathologic fracture, and spinal cord compression are the most common indications to treat bone metastases with localized therapy including radiation and surgery.

CLINICAL CONSIDERATIONS

A number of clinical, prognostic, and therapeutic factors must be considered to determine the most optimal treatment regimen for a course of palliative radiotherapy. The clinical status is accounted for in the treatment setup and in the number of treatments prescribed. Palliative radiation should effectively and efficiently relieve pain and suffering and minimize treatment-related morbidity. The radiation dose and fractionation schedule also should consider the integration of other therapies. Many options exist in the radiotherapeutic management of tumors that cause localized symptoms. Although any site of disease can be effectively palliated, treatment of bone metastases is one of the most common indications for palliative irradiation with external beam therapy (12,44,47,51).

The limited radiation tolerance of the normal tissues, such as the spinal cord, that are adjacent to a bone metastasis make it impossible to administer a large enough dose of radiation to eradicate a measurable volume of tumor. Palliative radiation should result in sufficient tumor regression of critical structures to relieve symptoms for the duration of the patient's life. Symptoms that recur after palliative radiation most commonly result from localized regrowth of tumor in the radiation field.

Because patients with metastatic disease have a limited life expectancy, palliative radiation is generally given over a shorter period of time. Unlike curative therapy, in which a high total dose of radiation is administered over 5 to 7 weeks to eradicate tumor (conventional radiation schedule), a low total dose is given with palliative radiation over 1 to 2 weeks (hypofractionated radiation schedule). Based on the radiation tolerance of normal tissues, a low daily radiation dose (1.8 to 2.0 Gy) is given with conventional radiation; in contrast, large daily radiation fractions are given with hypofractionated radiation schedules. Hypofractionated radiation schedules for palliative therapy can range from 2.5 Gy per fraction administered over 3 weeks for a total dose of 35 Gy to a single 8-Gy dose of radiation. Most frequently, 30 Gy is administered in 10 fractions over 2 weeks (9,12,43,44,47,48,73,74,75,76,77 and 78). Especially among patients with short life expectancies, many centers administer 20 Gy in 1 week because the rates of pain relief, mobility, and frequency of pathologic fractures are similar to more protracted radiation schedules.

Symptom Relief of Locally Advanced or Metastatic Disease

Most cancer patients present with symptoms. Symptoms must be controlled whether treatment is administered with curative or palliative intent. Curative treatment attempts to render the patient disease free. Curative therapy can be applied to either primary or metastatic disease. The prognosis of a patient who is rendered disease free after resection of a single liver metastasis from rectal cancer is better than the case of a patient who has an inoperable lung cancer who does not have metastatic disease.

Treatment with palliative intent is intended to control the symptoms of disease when the disease cannot be eradicated. Effective antineoplastic therapy provides the most palliative benefit for locally advanced or metastatic cancer in any organ. Radiation can be used alone, or in combination with other antineoplastic therapies such as chemotherapy and surgery. The symptoms most commonly relieved by radiation are pain, bleeding, and obstruction. The palliative interventions recommended depend on the patient's clinical status, burden of disease, and location of the symptomatic site. For either locally advanced or metastatic disease, these factors are indexed to the relative effectiveness, durability, and morbidity of each palliative intervention. The prognosis represents the single most important factor in deciding palliative therapy.

The symptomatic site becomes more important to the palliative approach than whether it results from locally advanced or metastatic tumor. Similar radiation portals are used to palliate bronchial obstruction caused by a primary lung cancer, recurrent breast cancer, or metastatic melanoma. The number of radiation fractions prescribed for treatment with palliative intent depends on prognosis and not primary histology. Common sites palliated by radiation, either alone or in combination with other treatments, include tumor involvement of the lung, pelvis, skin and subcutaneous tissues, brain, and bone. Symptoms resulting from cancer in these sites include pain, bleeding, visceral obstruction, and lymph-vascular obstruction.

Lung

Locally advanced primary or metastatic involvement of the lung often requires palliative intervention because cure is possible in only a few of these cases. A variety of symptoms, some of them emergent, can manifest because of tumor involvement of the lung (79). Pain can result from tumor invasion of the ribs and nerve roots of the chest wall. Vertebral involvement can be associated with spinal cord compression. Obstructive pneumonitis and hemoptysis can result from bronchial obstruction. Mediastinal infiltration can cause superior vena cava syndrome. All of these clinical presentations can be palliated with external beam radiation that encompasses the disease that is evident on diagnostic images and that treats pain referred along involved nerve roots. Radiation schedules that administer 30 Gy in 10 fractions over 2 weeks are typically prescribed to previously unirradiated sites. If the area has been previously irradiated, techniques that exclude critical anatomic structures, such as the spinal cord, are applied. Other approaches can be used when the symptomatic site is well localized and accessible. Brachytherapy, which applies radioactive sources next to tumors, can be used to treat bronchial obstruction and bleeding by placing a radioactive source directly against the tumor under bronchoscopic guidance. In these cases, large doses of radiation can be delivered over a few minutes by a high-dose-rate brachytherapy unit.

Pelvis

Hemorrhage and visceral, lymph-vascular, and nerve root obstruction present most commonly with locally advanced or metastatic disease in the pelvis. Treatment may require emergent radiotherapeutic, surgical interventions, or both. Hemorrhage is commonly associated with tumors involving the rectum and genitourinary tracts. As with tumors in the lung, radiation is an effective means of stopping active bleeding. Colorectal cancers are often diagnosed among patients with unexplained bleeding. Because these tumors are generally locally advanced, preoperative radiation is given in 25 treatments over 5 to 6 weeks if no or limited metastatic disease is evident; this is intended to stop bleeding, render the patient operable, and provide a chance for cure. With extensive metastatic disease, 30 Gy can be given over 2 to 3 weeks to palliate symptoms of bleeding and obstruction. Colorectal tumor involvement may also result in obstruction requiring stent placement to maintain the integrity of the visceral lumen while administering radiation (79). Occasionally, a diverting colostomy is required to bypass intestinal obstruction or fistula formation.

Tumors involving the cervix can hemorrhage and require emergent radiotherapeutic intervention. Superficial x-rays are applied directly to the bleeding cervix through a cone and treat the bleeding site and do not compromise later radiation of other pelvic structures. Usually, radiation doses between 5 and 10 Gy are administered in one to three applications of cone therapy. Brachytherapy also can be used to treat gynecologic tumors, especially in the vagina, cervix, and endometrium.

Bladder cancers or tumors that secondarily invade the bladder can also result in significant bleeding that can be palliated by external beam radiation. Urinary obstruction commonly occurs with locally advanced pelvic cancers, especially with prostate and cervical cancers. Occasionally, placement of a urinary stent or urostomy or nephrostomy is required until sufficient tumor regression can be accomplished by radiation to reestablish integrity of the urinary tract (79). As with the bowel and gynecologic tracts, a vesical fistula, resulting from either the tumor itself or from tumor regression, remains a concern.

The pelvic lymph nodes and major blood vessels may become obstructed by tumor. This most frequently is seen when tumors arise in pelvic structures, but can also occur with pelvic metastases from breast and other cancers. Lymph-vascular obstruction results in painful edema that is refractory to diuretic and other therapies. When severe, fluid and electrolyte imbalances can occur. Pelvic radiation can relieve lymph-vascular obstruction through tumor regression.

Pelvic tumors can also invade the sacral plexus and result in intractable pain. Tumor can track along nerve roots and can be associated with bony invasion of the sacrum. Pain caused by visceral, lymph-vascular, or both kinds of obstructions often responds more rapidly to palliative radiation than the neuropathic pain seen with sacral plexus involvement. Other radiotherapeutic approaches, such as brachytherapy, are extremely limited when the cancer persists or recurs after external beam radiation. Interventional pain management techniques are frequently required to control pain associated with sacral plexus involvement.

Skin and Subcutaneous Tissues

Tumors can cause ulceration of the skin and subcutaneous tissues that are often painful and distressing because of constant drainage. Representing a source for the development of sepsis in immunocompromised patients, localized radiation can be applied to destroy tumor and allow reepithelialization of the skin. Radiation that treats only the skin and subcutaneous tissues (electron beam therapy) is generally used to avoid radiation side effects to underlying uninvolved normal structures. Although usually 10 radiation treatments are given, the course of radiation can be abbreviated further, ranging from 1 to 5 days. Occasionally, these lesions are treated with brachytherapy. The radioactive sources can be placed in a mold that sits on top of the tumor and delivers treatment over a few minutes (high-dose rate)

or a few days (low-dose rate).

Brain Metastases

Radiation is used to relieve the symptoms of headache, seizure, nausea and vomiting, and neurologic dysfunction associated with brain metastases. Surgery, either alone or in combination with radiation, is often performed when a solitary brain metastasis is present, if the performance status is good and if the cancer burden is otherwise limited. Radiation is generally given over 2 to 3 weeks with daily fractions of 2.5 to 3.0 Gy per day; total radiation doses range from 25 Gy after resection to 30 Gy with unresectable disease and a poor prognosis (80).

Bone Metastases

There are two major sets of experience with palliative radiation for bone metastases. The Radiation Therapy Oncology Group (RTOG) conducted a prospective trial that included a variety of treatment schedules. To account for prognosis, patients were stratified on the basis of whether they had a solitary or multiple sites of bony metastases. The initial analysis of the study concluded that low-dose, short-course treatment schedules were as effective as high-dose protracted treatment programs (81). For solitary bone metastases, no difference existed in the relief of pain when 20 Gy using 4-Gy fractions was compared with 40.5 Gy delivered as 2.7 Gy per fraction. Relapse of pain occurred in 57% of patients at a median of 15 weeks after completion of therapy for each dose level. In patients with multiple bone metastases, the following dose schedules were compared: 30 Gy at 3 Gy per fraction, 15 Gy given as 3 Gy per fraction, 20 Gy using 4 Gy per fraction, and 25 Gy using 5 Gy per fraction. No difference was identified in the rates of pain relief between these treatment schedules. Partial relief of pain was achieved in 83% and complete relief occurred in 53% of the patients studied. More than 50% of these patients developed recurrent pain, the fracture rate equaled 8%, and the median duration of pain control was 12 weeks for all the radiation schedules used for multiple bony metastases. Prognostic factors for response included the initial pain score and site of the primary cancer.

In a reanalysis of the data, a different definition for complete pain relief was used and excluded the continued administration of analgesics. Using this definition, the relief of pain was significantly related to the number of fractions and the total dose of radiation that was administered (82). Complete relief of pain was achieved in 55% of patients with solitary bone metastases who received 40.5 Gy at 2.7 Gy per fraction as compared with 37% of patients who received a total dose of 20 Gy given as 4 Gy per fraction. A similar relationship was observed in the reanalysis of patients who had multiple bone metastases. Complete relief of pain was achieved in 46% of patients who received 30 Gy at 3 Gy per fraction versus 28% of patients treated to 25 Gy using 5-Gy fractions. In most cases, the interval to response was 4 weeks for both complete and minimal relief of symptoms.

Three important issues are identified from the RTOG experience. First, the results of the reanalysis demonstrate the importance of defining what represents a response to therapy. Second, this revised definition of response showed that the total radiation dose did influence the degree that pain was relieved (81,82). The response rates and the radiobiologically equivalent doses are listed from the reanalysis in Table 37A-2 for each of the treatment schedules used. Showing that higher radiation doses result in higher rates of pain relief, these results also correspond well to the results in another study with breast, prostate, and lung cancer patients (Table 37A-3). Patients treated with total doses of 40 Gy or more had a 75% rate of complete pain relief versus a 62% rate of complete pain relief for patients treated with total doses of less than 40 Gy (10). Third, the RTOG experience identified the amount of time that was needed to experience relief of pain after radiation for bone metastases (Table 37A-4). It is important to note that only one- half of the patients who were going to respond had relief of symptoms at 2 to 4 weeks after radiation (81,82). This underscores the need for continued analgesic support after completing radiation. Consistently, it took 12 to 20 weeks after radiation to accomplish the maximal level of relief. That period of time may reflect the time needed for reossification. Radiographic evidence of recalcification is observed in approximately one-fourth of cases, and in 70% of the time recalcification is seen within 6 months of completing radiation and other palliative therapies (42,43,45,46). Therefore, determining the time to response as well as defining the parameters of response are critical to an evaluation of outcome. The total dose of radiation may also be a significant factor for complete pain relief.

	Dose per fraction (Gy)	Total dose (Gy)	Tumor dose at 2 Gy per fraction[a]	Complete response rate (%)[b]	p Value

[a]This prospective trial, conducted by the Radiation Therapy Oncology Group, randomized radiation dose and number of fractions and treated the randomization on the basis of solitary or multiple bone metastases (RTOG). Also listed is the radiobiological equivalent dose if administered at 2 Gy per fraction.

TABLE 37A-4. Percentage of patients who responded to radiation relative to time, designated in weeks after completion of radiation therapy [a]

Similar issues were observed when pretreatment pain characteristics were used to determine the efficacy of palliative radiation. Among patients who had a life expectancy of only a few months, fewer than 25% of patients had a complete response to palliative radiation. In this case, a complete response was defined as becoming pain free within 28 days after the start of treatment with stable analgesic consumption. A partial response was achieved in 35% of patients, and 42% had no response to palliative radiation. Pretreatment evidence of neuropathic pain was the only significant prognostic or clinical variable that predicted for failure to respond to palliative radiation and severe neurogenic symptoms were present in 33% of patients treated (36,(83,84 and 85).

SINGLE FRACTION RADIATION

A single large radiation fraction is reportedly as effective in relieving pain as other radiation schedules that have more treatments. Radiobiologically, a single 8-Gy fraction would give the same side effects to late reacting tissues (tissues that do not regenerate like the spinal cord) as if 18 Gy were given over nine treatments at 2 Gy per fraction (86). Because the tumor and acute reacting tissues, such as the esophagus and other mucosal structures, respond differently than the late reacting tissues, the radiobiologically equivalent dose to the tumor for a single 8-Gy fraction would be 12 Gy if 2 Gy fractions were used. The most common dose fractionation schedule used for palliative radiation in the United States is 30 Gy over 10 fractions. Radiobiologically, this is equivalent to 36 Gy at 2 Gy per fraction for late reacting tissues and 32.5 Gy to the tumor. When a single dose of radiation was compared with a radiation schedule with multiple radiation fractions, no difference was reported in either how quickly symptoms resolved or the duration of pain relief (9,47,48,73,76,78,87,88,89 and 90). In each case, symptom relief lasted 3 months in 70% of patients, 6 months in 37%, and 12 months in 20% of cases. Like the RTOG study, approximately 69% respond at 4 weeks, and response rates plateau, totaling 80%, at 8 weeks (81,82,87,88,89 and 90). Complete response rates after a single 8-Gy fraction total 15% at 2 weeks, 23% at 4 weeks, 28% at 8 weeks, and 39% at 12 weeks postradiation.

Despite the radiobiological differences in the dose administered, the similarities in response may be caused by tumor regression and reossification that occurs at 3 months. The RTOG experience showed that the maximum response to therapy was seen consistently at 3 months and was independent of dose administered (81,82). The disparity in the relationship between radiation dose and clinical response may also be attributed to limited follow-up in the single fraction study because a significant proportion of patients in the study were lost to follow-up after 3 months (87,88,89 and 90). With longer follow-up, the response to a single radiation fraction may not prove to be as durable as multiple fractions that give high total radiation doses. These data demonstrate that prognosis needs to be linked to issues such as site irradiated, total radiation dose, and reirradiation (11).

A shorter radiation schedule, such as a single fraction, is advantageous for patients with poor prognostic factors. First, it is easier for patients with a poor KPS to complete therapy. Second, response rates are equal for single and multifraction therapy at 3 months because median survival is less than 6 months among patients with poor prognostic factors (9,48,73,75,87,88,89 and 90). The option of re-treatment after a single fraction of radiation may also provide an advantage among patients with good prognostic factors as a means to periodically reduce tumor burden and control symptoms in noncritical anatomic sites. Higher radiation doses that provide more durable pain relief are considered warranted for patients with good prognostic factors who require treatment over the spine and other critical sites (9,10,12,44,48,73,74,78,91,92,93,94,95,96 and 97).

The projected length of survival is the critical issue to determine the optimal radiation dose and schedule for palliative radiation. In one study, only 12 of 245 patients were alive at the time of analysis, with approximately 50% alive at 6 months, 25% at 1 year, 8% at 2 years, and 3% at 3 years after palliative radiation. For breast cancer patients the survival rates at these time points after palliative radiation were 60%, 44%, 20%, and 7%, respectively. For prostate cancer, the survival rates were 60% at 6 months, 24% at 1 year, and there were no patients who survived 2 years (77). In the RTOG trial the median survival for solitary bone metastases was 36 weeks and was 24 weeks for multiple bone metastases (81,82). The RTOG study also demonstrated that the level of pain correlated with prognosis among patients with multiple bone metastases. This survival difference may be an important observation because unrelieved pain and the resultant sequelae of immobility may contribute to mortality as well as morbidity (14,15 and 16,25,28,37,83). Larger data sets that include prognostic factors in multivariate analysis are required to determine the effect of pain and response to therapy on quality of life and survival outcomes. Although equal rates of response are observed between a single and multiple fractions of radiation, future analyses should evaluate survival and durability of response. Most important, these analyses should assess the efficacy and costs of treating symptoms that recur in an irradiated field.

Reirradiation for persistent or recurrent pain is often precluded when higher radiation doses are administered. Because the radiobiological dose is relatively low when a single fraction of radiation is administered, reirradiation is generally possible (11,86,87,88,89 and 90). Reirradiation was necessary in 25% of patients who received a single 8-Gy radiation fraction, but all of these patients were reported to respond to the second dose of radiation (87,88,89 and 90). When a single fraction of 4 Gy was compared with a single 8-Gy fraction, the rate of response was slightly lower and fewer acute radiation reactions were noted, but a greater proportion of patients required reirradiation (89). With reirradiation, the overall rate of response was equivalent for 8- and 4-Gy fractions. Acute radiation toxicities are a function of the dose per fraction, total dose, and the area and volume of tissue irradiated. If mucosal surfaces such as the upper aerodigestive tract, bowel, and bladder can be excluded from the radiation portals, acute radiation side effects can be significantly reduced. The radiation schedule used for palliative radiation is therefore influenced by the radiation tolerance of adjacent normal tissues as well as prognosis.

PATHOLOGIC FRACTURE

The most significant morbidity of bone metastases relates to pathologic fracture and spinal cord compression. Pain that persists or that recurs after palliative radiation should be evaluated to exclude progression of disease, possible extension of disease outside the radiation portal that results in referred pain, and bone fracture. Reduced cortical strength can result in compression, stress, or microfractures associated with reduced cortical strength. Plain radiography has a 91% concordance rate in detecting posttreatment disease progression and fractures in comparison with the 57% specificity rate of bone scans performed after radiotherapy (45). Pathologic fractures occur in 8% to 30% of patients with bone metastases (98,99,100,101,102 and 103). Proximal long bones are more commonly involved than distal bones. Consequently, pathologic fractures occur 50% of the time in the femur and 15% in the humerus (Fig. 37A-1). The femoral neck and head are the most frequent locations for pathologic fracture because of the propensity for metastases to involve proximal bones and the stress of weight placed on this part of the femur. More than 80% of pathologic fractures occur in breast (50%), kidney, lung, and thyroid cancers.

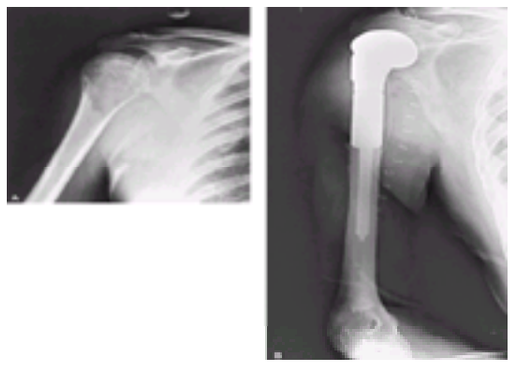

Figure 37A-1. **A:** An extensive lytic lesion in the proximal humerus. **B:** Prophylactic internal fixation performed to prevent pathologic fracture. This patient, who complained primarily of pain in the hip, would have been placed on crutches to reduce stress on the involved femur. A bone scan and radiography, obtained to exclude other sites of metastatic involvement, identified this lesion in the humerus. The humerus would have certainly fractured if all the patient's weight had been displaced to the upper extremities with crutches.

Approximately 10% to 30% of metastatic lesions in long bones develop a pathologic fracture that requires surgical intervention. Patients with pathologic fracture caused by bone metastases have clinical outcomes after surgical repair that are comparable with patients sustaining a traumatic fracture (99,100 and 101). Prognosis is generally poor if hypercalcemia is present and if parenteral opioids are required to control pain from other sites of bone metastases; in these cases, the decision for surgical intervention should be based on the severity of and the symptoms associated with the fracture (99). As shown in Figure 37A-2, postoperative radiation is often given after surgical fixation of a pathologic fracture to reduce risk of progressive disease in the bone that could result in instability of the internal fixation (100).

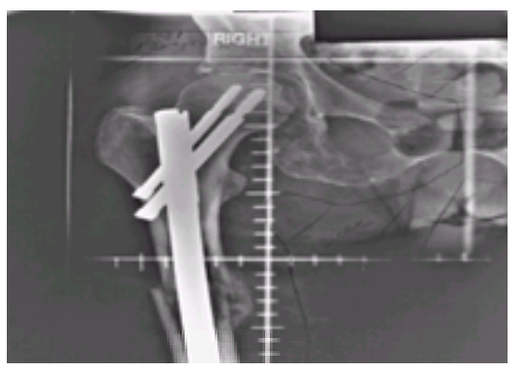

Figure 37A-2. ****missing****

Treatment of pathologic fracture or impending fracture depends on the bone involved and the clinical status of the patient. Indications for surgical intervention of pathologic fracture or impending fracture include these factors: (a) an expected survival of more than 6 weeks; (b) an ability to accomplish internal stability of the fracture site; (c) no coexistent medical conditions that preclude early mobilization; (d) metastases involving weight-bearing bones; (e) and lytic lesions more than 2 to 3 cm in size or metastases that destroy more than 50% of the cortex (99,100,101,102 and 103). It is unclear whether osteolytic metastases are more likely to fracture than osteoblastic lesions, because osteoblastic lesions, by definition, have an osteolytic component so that new bone can be formed.

SPINAL CORD COMPRESSION

Pain is the initial symptom in approximately 90% of patients with spinal cord compression, and the development of spinal cord compression is associated with a poor overall prognosis. Paraparesis or paraplegia occurs in more than 60%, sensory loss is noted in 70% to 80%, and 14% to 77% have bladder, bowel, or both kinds of disturbances (74,91,92,93,94,95,96 and 97). The extent of the epidural mass influences prognosis, because a complete spinal block results in greater residual neurologic impairment than a partial block. The clinical course of spinal cord compression resulting from malignant melanoma is similar to that resulting from breast or prostate cancer. The time from the original diagnosis of melanoma to the development of metastatic spinal disease averages 32 months, and the average time is reported to be 27 months from diagnosis of skeletal metastases to spinal cord compression. Median survival among patients with spinal cord compression is 7 months, with a 36% probability for a 1-year survival. For specific types of cancers, the mean survival time is 14 months for breast cancer, 12 months in prostate cancer, 6 months in malignant melanoma, and 3 months in lung cancer once epidural spinal cord compression is diagnosed (17,91,98). After the diagnosis of epidural spinal cord compression, the overall survival time averages 12 months, with a median survival time of 5 months. The vertebral column is involved by metastatic tumor in 40% of patients who die of cancer. Approximately 70% of vertebral metastases involve the thoracic spine, 20% the lumbosacral region, and 10% the cervical spine.

Weakness can signal the rapid progression of symptoms, and 30% of patients with weakness become paraplegic within 1 week. Rapid development of weakness, defined as occurring in less than 2 months, most commonly occurs in lung cancer, whereas breast and prostate cancers can progress more slowly. Neurologic deficits can develop within a few hours in up to 20% of patients with spinal cord compression (91,92,93,94,95,96 and 97,104). The severity of weakness at presentation is the most significant factor for recovery of function. Ninety percent of patients who are ambulatory at presentation are ambulatory after treatment. Only 13% of paraplegic patients regain function, particularly if paraplegia is present for more than 24 hours before the initiation of therapy. More than 30% of patients who develop spinal cord compression are alive 1 year later, and 50% of these patients remain ambulatory with appropriate therapy.

Pain can be present for months to days before neurologic dysfunction evolves. Unlike degenerative joint disease, which primarily occurs in the low cervical and low lumbar regions, pain caused by epidural spinal cord compression can occur anywhere in the spinal axis and is aggravated by recumbency. Any cancer patient with back pain, especially with known metastatic involvement of the vertebral bodies, should be suspected as having spinal cord compression. The risk of spinal cord compression exceeds 60% among patients with back pain and plain film evidence of vertebral collapse caused by metastatic cancer (74,91,92,93,94,95,96 and 97,105,106,107,108 and 109). Epidural spinal cord disease is documented in 17% of asymptomatic patients who have an abnormal bone scan but normal plain film results; 47% of asymptomatic patients with vertebral metastases noted both on bone scan and plain film also have associated epidural disease (104). Symptomatic patients with a normal vertebral contour and osteoblastic changes on plain film and bone scan should also be evaluated for spinal cord compression (Fig. 37A-3).

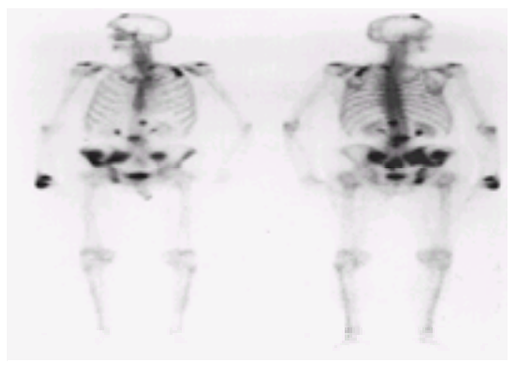

Figure 37A-3. Bone scan that demonstrates multifocal disease involvement. Metastatic involvement in weight-bearing areas such as the pelvis and lower lumbar area significantly affects mobility.

Radiographic determination of the involved spinal levels is critical to radiation treatment planning. Clinical determination of the location of epidural spinal cord compression in 33% of cases is incorrect (91,92 and 93). Plain film radiography shows involvement of more than one spinal level in approximately one-third of patients. If the results of MRI, tomographic studies, and surgical findings are included, more than 85% of patients have multiple sites of vertebral involvement (91,92,93,94,95,96 and 97,104,105,108). With plain radiography, the destruction of the pedicles is the most common finding that identifies spine metastases. In contrast, computed tomography shows that the initial anatomic location of metastases is in the posterior portion of the vertebral body and that destruction of the pedicles occurs only in combination with involvement of the vertebral body (Fig. 37A-4) (108). Osteoblastic bony expansion, commonly seen in both prostate and breast cancers, can result in spinal cord compromise as well as osteolytic vertebral compression fractures (107).

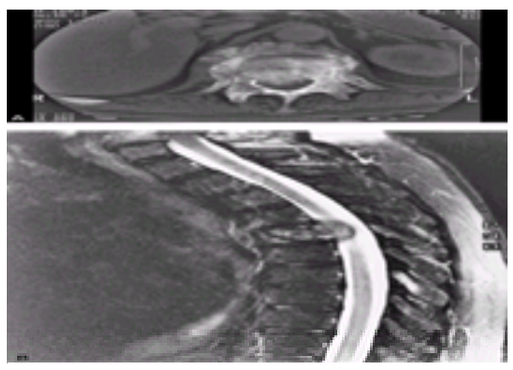

Figure 37A-4. **A:** Computed tomographic scan showing involvement of the posterior aspect of the vertebral body resulting in partial spinal cord compression. **B:**

Magnetic resonance imaging showing involvement of the posterior aspect of the vertebral body resulting in partial spinal cord compression.

Treatment of spinal cord compression includes emergent corticosteroids, radiotherapy, neurosurgical intervention, or all three therapies. Radiotherapy is the treatment of choice for most cases of spinal cord compression and is a radiotherapeutic emergency (Fig. 37A-5). Functional outcome is dependent on the level of symptoms at the time radiation is administered. Spinal cord compression resulting from metastatic tumor can be prevented or effectively treated when diagnosed early (91,92,93,94,95,96 and 97, 104,105). Most commonly, 30 Gy in 10 fractions is administered in the treatment of spinal cord compression and carcinomatous plexopathy. Pain relief can be accomplished in 73% of patients after treatment (104,105). A statistically significant improvement in functional outcome has been reported with laminectomy and radiotherapy in treatment of epidural spinal cord compression over either modality alone for selected clinical presentations. Laminectomy has been recommended to promptly reduce tumor volume in an attempt to relieve compression and injury of the spinal cord and provide stabilization to the spinal axis. The rate of tumor regression after radiotherapy is too slow in these cases to effect recovery of lost neurologic function. Surgical intervention should be considered among patients presenting with a complete spinal cord block because the results are significantly worse than those achieved with radiotherapy alone for partial compression of the spinal cord. After radiation alone to treat a partial spinal cord block, 64% of patients regain ambulation, 33% have normalization of sphincter tone, 72% are pain free, and median survival is 9 months (94,96,97,104,105). With a complete spinal cord block, only 27% have improvement in motor function, and 42% continue to have pain after radiation alone. In paraparetic patients who undergo laminectomy and radiation, 82% regain the ability to walk, 68% have improved sphincter function, and 88% have relief of pain.

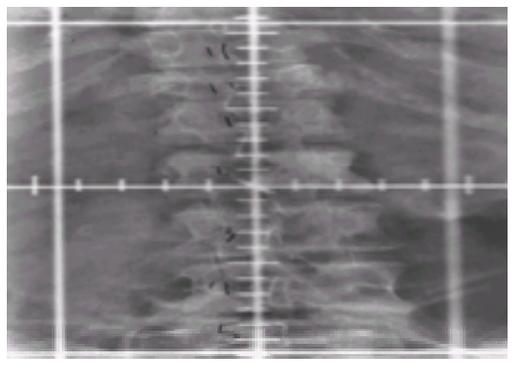

Figure 37A-5. Typical radiation portal to treat multifocal areas of disease involvement in the vertebral bodies and epidural region.

Neurosurgical intervention for vertebral and epidural metastases involves spinal cord decompression accomplished by a laminectomy. Laminectomy is indicated in a variety of clinical presentations (91,92 and 93,95,96 and 97,109). These include rapid neurologic deterioration, tumor progression in a previously irradiated area, and stabilization of the spine; in paraplegic patients with limited disease and good probability of survival; and to establish a diagnosis. Adjuvant radiotherapy is often given to treat microscopic residual disease after neurosurgical intervention (91,92,95,104). Laminectomy, however, carries risks associated with surgery and anesthesia. Pain may worsen after laminectomy if operative procedures fail to stabilize the spine. Surgical restoration of the vertebral alignment may be required because of neurologic compromise and pain caused by progressive vertebral collapse. Vertebral collapse may occur because of cancer or vertebral instability after cancer therapy (Fig. 37A-6). Appropriate diagnostic studies and intervention should be pursued because the neurologic compromise and pain from vertebral instability can be as devastating as that with epidural spinal cord metastases (96,109).

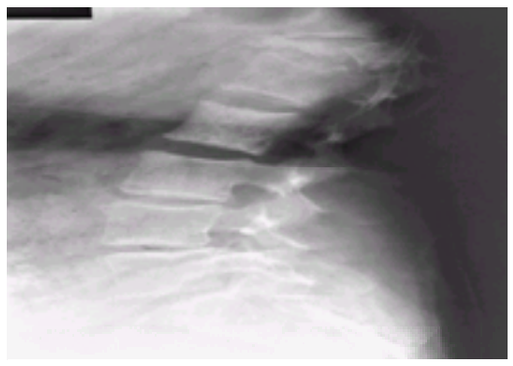

Figure 37A-6. Compression fracture of the twelfth thoracic vertebral body following an initial pain-free interval after palliative radiation. Vertebral weakness with rapid tumor regression resulted in a compression fracture that caused recurrent back pain because of spinal instability.

Paravertebral masses are most commonly associated with lung cancer and are rare in prostate cancer despite studies reporting that prostate cancer is the second most common primary tumor associated with and accounting for 22% of the incidence of spinal cord compression (98,110,111). Overall, approximately 20% of patients with epidural cord compression have an associated paravertebral mass. Surgical resection combined with radiation therapy has been suggested to improve functional outcome when a paravertebral mass is associated with spinal cord compression because radiation alone is less effective with larger tumor burdens.

Radiation Tolerance of the Spinal Cord

The potential for the development of radiation myelitis with total radiation doses that exceed 40 Gy at 2 Gy per fraction represents the limiting factor in the treatment of large tumor burdens near or involving the spinal canal. Furthermore, the length of spinal cord that needs to be irradiated significantly affects the radiation tolerance of the spinal cord (112,113 and 114). Histopathologic changes experimentally observed after fractionated irradiation of the spinal cord include white matter necrosis, massive hemorrhage, and segmental parenchymal atrophy that are consistently associated with abnormal neurologic signs (114). Other pathologic responses involve focal fiber loss and white matter vacuolation. Experimental data also have shown that the time course and the extent of long-term recovery from radiation are dependent on the specific type and age of tissue (112,114).

Radiation tolerance is based on the dose per fraction, total dose, and the volume of tissue treated. The dose per fraction is the most important factor in the tolerance of tissues to radiation. Clinical and experimental experience has failed to demonstrate any difference in radiosensitivity in different segments of the spinal cord (112). The risk of radiation myelitis in the cervicothoracic spine is less than 5% when 6,000 cGy is administered at 172 cGy per fraction, or 5,000 cGy is given with daily fractions of 200 cGy per fraction. Especially among patients who have received chemotherapy, the total dose to the spinal cord is generally limited to 4,000 cGy administered at 200 cGy per fraction to minimize any risk of irreversible radiation injury to the spinal cord. The total dose is also an extremely important factor defining the radiation tolerance of the spinal cord. A steep curve based on total radiation dose predicts the risk of developing radiation myelopathy; a small increase in total radiation dose can result in a large increased risk for radiation myelopathy (112,114). Re-treatment of a previously irradiated segment of spinal cord results in high risk for radiation-induced myelopathy because other neurologic pathways cannot compensate for an injury to a specific level of the spinal cord.

The radiation tolerance of the spinal cord can be compromised by prior injury. Difficulty arises in separating the pathologic and radiotherapeutic injury to spinal cord compression. Vasogenic edema of the spinal cord and nerve roots can be caused by compression injury. Metastatic epidural compression results in vasogenic spinal cord edema, venous hemorrhage, loss of myelin, and ischemia. Vasogenic edema results in an increased synthesis of prostaglandin E_2 that can be inhibited by corticosteroids or nonsteroidal antiinflammatory agents. Other consequences of pathologic compression include hemorrhage, loss of myelin, and ischemia (112,113

and 114).

Two separate mechanisms of radiation injury can occur and result from white matter damage and vasculopathies. White matter damage is associated with diffuse demyelination and swollen axons that can be focally necrotic and have associated glial reaction. Vascular damage has been shown experimentally to be age dependent and can result in hemorrhage, telangiectasia, and vascular necrosis (112,113 and 114). Six major types of injuries have been shown experimentally to result from radiation to the spinal column. Five of these occur in the spinal cord and one in the dorsal root ganglia. The most severe spinal lesions, all of which are caused by vascular damage and result in neurologic dysfunction, include white matter necrosis, hemorrhage, and segmental parenchymal atrophy. The two less severe spinal lesions included focal fiber loss and scattered white matter vacuolation caused by damage to glial cells, axons, the vasculature, or all three; these less severe sequelae are seen with lower total doses of radiation and are less likely to result in neurologic dysfunction. In dorsal root ganglia, radiation damage included intracytoplasmic vacuoles and loss of neurons and satellite cells that could affect sensory function. These findings are distinct from the demyelination of the posterior columns associated with the self-limiting Lhermitte's syndrome (113). Meningeal thickening and fibrosis can also be observed after radiation, but the clinical significance of this is unknown. Ependymal and nerve root damage from radiation is rare.

Clinical Management

Persistent pain after radiotherapy for vertebral metastases should be investigated to exclude the possibility of progressive disease in or outside the radiation portal, or mechanical spinal instability because of a vertebral compression fracture. Changes seen in the bone marrow on MRI after palliative radiotherapy initially include decreased cellularity, edema, and hemorrhage, followed by fatty replacement and fibrosis. These well-defined changes on MRI after radiotherapy can be distinguished from those seen with progressive disease (30,31 and 32,108,115,116).

Prior radiation portals may affect the ability to radiate spine metastases, especially in breast and lung cancer patients. Standard radiation portals currently used for breast cancer therapy infrequently treat the spinal axis. The upper thoracic and lower cervical region, however, may be irradiated in a field encompassing the supraclavicular nodes and axillary apex if significant axillary node involvement is documented. With techniques used in the past for breast cancer, the thoracic spine would receive a significant dose of radiation from a field that treated the internal mammary lymph nodes (105). Treatment of the mediastinum in lung cancer generally includes the majority of the thoracic spine treated to the maximum dose tolerated by the spinal cord (111). Previous radiation of the spine as part of definitive therapy does not reduce the risk for subsequent spinal cord compression as part of persistent or recurrent disease.

Surgery often is the only available option for therapy because previously administered radiation may preclude further radiotherapy in the region of the malignant spinal cord compression. This is often the case in lung cancer because metastases are located in the thoracic spine in over 70% of cases, and many of these patients have received mediastinal irradiation (111). Early involvement by the radiotherapist in the management of the patients with suspected spinal cord involvement is important to allow time to obtain prior radiotherapy records and determine if further radiation is possible and expedite the clinical decision-making process.

Based on clinical and radiographic grounds, leptomeningeal carcinomatosis must also be considered in the diagnostic evaluation. Leptomeningeal carcinomatosis occurs more commonly than expected. For example, only one-half of breast cancer patients with leptomeningeal carcinomatosis are diagnosed before death (91,97,105,117,118). Performing a lumbar puncture is a relative barrier to the diagnosis; at least three cerebrospinal fluid samples are necessary to cytologically exclude the diagnosis of leptomeningeal disease because in 10% to 40% of patients the initial cerebrospinal fluid sample fails to document tumor cells (117). MRI can identify leptomeningeal disease among patients with normal cerebrospinal fluid cytology and is sensitive and specific in locating regions of nodular leptomeningeal involvement. Except in the case of nodular leptomeningeal involvement, in which localized radiotherapy may be of benefit as an adjuvant, intrathecal chemotherapy is generally the treatment of choice (118).

TREATMENT OF DIFFUSE BONE METASTASES

Other therapeutic approaches, including wide field radiotherapy, systemic radionuclides, and bisphosphonates, have been used among patients with disseminated bone metastases. Both approaches are useful in augmenting the therapeutic effect of localized radiation and in preventing asymptomatic bony lesions from progressing. Although usually not a significant consideration in localized irradiation, adequate bone marrow reserve is required for wide field radiotherapy and systemic radionuclides. Bone marrow scans can be performed to determine the volume of functioning marrow and assess the feasibility of delivering wide field radiotherapy or radionuclides (9,30,34,61,62,65).

Wide Field Radiotherapy

Hemibody irradiation has been used to treat diffuse bone metastases by administering 6 to 10 Gy in one fraction to the upper, mid, or lower body. Response rates are consistently reported to be greater than 70%, and more than 20% of patients have complete relief of pain. In prostate cancer patients, the overall response rate is 80%, and complete relief of pain is 30%, respectively (119,120). Approximately one-half of patients experience relief of pain within 48 hours of treatment, and the overall response rates equal 80% for all types of primary tumors. More than one-half of the patients treated did not require further palliative irradiation for recurrent bone pain over the duration of their lives. For prostate cancer patients, the mean duration of pain relief is 15 weeks and mean survival time is 25 weeks.

An RTOG study demonstrated that hemibody radiation reduced the time to disease progression and decreased the need for subsequent palliative radiation of bone metastases at 1 year of follow-up when compared with local field irradiation alone. These results from the RTOG study are consistent with other reported experience using hemibody irradiation (119,120). Median survival after hemibody irradiation is significantly better among patients who present with a good performance status. Approximately 90% of patients with a complete response and 70% of patients with a partial response had a good to excellent performance status before radiotherapy. Prior systemic therapy does not influence response to wide field radiotherapy. Symptomatic bone metastases, which are also refractory to chemotherapy or hormonal therapy, have complete response rates of 70% and partial response rates of 24% with hemibody radiation. Symptoms are palliated in 88% of cases when a previously treated area is reirradiated. Premedication prevents nausea, and partial shielding minimizes lung dose and the risk for radiation pneumonitis. Hematologic depression is limited. Toxicity is observed in less than 10% of patients, whereas 50% experience stabilization of disease at 1 year.

Because of the potential toxicities to visceral structures and the difficulties in treatment setup, hemibody radiation is not routinely used to palliate multifocal bone metastases. Concerns regarding the permanent effects on bone marrow reserve also exist relative to the subsequent need for chemotherapy. For these reasons, radiopharmaceuticals, which have no systemic toxicities other than the effect on blood counts, have gained popularity over hemibody radiation in the treatment of multifocal bone metastases. However, radiopharmaceuticals are most useful in blastic bony lesions and hemibody radiation may be an important palliative option among patients with diffuse lytic bone metastases that are refractory to other therapies.

Radiopharmaceuticals

An alternative to hemibody irradiation for the treatment of widely disseminated bone metastases is the use of systemic radioisotopes. The most commonly used radiopharmaceutical in the treatment of bone metastases is strontium 89. Strontium 89 combines with the calcium component of hydroxyapatite in osteoblastic lesions. Many reports indicate effective palliation of pain lasting more than 6 months in 60% to 80% of patients with breast and prostate cancers (57,58,59,60,61 and 62,65,67,68,71). Improvements in functional status and quality of life have been observed, and approximately 20% of patients have complete resolution of pain. Pain control has been reported to be superior among patients with disseminated prostate cancer treated both with strontium 89 and local radiotherapy as compared with localized irradiation alone. Because the activity of strontium 89 is limited to bone, use of radiopharmaceuticals is contraindicated when epidural disease is associated with vertebral metastases. Myelotoxicity, resulting in a 25% decline of initial platelet and white blood cell counts, is usually transient and represents the only significant toxicity associated with strontium 89 (58,62,65). Experience from a number of clinical trials has demonstrated strontium 89 to be an effective therapy that is easily administered in an outpatient setting. The radiation dose absorbed by the bone marrow is 2 to 50 times less than the dose administered by strontium 89 to the osteoblastic lesion. Radiation doses to metastatic bony lesions with strontium 89 can range from 3 to more than 300 Gy.

Marrow suppression caused by radioisotopes is either caused by penetrating gamma radiation or by a radioisotope with a long half-life. For example, transient cytopenia is observed with strontium 89 because it has a fairly long half-life of 51 days, even thought it emits a beta particle of low penetrance and low energy (1.46 MeV) (Table 37A-5). Hematotoxicity is more pronounced in patients with pretreatment platelet counts of less than or equal to 60×10^3, white blood cell counts of less than or equal to 2.5×10^3, or greater than or equal to 30% involvement of the red marrow–bearing bone (62,65). Compromise of the red marrow–bearing bone can be a consequence of tumor or prior radiation and chemotherapy.

Radionuclide	Half-life (days)	Beta energy (MeV)	Gamma energy (keV)	Response rate (%)	Duration of response (mo)	Toxicity

TABLE 37A-5. Physical characteristics and clinical data for radionuclides

Clinical response to strontium 89 is comparable with wide field radiotherapy. Response to strontium 89 therapy has been documented both subjectively and objectively. Subjective response, manifested as symptomatic improvement, was reported by more than 80% of prostate cancer patients using a validated survey. Objective evidence of response was documented by reductions in alkaline and acid phosphatase levels that were also associated with a decrease in the uptake in metastatic lesions on sequential bone scans (58,59,60,61 and 62, 65,68). Prior therapies for prostate cancer, including local radiation therapy and systemic chemotherapy or hormone therapy, do not influence toxicity or affect clinical response to strontium 89. Administered as an adjuvant to localized external beam radiotherapy in metastatic prostate cancer, strontium 89 has been shown to improve pain relief and delay progression of disease in prospective randomized clinical trials. Almost twice as many patients treated with strontium 89 were reported to be pain free at 3 months in follow-up when compared with patients treated with localized external beam radiation. Analgesics were no longer required by 17% of patients treated with strontium 89, whereas only 2% of the patients treated with localized radiotherapy alone were able to discontinue analgesic use. Quality-of-life assessments demonstrated increased physical activity along with improved pain relief after strontium 89 was administered in conjunction with localized external beam radiation therapy. Cost-benefit analysis has also suggested an advantage to the administration of strontium 89 with reductions in costs of hospitalization for tertiary care (59,60,71).

Several other radiopharmaceuticals are available for clinical application including samarium 153, gallium nitrate, phosphorus 32, and rhenium 186 (57,63,64,66,69,70,72). The therapeutic mechanism of action relates to the physical and biological half-life in the bony lesion, the mean energy, and the delivered dose of the radiopharmaceutical. Table 37A-5 summarizes some of the physical characteristics and clinical data for various radionuclides. Phosphorus 32 and strontium 89 emit pure beta rays (little penetration in tissue), whereas rhenium 186 and samarium 153 emit both beta rays and relatively high energy gamma-ray photons that penetrate tissue for some distance (103 to 159 keV).

Because samarium 153 has a gamma-ray component, it is possible to directly image the distribution of the radiation dose. The scans after injection of samarium 153 are comparable to diagnostic scans obtained with technetium 99m. The mean skeletal uptake is over 50% of the dose (70). Nonskeletal sites receive negligible radiation doses, and complete clearance of radiation not absorbed by the radiation occurs within 6 to 8 hours of administration (69). In a double-blind placebo-controlled clinical trial, samarium 153 has been shown to be an effective agent in palliating painful bone metastases in breast cancer patients. Pain relief occurred within 1 week and lasted at least 16 weeks after administration (64). Approximately 65% of patients responded within the first 4 weeks and 43% had relief of pain of at least 16 weeks' duration. No significant bone marrow toxicities have been observed. Recommended doses range between 1.0 and 1.5 mCi per kg. In more than one-third of patients, multiple administrations are possible (72).

Selectively concentrating in bone, the mechanism of action of rhenium 186 is similar to that of technetium diphosphonate 99m, which is used in diagnostic bone scans. This characteristic allows direct imaging of the deposition of rhenium 186 in bony metastases. The metastatic lesion receives tens of grays in dose after the administration of rhenium 186, whereas the radiation dose to the marrow is limited to 0.75 Gy (57,66). Thrombocytopenia appears to be the dose-limiting toxicity. Similar to the reports that use strontium 89 among prostate cancer patients, decreases in PSA have been also observed after the administration of rhenium 186 (66).

Phosphorus 32 has been used to treat bone metastases in prostate cancer patients for over 30 years, with 77% of patients experiencing significant relief of pain (57). The response rates and duration of response with phosphorus 32 are similar to wide field radiation and strontium 89. However, the main disadvantage of phosphorus 32 is that more than 30% of patients develop severe hematologic toxicity.

Comparative clinical trials are necessary to determine whether any difference exists in the onset and pattern of response between samarium 153, strontium 89, and other radiopharmaceuticals. Clinical data for rhenium 186 and other radiopharmaceuticals is still limited and these agents are in various stages of clinical investigation (57,62,63,64,65 and 66). Several strategies have been proposed to further enhance the therapeutic response of radiopharmaceutical agents. These options include further dose intensity studies, adjunctive administration of bisphosphonates, and concurrent administration with chemotherapy (67). Although bone marrow toxicity is relatively limited in the doses of radiopharmaceuticals currently administered either alone or in combination with other agents, future dose intensity studies may require hematologic support with colony-stimulating factors.

Sequential radiography and bone scans after hormonal and radiopharmaceutical therapy for breast and prostate cancers demonstrate an osteoblastic response that reflects remodeling of the bone in osteolytic osseous metastases (45,46). Approximately one- third of patients have evidence of increased tracer uptake on bone scans (flare) obtained 8 to 16 weeks after treatment. Of these patients with a flare response on bone scan, 72% experience a response to the treatment. By comparison, only 36% have a response to treatment when a limited response or no flare response is observed.

Relapse of disease has been associated with an increase in the osteolytic component. Osteoclast resorption in bone metastases is associated with the release of acid and acid-dependent proteases that dissolve the organic matrix of the bone. Gallium nitrate has been shown to inhibit accelerated bone turnover among patients with widespread bone metastases and has been clinically applied in the treatment of hypercalcemia. Preferentially accumulating in the cortical surface, the most metabolically active region of the bone, gallium nitrate acts to inhibit osteoclast resorption. Additionally, gallium nitrate increases the absorption of calcium and phosphorus and the incorporation of collagen into the bone.

BISPHOSPHONATES

Bisphosphonates are a group of substances that have a high affinity for bone, a long half-life in the skeleton, and inhibit osteoclast activity. Acting as a metabolic toxin, biphosphonates block osteoclasts from generating acid. The efficacy of pain relief may be improved with the adjuvant administration of biphosphonates through these direct mechanisms of action or possibly by also increasing retention of the radiopharmaceutical in involved bone. Bisphosphonates have been shown to be effective in multiple myeloma and bone metastases from other cancers (52,53,54,55 and 56).

Considerable experience exists with the administration of bisphosphonates in breast cancer. Significantly fewer skeletal complications have been reported when bisphosphonates are administered to breast cancer patients with documented bony metastases (53,54,55 and 56). Sequential bone scans showed that the median time to disease progression was increased by 48% among patients who received pamidronate (56). Symptomatic improvement has been observed at 15, 18, 21, and 24 months in association with monthly infusions of pamidronate to a cohort of 382 women with metastatic breast cancer for over 2 years. The median time to progressive symptoms needing radiation or surgical intervention was 14 months in the pamidronate-treated group and 7 months in the placebo group. Palliative radiation was administered to 28% of the pamidronate group as compared with 45% of the placebo group. No difference was seen, however, in the rate of vertebral pathologic fracture between pamidronate and placebo groups. Prolonged administration was not associated with reduced tolerance to therapy (55). The costs of administration of pamidronate, especially over a prolonged period of time, may be offset by reducing the need for radiation and surgical interventions and by avoiding the functional impairment associated with progressive disease.

CONCLUSIONS

Diagnostic Recommendations

Pain that persists after palliative radiation should be evaluated to exclude progression of disease in the treated area, possible extension of disease outside the

radiation portal that causes referred pain, and bone fracture. Reduced cortical strength can result in compression, stress, or microfractures. Plain radiography often clearly delineates lytic changes and fractures after radiotherapy.

Therapeutic Recommendations

Radiation remains an important modality in palliative care. A number of clinical, prognostic, and therapeutic factors must be considered to determine the optimal treatment regimen in palliative radiotherapy. Adequate management of cancer-related pain is important both during and after completing palliative irradiation. Efficient and effective palliative treatment is imperative for locally advanced and metastatic cancer to relieve symptoms, improve function, and minimize disease-related morbidity.

Radiopharmaceuticals, such as strontium 89, are being used with greater frequency to treat bone metastases both as a primary modality for patients whose symptoms recur in a previously irradiated site, and as an adjuvant to external beam irradiation.

More specific criteria need to be delineated for prognosis to determine the appropriate treatment regimen for bone metastases. A staging system within the category of metastatic disease should incorporate the performance status, type and extent of bone and visceral involvement, time to disease progression, and primary tumor site and account for prior failed therapies. Because only the bone is treated, external beam radiation or radiopharmaceuticals continue to be considered localized therapies for systemic disease. Therefore, the response to and outcomes after radiation therapy must be specifically defined relative to the radiated and unirradiated sites of disease, and the other antineoplastic and supportive care therapies administered.

Radiation therapy is an important means of treating localized symptoms related to tumor involvement by providing a wide range of therapeutic options. Radiobiological principles, the radiation tolerance of adjacent normal tissues and the clinical condition influence the selection of radiation technique, dose, and fraction size. The optimal dose and treatment schedule, however, are not fully defined for palliative radiation of bone metastases. Further study is necessary to integrate validated pain scores, analgesic use, prognostic factors, and radiobiological principles to better define the most efficient and efficacious treatment schedule according to the clinical presentation.

Palliative irradiation should be integrated in a multidisciplinary therapeutic approach because of the need to treat associated symptoms and other underlying medical problems. Antineoplastic therapy can provide tumor regression, relief of cancer-related symptoms, and maintain functional integrity. Control of cancer-related pain with the use of analgesics is imperative to allow comfort during and while awaiting response to radiotherapy. Pain represents a sensitive measure of disease activity. Close follow-up should be performed to ensure control of cancer and treatment-related pain and assess for progressive disease or recurrent disease.

CHAPTER 37

Part B: Chemotherapeutic Management of Symptomatic Disease

J. Cameron Muir

“Cancer pain is best controlled by removing the cancer or causing it to regress” (1). These words of the renowned oncologist and palliative medicine specialist Dr. Neil MacDonald are a useful framework from which to consider the role of chemotherapy in the management of symptomatic disease. Half of all cancers are, in fact, cured surgically. Yet, when a tumor is deemed surgically unremovable (inoperable), the likelihood of long-term survival is remote: Of the remaining 50% of tumors that are not surgically curable, only 10% are cured by other modalities, namely radiotherapy or chemotherapy. Thus, “for the majority of patients . . . attempts to cure or bring about long term disease regression ultimately fail, and the patient, after an often prolonged period of pain and suffering, will die. Although improved understanding of the molecular biology of cancer may lead to fundamentally new techniques for its prevention, diagnosis, and treatment, this promise, for the moment, remains in the laboratories, and major changes in the curability of human malignancy are unlikely to occur during the next 5 years” (1). In fact, in 1998 in the United States, when 1.2 million cancers were diagnosed, the number of cancer deaths was 564,000 (2).

The emergence of the field of palliative medicine has placed increased emphasis on the assessment of subjective symptoms of life-threatening diseases such as cancer. Thus, there is reason to hope that, although the research toward the “magic bullet” to cure cancer marches on, increased attention will be paid to the management of patients' symptoms. Although a number of new chemotherapeutic agents have received Food and Drug Administration approval in the 1990s their impact on long-term survival remains to be fully appreciated. In fact, the death rates from the major solid tumor malignancies have not changed in over three decades— the time to treatment failure or disease progression, however, has increased (2).

The primary outcomes of oncologic therapy traditionally have been overall survival and radiographic response of the tumor to cytotoxic therapy (3,4 and 5). Only very recently has emphasis been placed on palliative outcomes of chemotherapy. Interestingly, due to the careful monitoring of acute and long-term drug toxicities in the field of oncology, there are far more data regarding the pain induced by chemotherapy (usually in the form of neurotoxicity) than there are for relief.

An important issue of ambiguity and confusion is the use of the term *palliative chemotherapy*: Technically speaking, there is very little evidence to support the existence of palliative chemotherapy. For something to be truly palliative it has to have a subjective benefit for the patient—relief of symptoms, improvement in quality of life, or both. Until very recently, these palliative end points have not been a component of clinical trials in oncology. In fact, it has only been recently that quality-of-life assessments have been included in active chemotherapy protocols; pain assessment remains an infrequent end point. Instead, the administration of chemotherapy to patients who are not going to be cured from their cancer has been called *palliative chemotherapy*. One could argue that, in the absence of true palliative data end points, it is impossible to distinguish chemotherapy that provides a subjective benefit to the patient—thus achieving a palliative end point—from that which is purely futile (no objective or subjective benefit).

It seems intuitive that any treatment that decreases the size of a tumor should lead to relief of cancer pain. However, many chemotherapeutic agents provide only relatively small objective response rates in the majority of common adult solid tumors. These antimitotic drugs are often highly toxic, particularly in patients with low performance status as a result of either disease or previous treatments. Consequently, one of the critical assessment and decision-making skills of the medical oncologist is to balance the expected benefits of chemotherapy against the risk of significant toxicities (3). Chapter 35 and Chapter 36 present general information about the diagnosis and treatment of cancer pain.

CHEMOTHERAPEUTIC AGENTS

Many different types of anticancer drugs are available (3,4,5,6,7 and 8), and they fall into six major classes based on their mechanisms of action: (a) alkylating agents, (b) antimetabolites, (c) plant alkaloids, (d) antitumor antibiotics, (e) endocrine agents, and (f) a miscellaneous group. The most important chemotherapeutic agents, their side effects, and indications are listed in Table 37B-1. All of these cytotoxic drugs interfere with cell division through a variety of mechanisms (interference with mitotic spindle formation, specific enzyme inhibition, cross-linkage of DNA or RNA), and some exert several actions simultaneously at different sites of the cell. The exact mechanism of action for each drug differs slightly, and this accounts for the variation in the pattern of normal tissue toxicity.

TABLE 37B-1. Commonly used cytotoxic anticancer agents

USES OF CHEMOTHERAPY

Chemotherapy is used for some patients after radiation therapy or surgery (as an adjuvant to these therapies). For others, a combination of these therapies is considered the primary treatment (combined-modality therapy). In still other patients, chemotherapy is used alone as the primary therapy (6,7). The administration of systemic chemotherapy has the distinct antitumor advantage, when compared with the local therapies of surgery or radiotherapy, of traveling throughout the body—wherever the bloodstream might take a cancer cell (this also accounts for the increased systemic toxicity of chemotherapy). Thus, adjuvant chemotherapy is used in patients who appear cured after surgery but are suspected of having residual disease or micrometastasis. Adjuvant chemotherapy has proven effective in node-positive breast cancer, Duke's B2 and C colorectal carcinoma, stage III ovarian carcinoma, and testicular carcinoma (7). Clinical trials are now under way to determine whether chemotherapy administered before surgery or radiation therapy (so-called neoadjuvant chemotherapy) can (a) decrease the size of the tumor to be removed or radiated; (b) increase the likelihood that the tumor will be surgically extirpable; and (c) decrease the likelihood of micrometastatic spread/seeding at the

time of surgery. Systemic chemotherapy is the primary treatment for disseminated/metastatic malignant disease.

Based on the mechanisms mentioned above, the goal of systemic chemotherapy is to interrupt the division of rapidly dividing cancer cells. It is usually administered in multiple (usually 4 to 6) cycles every 3 to 4 weeks. The timing and dosing of chemotherapy are established to maximize malignant cell kill, while at the same time not exceeding the body's ability to regenerate the normally rapidly dividing cells that are “innocent bystanders” of the cytotoxic effects of chemotherapy, namely the bone marrow progenitors, gastrointestinal epithelial cells, and hair follicles. The predominant effect of chemotherapy on the intestinal tract occurs in the first few days to a week after administration, whereas the peak effect on the blood progenitor cells occurs 10 to 14 days posttherapy. Thus, patients often receive prophylactic antiemetics for the days around therapy (of which the newer agents are usually quite effective) and “nadir” their blood counts, with variable risks of infection and bleeding, approximately 2 weeks after receiving treatment, respectively.

Regardless of the setting of administration (primary, adjuvant, neoadjuvant, or combined modality), substantial evidence suggests that combination chemotherapy with agents that have different mechanisms of action as well as different (noncumulative) toxicities yields significantly higher efficacy than single-agent chemotherapy. On the basis of an extensive review of *in vivo* and *in vitro* laboratory research and clinical experiences acquired during the 1950s and 1960s, DeVita and Schein (9) developed a set of basic principles of combination chemotherapy for cancer patients, and these are still the guiding principles today. Among the most important of these principles are the following: (a) All of the component drugs in a combination must have activity against the neoplasm being treated; (b) drugs must be administered at dosages close to the minimum effective dosage for each drug as a single agent, or beyond if possible (the higher the dosage of each drug is raised the more likely that beneficial results will be obtained); (c) drugs that interrupt the synthesis of cellular macromolecules at several sites can be combined for additive or synergistic effects on the various synthetic pathways; (d) drugs in combination should have as little cross-toxicity as possible; and (e) mechanisms of tumor cell resistance to two agents in combination must not be similar (9).

CLINICAL APPLICATIONS

An anticancer therapy always should be started for those types of cancers in which chemotherapeutic regimens have been proven effective. Conventionally, efficacy of chemotherapy is defined by an objective decrease in the radiographic size of the tumor [usually by computed tomography (CT)]. A so-called complete response (CR) represents total disappearance of all observable disease for a minimum of 1 to 3 months, depending on the criteria used (5,10,11 and 12), whereas a partial response (PR) represents a decrease in measurable tumor size of 50% or more. With the development of newer cytotoxic agents, many solid tumors display an objective response to specific chemotherapy. Although cure of most forms of cancers is still an elusive objective, current drug treatments produce good partial remission and even complete remission in some cancers, for which two decades ago only supportive therapy was available. As a general rule, the achievement of significant objective response [CR + PR = RR (response rate); i.e., some significant decrease in the size of the tumor radiographically] almost always translates into an improved survival of responders compared with nonresponders. It also translates into relief of pain related to the tumor mass—although pain relief from chemotherapy has rarely been the end point of clinical trials (Table 37B-2). Furthermore, in a fraction of patients with specific forms of cancers, such as pediatric tumors, lymphomas, testicular cancer, and ovarian cancer, complete remission of the neoplastic disease is followed by prolonged disease-free survival compatible with cure (3).

TABLE 37B-2. Efficacy of chemotherapy in relieving pain

There are, however, many patients whose tumor is resistant to chemotherapy. They have progressive disease either shortly after the completion of therapy or, in some cases, during the time of active therapy. The category that falls between an objective response and progressive disease, in which the tumor neither shrinks nor grows in the face of active anticancer therapy, is referred to as *stable disease*. Whether there is any analgesic benefit to the administration of chemotherapy in the setting of stable disease is largely unknown. Although there is speculation about the role of chemotherapy in altering peripheral sensory nerve function, thereby producing analgesia (1), as well as relieving pain by altering the “tumor-host milieu” (1), these hypotheses await clinical trials, with assessment of the analgesic outcomes as a primary end point of therapy. At the moment, one of the significant barriers to these studies is the lack of a universal language for a pain classification schema and staging system. Although such systems have been developed, they remain underused and underappreciated (13).

Thus, we are left with both the clinical impression and limited outcome data that generally support the claim that “systemically administered cytotoxic drugs do not relieve cancer pain in the absence of tumor regression” (1). It is therefore imperative to know the type of cancer that one is evaluating before initiating chemotherapy, paying particular attention to the histology (squamous cell carcinoma, adenocarcinoma, germ cell, lymphoma), the grade (high, intermediate, low) and the degree of differentiation (well differentiated, poorly differentiated), because these factors will give clues as to the likelihood of a response to chemotherapy. One must also follow the rapidly evolving literature on objective response rates for newer agents and various combination regimens on a given tumor type. Careful assessment of the overall performance status of patients will help to determine their ability to tolerate systemic chemotherapy and endure the likely associated toxicities.

In general, the more rapidly growing the tumor, the more frequent is cellular division and therefore the more responsive the cells are to cytotoxic therapy: Intervention can lead to increased pain control, long-term survival, and, potentially, cure. Ironically, the more rapid the cell division, the more aggressive the tumor and the more imminently life-threatening the tumor is if it is not responsive to cytotoxic therapy. Table 37B-3 summarizes the most common malignancies and their likelihood of response to chemotherapy. Of the most common solid tumors [lung, colorectal, prostate (men), and breast (women)], all except breast carcinoma are minimally responsive to current chemotherapeutic regimens. This and other evidence provides a basis for reviewing the palliative benefits of chemotherapy. However, most of the evidence describes the palliative use of chemotherapy as noncurative, or life prolonging, rather than for true subjective (palliative) benefit, in terms of either pain control or enhanced quality of life.

TABLE 37B-3. Effects of chemotherapy on various cancers

RESPONSE OF TUMORS TO CHEMOTHERAPY

Curable by Chemotherapy

The lymphomas, both Hodgkin's and non-Hodgkin's types, are considered “the cancers you want to get—if you have to get one.” They tend to respond better than most to combination chemotherapy. For Hodgkin's lymphoma, there are several active regimens, but the preferred treatment regimen, doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine, is highly active and produces a complete remission rate that varies from 98% for early-stage disease (overall survival of more than 93% at 6 years) to 82% for advanced stage disease (overall survival of 73% at 6 years) (14,15). The therapeutic effect of this combination regimen is rapid, even in advanced cases, providing prompt pain relief in those patients who have pain (although this has never been a primary end point), with observed resolution of other symptoms and signs as well. In non-Hodgkin's lymphomas (NHL), there is a larger variability based on histology, with high-grade NHL being significantly more responsive to therapy than low-grade types. For high-grade NHL, treatment with a variety of combination chemotherapy regimens, including bleomycin, Adriamycin, cyclophosphamide, vincristine, and prednisone; cyclophosphamide, Adriamycin, vincristine, and prednisone; or others, produces a CR in 44% to 59% of cases, with overall survival of approximately 50% at 3 years (16). Again, no studies of NHL have examined pain as a primary end point. Similar results are also obtained in carcinoma of the testicle with platinum, etoposide, and bleomycin, in Wilms' tumor, and in the leukemias (especially the lymphoblastic types) (17).

Chemotherapy Has Significant Activity

In moderately chemosensitive tumors (see Table 37B-3), the results obtained with the various chemotherapeutic combinations are less favorable (30% to 60% response rates), and in general, the therapeutic effect is slower in onset. Small cell lung cancer, for example, tends to be quite aggressive, and combination chemotherapy regimens with cisplatin and etoposide or cytoxan, Adriamycin, and vincristine can induce an objective response in approximately 60% of cases, with CR occurring in approximately 10% (18). Again, this and other studies have not attempted to quantify analgesia or relief from dyspnea in small cell lung cancer.

The course of recurrent or metastatic breast cancer follows two dominant pathways: The hormone receptor–positive tumors tend to occur in older (postmenopausal) women and follow a more indolent course, with a predominance of bone as the metastatic site, and can be managed with hormone therapy, often for years; the hormone receptor–negative tumors tend to occur in younger (premenopausal) women and follow a more aggressive course, with visceral and soft tissue involvement that often necessitates the use of, and responds to, chemotherapy (19). Standard combination chemotherapy for advanced breast cancer has been cytoxan, methotrexate, and 5-fluorouracil (5-FU); this combination achieves response rates of approximately 50%, with CR of approximately 15%. This regimen impacts positively on quality of life and tumor-related symptoms (20). Subsequent studies have shown similar results for the combination of cyclophosphamide and Adriamycin, with both regimens achieving an improvement in quality of life and tumor-related symptoms, including pain (21). Yet again, it is interesting to note that “given the prevalence of recurrent breast cancer, it is intriguing that few studies have specifically addressed quality of life issues” (19) and that even fewer address symptomatic benefits of therapy.

Newer agents, especially the taxanes (paclitaxel and docetaxel) have demonstrated significant activity in breast cancer, with response rates of 60%. Early data suggest that the taxanes, probably in combination with some configuration of cyclophosphamide and Adriamycin, will likely become the treatment of choice for chemotherapy-appropriate patients with breast cancer (19). A British study evaluating patients with advanced breast cancer who received first-line palliative chemotherapy (a variety of regimens) did have primary palliative (subjective patient-centered) outcomes that were assessed by using the Rotterdam Symptom Checklist. In this study, one-fourth of the patients (26%) felt better after having received chemotherapy, with statistically significant decreases in psychological distress, pain, and improvement in lack of energy and sense of tiredness. As might be expected, feeling better correlated with disease response ($p = .03$) (21). Other studies have evaluated novel agents, including vinorelbine, which has been shown to have significant activity in breast cancer, with similar response rates as the taxanes of approximately 60%, but none has assessed symptoms as a primary end point (22). The role of vinorelbine in breast cancer remains to be determined.

Head and neck cancer is one of the most challenging disease sites to treat. However, recent advances in combined modality therapy with combined modality chemoradiation have revealed promising results: Haraf et al. (23) reported that patients with stage II and III head and neck cancer who were treated with older drugs (hydroxyurea and 5-FU) used in a novel fashion as radiosensitizing agents, in conjunction with hyperfractionated (twice a day) radiotherapy, had long-term disease-free survival consistent with cure (65% at 5 years) (23). This new approach with combined modality therapy has made a previously dreadful disease potentially curable. One of the primary concerns, however, is the subsequent short- and long-term toxicity of such aggressive therapy, and strategies aimed at reducing long-term toxicities are under study. Additional work with the taxanes is encouraging, with response rates of 42% in one study (24). Paclitaxel has been added to the above-mentioned combined modality protocol for patients with further advanced stage IV disease, with encouraging results (Merrill Kies, M.D., *personal communication*, 1999).

Finally, ovarian cancer is “among the most sensitive of all malignancies to cytotoxic chemotherapy” (25). Combination regimens in which a platinum-based agent (cisplatin or carboplatin) is used achieve overall response rates of 60% to 80%. Newer agents, most notably the taxanes, also have significant activity in ovarian cancer, with overall response rates of 20% to 40%. The combination of carboplatin and paclitaxel has demonstrated superior response rates and has become the standard of care for ovarian cancer amenable to chemotherapy (25). In one review, Patnaik et al. (26) commented that few studies have addressed palliative end points in ovarian cancer but that those that did showed that half of patients derived a palliative benefit from chemotherapy that was above the objective response rate. This brings to the fore the question of potential symptomatic benefits of chemotherapy in the absence of objective tumor regression.

Chemotherapy Has Minor Activity

In tumors with poor chemosensitivity, such as adenocarcinoma (lung, colorectal, esophageal, pancreatic, and prostate), malignant melanoma, malignant brain tumors, and sarcoma of bone and soft tissue, long-term alteration of the course of disease is rarely obtained with chemotherapeutic drugs. In this group of tumors, anticancer modalities are rarely effective in reducing the size of the tumor (achieving neither PR nor CR), and as a result, the associated pain and other symptoms, although not studied as primary end points, are unlikely to be affected significantly by chemotherapy. There are many factors responsible for the limited efficacy of chemotherapy in these tumors. First, the cellular biology of these solid tumors that often produce pain is such that they have limited response to current drug regimens. Second, the size of the tumor is inversely related to the incidence of satisfactory drug penetration into the mass. Thus, the larger the mass, the poorer is the cytotoxic response. Furthermore, given that these tumors generally do not exhibit long-term responses to first-line therapy, additional therapy with second- or third-line drug treatments often yields a minimal (usually less than primary therapy) response rate. Finally, in certain target sites (e.g., head and neck, pelvis) prior radical surgery and/ or prior radiation therapy impair the vascular supply to the tumor bed, thus interfering with delivery of an effective drug concentration to the target site.

This group therefore represents not only the most prevalent sites of malignancy, but also the most challenging for the medical oncologist to demonstrate objective response rates to chemotherapy. Interestingly, this would be the ideal patient population in which to demonstrate a palliative benefit of chemotherapy in the absence of an objective tumor response—with subjective decreases in pain, dyspnea, and fatigue and increases in performance status, appetite, and weight gain. A few investigators have pursued this notion, with intriguing results. The initial Food and Drug Administration approval of one of the newer chemotherapeutic agents, gemcitabine, was earned not by data showing its benefits on overall survival or objective response rate, but by improvements in pain control, weight gain, and performance status in patients with pancreatic cancer (27).

Non–small cell lung cancer represents the epitome of the challenge of medical oncology. It is the most prevalent cancer type, and it has required years of study requiring the synthesis of metaanalyses and new drug development to conclude that chemotherapy provides a modest survival and probable quality-of-life benefit in a significant number of patients when contrasted with best supportive care (28). Newer agents, including vinorelbine, gemcitabine, and paclitaxel, show response rates in the 11% to 25% range when combined with platinum-based therapy. No study has examined the effects of therapy on pain or dyspnea, although a few have evaluated improvements in performance status and weight gain (29).

In the realm of gastrointestinal malignancies, the role of chemotherapy “even as an adjuvant treatment, has a proven benefit in only a limited subset . . . of patients” (30). The fluoropyrimidines (5-FU and its derivatives) are the agents with demonstrated efficacy in gastrointestinal malignancies. 5-FU can be given in multiple doses and schedules with variable toxicities, yet all have resulted in disappointingly consistent response rates of approximately 20%. Leucovorin, a reduced folate analog, enhances 5-FU activity modestly, with combination therapy (5-FU/leucovorin) yielding response rates of approximately 30% in advanced colorectal cancer. In a large study of more than 400 patients conducted by the North Central Cancer Treatment Group (31), 70% of patients who received 5- FU/low-dose leucovorin had improvements in performance status and weight gain; there was no assessment of pain as a primary end point. In pancreatic cancer, there is promise that new drug developments will have clinical benefits. In 1995, some claimed that “there currently is no role for chemotherapy in the palliation of pancreatic cancer” (30), yet as mentioned earlier, the approval of gemcitabine for pancreatic cancer was based on the palliative end point of “clinical benefit” over the conventional 5-FU therapy. In

this study, clinical benefit was defined by a composite of pain, performance status, and weight gain (27). This was one of the first studies to directly assess the primary end point of pain via patient report of pain intensity together with analgesic consumption. An additional study from Sweden examined the primary end point of quality of life (using the European Organization for Research and Treatment of Cancer– QLQ-C30) in pancreatic cancer for patients treated with either chemotherapy (5-FU, leucovorin, and etoposide) or best supportive care, and it demonstrated that 36% of patients treated with chemotherapy had statistically significant improvement or prolongation of quality of life (32).

Prostate cancer is yet another prevalent disease that is poorly responsive to conventional chemotherapy. There is more palliative end- point evidence supporting the use of chemotherapy in prostate cancer than any other disease, in part because it is a slow-growing tumor that tends to cause significant pain and disability for a prolonged period of time. The most widely discussed study is Tannock's Canadian study, which used mitoxantrone and prednisone for hormone-refractory metastatic prostate cancer where the primary end point was pain relief (10). In this study, pain relief was again defined differently from previous studies as a “2-point decrease in pain as assessed by a six- point pain scale . . . without an increase in analgesic medication and maintained for two consecutive evaluations at least 3 weeks apart.” They found that this chemotherapy combination produced a positive effect in 29% of patients—above the benefit of prednisone alone, with a decrease of the analgesic medication by 50%. Other studies are suggesting the positive impact of estramustine-based chemotherapy either with vinblastine or paclitaxel on pain in hormone-refractory metastatic prostate cancer (Timothy Kuzel, M.D., *personal communication,* 1999).

Finally, soft tissue sarcomas demonstrate a response rate of approximately 35% to combination chemotherapy with doxorubicin and ifosfamide, with no studies assessing quality of life or symptomatic benefit from chemotherapy in this disease (11).

DECISION MAKING ABOUT CHEMOTHERAPY

The diagnosis of cancer is often quite traumatic for both the patient and the family. As Hippocrates said in 500 BCE, the goal of medicine is “to do all that is within my ability to cure illness, but above all things, at least, to do no harm.” On the one hand, the administration of chemotherapy is, by definition, cytotoxic—to malignant cells as well as normal host cells. On the other hand, the risks of not treating the disease are also quite significant. Given the fact that pain is a prevalent feature of both early- and advanced- stage cancer—present in nearly 50% of patients with early-stage disease and in 70% to 90% of cases of advanced cancer—one must strike a balance between giving enough therapy directed at eliminating tumor without reaching toxicities sufficient to eliminate the patient. Thus, it is imperative that an interdisciplinary team of clinicians with expertise in oncologic surgery, radiation therapy and medical oncology, nursing, and pharmacology evaluate patients to determine the treatment plan that is likely to provide the greatest cumulative benefit for the patient. If, as ought to be the ideal, the patient is always to be kept at the center of the decision-making process, then studies that assess patient-centered outcomes (pain, dyspnea, fatigue, appetite, weight loss, performance status, anxiety) for chemotherapy merit a higher priority. Although it is generally accepted that patients with a poor performance status do not usually benefit from systemic chemotherapy, it is not known whether patients with, for example, lung cancer have improvements in dyspnea as a result of chemotherapy.

An additional challenge for the medical oncologist is decision making after the first-line of chemotherapy has failed to control the tumor. For some disease types, there is clear objective benefit from the administration of second-line therapy. For many, however, second-line therapy is more likely to lead to enhanced cumulative toxicities rather than objective tumor response. A sensitive and thoughtful discussion with the patient and the family regarding the goals of care is needed. Emphasis must be placed on the ability to successfully manage the symptoms of progressive advanced disease with nonchemotherapeutic modalities.

As mentioned above, the beneficial effects of chemotherapy on pain is not often evaluated. Yet, it is interesting that the adverse effects of chemotherapy are well understood from monitoring in clinical trials in which nausea, vomiting, alopecia, neuropathy, and other symptoms are evaluated.

SIDE EFFECTS AND COMPLICATIONS

Toxicities and the predictable side effects of each of the chemotherapeutic agents are indicated in Table 37B-1. Perhaps the most common painful sequela of chemotherapy administration is a toxic peripheral neuropathy manifested as painful paresthesia, hyporeflexia, and, less frequently, sensory or motor loss or autonomic dysfunction (12). The drugs most commonly associated with this complication are the vinca alkaloids, especially vincristine; the taxanes, especially paclitaxel; vinorelbine, cisplatin, procarbazine; and less frequently misonidazole and hexamethylmelamine (19,33). In some cases, the painful peripheral neuropathy not only limits the dosing of anticancer therapy, but also can be more debilitating than the cancer itself and more difficult to treat than the more common nociceptive aspects of cancer pain.

Another painful complication of cancer and its therapy is acute herpes zoster and postherpetic neuralgia, which occur with increased frequency in patients with cancer—especially in those receiving chemotherapy or immunosuppressive drugs. Although the palliative benefits of glucocorticoids on mood, pain (as an antiinflammatory coanalgesic), and appetite are well known, chronic steroid therapy can cause myopathy, as well as necrosis of the femoral and humeral heads (34). Furthermore, one should be aware of the fact that withdrawal of glucocorticoids can cause a sense of decreased well-being, with increased pain, decreased energy, and apathy called *pseudorheumatism* (35).

ENDOCRINE THERAPY

In the 1890s, Beatson (36) was the first to demonstrate hormonal control of breast cancer when he induced regression of metastatic tumor by ovariectomy. In 1941, Huggins and Hodges (37) reported the successful use of exogenous estrogen administration for prostatic carcinoma. Since then, several other tumors have been shown to respond to hormonal manipulation, which is achieved either by ablating endocrine glands or by administration of an exogenous hormone or hormone antagonist.

Mechanism of Action

The mechanism of action of these agents has been clarified by the demonstration that receptors that bind with estrogen exist in the cytosol of normal and malignant cells (5). Hormones bind to receptors in the cytoplasm and sterically alter the shape of the receptive protein itself, which, after transport to the cell nucleus, interacts with DNA, and this results in altered messenger RNA production and protein synthesis (6). After this interaction, cytoplasmic receptor concentration is restored and the cycle can be repeated. Estrogen receptors can be quantitated as 8S and 4S proteins (6). Primary tumors in humans have estrogen receptor values that range from zero to almost 1,000 fmol per mg cytosol protein. Receptors also exist for progesterones and androgens, and receptors for corticosteroids have been identified in the cytosol of leukemic cells (6).

Hormonal ablation can be achieved by surgical means, as occurs with oophorectomy, adrenalectomy, and hypophysectomy; by irradiation of the ovaries or ablating the pituitary gland with the various radioactive compounds; by injecting alcohol; or by surgical extirpation (see Chapter 104 and Chapter 108). Medical adrenalectomy can be achieved by administering aminoglutethimide, a potent inhibitor of the conversion of cholesterol to pregnenolone in the adrenal gland (6). Hormone additive therapy is achieved by the administration of estrogens, progestins, androgens, antiestrogens, corticosteroids, and thyroid hormones. Table 37B-4 lists the hormonal agents used in the treatment of various cancers, their dosage ranges, and side effects. The dosages used generally produce plasma levels that are substantially higher than physiologic levels. Such hormone changes can cause complex endocrine effects, such as pituitary inhibition of luteinizing hormone, follicle-stimulating hormone, and prolactin, as well as changes in endogenous steroid hormone production (6).

TABLE 37B-4. Hormonally active agents in cancer treatment

Endocrine Therapy for Relief of Cancer Pain

Pannuti and associates (38,39) were among the first to point out that most reports containing results of anticancer treatment in patients with advanced malignant neoplasm are usually concerned only with measuring volume reduction of the tumor masses. Most writers have neglected, and often deliberately excluded, the assessment of subjective responses, including those related to pain, because this factor was not thought to be a reliable measure of the efficacy of treatment. Pannuti and colleagues further pointed out that there was no universally accepted rating system or qualification of pain relief on the part of oncologists, and this obviously led to heterogeneous results that could not be compared.

At the First International Symposium on Cancer Pain (38) and at another symposium held subsequently (39), Pannuti and colleagues presented a comprehensive summary of the results reported by a number of oncologists. Table 37B-5 contains mean data presented by Pannuti et al. (38,39) that provide an overview of the response to hormonal therapy of patients with four types of cancers. These reports were one of the first in which the efficacy of hormonal therapy on pain relief was correlated with the efficacy of these agents on tumor remission. Unfortunately, a significant number of reports had no data on the degrees of pain relief.

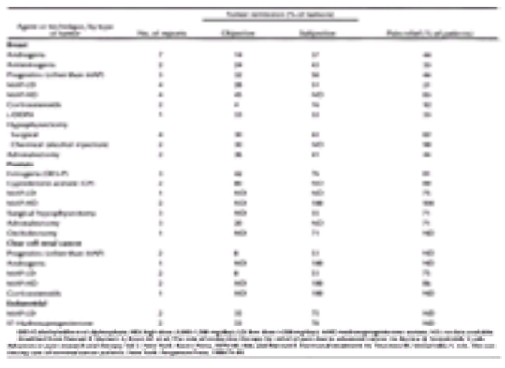

TABLE 37B-5. Results with hormonal therapy in advanced cancer

As can be noted in Table 37B-5, Pannuti et al. (38) gave progestin therapy in the form of high doses of injectable medroxyprogesterone acetate (MAP-HD) and noted pain relief in 83% of breast cancer patients with predominantly bone metastasis, although only 45% had objective evidence of tumor remission. In view of the corticosteroidlike side effects from these large doses of MAP-HD, it is possible that much of the subjective response was due to nonspecific steroid action. They also noted that hypophysectomy provided a high degree of pain relief. With regard to advanced cancer of the prostate, MAP-HD and hypophysectomy produced the highest degree of pain relief. For hypophysectomy, pain relief was twice as good as subjective tumor remission. With regard to renal carcinoma, androgens and progestins (particularly in the form of MAP-HD) provided pain relief and a subjective tumor remission in approximately 40% of the patients.

Although ovarian carcinoma contains steroid receptors, very little objective response to hormone has been demonstrated (38). Subjective response to the tumor occurred in some patients with progestin therapy, but no information is available concerning pain relief.

Well-differentiated papillary thyroid carcinoma, found particularly in women younger than the age of 40, is likely to be dependent on thyroid-stimulating hormone, and pituitary thyroid-stimulating hormone secretion can be suppressed by thyroxine administration, but no data are available concerning pain relief.

Side Effects

Endocrine therapy is generally much better tolerated than chemotherapy. None of these agents produces bone marrow suppression. Corticosteroids and high doses of medroxyprogesterone acetate (MPA), given for long periods of time, are associated with classic cushingoid side effects, and parenteral MPA can cause gluteal abscess (38).

Sex hormones, particularly estrogens, can cause intermittent uterine bleeding, which can be upsetting, especially for postmenopausal women. Androgens cause virilization and increased libido in some women. Estrogen given to men causes alopecia, testicular atrophy, gynecomastia, loss of libido, and impotence. Long-term administration of estrogen is also associated with a decrease in mortality from cardiac and cerebrovascular disease—presumably on the basis of favorable effects on lipoproteins—whereas androgens are thought to increase the risk of cardiovascular disease. Adrenalectomy causes side effects similar to those of estrogens, with the exception of the excess cardiovascular complications. Surgical adrenalectomy and hypophysectomy are both major operative procedures and carry a small but significant mortality risk. However, radiosurgical hypophysectomy using a gamma-knife is promising, as it has been reported to produce high incidences of pain relief with much less morbidity and virtually no mortality, although hormone replacement is required (40).

CHAPTER 38

Oral Mucositis in Cancer Patients

Joel B. Epstein and Mark M. Schubert

Pain in cancer patients may be related to the cancer or therapy of the malignant disease or may be unrelated the cancer or the therapy (Table 38-1) (see Chapter 35, Chapter 36 and Chapter 37). Pain caused by oral mucositis occurs secondary to tissue damage that results in erythema and ulceration. Ulcerative mucositis is a painful, debilitating condition that at times represents a dose- and rate-limiting toxicity of cancer chemotherapy and therapeutic irradiation. Sequelae consist of severe pain, increased risk for local and systemic infection, compromised oral and pharyngeal function, and bleeding that affect quality of life and increase the costs of care. Because oral pain associated with mucositis is the most common pain condition requiring management in patients receiving cancer treatment, this chapter reviews current strategies for managing oral mucositis as a means of preventing pain. This chapter also addresses the current approaches for pain management associated with oral mucositis. Finally, current research that may lead to improved management and prevention of oral mucositis is reviewed. Pain associated with head and neck cancer is discussed in Chapter 53.

I. Acute
1. Caused by disease: invasion of bone, nerve, muscle, mucosal damage; tumor pressure
2. Caused by cancer therapy: surgery, radiation therapy, and chemotherapy
a. Oral/dental pain: mucositis, infection, and neuropathy
3. Unrelated conditions causing pain
II. Chronic
1. Caused by persisting/progressive disease
2. Caused by cancer therapy: surgery, radiation therapy, and chemotherapy
a. Mucosal atrophy/xerostomia
b. Mucosal infection
c. Neuropathy
d. Temporomandibular (myofascial) disorders
e. Dental caries
f. Osteoradionecrosis/mucosal necrosis
g. Postherpetic neuralgia
h. Unrelated conditions causing pain

TABLE 38-1. Orofacial pain in cancer patients

EPIDEMIOLOGY

Mucositis is the most common cause of oral pain during treatment of cancer (1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28 and 29) (Table 38-2). Oral mucositis is a common complication resulting from bone marrow transplant (BMT) conditioning and is virtually universal in patients treated with tumoricidal radiation therapy that includes the oropharynx. The increasing use of more aggressive therapy to improve cancer cure rates has markedly increased the frequency and severity of oral complications. Changes in medical management include increased use of combined radiation and chemotherapy, hyperfractionation of radiation therapy, and increasingly aggressive BMT protocols, all of which result in increased toxicity (1,3,4,6,9,12,14,17,22,29). The use of growth factors to speed the recovery of the hematopoietic compartment has led to the recognition that oral mucositis has become a significant treatment-limiting complication in cancer therapy (30,31 and 32). Oral mucositis may also be coincident with toxicity at other sites, including venoocclusive disease (29) and gastrointestinal toxicity (33). The potential for systemic infection caused by oral opportunistic and acquired flora associated with oral mucositis has been documented in several studies of leukemia and BMT patients (34,35,36,37 and 38).

Acute pain during treatment:	
Oropharyngeal mucositis	
Chemotherapy	40–70%
Bone marrow transplant	60–85%
Radiation therapy	Up to 100%
Postsurgical therapy	Up to 100%
Chronic pain following cancer therapy	
Mucosal pain	Up to 33%
Pain associated with mucosal infection	
Candidiasis	
After bone marrow transplant	Up to 50%
After radiation therapy	20–33%
Herpes simplex in seropositive bone marrow transplant patients	Up to 90%
Neuropathy	16%
TMD/myofascial (patients with head and neck squamous cell carcinoma)	25–30%
TMD, temporomandibular disorder.	

TABLE 38-2. Frequencies of oral pain associated with cancer therapy

PATHOGENESIS

Intense cytotoxic chemotherapy and radiation therapy directly affect the proliferation of epithelial cells resulting in thinning of the epithelium and ultimately to loss of the barrier (Fig. 38-1 and Table 38-3). Mucosal damage is primarily related to the rate of cell proliferation of the epithelium. Epidermal growth factor (EGF) may increase the risk of mucositis, and cytokines that reduce epithelial cell proliferation may decrease the severity of tissue damage. Interaction with cytokines produced in the connective tissue such as granulocyte-macrophage stimulating factor (GM-CSF), tumor necrosis factor, and others may affect tissue damage. The oral microflora may play a role in the cause and progression of the mucosal damage, as suggested in studies of gram-negative bacterial flora in radiation-induced mucositis. The role

of the oral flora in chemotherapy-associated mucositis is not clear. The outcomes of infection caused by mucosal damage are conditioned by the potential effect of systemic therapy on the hematopoietic system and local and systemic immune function. Resolution of mucositis may be dependent on white blood cell function and the production of pluripotential growth factors (12,30,31,32 and 33). During resolution, cytokines inducing epithelial cell proliferation and migration, and angiogenic growth factors may play a role (39,40,41,42,43 and 44). Pain associated with mucositis is dependent on the degree of tissue damage, sensitization of nociceptors, and elaboration of inflammatory and pain mediators. The rate of resolution of mucositis appears to depend on epithelial growth and repair, recovery of white cell counts, and reduction of microbial and physical irritation in the mouth and likely reflects the complex interaction of various growth factors.

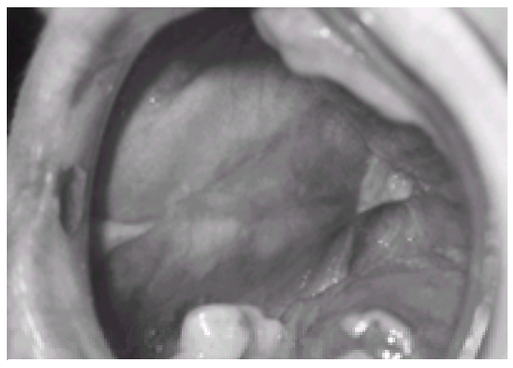

Figure 38-1. Mild mucositis with erythema and minor erosion of the cheek mucosa in a patient following autologous bone marrow transplant (at day +14). Mild mouth discomfort was reported.

Direct factors	Indirect factors
Radiation therapy	Myelosuppression
Dose/fraction	Immunosuppression
Total dose/days	T-cell loss/dysfunction
Chemotherapy	B-cell loss/dysfunction
Drug/dose/schedule	Reduced secretory IgA
Bone marrow transplant	Infections
Chemotherapy	Bacterial
Irradiation	Plaque control
Salivary gland dysfunction	Viral
Mucosal trauma	Herpes simplex
Physical	Varicella zoster
Chemical	Cytomegalovirus
Thermal	Other
Microbial flora	Fungal
Graft versus host disease	
Manifestations	
Prophylaxis	
Therapy	
Patient susceptibility	

TABLE 38-3. Factors contributing to oropharyngeal mucositis

ORAL MUCOSITIS

Bone Marrow Transplant

Ulcerative mucositis is the most common toxicity of BMT and treatment for hematologic cancer (14,15,20,22). Mucositis is more severe and of longer duration in patients with herpes simplex virus (HSV) reactivation and in those with poor oral hygiene (13,20,25,26). Reactivation of HSV is a contributor to severe ulcerative mucositis after BMT, especially in the first 30 days posttransplant (13,25,26). HSV prophylaxis has changed the frequency and severity of mucositis in BMT patients and represents an advance in prevention of ulcerative mucositis in at-risk patients. However, even in BMT patients provided acyclovir prophylaxis, oral ulcerative mucositis occurs in more than 75% of patients (15).

Mucositis begins at approximately 5 days after marrow infusion (day +5) with resolution in more than 90% of patients by day +15 when recovery of white cell count occurs (15). Damage to the mucosa most often presents in a bilateral pattern, primarily involving the cheeks, lip mucosa, lateral and ventral surfaces of the tongue, floor of the mouth, and soft palate. The mucosal reaction may begin shortly after exposure to the conditioning regimen and progress to erythema and ultimately ulceration (Fig. 38-2; see Fig. 38-1). Persistence of ulcers beyond day +15 occurs in patients who develop oral graft-versus-host disease and in patients who had more severe oral ulcerations. Increased mucosal toxicity is seen with the addition of total body irradiation (22,24,30). Mucositis is increased in BMT patients with xerostomia (23).

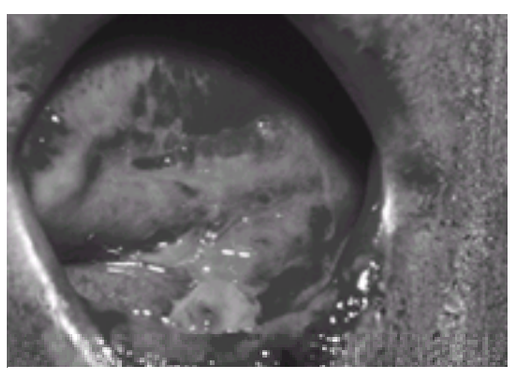

Figure 38-2. Severe ulcerated mucositis in a patient receiving an unrelated donor bone marrow transplant (day +14) requiring systemic opioid analgesic.

The influence of oral microflora and dental plaque on the severity of mucositis is increasingly clear (45,46,47,48,49,50 and 51). Intensive oral hygiene has been documented to reduce oral mucositis by 70% in BMT patients (45). The median time of onset of mucositis was delayed in the intensive oral care group (11 days versus 9 days) and the duration of moderate to severe mucositis was reduced. Septicemia was not increased in patients who continued intensive oral care (45). Immunoglobulins and other antimicrobial proteins in the saliva are dramatically decreased after BMT conditioning, which may be a factor in the increased risk of mucosal infection and in mucositis (33).

Radiation Therapy

Pain is commonly present at the time of diagnosis of head and neck and oral cancer (85%), although the pain is not severe (18,52). The presence and severity of pain are related to tumor stage, and pain is present in all cases with bone involvement (18). Pain occurs with treatment in all patients treated for oropharyngeal cancer and increases in severity throughout the course of radiation and persists after treatment (1,18,27,28) (see Chapter 37 and Chapter 53). Radiotherapy-related mucositis is the most frequent complication in patients submitted to irradiation for head and neck cancers (see Table 38-1). Mucositis affects the oral tissue involved in the primary treatment field, corresponding to the fields of irradiation and the dose of exposure, although considerable individual variability is seen (Fig. 38-3 and Fig. 38-4). Mucositis-related pain increases during radiation treatment, and typically resolves within 1 month. However, discomfort may continue for 6 to 12 months or longer, although the severity of pain decreases over time after treatment (18). Chronic complaints include mucosal sensitivity attributed to mucosal atrophy (33%), musculoskeletal syndromes (temporomandibular disorder) (25%), and neurologic syndromes attributed to deafferentation (16%) (18). In another study, the most

common persisting complaints after radiation treatment included xerostomia (57%), jaw pain involving the muscles of the jaw or joint pain (27%), and a 10% increased rate of dental caries (53). Pain may also be associated with other complications of radiation therapy including necrosis of bone and oral soft tissue. Chronic complications of radiation therapy were assessed in 676 head and neck cancer patients treated in a multicenter study (54). Eleven percent had severe complications (grade 3 or 4) involving the oral mucosa, bone, or muscle (54). Grade 3 mucosal change was defined as marked atrophy with complete dryness and ulceration; grade 3 muscle change was defined as severe induration and severe trismus; and grade 3 bone change was defined as pain or tenderness and bone exposure (54). These late complications were found to be related to total radiation dose; complications in bone were more common with large radiation fields, and complications in bone and muscle were related to fraction size. The severity of chronic mucosal damage may relate to severity of acute mucosal reaction.

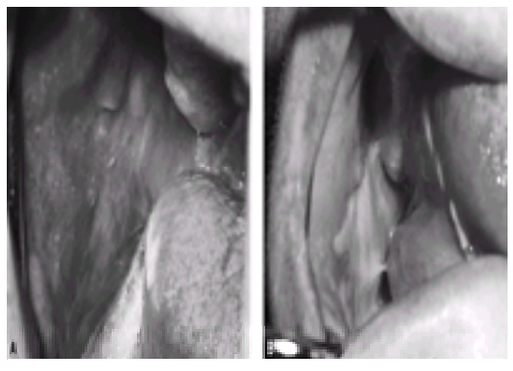

Figure 38-3. **A:** Initial tissue reaction in a patient receiving radiation therapy (dose received 1,400 cGy of planned 6,000 cGy) resulting in erythema and sensitivity of the right buccal mucosa. **B:** Late tissue reaction in the same patient receiving radiation therapy (total dose received 6,000 cGy) resulting in oral pain and mucosal ulceration within the radiation field.

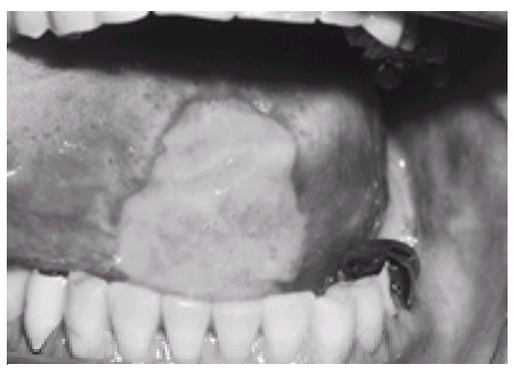

Figure 38-4. Localized ulcerative mucositis following brachytherapy for a squamous cell carcinoma of the middle portion of the lateral border of the tongue.

Combined Radiation Therapy with Surgery or Chemotherapy

Mucositis is a dose- and rate-limiting toxicity of the treatment for head and neck and oral cancer. The principal treatment-limiting side effect of head and neck cancer therapy is mucositis. Treatment of locally advanced head and neck carcinoma with surgery and radiotherapy is associated with significant treatment complications affecting oral function. Hyperfractionated radiotherapy and chemotherapy may improve survival, but treatment is frequently limited by the severity of oral toxicity (1,4,6,17,55,56). Severe oral mucositis occurs in all patients treated with accelerated fractionated irradiation for supraglottic cancer (1) and in those provided combined chemotherapy and radiation therapy (55,56). The primary factor limiting radiation treatment was severe mucositis, which caused considerable pain, limited oral intake, and required suspension of irradiation therapy (1,56). Changes in the delivery of radiotherapy including increasing total dose, hyperfractionation, and the combination of radiation therapy and chemotherapy have increased the severity of the resulting mucositis. Mucosal reactions in patients receiving radiation treatment for head and neck cancer are currently regarded as unavoidable side effects.

The importance of fungal colonization and infection in radiation mucositis is not clearly defined (57,58 and 59). In a group of patients receiving head and neck irradiation, patients on fluconazole developed one mycotic infection, and 14 nonscheduled breaks in radiation therapy occurred, compared with 19 fungal infections and 30 breaks in radiation therapy in those not on prophylaxis with fluconazole (57). However, others have not found an association between candidiasis or oral colonization and mucositis during cancer therapy (58,59).

PAIN ASSESSMENT

Most studies have used visual analogue scales or 5- or 10-point scales to assess oral pain (see Chapter 15 and Chapter 35). The McGill Pain Questionnaire has also been used (16,60). Approximately 90% of patients develop oral pain during BMT (16). The McGill Pain Questionnaire was compared with two different factor models in patients with oral mucositis pain after BMT, and it was recommended that a single pain rating may provide a better practical measurement (60). Clinically, patients may be unable or unwilling to complete lengthy questionnaires, particularly when their overall condition including pain is at its worst. Pain assessment may also be affected by use of systemic analgesics, which mask the pain experienced. Therefore, both pain and analgesic use need to be simultaneously assessed. Despite this, pain report is correlated with the severity of mucositis; most of the variance in pain report is explained by the severity of the mucositis rather than psychosocial variables (11).

MEDICAL MANAGEMENT OF ORAL MUCOSITIS

Most studies assessing management of oral mucositis involve small numbers of patients, and many suffer from use of outcome measures that are not validated and may lack sensitivity. Wide variation exists in quality of studies, making assessment of outcomes difficult and requiring reviewers to carefully assess the methods employed in the study. Guidelines for the use of outcome measures and approach to study design in management of mucositis may improve the value of many studies. Prevention and management of oral mucositis require an understanding of the multifactorial nature of the condition (Table 38-4).

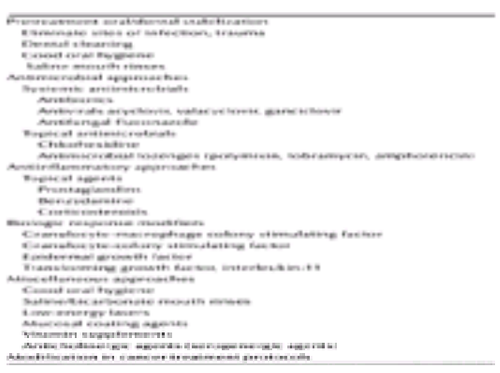

TABLE 38-4. Prevention and management of oral mucositis

Pain Management

Mucositis is the most common condition requiring the use of systemic analgesics during cancer therapy (5). Management of severe oropharyngeal mucositis often requires the use of systemic opioids. Guidelines are presented in Chapter 84.

Systemic analgesics should be prescribed following the World Health Organization analgesic ladder (21). These recommendations include the use of nonopioid analgesics alone, or in combination with opioids and adjunctive medications with increasing pain. In addition, analgesics should be provided on a time-contingent basis, with provision for management of breakthrough pain (see Chapter 83 and Chapter 84). In patients with oral mucositis pain, topical approaches should continue to be used in combination with systemic analgesics in order that the best pain management can be achieved with the least potent and lowest doses of systemic pain medications.

The equianalgesic dose of morphine and hydromorphone was evaluated in patient-controlled analgesia (PCA) in BMT patients with severe oral mucositis (61). A morphine to hydromorphone ratio of 3:1 was determined, which is different from doses in single- dose studies used in published dose equivalency recommendations (61). Another study assessed morphine or hydromorphone PCA use in preteen children during BMT (5). The median duration of PCA use was 19 days, depending on the severity of mucositis or other painful conditions. Ninety-five percent of children successfully mastered PCA to control pain associated with BMT. No instance of drug overdose or difficulty stopping the opioid was noted (5). Addiction is not a concern in oncology patients, rather the concern is with underuse and underdosing, leading to poor pain management (21). Another common concern is the lack of use of adjuvant analgesics and other methods of pain management in cancer patients (21).

Antimicrobial Approaches

Acyclovir prophylaxis in HSV-seropositive BMT patients is strongly supported in the literature. In HSV-seropositive BMT patients provided acyclovir prophylaxis, viral shedding was seen in 2.9% of patients, and one case of clinical HSV was diagnosed (62). Thus, acyclovir was confirmed as preventing HSV viral shedding in most cases. Oral ulcerations have been described caused by cytomegalovirus (CMV) in BMT (63). Acyclovir prophylaxis has also been shown to prevent shedding of CMV by one-half in BMT (64). In another study, shedding of CMV was detected in 13.3% of CMV-seropositive patients; however, no oral lesions consistent with CMV were identified. No correlation between severity of mucositis and serologic status of HSV or CMV was seen in patients provided acyclovir prophylaxis (62). Ganciclovir after engraftment in BMT has been shown effective in suppressing CMV infection (65).

Consecutive BMT recipients at risk of streptococcal bacteremia were treated for 5 days with clindamycin (900 mg intravenously three times a day) and ceftazidime (2 g three times a day) for the initial management of fever associated with severe oral mucositis (37). Bacteremia caused by *Viridans* streptococci occurred in 70% of patients when maximum mucositis was present, and culture results were positive a day before fever in approximately one-third of cases, indicating that mucosal ulceration predisposes to systemic infection by oral flora. Severe oral mucositis rather than infection appeared to induce fever, suggesting bacteremia caused by viridans streptococci may be a consequence of mucosal damage (37). These data indicate that rather than an antimicrobial approach, it may be more important to develop strategies that minimize mucosal damage in BMT (37).

In a series of patients with leukemia and BMT, fluconazole prophylaxis was compared with no prophylaxis (59). Although no differences in oropharyngeal or systemic candidiasis were seen, a trend to reduction in oropharyngeal colonization by *Candida albicans* was seen ($p = .07$). No relationship was seen between *Candida* species, antifungal prophylaxis, and mucositis, indicating that *Candida* was not involved in the etiology of mucosal damage in these patients (58). In a randomized controlled trial, fluconazole prevented systemic fungal infections (7% of fluconazole versus 18% of placebo patients) (66). The incidence of mucosal infection and oropharyngeal colonization by *C. albicans* was also significantly reduced. Fluconazole should be considered for prophylaxis of infection by *C. albicans* in BMT patients.

Antiinflammatory Approaches

Antiinflammatory approaches for prevention of mucositis have received preliminary study. Patients undergoing BMT received prostaglandin E_2 (Prostin E2, 0.5 mg per tablet) or placebo for prophylaxis of oral mucositis (67). The incidence, severity, and duration of oral mucositis were similar for both groups. However, the incidence of HSV infection was higher in patients receiving prostaglandin, and in these patients more severe oral mucositis was seen. These results indicate that prostaglandin E_2 is not a candidate for prophylaxis of mucositis in BMT recipients (67). Studies using other antiinflammatory medications or combinations with antiviral prophylaxis should be considered.

Pentoxifylline and methylprednisolone were provided to 12 BMT patients, and oral mucositis was assessed (7). The most common site of toxicity was the mouth (87.5%). Mucositis was less severe in patients receiving pentoxifylline and methylprednisolone, and pain medications were required less often in these patients (7). This trial could not determine if pentoxifylline or methylprednisolone or both may have had an effect on mucositis and further study is needed.

Xerostomia

Mucosal toxicity is dose limiting for patients on etoposide and may be related to direct effects of myoablative doses of etoposide on the mucosa that are secreted in saliva (19). Twelve patients received propantheline, 30 mg (an anticholinergic xerostomia-inducing agent), or placebo orally every 6 hours for six doses (19). Mucositis was less frequent and less severe ($p = .05$) in the propantheline arm. Another study investigated the effect of drug-induced xerostomia on mucositis during BMT by comparing patients with historic controls (68). Propantheline was found to significantly reduce oral mucositis, caused by high-dose etoposide, although no effect was seen in esophagitis and enteritis. Minor toxicities included constipation and asymptomatic tachycardia, and clinically significant toxicity was seen in two patients (tachycardia, urinary retention) (68). These studies suggest that for chemotherapeutics that are secreted in saliva, xerostomia may decrease the contact time of the chemotherapeutic to the mucosa and thereby reduce tissue damage.

Miscellaneous Approaches

Sixty-three patients with oral carcinoma treated with concomitant chemoradiotherapy were assigned to daily azelastine (2 mg) (69). Mucositis was mild in 21 patients and ulceration with severe pain was seen in 16 patients on azelastine, whereas, in the control group, mild reactions were observed in five cases, and severe mucositis occurred in 21 patients (69). Azelastine may suppress neutrophil respiratory burst activity by suppressing cytokine release from lymphocytes. Further study of azelastine for treatment of mucositis is indicated. An extensive analysis of the literature showed that external beam radiotherapy provided effective pain relief or substantial reduction of pain caused by skeletal metastases in nearly all cases (70). Systemic radiotherapy using radionuclides may be indicated for generalized skeletal pain in patients with metastatic disease (70,71). However, optimal doses and fractionation have not been established. Management of bone pain caused by metastatic disease has been assessed using strontium 89 and local radiation therapy (71). A common side effect of strontium 89 is bone marrow suppression, although this may not be clinically significant in patients with a pretreatment platelet count of more than 60,000 per µL and a white blood cell count of more than 2,400 per µL (71).

TOPICAL APPROACHES TO MANAGEMENT OF ORAL MUCOSITIS

Although no studies exist demonstrating the effectiveness of saline or bicarbonate rinses in decreasing mucositis, the use of frequent oral rinses is commonly included in oral care protocols. Also, because many institutions recommend frequent oral rinsing, these recommendations become incorporated into studies as a baseline oral care standard.

Forty patients undergoing radiotherapy to more than 50% of the oral cavity were randomized to an oral care protocol using either saline or hydrogen peroxide rinses (72). No significant differences were seen in mucositis, although oral sensitivity was greater in those using peroxide (72).

Topical tretinoin cream was assessed in six BMT patients beginning at day –7 and continuing until day +21 (73). This preliminary study showed a reduction in the severity of mucositis in those on tretinoin and fewer of these patients required systemic analgesics.

Topical Antimicrobials

Chlorhexidine has been assessed in BMT patients in a number of studies and conflicting results with the use of chlorhexidine in mucositis have been seen. The majority of studies do not demonstrate a prophylactic effect on mucositis, although a tendency to reduced oral colonization of *Candida* species has been seen in several studies (74). The effect of oral hygiene may represent a confounding factor in these studies. The effect of chlorhexidine rinsing on plaque levels, gingival inflammation, and caries risk have not been the primary end points in these studies, but may be valuable effects of chlorhexidine during cancer therapy.

Studies of an antimicrobial lozenge combining polymixin, tobramycin, and amphotericin B in head and neck radiation therapy have shown that ulcerative mucositis is prevented (75). The effect was attributed to a reduction in gram-negative bacteria. Double- blind studies are ongoing.

Miscellaneous Approaches

Coating agents used as oral rinses in patients with mucositis, such as milk of magnesia, liquid Amphojel, and loperamide (Kaopectate) have been recommended frequently, but have not been subjected to double-blind studies (21).

Sucralfate suspension has been studied in mucositis (76,77,78 and 79). Less severe mucositis has been reported with use of sucralfate (76,77 and 78), but not in all reports (79). A randomized prospective trial of sucralfate prophylaxis of oral mucositis during radiation therapy delivered with high daily fractions did not show a significant difference in mucositis (79). Less oral pain was reported early during radiation therapy in the sucralfate group (79). The lack of effect of sucralfate in this study may be caused by the large daily fractions of irradiation provided or the limited action of sucralfate in preventing oral mucositis. Another study showed reduced pain and a reduction in potentially pathogenic organisms (78). Taken together, the studies of sucralfate are inconclusive, and further studies are needed to determine if sucralfate reduces pain and mucosal damage during cancer therapy.

Lidocaine viscous is frequently recommended, although no studies are available that assess the benefit or the potential for toxicity with use in cancer patients (21). Lidocaine may result in burning with use, obtund taste, and the gag reflex, and may have cardiovascular and CNS effects. Other topical anesthetics also have been used including dyclonine HCl, which may be better accepted than lidocaine by patients. Benzydamine HCl (Tantrum rinse, 3M-Riker Canada; Difflam, 3M United Kingdom) has been shown to reduce mucositis and associated oral pain in radiation-induced mucositis (21,28). The mucosal effects include mild anesthesia and analgesia. Controlled studies of benzydamine rinse in chemotherapy-induced mucositis remain to be conducted. Local applications of topical anesthetic creams or gels may be useful for local painful mucosal ulcerations.

Topical capsaicin was assessed in a phase I study of mucositis pain (10). Oral capsaicin in a taffy-candy vehicle produced partial and temporary pain reduction in 11 patients with oral mucositis pain (10). The findings suggest that some of the pain of mucositis is mediated by substance P.

Radiation shields are often suggested during radiation therapy. The use of midline mucosa-sparing blocks for protection of the mucosa during radiation therapy resulted in less weight loss, fewer hospitalizations for nutritional support, and a trend toward fewer treatment interruptions ($p = .07$) than in control patients (8). Unfortunately, mucositis was not directly assessed.

Biological Response Modifiers and Cytokines

Studies have been conducted assessing the potential of growth factors to affect oral mucositis using a cheek pouch model of mucositis in Syrian Golden hamsters (39,40,41,42,43 and 44). The animal model yields mucositis in the hamster cheek pouch after infusion of 5-FU and local mucosa trauma. Outcome measures used in this model included assessment of severity of mucosal damage, weight loss, and survival. EGF was shown to increase the severity of mucosal damage when given concurrently with chemotherapy in the hamster model (80). Transforming growth factor-b_3 (TGF-b_3) given after chemotherapy has been shown to reduce the incidence, severity, and duration of mucositis, reduce weight loss, and increase survival of animals (41,43). Topical transforming growth factor (TGF) reduces the proliferation of oral epithelial cells *in vitro* and *in vivo* (41,43). The mechanism may be reduction in proliferation of the basal epithelial cells, as measured by proliferating cell nuclear antigen and DNA ploidy (41). Interleukin-11 (IL-11) has been shown to cause dose-dependent and statistically significant reduction in mucositis ($p < .05$) (39,40,44). Survival was 85% on IL-11 versus 46% in placebo, and less weight loss was seen in the IL-11 group. The lack of change in bone marrow cellularity suggests that the effects of IL-11 are caused by direct epithelial or connective tissue effects (39). A rat model of inflammatory bowel disease also showed reduction in gross and microscopic damage to the colon in animals treated with IL-11 (44).

EGF in saliva was assessed in patients receiving head and neck radiation therapy (42). The quantity of EGF in the oral environment decreased because of decreased volume of saliva and decreased in concentration per milliliter of saliva as mucositis increased throughout the course of radiation therapy (42). EGF may represent a marker for mucosal damage and has the potential to promote resolution of radiation-induced mucositis. Further study is required.

Several studies in humans have assessed the potential effect of GM-CSF on oral mucositis (30,31 and 32). In 20 patients treated for squamous cell carcinoma GM-CSF significantly reduced the incidence, duration, and severity of oral mucositis (81). An initial study of 14 head and neck cancer patients receiving radiotherapy treated with GM-CSF when mucositis developed showed that 79% of patients had reduction in severity of the reaction (82). In 26 children receiving BMT, the duration of mucositis was reduced in the GM-CSF group, although the severity of the mucosal reaction was not affected (30). Oral mucositis was improved in eight BMT patients who received topical GM-CSF compared with historic controls (32). A study of BMT for 22 patients provided granulocyte colony stimulating factor (G-CSF) versus 24 not given G-CSF found the most common toxicity was oral mucositis (38%) (12). Posttransplant G-CSF resulted in a trend toward a reduction in severity of mucositis ($p = .07$) (12). A multicenter controlled trial of G-CSF administration after BMT showed that G-CSF resulted in acceleration of neutrophil recovery. The length of stay in hospital was reduced; however, no difference in mucositis was seen (33). Further multicenter studies of GM-CSF and possibly G-CSF on prevention of oral mucositis appear warranted.

Miscellaneous Approaches

Low-energy lasers have been studied in the prevention and management of mucositis associated with BMT (83,84). The mechanism of action may be caused by effects of cytokine release caused by laser exposure of the tissue, but further study is needed. The helium-neon laser was assessed in 30 consecutive patients receiving peripheral stem cell BMT who received daily treatment from day -5 to day +1 (83). Reduced occurrence and duration of ulcerative mucositis as well as reduced oral pain and opioid use were seen. The requirement for parenteral nutrition was not reduced. Another study investigated unilateral application of helium-neon laser in 20 BMT patients (84). Oral mucositis and pain scores were significantly lower for the treated versus the untreated side (84). Further study is needed to determine the efficacy of low-energy laser in preventing mucositis.

COGNITIVE AND BEHAVIORAL INTERVENTIONS

There has been limited study of the use of these approaches to pain management (see Chapter 88, Chapter 89, Chapter 90, Chapter 91 and Chapter 92). Although relaxation, imagery, biofeedback, hypnosis, and transcutaneous electrical nerve stimulation have been employed in the management of cancer pain, few controlled studies have been conducted (21). The use of hypnosis also has been shown to be a valuable adjunct in cancer pain (85,86).

A survey of pediatric oncology and BMT centers was conducted to determine the cognitive behavioral interventions used (87). Interventions, such as providing information before procedures and positive reinforcement after procedures, were used more frequently than behavioral interventions, such as rhythmic breathing, distraction, and imagery, that require more time and training. Psychological services were primarily available on an as-needed basis and support groups were not generally offered. Increasing emphasis on psychological support and techniques for pain management may be useful for patients during BMT.

A controlled clinical trial of psychological interventions as adjuncts to medical treatment in cancer-related pain was conducted (88). This study assessed oral mucositis pain in 94 BMT patients in four groups: standard treatment, therapist support, relaxation and imagery training, and cognitive-behavioral coping skills combined with relaxation and imagery (88). It was shown that relaxation and imagery training reduces pain associated with oral mucositis and that adding cognitive-behavioral skills to relaxation and imagery did not improve pain relief (88).

SUMMARY

The study of pain management in oncology has focused on pain caused by oral mucositis because of the frequency of this complication, the effect oral symptoms have on patient quality of life, and the implications for medical management. Pain in the head and neck and oropharynx of cancer patients is a significant factor in the quality of life. Mucosal damage, particularly in the presence of immunosuppression and neutropenia, may result in risk of systemic infection (Fig. 38-5). Oropharyngeal pain in cancer patients frequently requires systemic analgesics, adjunctive medications, physical therapy, and psychological therapy, in addition to oral care and topical treatments (see Table 38-4). Good oral hygiene reduces the severity of oral mucositis and does not increase the risk of bacteremia.

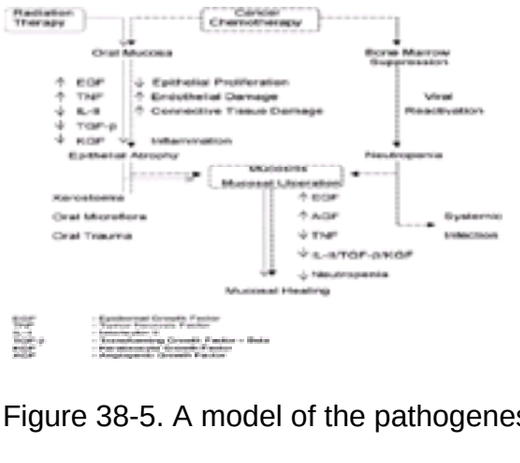

Figure 38-5. A model of the pathogenesis of oral mucositis.

Clinically apparent mucositis is the result of a number of toxicities and tissue damage and inflammation. The primary event is cell damage from chemotherapy, radiotherapy, or both. Secondary influences include indirect toxicities resulting in immunosuppression, neutropenia, reactivation of latent virus (herpes viruses), and opportunistic microbial (bacterial and fungal) infections. Salivary gland dysfunction caused by dehydration and direct effects of the cancer therapy on gland function may alter the local mucosal defenses. Because the etiology is multifactorial (see Table 38-3), approaches to prevention and treatment have been multifactorial (see Table 38-4). Effective prevention and management of mucositis affect the pain experienced during cancer treatment. When mucositis is present, symptomatic management is needed (Table 38-5).

Maintain good oral hygiene
Prevent mucosal damage (see Table 38-2)
Coating agents (milk of magnesia, aluminum hydroxide gel (Amphojel), sucralfate, loperamide (Kaopectate), and so forth)
Topical analgesic/antiinflammatory (benzydamine)
Topical anesthetics
Systemic analgesics
Adjuvant systemic medications
Adjuvant cognitive/psychological support
Physical therapy (rinsing, ice chips)
Miscellaneous agents

TABLE 38-5. Symptomatic management of pain of oral mucositis

Systemic analgesics are important in pain management, and continuing study has involved determination of dose and route of administration. Pain management approaches in addition to systemic analgesics of potential interest are agents that affect neurotransmitters of pain such as substance P. Research in topical analgesic and antiinflammatory agents is ongoing.

A number of approaches appear to be viable candidates for further study. Biological response modifiers offer the potential for prevention and to speed healing. Initial studies with G-CSF have been encouraging; however, the reports with GM-CSF have been less positive. Other cytokines will enter clinical trial in the near future and offer the potential for reduction of epithelial cell sensitivity to toxic effects of cancer therapy or to stimulate repair of the damaged tissue. Other approaches include the use of xerogenergic medications to reduce exposure of the oral mucosa to chemotherapeutic drugs that are secreted in saliva. Antimicrobial approaches have met with conflicting results, with little effect of chlorhexidine and systemic antimicrobials in preventing mucositis in radiation patients. In BMT and leukemic patients chlorhexidine may not prevent mucositis, although there may be an effect on *Candida* carriage. Initial studies of a topical antimicrobial lozenge (polymixin, tobramycin, and amphotericin B) have shown reduction in ulcerative mucositis during radiation therapy. Other approaches that require further study include low-energy lasers and antiinflammatory medications. These approaches to management have had initial study, but additional research is needed to determine effectiveness of newer approaches to prevention of mucositis and symptom management as well as to determine the appropriate dose and frequency of the intervention.

CHAPTER 39

*Pain in Human Immunodeficiency Virus Disease**

William Breitbart

Studies conducted between 1990 and 1995 have documented that pain in individuals with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) is highly prevalent, diverse, and varied in syndromal presentation; associated with significant psychological and functional morbidity; and alarmingly undertreated (1,2,3,4,5,6,7,8,9,10 and 11). With the introduction of highly active antiretroviral therapies (i.e., combination therapies including protease inhibitors) the face of the AIDS epidemic, particularly for those who can avail themselves of and tolerate these new therapies, is indeed changing. Death rates from AIDS in the United States have dropped dramatically since 1997, and rates of serious opportunistic infections and cancers are declining. Despite these hopeful developments, the future is still unclear, and millions of patients with HIV worldwide continue to die of AIDS and suffer from the enormous burden of physical and psychological symptoms. Even with the advances in AIDS therapies, pain continues to be an issue in the care of patients with HIV. As the epidemiology of the AIDS epidemic changes in the United States, the challenge of managing pain in AIDS patients with a history of substance abuse is becoming an ever-growing challenge. Pain management needs to be more integrated into the total care of patients with HIV. This chapter describes the prevalence and types of pain syndromes encountered in patients with HIV, and discusses the effect of pain on quality of life. Principles of pain management in AIDS, including pharmacologic and nonpharmacologic interventions, are described. In addition, undertreatment of pain in AIDS, barriers to adequate pain treatment in this population, and guidelines for the management of pain in HIV-infected patients with a history of substance abuse are presented.

PREVALENCE OF PAIN IN HUMAN IMMUNODEFICIENCY DISEASE

Estimates of the prevalence of pain in HIV-infected individuals have been reported to range from 30% to over 90%, with the prevalence of pain increasing as the disease progresses (3,11,12,13,14 and 15), particularly in the latest stages of illness.

Studies suggest that approximately 30% of ambulatory HIV-infected patients in early stages of HIV (pre-AIDS; category A or B disease) experience clinically significant pain, and as many as 56% have had episodic painful symptoms of less clear clinical significance (4,6,11). In a prospective cross-sectional survey of 438 ambulatory AIDS patients in New York City, 63% reported “frequent or persistent pain of at least two weeks' duration” at the time of assessment (4). The prevalence of pain in this large sample increased significantly as HIV progressed, with 45% of AIDS patients with category A3 disease reporting pain, 55% of those with category B3, and 67% of those with category C1, 2, or 3 disease reporting pain. Patients in this sample of ambulatory AIDS patients also were more likely to report pain if they had other concurrent HIV-related symptoms (e.g., fatigue, wasting), had received treatment for an AIDS- related opportunistic infection, or if they had not been receiving antiretroviral medications [e.g., zidovudine (AZT), didanosine (ddI), zalcitabine (ddC), stavudine (D4T)].

In a study of pain in hospitalized patients with AIDS in a public hospital in New York City, over 50% of patients required treatment for pain, with pain being the presenting complaint in 30% and the second most common presenting problem after fever (7). In a French multicenter study, 62% of hospitalized patients with HIV had clinically significant pain (6). Schofferman and Brody (15) reported that 53% of patients with far advanced AIDS cared for in a hospice setting had pain, whereas Kimball and McCormack (13) reported that up to 93% of AIDS patients in their hospice experienced at least one 48-hour period of pain during the last 2 weeks of life.

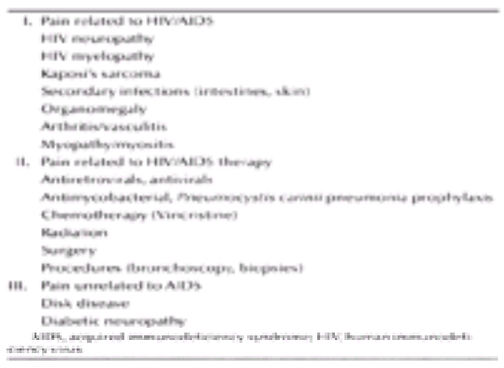
Larue and colleagues (14) demonstrated that patients with AIDS being cared for by hospice at home had prevalence rates and intensity ratings for pain that were comparable with, and even exceeded, those of cancer patients. Breitbart and colleagues (3) reported that ambulatory AIDS patients in their New York City sample reported a mean pain intensity “on average” of 5.4 (on the 0 to 10 numeric rating scale of the Brief Pain Inventory) and a mean pain “at its worst” of 7.4. In addition, as with pain prevalence, the intensity of pain experienced by patients with HIV increases significantly as disease progresses. AIDS patients with pain, like their counterparts with cancer pain, typically describe an average of 2.5 to 3.0 concurrent pains at a time (3,5).

PAIN SYNDROMES IN HUMAN IMMUNODEFICIENCY VIRUS AND ACQUIRED IMMUNODEFICIENCY SYNDROME

Etiologies and Classification

Pain syndromes encountered in AIDS are diverse in nature and etiology. The most common pain syndromes reported in studies to date include painful sensory peripheral neuropathy, pain caused by extensive Kaposi's sarcoma, headache, oral and pharyngeal pain, abdominal pain, chest pain, arthralgias and myalgias, as well as painful dermatologic conditions (4,5,7,9,11,12,14,15 and 16). In a sample of 151 ambulatory AIDS patients who underwent a research assessment that included a clinical interview, neurologic examination, and review of medical records (5), the most common pain diagnoses included headaches (46% of patients, 17% of all pains), joint pains (arthritis, arthralgias, and so forth in 31% of patients; 12% of pains), painful polyneuropathy (distal symmetric polyneuropathy in 28% of patients, 10% of pains), and muscle pains (myalgia, myositis in 27% of patients; 12% of pains). Other common pain diagnoses included skin pain (Kaposi's sarcoma, infections in 25% of patients; 30% of homosexual men in the sample had pain from extensive Kaposi's sarcoma lesions), bone pain (20% of patients), abdominal pain (17% of patients), chest pain (13%), and painful radiculopathy (12%). Patients in this sample had a total of 405 pains (averaging three concurrent pains), with 46% of patients diagnosed with neuropathic-type pain, 71% with somatic pain, 29% with visceral pain, and 46% with headache (classified separately because of controversy as to pathophysiology). When pain type was classified by pains (as opposed to patients) 25% were neuropathic pains, 44% were nociceptive-somatic, 14% were nociceptive-visceral, and 17% were idiopathic-type pains. Patients in this study with lower $CD4^{+}$ cell counts were significantly more likely to be diagnosed with polyneuropathy and headache. Hewitt and colleagues (5) demonstrated that although pains of a neuropathic nature (e.g., polyneuropathies and radiculopathies) certainly make up a large proportion of pain syndromes encountered in AIDS patients, pains of a somatic nature, visceral nature, or both are also extremely common.

Pain syndromes seen in HIV can be categorized into three types (Table 39-1): (a) those directly related to HIV infection or consequences of immunosuppression; (b) those caused by AIDS therapies; and (c) those unrelated to AIDS or AIDS therapies (2,5). In studies to date, approximately 45% of pain syndromes encountered are directly related to HIV infection or consequences of immunosuppression; 15% to 30% are caused by therapies for HIV- or AIDS-related conditions, as well as diagnostic procedures; and the remaining 25% to 40% are unrelated to HIV or its therapies (5).



I.	Pain related to HIV/AIDS
	HIV neuropathy
	HIV myelopathy
	Kaposi's sarcoma
	Secondary infections (intestines, skin)
	Organomegaly
	Arthritis/vasculitis
	Myopathy/myositis
II.	Pain related to HIV/AIDS therapy
	Antiretrovirals, antivirals
	Antimycobacterial, *Pneumocystis carinii* pneumonia prophylaxis
	Chemotherapy (Vincristine)
	Radiation
	Surgery
	Procedures (bronchoscopy, biopsies)
III.	Pain unrelated to AIDS
	Disk disease
	Diabetic neuropathy

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

TABLE 39-1. Pain syndromes in acquired immunodeficiency syndrome

Our group at Memorial Sloan-Kettering has reported on the experience of pain in women with AIDS (5,16). Although preliminary in nature, our studies suggest that women with HIV experience pain more frequently than men with HIV and report somewhat higher levels of pain intensity. This may in part be a reflection of the fact that women with AIDS-related pain are twice as likely to be undertreated for their pain compared with men (3). Women with HIV have unique pain syndromes of a gynecologic nature specifically related to opportunistic infectious processes and cancers of the pelvis and genitourinary tract. Women with AIDS were significantly more likely to be diagnosed with radiculopathy and headache in one survey (5).

Children with HIV infection also experience pain (17). HIV-related conditions in children that are observed to cause pain include meningitis and sinusitis (headaches); otitis media; shingles; cellulitis and abscesses; severe *Candida* dermatitis; dental caries; intestinal infections, such as *Mycobacterium avium intracellulare* (MAI) and cryptosporidium; hepatosplenomegaly; oral and esophageal candidiasis; and spasticity associated with encephalopathy that causes painful muscle spasms.

Specific Pain Syndromes in Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

The following section reviews, in detail, the various painful manifestations of HIV. The author acknowledges the important review by O'Neill and Sherrard (9) that formed the basis of this section on specific pain syndromes in HIV.

Gastrointestinal Pain Syndromes

Many of the opportunistic infections and HIV-associated neoplasms may present as pain referable to the gastrointestinal tract. Generally, the pain is alleviated by specific treatment of the causative diseases. Adequate analgesia should be provided during diagnostic assessment (9).

Oropharyngeal Pain

Oral cavity and throat pain is common, accounting for approximately 20% of the pain syndromes encountered in one study (7,18,19) (see Chapter 38). The sources of oral cavity pain have been well described (9). Oropharyngeal candidiasis occurs in up to 75% of HIV- positive individuals and, although frequently asymptomatic, it is the most common cause of oral cavity pain. Bacterial infections are mainly seen as necrotizing gingivitis and can arise in HIV-positive patients in spite of maintaining a good standard of oral hygiene (9). Dental abscesses occur more commonly in HIV-infected individuals than in the general population. Oral ulcerations are extremely common and can be the result of herpes simplex virus, cytomegalovirus (CMV), Epstein-Barr virus, atypical and typical mycobacterial infection, cryptococcal infection, or histoplasmosis. Frequently, no infectious agent can be identified, and these painful aphthous ulcers are a clinically challenging problem (9). Up to 75% of patients with cutaneous Kaposi's sarcoma also have intraoral lesions, most commonly on the palate, although these seldom cause pain (9).

Esophageal Pain

Approximately one-third of patients with HIV experience esophageal symptoms such as dysphagia or pain on swallowing (odynophagia) often caused by esophageal candidiasis. Esophageal candidiasis occurs in as many as 75% of patients with HIV disease (20,21 and 22) and may present as dysphagia or odynophagia. Ulcerative esophagitis, which can be quite painful, is usually a result of CMV infection but can be idiopathic. Infectious causes of esophagitis include herpes simplex, Epstein-Barr virus, mycobacteria, *Cryptosporidium*, and *Pneumocystis carinii* (21,22,23,24, and 25). Kaposi's sarcoma and lymphoma both have been reported to invade the esophagus, resulting in dysphagia, pain, and ulceration (9). AZT has also been reported to be a cause of esophageal ulceration (26).

Abdominal Pain

Abdominal pain is the primary site of pain in 12% to 25% of patients with HIV (5,7,27). Infectious causes of abdominal pain predominate and include cryptosporidiosis, *Shigella*, *Salmonella*, and *Campylobacter* enteritis, CMV ileitis, and mycobacterial (MAI) infection. Perforation of the small and large intestine secondary to CMV infection has been described (27). Repeated intussusception of the small intestine has been seen in association with *Campylobacter* infection (27). Lymphoma in the gastrointestinal tract can present with abdominal pain and intestinal obstruction (28). Kaposi's sarcoma spreads to the gastrointestinal tract of 40% to 50% of AIDS patients with cutaneous lesions (29). Rarely, intestinal Kaposi's sarcoma may cause obstruction, bleeding, perforation, and diarrhea (30). Other causes of abdominal pain in HIV-positive patients (9) include ileus, organomegaly, spontaneous aseptic peritonitis, toxic shock, herpes zoster, and Fitz-Hugh-Curtis syndrome (perihepatitis in association with tubal gonococcal or chlamydia infection).

Biliary Tract and Pancreatic Pain

Cholecystitis may occur in HIV-infected patients as a result of opportunistic infection, CMV and cryptosporidiosis being the most common infectious agents. Extrahepatic biliary tract obstruction secondary to Kaposi's sarcoma or MAI infection has been reported (9). Sclerosing cholangitis (CMV, cryptosporidiosis), also known as AIDS cholangiopathy, is another cause of right upper quadrant or epigastric pain (31). Opportunistic liver infections (CMV, MAI, fungal infections) as well as drug-induced hepatic toxicities (ddI, pentamidine) are sources of hepatitis and abdominal or right upper quadrant pain (32).

Pancreatitis is often related to adverse effects of HIV-related therapies, in particular the antiretroviral agents ddI and ddC. Between 7% and 10% of patients on ddI develop pancreatitis, and lower rates are reported with other antiretrovirals. Intravenous pentamidine is also associated with pancreatitis. Infectious causes of pancreatitis include CMV infection, MAI infection, and cryptococcal infection (33). Rarely, lymphoma or Kaposi's sarcoma may involve the pancreas, resulting in pancreatitis.

Anorectal Pain

Painful anorectal diseases are common, occurring in approximately one-third of homosexual men with HIV. Infectious causes of anorectal pain include perirectal abscesses, CMV proctitis, fissure-in-ano, and herpes simplex virus infection. A small increase has been noted in anal and anorectal carcinoma in HIV-positive homosexual men (34).

Chest Pain Syndromes

Chest pain is a common complaint in patients with HIV, making up approximately 13% of the pain syndromes encountered in a sample of ambulatory AIDS patients (5). Sources of chest pain in patients with HIV are similar to those encountered in the general population (i.e., cardiac, esophageal, lung and pleura, and chest wall); the etiologies may be somewhat unique (i.e., opportunistic infections and cancers). In immunosuppressed patients, infectious causes of chest pain should be considered, particularly in the presence of fever and some localizing sign such as dysphagia, dyspnea, or cough. Infectious causes of chest pain include *Pneumocystis* pneumonia (with or without a pneumothorax), esophagitis (CMV, candidiasis, herpes simplex), pleuritis and pericarditis (viral, bacterial, tuberculous), and postherpetic neuralgia. Opportunistic cancers (Kaposi's sarcoma, lymphoma) invading the esophagus, pericardium, chest wall, lung, and pleura may be sources

of chest pain. Rarely, pulmonary embolus or bacterial endocarditis may be the cause of chest pain.

NEUROLOGIC PAIN SYNDROMES IN ACQUIRED IMMUNODEFICIENCY SYNDROME

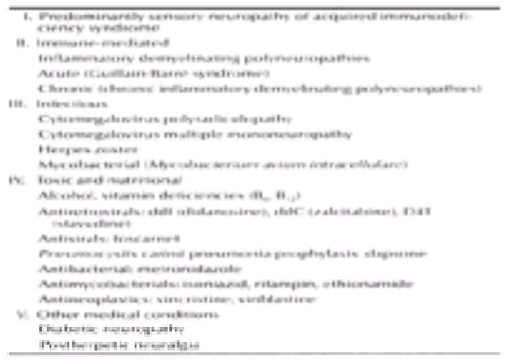
Pain syndromes originating in the nervous system include headache, painful peripheral neuropathies, radiculopathies, and myelopathies. The HIV virus is highly neurotropic, invading central and peripheral nervous system structures early in the course of HIV. As many as 75% of patients with late-stage AIDS have a neurologic complication (35,36,37,38 and 39) either directly caused by HIV itself (e.g., AIDS dementia, HIV peripheral neuropathy, HIV myelopathy) or secondary to opportunistic infection [e.g., central nervous system (CNS) toxoplasmosis, CMV neuropathy], cancer (e.g., CNS lymphoma), or medication side effects (toxic neuropathies caused by ddI, ddC, D4T, or AZT-induced headache). Headache is a frequent symptom in HIV-infected patients and may be an important indication of disease of the CNS including opportunistic infections and cancers. Rarely, cerebrovascular events (e.g., thalamic stroke) occurring in hypercoagulable states can result in central pain syndromes.

Headache

Headache is extremely common, reported by 40% to 50% of patients with HIV disease, particularly in the later stages of illness (5,40). Headache poses a diagnostic dilemma for physicians in that the underlying cause may range from benign stress and tension to life-threatening CNS infection (9) (see Chapter 48). The differential diagnosis of headache in patients with HIV includes HIV encephalitis and atypical aseptic meningitis, opportunistic infections of the nervous system, AIDS-related CNS neoplasms, sinusitis, tension, migraine, and AZT-induced headache (41). Toxoplasmosis and cryptococcal meningitis are the two most commonly encountered opportunistic infections of the CNS in patients with HIV (37). Cerebral toxoplasmosis usually presents with persistent headache, sometimes associated with focal signs, change in mental status, or seizures. Diagnosis is based on radiologic imaging (magnetic resonance imaging is more sensitive than computed tomography) with a characteristic appearance of multiple deep ring-enhancing lesions and a clinical response to a trial of empiric treatment for toxoplasmosis. A brain biopsy is sometimes necessary to establish a definitive diagnosis and to differentiate cerebral toxoplasmosis from cerebral lymphoma. Cryptococcal meningitis usually presents with symptoms of headache, neck stiffness, and recurring fever, although focal neurologic signs may occur. Other opportunistic infections of the CNS that can present as headache in the AIDS patient include CMV, herpes simplex virus and herpes zoster, progressive multifocal leukoencephalopathy (papovavirus), *Candida albicans*, *Mycobacterium tuberculosis*, MAI, and neurosyphilis. Headache related to sinus infection is common in immunocompetent patients with HIV who present with headache, but have no focal neurologic signs. Opportunistic cancers of the CNS include CNS lymphoma, metastatic systemic lymphoma, and metastatic intracranial Kaposi's sarcoma. These can present, particularly in the immunocompromised patient with HIV, with signs of increased intracranial pressure with or without focal neurologic signs, as well as fever and meningismus. More benign causes of headache in the patient with HIV include AZT-induced headache, occurring in 15% to 30% of patients; tension headache; migraine with or without aura, and unclassifiable or idiopathic headache (41,42).

Neuropathies Encountered in Patients Infected with Human Immunodeficiency Virus

Pain syndromes of a neuropathic nature occur in approximately 40% of AIDS patients with pain (5) (see Chapter 19). Although several types of peripheral neuropathies have been described in patients with HIV and AIDS (Table 39-2), the most common painful neuropathy encountered is the predominantly sensory neuropathy of AIDS, affecting up to 30% of people with HIV infection. Other potentially painful neuropathies encountered in HIV and AIDS patients, however, can be caused by viral and nonviral infectious processes (mononeuritis multiplex, including polyneuritis cranialis, polyradiculopathy of the lower limbs, cauda equina syndrome, and plexopathies caused by CMV, herpes zoster virus, MAI), immune-mediated inflammatory demyelination (acute and chronic Guillain-Barré syndrome), a variety of medical conditions (diabetic neuropathy, postherpetic neuralgia, entrapment neuropathies), nutritional deficiencies (B_6, B_{12}), toxins (alcohol), and HIV-related therapies. Several antiretroviral drugs, such as ddI, ddC, and D4T; chemotherapy agents used to treat Kaposi's sarcoma (vincristine); as well as a number of medications used in the treatment of *Pneumocystis carinii* pneumonia, mycobacterial infection, and other HIV-associated infections can cause painful toxic neuropathy (9,43,44).



I. Predominantly sensory neuropathy of acquired immunodeficiency syndrome
II. Immune-mediated
Inflammatory demyelinating polyneuropathies
Acute (Guillain-Barré syndrome)
Chronic (chronic inflammatory demyelinating polyneuropathy)
III. Infectious
Cytomegalovirus polyradiculopathy
Cytomegalovirus multiple mononeuropathy
Herpes zoster
Mycobacterial (Mycobacterium avium intracellulare)
IV. Toxic and nutritional
Alcohol, vitamin deficiencies (B_6, B_{12})
Antiretrovirals: ddI (didanosine), ddC (zalcitabine), D4T (stavudine)
Antivirals: foscarnet
Pneumocystis carinii pneumonia prophylaxis: dapsone
Antibacterial: metronidazole
Antimycobacterials: isoniazid, rifampin, ethionamide
Antineoplastics: vincristine, vinblastine
V. Other medical conditions
Diabetic neuropathy
Postherpetic neuralgia

TABLE 39-2. Neuropathies encountered in human immunodeficiency virus disease

Predominantly Sensory Neuropathy of Acquired Immunodeficiency Syndrome

The most frequently encountered neuropathy is a symmetric predominantly sensory painful peripheral neuropathy. This is a late manifestation, occurring most often in patients with an AIDS-defining illness, but has been reported earlier in the course of the disease (36). Prevalence in hospice populations ranges from 19% to 26% (15,45,46). It is the only peripheral sensory neuropathy that has been postulated to be a direct result of HIV infection of the peripheral nervous system (36,47,48). The predominant symptom in approximately 60% of patients is pain in the soles of the feet. Paresthesia is frequent and usually involves the dorsum of the feet in addition to the soles. Most patients have signs of peripheral neuropathy (most commonly, absent or reduced ankle jerks and elevated thresholds to pain and vibration sense); and while the signs progress, the symptoms often remain confined to the feet (37,48,49). Although the patients' complaints are predominantly sensory, electrophysiologic studies demonstrate both sensory and motor involvement.

Immune-Mediated Neuropathies

Acute Guillain-Barré syndrome has been described in association with seroconversion (group I infection) but may occur at any time. Both acute and chronic inflammatory demyelinating polyneuropathies are predominantly motor, and sensory abnormalities are rare (42). Mononeuritis multiplex presents with sensory or motor deficits in the distribution of multiple spinal, cranial, or peripheral nerves (49) and may progress into a chronic inflammatory demyelinating polyneuropathy (42).

Infectious Neuropathies

Polyradiculopathies (associated with CMV infection) often present with radicular pain and follow a distinct course (50). The onset is usually subacute and the deficit initially confined to sacral and lumbar nerve roots. Both sensory and motor functions are involved, and usually early involvement of sphincters is seen. Progression is relentless (42).

Toxic and Nutritional Neuropathies

Toxic and nutritional neuropathies in patients with HIV have been reported with the following: alcohol; vitamin deficiencies (B_6 and B_{12}); antiretroviral drugs such as ddI, ddC, and D4T; antivirals such as foscarnet; *Pneumocystis carinii* pneumonia prophylaxis such as dapsone; antibacterial drugs such as metronidazole; antimycobacterial drugs such as INH, rifampin, and ethionamide; and antineoplastics such as vincristine and vinblastine (44,47).

Painful Neuropathies According to Stage of Human Immunodeficiency Virus Infection

The type of neuropathy varies with the stage of infection. The acute or seroconversion phase of HIV is associated with mononeuritides, brachial plexopathy, and acute

demyelinating polyneuropathy. The latent or asymptomatic phase ($CD4^+$ T lymphocytes greater than 500 per mL) is characterized by acute and chronic demyelinating polyneuropathies. The transition phase (200 to 500 $CD4^+$ cells) is characterized by herpes zoster (shingles) and mononeuritis multiplex. The late phase of HIV disease (less than 200 $CD4^+$ cells) is characterized by predominantly sensory HIV polyneuropathy, CMV polyneuropathy, mononeuritis multiplex, autonomic neuropathy, mononeuropathies secondary to meningeal disease, and antiretroviral-induced toxic neuropathies (44).

RHEUMATOLOGIC PAIN SYNDROMES

In studies conducted by the Memorial Sloan-Kettering group (15), over 50% of pain syndromes were classified as rheumatologic in nature, including various forms of arthritis, arthropathy, arthralgia, myopathy, myositis, and myalgias. In another study, 72% of patients with different stages of HIV infection had painful symptoms involving the musculoskeletal system (51).

Arthritis and Arthropathies

HIV disease has been associated with several types of painful arthritis and arthropathies, including nonspecific arthralgias, reactive arthritis, psoriatic arthritis, HIV-associated arthritis, and rarely aseptic arthritis (52,53) (see Chapter 27). The most frequently reported arthritis is a reactive arthritis or Reiter's syndrome (53,54 and 55), often unresponsive to nonsteroidal antiinflammatory drug (NSAID) therapy. Reiter's syndrome can present with persistent oligoarthritis primarily affecting the large joints of the lower limbs, sacroiliitis, urethritis, conjunctivitis, keratoderma blenorrhagica, circinate balanitis, and oral ulceration. Many patients have positive results for HLA-B27 antigen. Diarrhea is a common precipitating event. Nonspecific arthralgias are common (51,52 and 53). Acute HIV infection may present with a polyarthralgia in association with a mononucleosislike illness. A syndrome of acute severe and intermittent articular pain also exists, often referred to as HIV-associated painful articular syndrome, which commonly affects the large joints of the lower limbs and shoulders. Psoriasis and psoriatic arthritis have been reported in patients with HIV infection (56,57). The arthritis is typically seen in conjunction with the skin changes of psoriasis, and authors suggest it may follow a disease course that proves refractory to conventional therapy (9). An HIV-associated arthritis has also been described (58), which typically presents as an oligoarthritis affecting the joints of the lower limbs. Synovial fluid is noninflammatory, and biopsy shows a mild chronic synovitis. No associated infection exists to suggest a reactive arthritis, and the patients reported have had HLA-B27–negative results. It appears that this arthritis is caused by the HIV virus itself (52). Septic arthritis has been reported in patients with HIV, including arthritis caused by bacterial infections, and infections with *Cryptococcus neoformans* and *Sporothrix schenckii* (52,53).

Myopathy and Myositis

Muscle pain is common in patients with HIV. Several types of myopathies and myositis have been described in HIV-infected patients, including HIV-associated myopathy or polymyositis, necrotizing noninflammatory myopathy in association with AZT and without AZT, pyomyositis, and microsporidiosis myositis (49,59,60,61,62,63 and 64). Polymyositis may occur at any stage of HIV infection, is thought to be the result of direct viral infection of muscle cells (53), and may present with a subacute onset of proximal muscle weakness and myalgia (49). Electromyographic evidence of myopathy, a raised serum creatinine kinase level, and biopsy evidence of polymyositis are common in symptomatic patients. Drugs used in the treatment of HIV may also be associated with the development of myalgia (65) and myositis (59,66). AZT has been particularly implicated. In these patients symptoms frequently improve after discontinuation of AZT therapy (9).

EFFECT OF PAIN ON QUALITY OF LIFE

Pain, in patients with HIV disease, has a profound negative effect on physical and psychological functioning, as well as overall quality of life (6,10). In a study of the effect of pain on psychological functioning and quality of life in ambulatory AIDS patients (10), depression was significantly correlated with the presence of pain. In addition to being significantly more distressed, depressed, and hopeless, those with pain were twice as likely to have suicidal ideation (40%) as those without pain (20%). HIV-infected patients with pain were more functionally impaired (10). Such functional interference was highly correlated to levels of pain intensity and depression. Patients with pain were more likely to be unemployed or disabled and reported less social support. Larue and colleagues (6) reported that HIV-infected patients with pain intensities greater than 5 (on a 0 to 10 numeric rating scale) reported significantly poorer quality of life during the week preceding their survey than patients without pain. Pain intensity had an independent negative effect on HIV patients' quality of life, even after adjustment for treatment setting, stage of disease, fatigue, sadness, and depression. Singer and colleagues (11) also reported an association between the frequency of multiple pains, increased disability, and higher levels of depression. Psychological variables, such as the amount of control people believe they have over pain, emotional associations and memories of pain, fears of death, depression, anxiety, and hopelessness, contribute to the experience of pain in people with AIDS and can increase suffering (10,67). Our group also reported (68) that negative thoughts related to pain were associated with greater pain intensity, psychological distress, and disability in ambulatory patients with AIDS. Those AIDS patients who thought that pain represented a progression of their HIV reported more intense pain than those who did not see pain as a threat.

MANAGEMENT OF PAIN IN ACQUIRED IMMUNODEFICIENCY SYNDROME

Assessment Issues

The initial step in pain management is a comprehensive assessment of pain symptoms. The health professional working in the AIDS setting must have a working knowledge of the etiology and treatment of pain in AIDS. This would include an understanding of the different types of AIDS pain syndromes discussed previously, as well as a familiarity with the parameters of appropriate pharmacologic treatment. A close collaboration of the entire health care team is optimal when attempting to adequately manage pain in the AIDS patient. A careful history and physical examination may disclose an identifiable syndrome (e.g., herpes zoster, bacterial infection, or neuropathy) that can be treated in a standard fashion (69,70). A standard pain history (71,72) may provide valuable clues to the nature of the underlying process and indeed may disclose other treatable disorders. A description of the qualitative features of the pain, its time course, and any maneuvers that increase or decrease pain intensity should be obtained. Pain intensity (current, average, at best, at worst) should be assessed to determine the need for weak versus potent analgesics and as a means to serially evaluate the effectiveness of ongoing treatment. Pain descriptors (e.g., burning, shooting, dull, or sharp) help determine the mechanism of pain (somatic, nociceptive, visceral nociceptive, or neuropathic) and may suggest the likelihood of response to various classes of traditional and adjuvant analgesics (e.g., NSAIDs, opioids, antidepressants, anticonvulsants, oral local anesthetics, corticosteroids) (73,74). Additionally, detailed medical, neurologic, and psychosocial assessments (including a history of substance use or abuse) must be conducted. Where possible, family members or partners should be interviewed. During the assessment phase, pain should be aggressively treated while pain complaints and psychosocial issues are subject to an ongoing process of reevaluation (72). Federal guidelines developed by the Agency for Health Care Policy and Research for the management of cancer pain (74) also address the issue of management of pain in AIDS and state the following: “The principles of pain assessment and treatment in the patient with HIV positive/AIDS are not fundamentally different from those in the patient with cancer and should be followed for patients with HIV-positive/AIDS.” In contrast to pain in cancer, pain in HIV may more commonly have an underlying treatable cause (9).

Multimodal Approach

Optimal management of pain in AIDS is multimodal and requires pharmacologic, psychotherapeutic, cognitive-behavioral, anesthetic, neurosurgical, and rehabilitative approaches (75). A multidimensional model of AIDS pain that recognizes the interaction of cognitive, emotional, socioenvironmental, and nociceptive aspects of pain suggests a model for multimodal intervention.

Pharmacologic Interventions: The World Health Organization Analgesic Ladder

The World Health Organization (WHO) (76) has devised guidelines for analgesic management of cancer pain that the Agency for Health Care Policy and Research has endorsed for the management of pain related to cancer or AIDS (73). These guidelines, also known widely as the *WHO analgesic ladder*, have been well validated (75). This approach advocates selection of analgesics based on severity of pain, as well as the type of pain (i.e., neuropathic versus nonneuropathic pain). For mild to moderate severity pain, nonopioid analgesics, such as NSAIDs and acetaminophen, are recommended. For pain that is persistent and moderate to severe in intensity, opioid analgesics of increasing potency (e.g., morphine) should be used. Adjuvant agents, such as laxatives and psychostimulants, are useful in preventing as well as treating opioid side effects such as constipation or sedation, respectively. Adjuvant analgesic drugs, such as the antidepressant analgesics, are suggested, along with opioids and NSAIDs, in all stages of the analgesic ladder (mild, moderate, or severe pain), but have their most important clinical application in the management of neuropathic pain.

This WHO approach, although not yet validated in AIDS, has been recommended by the Agency for Health Care Policy and Research and clinical authorities in the field of pain management and AIDS (7,9,11,15,43,73,76). Clinical reports describing the successful application of the principles of the WHO analgesic ladder to the

management of pain in AIDS, with particular emphasis on the use of opioids, have also appeared in the literature (8,13,15,77,78,79,80 and 81).

Nonopioid Analgesics

The nonopioid analgesics (Table 39-3) are prescribed principally for mild to moderate pain or to augment the analgesic effects of opioid analgesics in the treatment of severe pain. The use of NSAIDs in patients with AIDS must be accompanied by heightened awareness of toxicity and adverse effects. NSAIDs are highly protein bound, and the free fraction of available drug is increased in AIDS patients who are cachectic, wasted, and hypoalbuminemic, often resulting in toxicities and adverse effects. Patients with AIDS are frequently hypovolemic, on concurrent nephrotoxic drugs, and experiencing HIV nephropathy and so are at increased risk for renal toxicity related to NSAIDs. The antipyretic effects of the NSAIDs may also interfere with early detection of infection in patients with AIDS.

TABLE 39-3. Oral analgesics for mild to moderate pain in human immunodeficiency virus disease

The major adverse effects associated with NSAIDs include gastric ulceration, renal failure, hepatic dysfunction, and bleeding. The nonacetylated salicylates, such as salsalate, sodium salicylate, and choline magnesium salicylate, theoretically have fewer gastrointestinal side effects and might be considered in cases in which gastrointestinal distress is an issue. Prophylaxis for NSAID- associated gastrointestinal symptoms includes H_2 antagonist drugs (cimetidine, 300 mg three or four times a day, or ranitidine, 150 mg twice a day); misoprostol, 200 mg four times a day; omeprazole, 20 mg every day; or an antacid. Patients should be informed of these symptoms, issued guaiac cards with reagent, and taught to check their stool weekly. NSAIDs affect kidney function and should be used with caution. NSAIDs can cause a decrease in glomerular filtration, acute and chronic renal failure, interstitial nephritis, papillary necrosis, and hyperkalemia (82). In patients with renal impairment, NSAIDs should be used with great caution, because many (i.e., ketoprofen, fenoprofen, naproxen, and caprofen) are highly dependent on renal function for clearance. The risk of renal dysfunction is greatest in patients with advanced age, preexisting renal impairment, hypovolemia, concomitant therapy with nephrotoxic drugs, and heart failure. Prostaglandins modulate vascular tone, and their inhibition by the NSAIDs can cause hypertension as well as interference with the pharmacologic control of hypertension (83). Caution should be used in patients receiving b-adrenergic antagonists, diuretics, or angiotensin-converting enzyme inhibitors. Several studies have suggested that a substantial biliary excretion of several NSAIDs occurs, including indomethacin and sulindac. In patients with hepatic dysfunction, these drugs should be used with caution. NSAIDs, with the exception of the nonacetylated salicylates (e.g., sodium salicylate, choline magnesium trisalicylate), produce inhibition of platelet aggregation (usually reversible, but irreversible with aspirin). NSAIDs should be used with extreme caution, or avoided, in patients who are thrombocytopenic or who have clotting impairment.

Opioid Analgesics

Opioid analgesics are the mainstay of pharmacotherapy of moderate to severe intensity pain in the patient with HIV (Table 39-4) (see Chapter 84). Several reports describing the safe and effective use of opioid drugs in the management of moderate to severe pain in populations of patients with HIV (including patients with a history of injection drug use as their HIV transmission factor) have begun to appear in the literature (13,77,78,79,80 and 81). Kaplan and colleagues (83) conducted a multicenter study in which 44 patients with moderate to severe AIDS-related pain were treated with sustained-release oral morphine in an open-label prospective study of patients treated for up to 18 days. Pain intensity decreased by 65% in the patients who completed the study, quality of life was good in 80%, acceptability of therapy was 96% in the patients who completed the study, 92% of side effects were resolved, and total morphine dose remained stable through the course of the study. In a pilot study, Lefkowitz and Newshan (80) reported similar findings on the effectiveness and safety of the transdermal fentanyl patch in a small sample of patients with AIDS-related pain.

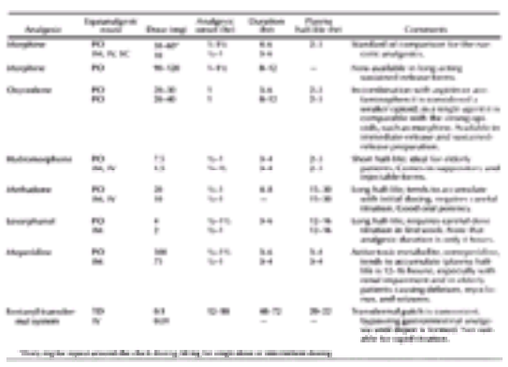


TABLE 39-4. Opioid analgesics for moderate to severe pain in human immunodeficiency virus disease

Principles that are useful in guiding the appropriate use of opioid analgesics for pain (74,76,84) include the following: (a) choose an appropriate drug; (b) start with lowest dose possible; (c) titrate dose; (d) use as-needed doses selectively; (e) use an appropriate route of administration; (f) be aware of equivalent analgesic doses; (g) use a combination of opioid, nonopioid, and adjuvant drugs; (h) be aware of tolerance; and (i) understand physical and psychological dependence. In choosing the appropriate opioid analgesic for cancer pain, Portenoy and Foley (73) highlight the following important considerations: (a) opioid class; (b) *weak* versus *strong* opioids; (c) pharmacokinetic characteristics; (d) duration of analgesic effect; (e) favorable prior response; and (f) opioid side effects.

Opioid analgesics are divided into two classes, the agonists and the agonist-antagonists, based on their affinity to opioid receptors. Pentazocine, butorphanol, and nalbuphine are examples of opioid analgesics with mixed agonist-antagonist properties. These drugs can reverse opioid effects and precipitate an opioid withdrawal syndrome in patients who are opioid tolerant or dependent. They are of limited use in the management of chronic pain in AIDS. Oxycodone (in combination with either aspirin or acetaminophen), hydrocodone, and codeine are the so-called weaker opioid analgesics and are indicated for use in step 2 of the WHO ladder for mild to moderate intensity pain. More severe pain is best managed with morphine or another of the stronger opioid analgesics, such as hydromorphone, methadone, levorphanol, or fentanyl. Oxycodone, as a single agent without aspirin or acetaminophen, is available in immediate and sustained-release forms and is considered a stronger opioid in these forms.

The oral route has often been described as the preferred route of administration of opioid analgesics from the perspectives of convenience and cost. However, the transdermal route of administration has gained rapid acceptance among clinicians and patients. Patients with HIV infection are burdened with the task of taking anywhere from 20 to 40 tablets of medication per day and often need to follow complicated regimens in which medication has to be taken on an empty stomach. In a study on patient-related barriers to pain management in AIDS patients (85), the vast majority of AIDS patients endorsed a preference to use a pain intervention that required a minimal number of additional pills (e.g., sustained-release preparations of oral opioids) or interventions that did not require taking pills at all (i.e., transdermal opioid system). Immediate-release oral morphine or hydromorphone preparations require that the drug be taken every 3 to 4 hours. Longer-acting, sustained-release oral morphine preparations and oxycodone preparations are available that provide up to 8 to 12 hours or more of analgesia, minimizing the number

of daily doses required for the control of persistent pain. Rescue doses of immediate-release, short-acting opioid are often necessary to supplement the use of sustained-release morphine or oxycodone, particularly during periods of titration or pain escalation. The transdermal fentanyl patch system (Duragesic) also has applications in the management of severe pain in AIDS (79,80). Each transdermal fentanyl patch contains a 48- to 72-hour supply of fentanyl that is absorbed from a depot in the skin. Levels in the plasma increase slowly over 12 to 18 hours after patch placement; so with the initial placement of a patch, alternative opioid analgesia (either oral, rectal, or parenteral) must be provided until adequate levels of fentanyl are attained. The elimination half-life of this dosage form of fentanyl is long (21 hours), and so it must be noted that significant levels of fentanyl remain in the plasma for approximately 24 hours after the removal of a transdermal patch. The transdermal system is not optimal for rapid dose titration of acutely exacerbated pain; however, a variety of dosage forms are available. As with sustained-release morphine preparations, all patients should be provided with oral or parenteral rapidly acting short-duration opioids to manage breakthrough pain. The transdermal system is convenient and can minimize the reminders of pain associated with repeated oral dosing of analgesics. In AIDS patients, it should be noted that the absorption of transdermal fentanyl can be increased with fever, resulting in increased plasma levels and shorter duration of analgesia from the patch.

It is important to note that opioids can be administered through a variety of routes: oral, rectal, transdermal, intravenous, subcutaneous, intraspinal, and even intraventricular (79). There are advantages and disadvantages, as well as indications for use of these various routes. Further discussion of such alternative delivery routes as the intraspinal route are beyond the scope of this chapter. Interested readers are directed to the Agency for Health Care Policy and Research Clinical Practice Guideline: Management of Cancer Pain (73), available free of charge through 1-800-4CANCER.

Opioid Side Effects

Although the opioids are extremely effective analgesics, their side effects are common and can be minimized if anticipated in advance. Sedation is a common CNS side effect, especially during the initiation of treatment. Sedation usually resolves after the patient has been maintained on a steady dosage. Persistent sedation can be alleviated with a psychostimulant, such as dextroamphetamine, pemoline, or methylphenidate. All are prescribed in divided doses in early morning and at noon. Additionally, psychostimulants can improve depressed mood and enhance analgesia (86,87). Delirium, of an either agitated or somnolent variety, can also occur while on opioid analgesics and is usually accompanied by attentional deficits, disorientation, and perceptual disturbances (visual hallucinations and more commonly illusions). Myoclonus and asterixis are often early signs of neurotoxicity that accompany the course of opioid-induced delirium. Meperidine (Demerol), when administered chronically in patients with renal impairment, can lead to a delirium caused by accumulation of the neuroexcitatory metabolite normeperidine (88). Opioid-induced delirium can be alleviated through the implementation of three possible strategies: (a) lowering the dose of the opioid drug presently in use; (b) changing to a different opioid; or (c) treating the delirium with low doses of high-potency neuroleptics, such as haloperidol. The third strategy is especially useful for agitation and clears the sensorium (89). For agitated states, intravenous haloperidol in doses starting at between 1 and 2 mg is useful, with rapid escalation of dose if no effect is noted. Gastrointestinal side effects of opioid analgesics are common. The most prevalent are nausea, vomiting, and constipation (74). Concomitant therapy with prochlorperazine for nausea is sometimes effective. Because all opioid analgesics are not tolerated in the same manner, switching to another opioid can be helpful if an antiemetic regimen fails to control nausea. Constipation caused by opioid effects on gut receptors is a problem frequently encountered, and it tends to be responsive to the regular use of senna derivatives. A careful review of medications is imperative, because anticholinergic drugs such as the tricyclic antidepressants can worsen opioid-induced constipation and can cause bowel obstruction. Respiratory depression is a worrisome but rare side effect of the opioid analgesics. Respiratory difficulties can almost always be avoided if two general principles are adhered to: (a) start opioid analgesics in low doses in opioid-naïve patients; and (b) be cognizant of relative potencies when switching opioid analgesics, routes of administration, or both.

Adjuvant Analgesics

Adjuvant analgesics are the third class of medications frequently prescribed for the treatment of chronic pain and have important applications in the management of pain in AIDS (Table 39-5). Adjuvant analgesic drugs are used to enhance the analgesic efficacy of opioids, treat concurrent symptoms that exacerbate pain, and provide independent analgesia (see Chapter 83). They may be used in all stages of the analgesic ladder. Commonly used adjuvant drugs include antidepressants, neuroleptics, psychostimulants, anticonvulsants, corticosteroids, and oral anesthetics (73,90,91).

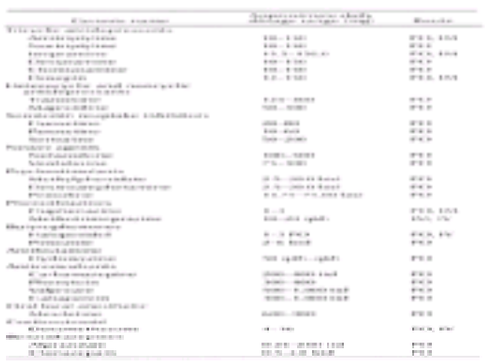

TABLE 39-5. Adjuvant analgesic drugs for pain in human immunodeficiency virus disease

Antidepressants

The current literature supports the use of antidepressants as adjuvant analgesic agents in the management of a wide variety of chronic pain syndromes, including cancer pain, postherpetic neuralgia, diabetic neuropathy, fibromyalgia, headache, and low back pain (92,93,94,95,96 and 97) (see Chapter 85). The antidepressants produce pain relief through a number of mechanisms that include antidepressant activity (93), potentiation or enhancement of opioid analgesia (94,98,99), and direct pain-relieving effects (100). The leading hypothesis suggests that both serotonergic and noradrenergic properties of the antidepressants are probably important and that variations among individuals in pain (as to the status of their own neurotransmitter systems) are an important variable (69). Other possible mechanisms of antidepressant pain-relieving activity that have been proposed include adrenergic and serotonin receptor effects (101), adenosinergic effects (102), antihistaminic effects (101), and direct neuronal effects, such as inhibition of paroxysmal neuronal discharge and decreasing sensitivity of adrenergic receptors on injured nerve sprouts (103).

Substantial evidence suggests that the tricyclic antidepressants in particular can relieve pain and are useful in the management of chronic neuropathic and nonneuropathic pain syndromes. Amitriptyline is the tricyclic antidepressant most studied and has been proved effective in a large number of clinical trials addressing a wide variety of chronic pain syndromes, including neuropathy, cancer pain, fibromyalgia, and others (69,93,94,104,105 and 106). Other tricyclics that have been shown to relieve pain include imipramine (107,108), desipramine (70,109,110 and 111), nortriptyline (112,113), doxepin (114), and clomipramine (113,115).

The heterocyclic and noncyclic antidepressant drugs, such as trazodone, mianserin, maprotiline, and the newer serotonin-specific reuptake inhibitors fluoxetine and paroxetine may also be useful as adjuvant analgesics for chronic pain syndromes (69,90,94,100,108,109,114,116,117 and 118). Fluoxetine, a potent antidepressant with specific serotonin reuptake inhibition activity (117), has been shown to have analgesic properties in experimental animal pain models (118) but failed to show analgesic effects in a clinical trial for neuropathy (109). Several case reports suggest fluoxetine may be a useful adjuvant analgesic in the management of headache and fibrositis (119). Paroxetine, a newer serotonin-specific reuptake inhibitor, is the first antidepressant of this class shown to be a highly effective analgesic in a controlled trial for the treatment of diabetic neuropathy (108). Newer antidepressants such as sertraline, venlafaxine, and nefazodone may also eventually prove to be clinically useful as adjuvant analgesics. Nefazodone, for instance, has been demonstrated to potentiate opioid analgesics in an animal model (120).

Given the diversity of clinical syndromes in which the antidepressants have been demonstrated to be analgesic, trials of these drugs can be justified in the treatment of virtually every type of chronic pain (91). The established benefit of several of the antidepressants in patients with neuropathic pains (105,108,109), however, suggests these drugs may be particularly useful in populations, such as cancer and AIDS patients, in which an underlying neuropathic component to the pain(s) often exists (91). Although studies of the analgesic efficacy of these drugs in HIV-related painful neuropathies have not yet been conducted, they are widely applied clinically using the model of diabetic and postherpetic neuropathies.

Although antidepressant drugs are analgesic in both neuropathic and nonneuropathic pain models, their clinical use is most commonly in combination with opioid

drugs, particularly for moderate to severe pain. Antidepressant adjuvant analgesics have their most broad application as *coanalgesics*, potentiating the analgesic effects of opioid drugs (73). The opioid-sparing effects of antidepressant analgesics have been demonstrated in a number of trials, especially in cancer populations with neuropathic, as well as nonneuropathic, pain syndromes (94,97).

The dose and time course of onset of analgesia for antidepressants when used as analgesics appears to be similar to their use as antidepressants. Compelling evidence exists that the therapeutic analgesic effects of amitriptyline are correlated with serum levels, as are the antidepressant effects, and that analgesic treatment failure is caused by low serum levels (105,109). A high-dose regimen of up to 150 mg of amitriptyline or higher is suggested. The proper analgesic dose for paroxetine is likely in the 40- to 60-mg range, with the major analgesic trial using a fixed dose of 40 mg (108). Anecdotal evidence suggests that the debilitated medically ill (cancer, AIDS patients) often respond (regarding depression or pain) to lower doses of antidepressant than are usually required in the physically healthy, probably because of impaired metabolism of these drugs (90). As to the time course of onset of analgesia, a biphasic process appears to occur. There are immediate or early analgesic effects that occur within hours or days, and these are probably mediated through inhibition of synaptic reuptake of catecholamines. In addition, there are later, longer analgesic effects that peak over a 2- to 4-week period that are probably caused by receptor effects of the antidepressants (104,105,109).

Neuroleptics and Benzodiazepines

Neuroleptic drugs, such as methotrimeprazine, fluphenazine, haloperidol, and pimozide, may play a role as adjuvant analgesics (111,121,122 and 123) in AIDS patients with pain; however, their use must be weighed against what appears to be an increased sensitivity to the extrapyramidal side effects of these drugs in AIDS patients with neurologic complications (124). Anxiolytics, such as alprazolam and clonazepam, may also be useful as adjuvant analgesics, particularly in the management of neuropathic pains (125,126 and 127).

Psychostimulants

Psychostimulants, such as dextroamphetamine, methylphenidate, and pemoline, may be useful antidepressants in patients with HIV infection or AIDS who are cognitively impaired (125). Psychostimulants enhance the analgesic effects of the opioid drugs (128). Psychostimulants are also useful in diminishing sedation secondary to opioid analgesics, and they are potent adjuvant analgesics. Bruera and colleagues (88) demonstrated that a regimen of 10 mg of methylphenidate with breakfast and 5 mg with lunch significantly decreased sedation and potentiated the effect of opioids in patients with cancer pain. Methylphenidate has also been demonstrated to improve functioning on a number of neuropsychological tests, including tests of memory, speed, and concentration, in patients receiving continuous infusions of opioids for cancer pain (88). Dextroamphetamine has also been reported to have additive analgesic effects when used with morphine in postoperative pain (129). In relatively low doses, psychostimulants stimulate appetite, promote a sense of well-being, and improve feelings of weakness and fatigue in cancer patients.

Pemoline is a unique alternative psychostimulant that is chemically unrelated to amphetamine but may have similar usefulness as an antidepressant and adjuvant analgesic in AIDS patients (87). Advantages of pemoline as a psychostimulant in AIDS pain patients include the lack of abuse potential, the lack of federal regulation through special triplicate prescriptions, the mild sympathomimetic effects, and the fact that it comes in a chewable tablet form that can be absorbed through the buccal mucosa and thus can be used by AIDS patients who have difficulty swallowing or who have intestinal obstruction. Clinically, pemoline is as effective as methylphenidate or dextroamphetamine in the treatment of depressive symptoms and in countering the sedating effects of opioid analgesics. No studies exist of pemoline's capacity to potentiate the analgesic properties of opioids. Pemoline should be used with caution in patients with liver impairment, and liver function tests should be monitored periodically with longer-term treatment.

Anticonvulsant Drugs

Selected anticonvulsant drugs appear to be analgesic for the lancinating dysesthesias that characterize diverse types of neuropathic pain (91) (see Chapter 86). Clinical experience also supports the use of these agents in patients with paroxysmal neuropathic pains that may not be lancinating, and to a far lesser extent, in those with neuropathic pains characterized solely by continuous dysesthesias. Although most practitioners prefer to begin with carbamazepine because of the extraordinarily good response rate observed in trigeminal neuralgia, this drug must be used cautiously in AIDS patients with thrombocytopenia, those at risk for marrow failure, and those whose blood counts must be monitored to determine disease status. If carbamazepine is used, a complete blood count should be obtained before the start of therapy, after 2 and 4 weeks, and then every 3 to 4 months thereafter. A leukocyte count below 4,000 is usually considered to be a contraindication to treatment, and a decline to less than 3,000, or an absolute neutrophil count of less than 1,500 during therapy, should prompt discontinuation of the drug. Other anticonvulsant drugs may be useful for managing neuropathic pain in AIDS patients, including phenytoin, clonazepam, valproate, and gabapentin (91).

Several newer anticonvulsants have been used in the treatment of neuropathic pain, particularly patients with reflex sympathetic dystrophy. These drugs include gabapentin, lamotrigine, and felbamate. Of these newer anticonvulsants, anecdotal experience has been most favorable with gabapentin, which is now being widely used by pain specialists to treat neuropathic pain of various types. Gabapentin has a relatively high degree of safety, including no known drug-drug interactions and a lack of hepatic metabolism (91). Treatment with gabapentin is usually initiated at a dose of 300 mg per day and then gradually increased to a dose range of 900 to 3,200 mg per day in three divided doses.

Corticosteroids

Corticosteroid drugs have analgesic potential in a variety of chronic pain syndromes, including neuropathic pains and pain syndromes resulting from inflammatory processes (91). Like other adjuvant analgesics, corticosteroids are usually added to an opioid regimen. In patients with advanced disease, these drugs may also improve appetite, nausea, malaise, and overall quality of life. Adverse effects include neuropsychiatric syndromes, gastrointestinal disturbances, and immunosuppression.

Baclofen

Baclofen is a gamma-aminobutyric acid agonist that has proven efficacy in the treatment of trigeminal neuralgia (130). On this basis, a trial of this drug is commonly used in the management of paroxysmal neuropathic pains of any type. Dosing is generally undertaken in a manner similar to the use of the drug for its primary indication, spasticity. A starting dose of 5 mg two to three times per day is gradually escalated to 30 to 90 mg per day, and sometimes higher if side effects do not occur. The most common adverse effects are sedation and confusion.

Oral Local Anesthetics

Local anesthetic drugs may be useful in the management of neuropathic pains characterized by either continuous or lancinating dysesthesias. Controlled trials have demonstrated the efficacy of tocainide (131) and mexiletine (132), and clinical evidence suggests similar effects from flecainide (133) and subcutaneous lidocaine (134). It is reasonable to undertake a trial with oral local anesthetic in patients with continuous dysesthesias who fail to respond adequately to, or who cannot tolerate, the tricyclic antidepressants, and with patients with lancinating pains refractory to trials of anticonvulsant drugs and baclofen. Mexiletine is preferred in the United States (91).

NONPHARMACOLOGIC INTERVENTIONS

A variety of physical and psychological therapies may also prove useful in the management of HIV-related pain (Table 39-6). Physical interventions range from bed rest and simple exercise programs to the application of cold packs or heat to affected sites. Other nonpharmacologic interventions include whirlpool baths, massage, the application of ultrasound, and transcutaneous electrical nerve stimulation. Increasing numbers of AIDS patients have resorted to acupuncture to relieve their pain, with anecdotal reports of efficacy.

Physical therapies
Cutaneous stimulation (superficial heat, cold, and massage)
Transcutaneous electrical nerve stimulation
Acupuncture
Bed rest
Psychological therapies
Relaxation, imagery, biofeedback, distraction, and reframing
Hypnosis
Patient education
Neurosurgical procedures
Nerve blocks
Cordotomy

TABLE 39-6. Nonpharmacologic interventions

Several psychological interventions have demonstrated potential efficacy in alleviating HIV-related pain, including hypnosis, relaxation, and distraction techniques such as biofeedback and imagery, and cognitive-behavioral techniques (see Part V, Section C). When nonpharmacologic and standard pharmacologic treatments fail, anesthetic and even neurosurgical procedures, such as nerve block, cordotomy, and spinal delivery of analgesics, are additional options available to the patient who appreciates the risks and limitations of these procedures (see Chapter 102, Chapter 103, Chapter 104, Chapter 105, Chapter 106 and Chapter 108).

UNDERTREATMENT OF PAIN IN ACQUIRED IMMUNODEFICIENCY SYNDROME

Reports of dramatic undertreatment of pain in AIDS patients have appeared in the literature (3,6,7 and 8). These studies suggest that all classes of analgesics, particularly opioid analgesics, are underused in the treatment of pain in AIDS. Our group has reported (3) that fewer than 8% of individuals in our cohort of ambulatory AIDS patients reporting pain in the severe range (8 to 10 on a numeric rating scale of pain intensity) received a strong opioid, such as morphine, as recommended by published guidelines (i.e., the WHO analgesic ladder). In addition, 18% of patients with severe pain were prescribed no analgesics whatsoever, 40% were prescribed a nonopioid analgesic (e.g., NSAID), and only 22% were prescribed a weak opioid (e.g., acetaminophen in combination with oxycodone). Using the Pain Management Index (PMI) (135), a measure of adequacy of analgesic therapy derived from the Brief Pain Inventory's record of pain intensity and strength of analgesia prescribed, we further examined adequacy of pain treatment. Only 15% of our sample received adequate analgesic therapy based on the PMI. This degree of undermedication of pain in AIDS (85%) far exceeds published reports of undermedication of pain (using the PMI) in cancer populations of 40%. Larue and colleagues (6) report that in France, 57% of patients with HIV reporting moderate to severe pain did not receive any analgesic treatment at all, and only 22% received a weak opioid.

Although opioid analgesics are underused, it is clear that adjuvant analgesic agents, such as the antidepressants, are also dramatically underused (3,6,7 and 8). Breitbart and colleagues (3) reported that less than 10% of AIDS patients reporting pain received an adjuvant analgesic drug (e.g., antidepressants, anticonvulsants), despite the fact that approximately 40% of the sample had neuropathic-type pain. This class of analgesic agents is a critical component of the WHO analgesic ladder, particularly in managing neuropathic pain, and is vastly underused in the management of HIV-related pain.

A number of different factors have been proposed as potential influences on the widespread undertreatment of pain in AIDS, including barriers related to patients, clinicians, and the health care system (3,85,136,137). Sociodemographic factors that have been reported to be associated with undertreatment of pain in AIDS include gender, education, and substance abuse history (3). Women, less educated patients, and patients who reported injection drug use as their HIV risk transmission factor are significantly more likely to receive inadequate analgesic therapy for HIV-related pain.

Breitbart and colleagues (85) surveyed 200 ambulatory AIDS patients using a modified version of the Barriers Questionnaire (BQ) (138), which assesses a variety of patient-related barriers to pain management (resulting in patient reluctance to report pain or take opioid analgesics). Results of this study demonstrated that patient-related barriers (as measured by BQ scores) were significantly correlated with undertreatment of pain (as measured by the PMI) in AIDS patients with pain. Additionally, BQ scores were significantly correlated with higher levels of psychological distress and depression, indicating that patient-related barriers contributed to undertreatment for pain and poorer quality of life. The most frequently endorsed BQ items were those concerning the addiction potential of opioids, side effects and discomfort related to opioid administration, and misconceptions about tolerance. Although no age, gender, or HIV risk transmission factors were associated with BQ scores, nonwhite and less educated patients scored higher on the BQ. Several additional AIDS-specific patient-related barriers examined (136,137) reveal that 66% of patients are trying to limit their overall intake of medications (i.e., pills) or use nonpharmacologic interventions for pain, 50% of patients cannot afford to fill a prescription for analgesics or have no access to pain specialists, and approximately 50% are reluctant to take opioids for pain out of a concern that family, friends, or physicians will assume they are misusing or abusing these drugs.

In a survey of approximately 500 AIDS care providers (85), clinicians (primarily physicians and nurses) rated the barriers to AIDS pain management they perceived to be the most important in the care of AIDS patients. The most frequently endorsed barriers were those regarding lack of knowledge about pain management or access to pain specialists and concerns regarding the use and addiction potential of opioid drugs in the AIDS population. The top five barriers endorsed by AIDS clinicians included lack of knowledge regarding pain management (51.8%); reluctance to prescribe opioids (51.5%); lack of access to pain specialists (50.9%); concern regarding drug addiction, abuse, or both (50.5%); and lack of psychological support or drug treatment services (43%). Patient reluctance to report pain and patient reluctance to take opioids were less commonly endorsed barriers, with approximately 24% of respondents endorsing those barriers. In contrast, past surveys of oncologists rated patient reluctance to report pain or take opioids as two of the top four barriers. Like AIDS care providers, oncologists also endorsed highly a reluctance to prescribe opioids, even to a population of cancer patients with a significantly lower prevalence of past or present substance abuse disorders. Both oncologists and AIDS care providers report they have inadequate knowledge of pain management and pain assessment skills.

Pain Management and Substance Abuse in Acquired Immunodeficiency Syndrome

Individuals who inject drugs are among the AIDS exposure categories with the highest rate of increase since 1994, especially in large urban centers. Pain management in the substance-abusing AIDS patient is perhaps the most challenging of clinical goals. Fears of addiction and concerns regarding drug abuse affect both patient compliance and physician management of pain and use of opioid analgesics, often leading to the undermedication of HIV-infected patients with pain.

Studies of patterns of chronic opioid analgesic use in patients with cancer, burns, and postoperative pain, however, have demonstrated that, although tolerance and physical dependence commonly occur, addictions (i.e., psychological dependence and drug abuse) are rare and almost never occur in individuals who do not have histories of drug abuse (139,140 and 141). More relevant to the clinical problem of pain management in AIDS patients, however, is the issue of managing pain in the growing segment of HIV-infected patients who have a history of substance abuse or who are actively abusing drugs. The use, specifically of opioids for pain control in patients with HIV infection and a history of substance abuse, raises several difficult pain treatment questions, including how to treat pain in people who have a high tolerance to opioid analgesics; how to mitigate this population's drug-seeking and potentially manipulative behavior; how to deal with patients who may offer unreliable medical histories or who may not comply with treatment recommendations; and how to counter the risk of patients' spreading HIV while high and disinhibited.

Perhaps of greatest concern to clinicians is the possibility that they are being lied to by substance-abusing AIDS patients complaining of pain. Clinicians must rely on a patient's subjective report, which is often the best or only indication of the presence and intensity of pain, as well as the degree of pain relief achieved by an intervention. Physicians who believe they are being manipulated by drug-seeking patients often hesitate to use appropriately high doses of opioid analgesics to control pain. The fear is that the clinician is being duped into prescribing narcotic analgesics that will then be abused or sold. Clinicians do not want to contribute to or help sustain addiction. This leads to an immediate defensiveness on the part of the clinician and an impulse to avoid prescribing opioids and even to avoid full assessment of a pain complaint.

Because concerns are often raised regarding the credibility of AIDS patients' reports of pain, particularly in cases in which a history of injection drug use exists, Breitbart and colleagues (142) conducted a study of 516 ambulatory AIDS patients, in which they compared the report of pain experience and the adequacy of pain management among patients with and without a history of substance abuse. This study found that there were no significant differences in the report of pain experience (i.e., pain prevalence, pain intensity, and pain-related functional interference) among patients who reported injection drug use as their HIV transmission risk factor and those who reported other transmission factors (non–injection drug use). Furthermore, no differences existed in the report of pain experience among patients who acknowledged current substance abuse, those in methadone maintenance, and those who were in drug-free recovery. The description of HIV-related

pain was comparable among injection drug use and non–injection drug use groups. What was different was the treatment received by these two groups. Patients in the injection drug use group were significantly more undermedicated for pain compared with the non–injection drug use group. In addition, clinicians did not distinguish among various types of patients in the injection drug use group (i.e., active users, those in drug-free recovery, and those in methadone maintenance), and withheld the use of opioids in all patients, resulting in only 8% to 10% of injection drug use patients' receiving adequate analgesia based on the PMI (143).

Unfortunately, the existence or severity of pain cannot be objectively proven. The clinician must accept and respect the report of pain in spite of the possibility of being duped and proceed in the evaluation, assessment, and management of pain. Experience from the cancer pain literature suggests that it is possible to adequately manage pain in substance abusers with life-threatening illness and to do so safely and responsibly using opioid analgesics and several sound principles of pain management outlined here (Table 39-7) (78,142,144,145). Most clinicians experienced in working with this population of patients recommend that practitioners set clear and direct limits. Although this is an important aspect of the care of intravenous drug-using people with HIV, it is by no means the whole answer. As much as possible, clinicians should attempt to eliminate the issue of drug abuse as an obstacle to pain management by dealing directly with the problems of opiate withdrawal and drug treatment. Clinicians should err on the side of believing patients when they complain of pain and should use knowledge of specific HIV-related pain syndromes to corroborate the report of a patient perceived as being unreliable.

Substance abusers with HIV deserve pain control: we have an obligation to treat pain and suffering in all of our patients.
Accept and respect the report of pain.
Be careful about the label *substance abuse*; distinguish between tolerance, physical dependence, and addiction (psychological dependence or drug abuse).
Not all substance abusers are the same; distinguish between active users, individuals in methadone maintenance, and those in recovery.
Individualize pain treatment plan.
Use the principles of pain management outlined for all patients with human immunodeficiency virus disease and pain (World Health Organization analgesic ladder).
Set clear goals and conditions for opioid therapy: set limits, recognize drug abuse behaviors, make consequences clear, use written contracts, and establish a single prescriber.
Use a multidimensional approach: pharmacologic and nonpharmacologic interventions, attention to psychosocial issues, team approach.

TABLE 39-7. Approach to pain management in substance abusers with human immunodeficiency virus disease

The clinician must be familiar with and understand the current terminology relevant to substance abuse and addiction. It is important to distinguish between the terms *tolerance*, *physical dependence*, and *addiction* or *abuse* (psychological dependence). Tolerance is a pharmacologic property of opioid drugs defined by the need for increasing doses to maintain an (analgesic) effect. Physical dependence is characterized by the onset of signs and symptoms of withdrawal if opioid analgesics are abruptly stopped or an opioid antagonist is administered. Tolerance usually occurs in association with physical dependence. Addiction or abuse (also often termed *psychological dependence*) is a psychological and behavioral syndrome in which drug craving, compulsive use (despite physical, psychological, or social harm to user), other aberrant drug-related behaviors, and relapse after abstinence occur (76). The term *pseudoaddiction* has been coined to describe the patient who exhibits behavior that clinicians associate with addiction, such as requests for higher doses of opioid, but in fact is caused by uncontrolled pain and inadequate pain management (146,147).

The clinician must also distinguish between the former addict who has been drug free for years, the addict in a methadone maintenance program, and the addict who is actively abusing illicit drugs, prescription drugs, or both. Actively using addicts and those on methadone maintenance with pain must be assumed to have some tolerance to opioids and may require higher starting and maintenance doses of opioids. Preventing withdrawal is an essential first step in managing pain in this population. In addition, active addicts with AIDS understandably require more in the way of psychosocial support and services to adequately deal with the distress of the pain and illness. Former addicts may pose the challenge of refusing opioids for pain because of fears of relapse. Such patients can be assured that opioids, when prescribed and monitored responsibly, may be an essential part of pain management, and the use of the drug for pain is quite different from its use when they were abusing similar drugs. Some authorities emphasize the importance of conducting a comprehensive pain assessment to define the pain syndrome. Specific pain syndromes often respond best to specific interventions (i.e., neuropathic pains respond well to antidepressants or anticonvulsants). Adequate assessment of the cause of pain is essential in all AIDS patients, and particularly in the substance abuser. It is critical that adequate analgesia be provided while diagnostic studies are under way. Often, treatments directed at the underlying disorder causing pain are effective as well. For example, headache from CNS toxoplasmosis responds well to primary treatments and corticosteroids.

When deciding on an appropriate pharmacologic intervention in the substance abuser, it is advisable to follow the WHO analgesic ladder. This approach advocates selection of analgesics based on severity of pain; however, clinicians also often take into account the nature of the pain syndrome in selecting analgesics. For mild to moderate pain, NSAIDs are indicated. The NSAIDs are continued with adjuvant analgesics (antidepressants, anticonvulsants, neuroleptics, corticosteroids) if a specific indication exists. Patients with moderate to severe pain or those who do not achieve relief from NSAIDs are treated with a weak opioid, often in combination with NSAIDs and adjuvant drugs, if indicated.

It has been pointed out that it is critical to apply appropriate pharmacologic principles for opioid use. One should avoid using agonist-antagonist opioid drugs. The use of as-needed dosing often leads to excessive drug-centered interactions with staff that are not productive. Although patients should not necessarily be given the specific drug or route they want, every effort should be made to give patients more of a sense of control and a sense of collaboration with the clinician. Often a patient's report of beneficial or adverse effects of a specific agent is useful to the clinician.

The management of pain in substance-abusing AIDS patients requires a team approach. Early involvement of pain specialists, psychiatric clinicians, and substance abuse specialists is critical. Nonpharmacologic pain interventions should be appropriately applied, not as a substitute for opioids, but as an important adjunct. Realistic goals for treatment must be set, and problems related to inappropriate behavior around the handling of prescription and interactions with staff should be anticipated.

Hospital staff must be educated and made aware that such difficult patients evoke feelings that if acted on could interfere with providing good care. Clear limit setting is helpful for both the patient and treating staff. Sometimes written rules about what behaviors are expected and what behaviors are not tolerated and the consequence should be provided. The use of urine toxicology monitoring, restrictions of visitors, and strict limits on amount of drug per prescription can all be useful. It is important to also remember that rehabilitation or detoxification from opioids is not appropriate during an acute medical crisis and should not be attempted at that time. Once more stable medical conditions exist, referral to a drug rehabilitation program may be useful. Constant assessment and reevaluation of the effects of pain interventions must also take place to optimize care. Special attention should be given to points in treatment when routes of administration are changed or when opioids are tapered. It must be made clear to patients what drugs, regimen, or both would be introduced to control pain when opioids are tapered or withdrawn, and what options are available if that nonopioid regimen is ineffective.

Finally, it is important to recognize that substance abusers with AIDS are quite likely to have comorbid psychiatric symptoms as well as multiple other physical symptoms that can all contribute to increased pain and suffering. Adequate attention must be paid to these physical and psychological symptoms for pain management to be optimized.

CONCLUSIONS

Pain in AIDS, even in this era of protease inhibitors and decreased AIDS death rates, is a clinically significant problem contributing greatly to psychological and functional morbidity. Pain can be adequately treated and so must be a focus of care in the AIDS patient. The principles of managing pain in HIV are similar to those principles that have been developed previously from the management of cancer pain. Substance abusers and women are a particularly undertreated segment of the AIDS pain population and need special attention.

Managing pain in AIDS patients with a history of substance abuse is a particularly challenging problem that pain specialists and AIDS care providers will be facing with increasing frequency. A multimodal, multidisciplinary approach for managing pain in HIV is optimal, particularly in the management of pain in AIDS patients with a

history of substance abuse.

CHAPTER 40

Palliative Care

Eduardo Bruera, Irene Higginson, and Catherine M. Neumann

More than 80% of patients with advanced cancer develop pain before death (1,2). During the last 10 years, there have been major advances in both the assessment and management of cancer pain that allow for adequate pain control in the great majority of cancer patients (see Chapter 35 and Chapter 36). Additional information can also be found in the *Oxford Textbook of Palliative Medicine* edited by Doyle, Hanks, and MacDonald (3).

During the terminal stages of the illness, patients with cancer pain present a number of unique challenges. Palliative care emerged during the 1960s as a response to the unmet needs of these patients and their families. It has been defined as “the active, total care offered to a patient with a progressive disease and their family when it is recognized that the illness is no longer curable, in order to concentrate on the quality of life and the alleviation of distressing symptoms within the framework of a coordinated service” (4). Physicians and other health professionals involved in the delivery of palliative cancer care need to modify the assessment and management of pain in order to meet some of these challenges.

The purpose of this chapter is to discuss these unique issues encountered in the delivery of palliative care. In most of the chapter, emphasis is on the management of patients with terminal cancer, because they are the majority of the palliative care population (1,2). However, most of these concepts are readily applicable to palliative care patients with pain caused by acquired immunodeficiency syndrome, neurologic disorders, and other terminal chronic illnesses (see Chapter 39).

EPIDEMIOLOGY AND ASSESSMENT OF PAIN AND OTHER SYMPTOMS IN PALLIATIVE CARE

Cancer pain is reported by approximately 50% of patients at all stages and by more than 70% of terminal cancer patients. This percentage varies by cancer type and stage. Pain is more prevalent in patients with advanced cancer of the gastrointestinal tract and bone, and less prevalent in hematologic malignancies (5). Table 40-1 summarizes the frequency of pain in patients with different primary tumors (6,7,8,9,10,11,12,13 and 14).

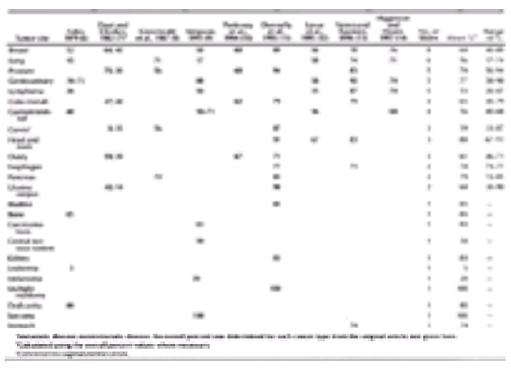

TABLE 40-1. Frequency of pain by primary tumor site (%)

In conjunction with mortality data, available data on the frequency of cancer pain imply that each year approximately 100,455 cancer patients in England and Wales, and 376,600 in the United States, potentially experience pain at the time of death (the total number of deaths is 143,500 in England and Wales and 538,000 in the United States).

Different studies report marked variations in the frequency of cancer pain. Study designs are often limited and not generalized. Pain has been studied in health care settings, rather than in communities, so prevalence pertains to a group of patients referred to a specific service such as a pain clinic. In addition, measures of pain are not constant between studies. Although pain severity and its effect on patient function are both crucial to assessment, severity is the main factor that determines the effect of pain (15). Failure to assess the severity of pain and the variety of methods used for its categorization (visual analog scales; ordinal scales; patient interviews; and physician, nurse, or patient assessments) compound the difficulties in assessment. Much more work is needed to develop systematic assessments of pain for use in routine care and epidemiologic monitoring.

In the great majority of patients with advanced cancer, pain is related to the presence of primary or metastatic cancer (1,2,15,16). However, a number of devastating psychosocial symptoms such as anxiety, depression, delirium, and spiritual or financial concerns can influence the expression of the intensity of pain (17,18 and 19). In palliative care, an appropriate multidimensional assessment is even more important than the assessment that takes place at earlier stages of cancer.

Pain is only one of the many symptoms experienced by cancer patients (20). It is important to assess pain within the context of other symptoms for several reasons. Pain may not necessarily be the symptom that is having the greatest effect on a patient's quality of life at a given point in time. The experience of pain may affect the perception and expression of other symptoms, and vice versa, resulting in misinterpretation and inappropriate management. Also, the treatment of pain may lead directly to a worsening of other highly prevalent symptoms in the terminally ill such as nausea, constipation, somatization, and delirium.

In the clinical situation, current knowledge of the interrelation between different factors indicate that different facets (physical, emotional, social, spiritual, and health care related) need to be assessed, particularly in patients who continue to express high levels of pain intensity in spite of otherwise appropriate treatment.

Table 40-2 summarizes some of the outcome and quality of life measures used or proposed for use in palliative care. Four criteria are important in choosing a clinical measure:

TABLE 40-2. Measures for assessing the outcome of palliative care for people with advanced cancer

- Validity: It is important to measure what you think you are measuring.
- Reliability: If staff changes, it is important that the measurement does not.
- Responsiveness: Clinically important changes should be detectable.
- Appropriateness: Patients, families, and staff should feel comfortable using the measure in this setting, should not be burdened by it, and should find it clinically useful.

By using these four criteria to conduct a systematic literature review that examined all measures identified from MEDLINE, PsychLit, and CancerLit data bases (21), 12 assessment systems were identified that could be used for the multidimensional assessment of pain in palliative care patients (22,23,24,25,26,27,28,29,30,31 and 32).

Unfortunately, at the present time, no gold standard exists. A number of studies are being conducted comparing simplified forms of these tools in different palliative care populations. It is hoped that as a result of this research, a smaller number of highly accepted tools will emerge.

CHARACTERISTICS OF PALLIATIVE CARE PATIENTS

Table 40-3 summarizes some of the main characteristics and therapeutic challenges in palliative care patients. In the following paragraphs, the main issues associated with these characteristics are discussed.

Multiple physical symptoms
Frequent psychosocial distress
Cachexia (decreased albumin level)
Low intravascular volume
Reduced glomerular filtration
Need for alternate opioid routes
Borderline cognition
Polypharmacy

TABLE 40-3. Characteristics of palliative care patients

Multiple Physical Symptoms

As discussed previously, pain in palliative care patients coexists with a number of severe physical symptoms, such as anorexia, chronic nausea, constipation, asthenia, and confusion (33,34). The coexistence of other physical symptoms with pain can significantly aggravate the overall sensation of well-being and increase the psychosocial distress in palliative care patients. Analgesic treatments may not improve and occasionally may even aggravate some of these coexisting symptoms, such as nausea, confusion, or constipation (34,35 and 36). Figure 40-1 summarizes some of the complex interactions between opioid treatment and some of the common symptoms in palliative care patients. These complex interactions necessitate multiple symptom analysis in palliative care.

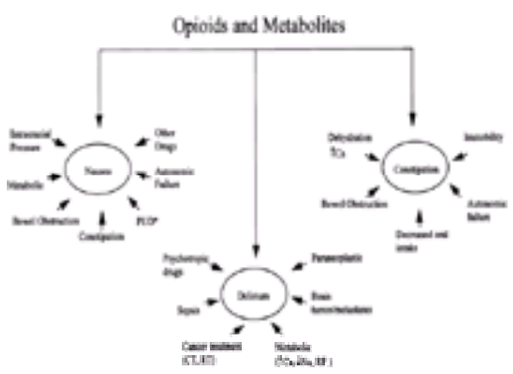

Figure 40-1. Complex interactions between opioid treatment and some of the common symptoms in palliative care patients. (CT, chemotherapy; PUD, peptic ulcer disease; RF, renal failure; RT, radiation therapy.)

Palliative care assessment tools differ from those used in earlier stages of cancer and those used for nonmalignant pain: They focus on multiple different symptoms simultaneously. The outcome and quality of life measures summarized in Table 40-2 cover anywhere from 5 to 34 different items. Regular monitoring of a variety of symptoms is of major relevance to palliative care.

Psychosocial Distress

Pain is only one component of the overall psychosocial distress at the end of life (37,38). Affective disorders including anxiety or depression are a frequent problem in terminally ill patients (37,38). Somatization is a frequent finding in cancer patients with affective symptoms (39). Therefore, the expression of pain intensity and other symptoms may be increased in terminally ill patients who have significant affective symptoms. Somatization is more likely to be a component of the pain intensity expression in those patients who have had either a history of psychiatric illness or who have displayed somatization as a coping strategy in the past (37,38,39 and 40). The presence of psychosocial distress and somatization has been identified as an independent poor prognostic factor for the control of cancer pain (41,42). The inability to recognize somatization as an expression of suffering in palliative care patients can lead to excessive opioid administration and opioid-induced neurotoxicity (35,43). A positive history of alcoholism, drug abuse, or both is a marker of chemical coping and an independent poor predictor for pain control in palliative care patients (41). However, appropriate screening, diagnosis, and multidisciplinary care result in similar levels of pain control and opioid use as compared with

nonalcoholics (44).

Regular monitoring of the level of affective symptoms, history of psychiatric disease, and coping strategy greatly assists palliative care teams in optimizing pharmacologic and nonpharmacologic interventions for pain control.

Cachexia, Low Intravascular Volume

Cachexia consists of progressive weight loss, lipolysis, loss of visceral and skeletal protein mass, and profound anorexia. The great majority of patients experience this devastating complication before dying of cancer and AIDS (45,46). Weight loss is an independent risk for poor survival, and cachectic patients have a higher incidence of complications after surgery, radiation therapy, and chemotherapy. In addition, cachexia aggravates weakness, is frequently associated with anorexia and chronic nausea, and is a source of psychological distress for patients and families because of the associated symptoms and the change in body image.

This syndrome was previously interpreted as a result of increased energy demand from the growing tumor mass. Research has demonstrated that cachexia occurs mostly as a result of major metabolic abnormalities, including profound lipolysis and loss of skeletal and visceral proteins caused by immune mediators, such as tumor necrosis factor and interleukin-6, as well as tumor by-products including lipolytic hormone (47). Anorexia is an almost universal component of cachexia and should be interpreted as a result of the metabolic abnormalities rather than the main cause of cachexia (45,46).

Chronic nausea and profound anorexia frequently lead to different levels of dehydration in cachectic patients (48). The presence of reduced body mass, decreased circulating albumin, and reduced intravascular volume has major implications for the pharmacologic management of pain. Drugs with a large volume of distribution, or those drugs that bind significantly to albumin should be used in reduced doses in terminally ill patients. This is particularly applicable to the use of nonsteroidal antiinflammatory drugs and methadone. In addition, cachectic patients frequently have reduced glomerular filtration. This may result in the accumulation of active opioid metabolites after chronic administration, after an increase in the dose of opioids, or in patients who receive a combination of opioids and nonsteroidal antiinflammatory drugs (35,43).

Alternating Opioid Routes

Because of the presence of cachexia, asthenia, muscle weakness, and chronic nausea, more than 80% of terminal cancer patients require alternate routes for the delivery of opioids (49,50). Ideally, the route and modality of administration should allow patients to be appropriately managed at home or in rural areas. Table 40-4 summarizes some of the alternate routes for opioid delivery in terminally ill patients.

Feature	Rectal	Intravenous	Sublingual[a]	Buccal[a]	Transdermal	Subcutaneous	Inhalatory[a]
Uremia, bowel obstruction, dysphagia	++	++	++	++	++	++	++
Cognitive failure, comatose patients	++	++	0	0	++	++	0

Breakthrough pain	++	++	++	++	0	++	++
Home care	+	+	++	++	++	++	+
Rural areas, developing countries	++	0	++	++	0	0	0

[a]Not enough information available to recommend clinical use.
++, useful; +, partially useful; 0, not useful.

TABLE 40-4. Alternate routes for systemic opioid delivery in palliative care

The subcutaneous route is particularly useful in terminally ill patients. Because of cachexia as well as multiple intravenous therapies, peripheral vein access is usually difficult in these patients. In addition, peripheral intravenous routes need frequent changes, reduce the mobility of the upper limbs, and are generally more expensive than the subcutaneous route (50).

A subcutaneous needle can be left in place usually for periods of one week or more (51,52). The needle can usually be inserted under the skin of the thoracic or abdominal region, thereby allowing free use of the limbs. There is no need for anticoagulation of the site of infusion. The bioavailability of opioids administered subcutaneously is excellent and similar to that of intravenous opioids (53). The patients themselves or with the help of their relatives can frequently administer the opioid analgesics using preloaded syringes or low-cost infusion devices such as the Edmonton Injector (Auto Control Medical, Mississauga, Ontario) (50,54).

The rectal route also allows for safe and effective absorption of a number of opioid analgesics (55,56). One of the main limitations of this route is the discomfort associated with frequent opioid administration. Evidence suggests that slow-release morphine suppositories can be administered every 12 hours (57) and methadone can be administered every 8 to 12 hours (58). Preliminary evidence suggests that in some patients, rectal suppositories of slow-release morphine can be administered once a day (59).

Delirium

Delirium is the most frequent neuropsychiatric complication in patients with terminal cancer, and most patients die in delirium (57,60,61). Despite its high prevalence in patients with cancer and acquired immunodeficiency syndrome, delirium is frequently underdiagnosed (62). Patients with delirium present with combinations of cognitive failure, fluctuating levels of consciousness, changes in the sleep-wake cycle, variable severity of psychomotor agitation, hallucinations, delusions, and other perceptual abnormalities (62). Delirium is often a multicausal syndrome. Some of the most frequent causes are summarized in Figure 40-1. Although opioid toxicity is one of the most frequent causes (43,63), other possible causes include infection, dehydration, and metabolic abnormalities. Various drugs frequently administered to terminally ill patients, including benzodiazepines, tricyclic antidepressants, and drugs with a central anticholinergic effect are capable of causing or aggravating delirium. Figure 40-2 summarizes the clinical approach for the treatment of delirium in palliative care.

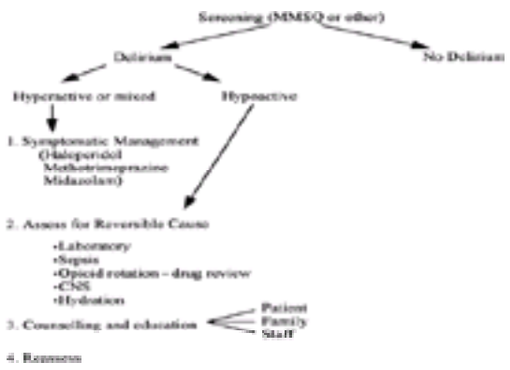

Figure 40-2. Clinical approach to delirium in palliative care. (CNS, central nervous system; MMSQ, Mini-Mental State Questionnaire.)

Approximately 30% of patients with cancer-related delirium experience complete improvement in cognition (64). The remaining patients usually continue in hypoactive delirium or progressively become hypoactive if they were in hyperactive or mixed delirium. A small minority of patients may remain in a state of chronic hyperactive or

mixed delirium and require chronic neuroleptic medication.

Haloperidol is indicated in the symptomatic management of patients presenting with hyperactive forms of delirium including psychomotor agitation, delusions, or hallucinations (65). Haloperidol should be considered a temporary measure while other strategies such as change in the type of opioid, hydration, or the management of metabolic or infectious complications are introduced. In most patients, the hyperactive symptoms improve within 3 to 5 days. If no response is observed within 24 to 48 hours, other, more sedating neuroleptics such as methotrimeprazine have been proposed as an alternative.

Patients who have failed to improve with at least two courses of neuroleptics may require aggressive sedation including the use of subcutaneous infusions of midazolam (43). This highly liposoluble benzodiazepine is potent with a short half-life, allowing for rapid titration. As in the case of other neuroleptics, the use of midazolam should normally be considered as a short-term measure, while other causes of reversible delirium are investigated and treated.

Delirium can be one of the most distressing syndromes for patients, health care professionals, and families. This is at least partially because the assessment of pain in these patients is extremely difficult. In patients with agitated delirium related to cancer, evidence exists that the patient's behavior was frequently misinterpreted by families and health care professionals as increased pain. This leads to increased use of extra opioid analgesics during the agitated period (66). In addition, conflict, defined as consistent expression of dissatisfaction with care of a family member, occurred in almost one-third of the families of patients with delirium as compared with only 5% of patients with no delirium (66). Both the interpretation of behaviors as pain and conflict appear to be observed only in those patients with hyperactive or mixed types of delirium. Unfortunately, no effective methods exist that might assist clinicians in the assessment of pain in patients with severe confusion, delirium, or dementia.

Polypharmacy

Because of the physical and psychosocial symptoms, palliative care patients are frequently receiving a large number of drugs. Analgesics are likely to interact with some of these drugs, particularly because of the presence of previously described characteristics, such as borderline cognition, cachexia, low intravascular volume, and reduced glomerular filtration. As a result, a complete drug review is required before the addition or modification in the dose of analgesic drugs.

Adjuvant analgesic drugs are commonly used in advanced cancer patients for multiple purposes including the enhancement of analgesia initiated by other medications (typically an opioid), their own analgesic effect, treatment of opioid-induced side effects, or all three. The use of adjuvant drugs was reported in approximately one-half of patients with cancer pain in 35 Italian oncology cancer centers (67). Increasing use of adjuvant drugs ranging from more than 50% to more than 66% of patients was reported in an American cancer center (68), an English hospital (69), and a Canadian cancer center (70). Table 40-5 summarizes the potential side effects of frequently used adjuvant drugs in combination with opioids. These effects are mostly manifested as autonomic (orthostatic hypotension, gastroparesis, urinary dysfunction) or central (sedation, delirium).

Drug	Interaction
Nonsteroidal antiinflammatory drugs	Risk of decreased glomerular filtration resulting in enhancement of opioid metabolite accumulation
Corticosteroids	Possible increased risk of organic mental disorders in cancer patients when combined with opioids
Psychotropic medications (e.g., tricyclic antidepressants, neuroleptics, benzodiazepines)	Autonomic dysfunction: gastric stasis, orthostatic hypotension, urinary dysfunction, sedation delirium

TABLE 40-5. Adjuvant drug interactions with opioids in terminally ill patients

One of the main pitfalls of adjuvant drug use in the terminally ill is its risk of general obtundation. Although the development of obtundation may not have initially been targeted as the desired outcome, its occurrence may be erroneously equated with having achieved adequate symptom management, particularly pain control and alleviation of distressing psychiatric symptoms such as agitated delirium or anxiety.

The *lytic cocktails*, which customarily combined a neuroleptic, opioid, and antihistamine, were originally designed during the 1950s as an acute treatment of shock and anesthesia. With time, lytic cocktails were applied to the treatment of pain in cancer patients (71). Lytic cocktails have been perceived by many physicians and patients as a type of disguised euthanasia based on their low potential for analgesia, high sedative properties, and possibility of acceleration of the dying process (72). The Brompton cocktail, a mixture of an opioid such as morphine, or diamorphine in the United Kingdom; cocaine; ethyl alcohol; chloroform water; and flavoring syrup, with a frequent addition of a phenothiazine, gained popularity in the 1960s and early 1970s (73,74). This cocktail has been criticized not only for its inability to provide improved analgesia above and beyond the use of an opioid alone, but for the increased adverse effects caused by the four substances accompanying the morphine, particularly the addition of cocaine. It was discovered that some patients, notably older ones, developed an agitated delirium with hallucinations when given morphine and cocaine, and their symptoms abated when the cocaine was withdrawn (75). An evaluation of the use of lytic cocktails in a French general hospital revealed that improved pain education resulted in an increase in the use of morphine and a decreased use of lytic cocktail practices (72).

Similar to the use of lytic cocktails, the use of combinations of psychotropics can also increase the risk of sedation, confusion, and general obtundation in terminal cancer patients. To prevent the development of excessive sedation and decline in cognition, routine monitoring of these symptoms is advisable. The latter can be accomplished by regular physician and nursing clinical bedside assessments, coupled with the screening detection methods such as the Mini-Mental State Questionnaire (76) or the confusional assessment methods (77). Table 40-6 summarizes some recommendations for the prevention of toxicity associated with polypharmacy in palliative care.

Identify opioids as the first-line treatment for the majority of cancer pain syndromes.
Remember opioid *responsiveness* when titrating dose (reach dose-limiting toxicity before adding another drug).
Add one adjuvant drug at a time to avoid combined or enhanced side effects.
If a decision is made to use an adjuvant drug, use an effective (high) dose.
Define outcome measures at the start of treatment.
Discontinue the adjuvant drug if ineffective.
Always monitor sedation and cognition.

TABLE 40-6. Preventing the toxicity of adjuvant drugs in palliative care

COMMUNICATION

Poor communication is one of the most common reasons for litigation and complaint in palliative care (78). Good verbal and nonverbal communication is viewed positively by patients, even in the most adverse situations, and can increase satisfaction with services and allow patients to make informed choices about their care. This includes information about the disease, procedures, treatment options and effects, and a realistic assessment of predicted outcome. Patients and families should

also be given information about sources of support and practical help. This information should be provided in appropriate forms and language for patients from ethnic minority groups.

One of the best predictors of patients' ability to adapt to the news that they have cancer and require treatment is that they should perceive the information they have been given as adequate for their specific needs (79). The information needs of patients may vary during the course of their illness. Therefore, it is important to establish what individuals' needs are, rather than to make assumptions about the kind of person they are and how much they want to be told (80). Doctors need to be aware that patients often find it difficult to take in or recall complex information given during a consultation, particularly after receiving bad news. Studies on patient preferences for the amount of information they receive report that up to 90% of patients wanted to know if their illness was cancer. Once patients are aware of their diagnosis, up to 97% have been reported as wanting to know about the treatments, investigations, and side effects (81), and 93% were opposed to their family's influencing the information they were given (82). The role of staff is to help individuals adjust to their terminal condition in the best way possible, taking into account their familial, cultural, and spiritual background. Staff who distance themselves, feeling that they can bring nothing but a lack of comprehension, do not realize that it is often the attempt to understand and to listen that aids the patient.

CONCLUSIONS

The majority of patients with advanced cancer and acquired immunodeficiency syndrome develop pain before death. Appropriate management of pain in these patients is the most important aspect of adequate palliative care. It has become evident that appropriate multidimensional assessment is the most important component of adequate palliative care delivery. A number of reliable assessment systems are available for research and clinical use.

Opioids remain the mainstay in the management of these patients. However, the special characteristics of palliative care patients make drug combinations difficult and increase the risk of opioid side effects. Unfortunately, there has been limited research on the appropriate use of opioids in these debilitated subgroups of patients. Increased emphasis on pharmacologic and nonpharmacologic studies is required in palliative care patients.

CHAPTER 41

Postoperative Pain

Michael A. Ashburn and L. Brian Ready

In spite of the advances in the availability of acute pain management services, many individuals continue to endure pain during hospitalization (1,2 and 3). In one survey of 500 U.S. households, 57% of those who had surgery cited concern about pain after surgery as their primary fear experienced before surgery. Their fear appears to have been well founded, because the same survey reported that 77% of adults reported pain after surgery, with 80% of those experiencing moderate to extreme pain (4).

Pain after surgery occurs not only after major surgery, but is a problem even for relatively minor surgery. As the health care environment changes, increasing pressure is felt to complete operations in the ambulatory setting that would have traditionally been undertaken as an inpatient. As a result, physicians are challenged to provide aggressive pain control in new settings. Unfortunately, our current efforts have not been entirely effective. Although major morbidity is uncommon after ambulatory surgery, symptom distress and reduced functional status are common up to 7 days postoperatively (5). One in 20 patients reports severe pain after ambulatory surgery, some of whom required hospital admission only for pain control (6).

To provide acute pain management modalities to the surgical patients who might benefit from them, anesthesiology-based acute pain services (APS) have been developed. First described by Ready in 1988 (7), an APS can provide the interdisciplinary support necessary to safely and effectively manage severe postoperative pain. Originally found mainly in academic institutions, APSs are now found in the private hospital setting as well. In a survey by Ready and associates, nearly all hospitals in the United States with more than 100 beds had some form of patient-controlled analgesia (PCA) service available for use, and 73% had some form of anesthesiology-based APS (8). In another survey that included hospitals of all sizes, 42% of the hospitals had APSs, and an additional 13% had plans to establish such a service (4).

Many pain treatment modalities have become available that have been shown to provide superior analgesia when compared with intramuscular as-needed opioid administration. PCA provides excellent analgesia to patients in a variety of settings. Likewise, epidural and intrathecal opioids, as well as combinations of opioids with local anesthetics, have been shown to provide excellent analgesia (9,10 and 11). More recently, aggressive use of regional anesthetic techniques has become popular again, as has the concept of multimodal or balanced analgesic techniques. This chapter addresses current methods of treating postsurgical pain. In addition, we discuss some of the changes that are occurring in the way this care is provided in the perioperative setting.

BASIC CONSIDERATIONS

Surgical trauma and pain cause an endocrine response that increases the secretion of cortisol, catecholamines, and other stress hormones (12,13 and 14) (see Chapter 9). Tachycardia, hypertension, regional decreases in blood flow, alterations in immune response, hyperglycemia, lipolysis, and a negative nitrogen balance can occur as a result of these and other metabolic changes (15). The stress response may play a role in perioperative morbidity and mortality. Breslow and associates evaluated the effect epidural opioids may have in patients undergoing abdominal aortic surgery (16). In this study, patients received in a double-blind, randomized fashion either 5 mg of epidural morphine or 5 mL of epidural saline as a one-time dose after induction of general anesthesia, but before surgery. The patients were then followed postoperatively in the intensive care unit and data were collected on norepinephrine levels and opioid use, as well as the incidence and severity of hypertension and tachycardia. They found that patients who received epidural morphine had a decreased incidence of postoperative hypertension, used fewer doses of systemic morphine, had better pain control, and experienced lower norepinephrine levels as compared with the patients who received epidural saline (Fig. 41-1 and Fig. 41-2). These changes were attributed to an attenuation of sympathetic outflow, which was in part caused by improved analgesia experienced by the patients receiving epidural morphine.

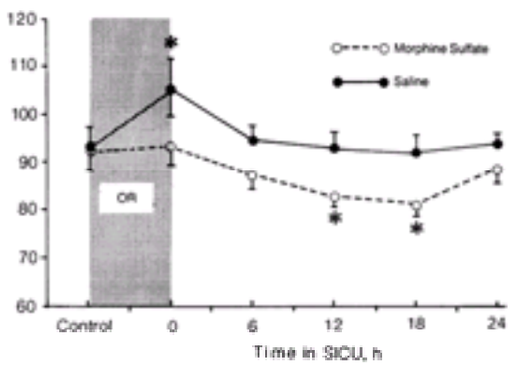

Figure 41-1. Mean arterial pressure before induction of anesthesia (control) and 0, 6, 12, 18, and 24 hours following aortic surgery. Surgical intensive care (SICU), operating room (OR, *shaded area*), and asterisk, $p < .05$ compared with preinduction value. Data are mean ± SE (*vertical bars*) of 12 patients per group. (Reprinted from Breslow MJ, Jordan DA, Christopherson R, et al. Epidural morphine decreases postoperative hypertension by attenuating sympathetic nervous system hyperactivity. *JAMA* 1989;261:3579, with permission.)

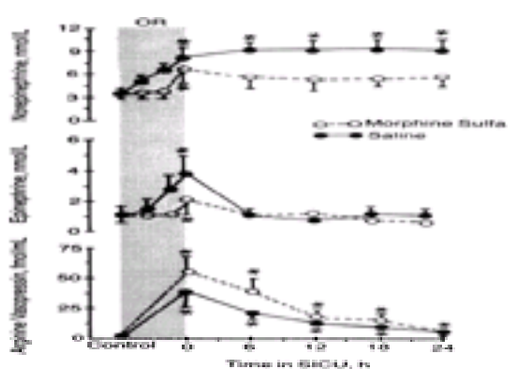

Figure 41-2. Arterial plasma concentrations of norepinephrine (top), epinephrine (center), and arginine vasopressin (bottom) before induction of anesthesia (control);

at two points during surgery; and 0, 6, 12, 18, and 24 hours following aortic surgery. Surgical intensive care (SICU), operating room (OR, *shaded area*), and asterisk, *p* <.05 compared with preinduction value. Data are mean ± SE (*vertical bars*). (Reprinted from Breslow MJ, Jordan DA, Christopherson R, et al. Epidural morphine decreases postoperative hypertension by attenuating sympathetic nervous system hyperactivity. *JAMA* 1989;261:3579, with permission.)

In another study, Yeager and associates evaluated the effect of combined general and epidural anesthesia followed by epidural morphine analgesia in high-risk surgical patients (17). Their prospective, randomized study compared the perioperative morbidity and mortality of high-risk surgical patients who had combined general and epidural anesthesia followed by epidural morphine analgesia with patients who had a routine general anesthetic followed by systemic morphine analgesia. They found a significant decrease in mortality, cardiovascular morbidity, and infection in the group that received combined general and epidural anesthesia followed by epidural morphine analgesia.

Brodner and associates reported results similar to those seen by Yeager. This study compared outcome in patients undergoing abdominothoracic esophagectomy receiving aggressive multimodal pain control versus historic controls (18). Both treatment groups had a thoracic epidural catheter placed before surgery. The control group (n = 49) received a general anesthetic for surgery followed by an epidural infusion of bupivacaine, 1.25 mg per mL, with sufentanil, 1 mg per mL. The treatment group (n = 42) received a preoperative bolus of bupivacaine, 2.5 mg per mL, with 20 to 30 mg of sufentanil, sufficient to obtain a T-4 sensory blockade. Patients then received a general anesthetic with perioperative infusion of bupivacaine with sufentanil for surgery. Postoperative pain in the treatment group was controlled with an epidural PCA using bupivacaine with sufentanil. When compared with the historic controls, the treatment group experienced superior pain relief, had improved nutritional status, had earlier tracheal extubation, had more rapid discharge from the intensive care unit, and met hospital discharge criteria earlier (Table 41-1).

	Group 1 (n = 49)		Group 2 (n = 42)	
	Mean	Standard deviation	Mean	Standard deviation
Extubation (hours after admission to the intensive care unit)	25.06	31.57	6.73*	3.03
first resting on the bedside (days after surgery)	1.57	1.71	1.02*	0.35
first time out of the bed (days after surgery)	1.94	2.26	1.17*	0.49
Intensive care discharge (days after surgery)	4.02	4.34	1.67*	1.95
Intermediate care discharge criteria (day after discharge)	6.37	3.95	4.86*	2.32

*Group 1 are historic controls receiving general anesthetic followed by thoracic epidural bupivacaine-sufentanil infusion. Group 2 patients received a preoperative T-4 local anesthetic block, epigastral anesthesia, followed by thoracic epidural patient-controlled analgesia with bupivacaine-sufentanil.
*p <.01 compared with group 1.

TABLE 41-1. Postoperative recovery of patients undergoing abdominothoracic esophageal surgery [a]

A metaanalysis of randomized, controlled trials on the effect of postoperative analgesic techniques on pulmonary outcome has been completed (19). Ballantyne and associates evaluated the effect on pulmonary outcome of a variety of analgesic techniques, including epidural opioid, epidural local anesthetic, epidural opioid with local anesthetic, thoracic versus lumbar epidural opioid, intercostal nerve block, wound infiltration with local anesthetic, and intrapleural local anesthetic. The analysis failed to find improvements in pulmonary outcome for any modality studied other than epidural techniques. Compared with systemic opioids, epidural opioids decreased the incidence of atelectasis and had a tendency to reduce the incidence of pulmonary infections and pulmonary complications. Epidural local anesthetics decreased the incidence of pulmonary infections and pulmonary complications when compared with systemic opioids. The study concluded that postoperative epidural pain control can significantly decrease the incidence of pulmonary morbidity.

Surgery also leads to suppression of immune function in humans (20), and this suppression appears to be directly related to the invasiveness of surgery (21). Although limited data are available in humans, animal data suggest that this immune suppression can be attenuated by the administration of analgesics, potentially improving outcome (22,23).

Preemptive Analgesia

More recent studies document that even the timing of pain control can have an effect on patient care extending to months after surgery.

CLINICAL CONSIDERATIONS

Process of Acute Pain Management

In the early 1990s, the practice of pain management came under increased scrutiny. To foster continued improvement in acute pain management, the Agency for Health Care Policy and Research (AHCPR) published clinical practice guidelines for the management of acute pain (24). The stated goal of the guideline was to reduce the incidence and severity of patients' acute postoperative or posttraumatic pain, educate patients about the need to communicate unrelieved pain so they can receive prompt evaluation and effective treatment, enhance patient comfort and satisfaction, and contribute to fewer postoperative complications and, in some cases, shorter stays after surgical procedures.

AHCPR guidelines emphasized a collaborative, interdisciplinary approach to pain control. The guidelines advocated the inclusion of all members of the health care team in the process of pain management, with input from the patient and the patient's family, when appropriate. To accomplish this, the guidelines recommended a formal, institutional approach to the management of acute pain, with clear lines of responsibility. The institutional plan should include the use of an individualized, proactive pain control plan, developed preoperatively by patients and practitioners, frequent patient assessment, and the use of both drug and nondrug therapies to prevent and control pain.

Other organizations have also developed acute pain management guides or practice guidelines. These include the International Association for the Study of Pain (25) and the American Society of Anesthesiologists (26). It is believed by many that these guidelines have led to improved acute pain management. However, the effect acute pain guidelines have had on establishment and potential preservation of an APS in a particular institution is questionable. Decisions on the development, maintenance, or both of an APS appear to be made, to a large extent, on the financial viability of these programs. And, as a result, the survival of these programs is in doubt in many areas of the country.

Unfortunately, the increased interest in acute pain management by government and private organizations is not reflected by the establishment of a commitment by health care payers to pay for such services (27). Although the AHCPR guidelines advise that institutions should give the responsibility of acute pain management to those most knowledgeable, experienced, interested, and available to deal with patients' needs in a timely fashion, they offer no suggestions on how such services should be paid for (28).

For example, Medicare does not pay for pain consultation after surgery if PCA is used, with rare exception. Some private insurers have adopted this payment practice. Difficulties in obtaining reimbursement for professional services have led to variability in access to expert pain management. Some health policy experts are advocating that payment should be based on the medical necessity for the services, rather then eliminating payment based solely on the types of services provided. Unfortunately, denials for payment may be increasing in frequency. Medicare often argues that the management of postoperative pain is part of the global fee paid to the surgeon and has been slow to recognize that the intensity of pain management between *traditional* pain management (i.e., as needed, intramuscular opioids) and more modern techniques is large.

Health care reform has led to the development of health care alliances and the establishment of bundled fees for hospital-related services. In this environment, acute pain management may actually fare better than in the fee-for-service system. An APS can provide perioperative pain management in an efficient, cost-effective

manner, improving outcomes while holding down overall costs. However, it is essential to the future of acute pain management that we prove this to be true.

As was discussed earlier, AHCPR guidelines have advocated that health care institutions develop and implement an institutional plan for pain management. Since the publication of the AHCPR guidelines, other accrediting agencies in the United States have acknowledged the importance of pain management and have made an institutional pain management plan a part of their standards for acute care hospitals.

Although such an institutional plan is important in establishing an environment conducive to the appropriate management of pain for the hospitalized patient, evidence is lacking that the presence of such a plan improves pain management in hospitalized patients (29). In addition to an institutional plan establishing the need for adequate pain management, there needs to be a process to ensure that this care is being provided. In response to this perceived need, the American Pain Society's Quality of Care Committee published guidelines for a quality improvement plan to ensure adequate acute and cancer pain management in the hospitalized patient (30). This plan should contain several key elements that are outlined in Table 41-2.

Ensuring that a report of unrelieved pain raises a *red flag* that attracts clinicians' attention
Making information about analgesics convenient where orders are written
Promising patients responsive analgesic care and urging them to communicate pain
Implementing policies and safeguards for the use of modern analgesic technologies
Coordinating and assessing implementation of these measures

Reprinted from American Pain Society Quality of Care Committee. Quality improvement guidelines for the treatment of acute pain and cancer pain. JAMA 1995;274:1874–1880, with permission.

Integrated Perioperative Care

Considerable interest exists in the development and use of utilization management and critical pathways (31). Critical pathways describe a course of care for patients with similar problems and treatments (32). A critical pathway should be an integrated interdisciplinary plan that leads to high-quality, cost-effective care (Table 41-3). Increasing amounts of data demonstrate that this model of care does lead to improved outcomes and reduced cost (33,34). This model of care for the hospitalized patient, which resembles the integrated interdisciplinary approach advocated for the chronic pain patient, may be an opportunity for the survival of APSs.

Standardize the course of events that lead to a successful outcome.
Interdisciplinary approach to patient care.
Include health care team education in the implementation of the plan.
Monitor the cost of care and patient outcome to ensure the pathway meets established goals.

TABLE 41-3. Critical aspects in the development of a critical pathway

In the case of acute pain management, it appears that gains in improving patient care could be obtained by exploring the use of the concepts seen in the creation of critical pathways for selected patient populations. A traditional APS often provides pain management in consultation with the primary care service by carving out pain management from the remainder of the patient's care. In the postoperative setting, interaction with the surgeon can be infrequent, and pain management may not be integrated with the overall care plan of the patient. In fact, the APS and the surgical service may only interact when a critical adverse event occurs, straining relationships between health care providers.

The development of a critical pathway for the surgical patient should begin with the decision to operate and extend to the moment of discharge. Although acute pain management would be a vital part of such a plan, other elements are equally important. For example, Fisher presented a model for a preoperative evaluation clinic that he believes provides high-quality, cost-effective care (35). Other investigators have shown that the selection of anesthetic technique has a direct effect on the quality of postoperative pain control (36). Many clinicians have emphasized that pain control at rest is not as important as pain control with movement, which allows the patient to participate in rehabilitation after surgery. Still others have shown that early effective postoperative pain control may reduce the chances for long-term chronic pain problems (37). All of these parts of the patient care experience have to be integrated into a seamless perioperative critical pathway for the surgical patient.

Some investigators have begun to integrate acute pain management into the postoperative rehabilitation of the surgical patient. Using a patient-focused approach similar to critical pathway development, pain management has been integrated into a global rehabilitation plan for the surgical patient (38). Although the role of the APS remains important, this care is not provided in isolation from other portions of the patient's care, but in the broader context of integrated rehabilitation of the patient (39). Early data indicate that this approach may lead to improved outcomes as well as earlier recovery and faster hospital discharge (40,41,42,43,44,45 and 46).

Participation in perioperative care by an organized APS can not only improve the quality of pain control, but should also decrease the incidence and severity of some adverse events. Pain therapy has risks, many of which can lead to patient harm. For example, although PCA therapy is considered to be safe, the potential for serious adverse outcome exists (47,48 and 49). Opioid administration is associated with alterations in ventilation (50). Life-threatening respiratory events associated with the use of PCA have been reported (48,51,52). These events are almost always associated with human error. Patient care through an APS may decrease the incidence and severity of these adverse events, thus improving outcomes and decreasing health care cost.

Other acute pain management modalities are also associated with the potential for serious adverse events. Neuraxial opioid therapy is associated with an incidence of respiratory depression of 1 per 1,000 to 1 per 1,300 (53,54,55,56,57,58,59,60,61,62,63,64 and 65). Although this therapy is considered to be safe in many patient care settings, it is clear that patients receiving neuraxial analgesics require monitoring by trained individuals who are immediately available to provide this care.

The APS has taken a leadership role in the establishment of monitoring standards and is often responsible for the training of nurses with regard to these standards. Changes in staffing of acute care hospitals may make it more difficult to ensure conformance with patient monitoring requirements in some settings. As hospital care evolves, it is vital that individuals expert in providing pain management maintain a leadership role to ensure adequate care to these individuals.

Although most APSs concentrate their services on behalf of individuals experiencing pain from surgery or trauma, other hospitalized patients frequently experience poorly controlled pain. For example, in a manuscript on the care of the dying patient, the Council on Scientific Affairs of the American Medical Association stated the following (57): “The current patient care delivery system is deficient in regard to the care of the terminally ill. Expertise in pain management is often not available to

patients, and comprehensive and enduring care is the exception.”

Clearly, this patient population can also benefit from the development of a critical pathway that integrates pain management into comprehensive care and ensures patients' access to experts in the field of pain management when indicated. A hospital- based APS can play a vital role in providing these necessary services.

Acute Pain Service

The goal of an APS is to improve postoperative pain management by applying effective methods of analgesic control (7). In addition, the APS provides education for residents and nursing staff and conducts research on the treatment of acute pain. In a university setting, the service is usually staffed by a pain management physician attending, an anesthesiology resident, a clinical nurse specialist, and a pharmacist. Staffing in a private practice setting varies with the available resources and pain treatment modalities offered.

The traditional APS patient care team is often composed of a pain management physician, advanced practice nurse, and pharmacist. Patients who are receiving care through the APS should be seen by the service at least daily. Evaluation of the quality of analgesia, side effects, medication dose, and inspection of the intravenous and epidural sites are completed. An APS physician should be available 24 hours a day for consultation and routine patient management problems.

A nurse specialist experienced in acute pain management is vital to the success of the service (58). The APS clinical nurse specialist ensures that the unit nurses have the special skills necessary to care for patients on the APS. Unit nurses are instructed on how to monitor patients receiving intrathecal or epidural medications, as well as patients receiving PCA for possible adverse reactions including inadequate analgesia, pruritus, nausea, or delayed respiratory depression. In addition, they are instructed on how to administer epidural medications and how to program and manage PCA devices. The APS clinical nurse specialist also acts as a liaison between the physician and nursing staff and functions as the quality control coordinator for the APS.

The pharmacist should also take an active role in the acute pain management. Frequently, the pharmacist can become aware of physician orders for drug combinations that could lead to an adverse event. In addition, the pharmacist should actively participate in the selection of standard analgesics to be used, including the establishment of standard concentrations and labeling practices. In many institutions, the pharmacist participates in acute pain team patient rounds, periodic team meetings, or both.

The APS is often responsible for establishing a pain treatment policy for the hospital. Such a policy should be in conformance with national guidelines and should emphasize that pain assessment and treatment are the responsibility of all health care providers. Pain care should be integrated into the patient's treatment plan, and pain assessment should be considered a fifth vital sign.

In addition to the institutional pain management policy, the APS often establishes policy for the use of available pain treatment modalities. For example, the University of Washington has established a process for credentialing physicians with appropriate training and experience to provide intravenous PCA. This process allows all qualified physicians to provide PCA therapy to *routine* patients, whereas patients who are not *routine* receive this care through the APS (Fig. 41-3 and Table 41-4). However, one study reported subtle differences in outcome when PCA therapy was provided by an APS compared with the primary surgeon. Stacey and associates reported that although pain scores were not different between patients cared for through the APS and the primary surgeon, APS patients had fewer side effects, were more likely to receive a loading dose, had their PCA settings adjusted more often, and used more opioid (59). Patients cared for by the primary surgeon also were more likely to receive intramuscular medications after PCA discontinuation. Whether these differences affect overall outcome has yet to be determined.

Definition of routine patient-controlled analgesia patient
Age <70 yr
No history of difficult pain management problems
No history of opioid tolerance (regular opioid use >1 mo), ethyl alcohol abuse, or ongoing substance abuse
No concomitant use of epidural local anesthetic infusions, epidural opioids, or intrathecal opioids or other analgesics
Definition of complex patient-controlled analgesia patient
Age >70 yr
Positive history of difficult pain management problems
Positive history of opioid tolerance (regular opioid use >1 mo), ethyl alcohol abuse, or ongoing substance abuse
Concomitant use of epidural local anesthetic infusions, epidural opioids, or intrathecal opioids or other analgesics

TABLE 41-4. Definitions of routine and complex patients for patient-controlled analgesia therapy

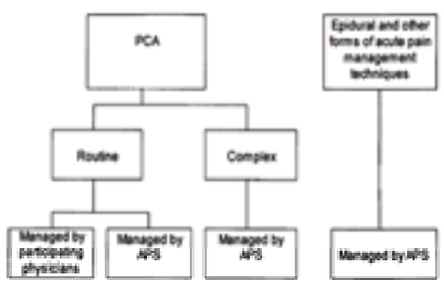

Figure 41-3. Process for provision of intravenous patient-controlled analgesia (PCA), as developed at the University of Washington. Patients meeting the definition of a routine PCA patient can receive intravenous PCA therapy by either a qualified participating physician or the acute pain service (APS). All other patients receive acute pain management by the APS.

The APS, in consultation with others, often establishes the drug formulary for PCA and other pain treatment modalities, which includes the establishment of drug concentrations to be used in selected drug delivery devices. The establishment of a limited number of drugs and drug concentrations decreases the risk of human error associated with device programming. Finally, the APS often is involved in the standardization of physician order forms for the provision of pain treatment modalities, which includes the use of standardized monitoring and treatment protocols, as seen in Figure 41-4 and Figure 41-5.

Figure 41-4. Standard preprinted patient-controlled analgesia orders used by the Acute Pain Service, University of Utah.

Figure 41-5. Standard preprinted epidural opioid orders used by the Acute Pain Service, University of Utah.

Pain assessment is the cornerstone of acute pain management (see Chapter 15). Assessment should be made using a valid measurement tool. Although the 0- to 10-cm visual analog scale is frequently used in clinical pain trials, it is less useful in a busy clinical setting. For older children and adults, the 0 to 10 verbal pain assessment tool, with 0 equal to *no pain* and 10 equal to *worst pain imaginable*, can be easily integrated into a busy clinical practice. Pain assessment tools appropriate to the developmental age of younger children should be used as indicated.

Pain assessment should be made for patients both at rest and with activity. Because activity is often an important part of the rehabilitation of the surgical patient, it is critical that one assess movement pain. Some studies have confirmed that some pain treatment modalities are more effective in controlling pain with movement when efficacy of pain control at rest is similar.

The incidence and severity of treatment-induced adverse side effects should be assessed frequently. Sedation, respiratory depression, pruritus, and nausea and vomiting are assessed in all patients. Additional treatment-related potential adverse side effects may be assessed, depending on the treatment modality used. A standardized method for documenting adverse side effects is important, so that this information can be collected and documented in a consistent manner. One method for assessment of adverse side effects is shown in Table 41-5. In addition, standardization of treatment of side effects, when present, improves efficacy of care and may lead to the selection of therapy that decreases costs. For example, droperidol has been shown to be as effective as ondansetron for the treatment of postoperative nausea and vomiting after ambulatory surgery (60).

0 Side effect not present

SPECIFIC TREATMENT MODALITIES

Nonsteroidal Antiinflammatory Drugs

In an effort to improve pain control and decrease the incidence and severity of drug-induced adverse side effects, many clinicians have introduced the use of nonsteroidal antiinflammatory drugs (NSAIDs) into the management of postoperative pain. In fact, the AHCPR guidelines suggest that NSAIDs should be the first-line drug for the treatment of mild to moderate pain and should be used in combination with opioids if not contraindicated for more severe pain.

Some investigators have reported that the combination of NSAIDs with opioids in this setting is more effective than either class of drug alone, and the use of NSAIDs with opioids decreases the necessary dose of the opioid and therefore decreases the incidence and severity of opioid-induced adverse side effects (61,62,63 and 64). Others have reported improved analgesia and reduced side effects when NSAIDs are used in combination with intrathecal opioids (65). However, NSAIDs alone and in combination with other medications can lead to adverse side effects, with some patients at increased risk. In this section, we review the use of NSAIDs for the management of postoperative pain (see Chapter 83).

The pain-reducing capacity of NSAIDs is attributed to their influence on the peripheral nervous system. This action is achieved through the partial inactivation of both cyclooxygenase 1 (COX-1) and cyclooxygenase 2 (COX-2), which in turn inhibit prostaglandin biosynthesis (Fig. 41-6 and Fig. 41-7). The inactivation of these enzymes blocks sensitization and activation of peripheral nerve fibers and decreases the number of pain impulses delivered to the central nervous system.

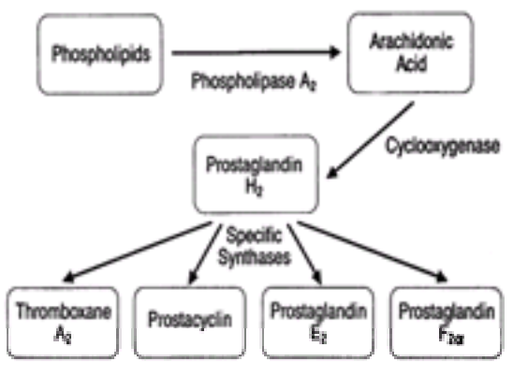

Figure 41-6. The cyclooxygenase pathway. [Reprinted from Lindgren JA. Overview of the physiology of COX-1 and COX-2 and selectivity of NSAIDs. *Am J Man Care* 1996;2(Suppl):S16–S17, with permission. All rights reserved.]

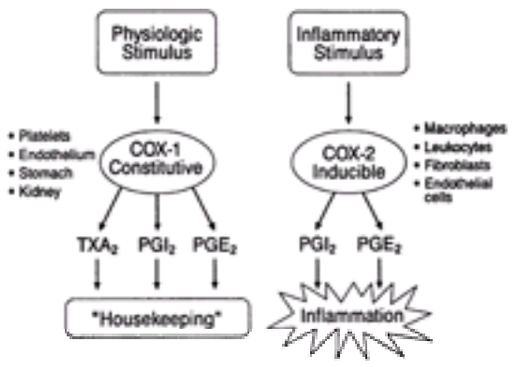

Figure 41-7. Role of COX-1 and COX-2. [Reprinted from Lindgren JA. Overview of the physiology of COX-1 and COX-2 and selectivity of NSAIDs. *Am J Man Care* 1996;2(Suppl):S16–S17, with permission. All rights reserved.]

COX-1 is present in a wide variety of cell types and influences the *housekeeping* functions of prostaglandins. This activity is particularly important in the gastrointestinal tract, kidney, and the circulatory system.

In the gastrointestinal tract, prostaglandin F_2 and prostacyclin maintain mucosal integrity by inhibiting acid secretion and stimulating bicarbonate and mucous secretion. The suppression of these cytoprotective functions by NSAIDs explains the gastrointestinal complications associated with the use of these drugs.

In the kidney, prostaglandins increase renal blood flow, which in turn elevates glomerular filtration and helps regulate both tubular salt and water resorption. Again, the suppression of these functions by NSAIDs explains the adverse effects on renal function seen with this class of drugs.

In the circulatory system, prostaglandins participate in maintaining vascular tone and are involved in control of platelet function. Administration of NSAIDs can adversely affect platelet function, resulting in clinically important bleeding disorders.

COX-2, on the other hand, is found in only a few cell types, especially macrophages and other leukocytes, fibroblasts, and endothelial cells, including those of the vascular system. COX-2 is involved in those aspects of the inflammatory process that are mediated by prostaglandins. Specifically, large volumes of prostaglandins are produced as an inflammatory response begins to build after tissue injury, such as a surgical incision. These prostaglandins potentiate other inflammatory mediators, including leukotrienes, histamine, and bradykinin, the last of which is the most powerful normal vasodilatory substance in human physiology. By potentiating vasodilatation and hyperalgesia, prostaglandins contribute to vascular permeability and, therefore, to edema.

NSAIDs do not cause the respiratory depression seen with opioids. In addition, NSAIDs do not interfere with either bowel or bladder function. However, that does not mean that they are devoid of potential adverse effects. The most common adverse side effects of NSAIDs are gastritis, peptic ulceration, and bleeding (66). In general, the incidence of these effects increases with increased daily dose of NSAID and increased duration of NSAID therapy. Individuals with a prior history of peptic ulcer disease appear to be at increased risk for these complications.

In the postoperative setting, considerable attention has been paid to the potential for NSAIDs to increase the likelihood of bleeding (67). NSAIDs lead to reversible inhibition of the platelet function. Postoperative administration of NSAIDs has been reported to lead to an increased incidence of bleeding (68). However, this is usually associated with selected patient populations, or in individuals who have received other anticoagulants in combination with the NSAID (69).

A rare but potentially serious complication is NSAID-induced depression of renal function (70). Individuals who suffer from chronic renal insufficiency, who are receiving concurrent diuretic therapy, or who are experiencing intravascular volume depletion are at increased risk for this adverse event. Usually, this complication is reversible with discontinuation of the NSAID, but long-term impairment of renal function has been reported.

The risk for adverse events associated with NSAID therapy is increased when some drugs are used in combination with NSAIDs. As stated previously, concurrent diuretic therapy increases the risk of renal complications. In addition, concurrent use of corticosteroids dramatically increases the risk of life-threatening gastrointestinal bleeding. Finally, the use of any other drug that impairs coagulation, such as coumadin or heparin, increases the likelihood of a clinically significant bleeding disorder.

Caution should be exercised when using NSAIDs during pregnancy. Analgesic therapy during pregnancy has been described in detail elsewhere (71).

Selected patients may also be at increased risk for NSAID-induced adverse events. Individuals with congestive heart failure, hepatic cirrhosis with ascites, systemic lupus erythematosus, and multiple myeloma are at increased risk for an adverse event. In addition, elderly persons with significant atherosclerotic disease are at elevated risk for such side effects (72). Care should be taken in these patient populations, dosing may need to be changed to decrease the potential for adverse events, and appropriate monitoring should be instituted when indicated (73). The recent clinical release of COX-2–specific drugs may reduce the side effects experienced with NSAIDs.

Patient-Controlled Analgesia

A PCA device consists of an electronic infusion pump that allows the patient to self-administer an analgesic medication. When the patient experiences pain, he or she pushes a button attached by a cord to the instrument. It then delivers a preset dose (interval dose) of medication via an indwelling intravenous catheter. The machine has a programmable period of time (lock-out time) after each interval dose administration during which it will not deliver another interval dose even when activated by the patient. This lock-out time is intended to prevent the patient from receiving an additional dose of the analgesic before the maximum effect of the previous dose is attained, thus decreasing the possibility of overmedication.

The use of as-needed intramuscular analgesia requires the patient to contact the nurse when he or she experiences pain. The nurse must then check the physician's orders, identify the analgesic, obtain the drug, prepare it for injection, and administer the medication. After drug administration, there is a period of time before the drug is systemically absorbed and reaches analgesic blood levels. Because high intramuscular doses are required to decrease the time to analgesia, there is often a period of high blood concentration and oversedation. The patient experiences analgesia for a relatively short period of time, and then the cycle repeats itself as the drug level decreases below analgesic levels (Fig. 41-8) (74).

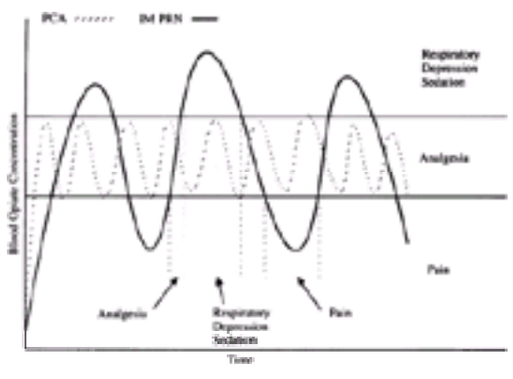

Figure 41-8. The difference in opioid levels between patient-controlled analgesia (PCA) and intramuscular routes of administration. (Reprinted from Ashburn M, Smith K. The management of postoperative pain. *Surg Rounds* 1991;14:129–134, with permission.)

PCA allows the patient to receive medication intravenously as soon as he or she begins to experience pain and eliminates the obligatory delays in drug administration and absorption seen with intramuscular dosing. The administration of smaller intravenous doses allows the patient to titrate the opioid to analgesic levels more accurately and decreases the risk of oversedation associated with intramuscular opioid dosing.

Although PCA devices have been in existence since the late 1960s, they have not met with widespread acceptance until more recently. This is caused, in part, by improved device technology, such as improved device memory and safety features. In addition, the introduction of anesthesiology-based APSs into clinical practice has made this treatment modality more widely available.

PCA therapy provides improved analgesia compared with as-needed intramuscular opioid administration in patients undergoing a variety of surgical procedures (75,76,77,78,79 and 80). Patients usually require less analgesic via the PCA device than those receiving equianalgesic doses of intramuscular opioids (81).

Approximately 85% of the patients who receive PCA for the management of acute pain experience good to excellent pain control (82). Many patient factors may influence the ability of PCA therapy to be successful, including the ability of the patient to understand the correct use of the device, the patient's prior pain experience, and other psychosocial factors (83,84,85 and 86). These factors must be taken into account when considering patients for this therapy, and when making decisions on the appropriateness of continuing therapy once begun.

Patient selection for PCA therapy is based on the patient's ability to understand the concept of PCA therapy and appropriately interact with the device. No arbitrary age limit is set, as PCA therapy has been proven to be effective in pediatric and adolescent age groups (80,87,88 and 89). Preoperative patient education on the use of the PCA device greatly enhances success.

The analgesic used in the PCA device is usually a potent opioid, such as morphine or hydromorphone (Dilaudid). Opioid antagonists, such as nalbuphine, have also been employed successfully (90), as have NSAIDs (91). Interval dose and lock-out time for the different agents are determined by the potency of the drug and the time necessary for maximum effect after intravenous administration (Table 41-6).

Drug	Bolus dose (mg)	Lock-out interval (min)
Agonist		
Morphine	0.5–3.0	5–20
Methadone	0.5–3.0	10–20
Hydromorphone	0.1–0.5	5–15
Oxymorphone	0.2–0.8	5–15
Meperidine	5–15	5–15
Fentanyl	0.015–0.075	5–10
Sufentanil	0.002–0.015	5–10
Agonist-antagonists		
Pentazocine	5–20	5–15
Nalbuphine	1–5	5–15
Buprenorphine	0.03–0.20	10–20

TABLE 41-6. Guidelines regarding the bolus dosages and lock-out intervals for various parenteral analgesics when using a patient- controlled analgesia system

Meperidine is a commonly used opioid for intramuscular, as-needed analgesia. Many institutions continue to use this opioid for intravenous PCA analgesia. However, it should not be used as the first-line opioid for acute pain management. Meperidine has a short duration of action (2.5 to 3.5 hours), which necessitates frequent dosing. In addition, excessive use or decreased renal clearance can lead to the accumulation of normeperidine (6-desmethylmeperidine). This metabolite can accumulate because of its long half-life (24 to 36 hours), especially in elderly patients and patients with impaired renal function. It is a cerebral irritant that can cause effects ranging from mood irritability to grand mal seizures (92). As a result of the potential for these serious drug-specific side effects, many institutions are changing their acute pain processes to significantly limit the use of meperidine or are removing meperidine from their formulary entirely.

The use of a basal infusion with PCA opioids does not appear to increase the effectiveness of analgesia and may increase the incidence of adverse side effects in adult (93,94) and pediatric (95) patient populations. Others have noted that the addition of an infusion may increase the risk of programming error (49,51,96).

Although PCA therapy is considered to be safe, the potential for serious adverse outcome exists (Table 41-7) (47,48,52,97). Opioid administration is associated with alterations in ventilation (50). Life-threatening respiratory events associated with the use of PCA have been reported (48,49 and 50,52,98,99). The incidence of these events has recently been reported to be 0.01%, similar to that seen with intramuscular opioid administration or epidural morphine administration (51). These events are most often associated with human error, usually related to pump programming (see Table 41-7).

Operator errors
Misprogramming PCA device
Inappropriate drug, dose, or concentration
Inappropriate lock-out period
Inadvertent addition or deletion of a basal infusion
Failure to clamp or unclamp tubing while loading or unloading the drug reservoir
Improperly loading syringe or cartridge
Inability to respond to safety alarms
Misplacing PCA pump key
Patient errors
Failure to understand PCA therapy
Alterations in negative feedback loop
Misunderstanding PCA device
Intentional analgesic abuse
Mechanical errors
Failure to deliver on demand
Cracked drug reservoir
Defective one-way valve at Y-connector
Faulty alarm system
Malfunctions (e.g., leak)
Nonpatient delivery system
Block or kink in the intravenous catheter or tubing, leak, or disconnect

PCA, patient-controlled analgesia.
From Weiss H. Management of patient-controlled analgesia. Anesthesiology 1985;63, with permission.

TABLE 41-7. Summary of problems that may occur during patient- controlled analgesia therapy

Interdisciplinary acute pain management can be used to decrease the incidence and severity of adverse outcomes while providing the highest quality patient care possible. Acute pain management requires the involvement of the patient and family, primary care physician, pain management physician, primary nurse, pain management nurse, and pharmacist.

Although PCA is most commonly used for systemic delivery of potent opioids, it has also been used in other settings. PCA has been used for systemic delivery of nonopioid analgesics, such as NSAIDs (91). In addition, PCA has been used to administer epidural analgesia (100), which is discussed later in this chapter, as well as in the chapter on spinal opioids. Finally, PCA has also been used to deliver regional local anesthetics, such as patient-controlled interscalene analgesia (101).

In addition to the management of postoperative pain, PCA has been effectively used in other patient populations. PCA can be used to manage pain associated with acute medical illness, prolonged cancer therapy (102), and terminal illness. Newer designs of the PCA device have allowed it to be effectively used in the ambulatory setting. However, regardless of the setting, systemic administration of a potent analgesic can lead to serious adverse outcome. Therefore, prudent use of PCA in any setting must be accompanied by appropriate monitoring.

Spinal Opioids

Intrathecal and epidural administration of opioids is a relatively new technique first described in humans in 1979 (103). The technique gained rapid, widespread use because of the long duration of intense analgesia caused by opioids administered directly on the spinal axis (10). However, this enthusiasm was soon tempered by reports of side effects such as pruritus, urinary retention, nausea and vomiting, and delayed respiratory depression.

In contrast to the local anesthetics, which act at the spinal nerve root level, opioids act at receptor sites in the dorsal horn of the spinal cord. Because of this selective effect at opioid receptor sites, they do not lead to hypotension caused by sympathetic blockade. Opioids also do not cause any motor blockade that could lead to reduced patient mobility.

The onset and duration of analgesia of spinal opioids is closely related to their lipid solubility. Morphine, with a relatively low lipid solubility, has a slow onset time of approximately 45 minutes, but a long duration of action of up to 24 hours. Meperidine, on the other hand, is relatively lipid soluble, when compared with morphine, and has an onset time to analgesia of approximately 15 minutes, with an average duration of 2 to 6 hours (104,105,106 and 107). The relatively fast onset and intermediate duration of action of epidurally administered meperidine makes it a possible candidate for epidural PCA. Initial reports of its use in this setting have been promising (108,109).

Very lipid-soluble opioids, such as fentanyl and sufentanil, have a relatively short duration of action when administered intrathecally. Controversy exists, however, on the location of action (either systemic or spinal) after the epidural administration of fentanyl or sufentanil. Pharmacokinetic studies of epidural fentanyl reveal rapid absorption of fentanyl across the dura mater and into the cerebrospinal fluid (110). However, clinical studies fail to show a difference in the pain control provided by epidural versus intravenous fentanyl (111,112). Other relatively lipid-soluble opioids, such as meperidine and hydromorphone, have a spinal effect when administered epidurally (113). However, it appears that epidural fentanyl and sufentanil have their primary effect as a result of systemic absorption, rather than at the dorsal horn of the spinal column (114,115).

Intrathecal and epidural administration of opioids is associated with several potential adverse side effects. These include pruritus, nausea, vomiting, urinary retention, early- and late-onset respiratory depression, infection, and bleeding. Pruritus and urinary retention are common with the administration of spinal opioids, but are usually controllable and infrequently lead to discontinuation of drug administration. The incidence of nausea and vomiting associated with spinal opioid administration is similar to or less than that seen with intramuscular opioid administration. These side effects can be effectively managed with intravenous naloxone, usually without decreasing the effectiveness of pain relief. In spite of these potential side effects, numerous clinical trials have documented that 90% of the patients who receive either intrathecal or epidural opioids report excellent analgesia (116).

Both early and late respiratory depression has been seen with spinal opioid administration (117). Early respiratory depression is thought to be secondary to the effect of systemically absorbed drug, whereas late respiratory depression is thought to be secondary to the central effect of the drug that has flowed cephalad from the point of injection. Late-onset respiratory depression is usually associated with the administration of morphine and is rarely seen with the administration of the lipid-soluble opioids. Late-onset respiratory depression is most likely caused by rostral spread of the opioid to the respiratory centers of the brainstem (118) and appears to be dose related (Table 41-8 and Table 41-9) (119). Respiratory depression is usually associated with relatively high doses (epidural morphine more than 5 mg, intrathecal morphine more than 0.5 mg) and is seen more frequently in patients who are elderly, debilitated, or have received systemic opioids or benzodiazepines.

TABLE 41-9. Percent (and number) of adult volunteers by intrathecal morphine dose experiencing one or more episodes of SpO2 less than 90% and less than 85%, respiratory rate less than 8, and requiring supplemental oxygen

Because of the risk of late respiratory depression, some investigators advocate aggressive monitoring of patients receiving spinal opioids or limiting their use to special nursing areas, such as the intensive care unit. However, when late respiratory depression does occur, it usually has a gradual onset and is associated with a gradual increase in somnolence. These drugs can be safely administered on any patient care unit in which the nursing staff caring for the patient has been instructed on the correct monitoring of these patients and where appropriate physician care is available (7).

Bernards and associates reported on the effect of needle puncture on morphine and lidocaine flux through the spinal meninges of the monkey (120). In an *in vitro* model, they demonstrated a significant increase in the flux of morphine through meningeal tissue after needle puncture. This has been confirmed in the animal model with morphine and sufentanil (121,122), and a case report of late-onset respiratory arrest after the use of the combined spinal-epidural technique has been published (123). As a result, some pain management physicians avoid the use of morphine in a patient who has had an inadvertent dural puncture with an epidural needle, followed by placement of an epidural catheter. Certainly, caution and careful monitoring for respiratory depression are indicated.

Opioids with Local Anesthetics

Local anesthetics have been used for years for spinal and epidural anesthesia and analgesia and can provide excellent analgesia. Investigators have documented in the animal model a synergistic effect when dilute local anesthetics are combined with opioids for epidural analgesia (124,125). Good analgesia has been reported with the use of continuous epidural infusions of bupivacaine and morphine (53), bupivacaine and fentanyl (56), and bupivacaine and sufentanil (126). Only a few studies have compared the efficacy of local anesthetics with morphine versus more lipid-soluble opioids. However, it appears that the use of the more lipid-soluble opioids, such as fentanyl, may be associated with similar analgesia and fewer side effects (127).

The use of epidural local anesthetics with opioids may allow for comparable or improved analgesia with fewer side effects when compared with using either agent alone. For example, Liu and associates evaluated the effects of various analgesic techniques on rate of recovery after colon surgery (43). They studied four analgesic techniques: epidural infusion of morphine, epidural infusion of bupivacaine, intravenous patient-controlled morphine, and an epidural infusion of bupivacaine with morphine. They reported superior analgesia with activity in the epidural bupivacaine and epidural bupivacaine-morphine groups. Both groups experienced more rapid recovery of gastrointestinal function and met hospital discharge criteria approximately 1.5 days earlier than the other study groups. However, the epidural bupivacaine-morphine group experienced fewer adverse side effects when compared with all other analgesic study groups.

When using dilute epidural local anesthetics with opioids, the catheter should be placed at a vertebral level corresponding to the dermatomal level of the surgical incision. As a result, more catheters will be placed at the high lumbar and thoracic levels. Although placement of the catheter at higher levels has been thought to lead to an increased risk of neurologic injury, reports refute this belief (128). The risk of neurologic injury associated with the placement of an epidural catheter appears to be 0.07% (129).

Even with dilute local anesthetic solutions, a risk of hypotension and motor block exists. The risk of motor block appears to be related to both the concentration of local anesthetic used as well as the position of the epidural catheter, with a low lumbar catheter having the highest risk of motor block compared with either a high lumbar or thoracic catheter (100,130).

Several investigators have reported on the use of patient-controlled epidural analgesia with opioids alone or local anesthetic- opioid mixtures. Early studies with relatively small numbers of patients report excellent analgesia in both obstetric (131,132) and surgical patients (133). When compared with continuous infusions, epidural PCA appears to provide comparable or improved analgesia with less medication (134). A more extensive surveillance study reported excellent analgesia in 1,030 surgical patients (100). Liu and associates reported on the use of patient-controlled bupivacaine 0.05% with fentanyl, 4 mg per mL. This technique provided excellent analgesia both at rest and with movement, with an acceptable adverse-event profile (Table 41-10).

Side effect	% Incidence (95% confidence interval)
Pruritus (patient request for antipruritic)	16.7 (14.7–18.7)
Nausea (patient request for antiemetic)	14.8 (12.8–16.8)
Sedation	
Mildly drowsy	11.7 (9.7–13.7)
Moderately drowsy	0.9 (0.3–1.5)
Very drowsy	0.5 (0.1–0.9)
Difficult to rouse	0.1 (0.0–0.2)
Hypotension (systolic blood pressure <90 mm Hg)	6.8 (5.0–9.0)
Motor block (inability to ambulate because of lower extremity weakness)	2.0 (1.0–3.0)
Respiratory depression (respiratory rate <8 breaths per minute)	0.3 (0.0–0.6)
Requiring naloxone	0.2 (0.0–0.4)

TABLE 41-10. Incidence and maximal risk of side effects associated with epidural patient-controlled analgesia using bupivacaine 0.05% with fentanyl, 4 µg per mL

As with other complex pain management modalities, standardization of therapy decreases the risk for human error. Liu and associates have published their recommendations for standard orders for epidural PCA therapy (Table 41-11), monitoring (Table 41-12), and treatment of adverse side effects (Table 41-13) (100). A survey of monitoring practices in the United States after epidural analgesics has also been published (135). It appears, however, that with appropriate monitoring these techniques can be safely used on the hospital ward (56).

1. Epidural analgesic solution is 0.05% bupivacaine with 4 µg/mL of fentanyl.
2. Set the background infusion rate to 4 mL/hr.
3. Set the loading dose to 5 mL.
4. Set 1-hour limit to 14 mL.
5. Set patient-controlled epidural analgesia bolus to 2 mL and lock-out to 10 minutes.
6. If analgesia is inadequate (verbal pain score >5 at rest or with activity), then administer a 5 mL loading dose, increase the infusion rate by 2 mL/hr, and increase the 1-hour limit to 24 mL.
7. If more than two adjustments to patient-controlled epidural analgesia are needed within a 24-hour period, then call the acute pain service.
8. No other analgesics or hypnotics are to be given without notifying the acute pain service.

Modified from Liu S, Allen H, Olsson G. Patient-controlled epidural analgesia with bupivacaine and fentanyl on hospital wards. Anesthesiology 1998;88:693, with permission.

TABLE 41-11. Standing orders for patient-controlled epidural analgesia settings and analgesic therapy

1. Check respiratory rate, level of consciousness, and blood pressure/heart rate every 1 hour for 12 hours, then every 2 hours for 12 hours, then every 4 hours thereafter.
2. If systolic blood pressure is <90 mm Hg, call the acute pain service.
3. Check postural pressure on the morning of postoperative days 1 and 2.
4. Check the level of sensory block every 8 hours. Notify the acute pain service for T-4 block or increasing sensory level.
5. Maintain intravenous access for 2 hours after the epidural infusion is discontinued.

Modified from Liu S, Allen H, Olsson G. Patient-controlled epidural analgesia with bupivacaine and fentanyl on hospital wards. Anesthesiology 1998;88:693, with permission.

TABLE 41-12. Standing orders for nursing monitoring for epidural patient-controlled analgesia

1. Respiratory depression.
   If respiratory rate is <8 breaths per minute and unable to arouse patient, then give 0.1 mg of naloxone intravenously STAT (may repeat 3 times). Call the acute pain service STAT.
   If respiratory rate is <10 breaths per minute, call the acute pain service.
2. For nausea and vomiting, administer 0.5 mg of droperidol intravenously every 4 hours as needed.
3. For pruritus, administer 25 to 50 mg of diphenhydramine intravenously or by mouth every 4 hours as needed.
4. If systolic blood pressure is <90 mm Hg, call the acute pain service.
5. Allow assisted ambulation only. Call the acute pain service for motor weakness.

Modified from Liu S, Allen H, Olsson G. Patient-controlled epidural analgesia with bupivacaine and fentanyl on hospital wards. Anesthesiology 1998;88:693, with permission.

TABLE 41-13. Standing orders for the treatment of side effects associated with epidural patient-controlled analgesia

Placement of an epidural catheter is associated with a risk of infection. Surveillance studies report a low incidence of infection in both adults and children with epidural catheters used for short-term postoperative analgesia (136,137). However, life-threatening infections can occur (138). Appropriate monitoring for this potential complication should be completed.

A potentially serious complication of epidural analgesia is the development of an epidural hematoma, leading to severe neurologic injury. The occurrence of symptomatic hematomas after epidural catheter placement is rare (139). However, patients who are anticoagulated are at increased risk. Surgical patients are frequently placed on anticoagulants to avoid the development of thrombotic complications. Studies evaluating the risk of bleeding associated with epidural analgesia after oral anticoagulant prophylaxis revealed a low rate of bleeding (140). However, other investigators have documented a wide variation in response to anticoagulation therapy (141); the more anticoagulated a patient is, the higher the risk of bleeding. In addition, the use of other drugs that interfere with the coagulation process, such as NSAIDs, platelet inhibitors, or other anticoagulants, also increases the risk of bleeding.

Low-molecular-weight heparin compounds have been introduced into practice (142). Initial studies indicated that low-molecular-weight heparin, when administered at equivalent antithrombotic doses, caused less bleeding than standard heparin. However, there have been reports of spinal hematoma occurring spontaneously and in association with regional anesthesia in patients who have received low-molecular-weight heparin (143). The Food and Drug Administration published a public health advisory in December 1997 outlining the agency's concern over the use of regional anesthesia and analgesia in patients receiving low- molecular-weight heparin. The Food and Drug Administration cited 30 spontaneous safety reports describing patients who have developed epidural or spinal hematomas with concurrent use of enoxaparin sodium and spinal or epidural anesthesia or spinal puncture. The Food and Drug Administration reported that many of the epidural or spinal hematomas caused neurologic injury, including long-term or permanent paralysis. The risk for serious bleeding appeared to be increased by traumatic or repeated epidural or spinal puncture.

Horlocker and Heit published guidelines for regional anesthetic management in patients receiving low-molecular-weight heparin (Table 41-14 and Table 41-15) (144). Clearly, the pain management physician should consider the risk for this and other rare but serious events when considering a regional analgesic technique. Appropriate monitoring is critical, especially with regard to risk of bleeding and infection, because prompt diagnosis and treatment of these complications are critical to avoid long-term neurologic injury (143).

CONCLUSIONS

A goal of acute pain management programs is to ensure that individuals experiencing pain receive the best possible pain management. Anesthesiologists have had a significant effect on improving care to those suffering from pain and will continue to do so. Individuals who experience trauma and surgery will continue to experience pain and will require the care that anesthesiologists provide. However, the organizational structure through which acute pain care is provided will likely continue to evolve. It is vital that anesthesiologists continue to strive to meet the needs of the people we serve, and in doing so we will remain a vital part of an integrated, interdisciplinary system of care for the perioperative patient.

CHAPTER 42

*Burn Pain**

David R. Patterson and Sam R. Sharar

If burn injuries in themselves are not the most painful type of trauma a person can sustain, then they likely reach this status once the nature of their treatment is considered. Treatment for burn injury involves a multitude of invasive procedures that may continue for months. Each intervention has the potential of inflicting more pain than that of the initial trauma. Burn injuries are pervasive in the United States and the world and tend to affect individuals across a wide demographic span. Estimates of burn incidence in the United States suggest 1.25 million episodes with 51,000 acute hospitalizations and 5,500 deaths annually (1). Substantial evidence suggests that pain from burn injuries is undertreated, particularly in children (2). This is unfortunate, because the pain from acute burns has physiologic effects that are likely to impede wound healing (3. Furthermore, pain correlates strongly with psychological outcome in this patient population. Thus, there are humane reasons to control burn pain in a better fashion, as well as practical, cost-effective ones.

NATURE OF BURN PAIN

Burn pain is an unpleasant form of suffering to treat, from the perspective of both the patient and the clinician. It is well known that a burn injury results in one of the most intense types of nociception imaginable. However, it is the treatment of a burn injury that creates the true challenge, for typical burn care involves a series of aggressive procedures that stimulate nociceptive afferent fibers on a daily basis for days, weeks, or months after the initial injury. In conventional care, a burn injury is assessed as to its depth and treated accordingly. Shallow burns are left to heal on their own, and full-thickness thermal injuries typically are excised and covered with a skin graft (4). Patients with burns of indeterminate depth in many burn centers undergo a series of wound debridements and dressing changes on a daily basis. The pain of a burn patient can be anticipated and treated, to a large degree, based on the phase of care in which he or she is involved. Wound cleaning, mobility, therapeutic stretching, and other medical procedures result in procedural pain, which is of high intensity, but limited duration. Patients who are between procedures, showing minimal activity, still experience resting pain that is of less intensity but almost constant duration. When pain control interventions fail to control resting pain, patients experience breakthrough pain. Finally, because surgical interventions are a frequent treatment for severe burn injuries, postoperative pain is an additional type of pain to be considered. Each of these types of pain has specific treatment strategies associated with them.

Although the nature of burn care provides some prediction as to the pain a patient will experience, the overall quality of a given individual's pain experience has proved to be extremely difficult to anticipate. The sensory and affective quality of burn pain has received scant attention in the literature, and almost no studies have addressed patterns over the course of hospitalization. Patients have been found to report their pain as severe or excruciating, despite receiving intravenous (IV) morphine (5). Pain from burn injuries has also been found to be linked to emotional factors, such as depression and posttraumatic stress disorder (6,7 and 8). Choiniere and colleagues (9) followed pain over the course of hospitalization and found that it varied substantially both within and across patients over time. They also reported that burn pain is not predicted well by social-demographic factors or burn size (the latter finding is contrary to the inaccurate assumptions of many clinicians treating burns). The unpredictable and often opioid-resistant nature of burn pain has been hypothetically linked to underlying sensory nerve damage (10,11).

The literature suggests that the times burn pain is at its worst can be anticipated, but only within broad parameters. Capturing the individual pain experience of a patient will likely continue to prove to be elusive. In spite of the challenge inherent in adequately treating burn pain, it remains important to continue to treat this problem aggressively. First of all, burn recovery, as is the case with any type of trauma, can be hindered by the presence of acute pain (3,12,13 and 14). Remarkably, burn pain has been reported to influence posthospitalization emotional recovery, more than the size of the burn, the length of hospitalization, or even the patient's preinjury mental health. Ptacek and colleagues (15) reported that pain scores correlated higher with 1-month distress and quality of life scores than other variables measured. A more recent study suggested that this relationship held at 1 year posthospitalization (16). Future studies will likely substantiate the practical utility of adequately treating burn pain.

PSYCHOLOGICAL FACTORS

As discussed previously, the pain experienced by burn patients is influenced by their emotional state. Unfortunately, a burn injury is a form of trauma that has dire emotional consequences for many survivors. Equally important, patients who sustain severe burn injuries often do so because of their predisposing psychological status. In considering psychological factors, then, it is important to consider the preinjury status of patients, as well as their emotional adjustment during and after hospitalization.

The estimates of preinjury psychological problems in some studies of burn patients are so high that injuries of this type should be considered to be, in part, a symptom of social ills (17). Estimated rates of psychiatric diagnoses in patients admitted for burn care have ranged from 25% to 75%, with the most prevalent diagnoses including depression, character disorder, and substance abuse (17). In addition, the nature in which the burn injury occurred is often cause for concern: suicide attempts, child and elder abuse (or neglect), adult batterings, and juvenile fire setting are all unfortunately common sources of injury. Psychological disturbances that predate the burn injury have the potential to increase complications, lengthen hospital stays, and lead to more serious long-term adjustment problems (18,19 and 20). A number of these preinjury complications have direct relevance to pain control. Patients with drug and alcohol histories may show lower pain tolerance, more drug-seeking behaviors, and greater tolerance to opioid analgesics. *Diagnostic and Statistical Manual*, fourth edition, axis II character disorders can present a particular challenge to clinicians. Patients with such personality predispositions may not only show drug-seeking but also dramatic acting out behaviors, manipulation, staff-splitting, and low frustration tolerance. Patients with borderline personality disorders, in particular, engage in parasuicide behavior and self-mutilation. The latter groups of patients can provide clinicians with notable behavioral challenges on top of already difficult pain control issues.

The nature of burn care, hospitalization, and the significance of sustaining a burn injury can cause psychological complications that complicate pain control. Patients with large unhealed burn areas or other significant medical complications are usually placed in intensive care units. In the intensive care unit, delirium and other psychotic reactions are common (20,21). Infections, alcohol withdrawal, and metabolic complications are the most frequent etiologies (22). Poor communications from altered mental status or endotracheal intubation may impede pain assessment. Anxiety can be particularly intense on the intensive care unit, which is particularly significant, given the cyclic interaction between anxiety and nociception (3). Anxiety, in fact, is a frequently reported psychological complication that persists into the acute phase of burn care. As hospitalization persists and patients show greater mental capacity, depression becomes increasingly common and is well known to interact with pain (23). Posttraumatic stress disorder is another complication that can affect pain control. Perry (24) warned against undermedicating such patients who are quiet and withdrawn as a function of their reaction to stress.

With pediatric burn patients, the interaction between psychological factors and pain control can be particularly notable. For children, the burn unit environment can be extremely strange and frightening. Little opportunity exists for the burn staff to prepare children psychologically for the repeated medical procedures they must endure, and conditioned anxiety to the stimuli associated with burn care can be expected. Children also often demonstrate regression and behavioral acting out in response to hospitalization, making pain control during procedures a particular challenge.

In the long-term rehabilitation phase of burn recovery, both acute pain and psychological symptoms are less common. However, patients may show persistent depression or posttraumatic stress disorder that interacts with pain control. Sleep problems are prevalent, frequently underaddressed in posthospitalization, and may reflect undertreatment for pain. When psychological or pain problems persist long after hospital discharge, the possibility of social or financial disincentives should be entertained. Although some patients certainly have internally generated psychological problems, for others, the issues persist because of such factors as litigation or the desire to avoid returning to an undesirable job.

GENERALIZED TREATMENT PARADIGM FOR BURN PAIN

Because burn pain is highly variable and cannot be reliably predicted by clinical assessment of the patient or the burn wound, we recommend a structured approach to burn analgesia that incorporates both pharmacologic and nonpharmacologic therapies, targets specific pain issues unique to the burn patient, and can be tailored to anticipated variations in patient need and institutional capability. One clear goal of such a paradigm is to avoid the undertreatment of burn pain, an unfortunate reality in the settings of adult (25) and pediatric (2,26) burn care, and more historically described for other acute pain settings (27). Perry and colleagues (28) noted that burn staff members failed to medicate patients adequately with opioids, despite education regarding the low risks for addictive and other side effects. These investigators offered a psychodynamic conceptualization of this issue, proposing that staff members required to perform repeated and painful procedures on these patients had a need for patients to demonstrate pain as a means to create a psychological distance between themselves and the realities of burn care. Alternatively, the fear of creating psychological dependence on opioids may explain the reluctance of some burn care staff to aggressively treat burn pain. However, currently no evidence exists that opioid addiction occurs more commonly in burn patients than in other populations requiring opioids for acute pain (approximately 1 in 3,000) (29).

In the generalized burn pain management paradigm, selection of an analgesic regimen is individualized and based on two broad categories: (a) the clinical need for analgesia (i.e., treatment of background versus procedural versus postoperative pain), and (b) limitations imposed by the patient (presence of IV access, endotracheal tube, or opioid tolerance) or by clinical facilities (available monitoring capabilities and personnel). The presence or absence of IV access directly influences analgesic drug choice, particularly in children in whom IV access may be problematic. Patients who are endotracheally intubated and ventilated are “protected” from the risk of opioid-induced respiratory depression; thus, opioids may be more generously administered in these individuals, as is often indicated for complex burn debridement procedures in patients with more extensive or severe burn injuries. Individual differences in opioid efficacy should be considered in all patients, including opioid tolerance in patients requiring prolonged opioid analgesic therapy or in those with preexisting substance abuse histories. Because of the development of drug tolerance with prolonged medical use (more than 2 weeks) or recreational abuse of opioids (both commonly seen in burn patients), opioid analgesic doses needed for burn analgesia may significantly exceed those recommended in standard dosing guidelines. One clinically relevant consequence of drug tolerance is the potential for opioid withdrawal to occur during inpatient burn treatment. Thus, the period of inpatient burn care is not an appropriate time to institute deliberate opioid withdrawal or detoxification measures in the substance-abusing patient, because such treatment ignores the real analgesic needs (background pain and wound care pain) of these patients. Similarly, when reductions in analgesic therapy are considered as burn wounds heal, reductions should occur by careful taper, in order to prevent acute opioid withdrawal syndrome.

Institutional capability to provide adequate monitoring (pulse oximetry, independent patient observer) as required for conscious sedation may also dictate which agents are used for procedural analgesia, as some of the more potent opioids (e.g., fentanyl) and agents such as ketamine may provide levels of sedation beyond those of mere analgesia. Obviously, this distinction between analgesia and conscious sedation is subjective and requires both individual and institutional interpretation to ensure safety and practicality in meeting proposed monitoring guidelines for conscious sedation. The use of potent opioids and anxiolytics should only occur in settings with adequate monitoring, personnel, and resuscitation equipment appropriate for the degree of sedation anticipated. For most wound debridement procedures, opioid analgesia with minimal sedation is sufficient, and no special monitoring is required. Larger or more potent doses of opioids, or the concurrent use of anxiolytic sedatives (e.g., benzodiazepines) may produce more pronounced sedation (deep sedation) in which patient-staff communication, consciousness, or both are lost. Current guidelines of the Joint Commission on Accreditation of Healthcare Organizations (30), as well as physician specialty professional organizations (31), dictate both general and specific levels of monitoring (e.g., continuous pulse oximetry, presence of an independent observer specifically responsible for monitoring ventilation and vital signs) for patients requiring this level of analgesia and sedation.

Because nociception at the burn site is the predominant mechanism of pain and suffering in these patients acutely, pharmacologic treatment with potent opioids, anxiolytics, and other agents (e.g., ketamine) is the first line of therapy. We believe that nonpharmacologic methods of treating burn pain are also extremely useful, although some nonpharmacologic pain control techniques should be second nature to the staff and integrated into standard care (e.g., minimizing the number and intrusiveness of dressing changes, limb elevation, brief educational approaches). Others are more practically implemented after a stable pharmacologic regimen is established (e.g., hypnosis). To reinforce a consistent approach to analgesic management, particularly in centers where house staff physicians, nursing staff, or both may rotate or change frequently, the establishment of succinct yet detailed institutional guidelines may help physicians and nurses with choosing and administering analgesics that target specific analgesic needs (32,33), as shown in Table 42-1. To maximize simplicity and utility, it is recommended that such guidelines be safe and effective over a broad range of ages, be explicit in their dosing recommendations, have a limited formulary to maximize staff familiarity, and allow the bedside nurse continuously to evaluate efficacy and safety (33). In addition, the regular use of a weight-based pediatric medication worksheet (placed at the bedside and in the patient record), containing all analgesic and resuscitation drugs likely to be administered, provides a supplemental safeguard against accidental overdose, particularly in the young pediatric age group (34).

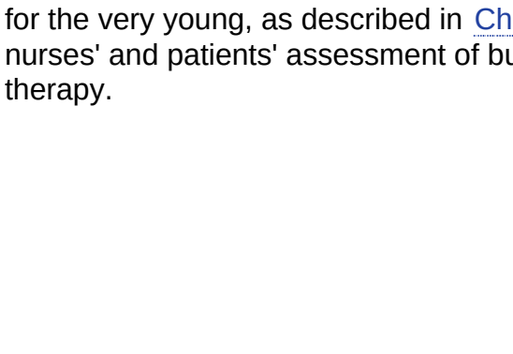

TABLE 42-1. Harborview Medical Center/University of Washington Burn Center burn analgesic guidelines for adults [a]

PHARMACOLOGIC APPROACHES

In describing pharmacologic approaches for burn analgesia, three consistent observations can be made. First, for patients with injuries extensive enough to require hospitalization, pain from the burn itself is severe. Thus, potent opioids form the cornerstone of pharmacologic pain control in these patients, leaving few indications for the mild to moderate analgesia provided by nonsteroidal antiinflammatory or acetaminophen, with notable exceptions of the rehabilitative phase of care and outpatient treatment. Second, because burn pain has well-defined components (e.g., background, procedural, and postoperative pain) pharmacologic choices for analgesia should target each pain pattern individually. Finally, because burn pain varies somewhat unpredictably throughout hospitalization because of surgical intervention, activity levels, and so forth, analgesic regimens should be continuously evaluated and reassessed to avoid problems of undermedication or overmedication. Pain assessment is facilitated by the regular use of standardized, self-report scales for adults and older children, and observational scoring systems for the very young, as described in Chapter 15. A reliance on nurse assessment of patients' burn pain can be problematic, however, as it is well documented that nurses' and patients' assessment of burn pain and analgesia are not always comparable (25,35,36), with nursing staff typically underestimating the need for analgesic therapy.

Opioids

Opioid agonists are the most commonly used analgesics in the treatment of burn pain, in part because (a) they are potent; (b) the benefits and risks of their use are familiar to the majority of care providers; and (c) they provide some dose-dependent degree of sedation that can be advantageous to both burn patients and staff, particularly during burn wound care procedures. The wide spectrum of opioids available for clinical use (see Chapter 84) provides dosing flexibility (i.e., variable routes of administration, variable duration of action) that is ideal for the targeted treatment of burn pain. The pharmacokinetics of opioids in burn patients are not consistently different from nonburn patients (37,38), although decreased volume of distribution and clearance, and increased elimination half-life have been reported for morphine in this population (39). Similarly, the pharmacodynamic potency of opioids has inconsistently been reported as increased (40) and decreased (39) in burn patients.

The route of opioid administration is an important issue in burn patients, with the principal choice between IV or oral administration dictated by the severity of burn (critically ill patients require IV access and may have abnormal gut function) and the high risk of burn patients for developing intravascular catheter-related sepsis (hence, physician reluctance to maintain long-term IV access) (41). Intramuscular opioid administration is avoided because of the need for repeated, painful injections, and because of variable vascular absorption caused by unpredictable compartmental fluid shifts and muscle perfusion in burn patients, particularly those undergoing acute, burn shock resuscitation. Patient-controlled analgesia (PCA) with IV opioids offers the burn patient a safe and efficient method of achieving more flexible analgesia. PCA also offers the patient some degree of control over his or her medical care, this often being a major issue for burn patients whose waking hours are often completely scheduled with care activities ranging from wound care to physical and rehabilitation therapy. Some studies comparing PCA opioid use to other routes of administration in the burn population have shown positive, but limited benefits of PCA (42,43), although others have shown that patients may prefer an attentive nurse and that the cost of this technology when used with burn patients may not be justified (44,45). The PCA administration of potent, short-acting opioids (e.g., alfentanil, remifentanil) for procedural analgesia may also have a useful role in burn analgesic management, but is yet to be investigated. Finally, oral transmucosal administration of opioids has been reported in burn patients (46) and appears to be particularly advantageous in those patients without IV access and in children.

Nonopioids

The list of nonopioid analgesics in widespread use for the treatment of burn pain is currently limited, although not without potential benefit. Oral nonsteroidal antiinflammatory drugs and acetaminophen, as outlined previously, are only mild analgesics that exhibit a ceiling effect in their dose-response relationship, rendering them unsuitable for the treatment of typical, severe burn pain. However, they are of benefit in treating minor burns, particularly in the outpatient setting. Topical applications of nonsteroidal antiinflammatory drugs on burn wounds can theoretically reduce nociception at the injury site with minimal systemic uptake (47), yet do not result in significant analgesia (48). The opioid agonist-antagonist drugs (e.g., nalbuphine, butorphanol) produce mixed actions at the opiate receptor level, theoretically providing analgesia (agonist property) with lesser side effects (antagonist properties), but also exhibit ceiling effects. Although studies have shown this class of drugs to be effective in treating burn pain (49), experience with them is both limited and suggestive of efficacy in patients with only relatively mild burn pain.

Antidepressants, anticonvulsants, and clonidine have been proposed as potential analgesic agents for burn pain (50) based on their known mechanisms of action in other pain states, yet have not been studied in the setting of burns. As neuropathic pain can occur in patients with healed burns (11), these agents may have specific application in this fortunately uncommon setting.

Anxiolytics

Current aggressive therapies for cutaneous burn wounds, together with the persistent and repetitive qualities of background and procedural pain, make burn care an experience that is likely to engender anxiety in both adult and pediatric patients. It is also recognized that anxiety can exacerbate acute pain (12). This has led to the common practice in U.S. burn centers of using anxiolytic drugs in combination with opioid analgesics (51). Intuitively, this practice is particularly useful in premedicating patients for wound care, because of the anticipatory anxiety experienced by these patients before and during debridement. Although previously shown that benzodiazepine therapy improves postoperative pain scores in nonburn settings (52), it has been recently reported that low-dose benzodiazepine administration significantly reduces burn wound care pain reports (53). It appears that the patients most likely to benefit from this therapy are not those with high trait (premorbid) anxiety, but rather those with high state (at the time of the procedure) anxiety or those with high baseline pain scores.

Anesthetics

Inhaled nitrous oxide is an analgesic agent safe for administration by nonanesthesia personnel. It provides safe and effective analgesia without loss of consciousness for moderately painful procedures in other health care settings and is also a commonly used, although less well-studied, agent for the treatment of burn pain (54,55). It is typically used as a 50% mixture in 50% oxygen and is self-administered by an awake, cooperative, spontaneously breathing patient via a mouthpiece or mask. A secondary benefit of nitrous oxide use, like that of PCA opioid administration, is the element of control given to the patient for his or her care. Nitrous oxide is less useful with critically ill or uncooperative patients. It has also been implicated in a small, but measurable, incidence of toxicity issues (e.g., spontaneous abortion, bone marrow suppression) to patients or staff exposed for prolonged periods (56,57), although not in the setting of burn pain treatment.

Although it is obvious that general anesthesia is required for the excision and grafting of deep burn wounds, a small population of patients requires specific wound care procedures on a scale well below that of surgical burn care, but that are difficult to perform on a conscious patient. These procedures include (a) the removal of hundreds of skin staples from recently grafted wounds; (b) meticulous wound care of recently grafted and often tenuous skin on the face or neck; and (c) wound care procedures in variably cooperative children. Historically, IV or intramuscular ketamine has been used for these procedures (58,59), and, more recently, oral ketamine use is described for pediatric burn patients (60). However, ketamine use is limited by the potential risk of associated emergence delirium reactions (5% to 30% incidence), particularly in the elderly.

The extension of full anesthetic care capabilities outside of the operating room and into the burn unit has been implemented in some specialized burn centers with apparent success (43,61). This has been facilitated by the introduction into clinical anesthetic practice of a variety of drugs with a rapid onset and short duration of action, a more rapid awakening and recovery, and fewer associated side effects, which are ideal qualities for agents to be used for procedural burn wound care. These agents include IV propofol and remifentanil and inhaled sevoflurane. Propofol is particularly advantageous and can be titrated to effect both in terms of level of consciousness and duration of action using continuous IV infusion techniques. The provision of brief, dense analgesia and anesthesia in a comprehensively monitored setting by individuals specifically trained to provide the service appears safe and efficient, both in terms of allowing wound care to proceed rapidly under ideal conditions for patient and nursing staff, and in terms of cost-effective use of the operating room only for true surgical burn care procedures.

Local anesthetics are of obvious use in regional blockade for wound care procedures, but have also been used for burn pain analgesia as a topical gel or IV infusion. Topical local anesthetic use on the burn wound is controversial. Prilocaine-lidocaine cream (EMLA) has no effect on burn pain in volunteers (62); however, topical 5% lidocaine applied at 1 mg per cm^2 offers analgesic benefit without associated side effects (63). Topical lidocaine use is significantly tempered by reports of local anesthetic- induced seizures caused by enhanced systemic absorption at the open wound site (64). The analgesic benefit of an IV lidocaine bolus (1 mg per kg) and 3-day continuous infusion (40 mg per kg per minute) has also been reported in acute burn injuries (65), although whether its mechanism is caused by antiinflammatory or analgesic actions is unclear (50). Neuraxial administration of local anesthetics (or opioids, or both) via epidural catheter would seem to be of benefit in patients with lower extremity burns, resulting in both analgesia (particularly during procedural burn care) and sympathectomy (of theoretical benefit to wound healing). However, such use has only been reported anecdotally (66). A major drawback of this technique is the use of an indwelling catheter in patients densely colonized with infectious organisms at the wound site, thus increasing the risk for epidural abscess formation (67).

Background Pain Management

Because background pain is relatively constant, it is best treated with mild to moderately potent analgesics administered so that plasma drug concentrations remain relatively constant throughout the day. Examples include the continuous IV infusion of fentanyl or morphine (with or without PCA), the oral administration of long-acting opioids with prolonged elimination (methadone) or prolonged enteral absorption (sustained-release morphine, sustained-release oxycodone), or oral administration on a regular schedule of short-acting oral analgesics (oxycodone, hydromorphone, codeine, acetaminophen). Background pain decreases with time as the burn wound (and associated donor sites) heals, so that analgesics can be slowly tapered (in the absence of significant analgesic tolerance).

Procedural Pain Management

In contrast to background pain, procedural pain is significantly more intense, but shorter in duration; therefore, analgesic regimens for procedural pain are best comprised of moderately to highly potent opioids that have a short duration of action. IV access is helpful in this setting, with ketamine and short-acting opioids (fentanyl, alfentanil) offering a potential advantage over longer-acting agents (morphine, hydromorphone). In the absence of IV access, orally administered opioids (morphine, hydromorphone, oxycodone, codeine) are commonly used, although their relatively long durations of action (2 to 6 hours) may potentially limit postprocedure recovery for other rehabilitative or nutritional activities. Oral ketamine (60), oral transmucosal fentanyl (46), and nitrous oxide (54,55) are agents of particular use when IV access is not present, because of their rapid onsets and short durations of action. Finally, when a particularly painful dressing change or one that requires extreme cooperation in a noncompliant patient (e.g., face debridement in a young child) is anticipated, the provision of brief general anesthesia in the burn unit setting has been shown to be safe and effective (44,61).

Postoperative Pain Management

Postoperative pain deserves special mention because of the increased analgesic needs that should be anticipated following burn excision and grafting. This is particularly true when donor sites have been harvested, as these are often the principal source of increased postoperative pain complaints, rather than the grafted burn. Typically, this increased analgesic need is limited to 1 to 4 days following surgery before returning to preoperative levels.

NONPHARMACOLOGIC APPROACHES

Cognitive Interventions

The application of cognitive-behavioral interventions has been reported more in chronic than acute pain (68,69). However, such techniques have been also applied to a number of types of acute pain, including that from rectal examinations (70), surgery (71), and dental work (72). Only a handful of studies have looked at the use of cognitive approaches with burn pain (72). Certainly, however, the work that has been done with other types of acute pain is applicable to patients with burn pain.

Patients vary in the manner in which they respond to stressful medical procedures. Whereas some patients seek out as much information as possible, others would just as soon leave their care to health care professionals (73,74). In applying cognitive interventions to burn patients, it behooves the clinician to be aware of how they cope with stressful medical procedures. Paramount to such thinking is whether the patient will approach procedures with a tendency toward cognitive avoidance, in which case they will distract or dissociate themselves from painful stimuli. This is in contrast to patients who tend to respond to acute pain by focusing on the procedures. Such patients may take a hypervigilant stance toward pain and may find distractions difficult.

Patients who tend to respond to acute pain with avoidance will likely benefit from distraction. In the burn unit, simple distraction is more likely to be of benefit with brief procedures, such as blood draws or line placements. Children at certain development levels may benefit by not seeing their wounds or by being engaged by the clinicians. Such distraction is less effective with older children or adults during the more extensive wound care procedures. In such instances, engaging patients in deep relaxation with distracting imagery will likely be more useful. Although a form of distraction, relaxation and imagery techniques are far more extensive and require substantially more training time for both patients and staff.

Patients who must focus their attention on medical procedures are usually poor candidates for distraction techniques. Such patients may benefit by reappraisal techniques. Rather than focusing away from pain, reappraisal techniques might encourage patients to attend to their nociception. They can then be encouraged to differentiate sensory from affective components of pain as well as evaluate the meaning of the sensation. As is the case with chronic pain, patients may benefit from being taught to differentiate “hurt from harm” with respect to their pain sensations (75). It is also useful to teach patients that increased pain sensation is usually a positive sign with respect to burn wound healing. Specifically, full-thickness burns often destroy nerve endings and the capacity for nociception. As burn wounds heal, skin buds emerge that are highly innervated and sensitive to pain and temperature. Teaching patients the latter two principles will likely be useful to them independent of their cognitive styles in response to acute pain.

Preparatory Information

Preparatory information involves providing patients with information about impending procedures as a way of mitigating pain and anxiety. Such interventions have been found to enhance pain control with acute pain from a variety of different procedures (76). Patients may be provided with preparatory information (what they can expect to occur mechanically during a procedure) or sensory information (what they will likely feel). The use of preparatory information has not been studied with burn patients, but evidence suggests that it can be useful with a variety of medical procedures such as cardiac catheterization, endoscopies, cast removal, and surgery (71,77,78 and 79). Unfortunately, burn injuries often do not lend themselves to such interventions. Certainly, it is not possible to anticipate that a burn injury will occur, and medical procedures are often performed quickly, and in an invasive matter. There is little time to prepare patients, and this can be particularly difficult for children.

At least two phenomena are associated with burn care that lend themselves well to preparatory information. First of all, nociceptive input often increases after the time of the initial burn injury. As mentioned earlier, full-thickness burn injuries may not be that painful, whereas healing injuries with new skin buds may be particularly sensitive. Patients can be warned accordingly. Also, patients often show periods of delirium on the intensive care unit, a clinical phenomenon that can be frightening to both patients and their family members. Letting them know in advance that such confusion is a common and usually benign occurrence can mitigate subsequent anxiety.

Irrational fears related to the use of opioid analgesics can also be minimized through preparatory information. Patients may believe that pain medications lead to addiction or are a sign of weakness. Information about the negligible rates of opioid addiction among burn patients can be useful in this regard. Also, it is useful to let the patients know that good analgesia likely promotes recovery. Our research indicates that high levels of pain are one of the most significant predictors of posthospital adjustment problems (15).

Behavioral Interventions

The application of behavioral principles to burn pain care can be divided into classical (stimulus) and operant (respondant) strategies. Stimulus conditioning applications have to do with the patient's state before wound care. Certainly, decreasing the patient's level of arousal through relaxation training, or any other means available, can minimize the ensuing cycle between anxiety and nociception. With children, the stimulus context of painful procedures can be particularly relevant. Children (and many adults) often show heightened anxiety and fear just by being exposed to the stimuli associated with painful procedures (e.g., nursing scrubs, procedures rooms, and so forth). If the threatening nature of the wound care environment can be reduced, pain control can be enhanced by virtue of stimulus-response principles. As an example, some children's hospitals have instituted the creative approach of having a magnetic resonance imaging scan tunnel appear as a cave in a jungle environment (rather than the morguelike drawer such equipment more typically seems to resemble).

Operant (reinforcement) principles can be applied to burn pain management in several ways. The first application has to do with medication scheduling. The tendency in many acute care settings is to medicate patients on an as-needed schedule. Certainly, the notion of waiting until the patient hurts does not make sense from a pharmacologic perspective (2). However, operant principles would also suggest that as-needed medication schedules reinforce patients for complaining of pain both in terms of the euphoria-producing properties of opioid analgesics and the attention received from caregivers. Providing opioid analgesics on a regular schedule that reflects their pharmacokinetic properties minimizes the potential for operant factors to exacerbate the pain problem.

The importance of a regular drug schedule is particularly salient to patients with substance abuse histories. Such patients may demonstrate frequent pain complaints or drug-seeking behaviors on the burn unit. The tendency of such patients to approach multiple caregivers for analgesics has the potential to create staff-splitting and resentment toward the patients. Furthermore, the burn unit staff may hold punitive attitudes about the patient's substance abuse history, the excessive nature of his or her pain complaints, or both. Regularly scheduled medications often minimize such problems. Also, channeling communications and negotiations about changing doses or types of medications through a single caregiver also serves to improve the behavior of such patients.

Occasionally, a patient's presentation might dictate that the burn staff abandon an acute care model in favor of an operant-based model of pain management. Effective burn team members are trained to be highly attentive to the pain complaints of their patients. However, occasional patients may show excessive complaints based on such factors as strong dependency needs or somatic tendencies. As in any case, it is important that such patients receive adequate doses of analgesics.

However, operant approaches, in which discussions of pain are minimized and patients are distracted from their complaints (75), may become the prominent intervention.

The quota system (80) represents another useful application of operant principles to burn care. The repeated, invasive nature of burn care has the potential to create a state of learned helplessness in patients (81). The quota system uses rest as a reinforcement for activity and keeps activity levels well within the patient's level of physical endurance. Ehde and colleagues have reported that with overwhelmed, seemingly unmotivated patients, it is useful to encourage the burn team to reduce their overall demands, take baseline behaviors, and *gradually* increase demands on what the patient's baseline behavior suggests is within the range of tolerance. It is hoped that such interventions create a sense of mastery in patients as they are able to see steady improvement in their activities.

A final application of operant principles is to avoid inappropriately rewarding escape behavior during procedures. With children, it is particularly essential to do all the interventions possible to enhance procedural pain control, such as adequate analgesics and anxiolytics, sufficient emotional preparation, optimizing the wound care environment, and including parents when appropriate. Children also do better if allowed to have control of their wound care procedures, perhaps by doing their own dressing removal (81). However, there are times when it is important to set firm limits during wound care by following through with procedures; otherwise, pain behaviors can be exacerbated. Establishing this balance can certainly be a challenge for caregivers.

Hypnosis

A surprising number of reports have been published on hypnosis and burn pain. In 1987, there were at least 14 papers published on this subject (82), and a number of new reports have appeared since then. Further, a number of additional reports have focused on the use of hypnosis to treat complications from burns other than pain. Although a number of reports have been published, the vast majority of them have been anecdotal. However, the controlled studies that have been published also support the efficacy of this intervention (82,83).

Patterson and colleagues (84) have proposed four reasons why burn patients appear to be such good candidates for hypnotic-based pain control interventions. First of all, because burn patients are in high levels of pain, they are motivated to engage in hypnosis, a technique that they might ordinarily resist. In support of this, patients with high levels of initial pain seem to show a better analgesic response to hypnosis (85,86). Second, patients in trauma care may be more cooperative because of the regression that might often be a normal reaction to trauma care (i.e., a willingness to allow others to take care of one). Third, the dissociation that may accompany a burn injury may also be a factor that moderates hypnotizability. Certainly, dissociative tendencies have been related to hypnosis (87). Finally, and on a more simplistic level, clinicians are able to predict that patients will show more pain during procedures, and hypnosis is nicely suited for preparing a patient for a future, adversive event.

Ewin (88,89) has published anecdotal data to suggest that hypnosis used early in burn care can not only enhance pain control, but might even facilitate wound healing. This work has received a great deal of attention as well as criticism because of the lack of controlled studies to support the underlying premise (90). It is hoped that the question of whether hypnosis can have such powerful effects when used early in care will be the subject of a controlled study. It would be of great utility to determine what effects aggressive pain interventions of any modality have when used early in the patient's care.

SUMMARY

Effective treatment of burn injuries requires an appreciation of the unique patterns of nociception caused by this trauma and their interaction with psychological factors. We recommend that aggressive use of opioid analgesics tailored to the nature of the pain (e.g., procedural, background, postoperative) serve as the cornerstone of a multifaceted approach to burn pain. Procedural pain often involves consideration of a variety of supplemental pharmacologic approaches, ranging from benzodiazepines to mild sedation. Nonpharmacologic approaches should be woven into the structure of burn care, with more time-consuming psychological approaches instituted with the failure of opioid analgesics. The undertreatment of burn pain remains an unfortunate reality, particularly because adequate analgesia may facilitate recovery, and posthospital adjustment, as well as represent a more humane course of treatment.

CHAPTER 43

Posttrauma Pain

W. Thomas Edwards

This chapter focuses on the issues of pain after major trauma. In some ways, the problems of pain after trauma are no different from other acute pain states (see Chapter 41 and Chapter 42). Tissue damage leads to nociception and thence pain and suffering. An easy intellectual connection is that greater tissue damage leads to greater pain. Although this is certainly true, as evidenced by correlation of the size of a burn with pain reports (1), we must keep in mind that pain is an *experience* (2), and the entirety of the pain experience occurs in the context of what is usually a catastrophic event to the individual who suffers major trauma. The patient who is injured brings to pain treatment all those issues that affect anyone undergoing *elective* surgery, including fear and anxiety about the events associated with the trauma, as well as concerns about the recovery and the ability to function after major trauma. There may be issues of guilt, loss of loved ones, and other issues that will play an important role in how effective pain management will be. A useful management plan requires an awareness of and sensitivity to these issues.

Pain will be a constant presence from the time of injury through correction of those injuries (often surgically) and through the time of rehabilitation to the restoration of normal function. In fact, a useful approach that we take to the categorization of pain and its treatment after trauma is according to the stages of trauma management (Table 43-1). Other categorizations may lead to different approaches and to subtly different understanding of the value of these approaches (Table 43-2 and Table 43-3). Categorization schemes are not mutually exclusive, and understanding a problem in pain management may turn on how one sees the problem in context. So, for example, the management of pain of chest wall trauma as an isolated injury will be very different depending on whether the patient is in the emergency or the acute phase of trauma management and on whether it is pain at rest (background pain) or pain associated with chest physiotherapy (incident pain).

Phase of trauma care	Time course of stage
Emergency	*Begins* at time of injury *Ends* when resuscitation and emergency stabilization of wounds and/or life-threatening injuries are complete
Acute or healing	*Begins* at completion of emergency stabilization *Ends* when all wounds are closed and surgical treatment of injuries is complete
Rehabilitation	*Begins* when surgical treatment of injuries is complete *Ends* with restoration of acceptable levels of functioning

TABLE 43-1. Pain categorization by phases of trauma care

Injury pattern	Description
Regionalized	Injuries are confined to one or a limited number of body regions (e.g., leg and knee).
Broadly regionalized	Peripheral injuries are bilateral or injuries involve trunk (chest and abdomen). Injuries may be widely separated but limited in number (e.g., scapula and pelvis fractures).
Generalized	Injuries involve large regions, are complex (e.g., large burn with blunt trauma), or involve the central nervous system.

TABLE 43-2. Pain categorization by injury pattern

Circumstance	Description
Background pain	Pain is always present or occurs with ordinary activity such as moving in bed.
Breakthrough pain	Pain appears spontaneously from a well-controlled background. Pain may be related to more vigorous ordinary activity such as walking or mild exercise.
Incident pain	Pain occurs associated with a specific activity such as wound manipulation or physical therapy.

TABLE 43-3. Pain categorization by circumstance

Both background and incident pain may be poorly localized when injuries are widespread (generalized pain), involving multiple organ systems or anatomic locations. Blunt trauma with an associated burn or chest, pelvic, and lower extremity fractures are good examples of clinical states leading to generalized pain states.

Pain may be well localized or at least confined to a limited region of the body (regionalized or broadly regionalized pain). Both background and incident pain under these circumstances may be managed by thoughtful application of the techniques of regional anesthesia (see Chapter 102).

PROBLEMS POSED BY TRAUMA IN DEVELOPING PAIN MANAGEMENT PLANS

Trauma poses particular problems in developing pain management plans, including the following:

- *Anatomic derangement may preclude certain approaches to pain treatment.* These might include such examples as four extremity fractures that prevent the patient from using a patient-controlled analgesia (PCA) demand switch, or burn or soft tissue loss over the back that would interfere with placement of an epidural catheter. Spinal column injury constitutes a special consideration and is covered separately later in this chapter.
- *Pain levels vary widely and are highly incident dependent.* Unstable fractures, for example, can cause high levels of pain over a perfectly well-controlled background pain when the patient is subject to routine nursing care such as turning from side to side. The need to manage open wounds with dressing changes or hydrotherapy (water pick) constitutes another of these types of problems.
- *Physiologic derangement may cause difficulty in pain management.* This problem is common in the emergency phase of trauma care, when resuscitation is taking place. Patients who are actively bleeding or whose intravascular volume status is uncertain present difficult challenges in pain management, especially when they are conscious. A patient who is sustaining blood pressure in part because his or her own intrinsic catecholamine output is high from high levels of pain may drop his or her blood pressure precipitously when pain is relieved.

PAIN MANAGEMENT AND THE PHASES OF TRAUMA CARE

The phases of trauma care describe the clinical course of a patient from the time of the injury until the return to normal function (see Table 43-2). Pain management plans need to be formulated to meet changing patient needs within each of these phases as well as during movement from one phase to the next. Movement through the phases may not be monotonic (i.e., patients may enter a later phase and then require additional surgery that sets them back to an earlier phase). Physiologic responses to treatment during movement among phases may be influenced by treatments used before (e.g., opioid tolerance). The phase of trauma care is a useful context in which to consider pain management plans as they are being formulated.

Emergency Phase

Pain during the emergency phase occurs in an extremely stressful situation and is caused by direct massive and prolonged nociceptive stimulation originating in damaged tissue. During this phase, the goal is always stabilization of the injured patient, and treatment is directed toward preservation of life and function. The duration of this phase is variable, and it persists until open wounds are stabilized and life-threatening injuries are controlled. Modalities of pain control are dependent on the physiologic condition of the patient and the experience of personnel in any given institution. Some pain relief is obtained by treating the underlying result of injury in this phase–for example, relieving a hemopneumothorax or stabilizing an unstable fracture. Often multiply injured patients require emergency major surgical intervention in this phase, and the issue of pain relief becomes moot in the face of need for a general anesthetic.

In managing pain during the emergency phase, anxiety and fear must be carefully assessed. Reassurance and information may help considerably in managing agitation often assumed to be a pain response during this phase. Often an uncooperative patient has consumed alcohol or some other mood-altering substance before trauma. Studies at the University of Washington Harborview Medical Center and the Maryland Shock Trauma Center found that 35% to 41% of all multiple trauma admissions to the emergency department were positive for alcohol (3), with a high percentage of these patients meeting criteria for alcohol dependence (4). A pattern of repeated injuries is strongly correlated with alcohol dependence (5). The presence of mood-altering drugs must be taken into account in planning any pain management scheme, as it may herald a difficult pain management course. Tolerance to opioids is likely to be a problem in this setting, and when substance abuse is part of the presenting history, planning for pain management must include prevention of drug withdrawal as well.

The provision of analgesia during the emergency phase of trauma care is not contraindicated once the urgent surgical and neurologic evaluations of the trauma patient are performed. The improved cooperation of the injured patient that can ensue from providing adequate pain relief may facilitate completion of the indicated examinations. Once the decision is made to treat the patient's pain, adequate monitoring of vital signs and adequacy of ventilation must be continued, especially if the patient is moved out of an emergency resuscitation area. A subtle decrease in intravascular volume can dramatically augment response to opioids. While patients undergo additional workup in radiology, computed tomography, or magnetic resonance imaging, for example, they should be attended by personnel able to detect, evaluate, and respond to a shifting level of alertness.

Systemic opioids and some regional anesthesia techniques will be the mainstay of pain therapy during the emergency phase of care. As much as possible, systemic therapy should be patient directed because of the widely varying pain levels experienced by patients after a given injury. For opioids, the intravenous route is best. Opioid loading to patient satisfaction requires attention, repeated evaluation of pain level, and repeated treatment. Once a satisfactory degree of pain relief is achieved, intravenous PCA will be useful in maintaining analgesia if the patient can interact with the PCA device (6). Although shorter-acting high-potency opioids such as fentanyl may have a place, especially during the early phase of emergency stabilization, more definitive therapy using morphine, hydromorphone, or meperidine will prove easier to manage. Long-acting opioids such as methadone or levorphanol have no routine place in this phase of care.

Most often during the emergency phase of care, particularly after multiple trauma, it is difficult to obtain definitive information on the integrity of the spine. This lack of “spine clearance” most often precludes the use of central conduction analgesia. Peripheral regional analgesia, however, can be very useful in selected patients (see Chapter 102). Those techniques include isolated peripheral nerve blocks [e.g., femoral nerve block for dislocated patella (7), intercostal blocks for a limited number of fractured ribs] and blocks of the major neural plexuses (brachial, lumbar) for more extensive unilateral limb injuries. Table 43-4 illustrates useful approaches to pain management during emergency care of the trauma patient. Breakthrough pain is usually not considered as a separate issue during this phase, and therapy is directed exclusively to background and incident pain.

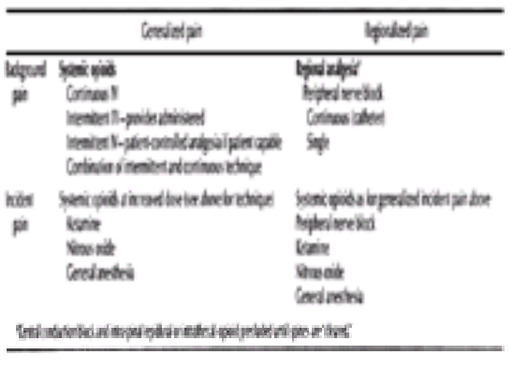

TABLE 43-4. Approaches to the management of pain in the posttrauma emergency phase

Acute or Healing Phase

The beginning and end of the healing phase of trauma care are set out in Table 43-1. It may very well begin while the patient is in the intensive care unit being ventilated. Pain management techniques for critically ill patients during this phase of trauma care may require imaginative approaches that combine regional and systemic analgesia techniques (8). This phase may continue for weeks or months, depending on the nature of the injuries. There are frequently multiple surgical procedures during this phase, especially to correct orthopedic injuries, and the problems of pain control change to considerations of postoperative pain during these periods. Approaches to pain management during the healing phase are most easily conceptualized by thinking of the time after all surgical procedures have been completed and before the period of rehabilitation begins.

One of the hallmarks of this phase of trauma care is background pain, often punctuated by breakthrough pain. Incident pain is most often procedure-related, frequently associated with mobilization procedures, and sometimes occurs more frequently than daily if twice or three times daily care of open wounds is necessary. One of the goals of therapy is the provision of adequate baseline analgesia by a technique or combination of techniques with adequate flexibility to treat breakthrough pain. A second equally important goal is to provide brief, intense analgesia for “incidents” that does not leave the patient oversedated and uncooperative for an

extended period afterward.

A gradual decrease in a patient's ability to tolerate procedures may develop, although the pain reports may not reflect this. This is the time to begin to help the patient deal with the emotional impact of the injury (9). It is important to be alert to the development of the early signs of posttraumatic stress disorder (see Chapter 26).

When behavioral issues such as failure to cooperate with scheduled treatments, acting out, or conflict with nursing staff develop, the advice and help of a behavioral specialist will be needed. Pharmacologic management should involve such techniques as non–pain-contingent timed administration of analgesics. Supportive psychotherapy is often valuable in helping patients deal with many aspects of trauma. Patients often need a route to uncovering their feelings about loss of a body part and alteration in body image. This therapy can be coupled with cognitive pain control and coping skills training, and even with techniques of hypnosis (10,11) (as described in Chapter 42, Chapter 91, and Chapter 92).

Longer-acting agents should be incorporated into the pharmacologic plan when the patient's opioid requirement has been established by use of a flexible demand technique such as intravenous PCA. This is the time when sustained-release opioids and long-acting agents become most useful in the management of background pain. Sustained-release opioids (morphine, oxycodone) and methadone or levorphanol are useful agents for oral administration during this phase. Analgesic agents with high bioavailability and short duration of action should be used for the management of incident pain. When intravenous administration is no longer the ideal approach, oral oxycodone or hydromorphone can be useful for incident pain management. Oral transmucosal fentanyl citrate provides another option for brief intense analgesia. Oral ketamine has been used successfully (12,13). Table 43-5 illustrates analgesic approaches that are useful during this phase.

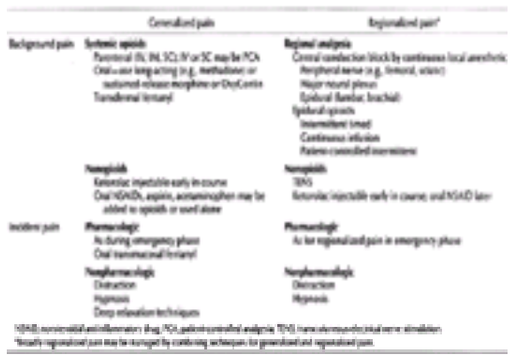

TABLE 43-5. Approaches to the management of pain in posttrauma healing phase

If regional analgesia techniques are used, they are best used early in this phase and after the multiple surgical procedures that occur during this period. It is not difficult to maintain thoracic or lumbar epidural catheters for extended periods in hospitalized patients (14), and the techniques of epidural opioid administration are effective for both background and incident pain when they are correctly applied (see Chapter 103).

Rehabilitation Phase

The length of the rehabilitation phase is indeterminate. Trauma patients will have been fully mobilized and in all cases will be out of an acute-care hospital setting. The character of the pain experienced during this phase is usually described as deep and aching, perhaps akin to the pain of arthritis. Pain tends to become progressively more regionalized during this phase and the problems of pain management more focused. Chronic pain states can begin to develop during this phase. Opioid therapy is rarely necessary for the entirety of this phase but may be necessary in the early part, especially for those patients whose prolonged use of opioids during the healing phase has rendered them physiologically dependent on opioids. Patients who had a problem of opioid dependency before their injury will need to have that problem addressed during this phase.

A weaning schedule from potent opioids is usually developed for patients with physiologic opioid dependencies during this phase. Time-contingent opioid administration using a long-acting agent on a gradually declining dosage scale can usually be developed. The time required for complete cessation of opioid administration varies depending on the starting dose. A step-down schedule of 10% every 3 to 4 days usually is tolerated reasonably well, but it is sometimes necessary to go more slowly, reducing the dose on a weekly schedule. Although it was not originally developed for this application, a pain cocktail strategy (blind dosing) can be used to allay patient anxiety about dose reduction. We routinely use methadone as the opioid in pain cocktails; anxiolytics can be added if necessary. Pain cocktails may also be helpful in the case of a preexisting substance abuse problem or to help in the management during this phase of some behavioral issues such as manipulative behavior.

Background pain management is best accomplished with nonsteroidal antiinflammatory agents, acetaminophen, or if necessary, a weak opioid such as codeine. Pain associated with procedures, physical therapy, joint manipulations and the like is treated exactly as it would be during the healing phase, with a short-acting agent such as oxycodone. The general approach is contained in Table 43-6.

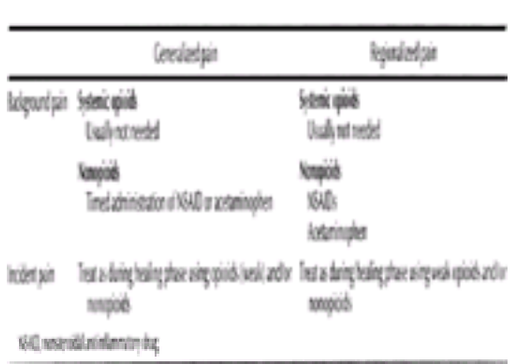

TABLE 43-6. Approaches to the management of pain in posttrauma rehabilitation phase

PROBLEM OF NEUROPATHIC PAIN

A particular type of background pain, often burning in nature, may be associated with trauma to some part of the nervous system, either peripheral or central. Various terms have been applied to this condition in the past– *deafferentation pain*, *dysesthetic pain*, and a whole range of terms meaning pain involving the sympathetic nervous system, such as *reflex sympathetic dystrophy.* We have generally chosen to use the more inclusive term– *neuropathic pain*. The problems and management of neuropathic pain and complex regional pain syndromes are covered in Chapter 19, Chapter 20, and Chapter 23.

In the setting of multiple traumas, neuropathic pain often presents early in the course but is usually delayed in onset by days or weeks after injury. It is important to distinguish this pain from pain arising in other damaged tissue (nociceptive pain), as neuropathic pain is frequently unresponsive to opioids. Management with tricyclic antidepressants (amitriptyline, nortriptyline, others), antiseizure medications (gabapentin, lamotrigine, carbamazepine, others), sodium channel–blocking agents (lidocaine, mexiletine), or combinations of these may be indicated (15,16) (see Chapter 85 and Chapter 86).

Some of these neuropathic pain states respond to transcutaneous electrical nerve stimulation (17,18 and 19). The perception of electrical stimulation is required to generate pain relief: An anesthetic region cannot be the site of stimulation. Long-term management of brachial plexus avulsion pain is a particularly vexing problem in

chronic pain management. A variety of neurosurgical procedures can be tried if pharmacologic techniques fail. Limb amputation never relieves this type of pain (20).

Although pain arising from tissue injury progresses through the three phases (emergency, healing, rehabilitation) described above, neuropathic pain does not. It frequently persists as a chronic pain state and is thus one of the points at which acute pain and chronic pain management may converge.

EPIDURAL ANALGESIA AFTER TRAUMA

A common request that comes from our surgical colleagues is to place an epidural catheter for a patient who has sustained multiple trauma, especially blunt trauma to the chest with simple multiple rib fractures or flail chest. Because it is perceived as being more specific than systemic analgesia, it is thought to be more desirable than systemic analgesia. It has often been our practice to optimize systemic analgesia before initiating epidural analgesia. Earlier invasive intervention really may be valuable, however, and some pain consultants have begun to be much more aggressive about epidural analgesia after trauma (21). There are data that indicate an improvement in outcome with epidural analgesia versus systemic analgesia in chest wall trauma (22,23 and 24). There are no data to indicate that epidural analgesia is preferable to any other form of regional analgesia, such as paravertebral (25) or intercostal (26) block, nor are there any data to indicate whether there is a critical number of fractured ribs or a size of a flail segment at which the benefits of epidural analgesia are specific to the technique. Epidural analgesia does appear to be superior to interpleural analgesia for blunt chest trauma (27).

Many different techniques can be used to provide analgesia, including continuous-infusion local anesthetic (18), continuous-infusion opioid (28), intermittent opioid by timed administration (18), and intermittent opioid by patient administration (29). Details of these administration techniques are covered in other chapters. Epidural techniques can be combined with one another, and continuous-infusion local anesthetic can be combined with systemic opioid analgesic techniques. Epidural opioid techniques should usually not be combined with systemic opioid techniques because of the risk of accentuating opioid central nervous system effects.

There are several common clinical scenarios wherein the request for epidural analgesia comes when chest trauma is part of the multiple trauma complex:

1. The patient has been extubated after emergency stabilization and is now showing increasing difficulty maintaining oxygenation because of inability to cough and clear secretions.
2. The patient is still intubated and is oxygenating well but cannot meet extubation criteria (vital capacity, inspiratory force, or both) because of pain of fractured ribs. Frequently these patients are judged to become excessively sedated with systemic opioids.
3. The patient is intubated and still requires ventilation but becomes excessively agitated when routine nursing care is attempted. This is thought by nurses and the primary team to be because of pain.

The algorithm presented in Table 43-7 provides the basis for decision making in each of these clinical situations.

TABLE 43-7. Indications for the use of epidural analgesia in critically ill patients after major trauma

Contraindications to the use of epidural analgesia after trauma are very similar to contraindications in other surgical settings. The following are the principal differences that are presented by the unique clinical setting of trauma:

A. *Lack of consent*. Initiation of epidural analgesia requires that consent be obtained. A patient's specific refusal of consent can never be overridden unless the patient is legally determined to be incompetent to give consent. A physician's judgment that the procedure is indicated in a circumstance in which the patient or his or her agent specifically declines consent for an invasive procedure cannot override the patient's wishes.
B. *Central nervous system trauma*
   1. Brain. Penetrating trauma to the brain or the brainstem, raised intracranial pressure, and bleeding into the cranial vault are all relative contraindications to instrumentation of the spinal epidural space because of both the risk of accidental dural tap and the fact that small changes in the volume of contents of the spinal canal may cause large changes in the intracranial pressure when intracranial compliance is low. Epidural analgesia has been used successfully and safely in the presence of closed-head injury when intracranial pressure is low (30).
   2. Spinal cord. Space-occupying lesions in the spinal canal such as epidural or intraparenchymal hemorrhage or the presence of localized swelling of the cord can be associated with sharp and prolonged rises in pressure in the spinal canal during injection of fluid and can result in markedly diminished blood flow to the spinal cord. Instrumentation of the spinal canal is contraindicated under these circumstances. The ability to judge that the spinal cord function is intact, or at least to define and document the degree of specific neurologic impairment, is necessary before such instrumentation.
C. *Spinal skeletal trauma present.* It is essential that the spinal column be documented to be intact before instrumentation of the spinal epidural space at any level. If trauma to the spinal column has occurred and it is the judgment of the consultant that the risk/benefit relationship is such that selective regional analgesia should be provided, that must be documented. The spinal canal should never be instrumented in the absence of documentation regarding trauma to the skeletal structures.
D. *Sepsis and infection.* Evidence of septicemia or apparent infection at the proposed epidural insertion site is usually considered an absolute contraindication. There may be a relative contraindication for patients with large, infected wounds because of the risk of bacterial showers into the circulation during wound manipulation (31). Fever otherwise unexplained in a multiple trauma victim is not necessarily a contraindication.
E. *Bleeding diatheses.* There are no absolutely incontrovertible data on when the risk of epidural hematoma associated with epidural analgesia is unacceptably high. Evidence of circulating anticoagulant present or severe dilution-based factor deficiency leading to prolongation of prothrombin time or partial thromboplastin time to greater than 1.5 times control is generally considered unacceptably high risk. Platelet counts commonly fall after trauma. Most clinicians would want to know that a falling platelet count had reached a nadir. A count of less than 40,000 may (but does not definitely) increase the risk of epidural hematoma formation. Many consultants believe the platelet count should be double this number to be safe. There is no documented correlation between bleeding time and the risk of clinical bleeding, but some prefer to know that the bleeding time is normal to assess adequacy of platelet function, particularly if the platelet count is below 75,000, the patient has received platelet transfusion within 24 hours, or both.

CONCLUSIONS

As with any other acute pain state or set of states, the management of pain after major trauma requires an understanding of the pathology of the nociception and attention to the patient's complaints. An understanding of the natural history of the problems involved in the particular set of injuries helps in the planning of pain treatment strategies to fit the position of the patient in the time course of trauma treatment. Treatment plans must take account of whether one is dealing with the emergency, acute, or rehabilitation phase of care. Management of background, breakthrough, and incident pain in each phase is different and makes use of different pharmacologic “tricks.” Treatment of pain should draw on different strategies of combining systemic and regional analgesia suited to the appropriate phase of trauma care.

CHAPTER 44

Pain and Its Management in Children

Kenneth R. Goldschneider, Thomas J. Mancuso, and Charles B. Berde

> “Hurting isn't necessary.”
> Sarah Jaye, age 4

Few things stimulate a caregiver's helping instinct more than the pain cry of a child. Organized pain relief for children, however, historically has been hampered by societal and medical misinformation and by the slow and deliberate nature of good basic research. The fields of developmental biology, pain assessment, and treatment have seen tremendous gains. Progress is reflected in the fact that treatment for the pain of infants and children in both acute and chronic settings has become safe and effective. Assessment and measurement of pain in infants and preverbal children continue to be difficult. On the other hand, cognitive-behavioral treatments can be used quite effectively for children undergoing medical procedures as well as in the treatment of a range of acute and chronic pain problems. For many children, fear and anxiety dominate their thought processes regarding medical encounters. Making interactions in medical settings less terrifying for children therefore is an essential component of pediatric pain management. Although the pharmacopoeia of pain control is essentially the same for children as for adults, there are age-related differences in several pharmacokinetic and pharmacodynamic factors. Many of these age-related pharmacologic differences become less important after a year of age. Understanding what is unique and dynamic about the psychological, physiologic, and pharmacologic treatment of pediatric pain is critical to the safe and effective alleviation of pain and suffering in children.

UNDERTREATMENT OF PAIN IN CHILDREN

As recently as the mid-1980s, pediatric postoperative and trauma patients received greatly different pain treatment than did adults with comparable diagnoses (1). At the same time the great majority of physicians responding to a survey in the same geographic region expressed the belief that children felt pain similarly to adults by the age of 2 years (2). Despite this belief, 87% of children in one survey reported unrelieved pain during hospitalization (3).

Furthermore, a comparison of pediatric cardiac patients with adult patients undergoing cardiac surgery revealed a significant discrepancy in the amount of pain medications administered for postoperative analgesia (4).

As the data have accumulated in favor of improved outcomes (5), health care workers are being compelled to make the same use of pain control techniques for children as they do in adults. For example, in 1992, the Agency for Health Care Policy and Research published acute pain management guidelines for children (6). These clinical practice guidelines, titled *Acute Pain Management in Infants, Children and Adolescents: Operative and Medical Procedures and Trauma* , outline four general responsibilities for institutions (Table 44-1).

1. Children and families must be educated about pain relief and their role in assisting with assessment of comfort.
2. Pain assessment and management must be documented.
3. Each institution must adopt a standard of care for pain relief.
4. Institutional quality-improvement programs must include effectiveness of pain relief efforts.

TABLE 44-1. Institutional responsibilities for pain services

To provide care at the level suggested by these guidelines, it is important to understand the neurodevelopment of pain processing in children and infants and the methods by which the expression of pain are measured.

PAIN IN INFANCY

Developmental Neurobiology of Pain

The study of pain in infancy and of the longer-term implications of noxious stimuli has intensified over the past 20 years. Pain plays an important role in learning and neurologic development. Thus, it would be expected that the afferent pathways for pain sensation and perception would develop early in life.

At the time of birth, the nociceptive pathways and connections are well established. In fact, thalamocortical projections begin synapse formation with cortical neurons by 20 to 24 weeks' gestational age, and myelination of afferent pathways to the thalamus is generally complete by 30 weeks. Myelination of thalamocortical fibers is complete by roughly 37 weeks' gestational age. Although afferent nociceptive paths appear well developed by birth, descending control of pain is slower to develop (7).

Primary afferent nerve fibers project to peripheral targets midway through fetal life in rats and in humans. Infant rats show lower- impulse thresholds and more prolonged discharges in primary afferent C and A fibers when exposed to noxious stimuli than do adult rats. In addition, newborn rat pups respond to skin wound with extensive proliferation of A and C fibers in the region of the wound. Functionally, the rat pups display hyperalgesia manifested by decreased flexion withdrawal

thresholds (8). These behavioral and neuroanatomic responses appear to decrease in magnitude with advancing age.

The flexion withdrawal reflex is well developed in neonatal rats and human newborns. Interestingly, younger premature infants exhibit sensitization to repeated noxious stimuli (9). The closer the infants are to full-term gestational age, the more likely they are to habituate to the stimuli, a response characteristic of children and adults. Human newborns receiving repeated heel lancing for blood sampling develop secondary hyperalgesia, a manifestation of spinal plasticity (10).

In a number of studies, the protooncogene c-*fos* has been used as a marker of neuronal activity. In adult animals, noxious stimulation evokes c-*fos* expression in the superficial dorsal horn laminae. Jennings and Fitzgerald showed that even nonnoxious stimulation evokes prominent c-*fos* expression in laminae 1 and 2 in neonatal rats (11). This finding correlates with the findings of Coggeshall and coworkers that neonatal rats have A-fiber light-touch afferent projections to synaptic targets on lamina 1 and 2 dorsal horn neurons (12). The light-touch A-fiber afferents of the adult rat normally synapse in deeper laminae of the dorsal horn, not in the superficial laminae that receive projections from C- and A-delta-fiber afferent fibers that are involved in nociception. In addition, dorsal horn neurons in neonatal animals often show quite prolonged firing after noxious stimulation.

It is unclear how to interpret what the experiments regarding flexion withdrawal reflexes, c-*fos* expression, and A-fiber projection to superficial laminae mean in terms of pain *experience* in the neonate. It would be an overinterpretation to conclude that the neonate is inherently hyperalgesic.

Newborn rats respond with pain-specific behaviors (e.g., paw licking) to inflammatory stimuli, such as formalin. Such behaviors are ameliorated by morphine and appear to be inborn responses, not learned behaviors (13). The morphine-induced decrease in the response to pain is not due to sedation alone. Abbott and Guy found that both morphine and amphetamine produce analgesia, but pentobarbital produces sedation but not analgesia in this model (14). The reader is referred to a thorough review by Marsh and coworkers for a discussion of the ontogeny of opioid systems in newborns (15).

Overall, these results suggest that the neonatal nervous system is well equipped to process nociceptive input. In fact, the above- mentioned studies have been interpreted by some reviewers to suggest that the neonate may feel pain more intensely than older patients do. This finding has relevance to the manner in which we approach pain in the neonatal intensive care units. The relationship between pain and suffering, however, cannot be gleaned from data available at the present time. Comparatively little is known about the supraspinal processing of nociception in neonates, and even less is known about the affective aspect of their pain experiences. We will leave the discussion of the nature of suffering in newborns to others and turn to some of the studies of both short- and long-term consequences of pain in infancy and the role of anesthesia and analgesia for neonatal pain.

Outcome Studies

Short-Term Consequences of Pain in the Neonate

It is well known that opioids (16) and regional anesthesia can be used safely and effectively in neonates. Indeed, surgery performed on inadequately anesthetized newborns, whether premature or full-term, evokes dramatic hormonal and metabolic stress responses that have been associated with hemodynamic instability, catabolism, and poor postsurgical outcomes (17). In some cases, blunting of stress responses may improve outcomes in newborns as they do in adults. With proper expertise, neonates can be safely anesthetized for any type of surgery (18,19). No longer is the performance of surgery in neonates without adequate general and/or regional anesthesia justified.

Circumcision in newborns is often performed without anesthesia. Circumcision performed in this manner produces autonomic instability, manifested as increases in heart rate and blood pressure, hypoxemia, and sleep disturbances (20). Several methods have been studied to reduce the pain of circumcision. Kirya and Werthmann first studied dorsal penile nerve block (DPNB) for neonatal circumcision (21). Since then, the safety and efficacy of DPNBs have been confirmed (22). DPNB relieves the physiologic stress of circumcision in neonates (23). Topical anesthesia with a eutectic mixture of lidocaine and prilocaine (EMLA) appears to provide at least partial anesthesia for newborn circumcision (24). Lander and coworkers found that EMLA was more effective than placebo but less effective than DPNB or ring block (25). Nonpharmacologic measures, including use of a more comfortable papoose board and oral ingestion of sucrose (26), diminish but do not eliminate distress caused by circumcision. A multimodal approach may provide optimal comfort for this common, painful procedure.

Opioids and benzodiazepines are commonly used in neonatal intensive care units both for invasive procedures and to help patients tolerate mechanical ventilation. There is great variation in analgesic and sedative use among neonatal intensive care units (27). Outcome data are sparse and conflicting. A large, retrospective multicenter study focused on patterns of opioid administration in more than 1,000 low-birth-weight infants receiving mechanical ventilation in six different neonatal intensive care units (28). Mean opioid dosing varied 28-fold among units. The authors found minimal differences in outcomes, despite this wide variation. This study was retrospective and uncontrolled and did not examine long-term outcome measures. Thus, it is difficult to draw conclusions from this report regarding risks and benefits.

Potential Long-Term Consequences of Pain in Infants

Previously, a common rationalization for withholding opioids from newborns was that infants would not remember pain and that there were no long-term sequelae of untreated pain in infancy. There have been some recent forays into the long-term outcomes arena. Taddio and coworkers examined responses to intramuscular injections for immunization in cohorts of 4- to 6-month-old boys (29). Two of the study groups comprised infants who had participated as neonates in a randomized, blinded comparison of EMLA with placebo for circumcision. The control group comprised boys who were uncircumcised. Uncircumcised infants cried less and had lower pain ratings by blinded observers. For pain scores, but not cry duration or facial action score, the EMLA group had statistically lower pain ratings than the placebo group. Although these findings are suggestive, they should be interpreted cautiously in view of a potential for confounding factors.

Johnston et al. (30) examined responses to heel-stick procedures in two groups of infants at a gestational age of 32 weeks. The first group comprised relatively healthy babies born within that week. The second group included premature infants born at 28 weeks who had undergone a variety of invasive procedures. There were significant group differences in behavioral and physiologic parameters, both at baseline and after heel lancing. A history of multiple invasive procedures correlated inversely with the behavioral response to the heel-stick procedure. Whether these results reflect the neurocognitive deficits found in former premature infants (31) or a sense of “learned helplessness” is as yet unclear.

Overall, the long-term consequences of untreated pain in infancy remain difficult to quantify but merit further study. Safe and effective treatments are available for many forms of pain. In our opinion, the burden of proof lies with those who would withhold treatment, not with those who would treat pain aggressively.

PSYCHOLOGICAL AND DEVELOPMENTAL CONSIDERATIONS

One of the more challenging aspects of pediatric medicine is the need to adjust one's approach to meet the developmental needs of a particular child. A standard approach to children is insufficient at best and risks alienating both patient and family at a time when maximal cooperation is required. Several generalizations can be made, however, and are included in the following discussion of cognitive and emotional development.

The cognitive development of children was proposed by Piaget to proceed through four stages: sensorimotor, preoperational, concrete operational, and formal operational stages (32). The response to and understanding of pain by children have been discussed in detail elsewhere and are summarized in Table 44-2 (33,34 and 35). In brief, children younger than the age of approximately 2 years interact with their environment in a strict stimulus-response manner and have no sense of permanence, long-term anticipation, or cause and effect. The pretoddler will respond best to cuddling/swaddling, warm environments, soothing voices, and pharmacologic interventions. As the child becomes a toddler, a sense of permanence develops, and the child approaches the world in a strongly egocentric manner. Pain is seen by the child as a punishment, with the magnitude of pain correlating with how “bad” the child is. One must take care not to refer to the toddler as good or bad in the context of a painful procedure. Treatment often focuses on medicines, kissing/ rubbing the injury, and the “magic” Band-Aid. The child is still enmeshed in the ego strength of his or her parents and may benefit greatly from parental involvement. Due to the egocentricity and verbal capacity of the toddler, self-report becomes feasible as a measure of pain and intervention.

Age	Pain interpretation
0–3 mo	No apparent understanding of pain; memory likely but not conclusively demonstrated; responses are reflexive
3–6 mo	Pain response accompanied by sadness and anger response
6–18 mo	Develops fear of painful situations; localization of pain develops; words associated with pain (e.g., "owie," "booboo")
18–24 mo	Use of the word "hurt" to describe pain; noncognitive coping strategies
24–36 mo	Begins to describe pain and attribute an external cause to the pain
36–60 mo	Gives a gross indication of intensity of pain, use of descriptive adjectives; attaches emotional terms such as "sad" and "mad" to the pain
5–7 yr	Can more clearly differentiate levels of pain intensity; beginning to use cognitive coping strategies
7–10 yr	Can explain why pain hurts
11 yr	Can explain the value of pain

Adapted from McGrath PJ, McAlpine L. Psychologic perspectives on pediatric pain [review] [147 refs]. *J Pediatr* 1993;122:S2–S8.

TABLE 44-2. Developmental timeline of pain interpretation

As the child reaches school age, the concrete operations stage ensues. Pain can now be expressed in terms of affect. The child interacts with the world in simple, concrete ways; pain treatment focuses largely on medicine and physical interventions (e.g., rubbing). Pain is no longer viewed as a punishment (36). A sense of cause and effect develops, which is prerequisite for the use of patient- controlled analgesia (PCA) modalities. Young adolescents begin to master the skills of self-analysis, long-term anticipation, and delayed gratification. A sense of invulnerability also develops, leading to many of the risk-taking behaviors that bring the teenager to the hospital in the first place. Chronically ill adolescents, however, may report an increased negative quality to the sensations that accompany their disease. In the case of children with juvenile chronic arthritis, this has been suggested to result from increased appreciation of the pathophysiology of their disease (37). The teen may be treated in many ways like an adult; however, limited life experience, a strong sense of body image, and threats to the sense of invulnerability make the adolescent uniquely sensitive to the effects of disease and painful conditions. Independence from family has long been held to be a primary goal of adolescence (38); however, many teenagers still benefit from a hand to hold during procedures (39).

The stages of development are not attained immutably. Under stress, regression to earlier stages of cognitive and emotional development often occurs (34), necessitating use of therapeutic approaches geared to younger children. It is important not to address this apparent "immaturity" in a pejorative manner, but to accept it as the unique and dynamic part of pediatric development that it is.

The above discussion focuses on the normal, healthy child. Many mentally and physically handicapped children present for evaluation and treatment of painful conditions. The pain care of this set of patients can be extremely challenging, and new assessment tools are being evaluated (40).

PAIN ASSESSMENT

Assessment of pain in children, especially those in the preverbal age group, poses a particularly difficult problem. The reader is referred to an excellent series of discussions on measurement of pain in children and infants; the complexity of this topic precludes a full discussion here (41). Many health professionals report that adequate pain assessment is inconsistent and management is sporadic. In a national survey of pain practices in pediatric hospitals and residency programs (42), 60% of respondents stated that standard-of-care or pain protocols were present in their hospitals, but only 25% reported that the protocols were followed 80% or more of the time. Twenty-seven percent of respondents reported that they used none of the available pain assessment scales and 96% reported major obstacles to optimal pain management. Overall, it was believed that pain assessment and management were lower for infants and young children. A few of the many assessment tools that are available are displayed in Table 44-3,Table 44-4 and Table 44-5. The reader is referred to the Finley and McGrath monograph for a more comprehensive listing (41).

Age group	Assessment tool	Features
Infants	Neonatal infant pain scale	Good validation, multidimensional behaviors, can be done at bedside
	Premature infant pain profile	Good validation, multidimensional behaviors, can be done at bedside
	Neonatal facial coding	Good validation, original version required scoring from videos, although a rapid bedside version is now available (200)

Based on standardized observation of behaviors; facial activity most robust measure in infants.

TABLE 44-5. Self-report tools

Several investigators have attempted to develop self-report measures that can be used reliably by children aged 3 to 8 years. Faces scales have been quite popular, and these scales differ in several respects, including number of faces presented, the way the faces are drawn or photographed (43), and the faces layout of the page (44). In general, severe pain is depicted as a crying face, with eyes closed, brow furrowed, and nasolabial folds deepened. Some scales feature a single child photographed through a continuum of facial expressions from happy to screaming. The accuracy of the tool is influenced by the gender and the ethnicity of both the patient and the child pictured on the scale. In one study, Chambers and Craig showed that the pain ratings differ according to the choice of anchors on the scale, particularly according to whether the “no pain” end of the scale shows a neutral face or a happy face (45). Some children seem to be confused regarding ranking of happiness or well-being as opposed to absence of pain. Color analog scales (more pain corresponds to more intensely red color) appear acceptable to most children aged 4 and older (46,47) and show convergent validity to visual analog scales in older children.

To assess preverbal children, behavioral scales have been developed. These scales are largely for use in the assessment of toddlers and preschool children undergoing brief, painful procedures or surgery (48,49) and in the assessment of neonates undergoing procedures or intensive care. Work by Grunau, Craig, and their colleagues showed that facial expressions appear useful and valid as indicators of pain in neonates of all postconceptual ages (50). Audiologic evaluation of crying responses to various stimuli has allowed characterization of the “pain cry” (51). Overall, facial expression measures appear more robust and sensitive than measures of crying (50,52).

Johnston et al. and Stevens et al. characterized differences in pain-related behaviors in premature babies through the full range of postconceptional and postnatal ages, both in terms of cry characteristics and facial action components (53,54). They developed multidimensional measures that adjust for developmental stage. These tools are useful for the study of pain in neonates of different postconceptional and postnatal ages (55).

Differentiating pain from other negative experiences on the basis of behavior can be a frustrating endeavor. Attempts have been made to separate pain from other causes of agitated behavior in the postoperative period and underscore the confounded nature of deriving pure behavioral assessment tools (56). Behavioral scales, such as the Children's Hospital of Eastern Ontario Pain Scale, may therefore signal fear or anxiety instead of pain in the setting of acute medical procedures. Conversely, behavioral measures developed for acute procedures may underrate persistent pain, such as postsurgical pain (57) or oncologic pain. Many children with persistent pain lie still in bed, close their eyes, and inhibit their movements, not because they are comfortable or narcotized, but because it hurts too much to move. Therefore, one should not consider a child to be comfortable solely on the grounds that he or she is lying quietly. Gauvain-Picard and others have developed measures for pediatric cancer patients that incorporate assessment of social involvement and inhibition of movement (58).

At first glance, assessment of pain via physiologic parameters may appear attractive because of their presumed objectivity. Pain evokes increases in heart rate, blood pressure, and respiratory rate. Unfortunately, these signs are influenced by factors such as underlying disease, volume status, emotional state, and medications. Indices of vagal tone have been used to measure stress and distress in neonates undergoing painful procedures (59,60). Analysis of these parameters may be confounded by factors unrelated to pain (61,62 and 63). McIntosh and coworkers have provided evidence that measures of variability in physiologic parameters, including heart rate, blood pressure, and end-tidal carbon dioxide, may indeed be more useful than absolute trends in these physiologic parameters in painful situations (64). Although such studies provide fascinating insights into the physiologic response to painful stimuli, issues of sensitivity and specificity remain, as do issues of practicality of use in clinical settings. We discourage clinical investigators from overinterpreting physiologic measures without correlating them with behavior and the overall clinical situation.

DEVELOPMENTAL PHARMACOLOGY

Overview

A number of pharmacokinetic and pharmacodynamic factors modify responses to analgesic medication in the newborn and young infant, as summarized in Table 44-6.

Factor	Implications
Immature ventilatory reflexes “Leaky” blood–brain barrier	Opioid-induced hypoventilation more likely.
Greater percentage of total body water	Altered volume of distribution compared to older children.
Immature hepatic enzymes	Diminished drug metabolism. Potential for accumulation of opioids and/or local anesthetics with repeated dosing or infusions.
Decreased glomerular filtration rate and renal tubular secretion capacity	Diminished renal excretion of opioid and opioid metabolites.
Decreased plasma concentration of albumin and alpha$_1$ acid glycoprotein	Greater free fraction of drugs in the serum for the same total serum level, especially with local anesthetics.

TABLE 44-6. Factors that affect drug activity in neonates

Analgesic Pharmacology

Aspirin (acetylsalicylic acid) is by far the oldest nonopioid analgesic and antiinflammatory, having been used since 1899, and it still has an important place in the pharmacologic treatment of pain. The use of aspirin as an antipyretic for children has been associated with the development of Reye's syndrome, and this must be borne in mind when using this drug. Nevertheless, aspirin is an effective analgesic, and due to its long history of use, its side effects and toxicities are well described. The drug is effective as a treatment for mild to moderate pain associated with inflammation. Peak blood levels are seen 90 to 120 minutes after oral administration. Toxicity is possible with repeated dosing or with excessive single doses. Its elimination is nonlinear so that at higher concentrations, it is eliminated more slowly than it is at lower concentrations. Aspirin inhibits prostaglandin synthesis and release. This effect is responsible for the drug's analgesic effect as well as its antiplatelet effect. Aspirin binds to platelets, irreversibly affecting their function, whereas the antiprostaglandin effects of aspirin are transient in all other tissues of the body (65). The mild to moderate gastrointestinal (GI) upset that is commonly seen with aspirin administration is likely due to local irritation and can be minimized by administration of the drug with milk or food. Hypersensitivity to aspirin, usually manifested as wheezing, is not generally seen in children but does occur.

Acetaminophen (paracetamol) is a paraaminophenol derivative that has analgesic properties similar to aspirin and is useful for treatment of both mild pain and fever. In contrast to aspirin, acetaminophen has little antiinflammatory effect. Fortunately, acetaminophen has virtually no antiplatelet effect. When given at the recommended doses, acetaminophen has few effects. GI upset is rare, as is allergy to the drug. The dose of acetaminophen varies according to the route of administration, in contrast to aspirin. Conservative daily dose limits based on available pharmacokinetic data are 90 mg per kg per day in children, 60 mg per kg per day in infants, and 45 mg per kg per day in premature infants (66). The dose of acetaminophen needed to achieve analgesic levels when the drug is given per rectum has not been firmly established. Doses ranging from 20 to 40 mg per kg have been studied. Doses at the higher end of that range appear to provide therapeutic levels more consistently (67). Clearance after rectal administration is slow (68). Therefore, after an initial dose of 35 to 45 mg per kg, subsequent doses should be given 6 to 8 hours after the rectal dose.

Oral doses of 150 mg per kg have been associated with liver damage, and children who ingest this amount or more require intervention. With chronic overdosing, a smaller dose may lead to toxicity. Clinically, toxicity begins with 24 to 48 hours of nausea, vomiting, and malaise and is followed by laboratory and clinical evidence of liver dysfunction. If untreated, liver failure is possible (69).

Propacetamol is an intravenous prodrug of acetaminophen that has been used in Europe for adults (70,71); some pediatric data are available as well (72). This medication may be useful in a few situations in which both oral and rectal routes are not feasible. Several cases of contact dermatitis have been reported in health care workers who handled this medication (73).

Nonsteroidal antiinflammatory drugs (NSAIDs) are useful for many forms of pain, including but not limited to postoperative pain, arthritis and other inflammatory conditions, and pain in sickle-cell disease (see Chapter 83). Dosing for some of the more common compounds is shown in Table 44-7. A large number of NSAIDs have been examined for perioperative use in children, including indomethacin (74), ibuprofen, diclofenac, and ketorolac (75). NSAIDs can be effectively administered via oral, intravenous, rectal, and intramuscular routes. Intramuscular injection should be discouraged for use in most children because it is painful and offers no advantage over other delivery routes. The intravenous route offers convenience for administration intraoperatively or postoperatively. There is little evidence that this route is uniquely more effective than oral or rectal dosing for NSAIDs (76). NSAIDs reduce the requirement for opioids in a number of pediatric postoperative studies. In some of these studies, this reduction results in a decrease in opioid-related side effects (77). There is little evidence for differences between NSAIDs in analgesic effectiveness, and many studies do not compare them at a range of doses that would permit proper comparison of analgesia and side effects.

TABLE 44-7. Dosing guidelines for nonopioid analgesics

In one study, when compared with aspirin in children with rheumatoid arthritis, ibuprofen appeared equally effective and better tolerated (78). Another study found that short-term use of ibuprofen in children in the pediatric office practice has a very low risk of gastric irritation or bleeding (79). Overall, the safety of NSAIDs in children seems quite good, although rare cases of GI bleeding and nephropathy have been reported. NSAIDs should be used with caution in types of surgery where bleeding is of major concern. Ketorolac is a very effective analgesic for a variety of outpatient surgeries in children (80). Conversely, NSAIDs should not be used as an excuse for withholding opioids for children having severe pain. Although ketorolac was initially studied and approved for intramuscular use, it is now approved for intravenous use as well, and there is little justification for the intramuscular route for any patient who has intravenous access. Given the problem with decreased platelet function seen with the use of ketorolac, it is not recommended for children at risk for bleeding (75). A retrospective study of children undergoing tonsillectomy reported an increased incidence of postoperative bleeding when ketorolac was used (81).

Other NSAID side effects, in addition to decreased platelet function, include GI distress and GI bleeding, acute renal failure, and interstitial nephritis. Routine use of ketorolac, as with all NSAIDs, should be avoided in patients who are at risk for GI bleeding or renal dysfunction. A retrospective cohort involving hospitalized adults found that the rate of renal failure was no different in the ketorolac group versus the group treated with opioids so long as treatment was for 5 days or less (82). The authors suggest that there may be a greater risk for renal failure when ketorolac therapy is extended beyond 5 days. A pediatric case of acute renal failure has been reported (83). The safety and efficacy of NSAID-based analgesia in newborns have not been established.

Few data are currently available regarding the cyclooxygenase 2–specific inhibitors in children. Available data in adults suggest that they will be useful and may reduce some of the side effects and complications of NSAIDs. The lack of impairment of coagulation may be especially useful for pediatric postoperative use and for children with cancer pain.

Opioids can be used for infants and children of all ages, with proper understanding of age-related changes in pharmacokinetics (84) and pharmacodynamics. A number of opioids have undergone pharmacokinetic study in infants and children, including morphine (85), fentanyl (86), and sufentanil (87). Opioid infusion rates in infants should not be directly extrapolated from recommended dosing in older children. Opioid clearances in the first months of life, normalized by body weight, are diminished compared with mature values and reach mature values over the first 3 to 12 months of age. Therefore, drug accumulation can occur, leading to delayed sedation and respiratory depression. The time course of maturation may further be affected by the newborn's medical condition. For example, infants undergoing noncardiac surgery tend to show mature morphine clearances by 1 to 3 months of age, whereas infants undergoing cardiac surgery show reduced clearances through the first 6 to 9 months of life (88). Recommended opioid dosing is shown in Table 44-8.

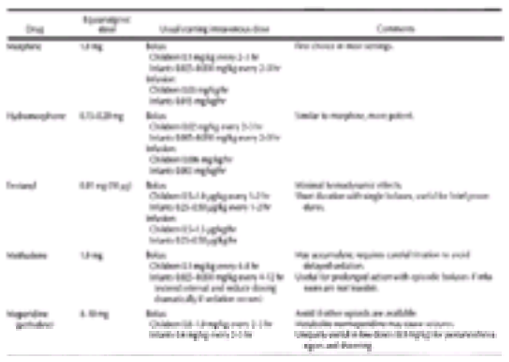

TABLE 44-8A. Intravenous opioid dosing guidelines

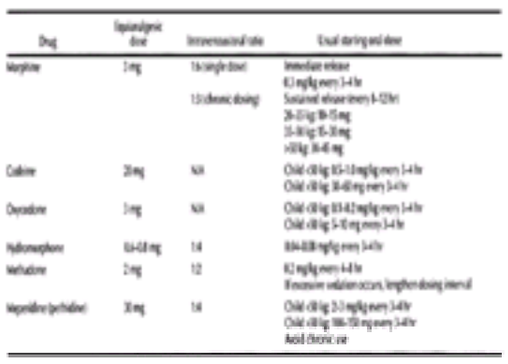

TABLE 44-8B. Oral opioid dosing guidelines

For many years, the issue of the pharmacodynamic respiratory sensitivity of neonates has been debated. Early observations by Way and others suggested that neonates had greater respiratory depression than older children and adults and that morphine may be more depressant than meperidine (89). Ventilatory reflexes to hypoxia and hypercarbia are indeed immature in human newborns and mature over the first weeks of life (90). Investigators have examined respiratory sensitivity in neonates by a number of methods, including carbon dioxide response curves, continuous oximetry, and impedance plethysmography. Healthy infants aged 3 months and older in these predominantly postoperative studies have similar analgesic responses and similar degrees of respiratory depression as adults at similar plasma

opioid concentrations (91). Opioid infusions have been used extensively for children with good efficacy and safety. Haberkern and colleagues, in a comparative trial, reconfirmed that both intravenous morphine and epidural morphine produce good analgesia but with a fairly high incidence of side effects, including itching, nausea, ileus, and urinary retention (92). Both routes of morphine administration resulted in reductions of approximately 50% in the slopes of the patients' carbon dioxide response curves.

Overall, opioid infusions in younger infants are useful and generally safe, but their dosing and titration require expertise and vigilance. Because pain assessment in infants is imprecise, titration to clinical effect is more troublesome. In the absence of conclusive evidence, there is debate over which forms of electronic monitoring are most useful for detecting hypoxemia or hypoventilation. Impedance apnea monitoring is widely available on hospital wards, with telemetry alarms that can ring in a hallway or nurses' station. There are case reports of significant hypoxemia in infants receiving opioids despite normal respiratory rates (93). For this reason, some clinicians have advocated continuous pulse oximetry as a method of monitoring. A false sense of security arises because remote telemetry of pulse oximeters is not widely available. Oximeter alarms may go undetected in a hospital room, defeating the purpose of continuous monitoring. These monitors also have practical limitations related to motion artifact. Convenient, low-cost, motion-insensitive oximetry with telemetry to a central site on a ward would be remarkably useful. No amount of technologic surveillance substitutes for clinical assessment and understanding of factors that modify opioid needs and risks.

MANAGEMENT OF SPECIFIC TYPES OF PAIN IN CHILDREN

Postoperative Pain

Overview

Amelioration of postoperative pain is best accomplished by coordinated efforts among parents, pediatricians, surgeons, anesthesiologists, nurses, pharmacists, child-life specialists, and others involved in perioperative care. Anxiety and fear, which can amplify pain, can be reduced with proper preoperative preparation. Children should receive explanations that are appropriate to their developmental stage. Preoperative education programs are now available at many pediatric centers, and these may be helpful in this process. Techniques of anesthetic induction should strive to be atraumatic. Parental presence for mask induction may reduce distress for many children. Use of EMLA or other topical anesthetics may reduce the distress of intravenous induction. Oral premedication can also reduce anxiety for many children.

Kehlet (94) and others have sponsored the concept of multimodal analgesia for adults undergoing surgery. It is likely that this concept applies for children as well. Combinations of opioids, local anesthetics, and NSAIDs may be ideal in many settings.

Acute pain services can provide patient advocacy and ensure that pain management is a priority. In many pediatric centers, these services have been developed and appear to provide extremely useful services. Standardized protocols are useful to ensure prompt and consistent management of both pain and side effects. Decimal point errors are common in pediatric hospitals. Provision of dosing protocols facilitates cross-checking for erroneous orders. If children are to be cared for in general hospitals, it is ideal to have pediatric specialists involved in the creation of specific pain management protocols for children. There are a variety of models for pain treatment services, and the choice of participants and specialists may depend on local expertise and availability.

Patient-Controlled Analgesia

PCA has been used for children for the past 10 years, with excellent safety, good efficacy, and excellent patient acceptance. In comparison with nurse-administered bolus dosing, PCA use results in better pain scores and better patient acceptance, without increasing opioid use or side effects (95). Compared with continuous opioid infusions, PCA provides either equivalent or improved pain scores, with a reduction of opioid use and side effects (96). PCA is generally well used by children aged 6 and older. Dosing parameters have been studied by Doyle and coworkers (98). Short lockout intervals (e.g., 7 to 8 minutes) are safe and allow more rapid “catch-up” in the setting of unrelieved pain. Basal infusions should be individualized according to medical risk factors, as well as psychological factors (97). Although basal infusions may increase patient satisfaction (98), they may also result in more episodes of nighttime oxygen desaturation (99).

There exist a variety of opioids from which to choose for PCA use. We use morphine most commonly, in a standard concentration of 1 mg per mL. In cases in which the patient has side effects from morphine, hydromorphone is prepared in a concentration of 0.5 mg per mL and dosed at a ratio of 1 to 5 with morphine (100). Fentanyl and meperidine are also used for selected patients. Meperidine has been associated with seizures in cases of renal insufficiency (101) and also in a healthy adolescent (102).

There is some controversy surrounding nurse-controlled and parent-controlled analgesia for children. Standard PCA is inherently safe because when patients become narcotized, they fall asleep. The plasma concentrations then fall, keeping the patients safe. Studies suggest good safety when nurses use the PCA pump for infants and children unable to dose themselves (103). There is similarly a very good experience with home dosing of PCA pumps by parents for infants and children in palliative care. Problems can arise when parents push the button for opioid-naïve children, particularly in a postoperative setting. Without specific training and monitoring, on rare occasions, well-meaning efforts may lead to overdose. We are aware of several cases around the world in which this has occurred, with disastrous consequences. The argument in favor of parental dosing is that parents are the children's primary caregivers and are in an ideal position to assess their needs. Pending further study, we recommend that if parent-controlled analgesia is to be used in nonpalliative situations, there should be a formal program of parent education and an increased level of patient observation.

Regional Anesthesia

Regional anesthesia in infants and children can be performed by specific modifications of techniques used in adults. The reader is referred to Dalens' excellent textbook for an illustrated, detailed discussion (104). A variety of peripheral nerve blocks can provide analgesia after surgery and have an excellent safety and side effect profile (105,106 and 107). Regional anesthesia is generally performed with the child anesthetized, as a method of providing postoperative analgesia. In general, the same range of peripheral blocks is available in the pediatric group as in adults. However, several factors limit the execution of pediatric regional blockade to practitioners especially familiar with pediatric anesthesia. Landmarks are often less well defined, proximity to neurovascular structures is greater, and the patients are usually anesthetized. Many of the blocks can be modified to provide prolonged analgesia via continuous infusions of local anesthetic.

Excessive doses of local anesthetics cause convulsions, arrhythmias, and cardiac depression that can be very difficult to treat. Kohane, Hu, and coworkers in our group recently demonstrated that rat pups have a narrower therapeutic index for local anesthetics than adult animals on the basis of scaling factors (107). The effective dose to block nerves scales comparatively weakly with body size. Toxic doses, on the other hand, scale more directly with body size (108). Recommended maximum doses for a single injection are displayed in Table 44-9.

Drug	Single bolus (mg/kg)		Continuous infusion (mg/kg/hr)
Birth to roughly 6–12 mo of age			
Lidocaine	4	5 with epi	0.8
Bupivacaine	1.5–2.0	2 with epi	0.2
Chloroprocaine	30	30 with epi	30
1 yr and older

TABLE 44-9. Dosing guidelines for local anesthetics

Epidural Analgesia

Epidural analgesia can provide outstanding analgesia for major thoracic, abdominal, pelvic, and lower extremity operations. When optimally managed, epidural analgesia may facilitate recovery of high-risk patients (109,110). Combinations of opioids and local anesthetics have excellent efficacy and are particularly effective when the catheter tip can be placed at the dermatomal level of the surgery. This goal can be achieved either by direct placement in older children or by cephalad advancement of a caudal catheter in younger children (111). Dosing for epidural infusions is displayed in Table 44-10.

Solution	Age <6 mo mL/kg/hr	Age >6 mo mL/kg/hr
Bupivacaine 0.1% with fentanyl 2 μg/mL	0.2-0.4	0.1-0.2
Bupivacaine 0.1% with fentanyl 2 μg/mL and clonidine 0.8 μg/mL	0.2-0.3	0.1-0.15
Bupivacaine 0.1% with hydromorphone 10 μg/mL[a]	0.2-0.3	0.05-0.15[b]
Chloroprocaine 1.2% with clonidine 0.1 μg/mL	Rarely used	0.4-0.8

[a] Apnea monitoring is recommended.
[b] Use with caution; may highly constrict urinary

TABLE 44-10. Recommended epidural infusion dosing guidelines

Epidural catheter placement is generally performed while children are receiving general anesthesia (112). Test dosing for intravascular placement is not entirely reliable. Incremental dosing and ECG monitoring are recommended. Fluoroscopic guidance or radiographic confirmation of catheter positioning may be useful in certain circumstances.

Single-shot caudal blockade with local anesthetics is generally safe and effective. Caudal analgesia is most often provided for analgesia after minor procedures below the umbilicus. a_2-Adrenergic agents, such as clonidine, prolong local anesthetic action and have received promising study in children (113,114).

Cancer and Palliative Care

Few areas of medicine are more emotionally challenging than the care of the child with cancer or of the terminally ill child. Many of the principles outlined in adult palliative care apply to children (115,116 and 117). Pharmacologic management by the World Health Organization analgesic ladder is effective for most children with pain due to widespread cancer (118). Some of the differences in the approach to palliative care for children involve consideration of the child's emotional and cognitive development (*vide supra*) and the family's roles in support and palliative care (119).

One of the great challenges of palliative care of children is the topic of dying, *per se*. Often the family is reluctant to discuss death with the child and to make the transition from curative therapy to palliation. The emotional angst suffered by the family is natural and understandable and must be handled compassionately and honestly. How one discusses palliative care with the patient depends largely on the progress family members are making in their own psychological journey. The child's concept of death, however, often develops much earlier than either the family or the health care team appreciates (120). As one 3-year-old stated about dying, “Mommy would be sad because there would be no more [me],” which at least partially reflects the concepts of loss, grief, and permanence inherent in an adult's concept of death. Often child-life workers, nurses, and behavioral medicine specialists can be invaluable allies in situations of terminal illness.

Brief Diagnostic and Therapeutic Procedures

Overview and General Approach

Needle procedures are a significant source of distress for children. Immunizations and blood draws are sources of medical pain for healthy children. Children with acute and chronic illness may in addition receive more frequent procedures, including intravenous cannulation, lumbar puncture, and bone marrow aspiration.

Several principles are crucial in managing acute procedure-related pain. First, never lie to the child about the discomfort she or he will experience. It is often very difficult to inform children that what is about to be done will cause discomfort, but denying the reality of the pain makes it unlikely that the child will trust the caregivers. Because both family members and caregivers would prefer that the child not be uncomfortable, it may occur that these individuals, whom the child looks to for comfort, actually begin to deny the child's complaints. Principle number two is therefore the following: Do not ignore, invalidate, minimize, or disbelieve the child's complaint of pain. The children must feel that they are worth listening to and that their complaints are important. When treating procedure-related pain with analgesics and sedatives, the American Academy of Pediatrics guidelines for monitoring children undergoing sedation and analgesia should be followed (121).

Approaches to these procedures must be individualized according to the child's age, cognitive development, coping style, and health status. Appropriate explanation and support can be helpful. Topical cooling may be beneficial for some children. As noted above, oral sucrose has been used for infants receiving distressing procedures (26) and appears safe and partially effective. Transcutaneous electrical nerve stimulation (TENS) has also been investigated in the context of procedural pain (122).

Cognitive-behavioral techniques, including guided imagery, hypnosis, and relaxation, can diminish the distress of these procedures for many children (123,124,125,126 and 127). There is some evidence suggesting that girls' distress ratings are higher than those of boys (128); it is not clear if this reflects cultural expectations on pain reporting. The various techniques are used very widely and can be taught to most children aged 5 to 7 and older. Some experts use them for children aged 3 to 5 as well (123).

Children often anticipate painful procedures with varying amounts of fear and anxiety. Children who have experienced blood draws anticipate their next procedure with greater anxiety than those children having their first blood draw (129). Providing either amnesia or a pleasant first experience, therefore, is extremely important. There is considerable debate over the logistics and ethics of “conscious sedation” versus general anesthesia for children undergoing a variety of noxious procedures. Conscious sedation, deep sedation, and general anesthesia represent a continuum, and the same doses of sedatives may leave one patient conscious but render another deeply unresponsive (130). More cooperative patients often do well with benzodiazepines (131) in combination with either opioid analgesics or low-dose ketamine (132). For higher-risk or highly uncooperative children or for more extensive procedures, general anesthesia may be a more effective alternative.

Local and Regional Anesthesia

Topical administration of local anesthetics is widely used for relieving the pain of needle procedures, laceration repairs, and removal of skin lesions. For intact skin, the most widely used preparation is EMLA (133), which has proved to be extremely safe in all age groups. The cream requires at least an hour for adequate cutaneous analgesia in most situations. Although high systemic concentrations of prilocaine can produce methemoglobinemia, this has not been a significant clinical problem in widespread use, even with repeated or prolonged dosing in younger infants. Iontophoretic transcutaneous delivery of lidocaine has been used effectively for placement of intravenous lines in children (134). Effective analgesia can be obtained in as little as 10 minutes. There have been several cases of cutaneous burns from the electrical devices; however, current devices appear to reduce this risk.

For application to cut skin, especially for suture of lacerations, combinations of local anesthetics with vasoconstrictors are widely used. The combination of tetracaine with epinephrine (adrenaline) and cocaine is known as TAC. Several studies have shown that these preparations are effective when used in emergency departments for repair of lacerations (135). TAC should be avoided in the vicinity of end arteries because ischemic complications have occurred. Rapid absorption of the tetracaine and cocaine with larger doses applied to mucosal surfaces has produced convulsions and death. More recent studies have found equivalent effectiveness using

preparations with the cocaine omitted, and combinations of tetracaine and phenylephrine appear useful in this setting (136).

Chronic “Benign” Pains of Childhood

Overview

The large majority of pain complaints in children are the result of benign processes, as they are in adults. Chronic and recurrent pains in children, however, have a different epidemiology from those in adults. Back and neck pains are less common in children. School avoidance issues replace work avoidance issues. Children commonly experience recurrent pains of the head, chest, abdomen, and limbs. These conditions typically involve painful episodes alternating with pain-free times in a child who is otherwise healthy. These conditions are very common, and population-based surveys suggest that between 4% and 10% of children experience these symptoms with some regularity (137,138,139,140 and 141).

Most children presenting with these benign complaints will be determined to be medically well. Despite this fact, complaints such as chest pain evoke fears of life-threatening illness in the minds of adolescents (142) and their parents. The primary pediatrician or general practitioner needs to develop a screening approach that emphasizes a sensitive medical history and physical exam that detects the small subset of patients who need further evaluation (143). Extensive laboratory and radiologic testing is rarely warranted, and unfocused laboratory testing should be deemphasized. Lifestyle interventions may be helpful, and questions should be included regarding family and school circumstances, diet, sleep, sports, and the child's daily and social activities.

Physical therapeutic approaches are extremely helpful for many chronic painful conditions in children. Physical therapists should be integral participants in multidisciplinary chronic pain programs for children. Aerobic conditioning and strength training may have specific, localized benefits—for example, for an adolescent with myofascial pain—and also have more generalized beneficial effects on mood, sleep, and general well-being. The following discussion focuses on a few of the more common problems that are seen in a pediatric pain clinic.

Neuropathic Pains

Neuropathic pain in children can be a source of considerable distress and suffering (144). The causes we see most frequently are complex regional pain syndrome type 1 (CRPS I)/reflex sympathetic dystrophy (RSD), postsurgical/posttraumatic peripheral CRPS II/causalgia metabolic neuropathies, spinal cord injuries, and cancer. Phantom pain after amputation is more common than once thought and can be prolonged and severe (112,145). In the absence of randomized controlled trials in children, we commonly extrapolate approaches used in adults. Tricyclic antidepressants and anticonvulsants form the mainstay of pharmacologic therapy, with cognitive-behavioral strategies and TENS technology completing the therapeutic triumvirate. We prescribe amitriptyline or nortriptyline after obtaining a baseline electrocardiogram, at 10 mg qhs. Starting at 5 to 7 days, the dose is elevated in 10-mg increments every several days to effect or as limited by side effects. The patient should be told that although the effect on sleep is immediate, the analgesic effects might take 1 to 3 weeks. Unacceptable side effects at any time or lack of clinical effect after a few weeks are reasons for switching to a different antidepressant. Side effects of the tricyclic antidepressants include dysrhythmias, dry mouth, constipation, urinary retention, and blurred vision. Even among patients for whom pain is not improved, the beneficial effect of a tricyclic on sleep may make them worthwhile.

Anticonvulsants have been used frequently in adults, with the best data supporting phenytoin and carbamazepine (see Chapter 86). Recently, gabapentin has become popular for the treatment of various neuropathic pains (146,147). Gabapentin has the benefits of the lack of hematologic or hepatic toxicities, minimal protein binding, and the lack of interactions with hepatic enzyme systems (148). Some adult studies suggest efficacy for several neuropathic pain conditions; pediatric experience is limited (149) and no pediatric controlled trials are available at this time. Although side effects have been a minor problem in our practice, there have been children for whom behavioral side effects have been problematic. Many of these children had preexisting neurologic or neuropsychiatric problems, and the prevalence of adverse behavioral effects may be lower in patients with chronic pain (150).

CRPS I/RSD in children and adolescents differs from that in adults in several ways (151). Pediatric CRPS I has a marked female predominance (roughly 6 to 1); a marked lower extremity predominance (roughly 6 to 1); and an apparently high association with competitive sports (152), gymnastics, and dance (153). The reasons for this association are unclear. Some clinicians regard this as a psychogenic condition (154), although evidence of causation, as opposed to association, is weak. The syndrome rarely progresses to the third of the three stages seen in adults: acute, dystrophic, and atrophic. Even when CRPS I in children is relatively advanced, prognosis for recovery is generally good, although many patients have recurrent episodes and a small percentage have persistent pain and limb dysfunction. Approaches to treatment of CRPS I/RSD have been extremely varied, ranging from rehabilitative (155) to more interventionist. A prospective controlled trial of physical therapy in the treatment of CRPS I is in progress. In our view, the major role for neural blockade in pediatric CRPS I/RSD is to facilitate aggressive physical therapy.

Sickle Cell Anemia

Sickle-cell disease refers to series of related hemoglobinopathies occurring predominantly in those of African and Middle Eastern descent. Sickling of red blood cells occurs when the abnormal hemoglobin molecules polymerize under certain conditions, including hypoxemia, acidosis, hypothermia, and erythrocyte cell water loss. Reduced deformability of the cell ensues, leading to impaired rheology in small vessels, vasoocclusion, and ischemic pain. Pain in sickle-cell disease is extremely variable in its frequency and severity (156). The majority of patients manage their persistent and episodic pains as outpatients, using oral hydration, NSAIDs, and oral opioids. Some patients may be on hydroxyurea, a medication used to promote hemoglobin F production, which results in fewer painful crises (157). A subgroup of patients has more severe episodes of vasoocclusive pain that require hospitalization. Opioids should be given as needed to provide comfort (158). Often, hospitalization occurs to provide intravenous opioids.

Some patients arriving for hospital care are opioid-tolerant secondary to their home opioid management. It is important to take their baseline opioid requirement into account when formulating an inpatient regimen. Often, a basal infusion at an equianalgesic amount will suffice. Use of a PCA with the basal infusion allows provision of adequate amount of opioid without the need for the patient to use the bolus doses frequently. Given the intensity of ischemic pain and the baseline opioid exposure, relatively large doses of opioid are required and should be prescribed. As the patient's total requirements become known (usually after a couple of days), conversion to a combination of long- and immediate-release opioid can be arranged. Opioid titration may require some additional care because hypoxemia and hypercarbia further exacerbate sickling of erythrocytes. Use of pulse oximetry (apnea monitoring in selected cases) adds a layer of safety. The opioid-sparing effect of ketorolac makes this drug especially useful for vasoocclusive crises, if renal function is normal (159). Epidural analgesia has been used safely in the setting of acute vasoocclusive crisis (160). For the potentially lethal “chest crisis,” a thoracic epidural should be considered early in the clinical course to facilitate chest physiotherapy and effective coughing and to promote full chest excursion.

Some studies evaluating aggressive oral opioid use suggest that decreased hospital admission rates can result (161,162). There is an increasing emphasis on home management (163), oral opioid dosing, avoidance of a “crisis” model, and teaching cognitive- behavioral techniques (164,165). Gil et al. suggest that the earlier adaptive coping skills are learned, the more likely they are to become a routine part of the sickle cell patients' armamentarium against the pain of their disease (166).

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

Human immunodeficiency virus (HIV) disease in children is now most commonly acquired by congenital infection (see Chapter 39). The natural history of HIV in infants has improved greatly in developed countries in recent years with multidrug treatment regimens. On the other hand, what was a relatively time-limited, fatal illness has become a longer-term chronic illness. Children with HIV undergo a large number of painful diagnostic and therapeutic procedures (167). Infants with encephalopathy and severe developmental delay sometimes present with persistent irritability and screaming of unclear etiology. Many of these infants respond to opioids. For other such children, anticonvulsants may be helpful, even when clinical seizures are not evident.

Headache

Both migraine and tension-type headaches increase in prevalence during the school-age years and into adolescence (168,169). Although the vast majority of headaches are benign in origin, the fear of brain tumors is prevalent, being seen in children as young as 5 to 7 years (170). Such fears can often be assuaged after careful history and physical and by a direct and honest discussion with the child. Certainly, any child with persistent early-morning headache accompanied by vomiting or who has focal neurologic signs deserves intracranial imaging.

There have been some recent clinical trials of analgesic treatment or prophylaxis of migraine pain in children, using trazodone (171), tricyclic antidepressants (172), and calcium channel blockers (173). Sumatriptan, which is effective in interrupting adult migraine attacks, has appeared less impressive in one pediatric trial (174). Similarly, propranolol appears less effective for migraine prophylaxis in children (175). There is a need for more controlled trials of a range of analgesics in children, especially in the setting of chronic or recurrent pain.

Before initiation of tricyclic antidepressants, we obtain an electrocardiogram to rule out conduction disturbances, including preexcitation syndromes or prolonged Q-T syndromes; there is a suggestion that patients with preexisting conduction abnormalities have a risk of developing atrioventricular block secondary to tricyclic antidepressant use (176). We start with nortriptyline at 10 mg nightly for adolescents or 5 mg nightly for school-aged children and escalate in 5- to 10-mg increments every 3 days until a response is obtained, until side effects arise, or until the daily dose escalates to 1.0 to 1.5 mg per kg per day. The side effects seen in children mirror those seen in adults. For patients who will benefit from nighttime sedating effects but who find peripheral anticholinergic effects bothersome, trazodone can be started at low doses (25 mg) at bedtime and escalated over a period of a few weeks to 50 to 100 mg nightly.

Behavioral medicine plays a prominent role in the prophylaxis of both muscle tension–type headaches (177) and pediatric migraine (178). In addition, TENS is also an effective adjunct for the treatment of tension headache (179). Acupuncture is beginning to receive attention for the management of pediatric headache and may prove to be a useful adjunctive treatment.

A common and very difficult headache type is the chronic daily headache, or mixed-type headache, most commonly presenting in mid-life (180). This type of daily headache originates in childhood and adolescence in almost 13% of respondents (181). Future investigations may lead to effective early treatment of these challenging headaches early in their development.

Others forms of head and facial pain occur less frequently. Trigeminal neuralgia is extraordinarily rare in children, and herpes zoster is much less likely to produce postherpetic neuralgia. Other unusual causes for head pain seen in the pediatric age group include headaches resulting from either high or low intracranial pressure as a result of interventions for hydrocephalus. Slit ventricle syndrome can be challenging to evaluate and treat (182), especially in children who are neurologically impaired, nonverbal, and prone to agitated behaviors at baseline. In this situation, close communication with the parents, careful titration of medications, and frequent reevaluation are the keys to success. There is some evidence for a relationship between facial pain and sexual or physical abuse (183), and pertinent histories should be obtained.

Abdominal Pain

Children commonly present to their pediatrician's office with a complaint of recurrent abdominal pain and, frequently, persistent school absenteeism. Although the majority of recurrent abdominal pain in children is “functional,” or nonorganic, indicators of potentially dangerous pathology should always be sought (Table 44-11). Such pathology should be dealt with as appropriate. Certainly, modifications of diet may have considerable benefit in some situations. For example, a subgroup of children with recurrent abdominal pain may improve by treating constipation or by treating lactose intolerance with oral lactase enzyme replacement or avoidance of milk products (184).

Focal pain (away from umbilicus)
Fever
Weight loss
Guaiac-positive stool
Elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) concentration
Dysuria
Pain-induced night wakening
Anemia

TABLE 44-11. Signs of organic abdominal pain

Often, the patient has undergone an extensive workup before his or her arrival in the pain clinic. The initial approach should be to assure the patient and parents that the workup has been inclusive to the extent that no dangerous pathology has been missed. Attention then can be turned (often against great resistance) to demedicalizing the situation. In most of these patients, behavioral psychologists can help the patient learn coping and adaptive behaviors (185,186). Under some conditions, diagnostic and therapeutic epidural or celiac plexus blockade can be conducted. Only under extreme circumstances should a lytic block be performed for these nononcologic conditions. The more devastating complications of a lytic celiac plexus block include intravascular, intrathecal, or intrarenal injection of phenol or alcohol; retroperitoneal fibrosis with repeated blocks; and disruption of a major blood vessel.

The pattern of back pain differs from that of adults. Discogenic pain has been found in 11% and muscle tendon strain in 6% of an adolescent population presenting to a pediatric sports medicine clinic. Forty-seven percent of this study population has pain arising from spondylolysis stress fractures of the pars interarticularis, whereas only 5% of adults are found to have such an etiology for their pain (187). In our clinic, the numbers of spondylolysis versus discogenic disease are more even, although referral bias plays a role. For spondylolysis pain, back bracing with graded physical therapy along with a course of nonsteroidal antiinflammatory agents and often a tricyclic antidepressant are the cornerstones of treatment. Sciatica secondary to disk protrusion responds to selected use of epidural steroids, physical therapy, and NSAIDs, as it does in adults. The need for surgery is unusual.

Pelvic Pain

We have seen an increasing number of young women presenting to our clinic for pelvic pain (see Chapter 72). The pain may or may not be related to the menstrual cycle. Sometimes, defecation or urination worsens the pain. The patients often have missed moderate to large amounts of school and can be extremely disabled, although this is highly variable. Often the pain is secondary to endometriosis. In our gynecology clinic, patients not responding to oral contraceptives and NSAIDs were found on laparoscopic exam to have endometriosis approximately 70% of the time, with stage 1 and 2 disease being most prevalent (188). Very similar results have been found elsewhere (189). Owing to the high rate of pelvic inflammatory disease in the adolescent population (190) a thorough sexual history must be taken, and referrals to a gynecologist for cultures made in select cases. Psoas muscle abscesses, musculoskeletal injury, ovarian cysts, and constipation make up the large portion of nonendometriosis pain in adolescent women with pelvic pain.

If endometriosis is found at laparoscopy, the initial approach taken by our gynecologists is laser ablation along with oral contraceptives. Although gonadotropin-releasing hormone inhibitors are effective in suppressing endometriosis-related pain, their use is limited for short term in women older than age 16. We have seen several cases of osteopenia in young women treated for longer periods of time. Tricyclic antidepressants, prostaglandin inhibitors, behavioral medicine, physical therapy, and TENS form the multimodal therapy for the majority of pelvic pains.

“Functional” and Somatoform Pain in Children

A number of the recurrent benign pains of childhood have been commonly regarded as psychogenic. The evidence that most children with these symptoms have psychiatric illnesses is generally weak (191,192). Many children and adolescents with these symptoms, in fact, are well adjusted and cope fairly well. Infrequently, a patient will present with a conversion pain disorder, in which there is no organic disease, and the pain results from psychic conflict. The somatoform or psychosomatic disorders feature minor organic disease with significant psychological or stress components. Symptoms may be limited to pain but often accompany other complaints. Oberlander, Rappaport, and others have argued against dichotomizing these conditions as purely “psychogenic” or purely “organic” (193). The term “functional” has been used to describe these pains that may arise from variations in normal functioning but are related neither to a specific disease nor to psychopathology. From the behaviorist's standpoint, therapy is directed against the pain behaviors more than an underlying psychological process. The distinction among these entities is often

blurred and may be of more theoretical significance than functional importance. For a few children, intensive psychiatric therapy or family therapy is indicated.

Psychiatric Disorders

A small subgroup of children presenting to pediatric pain clinics do have more severe psychiatric illness. A number are depressed, even suicidal. Some have true conversion disorders. Some have a range of posttraumatic stress conditions or a history of physical or sexual abuse. The history taken from any young person in chronic pain should include screening questions for suicidal attempts and ideation. Drug and alcohol use histories should be sought. Munchausen's syndrome by proxy is a condition in which symptoms and signs are generated by parental actions. In many cases, the parents have a strong need for attention and establish a perverse role in relation to the health care team, simultaneously harming the child and appearing to be a perfect, caring parent (194). This disorder has a spectrum of presentations and can be regarded as a form of child abuse.

BEHAVIORAL AND EMOTIONAL CONSIDERATIONS

School Absenteeism and Disability

In adults, chronic pain is a major social, economic, and political problem because it produces suffering and because it is an enormous cause of disability. The child's and adolescent's main “occupation” is school. Questions about school attendance and performance are invaluable in assessing the level of functioning of a pediatric patient. School absenteeism and school avoidance are extremely common among patients referred to our pediatric pain clinic. In our view, it is helpful to regard school avoidance in many (but not all) cases as a disability syndrome with analogies to work absenteeism in adults with chronic pain. Just as the workers' compensation system in adult pain patients may serve to reinforce disability, home-tutoring programs for pediatric pain patients may facilitate a sick role away from the mainstream of life in a school setting. In the future, multidisciplinary programs for pain management in children will need to address more proactively the process of return to school (195).

Biobehavioral Therapy

Behavioral medicine techniques have proven to be useful in the treatment of many pediatric pain syndromes. These therapies can be grouped into four categories: relaxation therapies, including hypnosis; biofeedback (both electromyographic and thermal); operant (or contingency) pain behavior management; and a more general category of cognitive-behavioral techniques using self- monitoring, coping strategies, and environmental modification. There is strong evidence for the efficacy of biobehavioral intervention for recurrent abdominal pain (185), pediatric migraine (178), and juvenile rheumatoid arthritis (196). There is also some evidence that biobehavioral treatment techniques are useful for neuropathic pain (197) and pain associated with sickle-cell disease (198). Conversion disorder can also be treated with a biobehavioral approach (199).

CONCLUSIONS

Early in the development of pediatric pain clinics, a need for multimodal therapy was seen. The interplay between psychology and physiology is strong and changes with the growth of the child. In addition, the patients' fear of needles and the technical challenge of nerve blocks in young patients prevented the development of an overreliance on a single modality of therapy. We have observed that outcomes are better when physical therapy and behavioral medicine are combined with the standard allopathic medical approach, even though this is labor intensive (200). Pain treatment in children and adolescents can influence the function of an individual for a lifetime. Even in these times of managed care and enforced cost cutting, we must emphasize that the children do best when the multidisciplinary approach is taken. Pediatric pain clinics ideally comprise facilities that allow evaluation and intervention by medical doctors, physical therapists, and psychologists, with consultation of orthopedic surgeons, neurologists, and rheumatologists on an as- needed basis.

Unrelieved pain continues to be a major problem in the care of our youngest patients. The cognitive, emotional, and physiologic dynamism of the child can seem quite daunting at first glance. With a thoughtful, multidisciplinary approach that takes advantage of the expertise of pediatric physical therapists and psychologists as well as that of the pain physician, assessing and treating the pediatric pain patient can be an extremely rewarding endeavor. There is still a tremendous amount to be learned about the proper evaluation and treatment of many pediatric pain syndromes; randomized controlled trials of therapeutic modalities clearly are needed.

CHAPTER 45

Aging and Pain

Stephen W. Harkins

> Senescence is not universal in nature, not even common. Most creatures out in the wild die off, or are killed off, at the first loss of physical or mental power. In a real sense, aging, real aging, the continuation of living through the whole long period of senescence, is a human invention, and perhaps a relative recent one at that (1).

This chapter reviews the effects of aging in the later years of life on pain sensation, perception, and behavior. A commonly accepted definition of being “old” is attaining an age of 65 years. This is artificial. The choice of 65 years of age for retirement and eligibility for Social Security in the United States was adopted in the 1930s from social policy of von Bismark's Germany during the 1880s. Such a definition of being old is subject to change based on epidemiologic, demographic, and political factors, as is illustrated by recent changes in retirement eligibility for Social Security.

There is need for a definition that allows more specific indication of the effects of chronologic time and individual differences on psychophysiologic integrity and homeostasis. In biogerontology, the term *senescence* serves this purpose and replaces *aging*. The Oxford English Dictionary (2) defines *aging* as a process without reference to any specific chronologic period. Aging, in this definition, begins at conception and continues across the life span without reference to specific developmental periods. In contrast, *senescence* in multicellular animals begins at some point post-maturity. Senescence is species specific, universal, and irreversible and results in reduced ability to withstand stress with an increase in probability of death. It is detrimental to the individual. Its value to the species is only now being explored but likely lies in aspects related to somatic cellular mutation or failure, telomere and telomerase activity during mitosis, and accumulated damage (particularly oxidative damage) in fixed postmitotic cells, following sexual maturity. In this regard, it is unclear whether senescence is independent of the selective process of evolution because organisms in nature seldom, as indicated by Lewis Thomas, live long enough to “senesce” (1). *Aging* in this chapter refers to developmental changes that occur during senescence.

Pain is a major force in quality of life for persons of all ages but is particularly so in those more dependent. Pain control in neonates and infants has received substantial attention in the past three decades, in contrast to pain and its control in the frail elderly individual. Critchley (3), in a highly influential paper on neurology of old age, stated that old people tolerate “minor” surgical and dental procedures with little or no “pain or discomfort.” This is certainly wrong, even though it is currently accepted by some in the health care community and by many elders as a “natural” part of “growing old.”

Although literature exists supporting no or at most minimal generalized impact of age, *per se*, on pain perception, there do appear to be very specific age differences in pain sensibilities. These may have important clinical significance in the diagnosis of specific disorders. Reviewing this literature reveals that, although the effect of aging on pain as a sensory/perceptual process differs from its effect on most other senses, another issue is more important for older persons: the impact of pain on successful aging. The major practical clinical concern may well be not whether loss of pain perception occurs with otherwise “normal” aging, but rather that considerable unnecessary suffering occurs from undertreatment of pain in the old. This is particularly true for the frail elderly and those with compromised cognitive capacity.

The purposes of this chapter are to provide the following:

- A summary of demographic changes over the recent past that has fueled awareness of the importance of understanding pain in the aged
- A definition of *presbyalgos* (*presby*, meaning old; *algos*, meaning pain)
- Evidence that the impact of pain on successful aging and maintenance of a quality life is more important to the older person than the impact of old age on pain perception

THE “GRAYING” OF AMERICA: THE COMPRESSION OF MORTALITY AND MORBIDITY

At the beginning of the “age of Social Security,” John Dewey wrote “In the United States, with decrease of birth-rate and the limitation of immigration (which had been mainly of the young and vigorous) we now have an unprecedented situation. Over one- third of the total population will soon be over fifty years of age. In 1980 the number of persons over sixty-five will be more than double that today” (4). Dewey was less than correct. The population has exceeded his projections from some two score and 10 years ago. This presents serious challenges to national imperatives, not the least of which include the solvency of Social Security, funding of health care in hospitals and skilled nursing facilities (Medicare), and home care for the frail elderly. From a demographic perspective, the change in the population has resulted in a compression of mortality into the later years of human life expectancy.

Compression of Mortality

Over the twentieth century in the United States, life expectancy from birth has increased from approximately 48 years to more than 76 years. This increase comes from substantial reductions in mortality early in life and not from an addition of years later in life; it has led to an increasing number of persons surviving into the seventh, eighth, or even ninth decades of life. In fact, those 85 years of age and older represent the fastest-growing segment, percentage-wise, of the total population. The number of persons 85 years of age and older is important because of the increased levels of disability in this group of older adults. For example, in community-dwelling individuals 85 years of age and older, one study estimates that 47% meet clinical criteria for probable Alzheimer's disease (AD) (5).

Numeric Growth

In 1900 there were approximately 3 million individuals aged 65 and older in the United States (approximately 4.1% of the total population). By 1994, the number of those 65 years of age and older increased to more than 33.2 million (approximately 12.5% of the population). Over the next decade (2000 to 2009), the growth in the elderly population will be moderate. Between 2010 and 2030, however, the number of older adults will increase. Individuals born between 1946 and 1964, the “baby boomer” generation, will begin entering a new “over-65 generation” in 2011. By 2030 those 65 years of age and older will number some 70 to 78 million (based on different mortality, fertility, and migration assumptions) and will comprise between 19% and 21% of the total population. Whereas in 1900 one in 25 was age 65 or older, by 2030 the most likely demographic scenarios project that one in five in the U.S. population will be 65 and older. This density of one to five will likely characterize the population from 2030 to 2050 (6). Substantial policy implications result from this broad shift in population structure, including a need for focusing clinical practice on identification and treatment of pain in the old. The baby boomer generation will have considerably different experiences with the health care system than previous generations of the “young-old,” and it is likely that they will place greater demand on pain control compared with their parents and grandparents (today's “old-old” and “oldest-old”).

Compressing mortality into the practical upper limit of human life expectancy (approximately 85 years of life) is not just an academic issue for gerontologists and demographers. The U.S. Congressional Budget Office estimates that in 1998 Social Security and Medicare spending was approximately 6% of the national gross domestic product of the United States. This is projected to rise to approximately 14% by 2060, a time when baby boomers will be entering the ranks of the oldest-old.

To fund Social Security and Medicare/Medicaid at current levels will require a reduction for defense, law enforcement, education, and other federal government spending from 13% of the gross national product to approximately 5% (7).

Numbers, however, do not tell the whole story. Increased individual variability is a major characteristic of the old. Focusing solely on the growth of the elderly population, no matter how dramatic, misses the fact that as a group they are characterized by greater social, psychological, and physiologic diversity than younger adults. “An increasingly numerous and diverse older population is destined to change our social landscape in ways we can only imagine” (8).

Compression of Morbidity

“Graying” of the more developed countries is due to a compression of mortality into the later years of the human life span. The aging of these populations will continue for another 50 years. This compression of mortality is a fact of history. In contrast, a critical question that is only now being answered with quality empirical information is whether new cohorts of elders will be healthier than past cohorts. The possibility of increasing health until the upper limit of the human life span essentially means the compression of morbidity into the upper limit of the human life span. It has been suggested that, presumably, generalized improvements in quality of life and health status in future generations of elders will result in future savings in health care and social support costs. No studies to date, unfortunately, have included pain as a factor influencing possible compression of morbidity or successful aging into the practical upper limits of the human life span.

The diversity and variability in the elderly as a group stem not only from social history but also from dynamic patterns of morbidity in the old. Patterns of illness in the elderly, particularly the frail elderly, are characterized by multiplicity, duplicity, and chronicity. This complicates identification of the specific etiology of pain problems.

One example of age-related changes in acute clinical pain is absence of pain associated with myocardial infarction (MI) in some older patients. Silent MI is more common in elderly than younger patients. In one study of MI occurring in residential care patients, 40% did not report pain as their major complaint, and 56% had atypical presentation (9). The high incidence of atypical MI in residential care patients may well reflect the inability of such patients to communicate their pain accurately or even the indifference to pain that some patients with frontal-cortical dementia manifest (see below). Dementia, aphasia, and significant depression are common problems in the nursing home and clearly influence the ability of the patient to accurately report presence of pain. Nevertheless, increased frequency of silent MIs also occurs in community-dwelling elderly. In a survey of 1,000 community-dwelling middle-aged and elderly MI patients presenting at the emergency room, 30% of the elderly and 23% of the middle-aged patients presented with the primary complaint being other than pain (10). The 7% difference between the middle-aged and old patients was significant.

Referred pain associated with cardiac ischemia apparently presents atypically in the old more frequently than in the young. This likely reflects some impairment of nociceptive transmission. As discussed in Chapter 61, pain consequent to MI develops when sufficient levels of afferent impulses are reached and when an appropriate activation of central ascending pathways has been established. In patients with silent MI, such levels are apparently not reached, perhaps because of insufficient stimulation by the myocardium, decreased capacity for cephalad transmission, altered age-related changes of mechanisms subserving referred pain at the level of the spinal cord (see Chapter 4), or for other unknown pathophysiologic reasons. This suggests a need for enhanced vigilance when evaluating older patients who may have suffered an MI.

Young-Old, Old-Old, and Oldest-Old

Because of the great variability between individuals in the older population, gerontologists have made several attempts to identify subgroups of elderly. One such grouping is based on chronologic age and identifies three groups: young-old, old-old, and oldest-old. The young-old consist of those between 65 and 75 years of age. This group is generally healthy and active with sufficient social and financial resources. The young-old as a group place limited strain on supportive and health care services. The old-old consist of those 76 to 90 years of age. This group is characterized by increasing morbidity, reduced independence, and decreasing social and financial resources. Demand for supportive services in their activities of daily living is increased compared to the young-old. The oldest-old consists of those older than 90 years of age and represents a group growing substantially in number. There is a high level of morbidity in this group, and a new uncontrolled or difficult-to-control pain problem will, for many of the oldest-old, represent a high probability of mortality in a short time interval after onset of the pain problem.

Currently there is no systematic research concerning pain in the oldest-old and only limited information on the old-old. The bulk of the laboratory and clinical research on age differences in pain perception is limited to the young-old.

Laboratory Studies of Pain in the Young-Old

What is the impact of aging on pain? Can pain studied in the psychophysics laboratory answer this important question? It is currently impossible to answer this question for a number of reasons, only one of which is the limited information on the old-old. Experimental pain, as studied in the laboratory, focuses on pain intensity and in a few studies on the immediate unpleasantness of nociceptive stimuli. For obvious reasons, laboratory and clinical studies of pain must not involve suffering, yet suffering is the hallmark of chronic pain.

Experimental pain involves primarily assessment of sensory processes. Change in sensory systems is a widely accepted part of the aging processes. As documented by well-controlled longitudinal studies, age-related changes in vision and audition mark the onset of old age for the eye and ear. No longitudinal studies of the effects of aging on pain perception exist. All laboratory studies of pain to date are cross-sectional in design, representing a contrast of younger and older individuals who differ not only chronologically but also in sociocultural history. Cross-sectional studies allow inferences concerning age difference, not age change. Table 45-1 summarizes a number of laboratory studies of human pain (11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31 and 32). It appears that the findings of these studies are at best inconclusive.

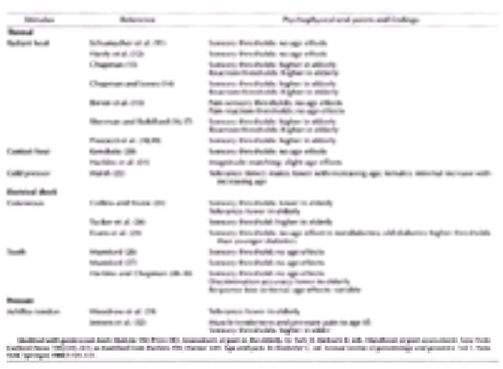

TABLE 45-1. Laboratory studies of the effect of age on psychophysical indices of pain sensitivity

Chronic Pain in the Old versus Young: Are There Differences?

General health status is a major factor in successfully coping with a chronic pain problem in any adult and may become paramount in the frail elderly with multiple-system disorders. The frailty of this population makes it particularly difficult to diagnosis a specific etiology of pain disorders and is thus a treatment challenge. There is, however, no question that chronic musculoskeletal pain complaints increase in both prevalence and incidence with aging. It is also clear that these conditions produce considerable morbidity. Figure 45-1 presents summary results from a stratified random sampling of community-dwelling individuals in the United States.

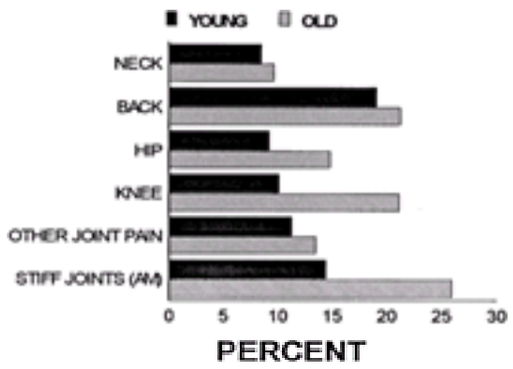

Figure 45-1. Prevalence of selected pains lasting at least 1 month and present during the past week in 5,659 community-dwelling individuals. Note that pain prevalence (percent) is greater in older [mean age, 75; standard deviation (sd) = 5.5 years; n = 2,863] compared with younger (mean age, 40; sd = 3.3 years; n = 2,796) respondents. [Data redrawn from Harkins et al. (40) based on original tabulations compiled from the National Health and Nutrition Follow-Up survey (33).] Significant group differences in pain prevalence were obtained for back pain (p <.05); hip pain (p <.001); knee pain (p <.0001); other joint pain (p <.01) and stiff joints on awakening (p <.0001). Knee pain associated with activities of daily living is likely to have a major impact on quality of life of the older adult.

As shown in Figure 45-1, prevalence of musculoskeletal and joint pain of the neck, back, hip, and knee and stiff joints on awakening is greater in older (mean age, 75; n = 2,836) compared with younger persons [mean age, 40; n = 2,796; original data tabulations from the National Health Nutrition Survey I Epidemiologic Follow-Up Study, 1982–1984 (33)] (see Table 45-1). Importantly, even in cases in which the prevalence of pain was not higher in the older group, pain intensity was reported as more severe (Fig. 45-2), as were symptoms associated with depression and limitations in activities of daily living (Fig. 45-3 and Fig. 45-4, respectively). Musculoskeletal pain in the old probably has an impact equal to or greater than that seen in the younger adult.

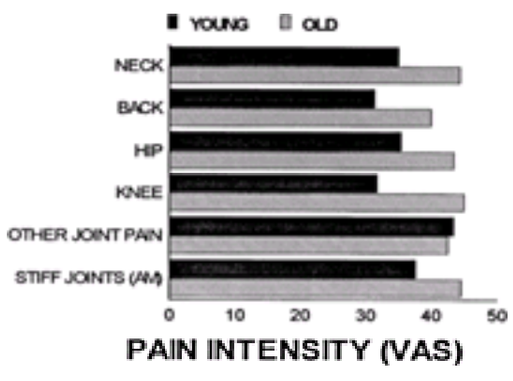

Figure 45-2. Pain intensity (visual analog scale) ratings for respondents shown in Figure 45-1. Pain intensity was assessed by visual analog scale rating of pain over the past week. Older respondents reported significantly higher pain intensity for all pain locations. This finding contrasts with laboratory findings that generally report decreased sensitivity in the elderly or no age differences (see Table 45-1 and Fig. 45-7 and Fig. 45-8). [Data redrawn from Harkins et al. (40) based on original tabulations compiled from the National Health and Nutrition Follow-Up survey (33).]

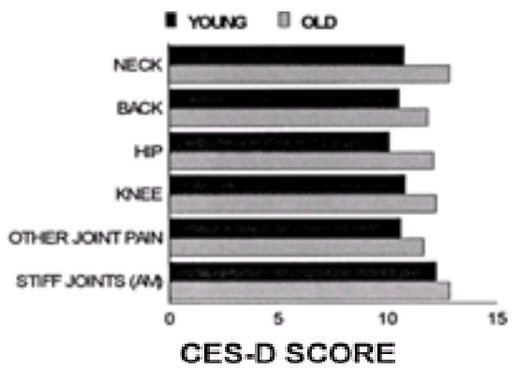

Figure 45-3. Negative affect (depressed mood over the past week) as assessed by the Center for Epidemiology Studies—Depression Inventory (Radloff LS. The CES-D Scale: a self-report depression scale for research in the general population. *Appl Psychological Measurement* 1977;1:385). Although CES-D scores were consistently higher in older compared with the younger respondents, the magnitude of this difference exceeded p <.05 for neck, back, and hip pains only. (AM, morning.) [Data redrawn from Harkins et al. (40) based on original tabulations compiled from the National Health and Nutrition Follow-Up survey (33).]

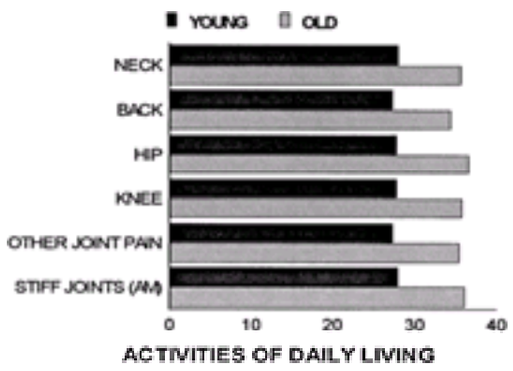

Figure 45-4. Age, pain, and limitations in activities of daily living (Lawton MP, Brody EM. Assessment of older people: self maintaining and instrumental activities of daily living. *Gerontologist* 1969;9:179). Note age is associated with a greater limitation in activities. It is currently unclear the degree to which pain, *per se*, contributes to the greater limitation in activities in the elderly (all differences significant at p <.001). [Data redrawn from Harkins et al. (40) based on original tabulations compiled from the National Health and Nutrition Follow-Up survey (33).]

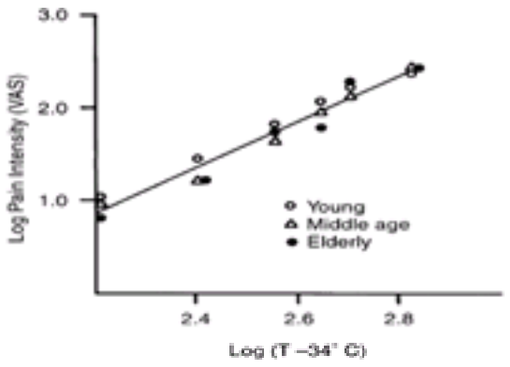

Figure 45-7. Effect of age on perceived intensity of thermal stimuli delivered to skin of the forearm in healthy young (mean, 25 years; range, 20 to 36), middle-aged (mean, 53 years; range, 45 to 60), and elderly (mean, 72.5 years; range, 65 to 80). Stimuli consisted of brief (5-second) heat pulses delivered to hairy skin of the forearm from an adapting temperature of 34°C to six intensities (43°C, 45°C, 47°C, 48°C, 49°C, and 51°C). Stimuli were presented twice randomly, and individuals reported pain intensity on a 150-mm visual analog scale (VAS). Care was taken to avoid stimulation of the same location more than once. Data are shown as log-log psychophysical functions. A significant main effect of age was observed (p = .05) and was due to older individuals rating lower intensity stimuli as less intense compared with younger individuals. At the higher stimulus intensities no age effects were statistically significant. This may represent age differences in response bias (cautiousness) rather than age differences in nociception. (From Harkins SW, Price DD, Martelli M. Effects of age on pain perception: thermonociception. *J Gerontol* 1986;41:58–63, with permission.)

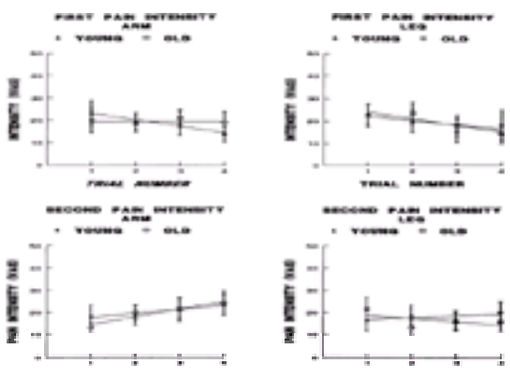

Figure 45-8. Suppression of first and slow temporal summation of second pain in relation to age (young mean, 26; range, 21 to 34; older mean, 65; range, 53 to 75). Top panels: visual analog scale (VAS) rating of very brief (0.7 seconds) 51°C (from an adapting temperature of 39°C) across four repeated stimuli (trial number) delivered to the same location on the arm and leg. First pain intensity decreased across repeated stimuli (interstimulus interval of 5 seconds). No age differences in pain intensity ratings were observed. Bottom panels: As in top panels but with interstimulus interval of 2.7 seconds. Slow temporal summation of second pain was observed at the arm for both younger and older subjects and no age effect was observed. For the leg a significant age effect was observed and was due to failure of the older group to show evidence of slow temporal summation of second pain. (From Harkins SW, Davis MD, Bush FM, et al. Suppression of first pain and slow temporal summation of second pain in relation to age. *J Gerontol A Biol Sci Med Sci* 1996;51:M260–265, with permission.)

The impact of specific types of pain on the quality of life of the older adult has not been systematically studied. Osteoarthritis is one of the most common joint disorders in the elderly (34) and has considerable impact on illness behavior and suffering. Radiographic severity of osteoarthritis of the knee is associated with symptomatology, morbidity, and psychological distress (35). Figure 45-5 shows prevalence of knee pain in different age groups as a function of age and expands the findings shown in Figure 45-1. Prevalence of knee pain increases to approximately 65 years of age and remains relatively stable in one in five adults aged 65 and older. As shown in Figure 45-6, prevalence of knee pain is considerably elevated in older women compared with older men. This interaction of age and gender is likely due to a combination of physiologic, psychological, and social factors. There is no systematic research of the interactions of age, gender, and specific musculoskeletal pains in relation to quality of life and well-being.

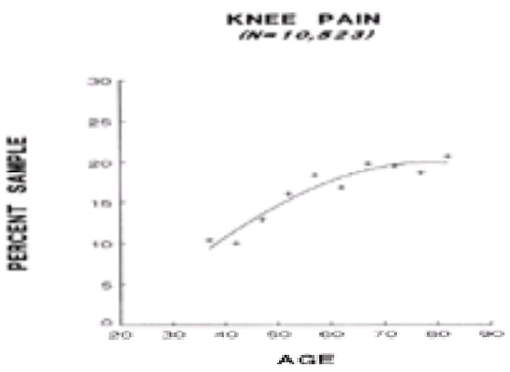

Figure 45-5. Knee pain in the general population in different age groups. Knee pain increases in prevalence to approximately the early 60s. Data as in Figure 45-1 but for age intervals between 37 and 89 years of age. Original tabulations from the National Health and Nutrition Survey I Epidemiologic Follow-Up Study (33).

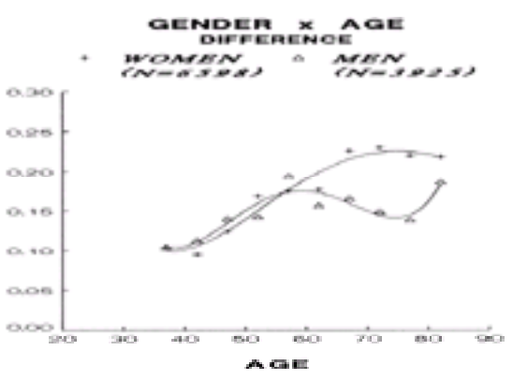

Figure 45-6. Age and gender on knee pain in the general population. Data as in Figure 45-5. Report of knee pain increases in women and decreases in men after 60 years of age. The degree to which this impacts on quality of life and activities of daily living and represents a sociocultural or physiological phenomenon is unclear. Stability of these descriptive prevalences estimated above age 80 is suspect due to the small sample size but may represent the fact that individuals who survive into their 80s and who reside in the community represent a special subpopulation of healthy, successfully aging individuals. Original data tabulations from National Health and Nutrition Survey I Epidemiologic Follow-Up Survery (33).

The Untidy Current State of Affairs

Age differences in pain perception appear to be study dependent (36,37,38,39,40,41,42,43 and 44). The findings are at best untidy. Some indicate a reduction in pain sensitivity, others an increase in pain sensitivity, and some no age differences in pain sensitivity. Findings from laboratory studies (see Table 45-1) contrast with findings from surveys on pain in the old (see Fig. 45-2). This variability in findings concerning pain sensitivity and aging reflects substantive differences in study design, psychophysical end points, pain-induction methods, subject selection criteria, practice on the psychophysical task, and instructions. Currently, the most parsimonious suggestion is that age differences in the perceived intensity of experimentally induced pain are minimal and likely reflect birth cohort effects and resulting psychosocial history more than the effects of time on the sensory processes of nociception. In turn, clinical studies are subject to biases in sample screening and selection. This is particularly true of studies based in the clinic, where selection biases include both self-referral bias and bias on the part of the primary health care provider. The recent and dramatic changes in the American health care system will likely further bias comparison of past and future clinical studies of pain in the frail elderly person.

PRESBYALGOS

Age in the later years of life systematically influencing pain sensitivity and perception is termed *presbyalgos*. Interestingly, there is no term parallel to *presbyopia* or *presbycusis* in the literature that summarizes age changes in the somatic senses, although there are well-documented age differences in vibrotactile sensitivity (45) proprioception and touch (46). Presbyalgos is limited to age effects on pain.

Presbyopia is defined as an age-related loss of ability to focus the lens at varying distances, but particularly in terms of near- point vision (loss of visual accommodation). The need for corrective lenses for near-point vision, so critical to reading and close work, is nearly universal by age 55 and marks the onset of old age for the eye. Additional age changes occur that degrade the visual image. These include increasing lens opaqueness and yellowing, resulting in decreases in light and its spectral properties reaching the retina (47). The major feature of presbyopia, the loss of accommodation, is due primarily to increased rigidity of the lens with age (sclerosis) and secondarily to decreased strength of the ciliary muscles.

Presbycusis refers to the progressive loss of higher-frequency sounds that is irreversible, progressive, and greater in men than women. The major clinical psychophysical feature of presbycusis is an increase in pure tone thresholds. Associated psychophysical findings include decreased temporal discrimination of tones and, more important, decreased speech recognition, particularly in noisy acoustic settings. Presbycusis is due, for the most part, to peripheral changes in the labyrinth and thus reflects the impact of changes over the life span on transduction processes (damage to outer hair cells particularly in the basal or high-frequency portion of the cochlea) (48). Thus, age changes in vision and hearing result more from accumulation of damage to mechanisms involving transduction of stimuli rather than from changes in central mechanisms of sensation and perception of light and sound.

Five components should be considered in the definition of presbyalgos: (a) age-dependent loss of receptors for pain (nociceptors); (b) changes in primary nociceptive afferents; (c) changes in more central mechanisms subserving pain sensation and perception; (d) changes in descending pain control mechanisms; and (e) birth cohort differences in social and cultural history that influence the meaning of pain.

Evidence for age changes or differences in density of nociceptors and primary nociceptive afferents is essentially nonexistent. Changes in nociceptor and primary nociceptive afferent density and function could result in age-related decreases in pain sensibilities. Although this would provide a blessing to those with chronic pain conditions, it would also confound the use of the symptom of pain as a diagnostic tool. Currently, inferences concerning the impact of old age on pain sensation are limited to clinical observations and psychophysical studies.

Most studies on age differences in pain sensitivity have used thermal stimuli in the nociceptive range and traditional psychophysical end points of pain threshold, pain reaction, and pain tolerance (see Table 45-1). More interesting are studies using multiple stimulus intensities and thus multiple levels of pain combined with subject reports of pain intensity by magnitude-matching procedures. Figure 45-7 presents results from an early study in our laboratory using contact thermal stimuli delivered to hairy skin in younger, middle-aged, and older adults (21). Although a significant age effect was observed, the explained variance due to age was very small (less than 0.1% of total variance). The age effect was due to lower levels of pain estimation at lower levels of stimulation in the elderly group. There were no age effects at the most intense levels of pain. These results suggest a response bias effect on the part of the old (elevated response criterion for lower level sensations) and not an age difference in pain sensitivity *per se*.

Several early studies from the 1940s and 1950s reported no age effect on thermal pain sensitivity when the subjects were well instructed and practiced and when the psychophysical end point was specifically defined as the pricking pain threshold (11,12,15). This is important not only for the emphasis on instructions and practice in the minimization of response biases, but also because the psychophysical end point, the pricking pain threshold, represents a specific sensation associated with so-called first pain. First pain sensation is mediated by A-d type II nociceptors that have an anatomic distribution mainly in hairy skin. A sharp, pricking sensation associated with first pain is absent from glabrous skin, which is innervated predominately by A-d type I and C fibers that are associated with the sensation of second pain (49) (see Chapter 3).

Thermal stimuli delivered to hairy skin of the arms or legs can produce a sensation of two distinct pains. The first is a brief, well- localized, sharp or pricking pain sensation that seldom outlasts the stimulus. This sensation is associated, as noted above, with activity in A-d type II mechano-heat afferents. These fibers are small (1 to 5 µm) and lightly myelinated, with a conduction velocity between 10 and 30 meters per second.

Under appropriate conditions, the sensation of first pain is followed by a painless period of up to 1 second, after which a second pain emerges. This second pain is characterized as a diffuse and poorly localized burning sensation that frequently outlasts the stimulus. This second sensation to thermal stimulation of hairy skin is associated with activation of “slow nociceptive” afferents or C fibers. This class of nociceptive afferents consists of small (0.05 to 2.00 µm) unmyelinated fibers with a conduction velocity of 0.5 to 2.0 meters per second. The differences in the sensory qualities of these two classes of nociceptors, including sensation onset times, allows evaluation of the selective effects of age on each. Several studies using fast rise–time thermal stimuli delivered to hairy skin have suggested that the elderly use information from C fibers more than type II A-d fibers (50,51).

Figure 45-8 shows pain intensity ratings of first and second pains in younger and older adults. No statistically significant group differences were obtained for previously unstimulated skin. The findings shown in Figure 45-7 and Figure 45-8 suggest that intensity of acute pain to thermal stimuli delivered to hairy skin is quite similar in younger and older adults, particularly for stimuli in the frankly painful range. It is this level of experimental pain that is relevant to an understanding of clinical pain, and not sensations that are near pain threshold.

Although the perceived intensity of frankly painful thermal stimuli delivered to hairy skin in the laboratory setting does not differ among age groups, there is increasing evidence that the quality of these sensations does change. We have observed that older adults do not describe brief thermal stimuli as sharp or pricking as frequently as do younger subjects. Rather, they tend to describe the sensations as burning. This suggests a greater reliance on second than first pain in older compared with younger persons. This possibility gains support from work by Helme's group (51), who report a greater use of second pain compared with first pain in older versus younger subjects in response to laser-produced radiant heat. A selective effect of age on first pain compared with second pain is also supported by recent age differences in response times to first and second pain (50).

Response time slowing is one of the most well-documented changes that occur with aging (52). One study, using thermal stimuli delivered to hairy skin of the arm and leg in healthy subjects, reported pain response time differences with age for onset of first pain but not for onset of second pain. Figure 45-9 summarizes these results. In this study, older subjects had longer reactions times to sensation onset to first pain from the leg compared with younger subjects. In contrast, there were no age group differences in onset to the sensation of second pain elicited from either arm or leg. Investigations interpreted these findings to indicate an age- dependent change in conduction properties of A-d type II nociceptive fibers, consistent with an age-related small-fiber peripheral neuropathy.

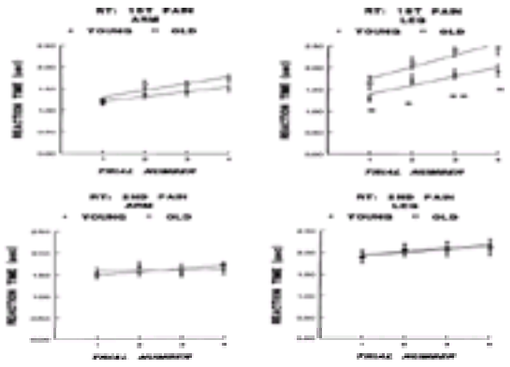

Figure 45-9. Effect of age on first and second pain onset (reaction time) to thermal stimuli delivered to arm and leg. Note that pain onset is delayed in elderly compared with younger individuals from the leg but not the arm for first pain but not second pain. These findings suggest that pain onset under well-controlled conditions may be of value in the study of small fiber peripheral neuropathy. Stimuli as in Figure 45-8. Response slowing with age is one of the more well-documented phenomena in the aging literature (52). The absence of any age differences for second pain suggests that the peripheral and, more important, the central components of generalized slowing do not apply to frankly noxious nociceptive stimuli delivered to hairy skin. Future research should focus on possible response slowing to similar stimuli delivered to glabrous skin. (From Harkins SW, Davis MD, Bush FM, et al. Suppression of first pain and slow temporal summation of second pain in relation to age. *J Gerontol A Biol Sci Med Sci* 1996;51:M260–265, with permission.)

There is growing evidence of subtle age-related differences in thermal pain sensitivity from hairy skin. This seems mainly related to changes in sensory qualities associated with first pain and thus changes in A-d type II mechano-heat nociceptors. There is less evidence that aging influences properties associated with the perception of second pain. Note that aging does not result in a marked reduction in pain intensity and thus the effects of aging on pain, at least from skin, do not parallel the effects of aging on many other senses. This should not be surprising. Age-related changes in sensory process are likely to be greater in systems with more complex transducer and receptor processes. Thus, changes with age in hearing (presbycusis) and vision (presbyopia) are due to loss of hair cells subserving audition and changes in the ability of the lens to accommodate for near-point vision and reflect effects of time on complex energy transduction and receptor mechanisms. The comparative simplicity of nociceptive afferents and their receptors suggests that “normal” aging will have minimal impact on pain sensation *per se*.

No studies to date have addressed possible age changes in central mechanisms of pain control in humans. This is an area in need of creative and well-conducted experiments. The fact that some individuals with Alzheimer's type dementia evidence altered reactions to painful events suggests that these illnesses may influence mechanisms subserving both pain sensitivity and responsivity. This is discussed below.

A few studies have indirectly addressed the possible influence of birth cohort effects on pain responses. Figure 45-7 summarizes one of these studies and suggests that the older adult reports less pain compared with younger pain patients. This probably reflects age differences in the meaning of chronic pain to different age groups (43).

Table 45-2 summarizes major characteristics of presbyalgos. As new information comes forth over time, this table is likely to change substantially. Note that the issues addressed in this definition of presbyalgos stress relations to sensory processes. This is consistent with earlier definitions of sensory changes with age. Nevertheless, it is critical in future research, clinical practice, and education to focus less on the sensory/perceptual changes (if any) in nociceptive processes with normal aging and more on the impact of recurrent and chronic pain on the older person. Although normal aging does not bring about major changes in the sensory/perceptual process subserving appreciation of pain, age-related cerebral disorders may directly influence pain and its expression. A special issue, as noted above, is that of dementia of the Alzheimer's type.

TABLE 45-2. Characteristics of presbyalgos

SPECIAL ISSUE

The impact of dementia on pain sensibilities and expression is unclear. AD is the most prevalent form of dementia in the older adult. Given the wide distribution of cerebral degeneration, loss of communicative and cognitive skills, as well as eventual failure of basic reflexes (e.g., gag reflex) critical to survival in the later stages of AD, altered pain expression in these patients would not seem surprising.

Early clinical reports suggested reduced pain sensibilities in some moderately demented AD patients (38). Pain reactions following what would normally be painful seem obtunded in these patients, and although this pain indifference appeared to be more obvious in more demented individuals, it was also present in some AD patients with mild to moderate dementia (53). These findings may stem from the increased “apathy” in some AD patients. In this case, apathy represents a state characterized by loss of interest and response to events that is independent of depression or depressed mood and affect (54).

Future research needs to be directed at identification of AD patients with pain indifference. It is likely that AD is a heterogeneous disorder with different etiologies but with a final common pathway that includes major cognitive symptoms. Subtle differences in natural history, including apathy and indifference to painful conditions may well have implications for identification of one or more subgroups of AD patients.

This is relevant to the study of pain because that specific cerebral pathology in subgroups of patients with AD may illuminate the mechanisms underlying selective properties of pain. The levels of emotional distress and apparent suffering due to chronic pain may be reduced in patients with AD. This would be consistent with loss of integrative cognitive ability, working and semantic memories that characterize this form of dementia. Helme suggests that chronic pain in AD patients is more like acute pain in nondemented individuals because the history of the pain is progressively lost (*personal communication*, R. Helme, 1997). This fits observed reduction in pain-related symptoms in AD patients with arthritis, frozen shoulder, Raynaud's disease, and osteoporosis (53). Additionally, the “I don't like this sensation” or the anhedonic and suffering dimension of pain is selectively reduced in a subgroup of AD patients.

The affective and sensory discriminative components of pain have different cortical representations. The sensory dimension, including aspects of pain quality, location, and intensity, is well represented at cortical areas SI and SII, with integration of pain, visceral, and limbic input at the insula (55). Insular volume appears to be relatively stable between 40 and 70 years of age in normal individuals and decreased in patients with a clinical diagnosis of AD (56).

It may also be that the natural history of pain perception, particularly pain affect and behavior, is different in patients with classic AD versus patients with frontotemporal dementia. Asymmetric frontal and anterior temporal atrophy is a distinctive finding thought to distinguish these two forms of dementia (57). Higher-order pain responses involving affect, emotion, and memory of pain appear well represented in prefrontal cortex (55). It may well be that patients with different

forms of later-life dementia react differently to pain as a direct result of the disease process.

Pain assessment in these dementia patients may allow more precise definition of the natural history of these various disorders. Given that new pharmacologic agents for the symptomatic treatment of dementia are becoming available, pain assessment could aid in identifying patients most likely to respond positively to such treatment. A better understanding of the relations among pain behavior and subforms of later-life dementia could also provide insight into cortical and subcortical representations of pain sensation and pain affect.

Pain perception that is obtunded or characterized by indifference and apathy in a subgroup of AD patients opens considerable care management and even legal issues. Fisher-Morris and Gellatly (53) report several cases of pain indifference in AD patients. One of these involved a nursing home resident who sustained a fractured femur sometime before death. Failure to diagnose the fracture was “primarily because she had not complained of any pain and has continued to ambulate without any apparent discomfort.” The coroner's inquiry noted that she must have died an “agonizing death” and pointed out that “as the man in the street feels pain, so should an elderly demented lady with a fracture.” Failure to recognize pain in AD patients is for the most part a failure to look. There may well, however, be a subgroup of older demented patients who are truly pain indifferent. This is an area in need of immediate and concerted attention.

CONCLUSIONS

An expanding literature has now begun to address issues related to geriatric pain assessment. Health care providers need to recognize certain principles for optimal care of the elderly patient. These include, as Ferrell (58) has pointed out, sensitivity to functional status in the face of limited potential for dramatic recovery. “Defining and treating pathologic entities [in the older adult] is often less complicated than intervening in the discomfort and disability of patients, but the latter is what truly constitutes the art of geriatric care.” Pain has a greater impact on successful aging and quality of life in the older adult than age has on pain sensitivity. Thus, presbyalgos differs from the other “presbys,” which by their very nature produce sensory loss and potential isolation and limitations in daily activities. The future in geriatric pain care should be less concerned with the psychophysics of sensory changes and more with the most efficient methods to clinically assess and treat pain in the frail elderly adult. In this regard, pain specialists need to educate care providers who are in daily contact with dependent elders. Table 45-3 summarizes several special considerations in geriatric pain assessment.

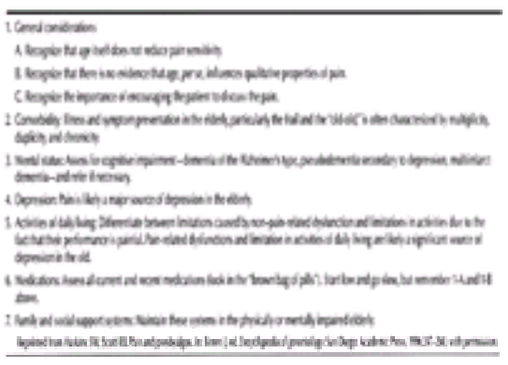

TABLE 45-3. Special considerations in geriatric pain assessment

It has been more than 20 years since the first modern review of geriatric pain (36), which was concerned primarily with sensory changes in pain with aging. The elderly, particularly the frail elderly, are now seen as a population that can be well served by recognition of the importance of pain control on activities of daily living and quality of life. This is a beneficial change in our understanding of pain in the elderly.

CHAPTER 46

General Considerations of Pain in the Head

John J. Bonica and John D. Loeser

ANATOMIC AND PHYSIOLOGIC BASIS

The nerve supply to various structures of the head is presented in this section. For obvious reasons, emphasis is placed on sensory (nociceptive) pathways, and, as discussed in Chapter 4, these are found in cranial nerves V, VII, VIII, and IX, and in the second and third cervical dorsal roots and the autonomic innervation to the head is summarized. This discussion is based on the first edition of this book (1) and *Gray's Anatomy* (2).

Trigeminal Nerve

The trigeminal nerve, the largest of the cranial nerves, is a mixed somatic nerve consisting of a large sensory and, usually, two small motor roots. It is short, extending from the ventrolateral surface of the pons in an anterolateral direction to the apex of the petrous portion of the temporal bone, in which it expands into the gasserian (trigeminal, semilunar) ganglion located in Meckel's cave (Fig. 46-1 and Fig. 46-2). This is an outpouching of dura from the posterior fossa that lies under the dura of the middle fossa. The sensory root, which is composed of the central branches of the unipolar cells contained in the ganglion, conducts sensation from the face and anterior two-thirds of the head. The motor root, the fibers of which originate in the motor nucleus of the trigeminal nerve located in the pons, courses beneath and medial to the sensory root and then beneath the semilunar ganglion in Meckel's cave to pass through the foramen ovale, in which it joins and becomes part of the mandibular division to supply motor fibers to the muscles of mastication. The distal processes of sensory neurons divide into the three major divisions: the ophthalmic, maxillary, and mandibular nerves (Fig. 46-3; see Fig. 46-2). (Chapter 4 provides a detailed discussion of the anatomy and physiology of the trigeminal system in the brainstem and its homologies with the spinal sensory systems.)

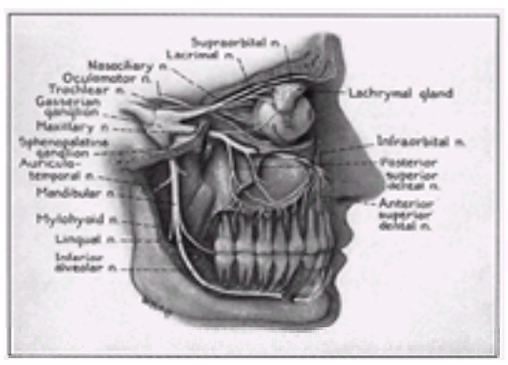

Figure 46-1. Anatomy of the trigeminal nerve and its three major divisions and their branches.

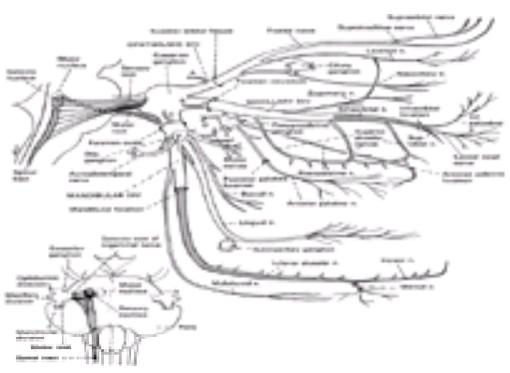

Figure 46-2. Schematic depiction of the trigeminal nerve and its branches. Also shown is its sensory root, composed of central branches of neurons in the gasserian ganglion that synapse with the main sensory nucleus and the descending tract and nucleus of the trigeminal nerve, as well as the origin of the motor root and its origin in the motor nucleus. Below is the anterior view showing the relationship of these nuclei and the gasserian ganglion. Recurrent branches of the major division of the trigeminal nerve that supply sensory fibers to the meningeal arteries and dura mater (*A*, *B*, and *C*). Nerve to the pterygoid canal (vidian nerve) (*D*). Middle and posterior palatine nerves and the pharyngeal branch from the pterygopalatine ganglion (*E*).

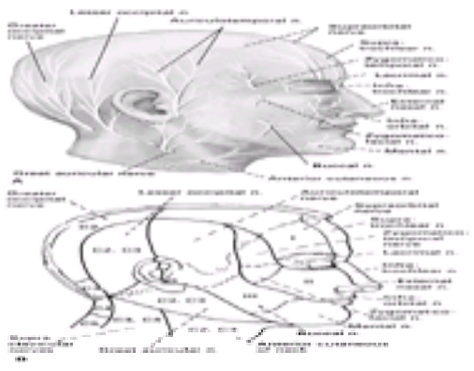

Figure 46-3. Cutaneous sensory supply to the head. **A:**Major cutaneous nerves. **B:** Border of the territory of each nerve.

Ophthalmic Nerve

The ophthalmic, the first and smallest division of the trigeminal nerve, is a short, somewhat flattened nerve approximately 2 cm long that arises from the anteromedial part of the gasserian ganglion (see Fig. 46-1 and Fig. 46-2). From this point the nerve proceeds in an anterior and slightly superior direction to pass through the lateral wall of the cavernous sinus and through the superior orbital fissure to reach the orbit (Fig. 46-4; see Fig. 46-2). It is solely sensory, conducting all somatic sensations from the eye and its adnexa, including the conjunctivae, lacrimal gland, part of the mucous membranes of the nose and paranasal sinuses, and the skin of the forehead, eyelids, and nose. Before passing through the fissure it gives off a recurrent branch to the tentorium cerebelli, a connecting filament to the oculomotor, trochlear, and abducens nerves, and it receives sympathetic filaments from the carotid plexus. In the superior orbital fissure it divides into three terminal branches: the lacrimal, frontal, and nasociliary nerves.

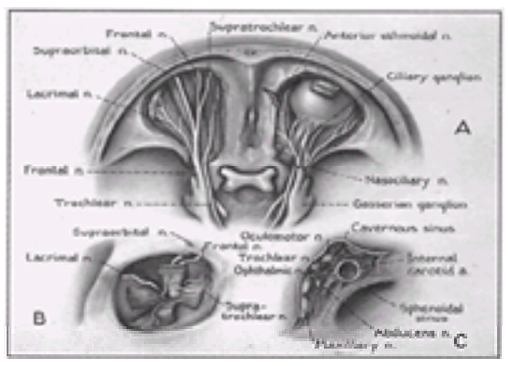

Figure 46-4. Ophthalmic division of the trigeminal nerve and its branches. **A:** The roof of the orbit has been removed and the nerves are viewed from the top. The main nerves are on the left; on the right these and the underlying muscles have been removed to show the course of the nasociliary nerve and the relationships of the ciliary ganglion. **B:** The eyeball of the right orbital cavity has been removed to show the relationships and courses of the branches of the ophthalmic division. **C:** Relationships of the ophthalmic and other nerves in the cavernous sinus.

Lacrimal Nerve. The lacrimal nerve, the smallest of the three branches of the ophthalmic nerve, passes into the orbit through the anterolateral part of the fissure above the ocular muscles, proceeds forward between the periosteum and the orbital contents to pass through the lacrimal gland, and finally pierces the orbital septum to end in the skin around the external canthus. Whereas it supplies filaments to the lacrimal gland and conjunctiva in the orbit and connects with the zygomatic branch of the maxillary nerve, in the subcutaneous tissues outside of the orbit it connects with branches of the facial nerve. In the orbit, through its connection with the zygomatic branch of the maxillary nerve, it receives postganglionic parasympathetic fibers that have their cell bodies in the pterygopalatine ganglion and are the secretomotor motor fibers to the lacrimal gland (see Autonomic Innervation of the Head, later in this chapter; also see Fig. 46-11).

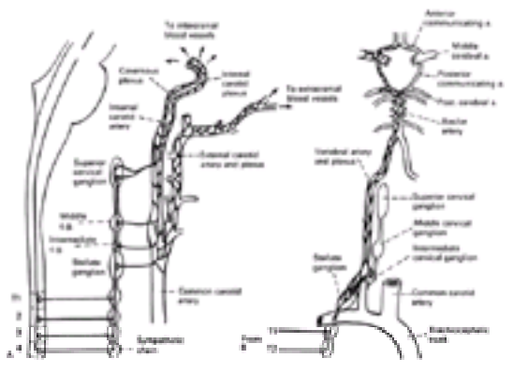

Figure 46-11. The sympathetic nerve supply to the head. **A:** Sympathetic supply through the carotid and cavernous plexuses. Preganglionic fibers originate in the first, second, third, and, frequently, the fourth thoracic segments of the spinal cord, pass through the white rami communicantes and from there to the paravertebral sympathetic chain to synapse in superior, middle, intermediate, and inferior cervical ganglia, in which they synapse with postganglionic neurons. The axons of the latter make up the internal carotid nerve, which passes to the internal carotid artery and soon divides into a lateral branch; this breaks up into the internal carotid plexus and a medial branch that forms the cavernous plexus. Both plexuses continue as subsidiary plexuses to supply all the branches of the internal carotid artery. The postganglionic fibers that make up the external carotid nerves arise primarily in the stellate ganglion but also in the middle and superior cervical ganglia, and then pass to the common carotid and the external carotid arteries. The external carotid nerves break up into intricate plexuses that continue as subsidiary plexuses to all the branches of this artery to supply the extracranial blood vessels as well as the middle and accessory meningeal arteries (a branch of the maxillary, which in turn is a branch of the external carotid artery). In addition to supplying blood vessels, sweat glands, and the arrector pili muscles, these plexuses also provide sympathetic nerves to intrinsic muscles of the eye and to the lacrimal, parotid, submandibular, sublingual, and parotid glands. **B:** Sympathetic supply to the vertebral artery and circle of Willis. Preganglionic neurons are located in the first and second thoracic segments, pass to the sympathetic chain, and ascend to the stellate ganglion and the middle and intermediate cervical ganglia, in which they synapse with postganglionic neurons. The axons of postganglionic neurons make up the vertebral nerve, consisting of two major branches that arise from the stellate ganglion and a minor branch that arises from the middle or intermediate cervical ganglion. On reaching the vertebral artery, the vertebral nerve breaks up into the vertebral plexus, which continues as a plexus around the basilar artery, the circle of Willis, and all its branches.

Frontal Nerve. The frontal nerve, the largest branch of the ophthalmic nerve, enters the orbit through the superior orbital fissure just medial to the lacrimal gland and then proceeds anteriorly and rostrally between the periosteum and levator palpebrae superioris muscle for approximately two-thirds the length of the orbital cavity, where it divides into a larger lateral branch, the supraorbital nerve, and a smaller medial branch, the supratrochlear nerve (Fig. 46-5; see Fig. 46-4). Both of these nerves continue their forward paths and finally leave the orbit by curving around the superior orbital margin to reach and supply the skin of the forehead, the anterior two-thirds of the scalp, and the underlying pericranium.

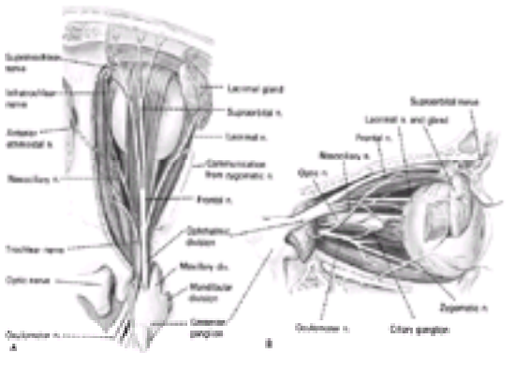

Figure 46-5. Anatomy of the ophthalmic nerve and its branches and relationship to other cranial nerves that supply the eye and lacrimal gland. **A:** Superior view. **B:** Lateral view. (Modified from Clemente CD, ed. *Gray's anatomy*, 30th Am. ed. Philadelphia: Lea & Febiger, 1985.)

Supratrochlear Nerve. The supratrochlear nerve within the orbit bends medially to pass above the pulley of the superior oblique muscle and gives off a filament that communicates with the infratrochlear branch of the nasociliary nerve. It pierces the orbital fascia and sends filaments to the conjunctiva and the skin of the medial part of the upper eyelid. It then curves around the supraorbital margin approximately 2 cm from the midline, passing deep to the corrugator and frontalis muscles, gives filaments to the pericranium, and divides into branches that pierce the muscles to supply the skin of the mesial lower part of the forehead (see Fig. 46-5).

Supraorbital Nerve. The supraorbital nerve, a continuation of the frontal nerve, leaves the orbit through the supraorbital foramen or notch, which is approximately 2.5 cm from the midline. In the notch it gives off a small filament that supplies the mucous membrane of the frontal sinus and also gives off filaments that supply the upper lid. The nerve then continues on the forehead beneath the frontalis muscle and divides into two branches. The smaller *medial branch,* often called the *frontal branch*, pierces the muscle and supplies the scalp as far back as the parietal bone. The larger *lateral branch* pierces the aponeurotica and supplies the scalp as far posteriorly as the lambdoidal suture.

Nasociliary Nerve. The nasociliary nerve is intermediate in size between the frontal and lacrimal nerves and is medially placed in the orbit (see Fig. 46-4 and Fig. 46-5). It enters the orbit through the medialmost portion of the superior orbital fissure, passes through the annulus of Zinn and between the two heads of the rectus lateralis, and proceeds obliquely in an anteromedial direction, crossing above the optic nerve to reach the anterior ethmoidal foramen on the medial wall of the orbit, where it is known as the *anterior ethmoidal nerve.* Through this foramen it passes into the anterior cranial fossa and immediately leaves by way of the nasal fissure of the cribiform plate to enter the nasal cavity where it divides into internal and external nasal branches. The nasociliary nerve gives off four important groups of branches while in the orbital cavity.

Long (Sensory) Root of the Ciliary Ganglion. The long root of the ciliary ganglion arises from the nasociliary nerve between the two heads of rectus lateralis muscles, runs anteriorly on the lateral side of the optic nerve, and enters the posterosuperior angle of the ciliary ganglion. It contains sensory fibers that pass through the ganglion without synapsing and continues on to the globe by way of the short ciliary nerves.

Long Ciliary Nerves. The long ciliary nerves, usually two or three, emerge from the parent nerve as it crosses the optic nerve and accompany the short ciliary nerves from the ciliary ganglion. They then pierce the posterior part of the sclera and proceed anteriorly between it and the choroid to become distributed to the iris and cornea. In addition to afferent fibers the long ciliary nerves contain sympathetic fibers from the superior cervical ganglion to the dilator pupillary muscles.

Infratrochlear Nerve. The infratrochlear nerve is given off from the nasociliary nerve just before the latter enters the anterior ethmoidal foramen and proceeds anteriorly along the superior border of the rectus medialis muscle near the pulley of the oblicus superior, where it is joined by the filament from the trochlear nerve. It then passes to the medial angle of the eye and supplies the skin of the eyelid, side of the nose, conjunctiva, lacrimal sac, and caruncula lacrimalis.

Ethmoidal Branches. The ethmoidal branches supply the mucous membrane of the sinuses. The *posterior ethmoidal nerve* leaves the orbit through the posterior ethmoidal foramen and supplies the posterior ethmoidal and sphenoidal sinuses. The *anterior ethmoidal branches* are filaments that are given off as the nerve passes through the anterior ethmoidal foramen and supply the anterior ethmoidal and frontal sinuses.

Nasal Branches. The internal nasal branch supplies the mucous membrane of the anterior part of the septum and the lateral wall of the nasal cavity. The external nasal branch emerges between the nasal bone and the lateral nasal cartilage, passes deep to the nasalis muscle, and supplies the skin of the ala and the apex of the nose (Fig. 46-6).

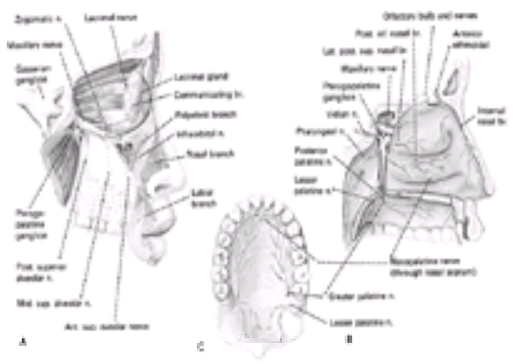

Figure 46-6. **A:** Anatomy of the maxillary nerve and its branches and the structures they supply. **B:** Sagittal section depicting the relationship of the pterygopalatine ganglion to the maxillary nerve and to the branches of the ganglion that supply the nasal cavity and the hard and soft palates. **C:** View of the inferior surface of the palate depicting distribution of the nerves to the structure. The nasopalatine nerves emerge through the anterior palatine foramina, the greater palatine nerves emerge through the greater palatine foramina, and the lesser palatine nerves emerge through the lesser palatine foramina.

Maxillary Nerve

The maxillary nerve, the second division of the trigeminal nerve, arises from the anterior border of the gasserian ganglion between the ophthalmic and mandibular nerves (see Fig. 46-1 and Fig. 46-2). Like the ophthalmic nerve, the maxillary nerve is entirely sensory, supplying the skin of the middle portion of the face, lower eyelid, side of the nose, and upper lip and the mucous membranes of the nasopharynx, maxillary sinus, soft palate, tonsil, and roof of the mouth, upper gums, and teeth. From its point of origin it proceeds anteriorly beneath the dura mater, passing first through the lateral wall of the cavernous sinus and then through the foramen rotundum, by which it leaves the cranial cavity to reach the pterygopalatine fossa. At its origin it gives off the *middle meningeal nerve,* which accompanies the ipsilateral middle meningeal artery and supplies this artery and its branches as well as the dura mater and other pain-sensitive structures within the cranium (see Chapter 48).

The maxillary nerve traverses the outer part of the pterygopalatine fossa in an anterior and slightly lateral direction and enters the orbit through the inferior orbital fissure to become the infraorbital nerve. Within the pterygopalatine fossa the maxillary nerve gives off the zygomatic nerve, pterygopalatine nerves, and posterior superior orbital branches. The nerve continues its anterior course, first occupying the infraorbital groove and canal in the floor of the orbit, in which it gives off the middle superior alveolar and anterior superior alveolar branches. It then passes through the infraorbital foramen to emerge on the face, where it immediately divides into its terminal branches, the inferior palpebral, lateral nasal, and superior labial nerves (see Fig. 46-6).

Zygomatic Nerve

Like its parent, the zygomatic nerve passes through the inferior orbital fissure and enters the orbit, where it gives off a filament that connects with the lacrimal nerve and then divides into the zygomaticotemporal and zygomaticofacial nerves (see Fig. 46-6A).

Zygomaticotemporal Nerve. The zygomaticotemporal nerve runs along the lateral wall of the orbit in a groove in the zygomatic bone, passes through a small foramen or suture, and enters the temporal fossa, in which it runs cephalad between the bone and the substance of the temporalis muscle. Approximately 2.5 cm above the zygomatic arch the nerve pierces the temporal fascia and becomes distributed to the skin of the side of the forehead; it usually communicates with the facial nerve and with the auriculotemporal branch of the mandibular nerve.

Zygomaticofacial Nerve. The zygomaticofacial (or malar) nerve passes along the inferior lateral angle of the orbit and through the zygomatic bone by way of the zygomaticoorbitale and zygomaticofacial foramina, emerges on the face, perforates the orbicularis oculi muscle, and supplies the skin on the prominence of the cheek. It also joins with the facial nerve and with the inferior palpebral branch of the infraorbital nerve.

Pterygopalatine (Sphenopalatine) Nerves. The pterygopalatine (sphenopalatine) nerves, formerly called the *sensory roots* of the pterygopalatine ganglion, connect

with preganglionic parasympathetic secretomotor fibers and pass through the ganglion without synapsing to become distributed into four groups: orbital branches, greater palatine nerves, posterior superior nasal branches, and pharyngeal branches (see Fig. 46-6B).

Orbital (Ascending) Branches. The orbital branches enter the orbit through the inferior orbital fissure to supply the periosteum and also give off filaments that pass through foramina in the frontal ethmoidal suture to supply the mucous membranes of the posterior ethmoidal and sphenoidal sinuses.

Greater (Anterior) Palatine Nerve. The greater (anterior) palatine nerve passes through the pterygopalatine canal, emerges on the hard palate through the greater palatine foramen, and divides into several branches, the longest of which passes anteriorly in a groove in the hard palate nearly as far as the incisor teeth. It also supplies the gums and mucous membranes of the hard palate and the adjacent part of the soft palate and communicates with the terminal filaments of the nasopalatine nerve. The *posterior inferior nasal branches* leave the greater palatine nerve while it is in the canal, enter the nasal cavity through the opening in the palatine bone, and ramify over the inferior concha and middle and inferior meatuses. The *lesser* (*middle and posterior*) *palatine nerves* emerge through the lesser palatine foramina and distribute branches to the soft palate, uvula, and tonsil and also join with the tonsillar branches across the pharyngeal nerve to form a plexus around the tonsil (circulus tonsillaris).

Posterior Superior Nasal Branches. The posterior superior nasal branches of the pterygopalatine nerve enter the posterior part of the nasal cavity by the sphenopalatine foramen, supply the mucous membrane covering the superior and middle conchae, the lining of the posterior ethmoidal sinus, and the posterior part of the septum, and give off the nasopalatine nerve. The latter passes across the roof of the nasal cavity inferior to the ostium of the sphenoidal sinus to reach the septum. The nasopalatine nerve proceeds anteriorly and caudad, lying between the mucous membrane and periosteum of the septum to reach and pass through the incisive canal, in which it communicates with the corresponding nerve of the opposite side and with the greater palatine nerve (see Fig. 46-6B and Fig. 46-6C).

Pharyngeal Branch. The pharyngeal branch of the pterygopalatine nerve emerges from the posterior part of the ganglion and, along with the pharyngeal branch of the maxillary artery, passes through the pharyngeal canal to become distributed to the mucous membrane of the nasal part of the pharynx, posterior to the auditory tube.

Posterior Superior Alveolar Nerves

The posterior superior alveolar (dental) branches, usually two, but occasionally only one, arise from the trunk of the maxillary nerve just before they enter the infraorbital groove. The branches arise and descend on the posterior surface of the maxilla, give off several twigs to the gums and neighboring parts of the mucous membrane of the cheek, and enter the posterior alveolar canals on the infratemporal surface of the maxilla (see Fig. 46-6).

They pass anteriorly in the substance of the bone, communicate with the middle superior alveolar nerve, and then give off branches to the lining membrane of the maxillary sinus and three twigs to each molar tooth, with each twig entering the foramen at the apex of the tooth (see Fig. 46-1, Fig 50-2, and Fig 51-4).

Middle and Anterior Superior Alveolar Branches

The middle superior alveolar (dental) branch of the maxillary nerve is given off in the posterior part of the infraorbital canal and proceeds caudad and anteriorly in a canal in the lateral wall of the maxillary sinus to supply the two premolar teeth. Filaments from these branches join with those of the anterior and posterior superior alveolar branches to form the *superior dental plexus*.

The large anterior superior alveolar (dental) branch is given off from the maxillary nerve just before its exit from the infraorbital foramen (see Fig. 46-6A). It courses in a canal in the anterior wall of the maxillary sinus and divides into branches that supply the incisor and the canine teeth. It gives off filaments that communicate with the middle superior alveolar branch, angles off a nasal branch that passes through the lateral wall of the inferior meatus, and supplies the mucous membrane of the anterior part of the inferior meatus and the floor of the nasal cavity.

Infraorbital Nerve

The infraorbital nerve is the terminal cutaneous branch of the maxillary nerve, which divides into three groups of branches (see Fig. 46-3 and Fig. 46-6A). The *inferior palpebral branches* pass cephalad deep through the orbicularis oculi muscle to supply the skin and conjunctiva of the lower eyelid and, at the lateral angle of the orbit, join with the facial and zygomaticofacial nerves. The *external nasal branches* supply the skin of the side of the nose and of the septum mobile nasi and also join with the terminal twigs of the nasociliary nerves. The *superior labial branches* pass deep to the levator labii superioris muscle and are distributed to the skin of the upper teeth, mucous membrane of the mouth, and labial glands.

Mandibular Nerve

The mandibular nerve is the third and only mixed division of the trigeminal nerve and is formed by the union of a large sensory root and a small motor root. The former arises from the anterolateral portion of the gasserian ganglion (see Fig. 46-1 and Fig. 46-2), whereas the latter arises from the pons and passes beneath the gasserian ganglion to reach the foramen ovale, through which it leaves the cranial cavity, together with the sensory root. The sensory fibers supply the skin of the temple region; auricula; external meatus; cheek, lower lip, and lower part of the face; the mucous membrane of the cheek, tongue, and mastoid air cells; the lower teeth and gums; the mandible and temporomandibular joint; and part of the dura mater and skull. The motor fibers supply the muscles of mastication (masseter, temporalis, pterygoids), the mylohyoid and anterior belly of the digastric muscles, and the tensores tympani and veli palatini.

Within or immediately outside the foramen ovale, the two roots fuse into a single short (2 to 3 mm) trunk, which lies just anterior to the middle meningeal artery, lateral to the otic ganglion and internal pterygoid muscle, and medial to the extensor pterygoid, masseter and temporal muscles, and ramus of the mandible. Soon after it is formed the nerve gives off two small branches, the *nervus spinosus*, which reenters the cranial cavity along with the middle meningeal artery to supply the anterior and posterior divisions of the artery and the dura mater, and the *medial pterygoid nerve*, which penetrates the otic ganglion, enters the deep surface of the medial (internal) pterygoid muscle, and ends in two branches, the nerve to the tensor veli palatini and the nerve to the tensor tympani. The trunk then divides into a small anterior trunk and a large posterior trunk.

Anterior Trunk

The anterior trunk (Fig. 46-7), composed mostly of motor fibers, promptly divides into the masseteric nerve, the deep anterior and posterior deep temporal nerves, and the external pterygoid nerve, which supply the aforementioned muscles of mastication. The anterior trunk also gives off a small sensory branch, the buccal (buccinator) nerve, which penetrates the pterygoid, temporalis, and masseter muscles and ramifies on the surface of the buccinator muscle, forming a plexus of communications with the buccal branches of the facial nerve. It supplies the skin of the cheek over this muscle and sends penetrating branches to supply the mucous membranes of the mouth and of part of the gums in the same area.

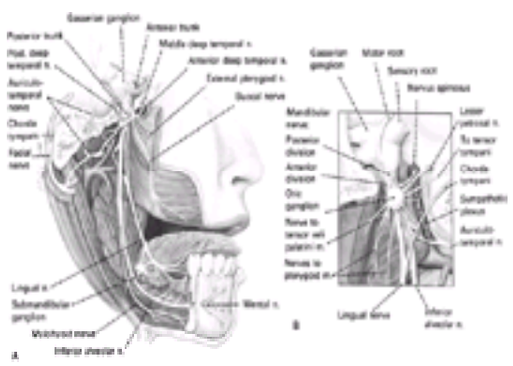

Figure 46-7. **A:** Anatomy of the right mandibular nerve and its branches and the structures they supply. **B:** Medial view of the right mandibular nerve showing its major branches and its relationship to the otic ganglion and its root (the lesser petrosal nerve), as well as its branches (see text for details).

Posterior Trunk

The large posterior trunk is composed mostly of sensory fibers and a small motor component. After a short course it divides into the auriculotemporal nerve, lingual nerve, and inferior alveolar nerve (see Fig. 46-7A).

Auriculotemporal Nerve

The auriculotemporal nerve arises by two roots from the posterior aspect of the trunk that encircles the middle meningeal artery close to the foramen spinosum and immediately runs posterolaterally beneath the external pterygoid muscle to reach the medial side of the neck of the mandible. Here it turns sharply cephalad to ascend between the anterior border of the auricle and the condyle of the mandible under cover of the parotid gland, finally reaching the subcutaneous tissue overlying the zygomatic arch in which it divides into five branches and communicates with the facial nerve and the otic ganglion.

The *anterior auricular branches*, usually two, supply the skin of the anterior superior part of the auricula, principally the helix and tragus. The two branches to the external acoustic meatus enter the meatus between its bony and cartilaginous portions and supply the skin lining it, the upper branch sending a filament to the tympanic membrane. The articular branches consist of one or two twigs that enter the posterior part of the temporomandibular joint. The parotid branches supply the parotid gland, carrying the parasympathetic postganglionic fibers transmitted by the communication between the auriculotemporal nerve and the otic ganglion. The superficial temporal branches accompany the superficial temporal artery to the vertex of the skull, supply the skin of the temporal region, and communicate with the facial and zygomaticotemporal nerve.

Inferior Alveolar Nerve

The inferior alveolar (dental) nerve accompanies the inferior alveolar artery, at first deep to the lateral pterygoid muscle and then between the sphenomandibular ligament and the ramus of the mandible, and enters the mandibular foramen (see Fig. 46-7A). Just before entering the foramen the inferior alveolar nerve gives off the mylohyoid branch that proceeds inferiorly and anteriorly in a groove on the deep surface of the ramus of the mandible to reach and supply the mylohyoid muscles and the anterior belly of the digastric muscle. On entering the mandibular foramen, the inferior alveolar nerve proceeds inferiorly and anteriorly within the mandibular canal until it reaches the mental foramen, in which it divides into two terminal branches: the incisor nerve, which continues its course through the bone to the midline to supply the incisor and canine teeth; and the mental nerve, which emerges out of the bone through the mental foramen to divide into several branches that supply the lower lip. While in the mandibular canal it gives off dental branches that form a plexus within the bone and supply the molar and premolar teeth. Filaments enter the pulp canal of each root through the apical foramen and supply the pulp of the tooth (see Chapter 50).

Lingual Nerve

The lingual nerve emerges from the medial aspect of the large posterior trunk and proceeds inferiorly, at first deep to the lateral pterygoid muscles, running parallel with the inferior alveolar nerve until the latter reaches the mandibular foramen. At this point the lingual nerve diverges anteromedially to reach the posterolateral portion of the tongue and courses along the undersurface of the tongue, lying immediately beneath the mucous membrane until it terminates in the tip of the tongue. The lingual nerve supplies sensory fibers to the anterior two-thirds of the tongue and to the mucous membranes on the inside wall and floor of the mouth and the sublingual gland. As it lies inferior to the external pterygoid muscle the lingual nerve is joined by the chorda tympani (Fig. 46-8; see Fig. 46-7A), a branch of the facial nerve that carries special sensory fibers of taste and parasympathetic preganglionic fibers for the submandibular ganglion (see Autonomic Innervation of the Head, later in this chapter). Both nerves take part in forming the roots of the submandibular ganglion, which appears to be suspended on the lingual nerve. The proximal nerves carry the preganglionic parasympathetic fibers communicated to the lingual nerve by the chorda tympani, while the distal branches contain postganglionic parasympathetic fibers for distribution to the submandibular, sublingual, lingual, and neighboring small salivary glands.

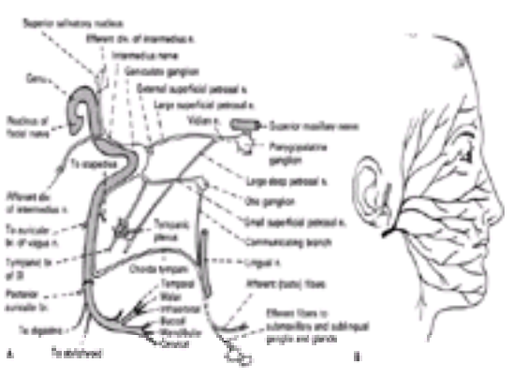

Figure 46-8. Anatomy of the facial nerve and its branches. **A:** Intracranial and extracranial portions of the motor portion of the nerve, nervus intermedius, geniculate ganglion, and chorda tympani and their connections with other nerves. **B:** Distribution of the branches of the facial nerve to the face. (**A** modified from Clemente CD, ed. *Gray's anatomy*, 30th Am. ed. Philadelphia: Lea & Febiger, 1985.)

Facial Nerve

The facial is a mixed cranial nerve composed of a large motor and a smaller sensory component and some parasympathetic fibers. The motor fibers arise from the motor nucleus of cranial nerve VII in the caudal portion of the pons, loop around the nucleus of the abducens (internal genu), and eventually terminate to supply the stapedius muscles of the middle ear, the muscles of facial expression, including those of the scalp and platysma, and the posterior belly of the digastric and stylohyoid muscles (see Fig. 46-8). The sensory fibers arise from the unipolar cells in the geniculate ganglion and immediately divide into central and peripheral branches. The central branches pass through the nervus intermedius (nerve of Wrisberg) to the nucleus of the tractus solitarius, whereas the peripheral branches pass distally through different courses to provide special and general sensation to various structures. Those that comprise most of the chorda tympani provide special taste fibers to the anterior two-thirds of the tongue. Other fibers convey general sensation (including pain) from the tympanic membrane, external auditory meatus, soft palate, and adjacent pharynx, whereas still others pass distally to supply the parotid gland by passing through the otic ganglion. The parasympathetic fibers originate from the superior salivatory nucleus and pass through the nervus intermedius, greater superficial petrosal nerve, and pterygopalatine (sphenopalatine) ganglion to the mucous membranes and glands of the pharynx, palate, paranasal sinuses, nasopharynx, and nasal cavity. Other parasympathetic fibers pass through the chorda tympani, lingual nerve, and submandibular ganglion to the submandibular and sublingual glands.

The facial nerve emerges from the posterolateral angle of the pons and proceeds laterally to enter the internal auditory meatus, which it traverses until it reaches the medial wall of the epitympanic recess where it suddenly curves posteriorly and inferiorly and travels within the facial canal to exit from the skull by way of the stylomastoid foramen. While the nerve is within the facial canal, approximately 0.5 cm above the stylomastoid foramen, it gives off the chorda tympani, which eventually reaches the lingual nerve to follow it to the anterior two-thirds of the tongue.

Glossopharyngeal Nerve

The glossopharyngeal nerve (cranial nerve IX) is a mixed nerve that contains visceral and somatic sensory fibers and somatic and autonomic (parasympathetic) motor fibers. The somatic sensory fibers arise from the unipolar cells in the superior and inferior petrosal ganglia and divide into central and peripheral branches. The former terminate in the tractus solitarius and its nucleus in the pons, whereas the latter are distributed to the pharynx, soft palate, posterior surface of the tongue, palatine tonsils, eustachian tube, and tympanic cavity to subserve general sensation to these parts. In addition, special sensory fibers form the carotid sinus nerve, which has special receptors in the carotid body and in the carotid sinus concerned with reflex control of respiration, blood pressure, and heart rate. The glossopharyngeal nerve also contains special visceral afferent fibers that supply the taste buds of the posterior third of the tongue.

The motor fibers arise from the nucleus ambiguous to terminate in the stylopharyngeus muscle. The parasympathetic fibers arise from the inferior salivatory nucleus to pass through the glossopharyngeal nerve by way of the tympanic plexus, Jacobson's nerve, and small superficial petrosal nerve to the otic ganglion, from which postganglionic fibers terminate in the parotid gland to convey secretory impulses.

The glossopharyngeal nerve emerges from the medulla at its posterolateral sulcus between the olive and peduncle in the form of three or four roots that soon fuse to form the nerve trunk (Fig. 46-9). After its formation, the trunk passes laterally to reach the central portion of the jugular foramen, through which it leaves the skull invested by a separate sheath of dura mater. Within the foramen it is situated anterolateral to the vagus and the accessory nerves, separated from both by the inferior petrosal sinus. After its emergence from the skull it passes anteriorly between the internal jugular vein and internal carotid artery and descends anteriorly to the latter vessel, medial to the styloid process and its attached muscles, and lateral to the vagus and accessory nerves to reach and wind around the lower border of the stylopharyngeus muscle. It curves anteriorly between the internal and external carotid arteries to form an arch on the side of the neck, lying first on the stylopharyngeus and medial constrictor muscles and then medial to the hyoglossus muscle to become distributed to the mucous membranes of the pharynx, palatine tonsils, and posterior third of the tongue.

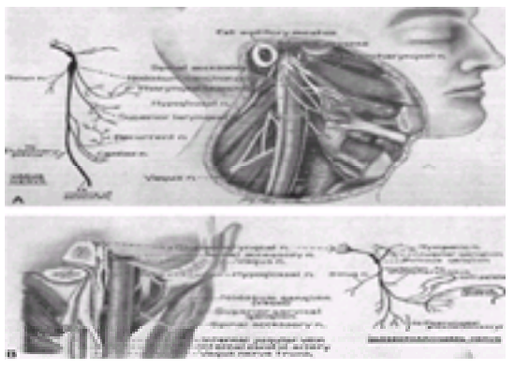

Figure 46-9. Deep dissection of the head and neck to show the anatomy of the ninth, tenth, eleventh, and twelfth cranial nerves. **A:** Lateral view. **B:** Posteroanterior view. Note especially the relationship of the glossopharyngeal and vagus nerves, shown schematically. The upper ganglion of the glossopharyngeal nerve should be labeled the *superior ganglion* and the upper ganglion of the vagus the *jugular ganglion*.

Vagus Nerve

The vagus is a mixed cranial nerve (cranial nerve X) and is composed of motor, parasympathetic, somatic, and visceral sensory fibers. The motor fibers of the vagus, together with the motor fibers of the glossopharyngeal and spinal accessory nerves, arise from the nucleus ambiguus and terminate in the muscles of the soft palate, pharynx, and larynx. The parasympathetic fibers originate in the dorsal motor nucleus of the vagus and terminate in the abdominal and thoracic terminal ganglia, from which postganglionic fibers arise to be distributed to the viscera.

The somatic sensory fibers arise from the unipolar cells of the jugular ganglion and soon divide into central and peripheral branches. The former terminate in the spinal tract of the trigeminal and its nucleus, whereas the latter ends in the external auditory meatus and ear by way of its auricular branch, and in the dura mater by way of its recurrent meningeal branch. The visceral sensory fibers, on the other hand, arise from the unipolar cells of the ganglion nodosum and also divide into central and peripheral branches. The central branches terminate in the tractus solitarius and its nucleus, whereas the peripheral branches terminate in the pharynx, larynx, trachea, esophagus, thoracic, and abdominal viscera. Somatic sensory fibers, which contribute to the pharyngeal, bronchial, pulmonary, and esophageal plexuses and to the superior laryngeal nerve, convey general sensations, including pain, from the mucous membranes of the pharynx, larynx, tracheobronchial tree, and upper part of the esophagus. Sensory fibers that supply viscera below the diaphragm do not convey thermal or mechanical nociceptive information but conduct the sensations of distension and nausea and impulses concerned with the regulation of respiration and blood pressure.

The vagus nerve trunk is formed by the fusion of 8 to 10 filaments that are attached to the medulla in its posterolateral groove between the olive and inferior cerebellar peduncle just caudad to the glossopharyngeal nerve. After it is formed, the flat cordlike nerve passes beneath the flocculus to reach the midportion of the jugular foramen, through which it leaves the skull within the same dural sheath as the spinal accessory nerve (cranial nerve XI). As it passes through the foramen it enlarges into the jugular ganglion, to which the accessory nerve is connected by one or two filaments. After the vagus emerges from the skull it is joined by the cranial portion of the spinal accessory nerve and enlarges into the ganglion nodosum, through which the accessory nerve fibers pass to be distributed uninterruptedly with the pharyngeal, superior laryngeal, and recurrent laryngeal branches of the vagus. In the neck the vagus proceeds caudad, lying within the carotid sheath between the internal jugular vein and internal carotid artery and slightly dorsal to both vessels as far as the thyroid cartilage. At the upper border of this cartilage it comes to lie between and behind the internal jugular vein and common carotid artery. It is still in this position when it leaves the neck at the superior thoracic aperture. Its distribution within the chest and abdomen is described in Chapter 60 and Chapter 65.

Pharyngeal Branches

The pharyngeal branches of the vagus, usually two, arise at the upper part of the inferior ganglion and contain sensory fibers from the ganglion and motor fibers from the communication with the accessory nerve. The branches pass distally and at the superior border of the constrictor pharyngis medius divide into several branches. These join glossopharyngeal, sympathetic, and external branches of the superior laryngeal nerve to form the pharyngeal plexus, which contributes sensory fibers to the mucous membrane and motor fibers to the muscles of the pharynx.

Superior Laryngeal Nerve

The superior laryngeal nerve arises from the lower pole of the ganglion nodosum and proceeds inferiorly (caudad) and medially behind and medial to the carotid arteries to reach the lateral side of the larynx. During its course the nerve receives a filament from the superior cervical sympathetic ganglion and communicates with the pharyngeal plexus by several branches. At a point 1 cm anterior and slightly inferior to the great cornu of the hyoid bone the nerve divides into a smaller external and larger internal branch (Fig. 46-10). The external branch descends on the lateral side of the thyroid cartilage between the inferior pharyngeal constrictor and sternothyroid muscles, and finally enters the cricothyroid muscle. It also contributes twigs to the inferior pharyngeal constrictor muscle. The internal branch proceeds inferiorly and medially for a short distance and then pierces the thyrohyoid membrane to enter the hypopharynx, in which it divides into an upper and a lower branch that supply the mucous membranes of the base of the tongue, pharynx, epiglottis, and larynx above the vocal cords, and perhaps send a few motor filaments to the arytenoideus muscle.

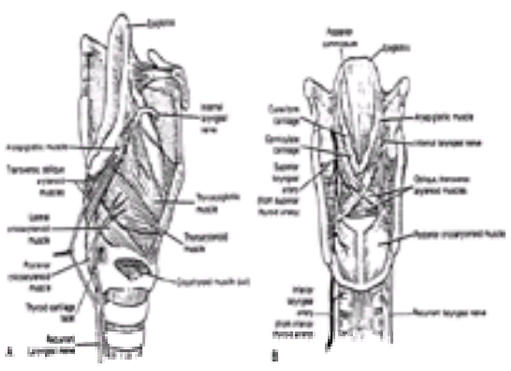

Figure 46-10. Anatomy and distribution of the superior and inferior laryngeal nerves. **A:** Lateral view of laryngeal muscles and nerves (half of thyroid cartilage and hyoid bone removed). **B:** Posterior view of laryngeal muscles, nerves, and arteries. Otolaryngology—head and neck surgery, 3rd ed. St. Louis: Mosby, 1998, with permission.)

Autonomic Innervation of the Head

Like other regions of the body, the head is supplied by sympathetic and parasympathetic nerves summarized in Table 8-6 and Figure 46-11, Figure 46-12, and Figure 46-13. These, together with the sensory nerves, supply the somatic and visceral structures in the head as well as the lacrimal, parotid, and submaxillary glands. The following briefly summarizes the course and distribution of sympathetic and parasympathetic nerves.

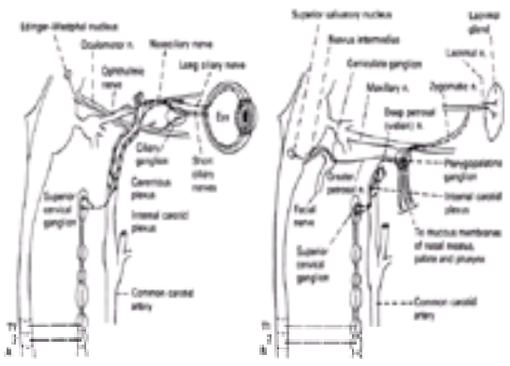

Figure 46-12. **A:** Autonomic nerve supply to the eye. The parasympathetic fibers arise in the Edinger-Westphal nucleus, which is part of the oculomotor nucleus, and traverse the ocular nerve and its inferior division. The fibers leave the oculomotor nerves to give rise to the short motor root of the ciliary ganglion. Within the ganglion they synapse with postganglionic neurons, whose axons pass to the eye by way of the short ciliary nerves. The cell bodies of the sympathetic preganglionic fibers are located in the upper two and frequently the third thoracic spinal cord segments; their axons pass to the sympathetic chain and ascend to end in the superior cervical ganglion, in which they synapse with postganglionic neurons. The axons of postganglionic neurons become part of the internal carotid plexus and eventually reach the eye by one of two courses; some of these are derived directly from the cavernous plexus and pass through the ciliary ganglion without synapsing, thus passing through the short ciliary nerves to reach the eye. Most sympathetic fibers course through the internal carotid plexus for a short distance, deviate into the middle ear accompanied by the caroticotympanic fibers, leave the middle ear, and pass through the base of the cranium lateral to the nerve of the pterygoid canal. They then become associated with the cavernous plexus, join the nasociliary nerve, and finally pass to the eye through the long ciliary nerves. **B:** Autonomic nerve supply to the lacrimal gland. The parasympathetic preganglionic fibers originate in the superior salivatory nucleus; their axons make up the efferent part of the nervus intermedius, which passes sequentially through the geniculate ganglion, the greater petrosal nerve, and the nerve of the pterygoid canal (vidian nerve) to end in the pterygopalatine ganglion, in which it synapses with postganglionic fibers. The latter then pass through the maxillary nerve, its zygomatic and zygomaticotemporal branches, and through fibers that connect these branches with the lacrimal nerve to end in the gland. The sympathetic preganglionic fibers originate in the upper two thoracic ganglia, pass through the paravertebral sympathetic chain, and travel cephalad from there to end in the superior cervical ganglion, in which they synapse with postganglionic fibers. These pass through the internal carotid plexus and leave the plexus as the deep petrosal nerve, which joins the greater petrosal nerve to form the nerve of the pterygoid canal. The postganglionic sympathetic fibers then pass through the pterygopalatine ganglion without synapsing, and thus have the same course as the parasympathetic fibers to reach the lacrimal gland. It can also be seen that both parasympathetic and sympathetic postganglionic fibers supply the mucous membranes of the nasal meatuses, palate, and pharynx through the various branches of the pterygopalatine ganglion (see text for details).

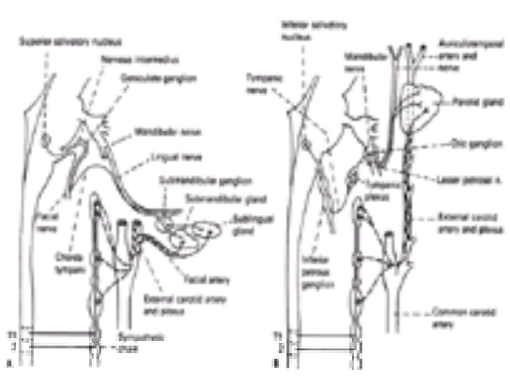

Figure 46-13. **A:** Autonomic nerve supply of the submandibular and sublingual glands. The parasympathetic preganglionic fibers originate in the superior salivatory nucleus and pass through the nervus intermedius, chorda tympani, and lingual nerves to end in the submandibular ganglion, in which they synapse with postganglionic fibers that pass to the submandibular and sublingual glands. The sympathetic preganglionic fibers have their cell bodies in the upper two thoracic segments, pass through the sympathetic chain, and ascend to end in the cervical sympathetic ganglia, in which they synapse with postganglionic fibers. These pass from the superior, middle, and inferior (stellate) cervical ganglia as the common carotid and external carotid nerves, which reach the arteries and break up into the common carotid and external carotid plexuses. The external carotid plexus continues and passes through the facial artery and its glandular branches to become distributed to the submandibular and sublingual glands. **B:** Autonomic nerve supply of the parotid gland. The parasympathetic preganglionic fibers have their cell bodies in the inferior salivatory nucleus and pass through the roots of the glossopharyngeal nerve and its inferior (petrous) ganglion from which they leave as the tympanic nerve. The tympanic nerve passes through the petrous portion of the temporal bone and enters the tympanic cavity, in which it joins with the caroticotympanic nerves to make up the tympanic plexus. Parasympathetic fibers then pass through the plexus to continue as a lesser petrosal nerve, terminating in the otic ganglion in which they synapse with postganglionic fibers. These pass from the otic ganglion into the auriculotemporal nerve and through its parotid branches to supply the parotid gland. The sympathetic preganglionic neurons have their cell bodies in the upper two thoracic spinal cord segments, pass to the sympathetic chain, and ascend to end in the cervical sympathetic ganglia, in which they synapse with postganglionic fibers. These pass as the external and common carotid nerves that break up into plexuses and proceed cephalad. The fibers pass through the plexus that surrounds the auriculotemporal artery and its transverse facial branch to reach and supply the parotid gland.

Sympathetic Nerves

The preganglionic neuron cell bodies are located in the intermediolateral column of the T-1 to T-2 segments for those destined for the brain, meninges, and related arteries, whereas those that supply the blood vessels of the face and neck are located in the T- 2 to T-4 segments of the spinal cord. As discussed in detail in Chapter 8, these cell bodies receive descending input from diencephalic autonomic centers through various descending pathways (see Fig. 46-11). The axons of these neurons pass through the anterior roots of the upper four thoracic spinal nerves and corresponding white rami communicantes to reach the sympathetic trunk. Here they ascend to terminate in the cervical ganglia, in which they synapse with cell bodies of postganglionic neurons. The axons of the latter pass cephalad as *nerves* and plexuses that come to surround the common carotid, external carotid, and internal carotid arteries and the vertebral and basilar arteries.

Internal Carotid Nerve. The internal carotid nerve is derived from the superior cervical sympathetic ganglion and accompanies the internal carotid artery as far as the carotid canal in the temporal bone, at which point it divides into a large branch that ramifies to become the internal carotid plexus and into a smaller branch that breaks up to become the cavernous plexus (see Fig. 46-11 and Fig. 46-12).

Internal Carotid Plexus. The internal carotid plexus ascends on the lateral side of the internal carotid artery and, within the cranial cavity, communicates with the gasserian ganglion and abducens nerve and gives off two branches, the deep petrosal and corticotympanic nerves. The deep petrosal nerve, comprised of postganglionic sympathetic fibers, joins the greater petrosal nerve to form the vidian nerve, which passes to the pterygopalatine ganglion and through the palatine nerves to supply the glands and blood vessels of the pharynx, nasal cavity, and palate, while some fibers that pass through the zygomatic nerve end in the lacrimal

gland. The corticotympanic nerve contributes to the tympanic plexus.

Cavernous Plexus. The cavernous plexus is situated just inferomedial to the internal carotid artery. As it passes through the cavernous sinus it communicates with the oculomotor, trochlear, ophthalmic, and abducens nerves and contributes the sympathetic root of the ciliary ganglion. The internal carotid and cavernous plexuses continue as subsidiary plexuses around the anterior and middle cerebral and ophthalmic arteries. Fibers on the cerebral arteries can be traced to the pia mater, whereas those on the ophthalmic artery accompany all its branches into the orbit. The filaments on the anterior communicating artery can connect the sympathetic nerves of the right and left sides.

Jugular Nerve. The jugular nerve arises from the superior pole of the superior cervical sympathetic ganglion, although in some cases it can arise from the internal carotid nerve. The jugular nerve ascends behind the internal carotid artery and hypoglossal nerve and reaches the base of the skull, in which it divides into two filaments, one joining the jugular ganglion of the vagus and the other joining the petrosal ganglion of the glossopharyngeal nerve.

External Carotid Nerves. The external carotid nerves containing postganglionic fibers from the cervical sympathetic ganglia pass to and break up into the plexuses that surround the external carotid artery and all its branches, giving off filaments along its course. The filaments on the facial artery join the submandibular ganglion and supply the submandibular and probably the sublingual glands. The network of filaments on the middle meningeal artery (which is usually a branch of the maxillary artery derived from the external carotid artery) gives off the small deep petrosal nerve that passes through the otic ganglion and accompanies the auriculotemporal nerve to the parotid gland. Other filaments form the external superficial petrosal nerve, which communicates with the geniculate ganglion. Filaments on the facial, superficial temporal, and other arteries that distribute to the skin supply vasomotor fibers as well as the arrectores pilorum muscles and sweat glands of the face.

Vertebral Nerve. The vertebral nerve, usually formed by two roots arising from the superior border of the superior cervical sympathetic ganglion, ascends along the posterior aspect of the vertebral artery within the vertebral canal and ramifies into several branches, some of which make up the vertebral plexus, which also receives a small filament from the intermediate cervical ganglion. The vertebral plexus follows the artery cephalad and continues on the basilar, posterior cerebral, and cerebellar arteries to contribute to the sympathetic innervation of the intracranial arteries and meninges.

Parasympathetic Nerves

The cranial outflow of the parasympathetic nervous system includes fibers in the oculomotor, facial, and glossopharyngeal nerves.

Oculomotor Nerve. The oculomotor nerve contains parasympathetic efferent fibers for the nonstriated muscle making up the ciliaris and sphincter pupillae muscles of the eyeball (see Fig. 46-12A). The preganglionic fibers arise from the cells in the Edinger-Westphal nucleus located in the anterior part of the oculomotor nucleus in the tegmentum of the midbrain. These fibers run in the inferior division of the oculomotor nerve to the ciliary ganglion, in which they synapse with cell bodies of postganglionic neurons. The axons of the latter proceed in the short ciliary nerves to the eyeball and penetrate the sclera to reach the aforementioned muscles.

Facial Nerve. The facial nerve contains parasympathetic fibers for the lacrimal, submandibular, and sublingual glands and for the many small glands in the mucous membranes of the nasal cavity, palate, and tongue. The cell bodies of the preganglionic fibers arise from cells in the superior salivatory nucleus and leave the brain in the nervus intermedius. Some axons of preganglionic fibers pass through the geniculate ganglion and the greater superficial petrosal nerve and end in the pterygopalatine (sphenopalatine) ganglion, in which they synapse with postganglionic fibers. Some of these postganglionic fibers reach the lacrimal gland by way of the maxillary, zygomatic, and lacrimal nerves (see Fig. 46-12B). Other postganglionic fibers accompany the branches of the maxillary nerve to the glands and mucous membranes of the nasal cavity and nasopharynx, and still others accompany the palatine nerves to supply the glands of the soft palate, tonsils, uvula, roof of the mouth, and upper lip. Other preganglionic fibers leave the facial nerve in the chorda tympani and with it join the lingual nerve to reach the submandibular ganglion in which they synapse with postganglionic fibers that become the secretomotor nerve supply to the submandibular and sublingual glands (Fig. 46-13A).

Glossopharyngeal Nerve. The glossopharyngeal nerve contains efferent parasympathetic fibers for the parotid gland and for small glands in the mucous membranes of the tongue and floor of the mouth. The cell bodies of the preganglionic neurons arise in the inferior salivatory nucleus in the medulla oblongata, traverse the tympanic and lesser superficial petrosal nerve, and end in the otic ganglion, in which they synapse with postganglionic fibers that supply the parotid gland (see Fig. 46-13B).

SUMMARY OF HISTORY AND PHYSICAL EXAMINATION

It is obvious from Table 46-1 that the diagnosis of head pain requires a detailed history and comprehensive physical examination, as discussed in Chapter 12 and in the book by de Jong (3). The characteristics of the pain must be ascertained in great detail by the history, including circumstances that precipitated the pain; character of onset (sudden or gradual); location; character (sharp or dull, lancinating, throbbing, or pulsating); severity; temporal characteristics (constant or intermittent; time of day, week, month, or season); duration (seconds, minutes, hours); character of termination (sudden or gradual); factors that reproduce, aggravate, or relieve it; and associated signs and symptoms. The latter include sensory changes (hyperalgesia or hypoalgesia), motor disturbances (tremors, weakness), autonomic dysfunction (e.g., hyperhidrosis, lacrimation), and any tinnitus, dizziness, syncope, or other nervous system dysfunction.

TABLE 46-1. Pain in the head (including headache): summary of etiology and differential diagnosis

The examination should include a general inspection, particularly of the facial expression; position of the head; color of the skin; and contour of the face, head, neck, eyes, nose, ears, lips, teeth, tongue, cheeks, pharynx, and larynx; and muscular expression and phonation. Palpation is carried out to determine the presence of trigger areas or zones, tenderness, and swelling or induration. The function of the muscles of the neck is examined in regard to flexion, extension, and lateral rotation and flexion for both right and left sides. The effect of head compression (Spurling's test) and head traction on the pain should be ascertained.

The patient who complains of face or head pain requires a detailed evaluation of the cranial nerves, the upper three cervical nerves, and sympathetic innervation of the head. Careful assessment of the extraocular muscles by testing for conjugate eye movements, nystagmus, and intraocular muscle function in response to light and near vision is required. Light touch and pinprick sensation of the scalp and of each of the three divisions of the trigeminal nerve should be assessed, over both lateral and anterior aspects of the face. Corneal sensation should be tested with a fine wisp of cotton. Taste (e.g., of sugar or salt) on the anterior tongue is important to evaluate.

The patient with face pain should have all facets of trigeminal function assessed, including the muscles of mastication. The facial nerves should be tested by asking the patient to whistle and then blow out the cheeks. The symmetry of the nasolabial folds and mouth movements should be noted. Strength of the orbicularis oculi muscles is assessed by asking the patient to keep the eyes shut while the examiner tries to open them. Although hearing can be crudely measured by testing with a watch or rubbing the fingers, a tuning fork permits one to ascertain that air conduction is greater than bone conduction and that a tuning fork applied to the forehead is heard equally in both ears. Audiometry is a much more precise method of evaluating hearing.

Testing for glossopharyngeal and vagal function is difficult. Taste over the posterior third of the tongue and pharynx is mediated by the glossopharyngeal nerve. A

cotton applicator stick moistened and coated with sugar or salt is an effective stimulus. The gag response should be elicited from each tonsillar fossa, and the elevation of the uvula in the midline should be noted. Accessory nerve function is tested by asking the patient to rotate the head against resistance while palpating the sternocleidomastoid muscle and by pressing down on the shoulders while the patient attempts to elevate them. Hypoglossal nerve function is assessed by observing the tongue for fasciculations and by testing strength and range of tongue motion.

Testing cranial nerve function is not time consuming and often indicates a structural lesion when abnormalities are found. Local tenderness in the regions of the paranasal sinuses and over the temporal arteries or the scalp can indicate the site of a pain-causing lesion. Skull tenderness to percussion can indicate a subjacent mass lesion, such as a tumor or subdural hematoma. Skin temperature and sweating, lacrimation, salivation, rhinitis, and pupillary size and reaction can be abnormal with lesions affecting parasympathetic or sympathetic innervation.

CHAPTER 47

Cranial Neuralgias

John D. Loeser

The classification of neuralgias of the face, head, and neck is difficult, and it is based more on opinion than on an understanding of the mechanisms or pathogenesis. Nonetheless, it is essential to impose some organization on this confusing area of chronic pain. Similar sentiments were expressed in the first edition of this book; little progress has been made in the understanding of the genesis of facial neuralgias, although new medications and surgical procedures have improved treatment efficacy. Headaches are discussed in detail in Chapter 48 and are not discussed here. Table 47-1 lists the pain syndromes that must be differentiated from cranial and facial neuralgias as well as the chapters in which a discussion of each is located.

Disorder	Chapter no.
Cranial neuralgias	47
Atypical facial pain	47
Temporomandibular joint pain	49
Myofascial pain of masticatory muscles	49
Temporal arteritis	49
Sinusitis	52
Tolosa-Hunt syndrome	51
Dental, gingival, and osseous pain	50
Migraine	48
Cluster headaches	48
Paratrigeminal syndrome of Raeder	52
Cancer of head and neck	53
Traumatic neuropathies	47
Muscle-tension headaches	48, 49
Occipital neuralgia	47
Eagle's syndrome	52

TABLE 47-1. Pain syndromes of the face, cranium, and upper neck

An old nomenclature is superimposed on advancing knowledge, and no scheme for categorizing neuralgias is perfect. In this chapter the term *typical neuralgia* refers to a pain syndrome restricted to the distribution of a specific cranial nerve or its branch. It can occur in any cranial nerve that has somatic afferent fibers—the trigeminal, facial (nervus intermedius), glossopharyngeal, and vagus—and is rarely seen in the uppermost cervical dorsal roots (C-2 and C-3). The most common typical neuralgia is tic douloureux, often called “classic trigeminal neuralgia' or “major trigeminal neuralgia.”

Other neuralgias occur in the cranial nerves but are continuous, may be associated with significant sensory loss, are usually described as burning or aching, perhaps with superimposed jabs, often not triggered, and are unilateral. Atypical neuralgias are frequently, but not always, associated with trauma to a nerve, chronic infection, or occult neoplasm in the face or base of the skull. These pains were formerly called “minor” the International Association for the Study of Pain (IASP) taxonomy system labels them as “secondary' neuralgias, but they are no more secondary than tic douloureux, which is almost always caused by vascular compression of the intracranial trigeminal nerve.

Herpes zoster can lead to both acute and chronic trigeminal and nervus intermedius pain syndromes. The pain can precede the vesicular eruption, and diagnosis can

be quite difficult at first.

The atypical neuralgias form a diverse group of facial pains. Some are not restricted to a specific cranial nerve distribution; can be bilateral, intraoral, or facial; and can extend into the neck. They are continuous, usually with little or no sensory deficit, are not triggered, and often occur in patients with significant psychopathology. The likelihood of establishing an etiology for this type of atypical facial pain is exceedingly small. Clinical studies have shown that the textbook distinctions among atypical facial pain, vascular headaches, and muscle tension headaches are not respected by all patients—that is, the borders of every syndrome are indistinct. Table 47-2 presents the characteristics of the major pain syndromes discussed in this chapter.

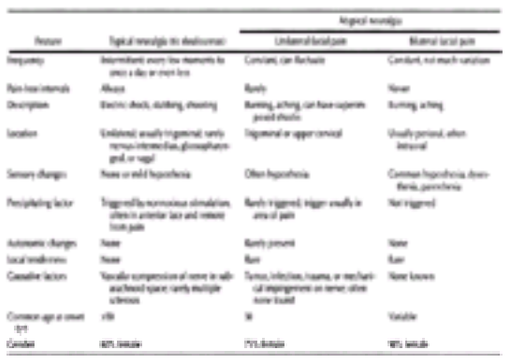

TABLE 47-2. Characteristics of facial pain syndromes

Correct diagnosis is mandatory with chronic facial pain because effective treatment strategies are available for some of the pains in this region. It is important to recognize the primary features of each of the facial neuralgias, and their differential diagnosis from pain of specific structural cause has relevance for the prompt implementation of effective care.

This chapter is organized around the specific types of neuralgias and commences with typical trigeminal neuralgia, or tic douloureux. A discussion of the other typical neuralgias follows; attention is then focused to the atypical neuralgias, unilateral and bilateral. The emphasis of this section is on diagnosis and the development of a logical management plan (1). More detailed descriptions of the cranial neuralgias and their management can be found elsewhere (2,3 and 4).

TRIGEMINAL NEURALGIA (TIC DOULOUREUX) (II-1)

The clinician must be able to identify a patient with tic douloureux, or classic trigeminal neuralgia, because this most severe pain syndrome can almost always be controlled by medication or surgery. Trigeminal neuralgia has long been recognized in the medical literature. It is believed that sixteenth-century stone carvings in Wells Cathedral depict the pain of trigeminal neuralgia (5). The first written description was ascribed to Johannes Bausch in 1672. André first used the term *tic douloureux* in 1756, and Fothergill provided a vivid description of this pain syndrome in 1773. Early medical therapies were without benefit; the first effective treatment was probably trichloroethylene inhalation, which was initiated in the 1920s.

Effective surgical procedures that injured the trigeminal nerve were developed in the early eighteenth century, although it was noted that Maréschal, surgeon to King Louis XIV, of France, cut the peripheral branches of the trigeminal nerve for pain (5). It was not until the studies of Bell and Magendie in the early nineteenth century that the different functions of the trigeminal and facial nerves were recognized. Mears, in 1884, discussed surgical extirpation of the gasserian ganglion; several surgeons undertook this procedure. A major step forward was Sir Victor Horsley's subtemporal retrogasserian neurotomy, first performed in 1891. Both Hartley and Krause developed similar operative approaches, and in 1900 Harvey Cushing described a simplified approach. Suboccipital retrogasserian neurotomy was developed by Fraser in 1901. Sjoqvist (6) described trigeminal medullary tractotomy in 1937. The history of neurosurgical treatments for facial pain has been reviewed by Walker and others (2,5).

Epidemiology

Tic douloureux is a disease of the elderly, but it does occur uncommonly in young adults (Fig. 47-1). The peak incidence is between ages 50 and 70. Although the early literature indicated a strong preponderance of women among patients with tic douloureux, current data suggest that only 60% of the patients are female (7). An earlier onset of tic douloureux is rarely a sign of multiple sclerosis; it does the patient a disservice to invoke the terrors of such a diagnosis when the only finding is tic pain. I have operated on a patient whose tic began when she was 17; she had a kinked superior cerebellar artery compressing the trigeminal root. There is no known racial or ethnic factor in the incidence of tic douloureux.

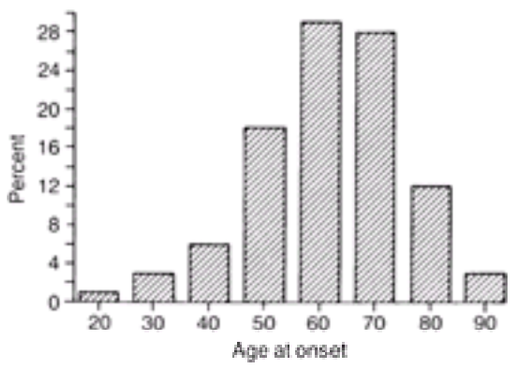

Figure 47-1. Distribution of age of onset of tic douloureux.

Etiology

Neither the etiology nor the pathophysiology of tic douloureux has been adequately explained. Certainly, the observations made by Dandy (7) and those of Jannetta (8) and other neurologic surgeons have made it apparent that the vast majority of patients with classic tic douloureux have mechanical compression of the trigeminal nerve as it leaves the pons and traverses the subarachnoid space toward Meckel's cave (see Chapter 107). The most common finding is cross-compression by a major artery, usually the superior cerebellar, but occasionally the posterior inferior cerebellar, vertebral, or anterior inferior cerebellar artery is involved. A few patients have been found to have a vein running across or even through the nerve, and a small incidence of arteriovenous malformation or tumors has also been reported (see Chapter 107).

The region of impingement of the blood vessel on the trigeminal root correlates with the region of face pain. When the pain is perceived in the second or third trigeminal division, the usual finding is compression of the rostral and anterior portion of the nerve by the superior cerebellar artery. If first-division pain is present, the most frequent finding is cross-compression of the trigeminal root in its caudal and posterior portion, most often by the anterior inferior cerebellar artery.

A small percentage of the patients with tic douloureux have multiple sclerosis as an underlying disease. The autopsy findings on these patients, which have been confirmed in a small number of surgical observations, include a demyelinating plaque in the trigeminal posterior root (9). It is well known, however, that plaques are frequently found in the descending trigeminal tract and in the lemniscal systems; it is not now possible to argue that a plaque in the trigeminal root is either necessary

or sufficient to cause tic douloureux. A patient with multiple sclerosis could also have arterial cross-compression of the trigeminal root.

Another theory has been described in the dental literature. Ratner et al. (10) and Shaber et al. (11) hypothesized that tic douloureux is caused by foci of abscess and bone resorption with irritation of the trigeminal nerve in the maxilla or mandible, but this theory is not widely accepted, even among dentists. Similar cavities are seen in the jaws of people with no pain or history of pain. The treatment of such cavities does not lead to symptom abatement uniformly and quickly. Some patients with tic douloureux cannot be shown to have these cavities. Even if the cause of the disease does not lie in the jaws, few would disagree that abscesses and other pathologic processes in the orofacial structures can act as the triggering stimulus for tic. Yet, this concept persists in the dental literature (12,13).

Pathophysiology

How a demyelinating plaque, infection in the jaw, or artery or tumor pressing on the trigeminal nerve can cause a unique pain such as tic douloureux is unknown. No animal model for a pain syndrome such as tic has been developed—only some theoretic explanations based on clinical information.

Two generic schemes for the explanation of tic douloureux can be identified, the “centralist' and “peripheralist.' The former is based on the similarities of tic douloureux to focal epilepsy and emphasizes the role of deafferentation in the genesis of neuronal hyperactivity (14). Epileptogenic agents injected into the trigeminal nucleus can cause neuronal hyperactivity and a pain syndrome in cats and monkeys (15). Changes in dorsal root reflexes and synaptic function in the trigeminal system have also been described (16). The peripheralist concept notes that changes in the trigeminal nerve myelin and axons can lead to altered peripheral nerve sensitivity to chemical and mechanical stimuli and ties the pain syndrome to suspected peripheral causes (17,18,19 and 20). Other theories based on ephaptic connections, reverberating circuits, and altered central connectivity caused by deafferentation have also been proposed (21,22).

Calvin and colleagues (23) concluded that both peripheral and central mechanisms are required for the production of tic douloureux. Fromm and associates (24) proposed a similar mechanism. Their studies indicated that a peripheral nerve lesion (in the trigeminal root or distal) is the first event in a process that leads to central synaptic changes. The response of the central synapses to altered peripheral events leads to the development of tic douloureux. Such a complex theory is required to explain many of the phenomena seen in tic douloureux: triggering by nonnoxious stimuli, separation of the trigger area from the painful region, sudden onset and cessation of pain, and response to anticonvulsant medications.

Symptoms and Signs

Even though the classification of pain syndromes of the face and head is often unclear, it should be possible to differentiate tic douloureux from any other type of pain (see Table 47-2). Tic is characterized by the following: electric shock–like stabbing pains; unilateral pain during any one episode; abrupt onset and termination of pain; pain-free intervals between attacks; nonnoxious stimulation triggering the pain, which is often in a different area of the face; minimal or no sensory loss in the region of pain; and pain restricted to the trigeminal nerve (1). Deviations from this typical picture can occur, but the more unusual features the patient manifests, the less likely is a favorable response either to medication or surgery.

The history of bilateral tic pain can be elicited in approximately 3% of patients. Rarely does a patient have bilateral tic pain during one episode; usually an interval of years separates the occurrence of pains on the two sides.

Surgical or anesthetic procedures that damage the trigeminal nerve can produce changes in the findings and in the patient's symptoms—it is essential to ascertain what the symptoms were before such an operation. Nerve damage can lead to a burning component of the pain that is uncommon in patients without nerve injury. Significant sensory loss mandates a thorough search for structural pathology such as tumor or infection that is damaging the trigeminal nerve.

Triggering

The average patient with tic douloureux describes a specific triggering stimulus, touching the face or chewing, talking, or swallowing. Many patients report that exposure of the face to cold triggers their pain. The cutaneous trigger is always a nonnoxious stimulus and is usually located in the anterior face (21) (Fig. 47-2).

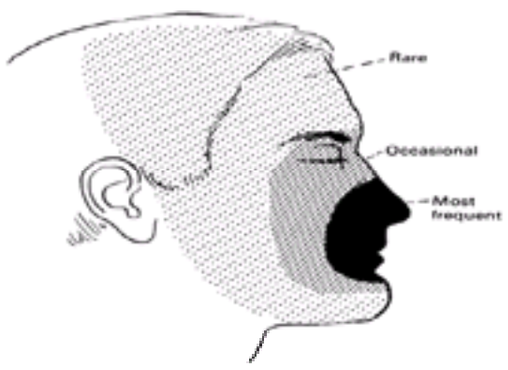

Figure 47-2. The most likely sites of triggering for tic douloureux are in the anterior face.

The trigger area is always ipsilateral to the pain but can be in the same or a different division of the trigeminal nerve. Rarely, the patient reports a trigger area outside the trigeminal territory, usually in the upper cervical dermatomes. Patients with triggering from the scalp often refuse to wash or brush their hair; shaving can be impossible for a man with triggering from the upper lip or face, and oral hygiene is often impossible when the triggering is from the teeth or gingivae. When swallowing or chewing triggers the pain, the patient may develop inadequate caloric intake or dehydration.

Distribution of the Pain

In the overwhelming majority of patients with tic douloureux the pain is restricted to the trigeminal dermatomes. A small number have pain both in the trigeminal areas and in the territory of the nervus intermedius (cranial nerve VII), glossopharyngeal nerve (cranial nerve IX), or vagus nerve (cranial nerve X) (25). The pains of tic douloureux can also be experienced exclusively in one of these areas (see below). The most common site of tic pain is the combination of the second and third divisions; the rarest site is the combination of the first and third divisions. Figure 47-3 depicts the distribution of pain from approximately 8,500 patients reported in the literature. Another way of analyzing these data is shown in Figure 47-4 —some pain is perceived in the second division in more than 44% of patients, the third division has some pain in 36% of patients, and the first division in 20% of patients. Thus, the malar area is the most likely to be involved in the patient with tic. This pain syndrome can and does occur, however, in every area of the face and anterior scalp, and all combinations of painful sites have been reported (4,26).

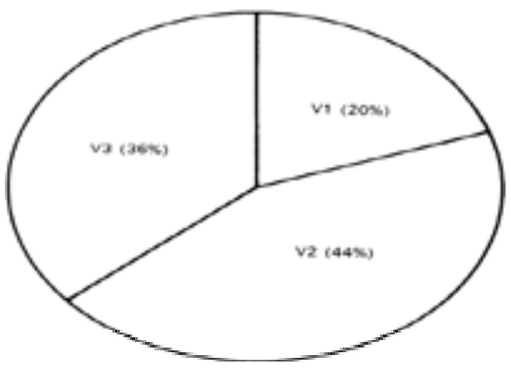

Figure 47-3. Distribution of pain among divisions of the trigeminal nerve in patients with tic douloureux.

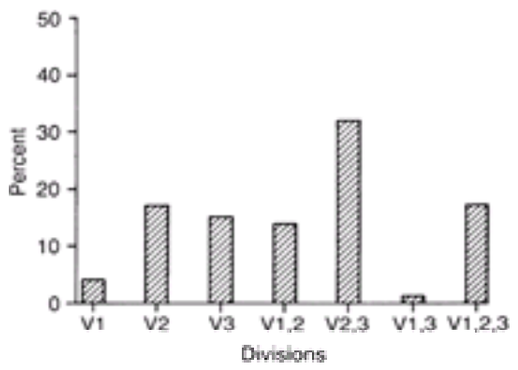

Figure 47-4. Trigeminal divisions involved in tic douloureux.

Chronology

Tic douloureux is often an intermittent disease. Many patients report intervals of months or even years between flurries of attacks. Recurrences are almost always in the same area of the face, but the painful areas tend to spread. It is common for intervals between attacks to decrease and episodes of severe pain to occur more often. Some patients never experience remission once their disease starts. Patients often report nonnoxious minor jabs in their painful areas between episodes of severe pain. Emotional and physical stress do appear to increase the likelihood of severe pain in the patient who has tic, but no evidence has been found to indicate that stress plays a causative role in this disease.

Diagnosis

Tic douloureux must be distinguished from all other face pains. The criteria already discussed suffice to establish the diagnosis. No diagnostic studies are available to confirm the presence of tic douloureux. Tic should be discriminated from a similar syndrome occurring in one of the other cranial sensory nerves (see below). This is readily accomplished by taking a careful history from the patient and by ascertaining the exact triggering stimulus and site of pain during the physical examination (see Table 46-1 for differential diagnosis of pain in the face and head).

The disease must also be distinguished from atypical facial pain of the unilateral variety (see Table 47-2). Atypical facial pains are discussed in detail below; they are characterized by continuous burning pain not like electric shock, that often is not triggered, and that often escapes the trigeminal territory. Atypical face pains are most common in younger women.

Myofascial pains involving the muscles of mastication and temporomandibular joint pain can be difficult to differentiate from each other but should not be confused with tic douloureux. These syndromes consist of pain that is predominantly in the lateral face, described as aching, burning, or cramping, is often associated with using the jaw or its muscles and with tenderness to palpation of the involved muscles and can radiate into the scalp or neck. Myofascial and temporomandibular facial pains are discussed in detail in Chapter 49.

Cluster headache and facial pains are a confusing group of pain syndromes (see Chapter 48). These are usually intermittent burning or throbbing dysesthetic pains that occur in clear-cut episodes and are frequently associated with autonomic signs, such as lacrimation, rhinitis, facial sweating, and facial flushing. The attacks can be random or clustered and have numerous variants that are often described by an eponym.

Local pathologic processes in the paranasal sinuses, jaws, teeth, pharynx, or base of the skull can lead to severe pain. This type of facial pain is usually constant and is described as aching, throbbing, or burning but rarely as shocklike. The pain is not triggered by nonnoxious stimulation remote from the painful area, and if a branch of the nerve is involved in the disease, sensory loss can occur. Physical examination and the appropriate diagnostic studies usually reveal the pathology (Chapter 52).

Pharmacologic Treatment

The primary treatment of tic douloureux is first pharmacologic, but, if this fails, surgical therapy is indicated.

The mainstays of the pharmacologic management of tic douloureux are the anticonvulsant medications carbamazepine and phenytoin (Table 47-3). Baclofen, gabapentin, and lamotrigine have more recently been introduced and can be helpful. Other drugs are sometimes useful but are not indicated as primary medication. Scattered reports of the efficacy of other anticonvulsants have appeared but have not been corroborated with appropriately controlled studies (27).

Generic name	Brand name	Pill size (mg)	Usual daily dose	Common side effects
Phenytoin	Dilantin, Eigamin, Phenytek	100	300–300 mg	Nausea, dizziness, unsteadiness, ataxia, dermatitis
Carbamazepine	Tegretol	200	600–1,600 mg	Nausea, dizziness, unsteadiness, hepatic and hematopoietic dysfunction
Lioresal	Baclofen	10	40–80 mg	Nausea, dizziness, confusion, drowsiness
Chlorpromazine	Thorazine	100	300–1,200 mg	Dizziness, unsteadiness
Amphetamine	Adderall, Dexedrine	30	5–15 g	Dizziness, nausea
Gabapentin	Neurontin	100, 300	1,200–4,800 mg	Dizziness, nausea
Lamotrigine	Lamictal	100	400 mg	Dizziness, nausea, unsteadiness

TABLE 47-3. Medications useful for typical neuralgias

Carbamazepine

Carbamazepine (Tegretol) is the most likely drug to control tic douloureux; approximately two-thirds of patients report symptomatic improvement (28). This drug should be started on a daily dosage of 100 mg (½ tablet); the dose is increased by increments of 100 mg every 2 days until a daily dosage of 600 mg is reached. Of course, if pain relief occurs on a lower dosage, the amount taken should not be increased. After 1 week at 600 mg per day, if no pain relief is seen, the daily dosage should be increased to 800 mg for 1 week. This process can be repeated until a total daily dosage of 1,800 mg is reached. Higher doses have not been more effective. Carbamazepine should be administered at least every 8 hours to maintain stable blood levels. A sustained-release form of this drug is now available.

Carbamazepine is a gastric irritant in some patients and should be taken with food or fluid. Some patients develop central nervous system side effects that render the drug intolerable. A small incidence of hematosuppression and liver dysfunction has been reported (29). Because of the gravity of this complication, a complete blood

count should be obtained monthly for the first year and quarterly thereafter. Most patients have some lowering of the white blood cell count; it is not necessary to stop this drug unless the white blood cell count falls below 3,500 cells per mL. The treatment strategy for this drug is to push the dosage until either pain relief or toxicity occurs. Serum levels have not been reliable predictors of either pain relief or toxicity. Because approximately 25% of patients find the side effects of carbamazepine unacceptable, it produces successful relief of symptoms without unacceptable side effects in approximately 50% of patients. Carbamazepine interacts with many other drugs and this must be carefully monitored (30).

Phenytoin

Phenytoin (Dilantin) is the second choice of medication for patients with tic douloureux. Approximately 25% of patients obtain satisfactory pain relief with serum levels of 15 to 25 g per mL. The strategy is to attain adequate serum levels for 3 weeks; if no relief of pain is seen, the drug should be discontinued because higher doses only lead to toxicity. The usual requirement for reaching the optimal serum level is 300 to 400 mg per day given in two doses. If the patient is having severe pain it is prudent to give a 1,000-mg loading dose to achieve rapid blood levels. Central nervous system side effects are usually related to toxic levels, but some patients cannot tolerate even low levels of this drug.

Other Drugs

Baclofen (Lioresal) is a drug that was developed for the treatment of spasticity but was found by Fromm and colleagues (31) to be effective in some patients with tic douloureux. It must be started gradually—5 mg is given, and the dose is increased by 5 mg every 2 days until either pain relief or toxicity occurs. The maximum dosage is 80 mg per day. The drug should be tapered and not suddenly discontinued, especially in the elderly (31,32). Gabapentin is a relatively recently developed anticonvulsant that may be effective for tic douloureux. The initial dose should be 100 mg for 3 days; if this is tolerated the dose can be immediately increased to 300 mg four times a day. If this is tolerated after 1 week, the dose can be increased gradually to a maximum of 4,800 mg per day. This drug is much more expensive than other anticonvulsants and good clinical trials are not yet available. Lamotrigine has also been shown to be effective in a small trial (33).

Chlorphenesin and mephenesin are no longer commonly used.

Nerve Blocks

Local Anesthetic Block

A local anesthetic injected either into the trigger area or painful site temporarily stops the pain of tic douloureux. Rarely, the patient reports pain relief that outlasts the expected duration of the local anesthetic. Nerve blocks can also be used to show the patient the effects of a planned neurectomy or total rhizotomy, but these are not optimal primary surgical procedures. Local anesthesia with a few milliliters of a long-acting agent such as bupivacaine can provide the patient with some peace while adequate serum levels of an anticonvulsant are being obtained or planned surgery is undertaken.

Neurolytic Block

Alcohol blocks of the peripheral branches of the trigeminal nerve or of the gasserian ganglion have a long history in the management of tic douloureux (26). Experienced operators have reported good results, but in most physicians' hands the long-term outcome is not favorable. Alcohol blocks rarely last longer than 1 year, and repeated blocks have a lower success rate and an increased morbidity rate. The amount of hypalgesia and anesthesia has been difficult to control except in the hands of experts (34,35). Alcohol blocks are less satisfactory than gangliolysis and are no longer standard therapy when modern technology is available. The technique of glycerol gangliolysis is actually a neurolytic block, but it is discussed below in conjunction with radiofrequency gangliolysis. When an experienced practitioner of gangliolysis is not available, an alcohol block might be the best alternative.

Dental Procedures

Physicians, dentists, and patients often believe that something must be wrong where it hurts, and this belief has led to the extraction of numerous healthy teeth and to extensive endodontic procedures. It is worth noting that tic douloureux perceived in the nose never results in surgical excision of that structure, whereas tic in the teeth often results in extraction. This is a commentary on the socially determined propriety of therapies, not on an understanding of pathophysiology. Similarly, surgical procedures on the paranasal sinuses are ineffective.

Surgical Therapies

The list of surgical treatments for tic douloureux extends from the peripheral nerve to the brainstem. The following are the commonly used surgical procedures:

Peripheral neurectomy
Peripheral radiofrequency or cryoprobe lesions
Gangliolysis (radiofrequency, mechanical, or glycerol)
Compression/decompression of the gasserian ganglion
Subtemporal retrogasserian neurotomy
Suboccipital retrogasserian neurotomy
Trigeminal tractotomy
Microvascular decompression of the trigeminal nerve
Stereotactic radiosurgery

No surgical procedure is warranted unless pharmacologic therapy has failed, either because of inadequate pain relief or unacceptable side effects. Currently, the two primary surgical treatments for tic douloureux are gangliolysis and microvascular decompression of the trigeminal nerve by a suboccipital craniectomy (8,36,37). These and other less frequently used operations are discussed in Chapter 107.

Gangliolysis

Gangliolysis is the most recent development in the long history of destructive procedures for tic douloureux (38). The goal is to produce the least neurologic deficit that will control the patient's pain. Gangliolysis is performed by placing a needle through the cheek and into the foramen ovale and then into the rootlets behind the gasserian ganglion (see Chapter 107). The placement of the needle is confirmed by roentgenography or fluoroscopy. Three methods are used for making a lesion: a thermally controlled radiofrequency current to heat and destroy anatomically selected portions of the posterior rootlets (37,38 and 39), injection of glycerol into the cistern of the trigeminal ganglion (37,40), and inflation of a balloon in Meckel's cave (41). Gangliolysis offers an 80% chance of 1 year of pain relief and a 60% chance of 5 years' success; the complication rate is less than 0.5% (3,40,42). Gangliolysis is particularly useful in the debilitated or elderly patient who would be at risk from a major surgical procedure. A detailed discussion of the techniques and results of various authors can be found in Chapter 107.

Microvascular Decompression

The popularity of microvascular decompression stems from the studies of Jannetta (8). It is performed under general anesthesia, with a suboccipital craniectomy, using a microscope to visualize the trigeminal nerve as it leaves the pons. Compression by a vascular structure is relieved by repositioning the offending artery or by coagulating a vein. This operation offers an approximately 85% 5-year success rate and does not lead to any sensory loss. The morbidity rate is approximately 5%, and the mortality rate is 0.5%. Chapter 107 contains a thorough discussion of this operative procedure.

Retrogasserian Neurotomy

Sectioning the trigeminal root between the gasserian ganglion and the pons was the standard intracranial procedure for the first half of the twentieth century (43). This operation is indicated when no compression of the trigeminal nerve is discovered during suboccipital craniectomy or if microvascular decompression fails to provide long-term pain relief. It is wisest to perform a partial rhizotomy, because this lessens the probability of inducing anesthesia dolorosa and reduces the morbidity of a

totally numb face. The standard approach today is by the posterior fossa; the subtemporal approach is seldom used. Chapter 107 provides a detailed discussion of this operation and its results and complications.

Peripheral Neurectomy

Peripheral neurectomy is indicated only when gangliolysis has failed and the patient cannot or will not tolerate a suboccipital craniectomy with microvascular decompression. It produces dense numbness and rarely provides more than a year of pain relief. Repeat avulsions of peripheral branches of the trigeminal nerve are even less likely to succeed. Peripheral cranial neurectomies are discussed in Chapter 107.

Compression or Decompression of the Gasserian Ganglion

Compression or decompression procedures were popular before the development of microvascular decompression and gangliolysis. They probably were effective because of minor damage to the trigeminal nerve, ganglion, or rootlets and require a craniotomy by way of the middle fossa. These procedures are not currently indicated.

Trigeminal Tractotomy

Section of the descending trigeminal tract in the medulla produces loss of pain and temperature sensation in the ipsilateral face and pharynx (6). It does not alter touch sensation. The operation is indicated when rhizotomy has failed to alleviate the patient's pain and when all other measures have failed. It is carried out through a small suboccipital craniectomy and laminectomy of C-1 and C-2. The surgical morbidity rate is high if the surgeon is inexperienced and does not use both anatomic and physiologic localization techniques. This operation can be used for tic pain that involves the territories of the nervus intermedius and glossopharyngeal and vagal nerves. Kunc (44) showed that the pain and temperature fibers for all three of the nerves travel in the medial aspect of the descending trigeminal tract. A detailed discussion of the anatomy of this region of the medulla can be found in Chapter 3; the surgical procedure is discussed in Chapter 107.

Stereotactic Radiosurgery

Using either a linear accelerator or a gamma knife, it is possible to place a radiosurgical lesion in the trigeminal root without damaging surrounding brain or vascular structures. The therapeutic effects of this single radiation treatment take weeks to a few months to be noted and there are no data available on the results after 5 years. The short-term results are as good as any other surgical treatment of tic douloureux, and this procedure is likely to have much more widespread use in the years to come (45).

SECONDARY TRIGEMINAL NEURALGIA (II-2)

Although no obvious reason for such a dichotomy is known, it is customary to separate tic douloureux associated with multiple sclerosis, brain tumor, or other recognized diseases from that which we now know to be caused by vascular compression of the trigeminal nerve (Table 47-4). As mentioned above, all trigeminal neuralgia appears to be secondary to a lesion of the trigeminal sensory system.

Neoplasms
Neurinoma of trigeminal nerve
Meningioma
Acoustic neurinoma
Brainstem glioma
Nasopharyngeal carcinoma
Metastatic tumor
Vascular lesions
Aneurysm of circle of Willis
Arteriovenous malformation
Ectatic basilar artery or branches
Arnold-Chiari malformation
Syringobulbia
Pseudotumor cerebri
Amyloidosis
Sarcoidosis
Syphilis
Dejerine-Sottas disease
Acromegaly
Paget's disease of skull
Scleroderma

TABLE 47-4. Identified causes of secondary trigeminal neuralgia

Multiple Sclerosis

Patients with multiple sclerosis can have classic trigeminal neuralgia, or they can have variants that resemble atypical facial pain. The number of patients with multiple sclerosis in any reported series of patients with trigeminal neuralgia is subject to various selection biases. The literature suggests that less than 0.5% of patients with tic douloureux have multiple sclerosis (2). Females younger than age 45 are the most likely to have tic due to multiple sclerosis. This diagnosis requires the identification of nervous system lesions disseminated in both time and space; if the patient's only symptom is tic douloureux, the diagnosis of multiple sclerosis should not be proposed, regardless of the patient's age.

Neoplasm

It is uncommon for a neoplasm to lead to classic trigeminal neuralgia. A constant pain associated with sensory loss, properly diagnosed as atypical facial pain, is much more common. A small fraction of patients with trigeminal neuralgia have a small benign neoplasm impinging on the trigeminal nerve in the subarachnoid space between the brainstem and Meckel's cave. These are usually meningioma, neurinoma, or cholesteatoma.

Neoplasms intrinsic to the trigeminal nerve or those that impinge on it in Meckel's cavity or further peripherally rarely produce classic trigeminal neuralgia. They are much more likely to lead to a constant, aching pain that is associated with sensory loss and to other cranial nerve involvement.

HERPES ZOSTER AND POSTHERPETIC NEURALGIA (II-4, II-5)

Herpes zoster can involve the trigeminal nerve and can lead to a painful neuropathy. Facial or deep ear pain often precedes the vesicular eruption, and this can lead to a diagnostic enigma for a day or so. If the pain persists after the eruption has healed, the diagnosis of postherpetic neuralgia can be made. This is a trying pain syndrome for both the patient and physician. It is fully discussed in Chapter 22. Ramsay-Hunt syndrome (IASP group II-6) follows herpes zoster infection of the geniculate ganglion. The vesicular eruption occurs on the ear, and the pain is felt within the ear or posterior pharynx.

Anesthesia dolorosa is the neurosurgeon's most dreaded complication of ablative lesions of the trigeminal nerve or its branches. A similar pain syndrome is occasionally seen after spinal rhizotomy, but it is seen more frequently in the trigeminal distribution. The term refers to the complaint of pain in an anesthetic region. It is most commonly noted after surgery for atypical facial pain, but it can occur after surgery for tic douloureux or after traumatic nerve injury. It is rarely reported after ablative lesions for cancer pain in the face. The patient complains bitterly of painful numbness, which can also have burning, stabbing, or aching components. The pain is not triggered and is constant.

Anesthesia dolorosa is more common after lesions that totally denervate a region of the face; partial rhizotomy or careful gangliolysis are much less likely to lead to this complaint than complete rhizotomy or dense sensory loss caused by gangliolysis.

No pharmacologic or ablative surgical treatment is effective for anesthesia dolorosa. Sporadic case reports of success are difficult to corroborate. Electrical stimulation of the thalamus-internal capsule has produced a few good results (see Chapter 101).

NERVUS INTERMEDIUS (GENICULATE) NEURALGIA (II-6)

Nervus intermedius neuralgia is an extremely uncommon pain syndrome in which the patient reports shocklike pains in the distribution of the nervus intermedius, which is the somatic sensory branch of cranial nerve VII. The pain is in every way similar to that of tic douloureux except for its location. Few cases have been reported since the original report by Clark and Taylor in 1909 (46,47).

Etiology

It is presumed that the etiology of nervus intermedius tic is analogous to that of trigeminal tic: cross-compression of the nerve at its central-peripheral myelin junction, a few millimeters from the lateral pons. Jannetta (8) described such a finding and the beneficial results produced by moving the offending vessel.

Symptoms and Signs

The patient complains of intermittent, stabbing, electric shock–like pain deep in the ear. The pain can be triggered by nonnoxious stimulation of the ear canal or can follow swallowing or talking. The patient is pain-free between attacks. Neurologic deficits are absent. The syndrome is always unilateral. Some patients have reported salivation, bitter taste, tinnitus, and vertigo during the pain attacks; perhaps this indicates involvement of central connections of the nervus intermedius or irritation of other components of cranial nerves VII and VIII. Rarely, patients with pain in the trigeminal distribution also have pain in the nervus intermedius territory.

Diagnosis

Geniculate neuralgia can also be caused by herpes zoster (see Chapter 22). The patient with geniculate neuralgia usually has a vesicular eruption on the eardrum and external canal that follows the onset of the pain by 1 or 2 days. The pain is constant and burning and can be readily discriminated from the intermittent stabbing pain of nervus intermedius tic.

Treatment

The medical management of nervus intermedius neuralgia is identical to that of tic douloureux (see Table 47-2). When medications do not control the pain, a surgical procedure is warranted. It is impossible to block the nervus intermedius with local anesthetics, but they can be injected into the glossopharyngeal or trigeminal nerve to establish the fact that these two nerves are not responsible for the pain, leaving, by subtraction, the nervus intermedius as the culprit. When medical management fails, suboccipital craniectomy with exploration of the nervus intermedius is indicated. If an offending vessel is found, it can be mobilized. If no vessel can be identified, the nervus intermedius should be sectioned. This procedure is highly likely to relieve the pain permanently, but when it does not, section of the medial aspect of the descending trigeminal tract is indicated (48).

GLOSSOPHARYNGEAL NEURALGIA (II-7)

Glossopharyngeal neuralgia is characterized by shocklike pains in the territory of the glossopharyngeal nerve. It is in every way similar to tic douloureux except for the distribution of the pain and the customary site of the triggering stimulus (48,49).

Etiology

The vast majority of patients with glossopharyngeal neuralgia are thought to have an artery compressing the nerve as it exits from the medulla and travels through the subarachnoid space to the jugular foramen (50). This syndrome can be seen in patients with multiple sclerosis, but it is rare.

Symptoms and Signs

Glossopharyngeal neuralgia is characterized by excruciating shocklike pain in the region of the tonsillar fossa, pharynx, or base of the tongue. It can radiate to the ear or the angle of the jaw or into the upper lateral neck. The trigger zone is often in the same area, and patients frequently report that swallowing, yawning, clearing the throat, or talking is the precipitating stimulus. The pain often appears to be spontaneous. Chewing or touching the face does not precipitate an attack. Glossopharyngeal neuralgia is much less common than tic douloureux—the incidence ratio is approximately 1 to 100 (49,50).

Diagnosis

The nature of the pain, its description by the patient, and the chronology of the attacks are identical to those of tic douloureux of the trigeminal nerve. Indeed, glossopharyngeal tic is sometimes mistaken for mandibular division trigeminal tic douloureux. Involvement of the glossopharyngeal nerve can be demonstrated by localizing the triggering stimulus to the pharyngeal structures that it innervates. Blocking the trigger area with local anesthetic can confirm the site of the trigger and nerve involvement. This is unsuccessful in some patients because the vagus nerve can contain the involved sensory fibers (35,51). The role of the glossopharyngeal nerve in the regulation of heart rate and blood pressure is thought to be why some patients with glossopharyngeal neuralgia have profound cardiac arrhythmias and even asystole with the attack of pain. The presence of such phenomena guarantees that the pain syndrome involves this nerve. The diagnosis can be confirmed by the cessation of pain when this nerve is blocked at the jugular foramen or when topical anesthesia of the pharynx stops the pain (35).

Treatment

The pharmacologic management is the same as that for tic douloureux of the trigeminal nerve (see Table 47-3). When medical management fails, suboccipital craniectomy with exploration of the glossopharyngeal nerve is indicated. If a compressing blood vessel is found it can be mobilized, and the pain usually stops without any loss of nerve function. When no structural pathology can be identified, the glossopharyngeal nerve should be sectioned. In such a case it is wise to section the upper fibers of the vagus nerve as well, because they can also be involved in the pain syndrome. When rhizotomy is unsuccessful, which happens rarely, the medial aspect of the descending tract of the trigeminal nerve can be sectioned to produce loss of pain and temperature sensation in the pharynx (44).

A percutaneous technique of glossopharyngeal neurolysis has been described, but it has not been widely used because of cardiovascular and laryngeal complications (52,53).

VAGAL AND SUPERIOR LARYNGEAL NEURALGIA (II-8)

The two somatic sensory branches of the vagus nerve, the auricular branch and the superior laryngeal nerve, can also be the site of a pain syndrome that resembles that of tic douloureux. This syndrome is rare (54).

Etiology

It is thought that compression of the upper fibers of the vagal nerve as they leave the brainstem and traverse the subarachnoid space to the jugular foramen is the cause of vagal neuralgia.

Symptoms and Signs

Vagus nerve neuralgia is characterized by paroxysms of shocklike pain in the side of the thyroid cartilage, pyriform sinus, angle of the jaw, and, rarely, in the ear (55). Occasionally the pain radiates into the upper thorax or up into the jaw. The trigger zone is usually in the larynx; attacks are precipitated by talking, swallowing, yawning, or coughing. When other portions of the vagus nerve are involved, the patient might have hiccups, inspiratory stridor, excessive salivation, or coughing. The pain is in every way typical of tic douloureux except for its location. The combination of glossopharyngeal and vagal as well as trigeminal pain has been reported.

Diagnosis

The diagnosis is established by the history and by identifying the site of the trigger zone. Associated vagal nerve findings, as described above, also pinpoint this nerve as the site of the pain. Laryngeal topical anesthesia or blockade of the superior laryngeal nerve stops the pain and is a useful diagnostic and prognostic procedure (35) (see Chapter 102).

Treatment

The pharmacologic treatment of vagal neuralgia is identical to that of tic douloureux (see Table 47-3). When medications do not control the pain, suboccipital craniectomy with decompression of the upper fibers of the vagus nerve is warranted. If no lesion is seen, the upper vagal and glossopharyngeal nerves should be sectioned. This procedure is usually successful, but when it is not, section of the medial portion of the descending trigeminal tract can be beneficial (44).

UNILATERAL ATYPICAL FACIAL NEURALGIA

Unilateral atypical facial neuralgia represents a diverse group of facial pain problems that have common symptoms and signs but varied causes. It is more frequent in females and seems to be a disease of young adults. The pain is rarely as severe as that of tic douloureux. The evidence for successful treatment is sparse; the literature is littered with unsubstantiated hypotheses of etiology and treatment schemes that lack any demonstrable efficacy. Part of the problem is the heterogeneity of this group of patients.

Etiology and Pathophysiology

No uniform etiology of unilateral atypical facial pain has been identified. Some patients are found to have an infection of the paranasal sinuses, jaws, or base of the skull; it is possible that the infectious and inflammatory processes can lead to nerve irritation and damage and thus be the originating factor for the pain. How such a process can lead to a pain syndrome that far outlasts the active phase of the disease process is unclear. A small number of patients are found to have a malignant neoplasm invading the base of the skull and traumatizing branches of the trigeminal nerve at their cranial foramina. Rarely, a benign tumor of the trigeminal nerve or the meninges can lead to atypical facial pain (56). Some neurosurgeons believe that vascular compression of the trigeminal nerve distal to the central-peripheral myelin junction (the site of the compression that seems to cause tic douloureux) can lead to atypical facial pain.

Some patients who sustain clear-cut trauma to the peripheral branches of the trigeminal nerve through facial lacerations and contusions develop an atypical pain syndrome in the territory of the damaged nerve. This type of pain can persist even after the sensory loss disappears.

The vast majority of patients with atypical facial pain do not have any discernible etiologic factors. Interestingly, almost all those in this latter group are young women and seem to have significant psychopathology (57). Many are reported to commit suicide.

Symptoms and Signs

Atypical facial pain differs from classic tic douloureux in every respect. The pain is reported as continuous but can fluctuate in intensity. Pain-free intervals are rarely reported. The pain is usually described as burning, aching, or cramping and not like electric shock, but the occasional patient has some shocks superimposed on the constant pain. The distribution of the pain is often within the trigeminal territory, but it can extend into the upper neck or posterior scalp. The patient frequently reports significant hypesthesia in the area of the pain and can also have allodynia or dysesthesia. The pains are not triggered by remote stimuli but can be intensified by stimulation of the painful area itself. Autonomic phenomena are rarely seen.

Diagnosis

The diagnosis of unilateral atypical facial pain is established when the patient complains of unilateral pain that meets the criteria described above. Unfortunately, not all patients present with such a clear-cut set of symptoms as described here. A few patients have a pain syndrome that combines some features of tic douloureux with some of those of atypical facial pain. An increasing number of reports describe patients with pain syndromes that have some features of cluster headaches or muscle-tension headaches with atypical facial pain. The most accurate diagnosis might actually be a combination of two or more of these syndromes. When a patient presents with unilateral atypical facial pain, the physician must undertake the search for a treatable causative lesion. This entails roentgenograms of the skull, computed tomography scan with particular attention to the skull base, magnetic resonance imaging scan, careful dental and otolaryngologic evaluation, and thorough neurologic examination.

Treatment

Atypical facial pain is difficult to manage, and there are few proven therapies. Because a small percentage of the patients will have a treatable structural lesion, the first step is always the search for pathology. This will usually be fruitless, but does at least reassure the patient that there is no major disease causing the pain. If no lesion can be found, the treatment is symptomatic. Antidepressants are of proven value (58,59). The combination of a tricyclic antidepressant and a phenothiazine has helped some patients (60). The standard dose is amitriptyline, 75 mg at bedtime, and fluphenazine, 1 mg four times a day. The risk of tardive dyskinesia has greatly reduced the use of phenothiazines, however. Other patients might respond to anticonvulsant medications, especially when their pain complaints contain some features of tic douloureux. Table 47-3 lists the commonly used anticonvulsants. One study revealed sumatriptan to be of no clinical value (61); another found negative results for calcitonin (62). Responses to almost every type of drug and nostrum have been reported, but little evidence exists to support the use of vitamins, amino acids, or physical therapies.

Psychotherapy for atypical facial pain has been extensively discussed in the psychiatric and psychological literature. Controlled studies cannot be found, however, and it is difficult to evaluate the role of these types of treatments. Certainly, if the patient has significant psychopathology in addition to the face pain, it is reasonable to use whatever form of psychotherapy that seems most appropriate.

Surgical treatments for atypical facial pain do not have a good track record. Operations that further damage the trigeminal nerve are unsuccessful in most patients and often lead to increased complaints of pain and numbness; a contrary opinion was offered by Ziccardi et al. in a relatively weak study (63). A few reports of the efficacy of trigeminal tractotomy and other ablative lesions of the midbrain, thalamus, and brainstem can be found (64,65). Other reports suggest some success with implanted stimulators of the trigeminal ganglion or thalamus (66). Some successes have also been noted with decompression of the trigeminal nerve in the subarachnoid space distal to the site of cross compression found in tic douloureux. Retrograde suicide axonal transport of doxorubicin (Adriamycin) has been reported to be a successful way of treating atypical facial pain in two patients (67). Generally, patients with unilateral atypical facial pain should not be offered destructive surgical procedures.

BILATERAL ATYPICAL FACIAL PAIN

Bilateral atypical facial pain is a disease with no known etiology. The patient is usually an older female but can be of any age. The pain is described as constant and burning and is not triggered. Sensory examination is either unremarkable or slight hypesthesia, paresthesia, allodynia, or dysesthesia can be found. Identical pains are seen by physicians on the face and intraorally by dentists (“burning mouth syndrome”). Indeed, a similar constant burning pain in the rectal area is also well known. None of these bilateral burning pains has been associated with any structural or physiologic pathology identified to date, and they do not usually respond to any drug, physical treatment, or surgical procedure (61). To the extent that allodynia is present, it is possible that brainstem function has been altered, resulting in abnormal responses to nonnoxious stimuli. There is some evidence that anticonvulsant medications may be helpful in a fraction of the patients (58). The patient often has significant emotional stressors and psychopathology, but how these relate to the pain is unclear (68,69). Psychologic therapies can be useful, but the most important thing the pain management specialist can do is to prevent the patient from undergoing inappropriate drug therapy or surgical procedures. Some have argued that there are specific causes of burning mouth syndrome or bilateral atypical facial pain, but the evidence is weak (70,71).

OCCIPITAL NEURALGIA (II-9)

Occipital neuralgia is characterized by pain in the suboccipital region and in the back of the head. A large number of patients have muscle-tension headaches in the

same distribution, but few of these patients have a true neuralgic pain. Muscle-tension headaches are discussed in Chapter 48.

Etiology

The two broad groupings of patients with occipital neuralgia include those with structural pathology and those with no apparent etiology. Known causes of neuralgic pains in this area include trauma to the greater or lesser occipital nerves, compression of these nerves or the upper cervical roots by arthritic changes in the spine, and tumors involving the second and third cervical dorsal roots. Most patients with occipital neuropathy do not have discernible lesions.

Symptoms and Signs

Occipital neuralgia is characterized by continuous aching and throbbing pain on which shocklike jabs can be superimposed. The pain starts in the suboccipital region and radiates over the posterior scalp and sometimes across the lateral scalp. Retroorbital pain is common in a severe attack. The pain is not triggered, but pressure over the occipital nerves can lead to an exacerbation. Both physical and emotional tension are common precipitating factors. Although textbooks usually distinguish between neuralgic and vascular pains, some patients have a pain syndrome that combines features of both types of pains. Patients with occipital neuralgia can have migrainelike symptoms and can develop autonomic changes similar to those seen in cluster headaches. When the pain is severe, the patient might note hypesthesia or dysesthesia in the posterior scalp.

Diagnosis

The region of the pain clearly establishes the diagnosis; the difficult task is determining whether the nerve lesion is primary or secondary. Vascular pains (migraine in the posterior scalp or cluster headaches in the anterior scalp and face) are usually characterized by discrete attacks of throbbing pain, often associated with nausea and vomiting and other autonomic phenomena. Migraine is often terminated by ergot alkaloids or sumatriptan; neuralgic pains are not.

Muscle tension headaches are a variant of myofascial pain syndrome and are common. They are clearly stress related. The patient usually has a long history of such headaches, which wax and wane over the years. Tender areas in the suboccipital muscles are frequently located by palpation.

Positive findings from neurologic examination lead to the suspicion of a structural lesion; roentgenography, computed tomography scan, or magnetic resonance imaging scan assists in the diagnosis.

Treatment

Obviously, when occipital neuralgia has a structural basis, surgical treatment may be aimed at the cause. In most patients, however, treatment is symptomatic. If the pains resemble those of tic douloureux, a trial of anticonvulsants (see Table 47-3) might be worthwhile. If they resemble those of atypical facial pain, a tricyclic antidepressant can be tried. Local nerve blocks can help to establish the diagnosis and sometimes provide even longer relief than the duration of the agent used. Some have advocated the injection of local anesthetics and steroids, but controlled studies of the outcomes of such treatments have not been undertaken.

Neurosurgeons have advocated decompression or sectioning of the second and third cervical roots as well as the greater and lesser occipital nerves (72). Information on the efficacy of these procedures is lacking; the vast majority of patients do not appear to require a surgical procedure.

SLUDER'S NEURALGIA

Sluder's neuralgia, also known as Sluder's syndrome, sphenopalatine ganglion neuralgia, lower half headache, and lower facial neuralgia, was first described by Sluder (73) in 1908 and later redefined by Eagle (74). This clinical entity is rare (if it exists at all) and is characterized by unilateral facial pain that never extends above the level of the eye and the ear. It is probably a variant of cluster headache and is further discussed in Chapter 48 (75).

Etiology

Sluder (73) suggested that this condition results from spread of paranasal infection, with consequent vasoconstriction, whereas Eagle (74) found swelling of the nasal mucosa and other intranasal pathology that he believed to cause stimulation of the pterygopalatine ganglion. Others have suggested a reflex vasomotor change, and still others believe it is a vasodilator syndrome (73,76,77).

Symptoms and Signs

Pain is said to begin in the root of the nose and to spread to the orbit, causing extreme soreness of the eyeball, nose, upper teeth, zygoma, palate, and pharynx, and even the shoulder and arm. Rhinorrhea, lacrimation, sneezing, photophobia, and salivation often occur, but no trigger point is found. The distribution and duration of pain vary and can simulate those of chronic paroxysmal hemicrania (Horton's histaminic syndrome).

Diagnosis

Eagle (74) believed that the diagnosis was conclusive if the symptoms and signs are relieved by anesthesia of the sphenopalatine (pterygopalatine) ganglion on the affected side. This can be achieved by application of 4% cocaine for 3 minutes or by injection of the pterygopalatine ganglion. The latter is achieved either through the nose or by inserting a needle bent to a 100-degree angle through the greater palatine foramen and then advancing it in a superior and slightly posterior direction along the pterygopalatine canal to a depth of 3.5 to 4.0 cm (47). Repeated blocks can be used to control recurrent attacks. Sluder (73) used alcohol injection to produce prolonged relief, whereas others have advocated resection of the ganglion for the same purpose (47).

Although a number of clinicians still believe that Sluder's neuralgia occurs and use the injection technique for its treatment, many investigators have denied that this syndrome exists as a distinct clinical entity and believe that it is probably a variant of atypical facial neuralgia.

VIDIAN NEURALGIA

Vidian neuralgia, also known as *Vail's syndrome*, was first described by Vail (78) in 1932. It is characterized by severe attacks of unilateral pain in the nose, face, eye, ear, head, neck, and shoulder, which often occur at night. The condition predominates in females. It too may be a variant of cluster headache (75).

Etiology and Pathophysiology

Vail (78) believed that this syndrome is caused by irritation or inflammation of the vidian nerve (nerve to the pterygoid canal) along its course in the pterygoid canal, secondary to infection of the sphenoid sinus. He theorized that this condition is the same as sphenopalatine neuralgia because the irritation of the nerve could extend forward to the pterygopalatine ganglion as well as backward to the geniculate ganglion (facial nerve) through the greater superficial petrosal nerve and from there to the sympathetic plexus around the internal carotid artery.

Diagnosis

A diagnosis should entail a thorough examination to determine if infection of the sinus is present. Block of the pterygopalatine ganglion by application of cocaine or through injection with another local anesthetic is a useful diagnostic and prognostic procedure.

Treatment

If at least four or five prognostic blocks produce complete relief of pain, alcohol injection of the pterygopalatine ganglion can be considered and has been reported to provide prolonged relief in some cases. Obviously, drainage of the sphenoid sinus should be carried out if infection is present. Vail (78) believed that this is essential

for permanent relief. Like sphenopalatine neuralgia, the existence of vidian neuralgia has been questioned by many clinicians.

PETROSAL NEURALGIA

Approximately four decades ago Gardner and associates (79) suggested that abnormal activity of the greater superficial petrosal nerve caused unilateral head pain, lacrimation, edema, rhinorrhea, and other symptoms and signs typical of cluster headache, in some patients. They based this observation on the fact that the greater superficial petrosal nerve contains parasympathetic secretory fibers for the lacrimal gland; vasodilator fibers to the nasal mucosa and cerebral hemisphere; and afferent fibers from the dura mater, internal carotid artery, and pterygopalatine ganglion. Gardner and colleagues (79) sectioned this nerve in 26 patients with the above signs and symptoms and noted excellent results (complete relief) in 25% of patients, fair to good relief in 50%, and failure in 25%.

CHAPTER 48

Headache

K. M. A. Welch

Headache is the most common human malady. Ample evidence exists that the subject was a topic of discussion and a focus of therapy of physicians in ancient Sumer, Babylonia, Egypt, Greece, and Rome (see references 1,2,3 and 4 for reviews of the history of headache). The Ebers Papyrus, written approximately 1550 bc, includes an early Egyptian pharmacopeia that contains a prescription for a mixture of opium to treat Ra's headache. Egyptians also used trephine of the skull to relieve headache. Discussions of headache can be found in the writings of Hippocrates and other Greek physicians, of Celus, Aretaeus, Galen, and other early Roman physicians, of the Arabian physician Abulcasis, and Avicenna during the Middle Ages, and of Paracelsus, Mondini, Vesalius, and others during the Renaissance.

In this chapter, the term *headache* is used for pain felt in or around the cranial vault and includes pain behind the eyes and at the junction between the neck and back of the head. Although pain located in the eyes, nose, face, or jaws often spreads to the head, pain in these areas is discussed in Chapter 49, Chapter 50, Chapter 51, Chapter 52 and Chapter 53.

CLASSIFICATION OF HEADACHE

Before 1988 the classification proposed by the Ad Hoc Committee of the National Institutes of Health in 1962 (5) was the most widely used. These definitions were not operational, but instead short descriptions of the clinical features of each syndrome. The classification and definition system of the International Headache Society (IHS) listed in Table 48-1 (6), although not perfect, now is accepted, at least for research purposes. This classification will be revised early in the twenty-first century.

TABLE 48-1. Classification of headache disorders, cranial neuralgias, and facial pain

Epidemiology

Subsequent to the IHS classification, epidemiologic studies have focused on specific headache types. Consequently, contemporary epidemiologic studies are discussed under the sections dealing with specific headache diagnoses. Most studies before 1988 and the IHS classification suffer from lack of accepted definition of headache diagnosis but remain of general interest related to unclassified headache. Some of these studies are briefly reviewed.

In 1985, *The Nuprin Pain Report*(7) provided a mass of data on the prevalence and severity of headache, the demographic characteristics of headache sufferers, the effect on their lives and work, and how they cope with headache. Table 48-2 is a summary of the data. Among those surveyed, headache occurred 1 to 5 days a year in 30%, 6 to 10 days in 14%, 11 to 30 days in 16%, 31 to 100 days in 8%, and 100 days or longer in 5%. Among those who had headache, nearly one-fifth had it for 6 to 10 days, 22% for 11 to 30 days, 11% for 31 to 100 days, and 7% for 101 or more days. The overall prevalence among the American women (78%) was similar to that among Welsh women (79%) reported by Waters and O'Connor (8), whereas the prevalence was significantly higher among American men and women than among the Finnish population reported by Nikiforow and Hokkanen (9,10). As in both the Welsh and the Finnish findings, the prevalence of headache was lower among those older than 60 years. By a 10% margin, women reported headache more frequently than men. Those with a college education had headache more frequently than those with a high school education, working mothers and advertising executives had headache more frequently than homemakers and those in other occupations, and retired persons had the lowest incidence. No difference in the prevalence of headache was seen between those living in urban and rural areas. Table 48-3 summarizes the profiles of those who had headaches 6 days or more and their ratings of its intensity. Among adults with headache, 638 million workdays were lost among all adults and a total of 157 million workdays among all adults employed full- time. Using 1985 figures, the total cost of headache to the American people likely exceeded $17 billion for that year.

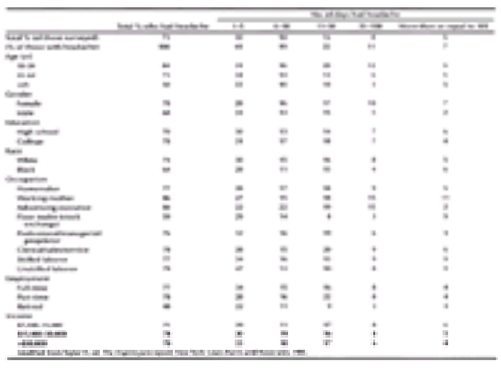

TABLE 48-2. Headache in Americans in 1985

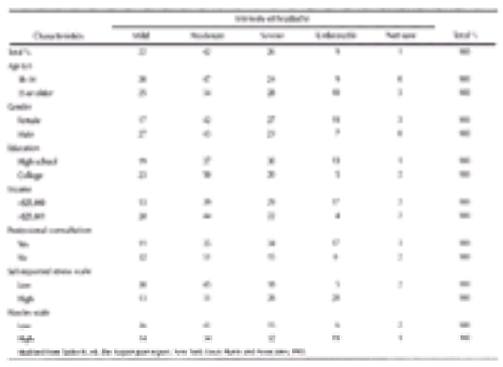

TABLE 48-3. Profiles of Americans who experienced headache in 1985 by intensity (in % of those who experience headache 6 days or more)

ANATOMY AND GENERAL PATHOPHYSIOLOGY

Innervation of the Cranium and Its Contents

Investigations on humans undergoing intracranial surgery under local anesthesia (11,12) have shown that the following structures are pain sensitive: (a) all of the extracranial structures, especially the arteries; (b) the great venous sinuses and their tributaries from the surface of the brain; (c) parts of the dura at the base of the brain; (d) the meningeal arteries and big cerebral arteries at the base of the brain; and (e) the fifth, ninth, and tenth cranial nerves and the upper three cervical nerves. The cranium (including the diploic and emissary veins), the parenchyma of the brain, some of the dura, almost all of the piaarachnoid, and the ependymal lining of the ventricles and the choroid plexus are insensitive to mechanical, thermal, electrical, or chemical stimuli (13).

Stimulation of pain-sensitive structures on or above the superior surface of the tentorium cerebelli causes pain in parts of the head anterior to a line drawn from the ears across the top of the head, whereas stimulation of structures on or below the inferior surface of the tentorium cerebelli generally causes pain behind the aforementioned line, but certain sites may project to the brow or behind the eyes (14). It has been further demonstrated that nociception from the supratentorial structures is mediated by the trigeminal nerve, whereas nociceptive impulses from stimulation of the infratentorial structures are transmitted by afferent fibers in the fifth, ninth, and tenth cranial nerves and the upper three cervical nerves.

The intracranial vessels also are supplied by afferent fibers, which run in the ophthalmic division of the trigeminal nerve and terminate in the trigeminal ganglion. In addition, the arteries are surrounded by dense networks of nerves containing a variety of neuropeptides.

Cranial bones are not pain sensitive, but stretch or other sensation of the periosteum, which surrounds them, evokes pain locally. The scalp, of course, is pain sensitive, as are the arteries that supply it (i.e., the supraorbital, frontal, superficial temporal, posterior auricular, and occipital arteries). The first three arteries are supplied by the trigeminal nerve, whereas the posterior auricular and occipital arteries are supplied by branches of the upper cervical nerves. The external carotid artery and its branches are also supplied by afferent fibers that are a part of the nerve plexuses surrounding these vessels and eventually reach the spinal dorsal horn or the trigeminal nucleus caudalis via the sensory roots of the upper four thoracic spinal nerves or the trigeminal nerve. The nerve fibers containing neuropeptides play a role both in nociception and in the regulation of vascular tone

Reference of Pain

Figure 48-1, Figure 48-2, and Figure 48-3 depict the site of reference of pain on stimulation of various intracranial and extracranial structures. Stimulation of the dura in the anterior fossa (supplied by a recurrent branch of the ophthalmic division of the trigeminal nerve) is referred to the ipsilateral eye, orbital region, and anterior part of the head (see Fig. 48-1). Stimulation of the dura in the middle cranial fossa, or the middle meningeal artery, which is supplied by the second and third division of the trigeminal nerve, causes pain to be referred to the ipsilateral supraorbital region and primarily to the temples and the ipsilateral aspect of the top of the head (see Fig. 48-1 and Fig. 48-2). Stimulation of the dura and the arteries of the posterior cranial fossa (supplied by recurrent branches of the glossopharyngeal and vagus nerves and the upper three cervical nerves) is referred to the ipsilateral ear, posterior auricular region, occiput, and suboccipital region. As noted in Figure 48-3, stimulation of the arteries of the scalp causes pain localized to that region. Pain from the eye, nasal sinuses, and teeth is felt locally at first, but then may be referred to the appropriate division of the trigeminal nerve, with some overflow to adjacent divisions if the nociceptive stimulation is intense.

Figure 48-1. Pain sensitivity of the dural floor of the skull, the tentorium cerebelli, and the adjacent venous sinuses and venous tributaries. *Circles* indicate points of stimulation that do not cause pain. *Black circles* indicate points of stimulation that cause pain. The diagrams show the area of pain after stimulation of (1 to 8) the dura of the floor of the anterior fossa; (9 and 17) the middle meningeal artery; (10 to 12) the dura of the floor of the posterior fossa; (13) the inferior wall of the transverse sinus; (14) the superior wall of the torcular Herophili; (15) the superior wall of the transverse sinus and upper surface of the tentorium cerebelli; and (16) the inferior cerebral veins. (From Wolff HG. *Headache and other pain*, 6th ed. New York: Oxford University Press, 1993, with permission.)

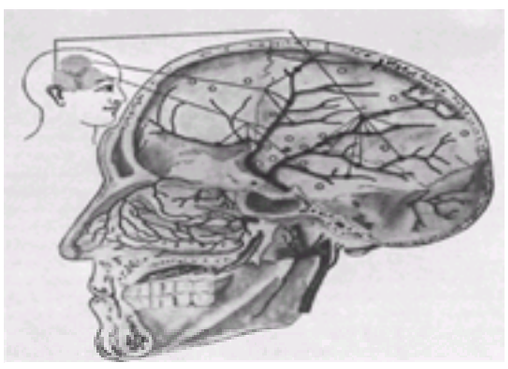

Figure 48-2. Pain sensitivity of the middle meningeal artery. *Open circles* indicate points of stimulation of the dura that do not cause pain. *Black circles* indicate points of stimulation that cause pain. The diagram shows three overlapping areas of pain in the parietotemporal region resulting from stimulation of different portions of the artery and its branches. (From Wolff HG. *Headache and other pain*, 6th ed. New York: Oxford University Press, 1993, with permission.)

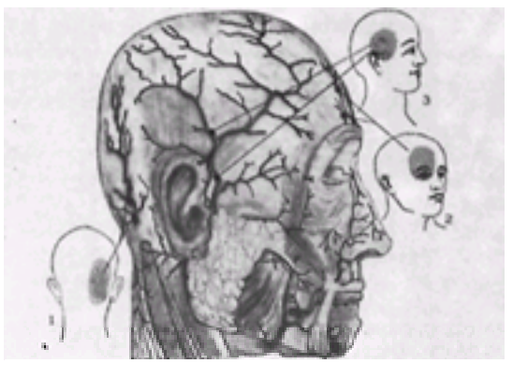

Figure 48-3. Pain sensitivity of the arteries of the scalp. *Black circles* indicate points of stimulation that cause pain. The diagrams show areas of pain following stimulation of (1) the occipital arteries; (2) the supraorbital and frontal arteries; and (3) the superficial temporal artery. (From Wolff HG. *Headache and other pain*, 6th ed. New York: Oxford University Press, 1993, with permission.)

Sympathetic Supply

The preganglionic neuron cell bodies are located in the intermediolateral column of T-1 to T-4 spinal cord segments, inclusively. Their axons course through the anterior nerve root of the upper four thoracic nerves, the white rami communicantes, and join the sympathetic trunk (see Fig. 46-11). Some of these end in the stellate ganglion, whereas others ascend to, and course through, the cervical sympathetic trunk to end in the superior cervical ganglion. The cerebral arteries are supplied exclusively by fibers from the superior cervical ganglion, whereas the extracerebral arteries are supplied partly from the stellate ganglion and partly from the superior cervical ganglion. Although neural control of the cerebral circulation remains controversial, evidence exists that, in some species, sympathetic fibers exert a mild constrictor effect on the cranial arteries that is greater in the external carotid than the internal carotid arterial system. This effect is weakest in the vertebral basilar arteries (14,15).

Parasympathetic Fibers

The parasympathetic fibers have their cell bodies in the midbrain, and their axons course through the facial and greater superficial petrosal nerve to end in ganglia located in the proximity of the anastomosis of the greater superficial petrosal and the internal carotid nerves (see Fig. 46-8, Fig. 46-12, and Fig. 46-13). Here they synapse with postganglionic neurons, the axons of which join and accompany the plexus that surrounds the internal carotid artery to reach and surround the cerebral arteries as far as the small arteries of the pia. Some evidence suggests that these are the efferent pathways for a vasodilator reflex with the trigeminal nerve as its afferent limb (4). This reflex may be responsible for some of the increases in cerebral and extracranial blood flow in painful conditions such as migraine (4).

General Headache Mechanisms

Human studies suggest that headaches can be brought about by (a) displacement, distension, and inflammation of cranial vascular structures including the branches of the external carotid artery and the intracranial arteries; (b) sustained contraction of muscles of the head and neck; and (c) direct pressure on the cranial and upper cervical nerves. Wolff and associates (11,12,14) suggested six basic mechanisms of headaches that arise from intracranial sources: (a) traction on the veins that pass to the venous sinuses from the surface of the brain and displacement of the great venous sinuses; (b) traction on the middle meningeal arteries; (c) traction on the large arteries at the base of the brain and their branches; (d) distension and dilatation of the intracranial arteries; (e) inflammation in or about any of the pain-sensitive structures of the head; and (f) direct pressure by tumors. Often, more than one of these mechanisms is involved in headaches of intracranial origin. Headache from extracranial sources may involve tender muscles of the head and neck, distension or inflammation of extracranial arteries, and pain referred from diseases of the eye, sinuses, and teeth.

EVALUATION OF THE HEADACHE PATIENT

History

To elicit a relevant history from an uncomfortable patient with a severe headache is a challenging task. A quiet, dark room usually helps in this situation. Because most patients with headache do not manifest positive neurologic findings on physical examination, history taking is essential to establish a diagnosis. The clinician may find it of help to ask four key questions in the following order: “How long have you had the headache?' “What do you think caused it?' “Where is the headache located?' and “What is it like?”

Duration, Onset, and Frequency of Headache

Among sufferers who present to a physician with the complaint of headache, three broad categories can be recognized: (a) patients coming to the emergency room with a first-time severe headache with no previous evaluation (they are a high-risk group for serious intracranial pathology); (b) patients with a history of chronic headache but change in the frequency, character, or intensity of the headache; and (c) patients with a chronic paroxysmal headache (e.g., migraine) in attacks occurring at regular intervals.

Information about onset of the headache provides further clues to its possible cause. *Thunderclap* onset may indicate a subarachnoid hemorrhage. If the patient survived, or had more than one such event, this is termed *sentinel headache*. Failure to recognize a sentinel headache should be the fear of every physician. A headache of onset 5 to 6 weeks before the consultation with increasing severity may point to raised intracranial pressure, for example, caused by a brain neoplasm. Awakening with a headache indicates an organic cause and may occur in conditions as varied as obstructive sleep apnea, cluster headache, migraine, hypertension, and cerebrovascular disease. Migraine and tension headaches almost always begin before the fourth decade of life. Before attributing a first-time headache in an elderly person to migraine or tension, more serious conditions should be excluded.

Cause

Knowledge about the precipitating factors of headache is most valuable in focusing the physician toward a particular diagnosis. Headache related to stress, fatigue, hunger, concentration, excitement, ingestion of chocolate, and the use of contraceptive pills or estrogens may support a diagnosis of migraine. Any recent head or neck trauma is an obvious cause for headache. Headache precipitated by activity, straining, blood pressure increase, and sudden head turning may indicate increased intracranial pressure. A first and worst headache during sexual intercourse should alert the physician to the possibility of subarachnoid hemorrhage. A history of fever, ingestion of toxins, caffeine, alcohol, tobacco, or nitrates suggests headache of infectious, chemical, toxic, or metabolic origin. Carbon monoxide poisoning must be considered when several patients from the same location present with a headache.

Location

Headache caused by infratentorial disease is most often localized to the occipital region. Supratentorial pathology usually produces pain in the frontal region. Remember, however, that pain from infratentorial structures may be referred to frontal regions and vice versa. Structural lesions obstructing the flow of cerebrospinal fluid (CSF) circulation in the infratentorial ventricular system also can produce frontal headache secondary to hydrocephalus of the lateral ventricles. Approximately two-thirds of migraine attacks are unilateral, although the location may vary with different attacks. Chronic pain experienced over the vertex or in a bandlike distribution around the head may suggest tension-type headache. A severe, pulsatile, retroorbital pain may suggest cluster headache, inflammatory lesions of the orbital structures, or an expanding aneurysm around the circle of Willis. Some other considerations concerning headache localization are listed here: (a) A headache that presents unilaterally and progresses over time to become bilateral may be caused by increasing intracranial pressure. (b) Lesions that cause traction on the falx or midline structures may cause pain in either eye. (c) Cerebellopontine angle tumors produce pain behind the ear and lesions involving the lateral sinus result in pain

deep in the ear.

Character

The character and intensity of pain are qualitative judgments made by the patient and are only occasionally helpful in making the diagnosis. In this regard, specific information on the increasing or decreasing severity of the headache becomes important. A steady, generalized pain increasing over several weeks may indicate increased intracranial pressure. Bending, stooping, coughing, defecation, or sexual intercourse enhances this type of headache. Headache of a pulsatile nature (corresponding to the radial/carotid pulse) is highly suggestive of vascular origin, whereas a throbbing pain is less specific. Sharp, lancinating, or a deep boring pain, when localized behind the eye, may suggest cluster headache. A stabbing, ice pick–like pain in the distribution of the fifth cranial nerve indicates trigeminal neuralgia. A constant vicelike gripping pain, or a dull pressure pain, may indicate muscle contraction headache.

Associated Symptoms

A sudden, severe headache with loss or alteration in consciousness or a drop attack should be taken as a sign of potentially serious intracranial pathology. Symptoms of paresis, paralysis, ataxia, or sensory disturbance associated with a headache indicate structural lesions. Visual symptoms are frequently associated with an acute headache and are helpful in formulating a differential diagnosis. A scintillating scotoma, photophobia, hemianopsia, and teichopsia occur as a part of the migraine aura. Raised intracranial pressure associated with a headache and papilledema may manifest as a rapid and progressive loss of vision with a centrocecal scotoma. Persistent field defects are a serious complication of temporal arteritis. Extracranial cerebrovascular disease may present with a headache and amaurosis fugax. Vomiting may accompany a severe migraine headache and may occasionally alleviate it. Projectile vomiting is classically associated with increased intracranial pressure. Vomiting may be a symptom of other systemic conditions likely to be associated with headache, such as fever, heat-related illness, and allergic reactions.

Physical Examination

Although history contributes greatly to diagnosing the cause of a headache, positive findings on the physical examination can make the difference between initiating emergent treatment versus nonemergent, routine outpatient workup. Examination should start with a review of the vital signs. Fever always mandates a search for meningitis, encephalitis, or brain abscess. Mild increases in blood pressure and heart rate are a normal physiologic response to pain. True hypertensive headache does not occur until the diastolic blood pressure is above 130 mm Hg. Blood pressure is often elevated as a secondary mechanism in cases of cerebral edema or acute stroke. Tachypnea may be present in conditions such as an exacerbation of chronic obstructive pulmonary disease and severe anemia.

Next, a general impression of the patient should be obtained through his or her appearance and response to pain. Most patients with headache lie still with eyes closed, unwilling to talk or move. Patients with meningeal irritation from any cause may exhibit extreme restlessness. Signs of any external trauma and head injury may be visible at first sight. Most pain-sensitive structures of the head and neck can be viewed directly or palpated. Palpating or tapping can easily discover local sources for pain over sinuses, teeth, and neck musculature. Tenderness overlying the superficial temporal artery is the hallmark of temporal arteritis. Tenderness of the internal carotid artery occurs in carotidynia. Infections in the head and neck often cause tender lymphadenopathy. An enlarging lymph node in the region of the occipital canal may entrap the occipital nerve and cause severe ipsilateral hemicranial pain. Tolosa-Hunt syndrome or painful ophthalmoplegia may be linked to enlarged tubercular nodes in the neck. In a patient with trauma, a boggy mass under the temporalis muscle is the site of a ruptured middle meningeal artery and an intracranial, extradural hematoma. Trapezius muscle spasm may be the primary cause of a muscle contraction headache or occur secondarily as a result of severe head pain of a different etiology. Always test for nuchal rigidity. It indicates meningismus caused by meningitis, encephalitis, severe cervical spondylosis, or a subarachnoid hemorrhage.

Ophthalmologic examination should seek the presence of redness, corneal clouding, and ciliary flush of iritis seen in glaucoma. A Tono-Pen can be used to easily measure the intraocular pressure. If untreated, glaucoma can rapidly progress to blindness. Errors of refraction rarely cause a headache. In the ear, look for signs of infection or cholesteatoma, which may erode intracranially, causing a brain abscess. Presence of hemotympanum or blood in the external auditory meatus suggests a basilar skull fracture as a result of head trauma. Listen over the carotid arteries for bruits of atherosclerotic origin and over the eyes and head for bruits of arteriovenous malformations. Dermatologic examination should look for the typical skin lesions of herpes zoster. The skin over the temporal arteries may be swollen or inflamed. Look for needle tracks or skin popping as evidence of intravenous drug abuse.

Neurologic Examination

Every patient with a headache should have a complete neurologic examination. Start by assessing the higher cortical functions and conscious state. Altered mentation and confusion are signs of serious intracranial pathology. Cranial nerve abnormalities are most frequently encountered in the ocular systems. Funduscopic examination should look for spontaneous venous pulsations, which suggest normal intracranial pressure. The pupil should not be dilated because this can either mask preexistent anisocoria or precipitate angle closure glaucoma in patients with a narrow angle. Papilledema, when present, is usually bilateral and points to increased intracranial pressure. With hypertensive emergencies, the fundus may show acute hemorrhages and exudates. Retinal and subhyaloid hemorrhages are virtually diagnostic of subarachnoid hemorrhage. Scotomas of hemianopic field defects may indicate less common causes of headache, such as a brain tumor, arteriovenous malformation, or expanding aneurysm. Bitemporal field defect in a patient with severe frontotemporal headache can be caused by an expanding pituitary adenoma. Unilateral ophthalmoplegia with sensory loss in the first division of the fifth cranial nerve in association with unilateral retroorbital headache may be caused by a superior orbital fissure syndrome, painful ophthalmoplegia, or Tolosa-Hunt syndrome. Ophthalmoplegic migraine is a rare syndrome. Unilateral third nerve or bilateral sixth nerve palsies are frequently related to aneurysms of the cerebral vasculature or increased intracranial pressure. Unilateral Horner's syndrome and headache may indicate carotid arterial dissection. Miosis together with excessive sweating may indicate posttraumatic dysautonomic cephalgia. Ischemic or hemorrhagic cerebrovascular disease may present with a headache, visual field defects, and motor weakness.

Diagnostic Evaluation

In the vast majority of headache patients the diagnosis can be made without a laboratory examination. When the history and physical examination lead to suspicion of disease, further neurodiagnostic tests are indicated. Laboratory studies (e.g., complete blood count, electrolyte profile) depend on underlying medical problems or search for secondary causes of headache. For example, in all patients over the age of 50 years in whom the diagnosis of temporal arteritis is suspected, an erythrocyte sedimentation rate should be ordered. As another example, carbon monoxide level or toxicology screen may be ordered in an emergency room setting. In the absence of focal neurologic deficits or papilledema it is safe to directly proceed to a lumbar puncture. Computed tomography (CT) scanning is commonly used in diagnosis, especially in the evaluation of headache in the emergency setting. Magnetic resonance imaging (MRI) is the most sensitive to structural disease causing secondary headache.

PRIMARY HEADACHES

Migraine

Migraine is the most important type of headache because of its frequency and severity. The term *migraine* evolved from the original Greek *hemikranios*, which the Romans translated into Latin as *hemicranium*. Galen introduced the term *hemicrania* to describe this type of headache. The term *hemicrania* remained in use throughout the Middle Ages and Renaissance and was used as a title of several books; in 1660, Van der Linden published a monograph *De Hemicrania Menstrua*, and a century later, Fordyce published *De Hemicrania*. Subsequently, the term was corrupted into lower Latin as *hemigranea* and *migranea*, which was translated into old English *mygrane* or *megrim*. This term was used by Liveing in his comprehensive treatise *On Megrim, Sick Headache and Some Allied Disorders*, published in 1873 and containing summaries of reports on the etiology, symptoms and signs, and therapy of headache reported by numerous other writers (16). In this book Liveing continued the debate as to whether migraine was vascular or neurogenic by stating that migraine was analogous to epilepsy and that the circulatory phenomena that occurred during the attacks were secondary to CNS discharges or “nerve storms,' views shared by Jackson and Gowers. The French term *migraine* gained widespread acceptance in the eighteenth century and has been used ever since. The term *migraineur*, derived from the French *migraineux*, denoting a migraine sufferer, is also common.

Classification

The classification adopted by the IHS has replaced classic migraine with the term *migraine with aura* and common migraine with the term *migraine without aura*. Migraine without aura is an idiopathic chronic headache disorder manifesting in attacks lasting 4 to 72 hours and characterized by headache that is unilateral, has a

pulsating quality, is of moderate or severe intensity, is associated with nausea or photophobia or phonophobia, and is aggravated by physical activity. In migraine with aura (classic migraine) these symptoms are accompanied by attacks of neurologic symptoms localized to the cerebral cortex or brainstem. The neurologic symptoms usually develop gradually over 5 to 20 minutes and last less than 60 minutes. Headache, nausea, photophobia, and phonophobia usually follow the neurologic aura directly or after a headache-free interval usually less than 1 hour. In some instances the headache phase might be completely absent (*migraine sine hemicrania*). As noted in Table 48-1, migraine with aura is further classified into subgroups including migraine with typical aura, migraine with prolonged aura, basilar migraine, migraine aura without headache, and migraine with acute onset aura. The classification also distinguishes the aforementioned types of migraines from ophthalmoplegic migraine, retinal migraine, migraines associated with intracranial disorders, and the group labeled possible precursors of migraine. Specific diagnostic criteria are also included in the IHS classification.

Epidemiology

Epidemiologic studies have provided estimates that, in the United States, migraine occurs in up to 18% of women and 6% of men; one-third is severely disabled or require bed rest during an attack (17). The peak prevalence occurs between the ages of 30 to 45, after which the prevalence declines. In children, the prevalence is 2.5% (7 to 9 years), 4.6% (10 to 12 years), and 5.3% (13 to 15 years). The overall prevalence of migraine with aura is approximately 4%, distinctly less than the prevalence of migraine without aura in women and approximately equal in men (18). Because of the sex differential, migraine is uncommon after the age of 45 in men, but remains common in women into the menopausal years and beyond. Although long thought to be a disorder of the highly intelligent or the upper social classes, migraine is in fact more prevalent in lower income groups (17). Possibly, this is caused by poor diet, stress, inadequate medical care, or else disabling migraine results in low income groups by disrupting education and occupation. Eight percent of male subjects and 14% of female subjects may miss all or part of a day of work or school in any 1 month (19). The estimates of cost of lost productivity in the United States range from $1.2 to $17.2 billion (19). Fifty percent of migraine sufferers account for 90% of the work lost (20).

Pathophysiology

The mechanisms of migraine remain to be determined. We review the relevant evidence and general hypotheses for the aura and migraine susceptibility, culminating in a synthesis of contemporary views.

Migraine Attack

Aura-Cerebral Vasospasm. Migraine, according to the theory of Wolff (21), was a primary defect of CNS vasculature. He postulated that the neurologic features of the aura were caused by vasospasm producing ischemia. Subsequently, brain acidosis caused cerebral vasodilation, which was painful. Points put forward in favor of the vascular concept were that the headache associated with migraine has a pulsating quality similar to the headaches secondary to stroke, arteritis, and hypertension. Also, blood vessels are predominantly the pain-sensitive structures in the brain. The drugs used to treat migraine produce vasoconstriction (e.g., ergotamines). Vasodilation (e.g., 10% carbon dioxide and 90% oxygen) was considered to prevent headache and abort the aura by increasing blood to brain regions undergoing vasospasm. Methysergide, a serotonin antagonist, prevents vasospasm induced by serotonin; because it is highly effective in preventing migraine, this linked serotonin release to triggering the attacks of vasospasm and hence aura.

This model of vasospasm giving way to vasodilation to explain both the aura and headache still has its supporters. Cerebral blood flow (CBF) measurements performed by earlier methods certainly supported this notion, and a critical appraisal of more recent CBF studies argues in favor of a primary ischemic basis for the aura (22). Nevertheless, the clinical features of the aura are distinctly unlike those of acute ischemia caused by cerebral vascular disease. For this and other reasons discussed later, this hypothesis is currently less favored than others.

Aura-Spreading Depression. In 1944, Leao reported an experimental phenomenon in rodent brain and retina that has come to be known as spreading depression (SD) (23), although it could also be termed spreading activation. Neuronal depolarization is followed by suppression of neuronal activity in a wave that spreads slowly across the surface of the brain. Two mechanisms have been proposed for SD, one based on the release of K^+ from neural tissue (24) and the other on release of the excitatory amino acid glutamate (25). Neural tissue may possess both mechanisms. Glutamate release from dendrites or soma of neurons depolarizes adjacent neurons that release additional glutamate, thus propagating SD. An increase of extracellular K^+ produces a similar train of events. Glutamate-induced SD is blocked by Mg^{2+} (25). The glutamate-induced Mg^{2+}-sensitive SD apparently propagates twice as fast as the K^+-induced Mg^{2+}-insensitive SD. Glutamate SD can be blocked by competitive and noncompetitive *N*-methyl-d-aspartate receptor antagonists.

The migraine aura, exemplified by an expanding visual scotoma (a suppressive, negative symptom) with preceding peripheral scintillations (a stimulative, positive symptom), was proposed as the clinical counterpart of SD years ago (26). Based on clinical observations and investigative studies, SD is now considered by most as a plausible explanation for the migraine aura (27). Investigation of this model in humans, however, remains far from complete and has not yet served to establish SD as the mechanism of aura. Most investigations have been limited to the indirect measure of blood flow, facilitated in migraine subjects by the development of noninvasive imaging techniques. CBF decreases, but only to oligemic values in posterior regions of the cortex in some patients during attacks of migraine with aura (28). During these studies it was also noted that the regional hypoperfusion developed before and outlasted the focal symptoms. Focal hyperemia, possibly related to neuronal depolarization, was also seen initially, followed by spreading oligemia (29). The oligemia was thought to be secondary to neuronal suppression, which progressively involved larger areas of the brain spreading at a rate similar to experimental SD (30). For the most part these CBF changes have been demonstrated in migraine with aura and not in migraine without aura. Also, these early studies were performed on migraine induced by cerebral arteriography.

One well-studied case report of dynamic blood flow measurements with positron-emission tomography and oxygen-15– labeled water demonstrated bilateral hypoperfusion that started in the occipital lobes and spread anteriorly (31). In this case, the patient had migraine without aura, suffering only minor visual blurring well into the attack of headache when CBF reduction was well established. This illustrated that migraine with and without aura could share a similar pathophysiology. Patients with spontaneous migraine with aura imaged with diffusion-weighted and perfusion-weighted MRI during the aura phase and during the headache phase had (20% to 37%) decreases in regional perfusion and (1.5% to 15%) regional cerebral blood volume (32). They had no change on diffusion-weighted imaging. Headache phase imaging did not reveal any consistent perfusion abnormalities. This supported the concept that the hypoperfusion seen in migraine aura may not be secondary to ischemia but to primary neuronal dysfunction. Most recently, Cao and associates (33) documented spreading suppression of neuronal activation during the early minutes of the aura and headache, made possible for the first time by using functional MRI.

Why, then, are some migraines not preceded by focal neurologic symptoms (i.e., migraine without aura) (34)? Although CBF is decreased in a spreading fashion in both migraine subtypes, it may require a certain threshold to produce symptoms in migraine with aura but not migraine without aura. (This is problematic to prove with CBF measures alone.) Alternative explanations include uncoupling of CBF from neuronal metabolism in some cases, spreading endothelial constriction, or spreading glial dysfunction with secondary neuronal dysfunction and consequent CBF reduction.

The most appropriate techniques to indicate SD are electrophysiologic, but because of limitations of EEG techniques, spontaneous SD has not been recorded previously in migraine sufferers. Okada and colleagues (35) reported biphasic, slow magnetic waves outside flattened isolated turtle cerebellum in which SD was produced by electrical stimulation and confirmed by electrocorticography. We have now used this technology to determine whether similar magnetic activity arises spontaneously in the migraine brain. We believe that DC magnetoencephalographic activity that we have observed supports SD occurring during an attack (36). Long-duration DC shifts and suppression of neuronal signals occur during the migraine aura and headache that were not found in patients with other forms of headache or in normal subjects. The DC shifts and neuronal symptoms are consistent with SD measured by electrocorticography and magnetoencephalography in experimental animals (37).

Headache, Trigeminovascular

The first, most convincing animal model of head pain was developed by Moskowitz in the rodent. This preparation involves electrical stimulation of the trigeminal ganglion with measurement of CBF or plasma extravasation in the dura mater. The resultant local release of peptides from sensory axons (involving an axon reflex) of the trigeminal nerve supply to certain extracranial arteries, meningeal tissues, dural arteries, and the dural sinuses sets up a pain-sensitive state (neurogenic inflammation) and promotes local vasodilatation, a state postulated to resemble that in pain-sensitive cranial structures during headache of the migraine attack (38). In support of this model, calcitonin-gene–related peptide is released into jugular venous blood during a migraine attack (39), and this release is blocked by sumatriptan (40). Sumatriptan is a selective agonist of the D subtype of 5-HT_1 receptors located on peripheral trigeminal nerve terminals that supply pain-sensitive vascular and meningeal structures. It has the same degree of affinity and selectivity for the subtype of 5-HT_1 receptors located on intracranial vessels, where it mediates contraction, particularly of large arteries. In the model, sumatriptan, acting presynaptically, blocks the neuropeptide-mediated inflammatory response after trigeminal

stimulation and may also block transmission in trigeminal neurons (38). The direct vasoconstrictive action of sumatriptan may be another mechanism by which this drug alleviates headache (41). A good deal of interest in this model attempts to find antimigraine drugs that are more selective, either on the 5-HT $_{1D_a}$ (predominantly neural) or 5-HT$_{1D_b}$ (predominantly vascular) receptor subtypes in the hope of avoiding vasoconstrictor side effects of the drugs. This should also provide insight into the critical mechanism for head pain, vasodilation or neuronal. Similarly, the 5-HT $_{1F}$ receptor is selectively distributed on neurons. Although agonists of the receptor have been in clinical trial, no published data support the effectiveness of this therapeutic approach, which if positive would substantiate the predominate neural origin of migraine pain.

Headache, Sagittal Sinus/Brainstem

A refinement of the trigeminovascular model involves a more specific stimulus to the sagittal sinus in the cat (42). This model allows electrophysiologic monitoring of activated neurons in the brainstem as well as identifying the same neurons by the c- *fos* technique. The model was validated by monitoring the increase of calcitonin gene-related peptide into the cranial circulation during sagittal sinus stimulation. The value of this model has been accentuated by a need to understand the function of brainstem nuclei that process nociceptive stimuli. Several observations have stimulated this approach. First is the observation that dihydroergotamine, a 5- HT $_{1D}$ agonist that is effective against migraine pain, passes the blood–brain barrier and binds to brainstem nuclei especially the dorsal raphe (43). Second, Weiller and colleagues (44) investigated whether the activation of brainstem nuclei could be visualized with positron emission tomography during acute attacks. Nine patients suffering from migraine without aura were studied within 6 hours of the onset of untreated migraine symptoms. Three regional CBF measurements were taken: (a) during the attack; (b) after relief of symptoms with sumatriptan subcutaneously; and (c) during the headache-free interval. During the acute migraine attack compared with the headache-free interval, regional CBF was greater in medial brainstem structures. This increase in regional CBF persisted even after complete symptom relief. This finding indicates that the change in regional CBF is not caused by pain or activity of the endogenous antinociceptive system but may be inherent to the migraine attack itself, possibly reflecting a brainstem headache generator. The identification of discrete brainstem nuclei was beyond the resolution of the positron emission tomography camera. However, the area of maximum increase coincided in the Talairach atlas, with the anatomic location of the dorsal raphe nuclei and locus coeruleus. Those areas are involved in antinociception and intracerebral vascular control, making them likely candidate foci for the many facets of migraine.

In sum, the SD model appears the most plausible to account for the aura and that the trigeminovascular and the sagittal sinus/ brainstem models complement and extend each other as headache models. The challenge is to establish how the mechanisms of the aura and the headache are linked.

Interictal Mechanisms

The concept that the migraine attack originates in brain and can be triggered by various factors under various conditions argues in favor of a threshold that governs the triggering of attacks. The nature of this final common pathway with which these factors interact probably constitutes the true cause of migraine.

Brain Hyperexcitability

Previous neurophysiologic, CBF, and brain metabolic measures have suggested neuronal and neurovascular instability between migraine attacks and have been reviewed elsewhere (45). Enhanced excitability of occipital cortex neurons has been proposed as the basis for the spontaneous or triggered onset of the migraine aura (46). Clinical studies of visual discrimination demonstrated that migraine sufferers had a greater sensitivity for low-level visual processing between attacks (47). But, to date, neurophysiologic evidence for hyperexcitability of occipital cortex between attacks is both limited and controversial. For instance, some studies have demonstrated differences in the amplitude of the visual-evoked responses in migraineurs compared with controls (48,49 and 50), whereas others found no abnormalities (51,52). The development of transcranial magnetic stimulation, however, has provided a new opportunity to noninvasively and more directly investigate brain cortex physiology and excitability (53,54 and 55). Indeed, migraineurs already have been investigated using transcranial magnetic stimulation, although only the motor cortex was examined (56,57). All three studies reported a lowered threshold for motor-evoked potentials in migraineurs compared with healthy subjects, supporting an increase in excitability of the motor cortex. We have used transcranial magnetic stimulation to evaluate occipital cortex excitability in migraine with aura. Our results confirmed that the threshold for observing phosphenes in migraine with aura subjects was lower than in controls (58). Furthermore, one patient who developed aura had the lowest stimulation threshold for eliciting sensory experiences among all subjects. To the best of our knowledge, this is the first, most direct neurophysiologic evidence confirming that the excitability threshold of the occipital cortex in migraine sufferers is low compared with healthy subjects, thus strongly indicating that the occipital cortex neurons can be hyperexcitable in this condition.

Abnormalities have been reported in migraine sufferers that could account, alone or in combination, for neuronal hyperexcitability. These are reviewed in the following sections. They include mitochondrial defect, disturbance in magnesium metabolism, and a calcium channelopathy.

Mitochondrial Defect. Migrainelike attacks occur in patients with mitochondrial encephalomyelopathies [mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like syndrome (MELAS)] in which disordered cellular energy metabolism is caused by a defect in mitochondrial metabolism. Dvorkin and colleagues (59) have described cases that they considered to be closely related to mitochondrial encephalomyelopathy with migrainelike episodes (usually with aura), seizures (benign at first, progressing to malignant), and stroke, particularly in the posterior cerebral artery territory. The authors postulated that a brain and generalized mitochondrial abnormality might be present in all cases and in vascular smooth muscle to account for the strokelike findings in their cases. MELAS also has been reported without stroke in a large family who had members with frequent migraine attacks (60). Mosewich and colleagues (60) described 12 patients from three generations in a family carrying the tRNA Leu (UUR) point mutation at position 3243 in mitochondrial DNA, known to be associated with MELAS. The family members had various combinations of sensorineural hearing loss, retinal pigmentary degeneration, migraine, hypothalamic hypogonadism, and mild myopathy. It was not stated whether the headaches were with or without aura or if they fulfilled IHS criteria. There was significant overlap between the MELAS and other forms of mitochondrial myopathy (e.g., Kearns-Sayre syndrome, myoclonus epilepsy with ragged red fibers, and progressive external ophthalmoplegia). In this family, migraine represented a common symptom of the underlying disease process that plagued successive generations. Although the exact relationship between migraine, stroke, and seizures in MELAS is unclear, the presence of the same point mutation in every affected member strongly suggests an association of these features with the mitochondrial defect.

Mitochondrial DNA analysis from a patient with recurrent migraine-related strokes revealed a DNA deletion (61) previously known to be associated with mitochondrial dysfunction. This patient also had evidence of brain cortical energy metabolic defect. Furthermore, in the family with MELAS and migraine who were referred to earlier (60), 6 of 12 had evidence of mutant mitochondrial DNA in blood or muscle or both.

Investigative studies using ^{31}phosphorous magnetic resonance spectroscopy (^{31}P MRS) have provided evidence of mitochondrial abnormality in platelets and muscle and have shown disordered cerebral cortex energy metabolism in migraine with aura subjects (62,63 and 64). The most recent studies of 12 migraine with aura subjects reported by Barbirolli and colleagues (63) have documented low brain phosphocreatine content in all subjects between attacks in the presence of high adenosine diphosphate, high Vmax for adenosine triphosphate (ATP), and a low phosphorylation potential, all features of unstable cerebral energy metabolism. Nine of the 12 patients also had abnormal muscle energy metabolism, considered to reflect mitochondrial dysfunction. We had previously reported a decreased phosphocreatine to inorganic phosphate ratio (an index of phosphorylation potential) and elevated inorganic phosphate in brain cortex between attacks in nine migraine patients with and without aura (62). Thus, two separate laboratories now have provided evidence for disordered energy metabolism between attacks of migraine, possibly caused by mitochondrial dysfunction. A study by Uncini and colleagues (65) also demonstrated altered energy metabolism in extraneural (muscle) and neural tissue via MRS in a kindred of familial hemiplegic migraineurs, suggesting a multisystems disorder of mitochondrial function.

Imaging metabolism during migraine attacks has been carried out only infrequently. Welch and colleagues (62) used ^{31}P-MRS to determine pH during migraine attacks. ^{31}P-MRS reliably determines pH *in vivo*, and some theories of pathogenesis implicate brain ischemia as the metabolic factor causing the neurologic deficits during the migraine attack. No significant differences in brain pH were found among healthy controls, migraineurs during the headache attack, and between attacks. It was concluded that without a shift of brain pH to acidosis, brain ischemia was excluded as a pathogenic event of the migraine attack. The studies demonstrated ictal loss of high- energy phosphates in the setting of normal pH, however, indicating energy failure in the brain not resultant from altered CBF but possibly from SD.

A primary disorder of mitochondria leads to cellular ionic inhomeostasis by impairment of the Mg^{2+}-sensitive Na^+/K^+ ATPase, which controls the active sodium pump, and by dysfunction of the Mg^{2+}-sensitive ATP-dependent Ca^{2+} pump. Mitochondrial membrane permeability itself further increases cytosolic Ca^{2+} (66) and secondarily increases the permeability of plasma membranes. Cells become loaded with Ca^{2+} and Na^+ and lose K^+ and phosphorous to cause relative depolarization of cell membranes. Thus, brain neurons may become primed for the triggered depolarization that may initiate SD and migraine aura.

Magnesium. A mitochondrial metabolic defect, if it is important in migraine, could be primary or secondary. Magnesium is among a number of systemic metabolic factors that influence mitochondrial function and is discussed here. An increasing body of evidence supports systemic and brain Mg^{2+} deficiency in migraine sufferers

(45). During a migraine attack, there is an approximately 20% decrease in brain Mg^{2+} that we have reasoned must be the case before the onset of the attack (67). However, with the exception of cases of familial hemiplegic migraine (FHM), we have been unable to document low free Mg^{2+} in brain cortex between attacks. This is not unexpected or incompatible with a low magnesium state. The CSF and brain are well buffered from fluctuations in the systemic concentrations of Mg^{2+} by the blood–brain barrier and blood–CSF barrier. CSF Mg^{2+} levels are maintained within narrow limits by an active transport system that moves Mg^{2+} from the plasma to the CSF. The carrier acts at well-below-normal levels of plasma Mg^{2+} but may desaturate after prolonged hypomagnesemia, presumably because it can no longer replenish losses. Thus, a threshold must exist whereupon a sudden further decrease in systemic Mg^{2+} levels (e.g., during acute stress) (68), superimposed on marginal systemic Mg^{2+} deficit, could deplete brain Mg^{2+} levels. As noted previously, we have reported a low occipital cortex Mg^{2+} in subjects with FHM (69).

Magnesium is among a number of systemic metabolic factors that influence energy metabolism and mitochondrial function and an integral part of the structure of cellular and subcellular membranes with the major function of providing membrane stability. Thus, Mg^{2+} deficit can (a) result in abnormality of mitochondrial oxidative phosphorylation; and (b) cause an instability of neuronal polarization, two features that appear to be characteristic of migraine. Neuronal hyperexcitability could be the result of Mg^{2+} deficiency or a defect in mitochondrial metabolism, or both, and could predispose the brain to the spontaneous initiation of SD or its activation by migraine trigger factors.

Channelopathy. From patients with FHM, Ophoff and colleagues (70) have isolated, on chromosome 19p13.1, a gene encoding the a_1-subunit of a brain-specific voltage-gated P/Q-type neuronal calcium channel (CACNL1A4). Four different missense mutations were identified in five unrelated FHM families. The investigators also detected premature stop mutations predicted to disrupt the reading frame of CACNL1A4 in two unrelated patients with episodic ataxia type 2. Thus, FHM and episodic ataxia type 2 can be considered as allelic channelopathies but of differing molecular mechanism, the former involving a gain of function variant of the Ca^{2+} channel subunit and the latter a decrease in channel density. The mutation in the gene for this particular Ca^{2+} channel in FHM is exciting because it is brain specific. The finding has served to place at least one form of migraine alongside other episodic disorders such as episodic ataxia type 2, hyperkalemic periodic paralysis, and episodic myotonias that are now identified as ion channel disorders.

The breakthrough in establishing the cause of FHM was achieved during the clinical investigation of CADASIL (cerebral autosomal dominant arteriopathy with subcortical leukoencephalopathy and stroke) (71). This disease is inherited in an autosomal dominant pattern and is characterized by recurring small deep infarcts, dementia, and leukoencephalopathy (71). Some patients also experience recurrent attacks of severe migrainelike headache with aura symptoms that include transient hemiparesis. Joutel and colleagues (72) published a report of two large family pedigrees of FHM, one with cerebellar signs and the other without. Linkage analysis was performed with a set of DNA markers spanning the most probable location for CADASIL, which was mapped previously by them to the short arm of chromosome 19. FHM did indeed map to chromosome 19, the location for the gene being a 30-cM interval between D19S216 and D19S215, which encompassed the probable position of the CADASIL locus.

Since this report, the same French group identified ten different missense mutations in the *Notch 3* genes of 14 unrelated families with CADASIL (73). The *Notch* genes are intimately involved in intercellular signaling during development. Proteins belonging to the *Notch* family are transmembrane receptors. Nine of the ten mutations either added or mutated a cysteine residue in one of the epidermal growth factor–like repeats; epidermal growth factor–like motifs are to be found in the extracellular domain. It is likely that this mutation strongly affects protein conformation, although how this leads to CADASIL remains to be established. Possibly, though, membrane instability and abnormality of cell signaling could be the underlying basis of the migraine attacks in this disorder. Thus, both appear to have mutations that could result in abnormal neuronal excitability. Missense mutations in the gene encoding the a_1- subunit of the presynaptic voltage gated P/Q type neuronal calcium channel (CACNL1A4), perhaps involving a gain of function variant of the Ca^{2+} channel subunit, would likely influence presynaptic neurotransmitter release, possibly of excitatory amino acid systems or inhibitory serotonergic systems (74), leading to postsynaptic neuronal excitability. The calcium channel abnormality also may explain our ^{31}P-MRS observations of low free Mg^{2+} in the occipital cortex, because Mg^{2+} may be fixed in the receptor that it gates for voltage-dependent Ca^{2+} permeability.

It remains to be seen if these findings can be extended to other subtypes of migraine, which would establish yet another episodic neurologic disorder as a channelopathy. It must be noted that cases of non-FHM studied by Ophoff and colleagues failed to show mutations. Also, the same group has suggested that chromosome 19 is the locus for migraine with and without aura (75), but review of other studies suggests that this may be controversial (76). Furthermore, the distribution of the abnormal calcium channel identified is densely cerebellar (77), a structure not obviously involved in the initiation of a migraine attack. This point is of interest, nevertheless, in view of the occurrence of cerebellar atrophy in a small number of FHM families (78). It is tempting to speculate that cerebellar atrophy might be explained by abnormal release of excitatory amino acids such as glutamate, which has cytotoxic consequences. It is also interesting to consider whether the episodic nature of migraine can be explained purely by the abnormal channel's providing a continuous background of neuronal instability or whether some unknown factor can precipitate an attack by directly switching the abnormal channel on or off. Were this to occur on the central pain-modulating serotonergic system, where apparently these aberrant channels may be found (74), it might support a central origin for the headache and offer a pharmacotherapeutic target.

Synthesis

A migraine attack is a response of the brain and its blood vessels to some trigger, often external. The brain is the target organ wherein the migraine attack originates; disordered neurogenic control of the intrinsic and extrinsic circulation is a secondary accompaniment of the attack. A neuroelectric event resembling the SD of Leao appears to be the basis of the aura. How the aura activates the headache remains to be determined. The period of time from the onset of the aura to the headache, usually up to 30 minutes, might be accounted for by the time it takes for the depolarizing wave of SD to pass from its site of origin into those parts of the cerebral cortex that are supplied by pain-sensitive arteries. On the other hand, brainstem centers for pain are influenced by the cortical event of SD as evidenced by the associated generation of c-*fos* in trigeminal ganglia (42). Activation of the central noradrenergic and serotonergic systems may secondarily initiate the events of neurogenic inflammation in the trigeminovascular system and modulate the transduction of pain via the same system. The evidence of continued activity in these central systems after pain has subsided, provided by the study by Weiller and colleagues (44), might also support the contention that these centers are the primary initiators of the attack, and would also explain the often-observed coincidence of the onset of aura with headache, as well as aura appearing well into the headache phase.

Assuming that the threshold for migraine is related to increased excitability of central neurons, how a migraine attack is triggered remains to be determined. This must involve those events leading from the postulated increased sensitivity for neuronal depolarization to the development of SD. The initiation of SD may be related to shifts in extracellular potassium or may involve glutamate release. The possibility that Ca^{2+} ion channels are abnormal in migraine may explain neuronal hyperexcitability, and the propagation of depolarization and prolonged recovery from depolarization that characterizes SD.

Finally, migraine patients may manifest all three states of migraine with and without aura and aura without headache at any time during their natural history. But these may not be different. Instead, pathophysiologic differences may have been recorded because patients were studied at different mechanistic points in the spectrum of the same disorder; the lack of a clear-cut aura of neurologic deficit in common migraine may mislead investigators. Alternatively, migraine without aura may originate in relatively silent brain areas (e.g., frontal, limbic, or visual association cortex), or perhaps, as some hemodynamic studies indicate, a dissociation occurs between neurologic symptoms and the underlying neurovascular event.

Symptoms and Signs

Clinical Syndromes of Migraine

The most frequently encountered migraine syndromes include typical headache without aura of neurologic deficit (previously termed *common migraine*) and headache associated with aura of neurologic deficit (previously termed *classic migraine*). Patients can have migraine headache both with and without neurologic aura at any time during the natural history of their disorder. They may also suffer neurologic deficit of migraine type without headache (migraine sine hemicrania).

In migraine with aura, visual disturbances account for well over one-half of the transient neurologic manifestations. Most often, these disturbances consist of positive phenomena, such as stars, sparks, photopsia, complex geometric patterns, and fortification spectra. These positive phenomena may leave in their wake negative phenomena, such as scotoma or hemianopsia. The symptoms are characteristically slow in onset and progression; however, onset can occasionally be abrupt. Visual symptoms sometimes progress to visual distortion or misperception, such as micropsia or dysmetropsia. The patterns of symptoms indicate the spread of neurologic dysfunction from the occipital cortex into the contiguous regions of the temporal or parietal lobes.

Somatosensory symptoms are the second most common manifestations and are characteristically distributed around the hand and lower face. Less frequently, the

symptoms include aphasia, hemiparesis, or clumsiness on one side. In most cases, a slow, marching progression is characteristic. The anatomic distribution of the neurologic deficit often overrides vascular boundaries. Some patients experience visual distortions of body image (i.e., metamorphopsia) and other visual illusions that occur in the Alice in Wonderland syndrome. Transient global amnesia can occur as a migraine aura, but only in rare instances. The aura usually lasts approximately 30 minutes before subsiding and is followed by a brief interlude of normality before the onset of headache that is unilateral or bilateral, pulsating, moderate to severe in intensity, and exacerbated by physical activity. In some instances, the aura continues into the headache phase. The headache may subside in as little as 6 hours or may last as long as 3 days. The longer duration is more typical of the headache of migraine without aura, which has similar features to migraine with aura but is characteristically moderate to severe in intensity and more prolonged in duration.

Migraine with Prolonged Aura (International Headache Society 1.2.2). This condition is characterized by one or more aura symptoms that last more than 60 minutes but with full recovery within 3 weeks and normal late CT scan results. Before attacks of migraine both with and without aura, a prodrome of behavioral changes may occur, which may include depression, anxiety, elation, increased sensitivity to external stimuli, and increased or decreased libido. In many instances, the characteristics of a person's prodrome are stereotypical, producing similar changes before each attack. Associated symptoms of both types of migraines include nausea, vomiting, photophobia, and phonophobia. In the 24 hours after the attack subsides, a spectrum of behavioral changes may arise, ranging from depression to exhilaration.

Migraine attacks both with and without aura may have characteristic triggers, including certain foods (e.g., chocolate, blue cheese, and alcohol), erratic mealtimes, sleep loss, acute stress, exercise, atmospheric pressure change, and the use of certain drugs, such as nitroglycerin and oral contraceptives. Menstruation is a common trigger. When migraine occurs only at the time of menses, it is termed *menstrual migraine*. Such patients may also suffer ovulatory migraine, and they are more likely to have experienced their first migraine in the year of menarche and to cease having attacks during pregnancy. Menopause is often a time of severe and frequent migraine attacks, which later resolve. It is helpful in the management of the disorder to distinguish between triggers that are time locked to a single attack and triggers that increase the frequency and severity of attacks. As an example of the latter, use of oral contraceptives may precipitate migraine for the first time, increase the frequency of attacks, and even convert migraine without aura to migraine with aura.

Hemiplegic Migraine. Transient hemiparesis associated with a migraine attack was first described by Liveing in 1873 (16). In 1910, Clarke published the first report of hemiplegic migraine occurring in a family (79). Hemiplegic migraine also has been described in children (80). The IHS classifies hemiplegic migraine under migraine with typical aura or migraine with prolonged aura. FHM is also classified as a subgroup of migraine with aura; the working definition includes the criteria for migraine with aura with hemiplegic features that may be prolonged, along with at least one first-degree relative having identical attacks.

Attacks are characterized by episodic hemiparesis or hemiplegia. In most attacks, the arm and leg are involved, often combined with face and hand paresis. Isolated facial and arm paresis occurs less often. The progression of the motor deficit is slow, with a spreading or marching quality. In most cases, symptoms are accompanied by homolateral sensory disturbance, particularly of hand and lower face, also with a slowly spreading or marching quality. Infrequently, the hemiparesis may alternate from side to side, even during an attack. Myoclonic jerks have been reported but are rare. Visual disturbance taking the form of hemianopic loss or typical visual aura is common, but homolateral or contralateral localization of the visual disturbance is uncertain. When dysphasia occurs, it is more often expressive than receptive. The neurologic symptoms last 30 to 60 minutes and are followed by severe pulsating headache that affects one or both sides of the head. Nausea, vomiting, photophobia, and phonophobia are associated features. In severe cases, the aura persists throughout the headache phase. Uncommon manifestations of severe hemiplegic migraine attacks include fever, drowsiness, confusion, and coma, all of which may be prolonged (i.e., from days to weeks).

FHM, which has an autosomal dominant inheritance pattern, is characterized by the same neurologic features as the nonfamilial form, with identical features occurring in at least one other first-degree relative. Additional neurologic deficits described with the disorder include a syndrome of progressive cerebellar disturbance, dysarthria, nystagmus, and ataxia (81). Retinitis pigmentosa, sensory neural deafness, tremor, dizziness, and oculomotor disturbances with nystagmus have also been described (82). These neurologic deficits are present between attacks and are not part of the aura.

The complications of hemiplegic migraine, although rare, can be serious. True migraine-induced stroke occurs when a typical migraine aura with hemiparesis persists after the attack; imaging studies of the brain show cerebral infarction appropriate to the neurologic deficit. In rare instances, severe hemiplegic migraine leads to persistent minor neurologic disorders; the cumulative effects of repeated attacks may produce profound multifocal neurologic damage or even dementia.

As noted previously, from patients with FHM, Ophoff and colleagues (70) have isolated, on chromosome 19p13.1, a gene encoding the a_1-subunit of a brain-specific voltage gated P/Q type neuronal calcium channel (CACNL1A4).

Basilar Artery Migraine. The concept of basilar artery migraine was first proposed by Bickerstaff (83). He later wrote how his attention was drawn to the syndrome when he saw, within a short period of time, two patients with identical symptoms explicable only on the basis of an abnormality of basilar artery circulation (84). One of these cases was a boy of 14 years whose symptoms lasted a few hours and were repeated on numerous occasions. The other was an elderly man whose symptoms progressed rapidly to coma and death and in whom infarction of the brainstem and occipital cortex was caused by thrombotic occlusion of the basilar artery demonstrated at autopsy. So it was by clinical analogy with the structural lesion in the basilar artery and the symptoms of basilar artery territory ischemia that the syndrome basilar artery migraine first was described.

No specific information exists on the prevalence of basilar migraine except that it is rare. Longitudinal studies are needed of the natural history of these serious migraine subtypes.

Classification. The IHS (85) classified this disorder as basilar migraine (IHS 1.2.4). The classification committee suggested that this term replace basilar artery migraine and other terms such as *Bickerstaff's migraine* and *syncopal migraine*. The diagnostic criteria include those for migraine with aura (IHS 1.2) plus two or more aura symptoms of the following types: visual symptoms in both the temporal and nasal fields of both eyes, dysarthria, vertigo, tinnitus, decreased hearing, double vision, ataxia, bilateral paresthesias, bilateral paresis, and decreased level of consciousness. The absence of consistent evidence for basilar artery spasm during migraine attacks and uncertainty about the origin of the mechanisms of the symptoms prompted the IHS classification committee to remove the word *artery* from the terminology. Further investigative studies were called for to definitively establish or disprove the existence of migraine aura originating in the brainstem.

Pathogenesis. Few studies have been made specifically of basilar migraine, and it has to be assumed that the pathogenetic mechanisms are the same as those of more clearly lateralized migrainous auras and headaches. Frequin and colleagues (86) describe a patient with recurrent prolonged coma in whom angiography showed profound narrowing of the basilar artery; they attribute this to vasospasm, although it remains possible that this appearance was actually produced by an inflammatory swelling of the vessel wall. In a transcranial Doppler study, La Spina and colleagues showed an increase in mean flow velocity in both posterior cerebral arteries, again consistent with narrowing of these vessels (87). It remains to be determined whether these changes are the cause of, the consequence of, or entirely unrelated to the aura symptoms.

Clinical Features. Of the 34 patients in Bickerstaff's original series, all were aged less than 35 years, and 32 were under the age of 23 years (83). Twenty-six of the 34 were female, and 28 gave a family history of migraine. A definite association existed with the menarche, and attacks were often then linked to the menstrual period. The attacks were infrequent although often interspersed with more typical migrainous attacks with aura. In Bickerstaff's series the headache was bilateral and occipital and was preceded by visual disturbances affecting both sides of the visual field, diplopia, bilateral circumoral or limb paresthesiae, dysarthria, bilateral ataxia, vertigo, and tinnitus, often lasting for 20 to 30 minutes and clearly resembling intoxication. The attacks were relieved by sleep. Bickerstaff himself noted that the attacks tended to become more typically migrainous as the patients grew older.

Several large series of such patients have been published more recently, and these give a breakdown of the proportion of patients with each type of aura symptom (88,89). More than one-third of subjects have their first attack in the second decade, and two-thirds have the first attack in their second or third decade. The condition also occurs frequently in children. A small number of cases, however, present for the first time over the age of 50 years. The condition may occur in combination with other forms of migraine, although basilar migraine remains the dominant problem in over 75%.

At first, Bickerstaff noted a predominance of teenage girls in his basilar artery migraine population, but subsequent experience revealed a female incidence that is similar to other forms of migraine (83). The highest gender ratio, approximately 3:1, is to be found when basilar migraine presents for the first time in the second decade of life (89). Not uncommonly, when basilar artery migraine starts in the teens the frequency of attacks diminishes, to be replaced in adult life by other forms of migraine (83).

Patients who suffer from basilar migraine identify trigger factors that are similar to those for other forms of migraine. Precipitating factors were identified by as many as

71% of subjects. Emotion, stress, menstruation, and weather change were the predominant triggers, but head injury, foodstuffs, and contraceptive drugs were also common. Of note, vascular risk factors were present in 41% of sufferers, including smoking, oral contraceptives, and diabetes mellitus.

In the majority of cases, the aura lasts between 5 and 60 minutes, but can extend up to 3 days. Visual symptoms commonly occur first, predominantly in the temporal and nasal fields of vision. The visual disturbance may consist of blurred vision, teichopsia, scintillating scotoma, graying of vision, or total loss of vision. The features may start in one visual field and then spread to become bilateral. Bickerstaff (84) pointed out that when vision is not completely obscured, diplopia may occur, usually sixth nerve weakness. Some form of diplopia occurs in up to 16% of cases.

Vertigo and gait ataxia are the next most common symptoms. Fenichel described a series of patients with isolated “benign recurrent vertigo,' which later evolved into migraine (90). This entity, first described by Basser (91), usually starts in preschoolers and progresses into the teens. Abrupt attacks of rotational sensation occur lasting seconds to minutes, accompanied by loss of balance, pallor, and vomiting. The disorder is self-limiting but may be a precursor to migraine or a migraine equivalent because many sufferers subsequently develop migraine with and without aura.

Ataxia can occur independently of vertigo. Tinnitus may accompany vertigo. Dysarthria is as common as ataxia and vertigo. Tingling and numbness, in the typical cheirooral spreading pattern seen in migraine with aura, occurs in over 60% of cases. This is usually bilateral and symmetric, but may alternate sides with a hemidistribution. Occasionally, dysesthesias extend to the trunk. Bilateral motor weakness occurs in over 50% of cases.

Impairment of consciousness in some form is common. Bickerstaff noted in his early work that patients enter a state of impaired consciousness that resembles sleep from which they may be easily aroused by stimulation, only to return to the same state. Rarely, this progresses to stupor and prolonged coma (92,93). Other forms of altered consciousness include amnesia and syncope. Drop attacks with transient loss of consciousness may occur as part of the full clinical syndrome, but this is rare.

Headache occurs in almost all patients. It has an occipital location in the majority and a throbbing, pounding quality and is accompanied by severe nausea and vomiting. It is unusual for the headache to be unilateral or localized to the more anterior parts of the cranium. Photophobia and phonophobia occur in one-third to one-half of the patients. As with other forms of migraine, the symptoms may occur without headache, but this is usually in no more than 4% of cases.

Seizures have been observed in association with basilar migraine (91,94). Eight percent of Sturzenegger et al.'s patients had overt seizures (89). Electroencephalographic (EEG) changes, without seizures, occurring with attacks of typical basilar artery migraine, also have been described (95). These cases are said to have a good response to anticonvulsants (95,96,97,98 and 99). Camfield and colleagues described a syndrome of basilar migraine and unilateral or bilateral temporal occipital EEG abnormality suppressed by opening the eyes. The epileptic seizures were either focal or generalized after the migraine aura (96). In all, EEG abnormalities are detected in less than one-fifth of cases with basilar migraine and are mostly independent of any clinical manifestation of the disorder (100). The EEG findings between attacks are usually spike wave or spike–slow wave complexes. During an attack, diffuse high-voltage slow waves occur and associated spikes with sharp waves and diffuse beta activity. In a long-term follow-up (8 to 16 years) of seven children affected by basilar migraine (101), who had EEG findings of occipital spike and wave complexes, basilar migraine resolved and the EEG became normal in all subjects. In one patient basilar migraine ceased and tonic-clonic seizures occurred 5 years after; these seizures also resolved. Four patients in this series later developed migraine with typical aura, two of whom had migraine aura associated with seizures that were partial with secondary generalization.

The prognosis of basilar migraine is generally good. The disorder declines in frequency as patients enter their 20s and 30s. Rarely, basilar migraine is complicated by stroke, which most often involves the posterior cerebral artery (84,102), although other terminal arteries may be involved (103).

Migraine Aura without Headache (International Headache Society Code 1.2.5). This condition is characterized by typical aura symptoms unaccompanied by headache, but it fulfills the criteria for migraine with aura. In many patients this condition develops as the individual gets older; the headaches might disappear completely, but the auras continue. Less commonly, this condition is present from the onset, usually after the age of 40.

Migraine with Acute Onset (International Headache Society Code 1.2.6). This condition is characterized by migraine with aura except that the neurologic symptoms develop suddenly (less than 4 minutes) and headache lasts 4 to 72 hours (untreated or unsuccessfully treated) and is associated with at least nausea, vomiting, or both and photophobia and phonophobia. In this condition intracranial lesions must be ruled out by neuroimaging procedures, and thromboembolic transient ischemic attacks are ruled out by angiography, cardiologic examination, and blood tests.

Other Types of Migraines

Ophthalmoplegic Migraine (International Headache Society Code 1.3). An attack of migraine headache can be accompanied by third, fourth, or sixth cranial nerve paresis ipsilateral to the side of the headache, beginning either as an aura or during the headache phase. In most cases, the ocular palsy involves the third nerve; the sixth and fourth nerves are involved only in rare instances. The ophthalmoplegia is at first transient, but after repeated episodes, it can become permanent. The mechanisms involved in the production of ophthalmoplegic migraine remain speculative. The major differential diagnosis is aneurysmal dilatation of the cerebral arteries, particularly the internal carotid artery or the posterior communicating artery. As a strict rule, all cases should be promptly evaluated. The diagnosis of ophthalmoplegic migraine has become an even greater rarity since brain imaging has become available, which suggests that many earlier cases were misdiagnosed.

Retinal Migraine. Retinal migraine occurs more frequently than ophthalmoplegic migraine (i.e., approximately one in 200 migraine sufferers). However, persons who experience homonymous field defects are often diagnosed with monocular migraine because the temporal hemifields of vision are larger than the nasal hemifields. The term *anterior visual pathway migraine* is actually preferred, because the disorder is not limited to the retina. Typically, visual disturbances identical to migraine with aura occur in a monocular distribution, which may include complete monocular visual loss. Often a previous history of migraine exists, with or without aura. Headache may or may not follow. Episodes can be precipitated by postural change or exercise.

The mechanism of anterior visual pathway migraine is uncertain, but retinal vasospasm has been observed in certain cases. Although permanent visual field loss is unusual, persons who experience frequent episodes of anterior visual pathway migraine should probably receive prophylactic therapy. The diagnosis of this disorder should be one of exclusion because the condition is relatively rare, and monocular visual loss can be a presenting syndrome of serious vascular or other structural disease.

Childhood Migraine. Migraine prevalence gradually increases from the age of 7 and reaches the adult level at puberty. The characteristics are similar to those of adult migraine, with the following differences: It occurs more frequently in boys than in girls; the attacks tend to be shorter in duration; lateralization and visual symptoms occur less frequently; and vertigo, motion sickness, and lightheadedness are common.

Complications of Migraine (International Headache Society Code 1.7). Migraine is associated with an increased risk of stroke between and during attacks (102). Various syndromes of migraine may mimic cerebrovascular syndromes, including migraine with aura of different types, retinal or ocular migraine, ophthalmoplegic migraine, hemiplegic migraine, and basilar artery migraine (104,105,106 and 107). If the deficit of a migraine attack remains, *migraine-induced stroke* should be suspected.

Head pain also occurs in various forms of acute ischemic stroke (108,109), particularly in posterior territory stroke. Headache usually occurs at the onset, although in some cases headache is premonitory or accompanied by transient ischemic attacks (110,111,112,113,114 and 115). Overall, the frequency of headache was 31% in carotid and 42% in vertebrobasilar disease. Mitsias and Ramadan have extensively reviewed the literature on this topic up to 1997 (108,109). The possible mechanisms of headache caused by ischemia remain to be determined (109).

The relationship of migraine and stroke is complex, and the opportunities for diagnostic confusion are multiple. This calls into question much of the published work before contemporary methods of investigation. Furthermore, working criteria for headache classification became available only recently, and even these do not address the classification of migraine-related stroke in a comprehensive fashion.

Epidemiology. Many of the hospital and population-based studies, even some in the 1980s, are severely flawed for reasons of classification and diagnosis. Many did not use contemporary epidemiologic methods. The data must therefore be interpreted with extreme caution.

A review of hospital-based studies conducted before 1989, most uncontrolled, showed that in patients younger than 50 years of age carrying a diagnosis of stroke, between 1% and 17% were attributed to migraine. In two-thirds of these the diagnosis was made in 1% to 8% of patients and 11% to 17% in one-third (116). A

compilation of studies up to the same time revealed a prevalence of 4% attributed to migraine in 448 total stroke patients, 31% of whom had an unknown cause. In clinical studies, stroke was reported as more common in patients with migraine with aura (117,118) and in patients with posterior cerebral artery strokes (119). No differences in stroke risk factors were found in migraine sufferers compared with controls without stroke, although those with migraine were more likely to have recurrent stroke, supporting migraine as an independent stroke risk factor (see following discussion) (118). Another study of migraine with aura reported that 91% of patients who had stroke during an attack had no arterial lesions, as opposed to 9% of migraine with aura patients who suffered stroke remote from a migraine attack and 18% of patients with stroke without a migraine history (120). In some instances, however, stroke risk factors increased stroke risk in migraine with aura.

The overall incidence of *migrainous infarction* has been estimated at 3.36 per 100,000 population per year (95% confidence interval, 0.87 to 4.8) but in the absence of other stroke risk factors becomes 1.44 per 100,000 population per year (95% confidence interval, 0.00 to 3.07)(121). This rate is similar to that reported later in subjects younger than 50 years (119); migrainous infarction accounted for 25% of cerebral infarcts. To place these data in context, the overall incidence of ischemic stroke under age 50 ranges from 6.5 per 100,000 (73) to 22.8 per 100,000 (122,123).

Controlled epidemiologic studies have been few. In a retrospective study of parents of migraine sufferers, no increased risk of stroke was found, but the frequency of hypertension was 1.7 times greater in persons with migraine than in those without (124). In an inconclusive study, the Collaborative Group for the Study of Stroke in Young Women found that the relative risk of thrombotic stroke was twofold higher, and greater for women with migraine compared with neighbor but not hospital controls (125). A hospital-based controlled study of 89 cases found that ischemic stroke was increased more than twofold in patients with migraine with aura (126), but when stroke risk factors were excluded in this group, there was no longer a statistically significant association.

Two cohort studies reported a twofold increased risk of stroke in migraine sufferers (125,126). Both studies have major diagnostic shortcomings. The most consistent studies of migraine as a stroke risk have been case controlled. Tzourio and colleagues showed no overall association between migraine and ischemic stroke, but among women aged less than 45, migraine and stroke were significantly associated; there was approximately a fourfold increased risk, more so in women who smoked (127). When this study was extended to a larger population, the results were confirmed and strengthened (128). The risk of stroke was three times control for migraine without aura and six times the risk of controls for migraine with aura. Furthermore, young women with migraine who smoked increased their stroke risk to approximately ten times control, more than three times greater than young women without migraine who smoked. For young women with migraine on oral contraceptives, the risk of stroke was 14 times control, and four times the risk of stroke and the dose of estrogen: The odds ratio was 4.8 for pills containing 50mg of estrogen, 2.7 for 30 to 40mg, 1.7 for 20mg, and 1mg for progesterone. In none of these cases was the stroke induced by the migraine attack.

Similar risk of stroke in women aged 15 to 44 years, close to three times, was confirmed in a questionnaire survey of 692 female subjects (107). In a later case-controlled study of 308 patients with either transient ischemic attacks or stroke, a history of migraine was more frequent than in controls (14.9% versus 9.1%) (129). Migraine was the only significant risk factor (odds ratio, 3.7) in women younger than 35 years of age. Although these risk figures appear startlingly high in both studies, it must be remembered that the absolute risk of stroke for this patient population translates to approximately 19 per 100,000 per year, which is a low rate.

The most recently published study was hospital based and case controlled involving five European centers. Two hundred ninety-one women aged 20 to 44 years with ischemic, hemorrhagic, or unclassified arterial stroke were compared with 736 age- and hospital- matched controls (105). Adjusted odds ratios associated with a personal history of migraine were 1.78 (95% confidence intervals, 1.14 to 2.77), 3.54 (1.30 to 9.61), and 1.10 (0.63 to 1.94) for all stroke, ischemic stroke, and hemorrhagic stroke, respectively. Odds ratios for ischemic stroke were similar for migraine with aura (3.81, 1.26 to 11.5) and migraine without aura (2.97, 0.66 to 13.5). A family history of migraine, irrespective of personal history, was also associated with increased odds ratios, not only for ischemic stroke but also hemorrhagic stroke. Use of oral contraceptives or a history of high blood pressure or smoking had greater than multiplicative effects on the odds ratios for ischemic stroke associated with migraine alone, although only smoking was statistically significant. Change in the frequency or type of migraine on using oral contraceptives did not predict subsequent stroke. Between 20% and 40% of strokes were possibly induced during a migraine attack. This study should be interpreted with particular caution on the basis of the methods, working criteria for the classification, and questionnaire used. Concerns are raised by the higher numbers of migraine with aura as compared with those without aura, and the difficulty in diagnosing migraine by questionnaire in family members. Also, clinical experience would not support the high incidence of true migraine-induced stroke.

In summation, based especially on case-controlled studies, an association between migraine and stroke appears confirmed. The risk increases threefold in young women. Common risk factors for stroke in general increase this risk. The studies emphasize that oral contraceptives should not be prescribed without the caution of stroke risk and migraine sufferers should not smoke.

Epilepsy. The reported frequency of migraine among patients with epilepsy varies from 8.4% to 23.0%. The frequency of epilepsy among patients with migraine ranges from 1% to 17%. Such data suggest that no conclusive evidence exists of any relation between the two disorders other than random coincidence. Nevertheless, in one study, 3% of a cohort of adult patients with epilepsy experienced seizures during or immediately after migraine (130). Furthermore, the genetic relation between migraine and epilepsy (which has always been controversial) was clarified in a 1993 study by Ottman and colleagues (131), who collected data on the prevalence of migraine in patients with epilepsy and in relatives with and without epilepsy. Of the probands, 24% had a migraine history; 26% of relatives with epilepsy had a migraine history. However, 15% of relatives who did not have epilepsy had a migraine history. The cumulative incidence of migraine was also higher in patients with epilepsy (24%) and relatives with epilepsy (23%), compared with relatives without epilepsy; and the risk of migraine for the first two groups was twice as high as that for the third group. There also appears to be a high incidence of migraine in persons with certain forms of epilepsies, such as benign rolandic epilepsy, benign occipital epilepsy, and corticoreticular epilepsy with absence.

Psychiatric Disorders and Personality Traits. A high incidence of neuroticism occurs in migraine sufferers. However, the stereotype of the rigid, obsessive migraine personality could well be a selection bias of a migraine subtype seen more frequently in the clinical population. A few studies have been made of migraine and psychiatric disorders. Epidemiologic studies have shown a major comorbidity with depression (132). Although this association with depression may represent a psychological reaction to frequent and disabling migraine attacks, depression carries with it a major risk for migraine, raising the possibility that there is a shared genetic or environmental risk between the disorders. A common abnormality of brain function may be responsible (e.g., dysregulation of the central serotoninergic system). Increased risk for episodes of mania, anxiety, and panic disorder have also been reported, together with an increased prevalence of illicit drug use and nicotine dependence. Perhaps the most disturbing feature of this report was the increased lifetime prevalence of suicidal ideation and suicide attempts independent of depression (133).

Chronic Daily Headache. Chronic daily headache (CDH) is best classified under the tension-type headaches and headaches associated with drug overuse, but is dealt with under the migraine section, because some consider this condition as an evolution of migraine.

Controversy abounds with this subject, however. Definitions are arbitrary and classifications vary without universal acceptance. Agreement exists on one issue. For headache specialists and neurologists this is an important clinical problem.

The first and only notable population-based study conducted found that 0.5% of 20,468 subjects reported daily severe headache (134). Daily headaches are rare in the population. In contrast, headache clinic population studies observe up to 30% of patients complaining of daily or almost daily headache.

The definitions of this disorder are based on clinical features, but clinical features also depend on definition. The history of confusion began with the writings of Sicuteri on the topic of *essential headache* (135), a term used to imply a state of “central dysnociception,' that apparently differed from tension-type headache but that was never convincingly delineated or understood clinically. The impetus for controversy came with Mathew and colleagues' pointing out that patients with episodic migraine at the outset of their illness later develop daily headache (136). The implication in the title of the paper was that migraine was *transformed* to this state. Here lay the apparent heresy. Before this time we only had recognized *mixed* or *combined* episodic migraine and tension-type headache. (In retrospect, such classification was not rigorously analyzed in terms of precise clinical features.) Furthermore, Mathew and colleagues implied in their paper that there were certain factors that contributed to the transformation, namely medication, stress, hypertension, and disturbed psychological status. This work was uncontrolled, retrospective, observational, and without statistical analysis. But in the light of subsequent papers evoked by this study [and with the usual caveat that in fact the observation had been made before (137)], it was a seminal paper that changed the way we think about daily headaches.

Some authorities believe that, until proven otherwise, the classification of CDH is incorporated in the currently most widely accepted classification of primary headache by the IHS. Others believe that the headache disorder is an entity worthy of separate classification. The latter view is supported by a headache clinic's retrospective studies of patients with almost daily headache that up to 30% of their subjects could not be categorized using IHS criteria for the primary tension-type, migraine, or other headaches (138). This also addressed the criticism that subjects can suffer two or more separate primary headache disorders occurring in close temporal proximity. In essence its detractors believe the IHS classification problems are created by a primarily cross-sectional analysis of clinical features, with

insufficient emphasis on temporal patterns to refine the clinical impression.

To add to the confusion, one study suggested that episodic tension-type headache could precede an unclassifiable daily headache syndrome (139). Alternatively, then, repeated attacks of the primary migraine and, less commonly, episodic tension-type headaches, under certain circumstances might induce a secondary headache syndrome, the nature of which remains to be determined.

Mindful that the IHS classification was created with the intention to stimulate nosologic and epidemiologic research, classification schemes have been proposed that recognize daily headache that fails to meet existing working criteria. More than 15 days a month with headache for at least 6 months (some expect a year) has been used to define this term. This liberality has been qualified by those who prefer *daily* or *near daily*. Daily headache may also be continuous or episodic and allow treatment resolution.

No specific diagnostic features of CDH have been described despite multiple studies. In general, the headache resembles features of migraine headache during the less severe phases of pain. Intriguingly, Mathew and colleagues described a minor preponderance of headache on the same side as the hemicrania of the now transformed episodic migraine, or at the same head locations as the prior episodic head pain (136). This observation has not been followed up or rigorously replicated.

CDH patients have a family history of migraine. Triggers are common, in particular menses. This is despite inconsistencies between studies on gender prevalence. In addition to tension-type headache and migraine without aura, migraine with aura can precede CDH, although the prevalence is low and variable. In sum, the clinical syndrome of CDH is not uniform.

Associated and Possibly Comorbid Factors

Drug Abuse. In most CDH series, drug overuse figures prominently. There are a number of issues with this association that evoke controversy. Can drug overuse itself cause headache? Is the use of drugs the factor in transforming episodic migraine or tension-type headache to CDH? Diener has reviewed the topic with clarity (140). He used individual studies and metaanalysis to evaluate working criteria of the IHS classification.

In almost all cases of CDH a history of primary headache exists; approximately two-thirds suffered migraine and one-third tension- type headache. Other headaches such as cluster rarely were involved. The time intervals for CDH to develop were approximately 5 years of exposure to medication and a history of primary headache for 10 years before that. No single drug induces headache exclusively. To develop CDH, a critical dose of a single drug or a combination of drugs used below the critical level of each is required. With the exception of codeine, narcotic induction of CDH is unusual. Acute withdrawal worsens headache. Treatment for the primary headache complaint fails if the drugs are not terminated. The effectiveness of treatment does not appear to be dependent on effective migraine or tension-type headache prevention, although blinded controlled studies have not been carried out. Up to 75% of cases improve. Headache usually remains, although less severe and less frequent.

It remains curious that similar drugs that are associated with CDH do not cause headache in subjects without primary headache. This emphasizes the importance of a history of prolonged primary headache increasing the susceptibility to CDH and drug-induced CDH and may provide some clues to pathogenesis.

The question of whether drugs are factors in transforming migraine to CDH in susceptible individuals remains to be answered. Transformed migraine occurs without drug exposure, however, in convincing numbers of subjects.

Depression and Psychological Factors. Depression and other psychiatric and psychological disturbances are comorbid with migraine (141). In the tested case of depression this appears caused by a common brain state. Depression occurs both before the start of migraine attacks as well as for the first time subsequent to migraine onset. The association of depression with CDH is unsurprising in view of the susceptibility to CDH that the primary headache induces.

Although several factors, as well as psychiatric factors, have been invoked to play a role in transforming migraine (e.g., stress and hypertension) (136), based on study design these cannot be treated as anything other than associations rather than the claimed causative role.

Mechanisms. The mechanisms of CDH have rarely been studied and remain to be determined. Past theories include a low serotonin state with receptor upregulation (142), central hyperexcitability of pain systems (143) or *N*-methyl-d-aspartate receptor dysfunction (144), low b-endorphin and opioid state (145), and a postviral syndrome (146). Platelet membrane studies in CDH related to drug overuse found evidence of abnormal signal transduction that recovered after successful drug withdrawal (147).

Treatment

The goals of migraine treatment are alleviation of the symptoms of an acute attack and prevention of further attacks, either by behavioral or pharmacologic means. The behavioral approach commonly involves regular sleep and meals and avoidance of initiating factors. Family-related or work-related stresses and emotional problems are often unavoidable and are best managed by stress coping or relaxation techniques. Pharmacologic treatments for migraine are available (Table 48-4).

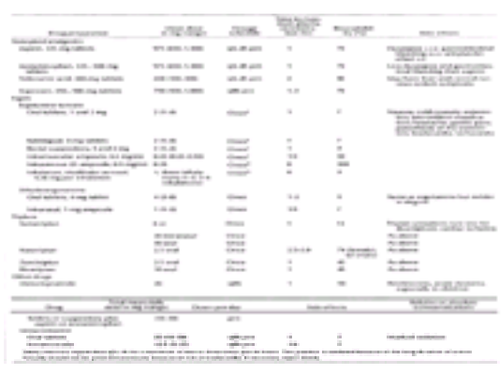

TABLE 48-4. Drug treatment for migraine attacks

Analgesic Drugs. During prolonged, severe attacks of migraine, the patient's judgment may be impaired, with consequent uncertainties as to the type of drug to be used or the amount to be taken. Family or friends should be instructed in the use of medications for acute cases of migraine. Mild or moderate attacks should be treated with simple analgesic drugs or nonsteroidal antiinflammatory drugs (NSAIDs). Aspirin, acetaminophen, propoxyphene, codeine, and certain NSAIDs are all superior to placebo in relieving the pain of migraine. Effervescent formulations are more effective because they are absorbed more rapidly. Because gastric stasis often accompanies migraine attacks, metoclopramide, a drug that increases gut motility and promotes gastric emptying, enhances the effectiveness of analgesic drugs. However, metoclopramide should be used sparingly in adults and should not be used at all in young patients, because it can cause dystonia. When nausea and vomiting are prominent, suppository preparations of analgesic and antiemetic drugs can be given. The most frequently used antiemetic drugs are perphenazine, prochlorperazine, and chlorpromazine.

Ergot Preparations. For many years, ergotamine tartrate was the drug of choice for treatment of moderate to severe acute migraine attacks. However, controlled trials have proved that ergotamine is effective in only one-half of patients when given orally, sublingually, rectally, or nasally. The addition of caffeine enhances the absorption and possibly the vasoconstrictive activity of ergotamine. Because absorption of ergotamine and related drugs is variable, the drug should be given by a route acceptable to the patient, and the dosages should be increased to find a single, effective dose as early as possible for subsequent attacks. Ergotamine is best absorbed rectally. An antiemetic drug (best given by suppository) may be needed together with ergotamine. Dihydroergotamine, which is available for parenteral administration in the United States, is also effective in migraine attacks. Patients can be instructed to self-administer dihydroergotamine subcutaneously. Dihydroergotamine is available in a nasal spray, enhancing the convenience of delivery. Probably because the drug has a prolonged dissociation with its receptors,

the drug is particularly useful in those patients who have prolonged attacks or a high recurrence rate with use of the triptan group of drugs to be discussed next. Ergot preparations are vasoconstrictors and should not be given to patients with vascular disease.

Sumatriptan. Sumatriptan is a serotonin receptor agonist that has proved to be effective in migraine. Sumatriptan is effective when administered subcutaneously during an attack of migraine. Subcutaneous administration of 6 mg of sumatriptan reduces migraine within 2 hours in up to 86% of patients (148). Nausea and vomiting are effectively relieved in most patients. Unfortunately, headache can recur in up to 46% of patients within 24 hours, probably because of the short half-life of the drug.

When sumatriptan is given orally in a dose of up to 100 mg, headache and associated symptoms are relieved within 4 hours in 75% of patients (149). The usual dose is 50 mg at the outset of the attack. As with subcutaneous administration, headache recurrence is a problem. Nasal spray is also available, the standard dose being 20 mg. Patients should be instructed to deliver the spray with the head bent forward because the taste of the drug is unpleasant. This preparation is useful when a more rapid action of the drug is required than can be obtained by the oral route, or for patients who find the injection unacceptable but require more rapid pain relief. The practitioner should attempt to characterize first the severity and rapidity of pain onset as well as monitor response to the modes of drug delivery and customize the drug regimen to the needs of the individual patient.

The side effects of subcutaneous and oral sumatriptan are similar. Most of the side effects are mild to moderate in intensity, are short lived, resolve spontaneously, and do not change with repeated use of sumatriptan. The most common side effects are injection site reaction after subcutaneous administration; sensations of flushing, heat, and tingling; and neck pain with stiffness. Three percent to 5% of patients experience chest tightness, heaviness, pressure, tingling, and pain. The cause of the chest symptoms is unknown, but in rare instances, coronary vasospasm has undoubtedly occurred. For patients who are likely to have unrecognized coronary artery disease (e.g., postmenopausal women, men older than 40 years, and patients with risk factors for coronary artery disease), the first dose of sumatriptan should be given under medical supervision. Sumatriptan is contraindicated in patients with a history of myocardial infarction, symptomatic ischemic heart disease, Prinzmetal's angina, and hypertension.

Newer members of the triptan class of drugs are now available. Zolmitriptan, naratriptan, and rizatriptan are in the formulary, and the release of eletriptan is expected. Zolmitriptan (149,150,151,152,153,154,155,156,157,158 and 159) was the second triptan to be marketed in the United States (150,151,152,153,154,155,156,157,158,159,160 and 161). It is available only in oral form, and the recommended dose is 2.5 mg, repeated if needed in 1 hour (150). Higher doses do not appear to increase efficacy, but increase side effects. Zolmitriptan varies from sumatriptan in both site of action and pharmacokinetics, which appear to provide limited advantages over oral sumatriptan (151). In addition to the peripheral effects of vasoconstriction and inhibition of neurogenic inflammation, common to both drugs, unlike sumatriptan, zolmitriptan penetrates the blood–brain barrier. Zolmitriptan also shows higher bioavailability (42%) when compared with sumatriptan (14%). Clinically, zolmitriptan has a more rapid onset of action when compared with oral sumatriptan (18% therapeutic gain at 1 hour versus only 10% for sumatriptan, 100 mg). After this initial gain, however, zolmitriptan's advantage is lost; the number of patients who are pain free 2 hours after treatment is nearly identical for both drugs (17% and 18%, respectively). Nausea, vomiting, and photophonophobia are also effectively treated. Zolmitriptan is effective regardless of time taken during the headache and has equal efficacy across headache types (migraine with aura, migraine without aura, menstrual migraine). A high response rate (81%) is maintained throughout multiple attacks. Headache recurrence appears to be lower for zolmitriptan as compared with oral sumatriptan. The side-effect profiles of the drugs remain similar, and despite the central penetration of the zolmitriptan, adverse CNS effects do not occur at a higher rate than sumatriptan. Most adverse events are mild and well tolerated, with onset in 20 to 45 minutes. The duration is typically less than 30 minutes, but symptoms may last up to 2 hours. Adverse events are similar to those of sumatriptan, including nausea, dizziness, somnolence, paresthesias, and tightness of the throat or chest. Contraindications to use remain the same as for sumatriptan, including its use in those with known or suspected cardiac disease. The use of vasoconstrictors, such as ergotamines, dihydroergotamine, and other triptans, is contraindicated within 24 hours.

Naratriptan is available only in oral form. The recommended dose is 2.5 mg, and the same contraindications and precautions apply as with other triptans (162). Naratriptan is not more effective than sumatriptan, rizatriptan, or zolmitriptan in either pain relief or pain-free responses (158,161,162). Adverse events occur overall at a lower rate than sumatriptan (0.1% when corrected for placebo), and the drug appears to be better tolerated. Headache recurrence after treatment with naratriptan may be lowest of all the triptan drugs.

Rizatriptan was most recently released for clinical use. It is available in 5- and 10-mg tablets, with a recommended dose of 10 mg in a single dose (163,164). Bioavailability (45%) is comparable with zolmitriptan (42%) (150,155,156), higher than sumatriptan (14%), but lower than naratriptan (74% for women, 63% for men). Like sumatriptan, rizatriptan does not cross the blood–brain barrier in significant amounts. The onset of action is comparable with oral sumatriptan and slower than zolmitriptan. Rizatriptan may prove more rapidly effective than other triptans, but this remains to be established. However, a substantial decrease in efficacy occurs 4 hours after treatment compared with sumatriptan. The rate of headache recurrence (44%) (163) is higher than that of oral sumatriptan (36%). Rizatriptan is effective against nausea, photophobia, and phonophobia. Adverse reactions are similar to those of the other triptans (163), although experimentally rizatriptan may have fewer constrictor effects on coronary arteries than sumatriptan (165,166). Nevertheless, the same cautions should be exerted when using this drug as with other triptans. Propranolol at doses typically higher than those used for headache prophylaxis (240 mg) may increase serum concentrations of rizatriptan.

Symptomatic Treatment in the Emergency Department. Migraine attacks that are severe, prolonged, and unresponsive to self- administered medication may be treated in the clinic or emergency department. Patients with such attacks should be treated with dihydroergotamine given intravenously or intramuscularly or with sumatriptan given subcutaneously. If these drugs fail, the preferred regimens are metoclopramide (10 mg intravenously), prochlorperazine (10 mg intravenously), or chlorpromazine administered in three intravenous injections of 0.1 mg per kg given 15 minutes apart. In addition to dystonia and tardive dyskinesia, the side effects of the three drugs are drowsiness, nausea, vomiting, dizziness, and hypotension, all of which are infrequent. The mechanism by which these dopamine antagonists relieve headache remains to be determined.

Major Narcotic Analgesic Drugs. Major narcotic analgesic drugs, particularly meperidine, are used in the emergency treatment of migraine attacks. The use of meperidine should be limited to patients who have attacks that do not respond to antimigraine preparations and patients in whom antimigraine drugs are contraindicated (e.g., those with peripheral vascular or coronary artery disease and pregnant women).

Acute attacks may be so frequent and the patient's pain so severe and continuous that hospitalization is needed. In these patients, it may be effective to administer dihydroergotamine intravenously for three to four days, discontinue all other drugs, and administer intravenous fluids (167).

Preventive Treatment

Preventive treatment should be considered only when attacks of migraine occur more than two or three times a month, when the attacks are severe and limit normal activity, when the patient is unable to cope with the attacks, when symptomatic therapies have failed or have had serious side effects, and when attempts at nonpharmacologic prevention have failed. Several points should be considered before preventive therapy is initiated. Some form of contraception, preferably barrier contraception rather than an oral contraceptive that may trigger headache, should be advised in women of child-bearing age. Costs of drugs should always be considered because prolonged treatment may be required.

Each medication should be given for a period adequate for its effectiveness to be determined. In patients with frequent migraine, this is usually 2 to 3 months. Preventive treatment is usually continued for 6 months or longer and gradually withdrawn after the frequency of headaches diminishes. Serotonin-influencing drugs were the first to be used effectively for migraine prevention (Table 48-5). Methysergide is more effective than amitriptyline but is not used much in the United States, because it can cause retroperitoneal, cardiac valvular, and pleural fibrosis. Methysergide is contraindicated in patients with vascular disease because of its vasoconstricting action. Amitriptyline is a useful drug for preventing migraine, especially in patients with depression or tension-type headaches, although its beneficial effect in migraine is independent of its antidepressant activity. Nortriptyline may also prove effective and, because it causes less weight gain, may be preferred by some patients.

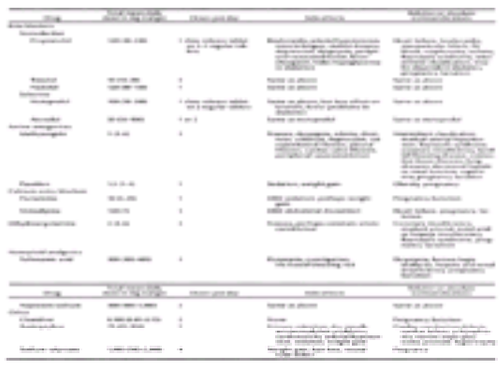

TABLE 48-5. Drug prophylaxis of migraine

b_2-Adrenergic antagonist drugs have proved effective in preventing migraine in numerous clinical trials. They should be considered the treatment of choice for preventing migraine, especially in patients with stress-related attacks. However, these drugs are effective in only up to 65% of treated patients and are contraindicated in patients with bronchospasm, congestive heart failure, cardiac arrhythmias, and a history of depression. b $_2$-Receptor antagonists with partial agonist activity are ineffective.

Despite initial enthusiasm for the use of calcium channel blocking agents to prevent migraine, their effect has been unimpressive. Verapamil is probably used the most. In general, the calcium channel blockers may decrease the frequency of attacks, but they have little effect on their severity. It may take weeks to months before an effect is noted, which reduces patient compliance. The vasodilatory action of calcium channel blockers sometimes causes severe headache that is indistinguishable from migraine.

NSAIDs have been used in satisfactorily controlled trials. Aspirin is also effective in preventing migraine. However, because of gastrointestinal ulceration and hemorrhage, prolonged prophylaxis with NSAIDs should be avoided. No comparison has been made of the relative effectiveness of the various classes of NSAIDs, but it is reasonable to change to another class if one has proved ineffective.

Valproic acid was introduced as preventive therapy for migraine, but it is only moderately effective in preventing migraine and reducing the frequency, severity, and duration of severe attacks. The mechanism of action of valproic acid is not known.

Menstrual migraine (i.e., an attack occurring only in association with menses) is frequently refractory to treatment. Women with menstrual migraine may benefit from preventive treatment limited to the period of menses. If they are already receiving prophylactic treatment, an increased dose at the time of menses may be beneficial. The use of percutaneous estradiol gel applied just before and throughout menses may reduce the frequency of headache (168). Patients already taking oral contraceptives who continue taking them throughout the menstrual cycle may experience fewer attacks. Bromocriptine, a dopamine D $_2$-receptor agonist that suppresses prolactin release, may be given during the luteal phase with some effect. Finally, Lupron, the gonadotropin-releasing hormone analog that suppresses ovulation, can be tried but has not been subjected to controlled trials. The menopause is often a time of severe and frequent migraine attacks. Those already taking estrogen who have frequent migraine attacks may improve if the hormone is either stopped or increased.

The mechanisms by which ovarian hormones influence migraine remain to be determined, but an abrupt decrease in serum estrogen concentrations before the onset of an attack appears to be a critical factor (169). The currently used low-dose estrogen oral contraceptive formulations are associated with a haphazard occurrence of attacks during the cycle, probably because of fluctuating serum estrogen concentrations. Thus, treatment strategies are aimed at preventing either a decrease or a substantial fluctuation in serum estrogen levels. Women already taking estrogen who have frequent migraine attacks may improve if the hormone is either stopped or increased.

A condition of near-daily or daily migrainelike headaches, with repeated therapeutic failure, multiple analgesic use and abuse of drugs such as codeine and barbiturate, and depression, can develop in migraine sufferers. This is among the most frequent of the headache disorders that present to specialized headache clinics, and a major management problem because the headache is commonly intractable. Management should be to withdraw the overused drug and consider a preventive approach with the standard drugs used for migraine. Sodium valproate is popularly regarded as most effective in these cases, although this remains to be established. Hospital admission and the use of intravenous dihydroergotamine may be indicated in intractable cases.

Cluster Headache

Cluster headache is a disorder that occurs six times more often in men than in women, usually beginning in the third or fourth decade of life. Attacks occur during defined periods that may last weeks to months and may return within a span of 1 or more years. Not infrequently, the cluster periods resume according to well-defined cycles that may be associated with seasons. As time passes, the cluster periods become longer and merge into one another as the duration of remission shortens, so that subjects enter a stage termed *chronic cluster headache*, clearly a misnomer. When headaches occur in a cluster, there are usually several clear-cut triggers of an attack (the most common being alcohol and nitroglycerin), all of which appear to have vasodilator properties.

Pathophysiology. The causes of cluster headache remain to be determined. Paresis of the sympathetic nerve fibers that traverse the cavernous sinus to innervate orbital and retroorbital structures appears to play an important role. Indeed, after severe and frequent attacks, persons may be left with permanent sympathetic palsy. In addition, the trigeminal system must transmit the pain, which probably originates in dilated and sensitized arteries and veins. A relapsing and remitting venous inflammatory process of unknown cause has been suggested as the underlying basis of cluster headache. Positron emission data have shown that hypothalamic centers are activated during a cluster attack, although the significance of this finding remains to be determined. The same center appears to be structurally different in cluster patients than normal controls.

Clinical Features. Cluster headache attacks are characteristically unilateral and periocular, although they may also occur in frontal, temporal, or maxillary locations. The pain is almost always excruciating and is usually described as boring, knifelike, or burning. The pain is accompanied by conjunctival injection, lacrimation, rhinorrhea, and miosis. The attacks are relatively short, lasting from 15 minutes to 3 hours. They may recur numerous times during the day but usually only two or three times. Cluster headache attacks often wake the patient during the night. These clinical features of cluster headache are so stereotypical that the diagnosis can be made on their basis alone without resorting to other investigations.

Cluster headache sufferers do not search for a quiet environment to relax. They tend to pace the floor and bang their heads against hard surfaces, hoping to relieve the excruciating pain. In rare instances, patients with cluster headache are photophobic, phonophobic, or both and require a dark room to alleviate the pain.

Treatment. One hundred percent oxygen is effective in approximately 70% of patients when it is delivered in a tight-fitting face mask at 7 L per minute for 10 minutes. Ergotamine nasal spray may provide rapid benefit. Dihydroergotamine given subcutaneously or intranasally may also be effective. Two percent lidocaine intranasal drops (or occasionally lidocaine gel) are sometimes beneficial in acute cluster attacks. The patient's head should be kept back and tilted toward the side of the headache when the lidocaine anesthetic is applied. Subcutaneous administration of sumatriptan is effective in treatment of acute episodes of cluster headache. Sumatriptan has a rapid onset of action, making it ideal for the treatment of severe cluster headaches of short duration. The availability of the sumatriptan nasal spray offers an alternative approach to rapidly deliver the drug. If treatment fails or medications are contraindicated, acute intravenous glucocorticoids or intramuscular meperidine may be indicated. Finally, hospital admission and the use of intravenous dihydroergotamine may be indicated in intractable cases.

Preventive Treatment. Prevention of attacks during the cluster period is almost always indicated because of the severity of pain. Preventive treatment is probably best achieved by a short course of glucocorticoids (e.g., prednisone, 60 mg per day), usually for 2 weeks and then tapered over 10 days. However, this strategy cannot be repeated regularly. Verapamil (up to 80 mg four times a day) or lithium carbonate (300 mg three times a day) can be given. Alternatively, 0.5 to 1.0 mg of ergotamine may be given in suppository form at night and may be effective. No published experience exists of the use of sumatriptan as a preventive treatment of cluster headache. Although it may have a similar action to ergotamine, it has a much shorter half-life and may have less utility for this purpose.

Chronic Paroxysmal Hemicrania

Chronic paroxysmal hemicrania is a primary headache so rare that it will probably never be diagnosed in a nonspecialist setting, but it demands mention because it resembles aspects of cluster headache. The pain is similar in intensity and location to cluster headache, but the attacks are short (rarely longer than 30 minutes) and frequent (up to 30 times a day). The disorder is also distinct from cluster headache because it rarely occurs in men and is entirely resolved by use of indomethacin. The condition also needs to be differentiated from other rare headache forms that occur around the eye, such as the cluster-tic syndrome and the SUNCT syndrome (short-lasting, unilateral, neuralgiform headache with conjunctival injection and tearing). Hemicrania continua, a controversial primary headache, is also selectively responsive to indomethacin.

Tension-Type Headache

Tension-type headache is typically pressing or tightening in quality, mild to moderate in intensity, and bilateral in location and does not worsen with physical activity. Phonophobia, photophobia, or both are occasionally present, but nausea is absent. An attack may last hours to days. If tension-type headache occurs more than 15 days a month for 6 months, the condition is termed chronic as opposed to episodic tension-type headache. Whereas almost 60% of the population may suffer episodic tension-type headache in any 1 year, the chronic form is present in fewer than 3% (170).

Pathophysiology. The mechanisms of tension-type headache remain to be determined. The previous term for this disorder, *tension headache*, was coined because the pericranial and pericervical muscles were thought to be involved (i.e., muscle contraction headache). Indeed, this may still be the cause in some cases. Neurophysiologic studies have found an abnormality of a temporalis muscle reflex that indicates a brainstem origin of disinhibited muscle contraction.

Differential Diagnosis. Episodic tension-type headache can pose a problem in differential diagnosis. Some authorities consider that the distinction between episodic tension-type headache and migraine without aura is unwarranted, whereas others disagree. The distinction is even more difficult in the context of the so-called mixed headaches, in which attacks of migraine with aura occur against a background of chronic tension-type headache. Contemporary headache specialists call this CDH, with the hallmark of the condition being its development over time (maturational migraine) from an earlier and unequivocal diagnosis of episodic migraine (see previous discussion). So-called CDH, as yet unrecognized in the IHS classification, is compounded by the frequent use of analgesic and sedative medications, which some experts consider to be instigators of the condition.

Treatment. An exacerbation of episodic tension-type headache is best treated by bed rest and complete relaxation. Precipitating factors should be sought, and reassurance and psychological support should be provided for the patient. Gentle massage of the head and neck area and application of hot packs to these areas are physical maneuvers that may be helpful in alleviating some of the pain. In view of the risk of analgesic addiction in patients with chronic headache, only minor analgesics should be used. If the patient has consistently used scheduled analgesics, such as codeine, the pain of an acute exacerbation of severe muscle contraction headache may not respond to anything but parenteral narcotics. Accordingly, instead of pursuing this line of treatment, it is preferable to treat the patient with tranquilizers that are also neuromuscular relaxants, such as diazepam, which may have the added beneficial effect of causing drowsiness and sleep. Muscle relaxants are occasionally effective in acute exacerbations. NSAIDs, such as naproxen and ibuprofen, are useful alternative analgesics that are effective in some patients.

For the management of chronic tension-type headache, a similar pain strategy is used. In this instance, it is better to avoid tranquilizers and to try preventive measures with pharmacotherapy, but only if behavioral measures, such as regular sleep and effective stress coping, have failed. The tricyclic antidepressants, such as amitriptyline, are the most effective preventive drugs.

Conversion Headache

Conversion headache is one of the most difficult forms of headache to diagnose; indeed, a long delay in diagnosis is almost a diagnostic feature. Most cases have an abrupt onset followed by exacerbations and remission. The incidence in men and that in women are nearly identical. Conversion headache occurs predominantly in adults 18 to 30 years of age, but it can be observed at all ages. The character of conversion headache often cannot be differentiated from that of other types of headaches. In addition, major abnormalities in mental status are seldom found in patients with conversion reaction. Laboratory, electrophysiologic, and radiologic studies are normal. The usual duration is from months to years, but in most cases, diagnosis is made within 1 year of initial presentation. Conversion headache is rarely relieved by medication.

On examination, the major abnormalities are behavioral in nature. Patients may have a total indifference to their symptomatology despite bitter complaints of pain. In addition, symptoms may be overdramatized, particularly when they are of an unusual description. Patients may exhibit extreme passivity or express hostile denials when they are asked about possible emotional problems. The psychiatric examination rarely reveals serious psychiatric disease, but the personality profile may indicate that the patient is an immature, dependent person.

Miscellaneous Headaches

The IHS has classified miscellaneous headaches under primary headaches even though less is known about the mechanisms of miscellaneous headaches than about the other primary headache syndromes. Notable characteristics of the miscellaneous headaches include a resemblance of the head pain to that of serious structural disorders; thus, miscellaneous headaches require special mention and, often, good clinical judgment as to the extent into which they are investigated.

Idiopathic Stabbing Pain. Idiopathic stabbing pain includes the syndromes of so-called ice pick headache and so-called jabs and jolts. Transient stabs or series of stabs of head pain lasting fractions of a second occur at irregular intervals of hours to days. Patients with migraine, cluster headache, and chronic paroxysmal hemicrania are predisposed to this condition (see previous discussions). An important differential diagnosis is the sentinel headache of subarachnoid hemorrhage, which most often can be discriminated from idiopathic stabbing pains by a history of past events in the case of subarachnoid hemorrhage.

External Compression Headache. External compression headache is a constant pain resulting from external pressure applied to the site from which it originates, usually by stimuli such as swim goggles. The pain is mediated by the trigeminal or occipital nerves.

Cold Stimulus Headache. As the name implies, cold stimulus headache results from exposure of the head to low temperatures. This includes a generalized headache from exposure of the bare head to subzero weather or from diving into cold water. Ingestion of a cold stimulus, best typified by ice cream headache, produces a more focused and more severe pain, usually frontal or retropharyngeal in location.

Benign Cough Headache. Benign cough headache is a bilateral headache of sudden onset lasting less than a minute that is precipitated by coughing. It can be diagnosed only after structural lesions, especially posterior fossa space-occupying lesions, have been excluded.

Benign Exertional Headache. In contrast to the benign cough headache, benign exertional headache is brought on by physical effort, lasts minutes, and has a throbbing, pounding quality. It too has the important differential diagnosis of intracranial mass.

Headache Associated with Sexual Activity. Headache associated with sexual activity, which is often known as *benign coital cephalalgia*, can take three forms. In one form, the headache has a sudden onset precisely at the time of orgasm. In another form, the headache can begin gradually during sexual excitement and then intensify at the time of orgasm. The headache of sudden onset is explosive in character, and the headache of gradual onset is a dull ache. In both headaches, but more commonly in the one of sudden onset, the headache occurs at the time of masturbation, a historic feature that may be helpful in distinguishing it from subarachnoid hemorrhage. Curiously, these headaches may occur with a clusterlike periodicity. The third type of headache associated with sexual activity is postural headache, resembling intracranial hypotension. Unlike the other types, which are short lived, the postural headache may persist for days. The mechanisms of these headaches remain to be determined. The conditions usually spontaneously remit; however, if preventive management is desired, propranolol may be tried. Propranolol has been successful in some cases, perhaps by preventing an increase in blood pressure at orgasm.

Headaches with Sudden Onset

Subarachnoid Hemorrhage (International Headache Society Code 6.3). Subarachnoid hemorrhage results from ruptured berry aneurysm, trauma, or an arteriovenous malformation (171). Most cases of subarachnoid hemorrhage occur between the ages of 20 and 40 years. An expanding aneurysm gives rise to intermittent headache in the same location. Almost 40% of patients describe a premonitory sentinel bleed before their major subarachnoid hemorrhage. The incidence of headache in a ruptured aneurysm approaches 100%. The leading symptom is the so-called *thunderclap headache*, which is present in approximately 80% of patients. The acute onset of headache is caused by a ruptured aneurysm and the entrance of blood into the subarachnoid space, rapidly causing meningeal irritation and clinical signs of meningismus, neck pain, and stiffness. Hemorrhagic CSF also causes varying degrees of cerebral vasoconstriction that causes alteration of consciousness ranging in spectrum from mild confusion to coma. Nausea, vomiting, diaphoresis, photophobia, neck pain, tachypnea, tachycardia, and hypertension are common associated symptoms and signs.

A third-generation CT scanner can accurately detect subarachnoid hemorrhage in up to 95% of cases; however, sensitivity decreases to 74% after 3 days (172). A lumbar puncture is mandatory if no blood is detected on CT. The remainder of the cases can be detected on lumbar puncture by the presence of red blood cells that do not clear in four samples of CSF. Subarachnoid hemorrhage can be distinguished from a traumatic tap by the presence of xanthochromia in the CSF sample. Once the diagnosis of subarachnoid hemorrhage is confirmed, prompt neurosurgical consultation is required to determine if the patient qualifies for arteriography and surgical clipping. Aneurysms are best confirmed by four-vessel catheter angiography. Patients in deep coma are managed conservatively. Medical management includes intravenous hydration, control of hypertension, and nimodipine therapy to reduce vasospasm. In most countries surgery is recommended within 72 hours after the headache onset, depending on the grade of the disease. For the appropriate neurosurgical management, Hunt and Hess (173) established a ranking scale ranging from headache plus nuchal pain (I°) until deep coma (V°). Overall mortality from subarachnoid hemorrhage is approximately 50%.

Cerebral Venous Thrombosis (International Headache Society Code 6.7). Cerebral sinus or venous thrombosis is the most important differential diagnosis of subarachnoid hemorrhage, because the leading symptom in cerebral venous thrombosis is headache (more than 80%). *Thunderclap headache* is the first symptom in approximately 25% (20). In other cases the headache is dull and waxing and waning. Cerebral sinus or venous thrombosis is most often accompanied by additional signs, especially epileptic seizures (50%) and drowsiness, somnolence, or coma (50%). Motor deficits occur in approximately one-third of the patients. In almost 50% of patients papilledema can be detected. A contrast-enhanced CT scan usually shows nonspecific signs of elevated intracranial pressure, such as small ventricles or diminished sulci. In certain circumstances the specific delta sign is observed (174), a contrast-sparing region within the occipital part of the superior sagittal sinus or the confluence of sinuses. If the CT scan is suspicious for cerebral venous thrombosis, the diagnosis can be confirmed by MR angiography, or digital subtraction angiography when the former is unavailable. Early diagnosis is essential because heparin therapy may improve consciousness and resolve neurologic function. Recently, tissue plasminogen activator has been used with anecdotal success. Patients with cerebral venous thrombosis should be monitored carefully, because of secondary complications such as infarction, intraparenchymal bleeding, hydrocephalus, and seizures. An antiepileptic strategy should be initiated on the first day.

Headache Caused by Dissection of Carotid or Vertebral Arteries (International Headache Society Code 6.6.1). The onset of pain is usually acute and of moderately severe intensity, often with pulsating character. The pain might be referred to the cranium or face or may be located in the neck. The most frequent associated signs are those of cerebral ischemia. Ischemic signs may be delayed up to 1 month after the onset of pain and may be caused by embolism from the site of dissection (175). The combination of cervical pain, headache, and ischemic signs is characteristic and provides a strong clue to the diagnosis. One of the most common features of carotid dissection is ipsilateral Horner's syndrome (40% to 60%), followed by tinnitus, hemiparesis, and cervical pain. Whether there is increased frequency of carotid or vertebral dissection in migraineurs remains controversial (176). Nevertheless, when ischemic signs occur in migraineurs, the differential diagnosis of dissection must always be considered. Doppler and duplex sonography are sensitive tests for dissection, but MR angiography is the preferred investigation, or catheter angiography if this is not available. Anticoagulant therapy to prevent embolism is given for up to 6 months, unless the dissection extends intracranially.

Hypertensive Headache. Acute, severe headache is a prominent symptom of hypertensive encephalopathy, which occurs when sustained elevation in blood pressure exceeds the upper limits of cerebral autoregulation. The rate of blood pressure increase is more important than the absolute value; nonetheless most patients have a blood pressure that is in the range of 250/150. Other symptoms of hypertensive encephalopathy include nausea, vomiting, visual disturbances, seizures, confusion, and coma. Evidence of other end- organ damage (e.g., proteinuria and azotemia), focal neurologic deficits, retinal hemorrhages, and papilledema may also be present.

One percent to 2% of patients with essential hypertension progress to hypertensive emergency for unknown reasons. Arteriolar distension and interstitial extravasation produce focal vasogenic edema that often shows as nonspecific bilateral abnormalities in the occipital lobes and subcortical white matter (177). The therapeutic goal in the treatment of hypertensive emergency is reduction of the mean arterial pressure by 15% to 25% in the first 48 hours. Intravenous nitroprusside is the drug of choice because it can be rapidly titrated and has a high efficacy. Invasive blood pressure monitoring should be done through an arterial line while infusing nitroprusside. Use of oral nifedipine has fallen out of favor because of its potential for causing a steep decrease in blood pressure and precipitating ischemic stroke.

Ischemic and Hemorrhagic Stroke. Headache is three times more common in intraparenchymal hemorrhage than in ischemic stroke (171). The headache is usually focal, mild to moderate in severity, and ipsilateral to the stroke. The character of the headache may vary widely depending on the location and extent of the hemorrhage. In general, the severity of the headache does not correlate well with the size of the stroke or cortical involvement (178). Headache was lateralized in only 46% of patients; of those cases, 68% of headaches were ipsilateral to the stroke. When a patient presents with a headache and lateralized findings, a CT scan without contrast is the initial investigation of choice (179).

Acute Posttraumatic Headache Associated with or without Epidural Hematoma (International Headache Society Codes 5.1, 6.2.3). After head trauma, headache is common. For example, headache is always present in epidural hematoma caused by ruptured meningeal arteries involved in skull fracture. Depending on the size of the hematoma, the patient appears to be normal during the first minutes or hours after the head injury. During this *lucid interval* only headache might be present. Subsequent symptoms and signs include anisocoria, deterioration of headache, nausea, and rapid loss of consciousness. If skull fracture is suspected, CT scan is the diagnostic procedure of choice. Epidural hematoma is a neurosurgical emergency (180).

Central Nervous System Infections. Patients with CNS infections such as bacterial and viral meningitis, encephalitis, brain abscess, and human immunodeficiency virus (HIV) disease often present to the emergency room with acute severe headache. Untreated bacterial meningitis has a high mortality. Fever (95%), neck stiffness (88%), and altered consciousness (80%) are the common associated findings in meningitis (181). A CSF protein of greater than 220 mg per 100 mL, cell count above 2,000 per mL and a CSF to serum glucose ratio of less than 0.23 are 99% specific for bacterial meningitis. Antibiotic therapy should not be delayed while waiting for a CT scan or a lumbar puncture result. Ceftriaxone or cefotaxime should be given as soon as possible. Ampicillin is added if infection with *Listeria* is suspected. Children with presumptive *Haemophilus influenzae* meningitis should also receive dexamethasone, 0.15 mg per kg every 6 hours for 2 to 4 days. Untreated herpes encephalitis has a 70% mortality, even though it accounts for only 3% of all cases of viral encephalitis (182). Associated symptoms and signs include headache, low-grade fever, altered consciousness, vomiting, seizures, and focal neurologic deficits. A contrast-enhanced CT is only 60% sensitive in diagnosing herpes encephalitis, and MRI with gadolinium is the neuroimaging study of choice. A definitive diagnosis may require temporal lobe biopsy. Herpes simplex encephalitis requires immediate treatment with intravenous acyclovir, 10 mg per kg every 8 hours for at least 10 days. Of all the patients with HIV who visit the emergency room, 20% do so with complaints of headache, and 82% of these headaches are from secondary causes (183).

Cryptococcal meningitis, toxoplasmosis, progressive multifocal leukoencephalopathy, HIV encephalitis, undiagnosed mass lesions, sepsis, and drug reactions are some of the common causes of headache in an HIV patient (184). All new headaches in patients with HIV should be evaluated with a neuroimaging study such as MRI and a lumbar puncture.

Acute Glaucoma. Patients with acute angle closure glaucoma usually present with severe pain localized to the eye and radiating to the ear, sinuses, teeth, or forehead. Accompanying signs are blurred vision, dilated unresponsive pupil, and ciliary injection. Nausea and vomiting are less common. Diagnosis is made by measuring intraocular pressure. Treatment is with miotics (b-receptor blocking eye drops, pilocarpine, or systemic acetazolamide).

Exercise Headache and Headache Associated with Sexual Activity (International Headache Society Codes 4.5 and 4.6). Recurrent headache associated with sexual activity is termed *coital cephalalgia*. It is categorized as explosive, similar to the thunderclap headache of subarachnoid hemorrhage. The differential diagnosis from the latter can be established if a series, even a cluster, of headache attacks under identical circumstances is reported. Often the diagnosis is helped when the headache is time locked with orgasm (orgasmic cephalalgia).

Exercise headache is also explosive in character and time locked with strenuous activity. Again, subarachnoid hemorrhage figures prominently in the differential diagnosis. Often the complaint is recurrent. All such patients should have an MRI scan of the head with particular attention to the posterior fossa structures, although

rarely is an abnormality found to explain the headache.

Subacute and Chronic Headache of High Intensity. In these cases, focal or generalized neurologic symptoms and signs, rather than the headache itself, usually cause the patient to present to an emergency room. Most of the diseases that cause acute secondary headaches discussed previously also may on occasion present with subacute headache (e.g., cerebral venous thrombosis). In the diseases discussed here, headache is subacute in onset with growing intensity during days or weeks.

Arteritis Cranialis (Headache Associated with Giant Cell Arteritis; International Headache Society Code 6.5.1). Headache is the leading symptom of giant cell arteritis, being present in approximately 80% to 90% of patients. It is described variably as unilateral or bilateral temporal headache, forehead pain, or diffuse headache. Occipital headache is rare, although occasionally patients complain about neck pain (185). Often the pain is severe and pulsating in nature and can be localized to the artery of involvement. Giant cell arteritis is associated with polymyalgia rheumatica. Additional symptoms include visual symptoms, especially transient or permanent unilateral or bilateral vision loss. An almost pathognomonic symptom is jaw or masticatory claudication. Furthermore, some patients present with tongue pain or tongue infarction. The disorder occurs in patients older than 60 years. Neurologic examination may reveal prominent, tender, nonpulsatile temporal arteries, although both temporal arteries might be normal. Funduscopy may reveal pale, swollen optic disks, indicating visual dysfunction. In the emergency room, the most rapid investigative information can be obtained from the erythrocyte sedimentation rate or C-reactive protein tests. The erythrocyte sedimentation rate might be as high as 100 mm, but may be normal. The sensitivity of this test decreases with the patient's age. Biopsy of the temporal artery is the investigation of choice, but the result may be negative if the arterial segment involved is limited in extent. Symptoms and signs respond rapidly to corticosteroids, usually 100 mg of oral prednisolone. To avoid visual loss, treatment with corticosteroids should be started urgently as soon as the diagnosis is suspected and before arterial biopsy.

Chronic Posttraumatic Headache Associated with or without Subdural Hematoma (International Headache Society Codes 5.2, 6.2.2). Subdural hematomas result from tearing of bridging veins. A history of trauma, presence of a CSF shunt catheter, or anticoagulation therapy should raise the suspicion of a subdural hematoma. Elderly persons are at high risk. Headache associated with subdural hematoma may present within as short a time as 6 hours or as long as 6 months. It may be a mild to moderate dull daily headache, without neurologic symptoms and only subtle neurologic signs. On the other hand, some patients report dizziness, drowsiness, disorientation, delusion, or personality changes, together with focal neurologic signs. A contrast-enhanced CT scan is the method of choice, if subdural hematoma is suspected. The management of a subdural hematoma, either conservative or surgical drainage, depends on its size and clinical signs.

Intracranial Infection (International Headache Society Code 7.3). Acute, severe secondary headaches associated with intracranial infections were discussed previously. Certain intracranial infections and encephalitides present with more indolent forms of headache, however.

Meningitis caused by *Mycobacterium tuberculosis* may take a chronic course of weeks to months. Immunosuppressed patients, patients with a history of pulmonary tuberculosis, or a history of tuberculosis in the neighborhood are at particular risk. Characteristically, CSF has a pleocytosis of less than 100 lymphocytes per milliliter, and an elevated protein of 100 mg per 100 mL. It may also be hemorrhagic. The CSF glucose level is moderately decreased to between 20 to 40 mg per 100 mL. Ziehl-Neelsen staining is negative in most cases. The sensitivity and specificity of diagnostic procedures for tuberculosis have been markedly improved by polymerase chain reaction. Indolent headache and clinical course are also features of cryptococcal meningitis and borreliosi *s*. The neurologic complications are much less severe in the former. CSF India ink or antigen tests may identify the *Cryptococcus*. Testing CSF for *Borrelia* produces variable positivity.

A specific virus is identified in less than one-half the cases of encephalitis; the most common virus identified is herpes simplex. No precise data exist on headache duration and localization in this disorder, but patient history can be short, lasting from hours to a few days. Occasionally, the headache and clinical presentation take an indolent course. Headache may be accompanied by meningism and fever (186). Other characteristic symptoms are fever, epileptic seizures, somnolence, coma, confusion, and focal neurologic deficits that localize to frontotemporal regions of brain cortex. MRI is the first-line diagnostic investigation. Mass lesions of necrotic tissue, usually in frontal or temporal cortex, can cause elevated intracranial pressure and shift of brain structures. Lumbar puncture should be performed immediately after scanning, mass effect permitting. CSF study may reveal a predominately lymphocytic pleocytosis of up to 300 per mm (186), a slightly elevated protein, higher if the CSF is hemorrhagic, and a moderately decreased glucose level. EEG may indicate a temporal focus. Treatment is with intravenous acyclovir.

Nasal and Sinus Headaches. Acute sinus infection often presents with moderate to severe headache and facial pain (see Chapter 52). Localization of the head pain corresponds to the affected sinus (e.g., retroorbital or temporal in ethmoid sinusitis or frontal in frontal sinusitis). Pain is often alleviated by an upright position (187). Sinusitis is typically associated with nasal obstruction, fever, and localized tenderness. Investigation with sinus radiography or CT scanning is diagnostic. To avoid intracranial complications, immediate antibiotic and anticongestant therapy is mandatory. Severe infections and pain may be relieved by sinus drainage if appropriate (e.g., maxillary sinusitis).

Headache Caused by Brain Tumor or Other Causes of Elevated Intracranial Pressure. Headache is the leading symptom in brain tumors, present in 48% of patients (188), or other conditions that elevate intracranial pressure. In brain tumors, headache usually takes a course of weeks to months, being of crescendo intensity. Initially, it may present only on wakening, before becoming continuous. Headache may reflect the tumor locus (e.g., posterior with cerebellar lesions) by involving contiguous pain- sensitive intracranial structures, later becoming generalized when intracranial pressure becomes elevated. Characteristically, the headache is briefly accentuated by behaviors that increase intracranial pressure such as coughing, sneezing, bending, defecation, and sexual intercourse. Patients with brain neoplasia usually present to the emergency room because of neurologic complications such as seizures, confusion, and paresis. A history of headache described previously and seizures in an emergency room patient require contrast-enhanced CT scanning to confirm the diagnosis and to estimate the degree of any mass shift and secondary hydrocephalus.

CHAPTER 49

Facial and Head Pain Caused by Myofascial and Temporomandibular Disorders

Edmond L. Truelove, Samuel F. Dworkin, Jeffrey A. Burgess, and John J. Bonica

This chapter presents a detailed discussion of temporomandibular disorders (TMD) that produce orofacial pain. It primarily deals with painful myofascial conditions involving the muscles of mastication, internal derangements (ID) of the contents of the temporomandibular joint (TMJ) space, degenerative and other changes of the condyle and other osseous components of the joint, and fractures, infections, and tumors of the joint. Myofascial pain syndromes produce orofacial and other head pain and contribute significantly to headache. Because myofascial pain syndromes with trigger points affect various parts of the body, the subject is discussed in detail in Chapter 28 and Chapter 29. Some of the myofascial syndromes cause referred pain to the TMJ and other oral and facial structures and are undoubtedly similar to those discussed elsewhere in the text, and although similarities in the pathophysiology, symptoms, and signs between myofascial pain of the muscles of mastication and other areas exist, the causative factors between the two groups can be somewhat different.

TMDs and myofascial pain of the muscles of mastication are the most common cause of pain in the face, cranial vault, and other parts of the head. Facial pain is of particular importance because it has special psychological meaning to the patient and because its frequency, variable etiology, and complex nature commonly cause both medical and dental professionals to be involved collaboratively in its diagnosis and management. Research Diagnostic Criteria for Temporomandibular Disorders (RDC/TMD) have become available as a reliable taxonomic system for diagnosing and classifying the subtypes of TMD (1). This classification system contains reliable criteria and examination methods, consensually validated by expert panels, for diagnosing the most common forms of TMD. They are addressed in the bulk of the content of this chapter. The RDC/TMD uses a dual-axis system, also referred to in this chapter, to allow simultaneous consideration of physical diagnosis (axis I) and psychosocial assessment (axis II). As with virtually all chronic pain conditions discussed throughout this text, chronic orofacial pain is associated for a significant minority of TMD clinic cases with psychological and psychosocial morbidity, chiefly in the form of depression and dysfunctional chronic pain behaviors such as excessive treatment seeking and use of analgesic medications. A graded chronic pain scale, incorporated into axis II of the RDC/TMD, indicates, for example, that approximately 20% to 30% of clinic cases may present with significant psychological disturbance in the form of elevated symptoms of depression, anxiety, and somatization. These forms of psychological dysfunction tend to occur with other chronic pain complaints. Multiple health care visits and prolonged reliance on pain medications are common. Taken together, these data support the view that TMD is best understood as a chronic pain condition often associated with appreciable pain intensity and periodic limitations in mandibular function while it shares, in common with the most prevalent pain conditions, namely persistent back pain and chronic headache, the risk for appreciable psychological and psychosocial disturbance.

TEMPOROMANDIBULAR DISORDERS (III-3)

Disorders of the TMJ and associated muscles of mastication are collectively classified as TMDs and are recognized as the major source of nondental chronic orofacial pain. It is useful to view TMD as a cluster of related disorders that have many common features. The most important and by far the most common presenting symptom is pain localized at the TMJ, in the preauricular area, or in the muscles of mastication. In addition to complaints of pain, patients with TMDs typically also present with findings of limited or asymmetric patterns of jaw opening and joint sounds usually described as clicking, popping, grating, or crepitus.

The pathophysiology of TMD is confusing because the site of pain does not always coincide with the site of pathology or dysfunction. Patients with persistent TMDs are at risk for increasingly aggressive treatment, with a focus on surgical and dental reconstruction. Scientific studies have not clearly identified the specific causes of TMD and therefore some of the treatments advocated are empiric and without scientific foundation. Furthermore, these procedures are invasive and costly and often have irreversible consequences. A recent National Institute of Health Technology Consensus Conference on the management of temporomandibular disorders (2) concluded that irreversible surgical procedures such as occlusal, or bite, adjustment and surgery of the TMJ are not indicated as early or initial treatments for this condition.

Wide differences of opinion regarding the etiology, pathophysiology, diagnosis, and treatment of TMD caused the American Dental Association to review the scientific literature about TMD and to prepare a Presidential Report meant to assist clinicians in understanding which of the many concepts regarding TMD were based on sound scientific principles and supported by valid research findings (3). The American Dental Association report continues to represent an excellent summary of current standards regarding the diagnosis and management of TMD, and the discussion of TMD that follows in this chapter is consistent with the outline and recommendations of that American Dental Association report and the National Institute of Health Technology Consensus Conference cited previously. More detailed information can be found elsewhere (4,5 and 6).

Basic Considerations

Epidemiology

Increased numbers of reliable epidemiologic studies assessing the prevalence of TMD related pain are available and show surprising agreement when comparable definitions and methods are used. Table 49-1 summarizes findings from several of those studies, as compiled by LeResche (7). In general, agreement exists that women report TMD pain on average approximately twice as frequently as men, with the population-based (as opposed to clinically based) prevalence rates varying from approximately 3% to 10% for male subjects and approximately 9% to 18% for female subjects, across all ages. These studies also agree that the modal age in the population for TMD-related pain occurs in women during their reproductive years, with the rate of TMD falling for both men and women after age 45 years.

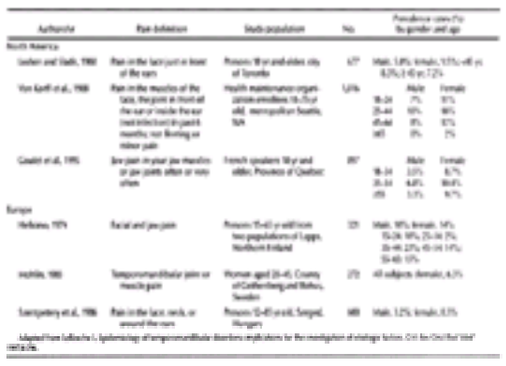

TABLE 49-1. Pain in the temporomandibular region: findings from population-based prevalence studies

The available epidemiologic data also support the conclusion that the presence of at least one sign or symptom of TMD, other than pain, is quite common (Table 49-2). Joint sounds elicited during functional excursions of the TMJ, for example, may be present in as much as 25% of an otherwise asymptomatic population (8).

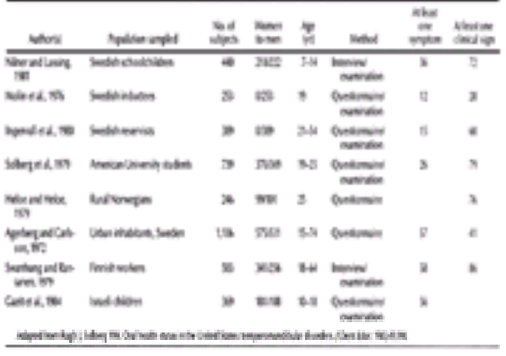

TABLE 49-2. Percentage of temporomandibular signs and symptoms in selected populations

We carried out a survey in a probability sample of 1,265 adults (aged 18 to 75 years) and of 320,000 enrollees of a large health maintenance organization, to which 1,060 persons responded (9). Analysis of the data indicated a 6-month prevalence of 12.1% for TMD pain in those enrolled in the study. The community cases showed a female-to-male ratio of 2:1, with approximately a 6:1 female-to-male ratio among clinic cases. As a major symptom compelling treatment, pain seems to diminish markedly in prevalence by the sixth decade of life. Our data indicated that only 2% of those aged 65 years or older had reported TMD pain in the prior 6 months. Only 23% of those who had pain sought health care. This lends support to the consensus that those seeking treatment are in an appreciably smaller group than those reporting symptoms. Some authors have suggested that painful TMD is even more prevalent than studies indicate, often being misdiagnosed as other forms of head and neck pain.

Anatomic and Physiologic Bases*

To appreciate the various painful disorders that are caused by pathophysiologic factors involving the TMJ, it is essential to understand the anatomy and function of the joint as well as the muscles of mastication.

Anatomy of the Temporomandibular Joint. Each TMJ is generally considered to be an ellipsoid synovial joint divided into upper and lower synovial cavities by a complete fibrous articular disk (5,10). Structures that make up the joint on each side are the anterior part of the mandibular fossa and the articular tubercle of the temporal bone above, and the condyle of the mandible below. Figure 49-1 depicts the ligaments of the joint.

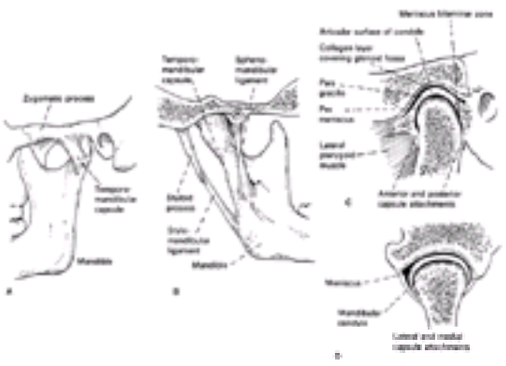

Figure 49-1. Anatomy of the left temporomandibular joint. **A:** Lateral view. **B:** Medial view. **C:** Sagittal section through the joint. **D:** Frontal section.

The articular capsule is a thin fibrous envelope attached above to the circumference of the mandibular fossa and the articular tubercle and below to the neck of the condyle of the mandible. The fibrous disk attaches to the inner surface of the articular capsule. The capsule is loose above the attachment to allow the disk to slide easily along the temporal bone, whereas below the disk the capsule is stretched more tautly.

The lateral ligament (formally called the temporomandibular ligament) strengthens the anterolateral aspect of the fibrous capsule. It is a rather short and narrow fibrous band attached superiorly to the lower lateral border of the zygomatic process of the temporal bone, with its fibers passing obliquely downward and backward to the lateral surface and posterior border of the neck of the mandible. It is covered by the parotid gland and by the integument.

The sphenomandibular ligament is a flat thin band of fibrous tissue attached to the spine of the sphenoid bone, becoming broader as it descends. It is fixed inferiorly to the lingula of the mandibular foramen. It lies medial to the capsule of the joint, and its upper lateral surface is in relation to the lateral pterygoid muscle and the auriculotemporal nerve. The stylomandibular ligament is a specialized band of the cervical fascia that extends from near the apex of the styloid process of the temporal bone to the angle and posterior border of the ramus of the mandible between the masseter and medial pterygoid muscles. This ligament separates the parotid from the submandibular gland.

The *articular disk* (see Fig. 49-1C) is formed of fibrous tissue; it is a thin oval plate placed between the condyle of the mandible and the mandibular fossa. Its circumference is connected to the articular capsule and anteriorly it attaches to the tendon of the lateral pterygoid muscles. The articular disk divides the joint into two cavities, each of which is lined by a synovial membrane. The upper cavity is above and the lower cavity below the articular disk. The upper cavity, the larger and looser of the two, continues from the margin of the cartilage covering the mandibular fossa and the articular tubercle onto the superior surface of the disk. The lower cavity passes from the undersurface of the disk to the neck of the condyle and is prolonged somewhat further inferiorly behind than in front.

The *synovial tissues* that line the periphery of the superior cavity appear as villi in sagittal section of the joint. The posterior villi are actually folds of synovial

membrane that are attached to the temporal bone and to the superior surface of the pars posterior of the meniscus. These folds allow the meniscus to translate as far as 2 cm forward by unfolding into a sheet when the jaws open. The synovial tissues of the inferior cavity are also folded into villi. The meniscus actually projects into the villi at the anterior portion of the cavity to form a heellike process of tissue. This pliable heel allows the meniscus to rotate posteriorly as the condyle translates forward.

Nerve Supply. The nerve supply of the TMJ is derived from branches of the mandibular nerve. The medial posterior lateral and lateral half of the anterior wall of the capsule are innervated by a large branch of the auriculotemporal nerve as it crosses posteriorly to the neck of the condylar process. The posterior temporal nerves innervate the lateral-anterior corner of the capsule, whereas the masseteric nerves supply the medial anterior corner. These nerves contain both large A and b fibers associated with pacinian, Ruffini, and Golgi proprioceptive endings and also contain small A- d and unmyelinated fibers. All these nerve endings supply the periphery of the meniscus where it attaches to the bone through the superior belly of the lateral pterygoid muscle.

Physiology of the Temporomandibular Joint. The muscles of mastication permit the movement of the mandible to be depressed (jaw opening) or elevated (jaw closing) (Fig. 49-2). Only the mandible moves because the maxilla is firmly articulated by sutures to the other bones of the skull and, when the mandible is at rest, the maxillary and mandibular teeth are slightly separated. On contact, the teeth assume their occlusal position. In addition to depression and elevation, the joint allows protrusion or retraction of the mandible as well as lateral displacement and some rotation. The two parts of the temporomandibular articulation are the one between the condyle and the articular disk and the other between the disk and the mandibular fossa. When the jaw is depressed or elevated (the mouth is open or closed), motion takes place in both parts. The disk glides anteriorly on the articular tubercle and the condyle moves on the disk like a hinge, causing the mandible to rotate around a horizontal access whose center of suspension traverses the rami of the mandible near their middle (4,5,10). Near this accidental lingula, which is adjacent to the mandibular foramen, is the attachment of the sphenomandibular ligament and the sling formed by the masseter and medial pterygoid muscles. When the jaw is open, the angle of the mandible moves posteriorly while the condyle glides forward as the short arm of a lever; the chin is the long arm of the lever and describes a wide arc. The motion between the condyle and articular disk is largely one of accommodation to the change of position. When the jaw is closed, some of the force is applied to the condyle as a fulcrum, especially when biting with the incisors. When chewing with the molars, however, pressure is applied more directly between the teeth, and the condyle acts more as a guide than as a fulcrum. In protrusion of the mandible both disks glide forward in the mandibular fossa, whereas during lateral displacement one disk glides forward and the other remains in place. During grinding or chewing the mandible is first displaced laterally by the forward movement of the one condyle, and the mandible is then brought back into place by the action of the closing muscles and the meshing of the teeth.

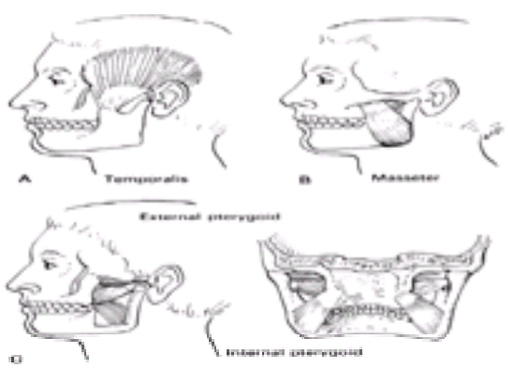

Figure 49-2. Anatomy of the muscles of mastication. **A:** The temporalis muscle is supplied by anterior and posterior deep temporal nerves from the anterior trunk of the mandibular division of the trigeminal nerve. **B:** The masseter muscle is supplied by the masseteric branch of the mandibular division. **C:** Lateral and medial pterygoid muscles. The medial pterygoid muscle is supplied by the medial pterygoid branch of the mandibular nerve, whereas the lateral is supplied by the lateral pterygoid nerve from the same nerve. (See text for function of each of these muscles.)

The mandible is depressed and the mouth is thereby opened by the lateral pterygoid muscles, which are assisted by the digastric mylohyoid and the geniohyoid muscles. Elevation of the mandible to close the mouth is accomplished by the masseter, medial pterygoid, and temporalis muscles. Protrusion of the mandible is effected by the simultaneous action of the lateral pterygoid muscles of both sides and by the synergistic action of the closing muscles. The mandible is retracted by the action of the posterior fibers of the temporalis, whereas lateral displacement is achieved by the action of the opposite lateral pterygoid muscle.

Clinical Considerations

The most common forms of TMD are most usefully divided following the RDC/TMD approach (1) into three major groups, depending on the presumed site of pathophysiology: Group I is disorders of the muscles of mastication [commonly referred to as *myofascial pain dysfunction* (MPD)] and which may or may not be associated with limitations in vertical range of mandibular motion; group II is ID of the contents of the joint space, commonly further classified depending on whether the articular disk reduces (returns to a functional position) after mandibular opening and excursions, and whether ID conditions are associated with limitations in ability to open or close the jaws (so-called closed-locking conditions of the mandible), the latter condition occurs with a low prevalence as data from our own population-based studies show and as confirmed by studies of clinical populations in Sweden, using the RDC/TMD (11); group III represents degenerative joint disorders (commonly labeled DJD) and other changes of the condyle associated with arthralgia of the TMJ (painful TMJ), a fairly prevalent condition among TMD clinic cases, degenerative changes consistent with diagnoses of TMJ arthritis and arthroses, which occur with low prevalences of less than 5% when RDC/TMD criteria are applied, or both conditions. In addition, other clinical conditions diagnosed as subtypes of TMD, but occurring rarely, include pain subsequent to mandibular or TMJ fractures, infections, and tumors of the joint.

The following discussion presents the etiology, clinical signs and symptoms, diagnosis, and treatment for MPD, ID, and DJD. The last category is included for completeness, but this far-ranging and much less prevalent miscellaneous category is discussed in less detail than the other groups.

Disorders of the Muscles of Mastication (III-3)

Myofascial pain (MPD) is a common pain complaint. It is generally chronic and the mechanisms associated with the etiology of the condition are poorly understood. No specific pathophysiologic process has been identified either peripherally or centrally and, at present, MPD is seen as a nonspecific pain condition of the muscular structures of the face, neck, and back. In severe cases, dysfunction occurs along with pain. The diagnosis of MPD is usually restricted to cases in which no underlying organic pathology can be detected and in cases of trauma when pain and muscle tenderness persist after normal healing. MPD is a common form of chronic musculoskeletal pain and accounts for significant treatment seeking, but only modest progress has been made in furthering our knowledge of the pathophysiology, etiology, or definitive treatment for the condition. Patients with MPD usually present with complaints of static facial pain that increases during or after jaw function. Stress and tension can also trigger episodes as can physical activities that strain the muscles of mastication. Mandibular opening may be limited because of muscle tightness. Frequently, pain is referred to adjacent sites including the dentition and the TMJ.

Etiology and Pathophysiology. The etiology of disorders of the muscles of mastication (MPD) has been the subject of much controversy, in part because several tissues are involved, and because separation of physical, behavioral, habitual, traumatic, and psychophysiologic factors is difficult. The following list includes the more common etiologic factors thought to be associated with the onset of MPD symptoms:

- Psychophysiologic factors (stress, tension, depression), traumatic dental occlusion (premature contact of teeth)
- Malalignment of the jaws (upper or lower jaw in a forward or retruded position)
- Incorrect position of the internal components of the joint space, resulting in muscular fatigue (displacement of the meniscus)
- Incorrect position of the joint in the fossa
- Excessive vertical spacing between the maxilla and mandible
- Habitual parafunction of the jaws (clenching and grinding of the teeth, fingernail biting, jaw posturing)
- Muscle splinting and posturing to limit movement of injured or inflamed joint
- Central deregulation of muscle activity

In some cases, however, the connection between the proposed cause and confirmation through controlled research findings are lacking. Peripheral and central theories of etiology compete to explain the pain and dysfunction of the muscles of mastication and other TMD categories. Hypotheses of peripheral pathophysiologic processes focus on the *occlusion* (i.e., how the teeth and jaws function in relation to each other) and on pathologic muscle function, arising mostly from hyperactivity. The extent to which malocclusion and malposition of the jaws play a role in the evolution of muscle dysfunction is unproved. Although a few studies indicated a causative role for dental malocclusion (12), several others showed no relationship between occlusion and MPD or the broader category of TMD (13,14 and 15). One study compared two sets of patients with malocclusion: One-half received orthodontic treatment, whereas the others were untreated (16). A 10-year follow-up failed to identify a difference in the incidence of TMD in either group, suggesting that malocclusion does not predispose to TMD and also that orthodontic treatment neither protects nor increases the risk of TMD, as suggested by some investigators and clinicians. In fact, the strikingly high prevalence of TMD in young women and the reduction in symptoms with age appear to argue against a major mechanical jaw position defect as the primary cause in the development of TMD (14,15), especially because malocclusion is equally common in both genders. Studies of the role of occlusions in all forms of TMD are technically complex; further studies might identify a relationship between occlusion and TMD in general, but at present one must proceed carefully in suggesting that malocclusion is a major causative factor (17).

Central Hypotheses. Central etiologic hypotheses for TMD give preeminence to psychosocial and psychophysiologic factors that burden the patient excessively and result in abnormal use of the muscles of mastication, as seen in excessive jaw clenching and tooth grinding (bruxism) (18). The presence of pain behaviors, stress responses, and other psychophysiologic factors appears to be better documented and investigated than other psychological factors such as overt psychopathology or clear-cut personality disorders. In general, studies suggest that, whereas the level of psychopathology is no greater in patients than in controls, MPD patients appear to respond less adequately to stressful stimuli than others (19). Also those with MPD have a greater tendency to contract the muscles of mastication and engage in parafunctional mandibular habits (e.g., clenching and bruxism) in response to stressful stimuli.

Many features of MPD are similar to overuse injuries seen in other soft tissues of the body, and several studies confirm that those with MPD have a greater frequency of tooth contact and clenching than those in control populations. Although the incidence of nocturnal bruxism has been investigated and found to be greater in MPD and ID cases (20,21), other studies have also confirmed an increased frequency of tooth contact during awake periods in some patients (22).

The primary factor associated with an increased rate of bruxism and clenching is observable stress leading to maladaptive and behavioral change. Contrary to widespread opinion, little evidence exists to link increased rates of jaw parafunction (bruxism and clenching) with malocclusion (tooth and jaw relationships) or traumatic occlusion (dental bite) (23,24 and 25).

Symptoms and Signs. The signs and symptoms of TMD depend to a degree on whether the muscles or joints are primarily affected. As with musculoskeletal disorders of other regions, however, a significant overlap in clinical findings and involvement of several structures frequently results in patients presenting with both joint and muscle symptoms. The major findings that occur in all forms of TMD are presented:

- Unilateral or bilateral pain in the ear, TMJ, side of face, temples, mandible, and preauricular region
- Report of limited mouth opening (less than 40 mm)
- Report of deviation of jaw laterally during opening
- Facial pain while chewing
- Clicking of the joint with function
- Report of periodic or continuous locking during attempted function
- Tinnitus or other vague ear symptoms
- Sensation of a change in the bite
- Recurrent headache with increase in pain on awaking and with stress
- Report of nocturnal clenching or bruxism
- Crepitus in joint during function
- Spasticity in the muscles of mastication with prolonged chewing
- Diffuse jaw pain in the presence of no dental pathology
- Associated complaint of neck pain and stiffness
- Swelling in the preauricular region
- Difficulty in chewing
- Rapid development of an open bite with loss of contact of the anterior maxillary and mandibular teeth
- Report of recent change in occlusion (bite)

Certain symptoms predominate in muscle disorders of the facial region, whereas others are primarily associated with IDs or degenerative changes of the joint. Later discussion attempts to separate the differences for each diagnosis.

A triad of symptoms (i.e., muscle pain, joint sounds, and limitation in jaw opening), uncomplicated by degenerative or inflammatory changes in the joint itself, makes up the most commonly encountered chronic orofacial pain syndrome. The term MPD has been given to this uncomplicated myogenic pain syndrome. Of those who seek treatment for MPD, women predominate over men by a ratio greater than 5:1. The mean age of onset for pain is the third decade of life (3,26).

Pain. Pain primarily arising from muscle is usually of moderate intensity and frequently bilateral. The pain is described as a persistent dull ache, often with a boring or gnawing quality. The regions of the masseter, temporalis, and preauricular areas are most often involved. The pain usually responds to mild analgesics such as aspirin, nonsteroidal antiinflammatory drugs, or acetaminophen. With progressive involvement the muscle pain becomes more severe and is associated with muscle trismus that fails to respond to nonnarcotic analgesics.

Adjacent sites of the head and neck are prone to referral of pain complaints that are often vague and diffuse (27). Patients frequently report deep ear pain and pain radiating throughout the maxilla and mandible. In persistent cases, patients typically seek diagnostic and treatment assistance from dentists and otolaryngologists, ascribing their symptoms to dental infection or middle ear pathology.

Pain is spontaneous and persistent, but remissions of varying duration do occur. Pain can frequently be elicited by palpation of the muscles of mastication but the clinical significance of pain elicited by palpation is not completely understood.

Changes in Jaw Function. Whether primarily of muscle or joint origin, changes in jaw function are a common occurrence. Reduction in mandibular opening can result from muscle spasm and fatigue, but can also occur in the presence of a displacement of the joint meniscus sometimes associated with inflammation of the joint contents. Inability to open the jaw can range from mild restriction of a few millimeters to total inability to separate the teeth.

Joint Sounds. MPD is frequently associated with joint sounds, most typically clicking of the joint with function. The true clinical significance of joint sounds is not well understood and, because joint sounds occur frequently in the general population, for this group of MPD patients such joints sounds are not viewed as particularly contributory (8,28). In some patients the clicking indicates the presence of both a muscle and joint disorder, but all clicking within the TMJ does not come from a displacement of the meniscus.

Clenching and Jaw Parafunction. If questioned, most patients with MPD and ID disorders report an increased incidence of waking or nocturnal bruxism (gnashing) or clenching of the teeth. When first questioned, patients might initially deny such activities but, after instructed to monitor the actions of their orofacial musculature, most report some level of parafunction. Other oral habits, including nail biting, frequent gum chewing, and cheek biting are contributing factors that require assessment when a diagnosis of TMD is suspected (29,30 and 31).

Behavioral and Psychological Factors. Most of those presenting with symptoms of both MPD and ID of longer than 1 month's duration experience an increase in stress or other adverse emotional reactions (29,30,31,32,33 and 34). They can report changes in sleep patterns, fatigue, and other signs of psychophysiologic dysfunction. Almost all studies consistently indicate that behavioral, emotional, and psychosocial issues are important contributing components in MPD and are frequently present in patients diagnosed with ID as well. The most frequently reported psychological concomitants of MPD are anxiety, depression, decreased interest or ability to cope with work and family responsibilities, and related illness and pain behaviors, including increased medical and dental treatment-seeking activities.

Hormonal Factors in Temporomandibular Disorders and Myofascial Pain Dysfunction. TMD and MPD are significantly more prevalent in female than male subjects,

and female sex hormones have been suggested to play a role in either susceptibility or persistence of chronic musculoskeletal facial pain. A community-based study of several thousand women over 40 years of age found hormones to be a risk factor for TMD, with a 30% excess risk of developing TMD if estrogen replacement was used (35). The study also analyzed data from more than 7,000 women between the ages of 15 and 35 and found a 20% higher risk for developing TMD or MPD if oral conceptives were used.

Diagnosis. Because TMDs frequently affect both the muscles and joint, clinical findings often overlap and make a firm diagnosis difficult. Correct diagnosis is most often based on history and clinical findings and is frequently assisted by the results of radiographic examinations. Less frequently, laboratory tests are needed. In complex cases special procedures such as arthrography and computed tomographic (CT) scans are required. Frequently, pathobiological changes (e.g., muscle or joint inflammation) and psychological distress (e.g., stress responses) factors must be identified and managed if all aspects of the patient's symptoms are to be treated successfully.

Clinical Findings. The following list presents the major clinical findings common in MPD:

- Spontaneous report of pain, usually not at the joint, but described as muscle ache, tenderness, or tired jaw; muscle tenderness with palpation (masseter, temporalis, lateral pterygoid, digastric, sternomastoid, and neck muscles)
- Muscle trigger points with pain referred to other sites
- Muscle pain with function (pain with prolonged contraction or stretching of the muscles)
- Deviation of the mandible or an asymmetric pattern of jaw movement during opening (deviation can be corrected at full opening or can remain)
- Restricted opening (restriction can be minor or moderate; less than 40 mm of opening considered restricted)
- Joint clicking during opening, closing, or both
- Percussion tenderness in several teeth (secondary to prolonged clenching or bruxism)
- Elevation of electromyographic levels (not a consistent finding but sometimes present)
- Pain reduction or elimination with ice or cooling spray to the affected muscles
- Pain elimination with local anesthetic infiltration of the affected muscle
- Evidence of tooth wear from clenching and bruxism (similar patterns can be seen without pain)
- Recent history of contributing behavioral factors (including stress, tension, anxiety), often stemming from psychosocial areas, such as family, work, or school

Several clinical findings and symptoms are usually encountered simultaneously and occur in both muscle and joint disorders. Fractures and degenerative changes of the joint can produce many secondary changes that are easily confused with primary muscle dysfunction or IDs. Differential diagnostic considerations are presented in the final section of this chapter and summarized in Table 49-3.

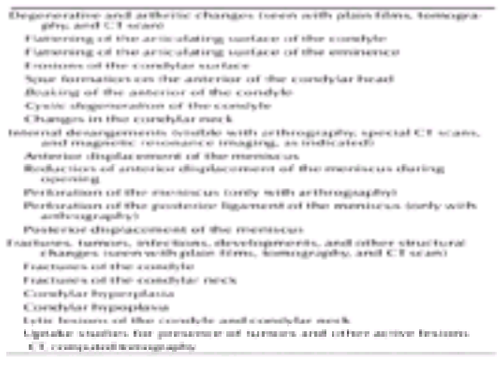

TABLE 49-3. Radiographic findings in temporomandibular disorders

Laboratory Findings. Laboratory studies for MPD are generally not required. They are usually limited to patients suspected of having orofacial symptoms secondary to generalized arthritic changes caused by such systemic disorders as rheumatoid arthritis and lupus erythematosus. Studies of chemical changes within the joint during acute and chronic TMD episodes have revealed differences between control subjects and patients with symptomatic joints. Interleukin-1 b levels in synovial fluid of the TMJ have been found to be associated with pain and hyperalgesia of the TMJ and also associated with anterior open bite, suggesting that elevated levels predict tissue damage and destruction within the joint (36).

Radiographic Findings. Radiographic findings are negative for MPD and extensive radiographic investigation is not warranted for this myogenic disorder. Radiography is potentially valuable, however, in establishing a diagnosis of arthritis and IDs. The timing and selection of radiography are important. Furthermore, the limitations of radiography should be considered in establishing a diagnosis.

Psychological and Behavioral Findings. As already mentioned, all chronic pain conditions are associated with appreciable morbidity for psychological and psychosocial dysfunction. For the majority of these patients, such negative affective and cognitive states appear to be transient and associated with the onset or exacerbation of jaw-related pain. However, studies repeatedly confirm that clinic populations dependably contain numbers of patients whose psychological disturbance meets criteria for major affective disorders, principally depression and elevated somatization. Somatization—the predisposition to identify nonspecific physical sensations as troubling symptoms and often associated with health care visits—has emerged as an important clinical consideration because it seems a reliable predictor of poor treatment outcome. In this regard, the presence of physical symptoms need not be so elevated as to meet formal (e.g., *Diagnostic and Statistical Manual*, fourth edition) criteria for a somatoform disorder; rather, an emerging clinical consensus views as problematic the presence of four to five nonspecific symptoms, such as tremors, night sweats, and heart palpitations, in the absence of confirming pathobiology. This relationship among psychological conditions of depression, anxiety, and somatization is probably not limited to TMD sufferers, but may be associated with a variety of conditions in which so-called chronic benign pain is a predominant feature, including headache, back pain, irritable bowel syndrome, and fibromyalgia.

Methods for assessing these psychological and psychosocial factors are included, for example, in the RDC/axis II assessment protocols, but a wide variety of measures have been used to support the finding that TMD clinic cases are at risk for important psychological disturbance. Some of the better-known measures for which an appreciable literature exists, even relevant to TMD, include use of the Minnesota Multiphasic Personality Inventory (MMPI), the Beck Depression Inventory, the Symptom-Checklist 90 (Revised), and the Multidimensional Pain Inventory developed by Turk and colleagues. The experienced clinician-interviewer—physician or dentist—can frequently obtain an excellent assessment of behavioral factors by the routine use of these measures, together with a structured psychosocial interview. Because family- and work-related stress can contribute significantly to the onset of symptoms, careful history-taking methods should be used to determine if psychosocial stressors, especially those related to career, family, and social factors, are important to the patient's current personal and interpersonal functioning.

Treatment. The treatment of all forms of TMD, including MPD, incorporates both general components used in treating all TMD patients and specific approaches limited to treatments applied only to particular forms of the problem. The functional nature of TMD furthermore requires that factors that might allow continued trauma to muscle and joint components be identified and eliminated. Although not always possible, therapy should first be directed toward removing causative factors, if known, to prevent continued damage and persistent symptoms (see following discussion).

Control of Causative Factors. The development of muscle pain is generally the result of overuse of the muscles of mastication, sometimes consciously. This typically occurs through the development of learned habits that allow muscle response to proceed outside of awareness. Control of muscle overuse requires several steps: counseling the patient to reduce the frequency of tooth contact caused by clenching, bruxing, and oral habits; reduction of stress through identification of behavioral factors that lead to clenching and muscle pain; and relaxation strategies or biofeedback to reduce muscle activity and produce physical relaxation (37,38).

Physiotherapy. Physiotherapy includes the use of ice packs on tender muscles, injection of muscle trigger points, passive or active stretching of the muscles of mastication, and general physical exercise to reduce the focus on excessive use of the jaw muscles (see Chapter 88 and Chapter 89). Interest has increased in the use of external energy sources such as laser, diathermy, and ultrasound in the treatment of TMD, but randomized trials have not shown significant differences in these approaches (39). Injection of trigger points has been a common treatment modality in MPD and TMD, with variable results reported in short- and long-term

outcomes. A number of preexisting nonphysical factors appear to influence the outcome of trigger point therapy including unemployment caused by pain, constant pain, and lack of relief with analgesic medications (40). Comparisons between use of dry needling, injection of sterile water, saline, and local anesthetics to treat trigger points have generally not demonstrated different results except for decreased postoperative discomfort with use of local anesthetics (41,42).

Drug Therapy. Drug therapy can include the use of skeletal muscle relaxants, sedative-hypnotics to ensure a good night's sleep, nonopioid analgesics, and opioids to relieve transient moderate to severe pain. Medications may be useful in the early stages of MPD and may be necessary to provide muscle relaxation and pain control at levels that improve patient function (43). It is essential to avoid prescribing opioids and other dependency-producing medications for long-term chronic nonmalignant pain unless all other treatment modalities have failed and the patient is enrolled in a chronic pain management program with careful monitoring of medications and regular follow-up. Diazepam is an effective muscle relaxant but shares the same risks for dependency seen in patients using opioids. Patients who have vegetative signs and symptoms of depression should be given a trial of antidepressants (44,45) (see Chapter 83, Chapter 84 and Chapter 85).

Appliances. Splints, bite guards, and habit control appliances, such as nonmandibular repositioning bite splints to alleviate jaw movement habits and reduce the frequency of nocturnal and waking clenching, have been shown to be effective. Comparisons of active versus placebo splints and splints worn for only a few minutes each day versus longer periods of use have shown little difference in treatment outcomes with placebo and brief splint use as effective as more aggressive splint therapy (46). Simple inexpensive splints that are made chair side or by the patient have been shown to provide equivalent pain reduction as more costly custom-made appliances (47). These findings and findings demonstrating nonsplint therapy as effective as splint therapy (47) raise questions about common current approaches to TMD treatment.

Occlusal Equilibration. Bite adjustment should *not* be used as the first line of treatment and is not indicated in most cases of MPD or TMD. Equilibration has been determined to be an irreversible procedure and should be avoided unless clearly indicated (3). A minor spot bite adjustment, however, can be useful in those patients in whom minor occlusal discrepancies have become a focus for parafunctional habits. Care should be exercised before initiating even small adjustments in the bite when the patient appears to be extremely focused on or obsessed with the discrepancy. In such cases behavioral evaluation should precede any irreversible treatment including bite adjustment.

Surgical Management. No surgical treatment is indicated for patients with MPD.

Psychological and Psychiatric Treatment. Studies have demonstrated a strong relationship between long-standing myofascial pain and emotional and behavioral changes (1,32,33). Some patients benefit from stress management or other forms of focused, brief counseling, whereas others justifiably require more definitive psychotherapy. It seems reasonable to assert that most TMD patients require less intensive forms of assistance in managing life stressors and psychosocial components of their problem. The patient should be given complete information regarding probable causative factors, the rationale for conservative reversible therapies, as outlined previously, and the benign noninvasive course of the problem. This often provides enough reassurance to preclude development of persistent treatment-seeking behavior.

Exacerbating conditions that provoke persistent anxiety and depression should be identified and discussed with the patient. In extreme cases, inquiry into suicidal ideation is appropriate and necessary, and consultation or referral to a mental health practitioner is often indicated, both for further psychological evaluation and cognitive-behavioral or psychodynamic psychotherapy. In general, psychological therapies that favor cognitive-behavioral approaches are more readily accepted by these often somatically focused patients. Psychophysiologic therapies that incorporate biofeedback and relaxation have proven helpful to many patients (48,49 and 50). A trend too recent to be validated with empirical data has been to consider tailoring biobehavioral therapies for specific TMD (and other chronic pain) patients based on their axis II level of psychological and psychosocial functioning and to do so cutting across their axis I or physical diagnosis (51,52). In summary, cognitive-behavioral therapies are the most commonly invoked for chronic pain patients with significant psychological and psychosocial disturbance. These cognitive-behavioral therapies emphasize relaxation and self-management strategies to alter patterns of negative thoughts and dysfunctional attitudes. This therapeutic approach incorporates education, skills acquisition, cognitive and behavioral rehearsal, and strategies for generalization and maintenance. A National Institute of Health Technology Assessment Conference (53) concluded that such approaches were usefully integrated into the treatment of chronic pain and many chapters of this text are devoted to the specific components of cognitive-behavioral therapies that can be applied across chronic pain conditions. Cognitive-behavioral therapies are the modal form of biobehavioral treatment provided by well-respected multidisciplinary pain centers.

INTERNAL DERANGEMENTS OF THE JOINT SPACE CONTENTS

Etiology and Pathophysiology

ID of the components of the joint space refer primarily to abnormalities in the functioning relations of the articular disk and the bony articular surfaces of the TMJ, articular fossa of the temporal bone, and articular surface of the condyle of the mandible (54,55). ID disorders can be initiated either by a traumatic blow to the mandible, producing relatively rapid, usually self-reversible, changes within the joint spaces, or by more slowly occurring changes produced by chronic pathologic patterns of muscle hyperactivity, restriction in condylar movement imposed by malocclusion, or, rarely, developmental defects or predisposition to derangement. Few data are available, however, to support the contention that malocclusion and ID are related causally.

In ID, the articular disk and the condylar surfaces acquire a maladaptive functional pattern that can cause the disk to be displaced in one of several directions. Sometimes, the displacement is not entirely self-correcting, provoking pain and dysfunctional patterns of jaw movement (55,56 and 57).

In general, the same role given to psychophysiologic, psychological, and psychosocial factors in the etiology of MPD that can lead to ID is also thought to apply to many ID syndromes. (See previous discussion of the role of anxiety, depression, stress, and psychosocial issues in the etiology of MPD.)

Symptoms and Signs

Pain

Pain may or may not be associated with ID. Nonpainful ID is likely to represent a nondisease adaptation phenomenon. When pain is a predominant symptom for ID patients, it is usually localized to the joint itself, but can also be referred to the preauricular area immediately in front of the joint or to the ear. Pain that occurs during function and movement is often described as sharp or shooting and of brief duration, with residual aching that can last for a considerable time. With ID, mild pain can usually be elicited by palpation of the joint.

Changes in Jaw Function

Joint pathology and IDs of the meniscus or its attachment usually affect one joint. In such cases the patient's symptoms, including pain and deviation on opening, are localized to the affected side. Deviation of the mandible from the midline as the jaw opens can vary from subtle to several millimeters. Anterior displacement of the meniscus with its self-reduction to normal position is associated with a return of the jaw to midline at full opening. More significant deviation without correction at full opening in association with severe jaw opening limitation in acute cases may suggest the presence of an anterior disk displacement without reduction.

Joint Sounds

Clicking sounds during function might indicate an ID of the meniscus, usually an anterior displacement. If the patient reports a prior pattern of clicking with cessation of clicking immediately before the onset of pain, accompanied by limited opening and deviation to the affected side with opening, a diagnosis of anterior displacement of the meniscus *without reduction* should be suspected.

Clicking alone should be used only in the most general way to assist in the determination of pathologic ID of the TMJ, because approximately 35% to 40% of adults surveyed have clicking sounds in the TMJ without other evidence of pathology (28,58). Several studies have reported a high incidence of clicking in patients presenting for TMD treatment, with approximately 35% to 40% continuing to experience clicking after pain and other signs of dysfunction have been eliminated. Such a high rate of clicking in normal populations and *cured* TMD patients suggests that clicking be used only as a secondary diagnostic criterion of TMD (3,28,59), and unless joint pain or significant physical dysfunction (catching or episodic locking) occurs, clicking should be considered an adaptive process.

Joint Pain and Swelling

The onset of actual joint pain and swelling suggests the presence either of acute inflammation, infection, or recent trauma with effusion within the joint. In such cases the changes are usually unilateral unless the inflammation is the result of immune system pathology, such as that encountered in lupus erythematosus and rheumatoid arthritis (see Chapter 27).

Rapid Changes in Dental Occlusion (Bite)

In normal adult populations the bite, or occlusion, is remarkably stable. A sudden change in the occlusion, particularly an anterior open bite with loss of contact between the anterior maxillary and mandibular teeth, indicates an aggressive change in the structures of the joint. Patients with preexisting malocclusion often report changes in their bite, but these tend to be subtle. For those with previously stable bites a sudden change in occlusion indicates the need for further clinical and radiographic evaluation.

Parafunction and Behavioral Factors

As mentioned previously, muscle hyperactivity in the form of clenching and bruxism, as well as behavioral and psychological factors, are present in patients with ID, as they are in MPD patients. Some tentative evidence has shown that patients with true joint pathology might not demonstrate maladaptive stress and related behaviors to the same extent as MPD patients, but further exploration of this distinction is necessary (60).

Diagnosis

The following major clinical findings contribute to the diagnosis of ID of the TMJ:

- Joint clicking during opening, closing, or both occurs with anterior displacement of the meniscus, with reduction of the meniscus to normal position during function
- Deviation of the mandible during opening and correction to midline at full opening (anterior displacement with reduction to normal position during opening)
- Significant deviation of the mandible to the affected side during opening without correction to midline at full opening (anterior displacement without reduction during function)
- Intermittent catching or locking necessitating manipulation of the mandible to effect full opening or closing
- Limited opening, frequently less than 30 mm
- Assisted opening of less than 40 mm
- Joint pain during function and movement
- Joint pain during palpation (mild)
- Elimination of joint click when opening and closing the mandible in a protruded (anterior) position (anterior displacement of the meniscus with reduction during function)
- Soft tissue crepitus in the joint during function (present in some IDs and with irregularities in the tissue lining of the joint)

As already noted, clinical findings for ID and MPD overlap, and the differential diagnosis can be difficult. The presence of both muscle and joint symptoms or findings usually suggests the presence of multiple TMD disorders with both muscular and joint problems. Frequently, locking of the jaws with inability to open more than 20 to 30 mm also indicates an anterior displacement of the meniscus without reduction (i.e., the anteriorly displaced meniscus cannot return to its initial position unassisted). If few muscle symptoms are present, the diagnosis of anterior displacement of the meniscus is even more probable. Another confounding factor in the diagnosis of TMD is the presence of otherwise asymptomatic clicking (anterior displacement of the meniscus with reduction) in a patient with severe myofascial pain. The presence of pain and joint sounds often leads the clinician to assume that the problem resides in the joint when symptoms are arising from muscle rather than joint dysfunction.

Laboratory Findings

Laboratory findings are of limited value for patients with ID unless concurrent local or systemic pathology affecting the joint is present. When laboratory studies for TMD are considered, they are usually limited to patients suspected of having orofacial symptoms secondary to generalized arthritic changes caused by such systemic disorders as rheumatoid arthritis and lupus erythematosus. As stated earlier, studies of chemical changes within the joint during episodes of joint pain have revealed higher levels of interleukin-1 b in synovial fluid that are associated with pain and hyperalgesia of the TMJ. Actual joint changes are also associated with these chemical findings, suggesting that elevated levels predict tissue damage and destruction within the joint (36).

Radiographic Findings

A substantial number of reports have been published regarding the value of radiographic findings and their reliability in the diagnosis of ID and degenerative disorders of the TMJ (61). Currently, radiography is of little value in determining correct condylar position, and CT scanning is the method of choice for visualizing the osseous contour of the joint and for identifying arthritic changes. Screening films such as transcranial views of the joint are of limited value, especially because they only allow assessment of the lateral aspect of the joint and are only two dimensional (61,62).

If an ID of the meniscus is suspected and previous therapy has failed to resolve symptoms, arthrography or magnetic resonance imaging studies of the joint to evaluate the disk and its attachment should be considered. Because arthrography is an invasive procedure with potential complications, it should be reserved for cases that are being considered for surgical intervention in which perforation of the disk is suspected. Many clinical centers have selected magnetic resonance imaging as the major imaging modality for detection of IDs of the TMJ (63,64). Magnetic resonance imaging is considerably less invasive than arthrography and provides dynamic images of the joint and capsule without artificially altering joint dynamics. Table 49-3 presents major findings of both standard and special radiography of the joint.

Certain considerations should be noted regarding radiography of the joint. Several methods of treatment for ID and DJDs are based on the concept that the joint is displaced in the fossa and requires repositioning with either surgical, orthodontic, or dental procedures. Clinicians who use these treatments use radiography to determine joint position, but studies conducted in several centers suggest that most radiographic techniques are unreliable in identifying the true position of the joint in the fossa. Therefore, radiography should be used with caution in suggesting either diagnosis or choice of therapy for ID (61,62,64,65). Arthrography, CT scans, and magnetic resonance imaging can provide such information, but the true role of disk displacement as a causative factor in chronic TMD pain is unresolved (66,67,68,69,70 and 71).

Psychological and Behavioral Findings

The psychological and behavioral factors for ID closely parallel those observed with MPD patients except, as previously noted, some reports indicate that ID patients might be better adjusted psychologically and be less maladaptive to stressful situations. The evidence is conflicting on this view and it may simply be that the ID group includes a smaller percentage of patients who exhibit pain or illness behaviors as compared with the percentage for those in the MPD and other pain groups, such as patients with chronic back pain.

Treatment

As with MPD, treatment should first seek to control causative factors that can be clearly identified and should proceed conservatively.

Control of Causative Factors

Avoidance of initial and repeated overt joint trauma such as a motor vehicle accident, sports injury, assault, or prolonged dental or medical treatment is important. Once joint function has been compromised from prior trauma or low-grade repetitive injury, the joint should be protected from additional injury during sports or medical

or dental treatment. Also, reduction in clenching and parafunctional habits (the same factors present in myofascial disorders) is essential. Posturing habits of the mandible, tensing the jaw either in an anterior or posterior position, and mechanical restriction of the mandible in a posterior position or habitual popping of the joint must be controlled to minimize repeated injury.

Nonsurgical Management

Nonsurgical management should include jaw habit control and home-based physiotherapy such as ice packs and passive opening exercises. If the disk is displaced and opening is restricted, it can sometimes be repositioned with gentle manipulation of the mandible while the joint is distracted from the fossa by using a *few* pounds of pressure. Nonsteroidal antiinflammatory drugs (Table 49-4) are frequently helpful in reducing joint symptoms.

Drug	Suggested dose
Aspirin	650–1,000 mg every 4–6 hr
Ibuprofen	600–800 mg every 6 hr
Naproxen	250–375 mg every 6–8 hr
Oxaprozin	600 mg every 12–24 hr
Sulindac	200 mg every 12 hr
Piroxicam	20 mg every 24 hr
Prednisone	10–30 mg every 24 hr

TABLE 49-4. Nonsteroidal antiinflammatory drugs used to treat internal derangements

Muscle relaxants are of value if the ID is accompanied by MPD (see previous discussion). Analgesics are frequently required and those recommended for myofascial pain are usually acceptable, except during episodes of moderate to severe pain when opioids may be required.

Splints and bite guards that are nonrepositioning and are designed to reduce habitual clenching and parafunction of the mandible are helpful. A repositioning splint to recapture the disk and prevent repeated disk displacement may be required if the patient repeatedly experiences mandibular locking. Repositioning splints might not improve joint function permanently and should be used conservatively, because their use can lead to irreversible changes in the joint and bite (5,9,24,72,73).

Surgical Therapy

Surgical therapy, including disk repositioning and plication of the ligament in cases in which the disk remains displaced and pain continues, is indicated (74,75). The most common and successful surgical procedure is arthroscopic rather than an open joint approach. In more chronic cases disk removal might be required, especially if the disk is perforated or extensively damaged (76). Some surgeons advocate implantation of an artificial meniscus, but that procedure has met with frequent complications and is rarely advocated (77). Rejection of implant material has been widely reported (78). Overall, the long-term prognosis for TMJ surgery is unclear and currently it should be advised with great caution (79).

Psychological and Psychiatric Treatment

If required, psychological and psychiatric treatment is carried out (as described previously; see Disorders of the Muscles of Mastication). Patients with organic disease of the TMJ may also have concurrent psychological or behavioral problems that reduce tolerance and coping or even generate additional symptoms. Considering any patient with chronic pain on both a physical and behavioral axis is important in planning and providing therapy.

DEGENERATIVE JOINT DISEASE OF THE CONDYLE AND OTHER OSSEOUS COMPONENTS OF THE TEMPOROMANDIBULAR JOINT (III-4,5)

Etiology

Evidence has shown that in some cases IDs appear to increase the risk for degenerative changes of the condyle and bony surface of the fossa, suggesting that the meniscus serves a protective role for the articulating osseous components of the joint (64,66,67). The relationship between arthritic TMD and coexisting systemic metabolic or autoimmune forms of arthritis seems to be clearly identifiable as a special causative factor in DJD. In specific cases, DJD can be clearly associated with elderly patients, in whom the few principal degenerative diseases are osteoarthritis and rheumatoid disease. The following etiologic factors are seen in DJD:

- Fractures of the condyle, condylar neck, and fossa
- Degenerative changes (secondary to overt jaw trauma or blunt impact, aging, adaptive remodeling)
- Nonreducing ID of the meniscus
- Autoimmune arthritis (rheumatoid arthritis, lupus erythematosus)
- Idiopathic condyliasis (condylar resorption)

Emotional and behavioral factors have been implicated as potential causative factors. According to some, prolonged parafunctional misuse of the muscles of mastication can result in pathologic remodeling of the condylar head (55). The proposed mechanism suggests that ID of the meniscus associated with excessive parafunction allows destructive forces to be applied directly to the osseous surface of the condyle, leading to condylar remodeling. The evidence for so-called pathologic remodeling under these conditions, however, is largely speculative.

Symptoms and Signs

Pain

The location and pattern of clinical pain symptoms of DJD closely resemble those reported with IDs of the joint. Pain is typically localized to the joint, ear, and preauricular area, with minimal radiation or referral to the surrounding regions. Painful symptoms include stiffness of the joint, which tends to develop gradually. Acute onset of pain is rare unless associated with trauma superimposed on underlying disease. Pain is generally dull in character and tends to be mild in intensity. Pain occurs during function and can be severe, and joint palpation results in localized joint pain.

Changes in Jaw Function

Jaw opening can be unimpaired or only slightly affected, yet major restriction in ability to open the jaw can be found when severe inflammation of the joint is present. If only one side is affected, deviation in the opening pattern to the affected side without correction (i.e., return to midline) at full opening can be observed. If the degenerative process triggers ankylosis of the condyle, jaw mobility is dramatically restricted and surgical intervention may be required.

Joint Sounds

The onset of crepitus, as opposed to discrete clicking and popping joint sounds, is a firm sign of degenerative arthritic changes in the articulating osseous surfaces of the joint and indicates loss or damage to the soft tissue articulating components, such as the meniscus. A change from soft tissue crepitus to hard bony grating signals a progressive degenerative process. Crepitus, however, is not invariably present in every patient.

Emotional and Behavioral Changes

Psychological factors cited for MPD can also present in this group of patients, but the clinical impression and some research findings suggest that those in the DJD group have less psychological disturbance than those in groups already discussed.

Diagnosis

Clinical Findings

Clinical findings associated with degenerative changes of the TMJ are presented:

- Joint pain during function
- Joint pain during palpation of the joint
- Joint crepitus during function (soft or hard tissue crepitus)
- Limited opening (major restriction with severe inflammation of the joint and ankylosis)
- Deviation to the affected side during opening (deviation without correction at full opening)
- Development of an anterior open bite (caused by posterior and superior shift of the mandible)
- Presence or absence of muscle pain and spasm
- Pain, swelling, or both in other joints indicative of systemic disease

Especially in the elderly, symptoms tend to be aggravated by cold and general poor health. Usually, the patient with rheumatoid disease is easily recognizable, because this generalized condition first presents itself in the TMJ only rarely. By contrast, osteoarthrosis associated with ID is probably of a secondary type, occurring as a result of altered disk anatomy and function. This secondary type of osteoarthrosis occurs in a localized area, generally in the absence of systemic involvement. Therefore, diagnosis in such a case would be based on local findings of the presence of joint pain, crepitus, restricted joint movement, and radiographic findings.

Laboratory Findings

Detailed discussion of all laboratory tests and their significance in systemic joint pathology are beyond the scope of this discussion. Those laboratory tests most frequently useful in the diagnosis of DJD are sedimentation rate, rheumatoid factor, and antinuclear antibody (they are helpful in lupus erythematosus and other immune system dysfunctions). Laboratory studies to identify gout or psoriatic arthritis are of infrequent value in DJD unless other findings indicate that disease. Newer laboratory studies are under investigation using synovial fluid aspirated from the joint, and although differences are seen in inflammatory mediators in healthy and TMJ patients, the value of these findings in the routine management of TMDs has not been established.

Radiographic Findings

Given the caveats concerning radiographic interpretation of the TMJ (see Internal Derangement of the Joint Space Contents, previously in this chapter), the diagnosis of DJD is more dependably associated with radiographic findings than are the other categories of temporomandibular disturbance. CT and newer imaging methods reveal osseous changes in both the condylar contour and, less frequently, in the articular cortical plate (66,67,80). These changes can appear as loss of continuity of the cortical area and as erosion of the bony surfaces, resulting in marked degenerative flattening of the condyle in particular and osteophyte formation on the peripheral joint surfaces. Although changes can occur with both osteoarthritic and rheumatoid disease, condylar destruction is more severe in cases of rheumatoid involvement.

Treatment

Because the specific nature of degenerative arthritic changes is not well understood, treatment directed toward causative factors is generally not available except for those patients with autoimmune forms of arthritis in whom antiinflammatory medications might slow or stop the damage caused by the inflammatory process. The extent to which the degenerative process can be controlled is unknown.

Nonsurgical Management

Nonsurgical treatment can include the use of physiotherapy, muscle relaxants, and analgesics, as for myofascial pain. Antiinflammatory medications can be helpful, as for IDs, except higher dosages are often required. Splints can be used as for myofascial pain, but not in the same way as for IDs. It is not thought that repositioning appliances are of value.

Surgical Therapy

Some patients with severe arthritis may benefit from surgical management of the joint including arthrocentesis or arthroscopy to remove osteophytes and irregularities caused by the degenerative process (74,75,79). In severe cases the placement of a prosthetic joint may be indicated. If the degenerative process has produced a severe open bite or malocclusion, orthognathic surgery can also be necessary to restore mandibular function.

FRACTURES, INFECTIONS, AND TUMORS OF THE JOINT

It is well beyond the scope of this chapter to present the etiologic and symptomatic picture, diagnosis, and treatment of such varying clinical conditions as jaw fracture and neoplastic or metastatic diseases of the TMJ. A full discussion of these conditions has been presented by Okeson (81).

Etiology

Except for traumatic or disease-related fractures of the condyle, condylar neck, or fossa (82), infections and tumors of the joint occur rarely, have not been systematically studied, and are managed on a case-by-case basis. Proposed causative factors for this category of TMD include gonococcal arthritis, streptococcal arthritis, local benign and malignant tumors, metastatic cancer, and trauma. Whiplash trauma to the TMJ has become an increasingly popular etiology that is advocated as the cause for chronic headache and facial pain after rear-end motor vehicle accidents, but analysis of data related to the role of whiplash in TMJ pain and dysfunction has failed to demonstrate that soft tissue trauma to the joint during vehicle collisions is a high risk factor (83).

Symptoms and Signs

Clinical and laboratory findings can vary greatly across these different disease categories. A number of endocrine and hormonal assays are helpful in monitoring the patient with a history of secreting tumors that can metastasize to the joint. The occurrence of such metastases is infrequent, and such tests are usually unwarranted. Nevertheless, these studies deserve consideration in patients with a history of malignancy. Description of atypical symptoms (e.g., numbness, tingling, dysesthesia) and unresponsiveness to appropriate biomedical and biobehavioral treatments coupled with increasing physical disability suggests the need for additional evaluation including imaging studies. The following are clinical findings relevant to infections and neoplasms of the joint and to trauma and fractures of the joint region.

- Infections and neoplasms of the joint: joint pain at rest and during function; joint pain during palpation; joint swelling; limited opening (can be severe); deviation of the mandible during opening; unilateral posterior open bite; joint pain during contact of posterior teeth; spontaneous fracture of the condyle or condylar neck; neurologic and neurosensory changes on the affected side (e.g., paresthesia, anesthesia, and muscle wasting secondary to damage to cranial nerves); drainage from preauricular region; fever (present in infection); inability to retrude mandible; mandible displaced to unaffected side
- Trauma and fractures of the joint region: sudden development of cross-bite; deviation of mandible to affected side; limited opening; joint swelling; sudden development of bite changes or open bite

Treatment

Treatment for this group of pain-producing TMJ problems is, of course, as diverse as the conditions themselves and is clearly beyond our purposes here. It should be appreciated that many non-TMD neoplastic conditions can affect jaw function and mimic TMD (e.g., nasopharyngeal tumor, parotid neoplasm, developmental cysts). Obviously, the potential risk from neoplasms and infections requires careful monitoring and aggressive treatment. High-dosage antibiotic therapy with penicillin or other appropriate antibiotics is essential, and establishment of drainage through incision is required if the infection remains uncontrolled. The presence of infection requires culturing of the joint fluid, if possible.

Surgical management of tumors is generally required unless they have metastasized from other sites. Radiotherapy is usually attempted in such cases for palliation and local control. Fractures of the condyle and condylar neck can require fixation, depending on the degree of displacement of the components.

FINAL COMMENT ON DIAGNOSIS AND TREATMENT

Establishing the most appropriate diagnosis is complicated in TMD because a significant percentage of patients have both muscle and joint involvement. Table 49-5 identifies factors involved in its differential diagnosis.

Finding	Myofascial pain	Internal derangement	Degenerative diseases
Limited opening	±	+	+
Deviation during opening	+	+	+
Joint pain	–	+	+
Clicking	±	±	±
Crepitus	–	–	+
Joint swelling	–	–	±
Muscle tenderness	+	±	±
Bite changes	–	–	±
Joint locking	–	+	–
Clenching	+	±	±
Pain	+	±	+

+, usually present; –, usually absent; ±, variable

TABLE 49-5. Differential diagnosis of temporomandibular disorders

The treatment of TMD entails many of the same risks and complications encountered in the management of other forms of musculoskeletal disorders and arthritis (84). Drug side effects include gastrointestinal symptoms, allergies, and blood dyscrasias. Those agents used to control pain, muscle spasm, anxiety, and behavioral changes can lead to chemical or psychological dependence or both. The use of oral appliances can produce changes in the bite and alignment of the jaws. Surgery can lead to open bite and skeletal changes in addition to the usual risks involved with general anesthesia and surgery.

Because the results of most studies clearly suggest that managing the overwhelming majority of TMDs with conservative and reversible therapies offers an excellent chance for success, the clinician is encouraged to limit the use of invasive procedures to those patients who have failed conservative treatment and in whom behavioral factors appear to be of limited contributing value (2,5).

The role of stress and psychological issues has been so well documented for the major categories of TMD discussed here that an important therapeutic focus should be to control those issues and their resultant parafunctional habits and muscle dysfunction (3,37,52,53). Failure to do so can contribute to the development of sufferers who manifest resistant chronic pain and illness behaviors.

CHAPTER 50

Pain of Dental and Intraoral Origin

Margaret R. Byers and Jeffrey A. Burgess

Overwhelming clinical evidence suggests that the most commonly experienced orofacial pain is toothache (1,2). During the past several decades there has been progress in many areas throughout the world in controlling tooth decay through fluoridation programs, the educational efforts of the World Health Organization, and increased access to dental services. However, poverty and social inequalities in both developed and undeveloped countries, lack of health care, neglect, and other social problems have allowed dental caries and other causes of oral and dental pain to continue to be major health problems.

Toothache varies considerably in expression and as a result is easily confused with other pains that occur in the orofacial region (3,4). Dental pain can originate from nociceptive endings inside teeth (activated by stimuli to dentin or pulp) for which dental caries, pulpitis, and dentin exposure are the principal causative agents, or from periodontal tissues, especially periapical ligament around the tooth root apex. Intraoral pain may also arise in the mucosal tissues surrounding the teeth and covering the hard and soft tissues of the oral cavity. Pain of mucosal origin can originate as a consequence of trauma (e.g., tooth eruption) or can represent the first sign of local infection or systemic diseases as varied as measles, herpes simplex, immune system dysfunction, and malignancy. Although much of the sensory and autonomic nerve activity in oral mucosa and dental tissues is similar to that found elsewhere, oral mucosa has special functions (detection of material entering the mouth; reflexes related to mastication, swallowing, or speech), as do teeth (dentin production, enamel support, regulation of fluid dynamics in a noncompliant chamber, production of reparative dentin during wound healing) that affect the specific types of sensory innervation and the pain characteristics of these tissues.

In this chapter we present a survey of the odontogenic and mucosal conditions frequently associated with orofacial pain in two major sections: Basic Considerations consists of summaries of the normal neurobiology, pathologic reactions, and plasticity of sensory nerves in oral mucosa, teeth, and periodontium, as well as far-reaching changes in trigeminal ganglion and the central nervous system (CNS). The reader is referred to reviews that provide much more information about these topics (5,6,7,8,9,10,11,12,13 and 14). The section Clinical Considerations consists of a discussion of pain of odontogenic and of mucosal origins. Where relevant, we have used the terminology consistent with the diagnostic nosology prepared by the International Association for the Study of Pain (IASP) (15). For the most frequently encountered pains of odontogenic and mucosal origin we present the etiology, clinical signs and symptoms, diagnosis, and therapeutic procedures. Other reviews of orofacial pain mechanisms and their relationship to clinical diagnosis and pain provide additional information and are highly recommended (2,16,17,18,19,20 and 21). In the concluding section of this chapter, we summarize key issues in current research and clinical management of dental and oral pain. A detailed discussion of the management of oral mucositis pain can be found in Chapter 38.

BASIC CONSIDERATIONS

Pain Mechanisms in Oral Mucosa and Dental Tissues

An overview of the nerve supply of the head, distribution of the trigeminal nerve, general considerations of pain in the head, and the sensory innervation of teeth and oral mucosa via the maxillary and mandibular nerves has already been given in Chapter 46 and the basic pain mechanisms for trigeminal systems are discussed in Chapter 3, Chapter 4 and Chapter 5. Here the sensory and autonomic nerve supply to these regions is depicted in more detail (Fig. 50-1, Fig. 50-2 and Fig. 50-3). As discussed in Chapter 3, all tissues have specific A-b, A-d, and C nociceptive fibers that respond to acute injury or threat of injury, as well as A-d and C polymodal receptors and A-d and C silent nociceptors, and these also occur in teeth and oral mucosa (14,22,23). The cervical sympathetic ganglia supply vasomotor innervation, and parasympathetic innervation comes from the sphenopalatine ganglion, and probably also the otic ganglion. Smaller parasympathetic ganglia also exist (e.g., in the tongue) (24) that contribute to innervation of orofacial tissues and to some pain conditions (25). In the oral mucosa and periodontium, the vasoconstriction functions of sympathetic fibers are opposed by sensory neuropeptides and by parasympathetic agents, but pulpal vasoregulation depends only on sympathetic vasoconstriction and sensory neuropeptide vasodilation (10,11).

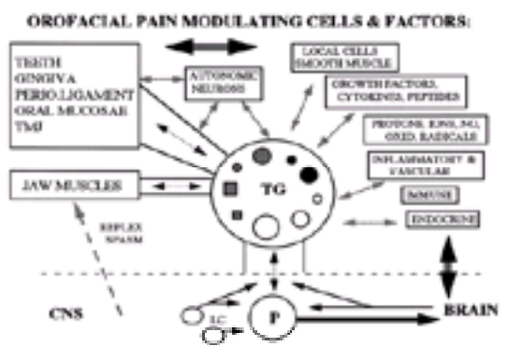

Figure 50-1. Schematic diagram showing the cells and factors that affect the flow of information in sensory nerves from tissues through the trigeminal ganglion (TG) and into the CNS. Modulating actions (*gray arrows*) that affect pain perceptions can occur at the nerve endings, along the nerve, in the TG, and at the central terminals. The intraneural dotted arrows are bidirectional because conduction and axonal transport can be bidirectional and because efferent release of neural factors affects the peripheral modulators and tissues. Neuronal types that affect pain are indicated in the TG by small circles for C fibers, medium size for A-d, and large for A-b. They are represented as black filled for nociceptive-specific; gray circles for polymodal; gray squares for *silent* nociceptors; and open circles for mechanoreceptive, thermoreceptive, or both kinds of neurons that have altered cytochemistry and activity in inflamed tissue. Whether a projection neuron (P) in the brainstem sends signals to the brain depends on the rate and intensity and combination of the incoming signals, and those depend on the variety of peripheral interactions and the modulations in the ganglion and dorsal horn. Each P neuron is modulated by local circuit (LC) neurons and by descending input from supraspinal centers, both of which can also affect the afferent presynaptic endings. Nociception-induced reflex spasms in jaw muscles (*dashed-line arrow*) may exacerbate pain conditions, possibly causing additional injury to the muscle and tendons, generating additional nociceptive signals. The endocrine and immune systems have additional important effects on the brain (*large arrow*) in addition to their peripheral actions. The peripheral modulation system has different properties in normal tissues compared with inflamed tissues, and both of those differ from neuropathic damage to the nerves.

Figure 50-1 depicts the main cellular interactions that affect the flow of afferent nociceptive information into the CNS. Information is conveyed by action potentials in milliseconds to seconds, primarily in the afferent direction through the ganglion to the CNS, but under some conditions, such as axon reflex or ganglion signal generation, the action potentials move out to the tissues where they cause the release of neurochemical agents such as substance P. In addition, a much slower system (many hours) carries molecular signals such as nerve growth factor via retrograde axonal transport from the peripheral endings to the cell body in the ganglion and delivers neuropeptides via anterograde transport to tissues for vasoregulatory and homeostatic functions. In some cases the transported signals move from the

peripheral endings all the way to the central endings (26) and into subsequent neurons (27), and also bidirectional transport occurs between the central endings and sensory cell body. For further details, see Chapter 3.

Depending on the rate of action potentials and the composition of the retrogradely transported material, the sensory neuronal cell body and neurons in trigeminal brainstem nuclei *know* whether peripheral tissues are normal, stressed, acutely injured, inflamed, necrotic, or healing. For example, nociceptor functions (including those of teeth and oral mucosa) are affected by (a) factors released from the damaged tissue such as protons, adenosine triphosphate, kinins, serotonin, prostaglandins, neuropeptides; (b) growth factors from injured local cells such as nerve growth factor; (c) inducible enzymes such as nitric oxide synthase and cyclooxygenase 2; (d) vascular factors such as platelet-derived growth factor and nerve growth factor; (e) neural agents such as substance P, calcitonin gene-related peptide, neurokinin A, excitatory amino acids, noradrenalin; and (f) cytokines or other signals from immune cells such as interleukin-1b, interleukin-6, interleukin-8, tumor necrosis factor-a, nerve growth factor, and opioid peptides (see Fig. 50-1). These agents interact with specific molecular receptors to initiate altered neuronal expression of membrane receptors, growth factors, neuropeptides, enzymes, and ion channels, as well as altered activity levels for those molecules (28,29,30 and 31). An additional set of agents such as galanin, neuropeptide Y, somatostatin, and opioid peptides appear to protect the nociceptive neurons from excessive reactions to neuroinflammatory conditions (32).

Once a tissue is injured and becomes inflamed, the complex cascade of cellular interactions in the periphery causes sensitization of the acute nociceptive physiology and of the polymodal receptors, specific efferent secretion of neuropeptides by sensory endings to cause neurogenic inflammation, altered sympathetic activity, altered tissue chemistry and signals (e.g., nerve growth factor, cytokines, inflammatory mediators), addition of some A-b fibers to the response, and activation of silent nociceptors. These features of peripheral neuroplasticity related to pain are discussed in greater detail in Chapter 3, and their effects on central neural function and pain perception are discussed in Chapter 4 and Chapter 5.

Given the extensive alteration of nociceptive functions and central mechanisms in response to inflammation, it should not be surprising that analgesics that are effective for inhibiting a healthy nerve may not work if inflammation or neuropathic injury is present, as appears to be the case for difficult anesthesia of inflamed teeth (*hot tooth* syndrome). Now that the mechanisms driving alteration of sensory phenotypes are becoming known, a major effort has been undertaken to develop new drugs to inhibit their inflammation-driven or neuropathic conditions, as suggested in analyses of tetrodotoxin-resistant sodium channels (33,34) and discussed further in Chapter 3. A number of clinical pain studies have used microdialysis of third molar extraction sockets in awake humans to correlate pain levels with the effects of nonsteroidal antiinflammatory agents on tissue levels of prostaglandin E_2 (35), gender differences in opioid mechanisms (36), and efficacy of preemptive analgesia on duration of postoperative pain (37). This is an important model system that will make fundamental contributions to our knowledge of mechanisms and to developing additional types of treatments, both for specific dental problems and for pain in general.

Oral Mucosa

The oral mucosa is extensively innervated by nociceptive, polymodal, mechanoreceptive, thermosensitive, and chemosensitive sensory fibers to provide a wealth of sensory information about material entering the mouth, and for sensory components of oral functions and reflexes. The innervation is regionally specialized so that each distinctive oral epithelium (e.g., palate, lip, cheek, tongue, buccal mucosa, gingiva, junctional epithelium) has its own pattern of sensory innervation (see Fig. 50-2). Within the oral cavity there is an anteroposterior gradient of sensory innervation density. Intraepithelial innervation consists of free endings, Merkel-neurite mechanoreceptive complexes, and chemosensory corpuscles (taste buds). Subepithelial receptors include various mechanosensory corpuscles, unencapsulated Ruffinilike receptors, and numerous free endings in subepithelial plexuses. In addition, sensory and autonomic innervation of the mucosal vasculature exists. Use of immunostains such as protein gene product 9.5 has enabled detailed studies of the sensory innervation of biopsies of human oral tissues (38); for example, showing reductions in innervation patterns of edentulous gingiva compared with focal increases in areas contacted by implant-retained dentures (39).

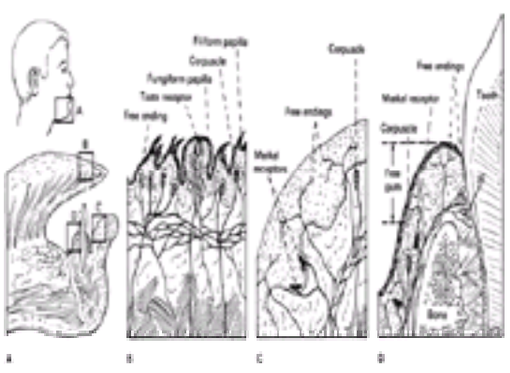

Figure 50-2. Oral mucosa. **A:** Sensory innervation has different components and patterns in different regions of the oral mucosa. **B:** Near the tip of the tongue numerous subepithelial corpuscles form a network of fine fibers beneath the epithelium with thin intraepithelial free endings in each filiform papilla. The larger fungiform papilla has a different epithelial structure, a taste receptor, and numerous fine fibers. **C:** In mucosa lining the inside of the lip, the epithelium is thicker, nonkeratinized, and less innervated than other regions. Fine intraepithelial fibers are found, as well as intraepithelial Merkel's receptors, subepithelial corpuscles, and fine fibers. **D:** The gum adjacent to the teeth has three different regions: junctional epithelium (JE), free gingiva extending above the alveolar bone, and attached gingiva next to the bone. The junctional epithelium has many free intraepithelial fibers. Free gingiva has fewer endings, most of which are in the crest. The attached gingiva has intraepithelial free endings above the dermal papillae, intraepithelial Merkel's receptors, and subepithelial mechanoreceptors, corpuscular endings, and a network of free fibers. Oral mucosa is also characterized by innervation of many blood vessels by fine sensory fibers.

Many of the thin fibers of oral mucosae are neuropeptide-rich, capsaicin-sensitive polymodal receptors that cause burning pain. These fibers promote neurogenic inflammation (40), and they play key roles in many mucosal pain syndromes. Some of them have widely dispersed branches to different dental regions, so that neurogenic inflammation and blood flow changes can be induced at distant sites, such as in gingiva, lip, buccal mucosa, tongue, and palate after stimulation of a maxillary tooth (10). These regional vasoregulatory reflexes involve interactions between the polymodal sensory fibers and the autonomic innervation (41).

Although oral mucosae are surface-covering tissues, their innervation differs from skin in some important ways. The elegantly detailed, receptor-specific neurotrophic and neuropeptide features of somatosensory innervation (42), do not hold true for all oral innervation. For example, in mice that do not produce the low-affinity p75 neurotrophin receptor molecule, the teeth and gingiva have dense neuropeptide-rich sensory innervation, whereas skin of those mice is only sparsely innervated (43,44). Also, calbindin D-28-K immunoreactivity characterizes the mechanoreceptive and thin fibers of oral mucosa (and is typical of viscerosensory fibers) but is not common in cutaneous innervation (45). The causes for special pain problems of the oral mucosae, such as burning mouth syndrome or other complex regional pains, must depend to some extent on its specialized neural cytochemistry, conditions of epithelial maintenance for the rapidly renewing mucosal epithelia, and responses of both the mucosa and nerve fibers to physiologic and pathologic stimuli, as discussed in this chapter (see Clinical Considerations) and in Chapter 38.

Teeth and Periodontium

The sensory nerve fibers in tooth pulp, dentin, gingiva, and periodontal ligament are specialized to contribute different kinds of somatosensory information needed for normal tooth use, tissue preservation, and injury responses. For example, warm and cold sensations from teeth depend on innervation in the adjacent gingiva, whereas information about tooth contact and movement during chewing, speech, jaw reflexes, and injury reactions depends on mechanoreceptors and nociceptors located outside the tooth in the periodontal ligament. Neuroanatomic and physiologic studies have shown that these receptors are concentrated in the apical third of the ligament and are mostly unencapsulated Ruffinilike mechanoreceptors with occasional corpuscular endings (see Fig. 50-3). The periodontal Ruffini endings from the trigeminal ganglion elicit conscious sensations of dental touch, whereas the mesencephalic trigeminal neurons provide the periodontal receptors for unconscious proprioceptive reflexes (46,47). The ligament is also supplied with acute nociceptive and polymodal A-d and C fibers that end in association with blood vessels and within the ligament bundles (48). The periodontal nerve fibers outside the roots react to pulpal inflammation and contribute to dental pain by becoming sensitized and undergoing extensive sprouting and altered cytochemistry (14,49).

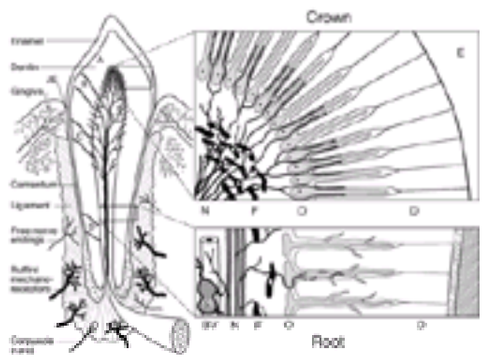

Figure 50-3. Schematic diagram of a mature erupted tooth and its dentinal, pulpal, and periodontal sensory innervation. The labeled dentinal zones were found by previous work to have more than 40% of the dentinal tubules innervated (A) compared with decreasing percentages in zones B (4% to 8%), C (0.2% to 1.0%), and D (0.02% to 0.2%). The higher magnification panels of crown and root compare their nerve (N) incidence, pulpal fibroblasts (F), odontoblast morphology (O), dentin (D), and enamel (E). Neither the odontoblasts (*stippled*) nor the sensory innervation of dentin reach the dentin-enamel junction. Perivascular immunocompetent dendritic cells (dc), and vascular innervation (BV) are shown in the root diagram. Periodontal innervation is primarily by large- or medium-sized branched Ruffini mechanoreceptors and thin-branched nociceptors, with rare encapsulated endings. For details of gingiva and junctional epithelium (JE) nerves, see Figure 50-2. (Modified from Byers MR, Närhi MVO. Dental injury models: experimental tools for understanding neuroinflammatory interactions and polymodal nociceptor functions. *Crit Rev Oral Biol Med* 1999;10:4–39.)

Pain is the predominant sensation that is perceived from within injured or inflamed teeth, regardless of whether the stimulus is electrical, thermal, mechanical, osmotic, or chemical. As a result, teeth have been one of the most useful tissues in which to analyze nociceptive functions. They have two different qualities of pain: sharp focal pain and diffuse toothache. The latter can cause diagnostic difficulty and confusion with other orofacial pain conditions because of its diffuse nature. That blurred location is caused by both widely dispersed endings in the brainstem (26) and wide branching in the periphery, between different teeth, or even with branches and vasodynamic reflexes between teeth and supporting tissues (10,50). In addition, inflammation causes large changes in receptive fields of sensory and central neurons (13,23). As long as teeth are not damaged significantly by stimuli, the pain sensations are brief.

The intradental sensory nerve fibers mostly terminate in the crown pulp and associated dentin in extensively branched endings that are close to the odontoblasts, but not in synaptic or gap junction contact with them (see Fig. 50-3). Extensive studies of dental pain in human subjects in the 1960s and 1970s demonstrated that fluid movement in dentin occurs whenever stimuli (heat, mechanical, osmotic, and so forth) cause rapid outflow of the interstitial fluid, as is common when dentinal tubules have become exposed in cervical roots or along coronal cracks (51,52 and 53). Single fiber studies in animals have shown that the acute sensation of dental sharp pain correlates with A- d innervation of dentin, and brief, dull ache depends on capsaicin-sensitive slow A-d and C fibers in pulp (54,55,56 and 57) (Table 50-1). Inflammation-driven nociceptors that are *silent* or *sleeping* in normal teeth are also present (23) and become active once tissue damage and inflammation have occurred. The A-b fibers have similar properties to the A-d fibers under most experimental conditions and cause brief prepain sensations at low stimulus intensities (58), although purely mechanoreceptive A-b activities have been found in cats when recordings were made from the trigeminal ganglion cell (59,60).

		Conduction velocity (m/s)		
Group	No.	Extrapulpal	Intrapulpal	Capsaicin response
A-β	21	42.5 ± 8.2	15.8 ± 3.2	0/11
A-δ fast	38	22.0 ± 4.1	7.1 ± 3.4	0/26
A-δ slow	43	5.0 ± 2.1	1.5 ± 0.3	6/25
C	37	1.7 ± 0.2	0.9 ± 0.2	10/20

TABLE 50-1. Dental nerve fiber conduction velocities and capsaicin response [a]

Sensory receptor mechanisms in normal dentin involve fluid movement that activates distant A-d and A-b nerve endings in inner portions of dentinal tubules or near the pulp border using hydrodynamic mechanisms (51,53,55,61). For much of this century, it has been popular to also attribute sensory activity to odontoblasts, because of the sharp sensitivity of the dentin-enamel junction and the presumed presence of odontoblast processes there. It is now known that neither odontoblast processes nor nerve endings reach the dentin- enamel junction (61,62). Thus, the sensitivity of the dentin-enamel junction must be caused by transfer of extracellular changes from that site to the sensory receptors in inner dentin and peripheral pulp. The sensory endings do not form synaptic or gap junctions with the odontoblasts, but some of the largest fibers do form adhesivelike junctions with the odontoblast cell body, most likely as a way of anchoring their endings near the openings to the dentinal tubules (9,14,53,63). Pulpal damage leads to activation of A-d and C fibers that are chemosensitive, polymodal, or both, with different receptor mechanisms from those of the dentinal sensory apparatus.

Teeth contain numerous sensory C and A-d fibers as well as some A-b axons and some unmyelinated sympathetic axons. However, estimates of their relative proportions are difficult because parent axons have often subdivided into smaller preterminal branches far away from endings, often branching before entry into the tooth, as shown by the faster conduction velocities outside the tooth (see Table 50-1) (50,57).

Most of the time teeth do not hurt, but that does not mean that their extensive innervation is inactive. Sensory nerves in teeth have many paracrine interactions (local cytochemical signaling) with pulp cells such as (a) orientation of the dentinal sensory endings in the regions with greatest production of nerve growth factor by coronal fibroblasts (64), (b) transfer of anterogradely transported tracers from trigeminal axons to the odontoblasts (65), and (c) efferent delivery of neuropeptides to the pulp for vasoregulation (10,66,67). During development, neurotrophin factors and receptors are expressed by different dental cell groups at different stages (68,69) that affect the distribution of arriving innervation and local nonneuronal interactions. During aging, as dentin thickens and pulp volume shrinks, the innervation shifts location and is correspondingly reduced (63,70). This suggests that dental innervation can shift the sensory apparatus volume and cytochemistry in relation to local growth factors and other paracrine signals concerning pulp and dentin status.

Although the sensory nerves of teeth have many nonsensory functions (vasoregulation, pulpal regulation), those nerve fibers, as all dental patients can testify, are ready to signal brief or acute noxious events via sharp pain as soon as dentin is injured (i.e., as soon as the drill breaks through the dentin-enamel junction) or via ache sensations for pulpal inflammation. Once pulpal inflammation has begun, there are complex cascades of changes in neural function, structure, cytochemistry, axonal transport, ganglionic gene expression, and central connections, so that normally nondetectable stimuli become algesic and the receptive fields for dental neurons expand (13,23,56). Neural cytochemistry and function change again as healing progresses to patterns that are relevant to the healing conditions (71) (Fig. 50-4), or if damage becomes irreversible in the tooth and its nerves. These phenotypic alterations in the structure, function, and chemistry of the nociceptive system must be considered when seeking to understand and treat the various types of dental and oral pains.

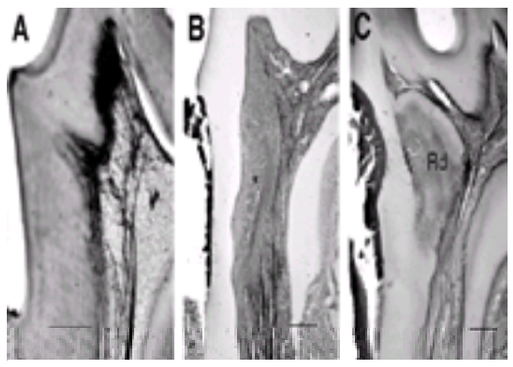

Figure 50-4. Comparison of rat molars and their calcitonin gene-related peptide–immunoreactive sensory innervation for **(A)** normal conditions with sensory endings concentrated in coronal pulp and dentin, **(B)** at 4 days after injury with nerve sprouting near a pulp abscess (*), and **(C)** at 3 weeks after injury when much reparative dentin (Rd) has been made. The sensory innervation has completely different anatomic distribution and calcitonin gene–related peptide intensity for each condition. Scales: 0.2 mm. (Reprinted from Taylor PE, Byers MR. An immunocytochemical study of the morphological reaction of nerves containing calcitonin gene-related peptide to microabscess formation and healing in rat molars. *Arch Oral Biol* 1990;35:629–638, with permission.)

Dental Injury Models and Neuroinflammatory Interactions

Tooth injury models are useful for correlating the degree of peripheral injury with inflammatory reactions, immune responses, healing mechanisms, and neural reactions (in tooth, ganglion, and CNS), because the depth, location, and duration of injury can be controlled (14,53,64,72). For example, a pulp exposure in rat or mouse molars causes a continuous acute inflammation that gradually destroys the pulp and spreads into periodontal tissues (49) and has been a useful way to induce experimental lesions in the periapex (73). Less extensive injuries allow production of different depths of dentin cavity for analyses of local pulpal injury, neural reactions, and rates of healing (see Fig. 50-4) (71,74). In previous studies, specific pulpal reactions, such as the rapid production of nerve growth factor by injured fibroblasts (64) and invasion of monocytes (8,11), were found to precede the local sprouting of pulpal sensory terminals that begins by 1 day and becomes profuse 2 to 3 days after injury. Ganglionic upregulation of glial fibrillary acidic protein in satellite cells was only found for pulp exposure injuries but not dentin cavities (75), even though both types of injuries cause increased expression of the trkA, trkB, and p75 neurotrophin receptors and brain-derived neurotrophin in dental neurons of the trigeminal ganglion (76). Finally, useful comparisons have been made between injury models at teeth, skin, and temporomandibular joint for understanding central plasticity reactions (13,74,75).

Most of the dental injury models have been in animals, but the studies of third molar extraction sites using pain testing, pharmacology, and microdialysis probes have correlated pain levels with specific inflammatory mediators such as prostaglandin E_2 (35) (Fig. 50-5) in the injury sockets, and demonstrated reduced postoperative pain when nociceptive signals during and just after oral surgery are inhibited by long-acting analgesia (37). This is a valuable clinical experimental model in which to develop better analgesics, antiinflammatory drugs, and overall pain management.

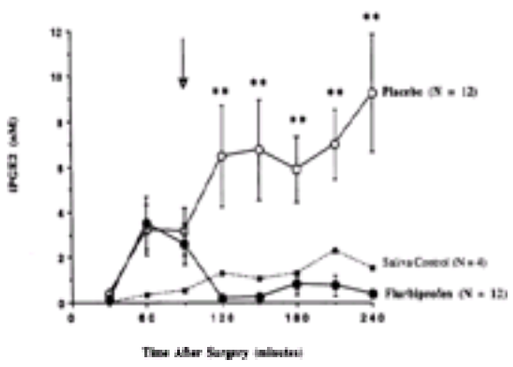

Figure 50-5. Tissue levels of immunoreactive prostaglandin E_2 ($iPGE_2$) from the surgical wound (third molar extraction) in patients receiving either 200 mg of flurbiprofen or placebo at postoperative pain onset. A separate group of patients served as negative controls in whom microdialysis probes were placed into the buccal vestibule, away from the sites of surgery, to evaluate salivary levels of $iPGE_2$. Wound dialysate samples were collected at 30-minute intervals, frozen, and analyzed for $iPGE_2$ with a previously validated enzyme immunoassay. Data are presented as the mean plus or minus standard error of the mean, corrected for percent recovery of $iPGE_2$. The arrow represents the mean time of drug administration for both treatment groups. $^{**}P < .001$ flurbiprofen versus placebo. [Reprinted from Roszkowski MT, Swift JQ, Hargreaves KM. Effect of nonsteroidal antiinflammatory agents administration on tissue levels of immunoreactive prostaglandin E_2, leukotriene B_4, and (S)-flurbiprofen following extraction of impacted third molars. *Pain* 1997;73: 339–345, with permission.]

Trigeminal Brainstem Mechanisms

Hyperexcitation of neurons in central pain pathways (indicated by expanded receptive fields and decreased thresholds) is a fundamental aspect of neuropathic and inflammation pain mechanisms in spinal cord and brainstem (13,79,80). Electrophysiologic studies have shown that orofacial nociceptive information is processed primarily in trigeminal nucleus caudalis, but there is also important input from C fibers and capsaicin-sensitive afferents to the main sensory nucleus and subnucleus oralis (12,81,82 and 83), and the caudal zone of nucleus interpolaris has important processing of nociceptive inputs (84,85). Those studies show that both subnormal and excessive activity of nociceptive fibers affect the functions of wide dynamic range and low-threshold mechanoreceptive neurons in those areas. Neuroanatomic mapping of central endings from dental afferents shows that they branch and end throughout the trigeminal region from the cervical dorsal horn to the main sensory nucleus (26). However, the endings in nucleus caudalis may have more direct effects on pain pathways than other regions where the terminals may be masked. It has been proposed that serotonin-mediated rapid activation of masked nociceptive endings is an important central mechanism that affects brainstem neuron functions within seconds (86). Similarly, antagonism of the excitatory *N*-methyl-d-aspartate channels rapidly reverses the expansion of receptive fields in nucleus caudalis that was induced by capsaicin depletion of C fibers (83,86). These studies show the kind of work that is in progress to correlate specific features of brief, acute transient and chronic persistent pain with molecular mechanisms in the CNS.

Activation of transcription factors such as c-*fos* in central neurons has been found to be a useful marker of *N*-methyl-d-aspartate–driven central plasticity (87), and there have been several studies of c-*fos* expression in brainstem trigeminal subnuclei after various tooth or mucosal injuries. By 2 to 4 hours after acute injury to teeth of rats, cats, or ferrets (a), the *fos* response in the periobex regions of nucleus caudalis is maximal, (b) the number and location of *fos* responding neurons depend on the type of stimulus, (c) the expression of *fos* in trigeminal nuclei is independent of altered motor reflex responses, and (d) there is greater rostrocaudal response when more teeth are involved (88,89 and 90). Analysis of chronic pulp exposure injury to rat molars (91) has shown that there is transient expression of *fos* at 1 week in large ipsilateral neurons of dorsomedial nucleus oralis and adjacent reticular zone, and persistent *fos* for at least 4 weeks in dynorphin-rich regions (lateral solitary nucleus, periobex nucleus caudalis, interstitial cells of the trigeminal tract, and medial superficial neurons of the cervical dorsal horn).

These persistent *fos*-reactive neurons are only a small proportion of the entire set that receive dental afferent terminations, so that most dental central endings do not induce *fos*-driven plasticity in the brainstem after dental or oral injuries. Similarly, the efficacy of synapses from orofacial nociceptive endings may vary in different trigeminal subregions and be under different regulatory control. The rapid regulation of afferent central terminal efficacy in relation to central plasticity of pain mechanisms and the subspecializations within the nociceptive afferent termination zones are important current areas of investigation (83,85,86). For further details see Chapter 4 and Chapter 5.

CLINICAL CONSIDERATIONS

A correct diagnosis of pain in the teeth and surrounding structures requires knowledge of the anatomy as well as a systematic approach for obtaining information and carrying out appropriate physical, laboratory, and radiographic examinations.

The general approach is similar to that described in Chapter 12. Obviously, the history and description of the pain are the first and perhaps the most important parts of the patient's evaluation. The patient should be encouraged to provide a detailed description of the characteristics of the pain when first experienced, during the interval, and at the time of the examination. Detailed information must be obtained about the site and distribution of the pain as well as about its quality, intensity, frequency, periodicity, and duration. If the pain is not constant, information must be obtained about the time of day the bouts of pain occur, the provoking factor(s), and that which relieves the pain. In addition to general examination of the mouth, the response elicited by tooth percussion, application of heat (by means of heated gutta-percha), or cold (by means of a CO_2 ice pencil or as cold water, ice, or cold air, or by a cotton pledget saturated with ethyl chloride applied directly to the tooth) should be ascertained. It is important to make a comparison between corresponding teeth on the opposite side of the midline. To evaluate pain location some practitioners use response of the pulp to electrical stimulation and the effect of local infiltration anesthesia on the pain. In addition, roentgenography is an essential part of the examination.

Pain of Odontogenic Origin

Dental pain, termed *odontalgia*, has been associated with pulpal and periodontal pathology, exposed dentin or cementum, cracked teeth, parafunctional jaw behavior (e.g., bruxism), or iatrogenic causation such as trauma related to osmotic change or placement of dental restorations. Tooth pain not associated with readily identified disease has been termed *atypical odontalgia*. These conditions, presented in the following section, are summarized in Table 50-2. In cases of pulpal or periapical pathology, dental caries are typically the principal causative agent.

Condition	Etiology	Clinical signs and symptoms
Pulpitis	Caries	Pain poorly localized; referred to the opposite arch, etc; characterized as throbbing or burning; intermittent, exacerbated by touch, pressure, sweet, heat, cold; clinical signs: caries
Periodontitis	Periapical infection	Pain easily localized; throbbing, long lasting; hours; exacerbated by heat; clinical signs: percussion sensitivity, tissue erythema and swelling; sometimes radiographic periapical change evident
Cracked tooth syndrome	Fractured cusp or crest	Pain intermittent, brief, sharp, or dullAche; eccentric (lateral) biting, chewing, percussion increases pain; radiography not beneficial except for horizontal root fractures
Dentinal and cementum pain	Hydrodynamic stimulation of pulp dentin (tubular) axon	Pain poorly localized; intermittent, sharp; follows mechanical, thermal, or chemical (sweet) stimulation; clinical signs: exposed dentin or root surface (cementum)
Bruxism pain	Pulpal or periapical inflammation	Pain poorly localized; involving the maxillary and mandibular teeth on both sides of the mouth; dull ache; clinical signs: tooth facets
Iatrogenic pain	Pulpal or periapical inflammation	Pain fairly well localized; intermittent, shooting (barometric) pain perceived during pressure changes occurring in flight; contact of metal with teeth causes galvanic pain

TABLE 50-2. Pain of odontogenic origin

Dental Caries

Etiology. Caries represents a complex pathologic process involving microbial infection of the organic component of the inorganic matrix of the tooth, resulting in biochemical changes that cause loss of the calcified material protecting the pulpal tissue (16). Caries progression appears to be mediated by several factors, including host resistance (e.g., enamel structure including fluoride content, saliva composition, or functional properties), species of microflora and local environment, the types and amounts of food substrates available to the bacteria (e.g., dietary sugar), and the quality and quantity of oral hygiene behaviors.

Pathophysiology. Fortunately, the carious process typically proceeds slowly in enamel (92), and pulpal tissue often has time to form secondary dentin as a protective barrier to microbial encroachment. Without interventions such as antimicrobial therapy, diet control, fluoride or sealant application, or removal of caries and tooth restoration, the eventual sequelae are typically invasion of the dentinal tubules by bacteria, pulpal inflammation, and necrosis, with spread of infection into the periapical ligament space and alveolar bone (20). Pain might or might not be experienced during the progression of these pathologic events. Nonetheless, even though only slight correlation has been demonstrated between pain characteristics and the histopathologic status of the pulp (93), pain remains a good predictor of carious extension into the dentin (94). Pain conditions associated with teeth, including those arising from caries, are categorized according to the IASP criteria as acute pulpitis, acute periapical inflammation, cracked tooth syndrome, dentin and cementum pain, atypical odontalgia, and pain of bruxism. Alternative nomenclature includes Ingle and Glick's taxonomy, which lists categories such as hyperreactive pulpalgia, acute pulpalgia, chronic pulpalgia, hyperplastic pulpitis, necrotic pulp, internal resorption, traumatic occlusion, and incomplete fracture. For additional information regarding this nomenclature, the reader is referred to the previously cited literature and to Ingle (2).

Odontalgia: Acute Pulpitis (IV-3) (Code 031.X2c) and Toothache Caused by Dentinoenamel Defects (IV-2; Code 034.X2b)

Etiology. Caries progression and infusion of microflora into the dentinal tubules cause intrapulpal arteriole and capillary dilation, increased vessel permeability, fluid extrusion and edema, increases in polymorphonuclear leukocytes, and an increase in intrapulpal pressure, cell lysis, and the release of algogenic agents. As previously discussed, physical (fluid pressure) and chemically mediated neural stimulation is thought to be to the primary cause of acute pulpitis (inflammation) pain (95).

Symptoms and Signs. Pain of pulpal origin is often poorly localized within the teeth, jaws, or face (18). Although pain is usually confined to one side and does not cross the midline (the exception is pain associated with the central incisors), it is not uncommon for pain emanating from a tooth in one arch (e.g., the maxilla) to be perceived as arising from a tooth in the opposite arch. In such cases, however, one class of tooth (e.g., molar, bicuspid) usually refers pain to the same class of tooth in the opposing arch. Pain can also be referred to adjacent mandibular, maxillary, or both kinds of teeth or, in cases of posterior teeth, to the ear, cheek, or temporomandibular joint.

Pulpitis can occur without apparent stimulation or can be activated (or exacerbated) by various stimuli such as touch, chewing pressure, and contact with sweet, hot, or cold foods. The degree of pulpal pathology does not appear to be highly correlated with pain experienced in response to stimulation (95). When severe, pain is described as throbbing or burning and can occur in paroxysms that are quite debilitating. The more usual course is for pain to be intermittent in nature, lasting a few minutes to hours.

In mild cases of acute pulpitis clinical signs might not be readily observed. Recurrent caries under old restorations or crowns is often difficult to detect by visual, tactile, or radiographic examination. The application of cold, heat, or electrical stimulation and probing, however, often (but not always) induces pain in the involved teeth. Tooth percussion is not typically a finding associated with mild pulpitis but is present if inflammation is severe. In addition, with severe pulpitis, visual and radiographic examination of the uncrowned tooth usually reveals dental caries extending into the dentin and in some cases the pulpal tissue (Fig. 50-6).

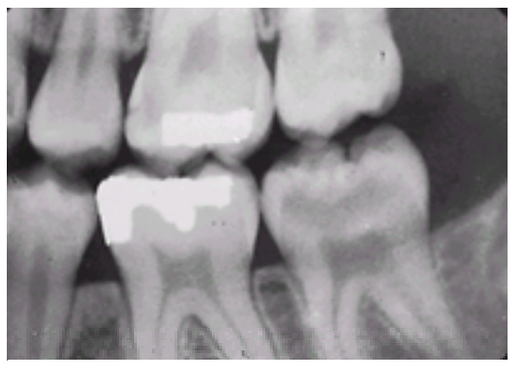

Figure 50-6. Bite-wing radiograph of posterior teeth showing multiple carious sites, as evidenced by radiolucencies between the teeth and extensive coronal radiolucency within the mandibular second molar. (Courtesy of H. Rumberg, Department of Oral Medicine, University of Washington.)

Differential Diagnosis. Acute pulpitis should be differentiated from pain of periapical origin such as acute periapical inflammation (see following discussion), acute periodontal pain, middle ear infection, sinusitis, metastatic cancer, and local neoplasm. It should be appreciated that persistent toothachelike pain has been associated with thoracic pathology including mediastinal lymphoma (96), lung cancer (97), and cardiac disease (98), as well as occipital neuralgia (99) and central neoplasm. Pain perceived in the teeth may also be referred from the masticatory musculature (100).

Brief shocklike pain has been described by Ingle and attributed to hyperreactive pulpalgia (2). This tooth pain problem, because it is associated with a trigger, may be confused with trigeminal neuralgia. Both types of pains are often initiated by intraoral stimulation. Unlike neuralgia, however, pulpalgia is not set off by light touch of the external face (e.g., showering, application of makeup, shaving), and this serves to differentiate the two conditions. Secondary trigeminal neuralgia arising from central neoplasm may also cause tooth pain mimicking pulpalgia. The presence of concomitant paresthesia or anesthesia differentiates this condition from pain of dental etiology. In the latter case, blocking the involved peripheral nerve with local anesthetic does not eliminate pain referred from central pathology.

Treatment. In some cases of slow caries progression, the pulpal tissue can successfully wall off and contain the inflammation (i.e., within a pulpal horn), thus preventing additional pathology. In such cases treatment includes caries removal, the application of a sedative base (e.g., zinc oxide and eugenol or calcium hydroxide), and tooth restoration (101). When caries extends into the pulp, as in cases of moderate to severe pulpitis without periapical involvement, partial (i.e., pulpotomy) or complete (i.e., pulpectomy) extirpation of the pulpal tissue might be necessary (1). Tooth extraction is the treatment of last resort.

Many patients are quite proficient at self-prescribing various “home remedies” for acute pulpitis pain. Several *toothache* solutions designed to be placed in the carious lesion, essentially containing eugenol, are also available as retail preparations. In general, mild pulpitis pain is managed with analgesics such as acetaminophen, acetylsalicylic acid, or other nonsteroidal antiinflammatory medications (e.g., ibuprofen). For moderate pain, a mild narcotic may be helpful. Also important is dental restoration. Promising research provides support for the development of a caries vaccine and therapy based on genetic manipulation.

Acute Periapical Inflammation (IV-4; Code 031.X2d)

Etiology. Acute periapical abscess is the most prevalent consequence of untreated caries-induced acute pulpitis. Infusion of bacteria through the root apex into the periodontal ligament space and alveolar bone is thought to contribute to this more generalized orofacial inflammatory process.

Symptoms and Signs. Pain produced by infection of the periodontium and alveolar bone is similar in quality and duration to pain of pulpal origin. In contrast to the pain of acute pulpitis, however, periapical inflammatory pain is typically severe, unremitting, and throbbing; lasts for hours; and awakens the patient from sleep. Generally, the infected tooth is more easily located by the patient. Intensity varies depending on the severity of the inflammatory process, cellular destruction, degree of pus production, and containment of infection. When intrapulpal necrosis occurs in association with gas-producing microorganisms, heat applied to the tooth often causes severe exacerbation of the pain. Ice water often ameliorates the pain temporarily.

A predominant feature of periapical inflammation is tooth percussion sensitivity. In addition, the patient might report that the offending tooth feels as though it has been displaced into supraocclusion so that closing the mouth becomes painful because of premature tooth contact. Depending on the severity of periapical pathology, associated symptoms can include localized tissue erythema, local or diffuse cellulitis, trismus, and lymphadenitis. In severe cases the patient can be febrile and appears quite ill.

Persistent (greater than 10 days) periapical inflammation can be associated with discernible radiographic bone loss (Fig. 50-7). Immediate radiographic examination is useful for establishing baseline data (i.e., the initial bone density) and, in cases of diffuse cellulitis, for defining the extent of associated fascial space involvement (102). Generally, however, radiographic findings have not been found to be highly correlated with clinical symptoms of pain (103).

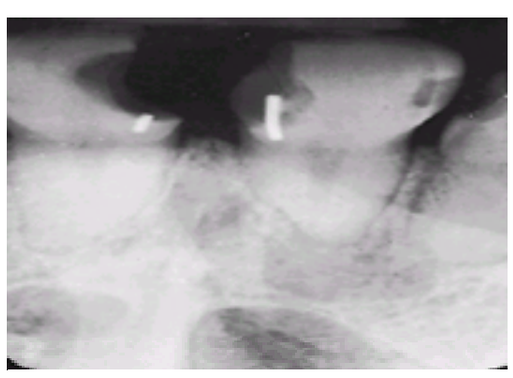

Figure 50-7. Periapical radiograph of a maxillary central incisor. The pin restoration was associated with pulpal necrosis and apical radiolucency. (Courtesy of H. Rumberg, Department of Oral Medicine, University of Washington.)

In more severe cases, diffuse parapharyngeal and carotid space cellulitis can result in life-threatening complications with potential airway obstruction, CNS involvement with cerebral abscess, or endocardial inflammation (104). Hematologic, histopathologic, and microbiological laboratory testing is, in these uncommon instances, a necessary component of diagnosis and treatment.

Differential Diagnosis. In the differential diagnosis, it should be determined whether other odontogenic infections are present, such as infection associated with apical cysts, or whether there is nonodontogenic infection or neoplasia (e.g., external periosteal or intrabony metastatic lesions). Sinusitis must also be considered for maxillary pain. Chronic pain associated with odontogenic infection, osteitis, or osteomyelitis of the mandible may result in additional myofascial abnormality that causes a more generalized unilateral or bilateral facial pain or headache.

Treatment. Occasionally, for some untreated patients, localized cellulitis occurring within the buccal vestibule of the maxilla and mandible, or the palate, is followed by the formation of an intraoral or extraoral sinus tract that allows drainage of the purulent material and produces an associated reduction in facial pain. In cases of localized cellulitis without sinus tract drainage, dramatic relief of pain can be gained by simply opening the pulpal chamber and extirpating the pulp; occasionally (in cases in which drainage does not occur) this intervention might need to be augmented by incision and drainage, analgesics, and judicious use of antibiotics. Incision and drainage procedures should be followed by therapy that includes either root canal filling and tooth restoration, or tooth extraction (21).

Patients with diffuse cellulitis warrant careful diagnosis and therapeutic evaluation. Infection involving the mentalis, submental, sublingual, submandibular, buccal, submasseteric, deep temporal, and superficial temporal fascial spaces has a relatively low risk for spread to other fascial planes. Culture for sensitivity testing followed by conservative management with oral antibiotics, such as penicillin V, 500 mg four times a day, can be sufficient for pain relief. Moderate to severe pain associated with diffuse cellulitis is usually managed with acetylsalicylic acid and codeine, oxycodone, or meperidine HCl.

Failure to obtain pain resolution or reduction of swelling with oral antibiotics, coupled with spread of infection to the pharyngeal (e.g., infratemporal, parotid, pterygomandibular), parapharyngeal (e.g., lateral or retropharyngeal, peritonsillar, cervical), or periorbital spaces, can produce a life-threatening medical emergency. In these cases hospitalization with appropriate parenteral or intravenous antibiotic coverage, airway or fluid support, and appropriate incision and drainage should be instituted promptly.

Cracked Tooth Syndrome (IV-7; Code 034.X1)

Etiology. As the term *cracked tooth syndrome* implies, this type of odontogenic pain is associated with cracked teeth. Teeth that have been weakened by caries, restoration, or root canal treatment, and unrestored teeth subject to traumatic loading (e.g., clenching or bruxism), are susceptible to cracking and fracture (Fig. 50-8). It is speculated that pain is produced in vital teeth from hydrodynamic events (51) or from mild pulpal inflammation caused by the infusion or oral fluids and microorganisms through the defect, and in nonvital teeth from irritation of the periodontal ligament.

Figure 50-8. Peridontal flap procedure demonstrates vertical root fracture in incisor tooth associated with slight discomfort. The pain followed compacting of root canal material. (Courtesy of G. Harrington, Department of Endodontics, University of Washington.)

Symptoms and Signs. Pain is intermittent, of brief duration, and described as sharp or shocklike. Eccentric (lateral) biting or chewing often exacerbates the pain (105). Percussion of the involved cusp during examination can recreate the pain experience. Coronal cracking is difficult to detect, and radiographs are not usually beneficial; in some cases of horizontal root fractures the abnormality can be detected by dental radiographic evaluation. Staining solutions designed to assist in locating surface enamel defects are available. It is important to note, however, that many normal teeth demonstrate signs of coronal cracks so the presence of this feature alone is not enough to define the diagnosis.

Differential Diagnosis. Pain resulting from a cracked tooth should be differentiated from other forms of pain of pulpal origin (e.g., early pulpitis, periapical abscess) and iatrogenic pain (e.g., loose restorations, failing root canal treatment), and neuropathic pain (e.g., neuralgia).

Treatment. Immediate pain reduction usually results from removal of the fractured portion of the tooth and conservative restorative treatment of the defect. Occasionally, the placement of a crown eliminates pain. Root fractures generally necessitate tooth extraction.

Dentin and Cementum Pain (IV-9; Code 034.X8f)

Etiology. Sensitivity in otherwise healthy teeth is thought to be the result of hydrodynamic stimulation of neural processes in the inner portions of the exposed dentinal tubules (51,106), as the external dentin and cementum are (as previously reviewed) not innervated (63).

Symptoms and Signs. Sharp intermittent pain often follows mechanical, thermal, or chemical (sweet) stimulation. Localization of the pain by the patient can be difficult. Examination may reveal exposed dentin or root surface (cementum) in a vital tooth that may also be eroded or abraded.

Differential Diagnosis. The differential diagnosis includes other forms of toothache, particularly cracked tooth syndrome and acute pulpitis.

Treatment. The application of strontium chloride solution, fluoride paste, or oxalate-containing compounds, or iontophoresis with fluoride (107) is generally an adequate pain control intervention for most patients. Sealing the exposed dentin with resins or tooth restoration (i.e., filling) is sometimes necessary in cases of persistent pain.

Bruxism Pain (IV-9; Code 34.X8f)

Etiology. It is presumed that bruxism or clenching pain is the result of prolonged trauma to the periodontium, which results in periodontal ligament or pulpal inflammation.

Symptoms and Signs. Periodontal pain resulting from trauma is described as a generalized dull ache involving the maxillary and mandibular teeth on one or both sides of the mouth.

Differential Diagnosis. This generalized oral orofacial pain that often accompanies a masticatory myofascial abnormality must be distinguished from this condition (see Chapter 29).

Treatment. Behavioral measures designed to eliminate daytime clenching may be all the management that is necessary for this problem. Experimental data suggest that appliances covering either the maxillary or mandibular teeth may be helpful in reducing nocturnal tooth clenching or gnashing (bruxism). Daytime parafunctional behaviors are typically more difficult to control in these cases (see Chapter 49). Appropriate habit modification can be coupled with a low-dose tricyclic antidepressant medication.

Iatrogenic Pain (IV-9; Code 03X.X8d)

Etiology. Infrequently, odontogenic pain results from restorative procedures. In such cases it is speculated that tenderness results from the following: thermal sensitivity secondary to deep caries removal or placement of an inadequate protective base or, in cases of plastic restoration, sensitivity to chemical components of the material; improper tooth preparation techniques resulting in hyperoccluding fillings or open margins; galvanism (formation of an intraoral electrical cell) associated with adjacent placement of dissimilar restorative metals, such as gold and silver amalgam; osmotic change related to defective and leaking restorations; or barodontalgia associated with the inclusion of fluid or air under a restoration (20). Toothache may also result from traumatic nerve injury associated with a variety of procedures (orthognathic surgery, dental implants, anesthesia, or root canal therapy).

Symptoms and Signs. These intermittent pains are typically described as sharp or shooting. Pain associated with barodontalgia is usually perceived during pressure changes occurring in flight. Galvanic pain can occur when metal, such as a stainless steel fork or aluminum foil, comes into contact with the involved teeth. Pain

associated with traumatic nerve injury can occur as paroxysms of electrical or sharp jabs or may be described as a persistent burning.

Differential Diagnosis. Iatrogenic pain should be differentiated from pain of pulpal or periapical origin, bruxism pain, and the pain of cracked tooth syndrome.

Treatment. These pains are generally self-limiting. Pain related to galvanism can be controlled temporarily by dental treatment including the coating of the offending tooth with protective varnish. In severe cases of postoperative pain, galvanism, or barodontalgia, removal of the offending filling, placement of a sedative pulpal dressing, and replacement of the restoration might be necessary.

Atypical Odontalgia (IV-5; Code 034.x8b)

Etiology. The underlying cause of atypical odontalgia is unknown. Given the lack of obvious underlying disease, it has been speculated that this chronic pain perceived in the teeth or gingiva may be of neuropathic origin (108) and possibly sympathetically maintained (109). Other factors historically linked to atypical odontalgia include vascular change, psychological factors such as depression (110), stress (111), and phantom (i.e., central) phenomenology. The possibility of interaction between preexisting vascular abnormality and deafferentation pain has also been reported (112).

Symptoms and Signs. The pain of atypical odontalgia persists for hours as a continuous mild to moderate or severe ache or throb. Duration ranges from months to years. Pain can be focal but is often diffuse, radiating, and migrating. It is frequently precipitated by a dental procedure such as crown placement, periodontal therapy, or dental surgery. It may move to a different adjacent site following tooth extraction. Although the epidemiologic research on orofacial pains is generally limited, and data for atypical odontalgia are virtually nonexistent, the condition is acknowledged to occur more frequently in women. Associated symptoms include psychological distress and other orofacial and head pain complaints (e.g., temporomandibular disorders). The history and examination are with inconsistent hot and cold sensitivity. Even though organic pathology is not identified, patients with atypical odontalgia are at great risk for unnecessary dental treatment such as root canal therapy and surgery.

Differential Diagnosis. Atypical odontalgia should be differentiated from pain of pathologic origin including pulpitis, periodontitis and abscess, cracked tooth syndrome, maxillary sinusitis, atypical facial migraine, intracranial pathology, neoplasm, and myofascial abnormality.

Treatment. Tricyclic antidepressants have demonstrated the greatest potential for pain control in this cohort of orofacial pain patients. Given pain chronicity, potential for overtreatment, and psychological distress, appropriate intervention should also include counseling and other biobehavioral strategies useful in the management of pain refractory to medical treatment. Additional therapeutic strategies that can be useful include topical application of analgesic (lidocaine patch or gel) or capsaicin, sympathetic blockade (stellate block or phentolamine infusion), or systemic lidocaine (mexiletine) (109).

Pain of Mucosal Origin

Pain can originate from the intraoral mucosa as a consequence of trauma (e.g., tooth eruption), infection or systemic disease, allergy, or tumor. Mucosal burning pain not associated with pathology has been termed *burning mouth syndrome* or *glossodynia* . Medical conditions associated with painful oral mucosal ulceration are listed in Table 50-3. Although pain intensity has been included as an outcome variable in therapeutic trials involving mucosal disease (113), the descriptive characteristics of pain associated with mucosal disease remains largely unstudied. Nonetheless, empirical evidence suggests that intraoral ulceration pain is, in most cases, well localized to the lesion site. It can vary considerably in presentation, however, depending on the extent of tissue involvement. The quality of pain is typically described as a dull ache or as a burning sensation. Discomfort is most frequently intermittent but, depending on the condition, can be quite persistent. Although mucosal pain is not typically paroxysmal, a trigeminal neuralgialike pain has been associated with mixed connective tissue disease with intraoral *lichenoid* mucosal lesions (114).

Blood dyscrasias: pancytopenia; cyclic neutropenia; sickle cell anemia
Infection: viral (primary herpes, herpangina, measles, herpes zoster); bacterial (acute necrotizing ulcerative gingivitis; gingivitis, periodontitis); fungal (candidiasis, actinomycosis in the immunosuppressed patient)
Allergy: stomatitis medicamentosa (erythema multiforme, Stevens-Johnson syndrome, Behçet's syndrome); contact stomatitis
Nutritional deficiencies: anemia; niacin deficiency (pellagra)
Exanthematous disease: migratory glossitis (psoriasis)
Pemphigus (vulgaris)
Benign mucous membrane pemphigoid
Lupus erythematosus
Erosive lichen planus
Diabetes
Neoplasm: squamous cell carcinoma; lymphosarcoma; metastatic tumor; acute leukemia
Acquired immunodeficiency syndrome
Recurrent aphthous ulcer: major; minor; herpetiform
Trauma: self-induced; iatrogenic; traumatized tumors (salivary gland tumors, minor gland; odontogenic tumors; metastatic tumors)
Wegener's granulomatosis

TABLE 50-3. Systemic and local mucosal conditions associated with intraoral pain

In this section, pain of mucosal origin is divided into pain associated with tissue attached to alveolar bone (e.g., gingiva of the palate), unattached tissue (e.g., buccal mucosa and soft palate), and the tongue. A comprehensive discussion of the etiology, clinical signs and symptoms, and treatment of all conditions causing intraoral pain is not within the scope of this chapter. The following discussion focuses on the important clinical pain characteristics and pain interventions for the most common intraoral conditions that cause pain of mucosal origin.

Gingival Pain

Etiology. Gingival mucosal tissues cover alveolar or palatal and mandibular bone surfaces that surround and support the teeth. Gingival pain can arise in these tissues as a result of trauma (e.g., self-mutilation, abrasion associated with tooth brushing or flossing habits, food impaction), chemical burns (e.g., aspirin, restorative materials), inflammation associated with teething or third molar eruption, infections caused by viral organisms (e.g., herpes), bacterial organisms (e.g., pericoronitis or acute necrotizing ulcerative gingivitis, Vincent's infection), fungal organisms (e.g., atrophic candidiasis), contact allergy (e.g., from toothpaste, mouthwash dental materials), or as a feature of a chronic dermatologic or other systemic disease process [e.g., benign mucous membrane pemphigoid (BMMP), pemphigus vulgaris, lichen planus, Wegener's granulomatosis, acquired immunodeficiency syndrome, leukemia].

Symptoms and Signs

Traumatic Pain. Pain resulting from trauma is usually characterized as a dull ache, and in cases of food impaction, there may be a sensation of pressure between the teeth. If infection occurs secondary to impaction, the pain often has a throbbing character. This type of pain presentation is also reported in cases of inflammation and infection of the pericoronal flap of tissue covering erupting teeth (particularly third molars) in which, in addition, the patient can be prevented from biting because of edematous enlargement and ulceration of the tissue.

Pain associated with chemical burns, if reported, is usually of a stinging or burning quality (115). Teething pain can occur along with slightly elevated temperature, intense agitation, and sleep disturbance.

Infection. Pain that results from primary ulcerative herpetic infection is often excruciating and accompanied by malaise, irritability, headache, and fever. Discomfort related to inflammation and ulceration of the buccal mucosa, lips, and attached gingiva (which serves to help differentiate this condition from herpetiform aphthous, occurring primarily on nongingival tissue) can prevent the patient from ingesting adequate fluids or nutrition (116).

Pain arising from bacterial conditions is usually perceived in the attached gingiva around the teeth. In gingivitis and periodontal disease pain is not usually present unless the condition includes development of giant cell granuloma (pyogenic granuloma), superimposed infection, or periapical (pulpal) abscess.

Acute necrotizing ulcerative gingivitis, characterized by erosive lesions localized to the interdental papilla and fetor oris, causes pain that is exacerbated by contact

with food or tooth brushing. Secondary symptoms frequently include malaise, but rarely is fever an associated finding (117). A rare variant of acute necrotizing ulcerative gingivitis, diffuse gangrenous stomatitis, can occur in patients with severe debilitating disease (e.g., advanced leukemia, malnutrition) (118).

Candidal infections produce pain of the gingiva, palate, or tongue that is characterized as burning in nature. Associated symptoms can include the presence of a metallic taste and dryness or sialorrhea.

Contact Allergy. Pain is not a frequent finding associated with intraoral allergy, unless it includes mucosal ulceration. If present, it is described as a mildly burning sensation.

Dermatologic Disease. Considerable oral discomfort is often associated with the generalized gingival and tissue ulceration and sloughing that occurs consequent to oral lesions of BMMP (cicatricial) (Fig. 50-9) or pemphigus vulgaris (Fig. 50-10). Pain, felt as a stinging or aching sensation, can be intensified by eating or drinking (especially alcohol).

Figure 50-9. Generalized gingival erythema with frank ulceration and slough observed adjacent to lower lateral incisors in patients with benign mucous membrane pemphigoid.

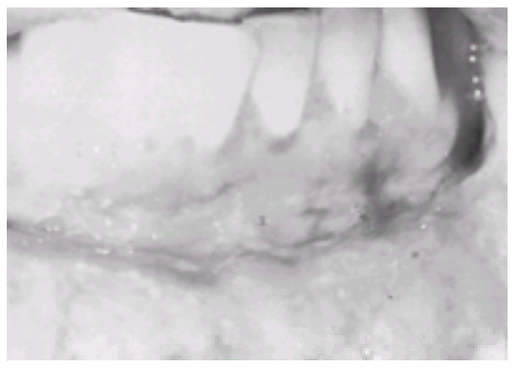

Figure 50-10. Ulceration of attached gingiva adjacent to lower incisors and ulceration of mucosa of buccal vestibule associated with pemphigus. (Courtesy of E. Sommers, Department of Oral Medicine, University of Washington.)

In pemphigus vulgaris, which has been reported to occur initially in the oral cavity in 50% to 60% of patients with the disease (119), associated symptoms can include weight loss and sore throat related to the pemphigus vulgaris lesions. In BMMP, which is considered to be a disease of the elderly but has been reported in children, ulceration can also involve the eyes, urethra, vagina, and rectum. Cutaneous lesions occur in approximately 25% of BMMP cases.

Ulceration identified with lichen planus occurs in approximately 33% of cases (in a random survey of 20,323 Swedish individuals, 1.9% were found to have oral lichen planus and, of these, approximately 33%, 134, had atrophic and ulcerative tissue changes) (120), but in contrast to BMMP and pemphigus vulgaris, it is usually limited to one or a few discrete lesion sites (Fig. 50-11). As a result, pain, described as a dull aching sensation, is relatively less severe. Patients might also complain of dryness of the oral mucosa (121). Malignant transformation of lichen planus lesions has been reported (122), but review of the literature suggests that this might be a relatively rare phenomenon (123).

Figure 50-11. Atrophic and lichenoid mucosa on dorsal tongue with ulceration of right lateral border in a patient with lichen planus. (Courtesy of B. Gandara, Department of Oral Medicine, University of Washington.)

Systemic Disease. Wegener's granulomatosis, a rare necrotizing granulomatous vasculitis involving the kidneys and respiratory tract, can initially present as a gingival lesion associated with considerable discomfort (124). Pain is usually described as a persistent dull ache. Development of oral gingival lesions of Kaposi's sarcoma related to advanced acquired immunodeficiency syndrome has been reported to cause severe pain (125).

Treatment

Traumatic Pain. Management of pain associated with trauma includes behavior modification if the condition is self-inflicted; removal of the foreign body, offending restoration, or broken portion of tooth if these structures are contributing to the pathology; and tissue excision in cases of pericoronitis. Several over-the-counter anesthetic solutions are available for teething pain, although simply allowing the child to suck on a chilled object (e.g., teething ring or flavored Popsicle) often provides more than adequate relief. Teething pain that inhibits sleep can often be managed with a prebedtime administration of acetaminophen.

Infection. Pain associated with acute herpetic ulceration, particularly in cases in which fluid and food intake is being compromised, can be reasonably managed before eating or drinking through application of a topical anesthetic rinse such as dyclonine hydrochloride, 0.5%, or in situations in which this is not available, a rinse of a mixture of 5 mL of diphenhydramine hydrochloride (10 mg per 5 mL as oral elixir) and 5 mL of milk of magnesia (117). Any surgical procedure aimed at the trigeminal

nerve or ganglion can lead to the activation of latent herpes virus and severe pain.

Paradoxically (because the procedure can cause considerable immediate pain), the most effective approach for managing pain resulting from acute necrotizing ulcerative gingivitis is repeated curettage and lavage of the tissues, reinforced by frequent brushing and rinses of 3% hydrogen peroxide (126).

Interventions for burning pain are discussed in the following section, Pain of Unattached Tissue and the Tongue.

Other Problems. Ulcerative pain resulting from allergy, dermatologic disorders, or systemic diseases of unknown cause can often be managed effectively by topical application of a low-potency (e.g., hydrocortisone 1% or methylprednisolone 0.25%), moderate-potency [e.g., triamcinolone acetonide 0.1% (Kenalog, Aristocort); fluocinonide 0.01%, as a gel], or high-potency (e.g., betamethasone dipropionate 0.05%, triamcinolone acetonide 0.5%) corticosteroid. In cases in which ulceration is severe, systemic corticosteroid therapy can be a more useful intervention. The therapeutic goal of a systemic corticosteroid therapy is to suppress lesion development and prevent scarring. This is best accomplished by an initial starting dose of 20 to 32 mg per day, tapered to 0 mg over 7 to 10 days (127).

In cases in which candidiasis is suspected of complicating the clinical course of the ulcerative process, use of topical nystatin rinses or antifungal troches can be helpful. Secondary bacterial infection and pain can be minimized by tooth brushing and flossing, oral hygiene techniques designed to eliminate dental plaque.

Patients with allergy may benefit from nutritional management. If trauma (e.g., from poor dental fillings or sharp tooth cusps) is suspected of contributing to ulcer formation, dental restorative treatment is appropriate (128).

Pain of Cheek, Tongue, and Soft Palate

Etiology. Pain identified with the buccal mucosa, tongue, and soft palate results primarily from ulceration associated with trauma (e.g., cheek or tongue biting, chemical burns) (Fig. 50-12); infection (e.g., primary herpes, herpangina); aphthous ulcers (major, minor, and herpetiform); systemic conditions such as erythema multiforme (Stevens-Johnson syndrome), Behçet's syndrome, lupus erythematosus, pemphigus, BMMP, lichen planus, diabetes, exanthematous disease (e.g., migratory glossitis associated with psoriasis), nutritional deficiency (e.g., anemia), or blood dyscrasia (e.g., cyclic neutropenia); and neoplasm (e.g., squamous cell carcinoma, lymphosarcoma, acute leukemia).

Figure 50-12. Ulceration and slough of the buccal mucosa in the left cheek adjacent to the lower molars following prolonged aspirin contact. (Courtesy of T. Morton, Department of Oral Pathology, University of Washington.)

The cause of perioral burning pain and glossodynia (burning tongue) is not presently understood. The condition has been associated with local irritation, chronic fungal infection (candidiasis), systemic nutritional deficiencies (primarily of vitamin B_{12} but also of vitamins B_1, B_2, and B_6), and xerostomia (129). In addition, depression has also been identified as contributing significantly to the condition (see Chapter 26).

Burning pain connected with numbness of the tongue has been reported following development of adenoid cystic carcinoma (a rare disease) in the floor of the mouth (130).

Symptoms and Signs. Depending on the extent of ulceration, mucosal ulcer pain is typically described as a mild to severe dull ache or burning. Whereas it is generally intermittent in presentation, ulceration associated with conditions such as bullous pemphigoid and its variants (e.g., pemphigus vulgaris), lupus erythematosus and its variants (e.g., chronic discoid lupus), neutropenia, periadenitis mucosa necrotica recurrens (major aphthous ulcer), and Behçet's syndrome can persist over weeks, months, or years. Typically, aggravation of ulcerated mucosal tissue by sour spicy food, alcohol, and superinfection increases pain severity.

Additional clinical features associated with erythema multiforme include hemorrhagic crusting of the lips and *target* or *iris* lesions on the skin. In Behçet's syndrome, ocular inflammation (conjunctivitis) and genital ulcers may also be evident. Erythematous cutaneous lesions occurring on the cheeks and bridge of the nose (in a butterfly pattern) are a characteristic clinical feature of chronic discoid lupus erythematosus, with oral lesions observed in approximately 20% to 25% of these cases. Oral ulceration is a more frequent finding with systemic lupus erythematosus (seen in 40% of cases), a disease that is also characterized by multiple signs and symptoms including arthritis, fever, renal involvement, cardiopulmonary abnormalities, and neurologic changes.

Historically, oral cancer (e.g., squamous cell carcinoma) has not been thought of as causing pain, although mild mucosal discomfort usually leads the patient to seek medical care (131). In some case reports, intraoral mucosal neoplasm is reported to cause pain that is shooting, stabbing, or radiating (132). Although only 3.2% of all neoplasms in patients in the United States are located intraorally (with 90% of these being squamous cell carcinoma), the increasing use of snuff might have a significant effect on future incidence of cancer pain (133). An observed intraoral feature of advanced acute leukemia is painful deep ulceration of the gingival and nongingival mucosa.

Patient description of the burning pain of the buccal mucosa, tongue, and soft palate is similar to that of gingival burning pain. It can also be combined with altered taste (metallic) and mouth dryness. Frequently, distinct intraoral pathologic findings are absent.

Treatment. As previously described, treatment of oral ulceration is primarily symptomatic, with adequate pain control generally obtained through the use of analgesics and topical or, in severe cases, systemic corticosteroids. Evidence has shown that for major aphthous ulcers the duration of painful episodes can be reduced with pharmacologic intervention consisting of immune stimulations such as levamisole (in a dosage as low as 150 mg a week) (134) or thalidomide (135).

Soft tissue wounds caused by trauma (e.g., by dental instruments, pencils) should be irrigated thoroughly with sterile saline solution. Tetanus immunization should always be considered. Pain resulting from secondary bacterial infection can be reduced by application of 3% H_2O_2 (on a cotton swab) and an emollient (Orabase) to the ulcer(s) (rinsing with 3% H_2O_2 can cause additional ulceration), by use of an oral rinse of 1% chlorhexidine gluconate (three times a day), or by vigorous rinsing with a suspension of tetracycline (e.g., Minocin, 100 mg every 12 hours or Achromycin V oral suspension) or Achrostatin V (a combination of tetracycline HCl, 125 mg per 5 mL, and nystatin, 125,000 U per 5 mL) followed by expectoration. A 5% paste of amlexanox has been reported to significantly affect healing time and pain resolution (136). Surgery and grafting might be necessary to control the nonresolving deep ulceration of a major aphthous.

Mucosal pain related to extensive infiltration of squamous cell carcinoma or to lymphosarcoma often required narcotic analgesics along with radiation, surgery, and chemotherapy. Adjunctive oral therapy in the management of mucositis from treatment of leukemia, covered in Chapter 38, include frequent saline rinses and appropriate antibiotic, viral, or fungal coverage.

Although the research is limited, pain resulting from persistent oral mucosal ulceration associated with conditions acknowledged to be highly stress related (e.g., BMMP, lichen planus, lupus erythematosus, aphthous ulcers) can benefit from psychological and behavioral strategies (i.e., interventions intended to managed stress, disability, and suffering), which have been found to be useful in managing other chronic pain and disease states. Dental treatment (e.g., restoration or a maxillary

splint) might be necessary if cheek biting is contributing to ulcer formation or maintenance.

Burning pain associated with candidiasis is most effectively managed with topical antifungal troches (e.g., clotrimazole or nystatin), because delivery of the drug in this fashion allows for prolonged dispersal. Burning pain associated with vitamin deficiency can be treated with appropriate replacement therapy.

Other recommended therapies for gingival, tongue, or mucosal burning include dental intervention (e.g., remaking of old dentures or bridges) management of xerostomia (e.g., artificial saliva, medication change), medication (e.g., Librium, 15 to 30 mg per day), and psychological management. The efficacy of antidepressants and major (e.g., Stelazine) or minor (e.g., Valium) tranquilizer use has not been thoroughly studied, although empiric evidence shows that these medications can be helpful in reducing perceived burning pain with or without associated disease (137).

CONCLUSIONS AND FUTURE DIRECTIONS

Clinical terminology in this chapter was chosen because of its consistency with nomenclature proposed by the IASP Subcommittee on Taxonomy. It should be appreciated, however, that the IASP classification system represents only a first step in the establishment of scientifically valid clinical criteria for defining odontogenic and mucosal problems causing facial pain. Future clinical research must focus on assessing the reliability, validity, and relative predictive values for the varied pain factors, signs, laboratory findings (if any), and radiologic findings associated with conditions causing odontogenic and mucosal pain. Future revision of the IASP taxonomy will also benefit from inclusion of a distinct diagnostic category for pain of mucosal origin associated with disease, which was neglected in the initial treatise (15). Given that chronic orofacial pain of odontogenic and mucosal origin may be associated with emergence of psychological and behavioral factors that can confound patient presentation and management, there is a need for research that not only elucidates biological disease issues but also enlightens with respect to the many potential biobehavioral factors effecting disease, chronicity, and management.

Advances during the 1990s, especially in the molecular neurobiology of pain, are bringing us into a new era of pain management using new and innovative pharmacologic tools. Current research should further improve our understanding of the special problems associated with orofacial pain in the young and elderly and the social problems of delivery of proven therapeutics to underserved world populations. In 1990 the use of tricyclic antidepressants was just beginning for complex regional pains including those in the orofacial area. Now that strategy is widespread and of proven efficacy. The information presented in this chapter suggests that there will be similar important advances in many areas including the following areas in the near future:

- Targeting of specific pharmacologic drugs to specific nociceptive mechanisms (138), as with the current efforts to develop nonsteroidal antiinflammatory agents that inhibit the inducible cyclooxygenase 2 enzyme without side effects from inhibition of cyclooxygenase 1 systems (139,140 and 141)
- Development of a new set of topical analgesics, such as capsaicin, for which clinical research has provided some intriguing data that should become firmly established soon (131,142)
- Introduction of centrally acting receptor antagonists such as the *N* -methyl-d-aspartate receptor antagonist or neurokinin receptor antagonists, as well as new generations of more specifically targeted drugs (143)
- Cellular engineering for delivery into the CNS of transplantable cells that make inhibitory agents for persistent pain problems of cancer or neuropathic injury (144,145)
- Human and animal genomic information to pinpoint the genes responsible for specific pain mechanisms, allowing more selective diagnosis and therapies (146,147)
- Better outcome analyses and educational efforts so that our present knowledge about orofacial pain management or prophylaxis can bring more effective care to underserved populations (148)

These potentially important strategies, coupled with continued international cooperation and efforts in providing improved access to service in developed as well as underdeveloped countries (via subsidization of care, improvement of socioeconomic status and elimination of gross social inequality, education with respect to diet and behavioral modification, and the implementation of fluoridation) should contribute significantly to a decline in worldwide caries and other oral infection problems and associated pain and suffering in the near future.

CHAPTER 51

Ocular and Periocular Pain

James C. Orcutt

Pain in and about the eyes is remarkable for its intensity and its ability to provoke anxiety. Second only to the fear of death, the fear of blindness aroused by ocular pain often leads to emotional responses on the part of both the patient and the physician that can hinder proper diagnosis and treatment. Systemic symptoms of eye disease including nausea, vomiting, and prostration in an anxious patient, on more than one occasion, have led the unwary physician astray in the diagnostic quest. Similarly, the fear generated by ocular pain can lead the patient to overemphasize the symptom. The nature of the pain (e.g., location, intensity, variability, tenderness) is an often underused clinical symptom. Although most ocular or periocular pain is not related to eye disease, specific indicators should be noted that increase the likelihood of eye disease (1). A specific example is the patient presenting with oculosympathetic paresis (Horner's syndrome), tearing and intense headache localized around the right eye (Fig. 51-1). The diagnosis of cluster headache was made; however, the unrelenting nature of the pain suggested another cause. Carotid arteriogram disclosed a dissection of the carotid artery. The differential symptom in this case was the temporal nature of the pain.

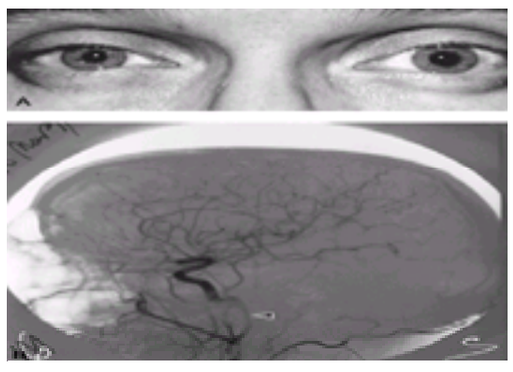

Figure 51-1. **A:** A 35-year-old man developed right-sided severe headaches 2 weeks after falling off a roof. The pain was constant, always right–sided, and associated with a small right pupil and mild ptosis (Horner's syndrome). **B:** Autography was ordered because of relentless pain, which disclosed a carotid artery dissection (*arrowhead*). (Reprinted from Orcutt JC. Neuro-ophthalmic aspects of orbital disease. In: Duane TD, ed. *Duane's clinical ophthalmology* . Vol 2. Philadelphia: Lippincott, 1992:20, with permission.)

Prompt attention to ocular pain is important not only for the relief and reassurance of the patient, but also to prevent vision loss caused by disorders such as angle closure glaucoma, in which the extent of structural and functional damage to the eye is directly related to the duration of the attack. The physician must guard against complacency when approaching the patient with ocular pain because of the great frequency of complaints of facial and head pain unrelated to potentially damaging organic disease. In contrast, pain is not a feature of the major blinding eye diseases (e.g., cataract, open angle glaucoma, and retinal diseases); attention to signs and symptoms other than pain, together with regular screening examinations, is required for accurate diagnosis.

This chapter is organized in three sections: anatomy; clinical signs and symptoms of ocular, periorbital, and functional pain; and management. The clinical section describes the signs and symptoms of the six types of ocular and periocular pains (i.e., ocular pain, pain with eye movement, deep orbital pain, tenderness, referred pain, and functional pain). Following the description of each type of pain, common clinical examples are described.

The reader is referred to the work of Tang and Pardo (2). Additional reviews of pain include those by Miller (3), Atkinson (4), Orcutt (5), Sires and Orcutt (6), Rootman (7), and Dalessio and Silberstein (8).

ANATOMY

Anatomy of Ocular and Orbital Pain

The primary sensory supply to the eye, orbit, and ocular adnexa is the ophthalmic division (V1) of the trigeminal nerve, although the maxillary division (V2) supplies most of the lower eyelid and the temporal aspect of the orbit (Fig. 51-2). The sensory (nociceptive) distribution, primarily through the nasociliary branch, does not parallel the visual sensory function because the ocular structures responsible for the sensation of light, the retina and optic nerve, are totally devoid of pain and touch sense. Conversely, the cornea has as many pain endings as any tissue in the body. The great sensitivity of the cornea to pain presumably serves to initiate avoidance behavior and the blink reflex serves to protect the eye. The cornea has a dual sensory input, an anterior subepithelial plexus, and a midstromal plexus (9).

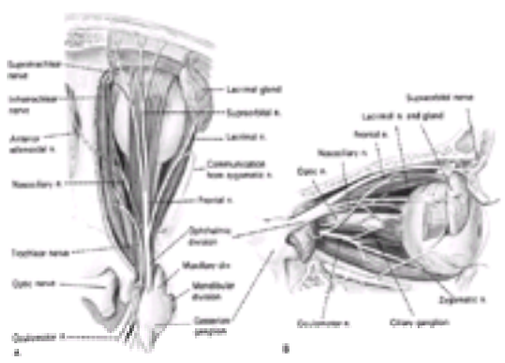

Figure 51-2. Anatomy of the nerves to the eye. **A:** Superior view. **B:** Lateral view.

In addition to many naked nerve endings mediating pain in the epithelium of the cornea and conjunctiva, receptors for touch and cold, and probably also for heat, are found. Photophobia can be induced by corneal epithelial erosion, intraocular inflammation, or even occipital injury (1). Unlike the cornea, the conjunctiva has many fewer nerves, resulting in only mild pain when irritated.

The uveal tract, especially the iris, contains abundant nociceptors, as demonstrated by the response of the patient undergoing surgical iridectomy when the previously placed retrobulbar block is inadequate. The iris also has heat receptors, because pain can be produced by laser burns of sufficient intensity (1).

Within the orbit, nociceptive endings within the extraocular muscles, the dural sheath of the optic nerve, and the periorbita are responsible for the sensation of pain when they are stretched (10). Tumor invasion of sensory nerves is occasionally responsible for periocular pain. Tenon's capsule surrounds the posterior globe, much like the synovial membrane in joints. As in inflammation in joints, inflammation of Tenon's capsule (i.e., scleritis) results in severe pain and tenderness.

Anatomy of Referred Orbital Pain

Without regard for the site at which the neural pathway of the trigeminal nerve in its course from the face to the cortex is stimulated, the sensation produced is interpreted by the patient to have originated from the location of the receptors for that sensation. The branches of the ophthalmic division (V1) include the nasociliary, frontal, lacrimal, and meningeal. The nasociliary branch of V1 supplies the globe as was described in the previous section on ocular pain. In addition, the nasociliary branch receives input from the ethmoid sinuses, nasal mucosa, skin on the tip of the nose, and medial eyelids. The meningeal branches of V1 innervate the cavernous sinus and meninges surrounding the cavernous sinus, including the cerebellar tentorium, falx cerebri, cribriform plate, and sphenoid wing. The lacrimal branch receives sensation from the lateral canthus and temporal conjunctiva. The sensory distribution of the lacrimal nerve may be manifest during cataract surgery when retrobulbar anesthesia is used. The temporal conjunctiva retains sensation because the lacrimal nerve is outside the muscle cone and is not blocked with the retrobulbar anesthetic. The frontal nerve innervates the forehead, medial upper eyelid, and the frontal sinus mucosa.

The maxillary division (V2) innervates the orbit and periocular structures through the zygomatic and infraorbital branches. The zygomatic branch innervates the lateral eyelids and temporal skin through its zygomaticotemporal and zygomaticofacial branches (Fig. 51-3). The parasympathetic fibers supplying the lacrimal gland traverse the zygomatic nerve in its course from the sphenopalatine ganglion to the lacrimal gland. Damage to the zygomatic nerve in the orbit may result in decreased ipsilateral reflex tearing. The infraorbital division supplies sensation to the upper teeth, oral mucosa, and the skin from the lower eyelid to the upper lip. Intracranial branches supply the dura of the middle cranial fossa.

Figure 51-3. Peripheral distribution of the zygomaticotemporal (ZT) and zygomaticofacial (ZF) nerves.

Irritation of any of these branches by inflammation, or occasionally by tumors, can result in pain referred to the globe. Examples include such diverse diagnoses as postherpetic neuralgia, sphenopalatine tumors, cavernous sinus aneurysms, sinus inflammation, neurotropic lacrimal gland tumors, and tension headaches.

The nucleus caudalis of the trigeminal complex extends into the upper cervical spinal cord (11). Nociceptive input from C-1 and C-2 (12) can result in pain sensation around the orbit, perhaps because of the medullary anatomy. Greater occipital neuralgia, trapezius muscle spasm, or cervical arthritis commonly result in referred ocular or periocular pain (2). Local injection of local anesthetic and corticosteroid may result in improvement of pain (13) (see Chapter 29).

SYMPTOMS AND SIGNS OF OCULAR AND PERIOCULAR PAIN

Ocular and periocular pain can be divided into three groups: ocular, orbital, and functional pain. Specific facial pain syndromes that may be distributed in the periocular region, such as temporomandibular joint syndrome, temporal arteritis, dental pain, sinusitis, and tic douloureux, are discussed in Chapter 46, Chapter 47, Chapter 48, Chapter 49 and Chapter 50, Chapter 52, and Chapter 53. The description of ocular pain provided by the patient is often graphic and complete, because it has occupied all the patient's attention for the preceding hours or days. The localization of the pain by the patient is often erroneous. Some knowledge of differential symptoms and signs allows the physician to direct the examination properly as well as to make preliminary decisions regarding the urgency to which the problem must be addressed.

Ocular Pain

Foreign Body Sensation

We have all experienced a foreign body sensation when a grain of sand or a hair gets into our eye and we blink violently to remove it. This sensation of a foreign body on the surface of the eye arises from interruption of the surface epithelium and from mechanical stimulation of the subepithelial plexus of nerves. Most commonly, the corneal epithelium has been abraded by trauma, exposing the pain fibers, and no foreign body is present in spite of the patient's insistence (Fig. 51-4). A thorough search should be made for a foreign body, but symptoms often exist in its absence. The patient localizes the foreign body under the upper eyelid, regardless of the actual site of the epithelial injury. This is because of Bell's phenomenon; every time the patient closes the eye, the cornea moves upward under the upper eyelid. Foreign body sensation usually causes the patient to seek attention promptly but rarely indicates a disorder likely to cause severe vision loss.

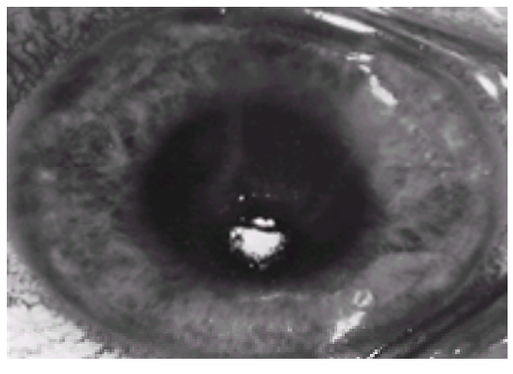

Figure 51-4. Corneal abrasion. A twig had brushed the cornea 6 hours previously. The patient localized a foreign body sensation under the upper lid. Increasing tearing and photophobia ensued. No foreign body was found. Fluorescein placed in the tear film stained the abrasion. Patching and cycloplegia with 5% homatropine

drops led to healing in 24 hours.

Aching Ocular Pain

Deep aching ocular pain originates from the uveal tract, especially the iris. The pain is caused by traction or stretching resulting either from acutely increased intraocular pressure or from the inflammation of anterior uveitis, often with secondary irritative spasm of the intraocular muscles. The pain can be referred to other ipsilateral parts of the face, especially the teeth. Systemic responses may include nausea, vomiting, and prostration and can overshadow the ocular disease. Laparotomy has been considered and in some cases performed before the proper ocular diagnosis was made. Systemic side effects can be caused in part by reflex vagal stimulation (14). Severe aching ocular pain indicates a disorder that requires prompt and effective therapy to prevent vision loss.

Pain with Use of the Eyes

A specific type of aching ocular pain deserves discussion, asthenopia, or *eye strain*. Pain syndromes, especially headaches, fatigue, and even vision loss, frequently have been attributed to the overuse of the eyes. The eyes are often blamed, particularly in the presence of a motor or refractive anomaly of the eyes that would have been considered trivial in the absence of the pain syndrome. Visual tasks require eye movements and alignment by the extraocular muscles as well as contraction or relaxation of the ciliary muscle to allow changes in focus. The muscles involved possess a contractile force many times greater than that which they are called on to exert and, because of their rich blood supply and other physiologic factors, they can contract actively for long periods of time without fatigue (15). Although it is true that, during a task such as reading, both the extraocular and intraocular muscles are in a nearly constant state of activity, no evidence has been found suggesting that these are not requirements of which they are easily capable or that such activity should result directly in pain or fatigue.

Too much importance has been attached to the correction of minor refractive errors, small degrees of eye muscle imbalance, and assorted other insignificant ocular variations. Headache, fatigue, and other discomfort frequently follow extensive use of the eyes, but these symptoms are related to the demands of the task itself, such as head posture or squinting, and are not mediated through the eyes. Therefore, it should not be expected that these mechanisms are influenced by spectacles or ocular alignment, and any benefits claimed for such treatments must be attributed to nonspecific effects (see Chapter 81). Similarly, no grounds exist for the popular belief that use of the eyes, especially under conditions of stress or when associated with headache and fatigue, leads to vision loss or permanent ocular damage.

Signs and Symptoms Associated with Ocular Pain

Photophobia or light-induced pain usually increases the pain associated with a corneal epithelial defect or the aching ocular pain associated with intraocular inflammation. Patients generally prefer to have the eye covered or use sunglasses to reduce photophobia. Paralyzing the ciliary muscle with a topical cycloplegic agent, such as atropine, reduces photophobia associated with intraocular inflammation.

The conjunctiva is often injected (conjunctivitis) and edematous (chemosis) when inflammation is the etiology of ocular pain. Typically, the injection is most intense around the edges of the cornea (ciliary flush) when the inflammation is intraocular. If the inflammation is anterior in the globe, the cornea commonly becomes edematous as well, resulting in decreased vision and halos around lights. Any of these symptoms associated with ocular pain should alert the clinician about the potential of vision-threatening intraocular inflammation.

Common Painful Ocular Diseases

Uveitis. Inflammatory disorders of the iris (iritis) or ciliary body (cyclitis) are collectively called *anterior uveitis* and can be exquisitely painful (16). Posterior uveal inflammations (choroiditis) are usually painless. Most nontraumatic inflammations of the uveal tract are idiopathic. Treatment directed at suppression of inflammation is often effective in the absence of specific therapy. Corticosteroids may be administered topically or by periocular injection (17). Oral corticosteroids are useful for short-term control of uveitis but should be replaced by topical or locally injectable preparations when possible to avoid undesirable effects with prolonged systemic use. Local and occasionally systemic corticosteroid therapy can produce glaucoma in susceptible persons, and periodic tonometry is indicated (18).

Although corticosteroids administered as described previously are important in the treatment of uveitis, the associated acute pain of anterior uveitis, especially the pain with light exposure, is caused by spasm of the irritated muscles of the iris and ciliary body. Prompt relief of the aching and photophobia is obtained by use of a cycloplegic drug such as atropine (Table 51-1). Cycloplegia should be maintained until all signs of inflammation have subsided.

Agent	Commonly used ophthalmic concentrations (%)	Duration of action	Indications
Cyclopentolate	1	6–48 hr	Diagnostic procedure; corneal abrasion
Homatropine	2–5	12–72 hr	Corneal abrasion; mild inflammation
Scopolamine	0.25	48 hr to 7 days	Inflammation
Atropine	1.0	5–14 days	Severe inflammation

TABLE 51-1. Cycloplegic drugs

Herpes zoster affecting the ophthalmic division of the trigeminal nerve can lead to a particularly recalcitrant uveitis associated with secondary glaucoma or hyphema (16,19). Whereas severe pain can precede cutaneous signs that lead to a diagnosis, uveitis usually appears after the disease is well established. The uveitis can occur alone or in association with corneal involvement. Treatment includes prolonged use of atropine and, if necessary, topical corticosteroids, together with acetazolamide to control secondary glaucoma. Chronic pain is usually not caused by uveitis but by postherpetic neuralgia (see Chapter 22).

Occasionally, recalcitrant intraocular inflammation may necessitate the use of systemic immunosuppression. Agents such as cyclosporin, azathioprine (Imuran), and methotrexate have been used in specific cases (20). The use of these agents requires monitoring for possible systemic side effects, such as immunosuppression and renal failure. Ideally, management of such cases can be facilitated by a team composed of ophthalmologists and rheumatologists, immunologists, or oncologists.

Corneal Diseases. Any interruption of the continuity of the corneal epithelium results in pain, tearing, and photophobia. Such symptoms are most often provoked by an obvious cause such as trauma (e.g., foreign body) or chronic abuse (e.g., contact lens overwearing). Apart from mechanical trauma to the cornea and infections, several corneal disorders are notable because of the prominence of pain as a symptom.

The use of prolonged topical anesthetics can lead to corneal epithelial breakdown. The patient might desire the drug for pain relief. Supervisors of workers who are exposed to such insults, particularly welders, have been known to provide eye drops that allow the injured person to continue working. This practice ultimately prolongs healing and results in more time loss than would be required for appropriate therapy. Nonsteroidal antiinflammatory drugs (NSAIDs) may provide some pain relief and do not carry the risk of corneal toxicity.

Ultraviolet Keratitis (Photophthalmia). Wavelengths of light between 314 and 250 nm (ultraviolet) are absorbed by proteins of the corneal epithelium and lead to cell death (21). Common sources of damaging ultraviolet radiation include arc welders, sunlamps, and reflected sunlight from snow or sand. The onset of symptoms, occurring 6 to 8 hours after exposure, is explosive, progressing rapidly from foreign body sensation to severe pain and photophobia with blepharospasm. Examination

after application of topical anesthetic shows diffuse corneal epithelial edema.

Treatment consists primarily of patching and cycloplegia, as with any corneal epithelial disturbance. NSAIDs and a bandage contact lens may be alternatives. Frequently, pain is severe enough to warrant the use of narcotic analgesia, a requirement that should be anticipated before allowing the patient to return home, where the effects of the diagnostic drop of topical anesthetic soon end. Healing is usually complete in 24 to 48 hours (22).

Recurrent Corneal Erosion. Recurrent episodes of pain, tearing, and foreign body sensation in one eye, usually on awaking in the morning, are typical symptoms associated with recurrent corneal erosion (23,24). Examination shows a corneal epithelial defect, often minute, in the same location with each episode. Frequently, a traumatic corneal abrasion has preceded the onset of the erosion by weeks or months. A deficiency of attachment of the regenerated epithelium to the basement membrane has been implicated as a causative factor (25,26). Each episode is treated in the same manner as a traumatic corneal abrasion by patching and cycloplegia, and recurrences eventually cease. A bland ophthalmic ointment can reduce the risk of recurrence if used before retiring each night. Dehydrating drops or ointment with sodium chloride may reduce the frequency of recurrence. Soft contact lenses are useful in some cases. Severe, recurrent erosions can be treated by micropuncture of the cornea (27) or phototherapeutic keratectomy with an excimer laser (28).

Bullous Keratopathy. The posterior layer of the cornea, the endothelium, functions to dehydrate the cornea against the hydrostatic effects of intraocular pressure (29). If the endothelium fails, either because of intrinsic disease or increased intraocular pressure, fluid accumulates throughout the cornea, especially within and beneath the basal layer of corneal epithelium. If severe, and particularly when chronic, corneal edema can elevate the corneal epithelium in blisters leading to bullous keratopathy. The bullae frequently rupture, resulting each time in an acute episode of pain and tearing.

Acute treatment of ruptured corneal epithelial bullae must promote healing through the use of patching, cycloplegia, and lubricating solutions, but healing is slow in a diseased cornea. More definitive treatment includes lowering of intraocular pressure, even if not originally elevated to levels usually considered pathologic, and replacement of the diseased cornea and its endothelium by corneal transplantation. Chronic dehydration of the edematous cornea by frequent topical application of hypertonic saline solution or ointment can be tried but is often unsuccessful because of failure to dehydrate sufficiently or because of irritation. Bandage and soft contact lenses can provide pain relief for patients for whom medical therapy has failed and surgery is not warranted (30,31).

Glaucoma

Angle Closure Glaucoma Angle closure glaucoma occurs in middle-aged and elderly persons who are anatomically predisposed because of developmental crowding of the anterior segment (32,33). The onset is sudden and often accompanied by nausea, vomiting, and prostration (34). The eye is injected, and the cornea is gray with edema. The pupil is middilated and fixed (Fig. 51-5). A few patients might have repeated subacute attacks of angle closure that terminate spontaneously but produce permanent anatomic damage to the anterior segment. The pain of angle closure is initially controlled medically by lowering the intraocular pressure (34) (Table 51-2). Historically, surgical iridotomy was performed through a small corneal incision; however, with the advent of laser technology, iridotomy can be performed with either the argon or yttrium-aluminum-garnet laser as a rapid clinical surgical procedure (35). Chronic pain control should not be required (34). The diagnosis of acutely elevated intraocular pressure must be made by tonometry, never by palpation of the globe or by history alone.

Drug	Suggested dosage
Pilocarpine, 1–4%	One drop to affected eye every 5 minutes x3
Diamox	250–500 mg PO or IV
Glycerol	0.7–1.5 mL (50% solution) per kg body weight PO
or	
Mannitol	1.0–2.0 g/kg body weight IV

TABLE 51-2. Emergency medical therapy of angle closure glaucoma

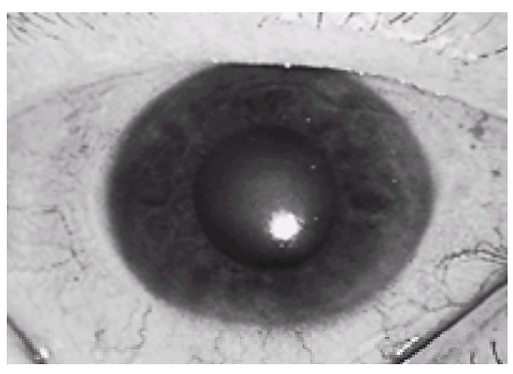

Figure 51-5. Angle closure glaucoma. The eye is acutely congested, with a hazy cornea. The pupil is middilated and fixed to light. The intraocular pressure is 50 mm Hg. Medical management (see Table 51-2) resulted in normal pressure, and laser iridectomy was performed 48 hours later.

Neovascular Glaucoma. Neovascular glaucoma is a form of glaucoma that is particularly difficult to control (35). It occurs most often in the eyes of diabetics, usually in combination with severe proliferative retinopathy. Neovascular glaucoma can also occur after occlusion of the central retinal vein, retinal vasculitis, or following trauma or ocular inflammatory disease (36,37). Rarely does neovascularization occur after central retinal artery occlusion. A fibrovascular membrane develops in the angle of the anterior chamber and on the surface of the iris, which leads to angle closure (36) (Fig. 51-6). The aqueous has no avenue for drainage. Repeated hemorrhage into the anterior chamber (hyphema) can occur. Pain is often severe and accompanied by vomiting and dehydration, a particularly serious management problem in the diabetic.

Figure 51-6. Histopathology of neovascular glaucoma. The iris root and filtration angle are shown. New vessels are present (*arrow*); they have caused closure of the filtration angle (*). (Hematoxylin and eosin stain, ×40.)

The angle closure of neovascular glaucoma is not relieved by iridectomy, and other conventional glaucoma operations often yield disappointing results. Procedures designed to decrease aqueous production by partial destruction of the ciliary body (e.g., cyclodiathermy, cyclocryotherapy) are often used, but these tend to be unpredictable, and often the result is a chronically agonizingly painful eye (32).

The medical therapy of neovascular glaucoma is designed to decrease intraocular pressure and control pain (37). The usual treatment of glaucoma must often be modified because acetazolamide and especially osmotic agents result in metabolic changes that might be unacceptable in the diabetic patient. Topically applied miotics are routinely used in the medical management of open angle glaucoma, but use of these agents in neovascular glaucoma produces a marked *increase* in pain with little or no effect on intraocular pressure.

Most often, the physician is faced with control of pain in an eye hopelessly affected by neovascular glaucoma. Although enucleation is the usual final result, such eyes with elevated intraocular pressure can usually be made comfortable for a time with the use of topical cycloplegics (see Table 51-1) and corticosteroids (prednisolone acetate 1%), perhaps combined with acetazolamide (250 mg four times a day), topical epinephrine solution (1%), or a topical b-blocker. Retrobulbar alcohol injection can also control pain, at least temporarily, and is especially indicated if useful vision remains (38,39). Thermocoagulation of the trigeminal ganglion can also provide pain relief in these patients.

Hyphema. Hemorrhage into the anterior chamber (hyphema) can occur following blunt trauma to the eye (Fig. 51-7). Most hyphemas clear spontaneously with rest. Rebleeding can occur, however, and the anterior chamber might become filled with blood, resulting in symptoms similar to those of angle closure glaucoma. Medical measures such as those described for angle closure glaucoma are usually sufficient to control the pressure and pain (40). Aminocaproic acid has been shown to be beneficial in decreasing the incidence of secondary hemorrhage (41). Occasionally, surgical removal of the hyphema is necessary to control the pressure (42).

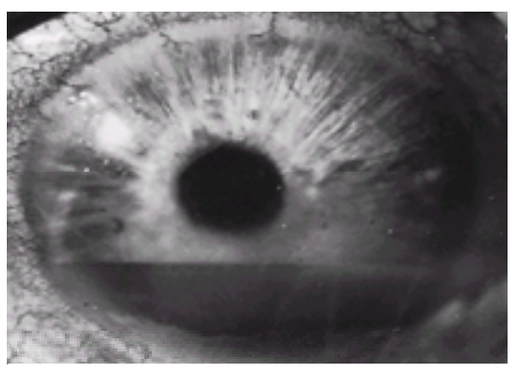

Figure 51-7. Forty percent hyphema following a handball injury. The eye was injected and mildly painful. The blood cleared over the next 5 days on a regimen of limited activity, eye protection, and aminocaproic acid.

Refractive Surgery. Refractive surgery is becoming a commonly performed surgical procedure to correct myopia or astigmatism. Commonly used procedures include radial keratotomy, photorefractive keratotomy, and laser *in situ* keratomileusis. Patients report mild to moderate pain for a few days following the procedure, more pronounced with radial keratotomy than the other procedures (43,44). Blurred vision, photophobia, halos, and glare are commonly reported, but usually clear several days to weeks after the procedure. The pain is usually managed with the use of a topical anesthetic, topical NSAIDs (e.g., indomethacin, diflorinac), and a bandage contact lens (45,46).

Accommodative Spasm. Accommodative spasm may accompany closed head injury or more commonly is functional. Typically, the patient presents with accommodative myopia caused by contraction of the ciliary body, meiosis, and esotropia (27). When prolonged, the patient may experience asthenopic or eye strain symptoms. Management consists of the use of cycloplegic agents (e.g., atropine, homatropine, scopolamine) and bifocals for several months.

Orbital and Periorbital Pain

Structures in the orbit with pain receptors include the optic nerve sheath, fascial sheath surrounding the globe (Tenon's capsule), periorbita, and sheaths of the extraocular muscles. When any of these structures is inflamed, pain is localized to the orbit. In addition, pain may be referred to the orbit from nerves with common innervation (i.e., referred pain). Typically, when orbital structures are involved, the associated orbital and periorbital pain presents in one of four scenarios: pain with eye movement, deep orbital pain, tenderness, and referred pain (47).

Pain with Movement of the Eyes

Approximately 80% to 92% of patients with optic neuritis complain at some time of pain intensified by movement of the eye (48,49). The pain usually lasts for approximately 1 week and improves as visual acuity improves. The pain is generally not overwhelmingly severe and presumably is caused by stretching of the inflamed pain-sensitive sheaths of the pain-insensitive optic nerve.

Anterior sinusitis can also present with pain on eye movement (10). This symptom is probably a result of inflammation of the adjacent periorbita or extraocular muscles that are mechanically stimulated with eye movement. Idiopathic inflammation of the orbit may also be localized to extraocular muscles (i.e., myositis). Movement of the eye with associated muscular contraction results in pain caused by mechanical stimulation of the muscular septa.

Deep Orbital Pain

Pain secondary to orbital disease is uncommon (Table 51-3); however, when present, it is useful diagnostically. Pain caused by orbital disease is generally moderate to severe, commonly keeps the patient awake at night or wakens him or her from sleep, is exquisitely localized directly behind the globe, is commonly associated with motor dysfunction (i.e., ptosis or diplopia), is deep and boring in nature, and is generally not in question by either the patient or physician (Fig. 51-8).

Orbital diseases commonly painful	Orbital diseases uncommonly painful
Idiopathic orbital inflammation (pseudotumor)	Metastatic disease to the orbit
Adenocystic carcinoma of the lacrimal gland	Lymphoma
Acute orbital hemorrhage	Orbital abscess
Cellulitis	Cavernous hemangioma
	Thyroid eye disease

TABLE 51-3. Pain caused by orbital disease

Figure 51-8. Patient presented with acute, severe, boring pain centered behind the left eye. Erythema, ptosis, and limited eye movement were present. Idiopathic orbital inflammation (pseudotumor) was diagnosed and responded to oral corticosteroids.

Orbital Inflammatory Pseudotumor. Pain is a common presenting symptom of idiopathic orbital pseudotumor, especially if onset is acute (48,50,51,52). Eyelid edema, proptosis, and diplopia commonly accompany the pain and can mimic signs of an intraorbital tumor. Most lesions respond to systemic corticosteroids (52,53). Occasionally, radiotherapy is required (51,54). Lesions unresponsive to corticosteroid therapy, especially if chronic, require biopsy to rule out the presence of a tumor.

Orbital Tumors. Primary and secondary orbital tumors are usually painless. The main exception is some malignant lacrimal gland tumors (55), primarily adenoid cystic carcinomas (56), and squamous cell carcinomas (57). The pain and often-accompanying decreased sensation are caused by the perineural invasion typical of these tumors (48,55,57). Decreased sensation in the distribution of the involved nerve is often associated (47).

Acute Orbital Hemorrhage. Trauma leads to most orbital hemorrhages, and the diagnosis is usually clear. Spontaneous orbital hemorrhages can produce sudden pain, proptosis, and nausea, commonly accompanied by vomiting (56). Most patients with spontaneous orbital hemorrhages have preexisting venous anomalies, but atherosclerosis, hypertension, blood dyscrasias, anemia, and obstetric labor have been associated (56).

Orbital Cellulitis. Orbital cellulitis is usually secondary to contiguous sinusitis. Proptosis, pain, chemosis, and ophthalmoplegia are diagnostic hallmarks. Institution of systemic antibiotics and sinus drainage usually produce resolution (58). Occasionally, orbital abscesses form and must be drained (59).

Tenderness

Tenderness implies that one of the pain-sensitive structures of the orbit anterior enough to be palpated must be inflamed. Typically the inflamed structures are either the fascia surrounding the globe or the anterior periorbita. Scleritis is inflammation of the visceral surface of the fascia surrounding the globe. Scleritis may be associated with chemosis, conjunctival inflammation, and occasionally with serous detachment of the retina. Ultrasound can be useful in the diagnosis, as fluid can be seen underlying the fascia (Fig. 51-9). The lacrimal sac is surrounded by periorbita. When obstruction of the lacrimal drainage system occurs, a secondary abscess may form in the lacrimal sac (dacryocystitis). Dacryocystitis causes pain because of inflammation of the surrounding periorbita, which generally increases significantly when the area is palpated.

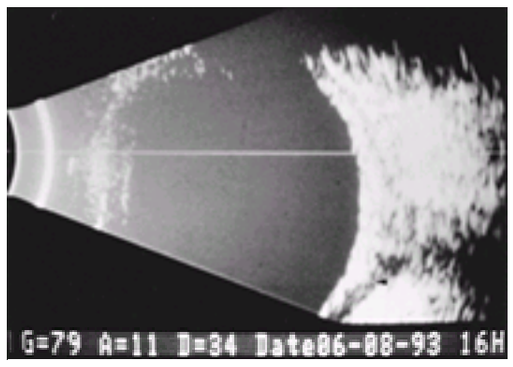

Figure 51-9. Orbital ultrasound of a patient with globe tenderness, erythema, and conjunctival swelling. Fluid collection is present outside the sclera (*arrowhead*). Posterior scleritis was responsive to oral corticosteroids.

Referred Pain

Referred pain is the most common etiology of orbital pain. Referred pain is diffusely represented around the orbit (Fig. 51-10). The pain is usually mild to moderate, rarely awakens the patient from sleep, and may be associated with other general symptoms such as cervical disease.

Figure 51-10. Typical clinical presentation of a patient with referred orbital pain.

Headache. Headache is the most common pain complaint to confront the practitioner, and the eyes are often suspected, if not blamed, as a contributing source (see Chapter 48). Most frequently, the physician must cope with the patient who appears to be entirely well and whose eyes appear normal and who has normal visual acuity, yet complains of chronic or recurrent headache. Usually chronic or recurrent headache is related to anxiety and muscular tension, without direct ocular implications. Many important causes of headache do have ocular manifestations (e.g., ischemic optic neuropathy with giant cell arteritis, papilledema with increased intracranial pressure, lid vesicles with herpes zoster, scintillating scotomata with classic migraine), but risking oversimplification, it can be said that headache in patients without ocular or periocular findings is never caused by primary ocular disorders. The eyes frequently are used extensively in anxiety-provoking or tension-producing pursuits, and it is not surprising, therefore, that the patient assumes a causal relationship when the true relationship is only coincidental.

The importance of migraine as a pain syndrome with ocular signs is so great as to warrant separate discussion. This well-known pain entity classically occurs in adults with a family history of the disorder and consists of unilateral head pain often associated with nausea and vomiting and terminates after hours or days. The onset of

headache frequently is preceded by a brief aura, most commonly visual. The visual aura can take many forms, ranging from diplopia to complete loss of vision, but most often consists of a hemianopic distribution of scintillating, often colored, jagged lines that persist for approximately 20 minutes, although less prominent visual field changes can last much longer. The spectacular aura can greatly alarm both the patient and physician, and the eyes can be further implicated in the syndrome because many patients suffer from photophobia during the period of headache. (See Chapter 48 for a more detailed discussion of migraine.)

When the migraine syndrome is complete, diagnosis is rarely difficult. Little appreciated, however, is the multiplicity of manifestations of migraine that often form an incomplete syndrome in which the diagnosis is not readily apparent. Probably the most common of the isolated manifestations of migraine is the scintillating scotoma, which often occurs in the absence of a subsequent headache. Full awareness of the characteristics and the benign nature of this superficially alarming symptom is necessary to avoid unnecessary and potentially hazardous diagnostic procedures in otherwise healthy persons.

Migrainous neuralgia (cluster headache) and Raeder's paratrigeminal neuralgia are headache syndromes that manifest with oculosympathetic findings. Migrainous neuralgia and Raeder's neuralgia can be accompanied by lacrimation and oculosympathetic palsy with ptosis, miosis, and anhydrosis (10,60,61) (see Chapter 47).

A diagnosis occasionally confused with cluster headache is dissection of the carotid artery. Dissection of the carotid may present days to weeks after a sudden deceleration trauma (e.g., falling off a roof). The patient commonly presents with ipsilateral headache and periocular pain associated with meiosis and ptosis (62).

Orbital Apex Syndrome. Inflammatory diseases located at the apex of the orbit, referred to as *orbital apex syndrome* , can inflame the frontal or nasociliary divisions of the trigeminal nerve, or both, leading to pain referred to the face or eye. Stretching or inflammation of the optic nerve sheath can also result in pain and vision loss. Inflammation can inhibit action potentials in the cranial nerves III and VI, and occasionally in the cranial nerve IV, resulting in ophthalmoplegia. Therefore, the combination of sensory loss, pain, ophthalmoplegia, and unilateral vision loss can indicate an orbital apex syndrome. Inflammation is usually caused either by orbital pseudotumor or infection (63). Rarely do tumors or vascular diseases in this area present with pain.

Parasellar Syndrome. Lesions involving the cavernous sinus lateral to the sella turcica, which can be accompanied by pain, ophthalmoplegia, and trigeminal sensory loss, include laterally expanding pituitary adenomas, intracavernous aneurysms, and nasopharyngeal carcinomas (31,64,65,66 and 67). Cavernous sinus thrombosis that follows petrositis can be accompanied by similar pain.

Fleeting Ocular Pain. Fleeting sharp ocular or periocular pain lasting 1 to 5 seconds is a common presenting complaint, sometimes called *ice-pick pain* . The pain occurs randomly, as a shooting, sharp, severe pain often described as going through the eye out the back of the head. In the face of a negative ocular history and a normal eye examination, however, these pains are unassociated with pathology (see Chapter 48).

Cervical Spine Disease. Cervical spine disease can lead to referred orbital pain. Greater occipital neuralgia, or neuritis, presents as occipital pain that spreads over the occiput to involve the periorbital region. Typically, the pain may be exacerbated by palpation of the occipital region in the distribution of the greater occipital nerve. Inflammation, arthritis, or compression of the nerve results in pain. Attacks commonly occur at night and may be associated with tearing, dizziness, and narrowing of the ipsilateral nasal passages (2,13). Initially, pain control is provided by local heat, massage, aspirin, and NSAIDs. However, if control is not obtained, local injection with anesthetic or corticosteroid is often helpful (2,13).

Other pain syndromes may result in referred pain. Temporomandibular joint syndrome, giant cell arteritis, sinusitis, and dental pain may have orbital or periorbital pain as part of the symptomatology. Trigeminal neuralgia (tic douloureux), herpes zoster, Raeder's paratrigeminal neuralgia, myofascial pain syndrome, nasopharyngeal tumors, and otalgia may also result in periorbital pain. These syndromes are covered specifically in Chapter 47, Chapter 49, Chapter 50, and Chapter 52.

Pain of Psychological Origin

Nonorganic pain syndromes are diagnoses of exclusion. A cause for ocular or orbital pain must be diligently evaluated in every patient. Only when no etiology can be found should the clinician entertain the diagnosis of functional pain. Emotional and psychological factors must be considered in the patient's response. Hypochondriasis, conversion reaction, hysteria, or other somatization disorders may be involved in the patient's report of pain. Secondary gain should also be evaluated; litigation and disability claims may be in process. It is often difficult for the physician to evaluate all the possible aspects of functional pain; assistance should be sought by psychological consultation when nonorganic factors seem to be involved in the complaint of pain.

MANAGEMENT

Topical Anesthetics and Analgesics

Instillation of 1 or 2 drops (0.05 to 0.10 mL) of a topical anesthetic solution (proparacaine hydrochloride 0.5%) immediately anesthetizes the surface of the globe and provides dramatic relief, lasting at least 15 minutes, from surface ocular pain. The patient might have been in agony moments before because of the pain and foreign body sensation of a mechanical, chemical, or photic injury to the corneal epithelium, but now rests comfortably. Use of a topical anesthetic to facilitate diagnosis is always permissible and allows thorough examination of the eye and institution of definitive therapy. The pain gradually returns, and the patient might beg for a prescription of the *miracle drug* , but topical anesthetics should *never* be prescribed for repeated instillation by the patient. All such agents are toxic to the corneal epithelium and can cause loss of the remaining corneal epithelium through their toxic effects and by acceleration of the breakup time of the lacrimal film, with resultant corneal drying (68).

Topical NSAIDs are available for ocular use (diclofenac 0.1%, flurbiprofen 0.03%, ketorolac 0.5%, and suprofen 1%). Diclofenac and suprofen are used to inhibit miosis during intraocular surgery. Some of these agents are also useful for seasonal allergies and postoperative inflammation. Reports have shown that topical NSAIDs may be useful in the management of pain associated with corneal abrasions and corneal surgery. Although patching is a useful technique in the management of corneal abrasions, studies show that management of corneal abrasions with topical NSAIDs and a bandage contact lens allows the patient to return to normal function more rapidly and therefore may be more acceptable to the patient (69,70 and 71). Laser refractive surgery is becoming commonplace; postoperative pain may be mild to moderate. Use of topical NSAIDs and a bandage contact lens has been shown to reduce the severity of postoperative pain (43,44 and 45).

Patching

Corneal epithelial defects are repaired by a combination of two mechanisms: sliding of cells from the periphery of the wound and division of neighboring cells (29). Frequent blinking delays the healing of the defect and contributes to the patient's discomfort. Presumably the delicate sliding of new cells is mechanically impeded or the cells are removed by the action of the eyelids.

The aim of a properly applied patch is forcible immobilization of the eyelids. The desired result is not accomplished by a quick application of a single eye pad with a strip of tape, but requires placement of at least two eye pads or other bulky dressing over the involved eye, secured with multiple strips of tape applied diagonally from the center of the forehead toward the angle of the mandible (Fig. 51-11). Successive tightly stretched layers of tape are added to increase the pressure on the dressing until the patient cannot open the eyelids voluntarily. Tincture of benzoin improves adherence of the tape to the skin. Because the eye under the patch moves with the unpatched eye, the patient is usually most comfortable with the unpatched eye closed, except for essential tasks, during the healing period, and is best advised to remain quiet.

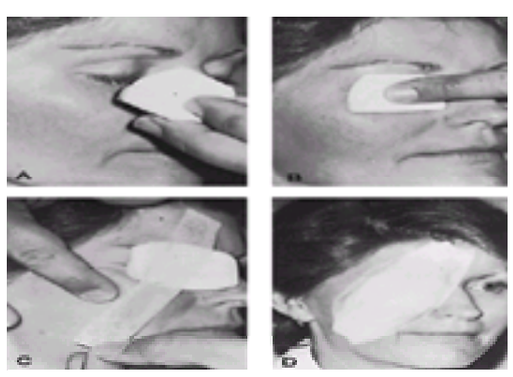

Figure 51-11. Patching. **A:** The first patch is folded to add bulk. **B:** The eye pads are applied while both eyes are closed. **C:** The tape is applied tightly over two patches from forehead to cheek. Addition of tincture of benzoin ensures adherence of the tape. **D:** Several strips of tape have been applied. Opening the unpatched eye should not allow the patched eye to open. If the patient reports that the eye has opened under the pad, it should be reapplied.

The corneal epithelium heals remarkably fast; all but the largest abrasions heal functionally within the first 48 hours. Patching, properly performed, is the most important single factor in promoting healing and relieving pain in any disorder in which the continuity of the corneal epithelium is interrupted. Patching raises the temperature of the cornea and conjunctival sac and provides an ideal milieu for bacterial growth. Therefore, antibiotics such as sulfacetamide 10%, gentamicin 0.3%, or tobramycin 0.3% should be instilled in the conjunctival sac before patching. Patching is contraindicated in bacterial corneal ulcers and conjunctivitis, in which incubation of the organisms would be expedited.

The cornea may be patched effectively with the use of bandage contact lenses. Bandage lenses may be either hydrogel lenses similar to normal soft contact lenses or collagen shields that dissolve over time (Fig. 51-12). These lenses protect the cornea from exposure to eyelid movement or the environment, allowing healing of the corneal epithelium. They are also clear and allow the patient some vision while the cornea is healing, often leading to more patient acceptance than the formal patching described previously.

Figure 51-12. Collagen corneal shield (Bausch and Lomb, Clearwater, FL).

Cycloplegic Agents

Inflammatory and traumatic disorders of the anterior segment of the globe frequently induce spastic contraction of the muscles of the ciliary body and iris, thereby inducing an aching pain. The pupil becomes miotic, and a large area of the posterior surface of the iris is in contact with the lens where, in the presence of inflammation, it can become permanently and undesirably adherent (posterior synechiae). Instillation of a cycloplegic (parasympatholytic) agent relieves the pain of ciliary spasm and dilates the pupil, preventing posterior synechiae.

The cycloplegic agent should be chosen according to the desired duration of action (see Table 51-1). Obviously, atropine is inappropriate for a corneal abrasion expected to be healed within 24 hours, because its duration of action lasts up to 14 days. Heavily pigmented eyes are generally less responsive to cycloplegic agents than are lightly pigmented eyes. The pupil can also be dilated for diagnostic purposes by the use of sympathomimetic drugs (e.g., phenylephrine), but such agents are not indicated for chronic therapeutic use because they do not relieve the ciliary spasm and can increase the inflammatory response.

Analgesics

Proper patching and use of cycloplegic agents, as described, markedly reduce or eliminate the requirement for systemic analgesics. The predisposition of ocular pain to provoke nausea and vomiting should be remembered, and drugs should be avoided that are likely to contribute to nausea or vomiting, either through irritation of the gastric mucosa or through systemic effects. Codeine or meperidine is usually satisfactory for short-term pain relief, but the parenteral route must be used if nausea exists.

Chronic administration of a narcotic agent is rarely, if ever, indicated for relief of ocular pain. Chronic ocular pain usually indicates a need for definitive treatment of the basic disorder or for enucleation of the eye if no hope exists for recovery of vision.

Retrobulbar Anesthetics and Alcohol

Blind, painful eyes are usually treated by surgical enucleation because they are disfiguring or because of the possibility that they harbor malignancy. Certain eyes that are painful as a result of chronic ocular disease, however, retain limited vision or some potential for future recovery of vision, but at present, clinical judgment dictates against definitive surgical therapy. The pain of such eyes can be relieved by retrobulbar injection of 1 to 2 mL of 20% to 95% alcohol (38,39). Palsies of extraocular muscles are common but transient; their risk of occurrence can be reduced by avoiding the deeper portion of the muscle cone with the injection. The immediate consequences of the injection, which should be preceded by injection of 1 to 2 mL of 2% lidocaine through the same needle left in place, are pain, proptosis, and chemosis, which subside over several days. The optic nerve resists the effects of alcohol because of its thick sheath; cases of vision loss caused by needles *properly placed* for retrobulbar alcohol injections have not been reported. Sharp disposable needles should be avoided to minimize the risk of direct injection of the optic nerve or blood vessels.

Surgery

Surgery can play a role in the control of ocular or periocular pain. Corneal pain, if not responsive to the usual therapy, can improve with a conjunctival flap, tarsorrhaphy (surgical eyelid adhesion), or corneal transplantation. Certain types of glaucomas, such as angle closure or neovascular glaucoma, can require surgery such as a peripheral iridectomy, laser surgery, or cryotherapy for pain relief. Orbital tumors or hemorrhage can require removal for pain relief. Chronic ocular or trigeminal pain can respond to thermocoagulation of the gasserian ganglion (72). Finally, when eye pain is chronic and severe and the visual potential is nil, enucleation is indicated for comfort.

Radiotherapy

Occasional patients have chronic pain caused by infiltrating tumors of the orbit or by orbital pseudotumor. Radiotherapy can be beneficial for pain relief in such cases if the pain is unresponsive to conventional therapy.

CHAPTER 52

Pain in the Ear, Midface, and Aerodigestive Tract

Todd G. Dray and Ernest A. Weymuller, Jr.

Pain in the ear, midface, and aerodigestive tract is concerning to the patient, both as a harbinger of significant illness and in regard to the emotional ramifications of having pain in an area that is at once so important and so little understood by the layperson.

One characteristic feature of disorders in the head and neck is the frequent occurrence of referred pain. Pain in the ear, for instance, in the absence of visible ear pathology, should alert the clinician to the possibility of disease in the oropharynx or hypopharynx. Pathology in and around the vocal cords can present early with hoarseness, but pathology elsewhere in the upper aerodigestive tract can be silent until a significant airway problem develops. The hypopharynx and deep neck structures are difficult for the clinician to examine, making a high index of suspicion vital in this area.

Epidemiologic studies suggest that more than 50% of office visits to general practitioners are related to symptoms in the ear, midface, and aerodigestive tract. More than two-thirds of office visits to general pediatricians are for symptoms in these areas. Billions of dollars are spent in the United States each year on symptomatic relief of pain, infection, or allergy relating to this region of the body. Although most disorders in this area are self-limited or of little significance in regard to long-term disability, it is difficult to differentiate between insignificant and significant disorders on symptoms alone. Recognition of the characteristics of painful disorders and an understanding of pain referral patterns can greatly facilitate early diagnosis.

Table 52-1 lists disorders in this region of the body that have pain as a prominent symptom. Disorders notable for not being associated with pain are presented in Table 52-2. This chapter consists of three sections that discuss pain in the ear, midface, and upper aerodigestive tract. Some of the disorders in these anatomic regions are also discussed in other sections of this book. More comprehensive discussions have been presented by Senturia and colleagues (1), Shambaugh and Glasscock (2), and Schuknecht (3) regarding pain in the ear, by Alling and Mahan (4) regarding pain in the midface, and by Cummings and associates (5) regarding surgical therapy of these regions.

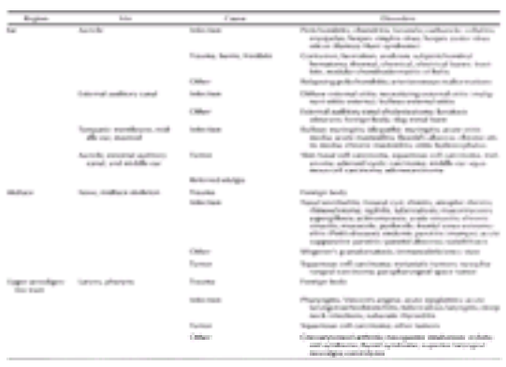

TABLE 52-1. Disorders that have pain as a prominent symptom

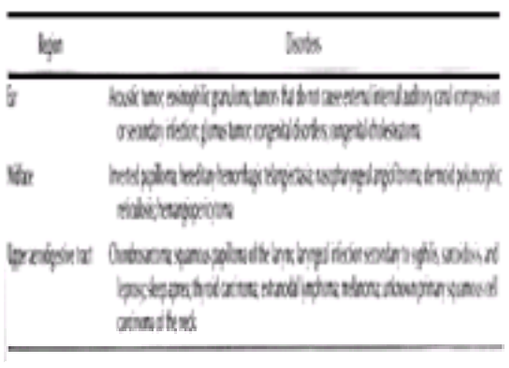

TABLE 52-2. Disorders in which pain is not a prominent symptom

PAIN IN THE EAR

Basic Considerations

Anatomy and Nerve Supply

The auricle is an exposed, irregular disk-shaped structure composed of cartilage and skin, with little subcutaneous tissue. The external auditory canal is a curved, skin-lined tube approximately 2.5 cm long that extends medially to the tympanic membrane. The lateral half is cartilaginous, whereas the medial half is bony. The

bony canal is an intact ring, but the cartilaginous portion is broken by several vertical fissures of Santorini along the anterior wall. Subcutaneous tissue is present in the cartilaginous portion but is nonexistent in the bony segment, contributing the extreme sensitivity of the canal skin in this area. The tympanic membrane forms the closed, skin-lined medial end of the external auditory canal. The middle ear is an air-containing space between the tympanic membrane, bony cochlea, eustachian tube, and mastoid air cells. The mastoid is bordered superiorly and posteriorly by intracranial structures. The bony labyrinth is located medially.

The ear is supplied by several cutaneous branches of the spinal and cranial nerves (Fig. 52-1). The auricle is innervated by the greater auricular and the lesser occipital nerves, which are derived from the cervical plexus and ascend from the neck along the sternocleidomastoid muscle; by the auricular branch of the vagus nerve, which travels laterally along the posterior aspect of the external auditory canal; and by the auriculotemporal branch of the mandibular nerve. The posterior and inferior aspects of the tympanic membrane receive their nerve supply from the auriculotemporal branch of the mandibular nerve, auricular branch of the vagus nerve, and tympanic branch of the glossopharyngeal nerve (Jacobson's nerve). The tympanic branch of the glossopharyngeal nerve, together with the caroticotympanic nerves (derived from the carotid sympathetic plexus) and the smaller superficial petrosal nerve, supply the other parts of the middle ear. The external auditory canal is also supplied by branches of the facial and glossopharyngeal nerves.

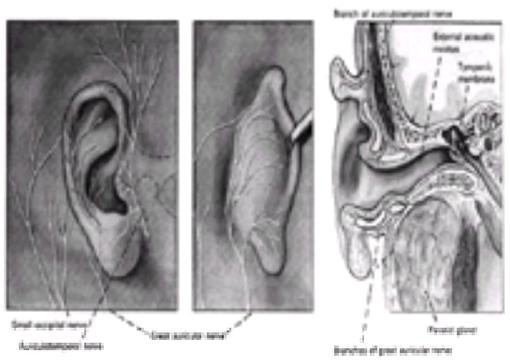

Figure 52-1. Innervation of the ear.

Characteristics of Pain in the Ear (Otalgia)

Pain in the ear can originate locally or can be referred from distant sites. Otalgia in the absence of physical findings can be a manifestation of an upper aerodigestive tract tumor or infectious process, sinus or dental infection, or temporomandibular joint disease. Referred otalgia accounts for up to 50% of all ear pain complaints (6). In such patients, all head and neck areas innervated by the trigeminal, facial, glossopharyngeal, and vagus nerves (all of which provide sensory innervation to the ear) must be carefully examined. The attention of a specialist is essential for full evaluation, and close follow-up and repeated examinations are mandated by unexplained otalgia, particularly when unilateral.

Pain of the auricle is caused primarily by nociceptive stimuli consequent to acute distension of the skin. Tumors and cartilaginous processes tend to be silent until the skin is stretched. Pain in the external auditory canal is related to compression of skin and nerve endings against unyielding circumferential cartilage or bone. The close proximity of the glenoid fossa and temporomandibular joint, just anterior to the external auditory canal, accounts for the pain from either structure to be generalized to this area. The close proximity of major intracranial structures also influences pain in this area. Unilateral or diffuse headaches as well as meningism can all be directly attributable to an otic source.

Infections of the Auricle

Patients tend to present relatively early in the course of auricular infectious processes because of the location of the auricle as an appendage on the face and because of the intensity of the pain. The main infectious processes are perichondritis and chondritis, furuncle, carbuncle, cellulitis, erysipelas, herpes simplex virus, herpes zoster virus oticus, and Ramsay Hunt syndrome.

Furuncles and Carbuncles

Furuncles and carbuncles are infectious processes that present with pain in a circumscribed area around an infected hair shaft. They are usually caused by staphylococcal organisms. These occasionally occur in the lateral external auditory canal as well as at the meatus. Ear pain is typically intense. Examination demonstrates erythema, edema, and possibly abscess formation. Furuncles and carbuncles may be large with considerable erythematous reaction, and the key to differential diagnosis is observing a normal tympanic membrane. If the condition is localized, incision and drainage are all that is necessary. If a considerable erythematous reaction occurs, an antistaphylococcal antibiotic such as dicloxacillin (orally, 250 to 500 mg three times a day for 10 days) should be added (7).

Cellulitis

Cellulitis of the auricle is diagnosed by redness, swelling, and localized pain. Usually, a history of trauma or otitis externa is given. *Streptococcus* and *Staphylococcus* are the usual causative organisms, and the diagnosis of acute mastoiditis can be difficult to rule out unless the eardrum appears to be normal. Antibiotics such as oral penicillin, erythromycin, or clindamycin are used, together with local care, avoiding abrasion, using warm saline solution or Burow's soaks. Intensive periauricular involvement is best treated in hospital with intravenous antibiotics (8).

Erysipelas

Erysipelas is an erythematous reaction that can present in and around the auricle and is caused by group A b-hemolytic streptococci. It is marked by local pain and redness, with a sharply demarcated advancing border. Often, it is associated with systemic symptoms and the patient appears quite ill. Treatment consists primarily of penicillin G given intravenously, which provides rapid relief. Local measures such as those used for cellulitis can alleviate the patient's discomfort.

Perichondritis and Chondritis

Perichondritis and chondritis are infectious processes that involve the cartilage and are usually associated with severe local pain, heat, redness, and fluctuance over the cartilaginous parts of the auricle only, leaving the lobule free of any reaction. The processes can be indolent or acute in nature and usually follow trauma. These infections can cause considerable disfigurement and need to be treated with great care.

Local treatment with compresses can be used; perichondrial collections of blood or pus often require incision and drainage, followed by a carefully applied mastoid dressing with conforming cotton soaked in antibiotic ointment, to reapproximate the skin and subcutaneous tissue back onto the cartilage. Antibiotics effective against gram-negative bacilli should be used, and for severe infections direct cartilaginous irrigations with antibiotic solutions might be necessary.

Herpes Simplex and Herpes Zoster

Herpes simplex virus involvement of the auricle is similar to herpes simplex I infections elsewhere. Typical findings include an initial burning pain and redness, followed by firm, small vesicles. The problem is self-limited but can be highlighted by intense pain and discomfort. Local care is all that is presently used for treatment of the disorder.

Herpes zoster oticus is characterized by groups of tender, painful vesicles with an erythematous base that appear along the course of a dermatome (see Chapter 22). Pain can precede the eruption by several days, and the rash typically spreads and peaks in 10 days. It is usually self-limiting, and local care is all that is indicated (4).

In the elderly patient, postherpetic neuralgia can develop, which can last for months and is difficult to treat. Acyclovir may have a role in suppressing the pain.

Ramsay Hunt Syndrome

Ramsay Hunt syndrome is a related but more serious disorder caused by reactivation of herpes zoster virus within the geniculate ganglion. The syndrome consists of a painful rash (facial and neck), the acoustic symptoms of hearing loss and dysequilibrium, and facial palsy. It is the second most common cause of facial paralysis (9). Treatment is highly controversial. If evidence of motor end-plate denervation is seen on electroneuronography, some physicians treat this lesion by decompression of the facial nerve using a middle fossa approach within 10 days of onset (10). Often patients are given corticosteroids when first seen; high doses of 100 mg or more of prednisone daily for 1 week are used, after which the dose is gradually decreased.

Trauma, Burns, and Other Painful Conditions of the Auricle

Trauma

Contusion of the auricle is characterized by localized pain. Severe blunt trauma to the auricle can cause injury of the cartilage, with shearing of the perichondrium from the cartilage and consequent subperichondrial hematoma that produces severe or excruciating local pain. It is treated by draining any fluid or blood present and by use of a compression dressing to prevent reaccumulation of fluid. A frank hematoma is an indication for administration of an antibiotic such as penicillin or a cephalosporin given orally.

Laceration or avulsion of the auricle, or both, is not uncommon. The excellent blood supply of the auricle, however, greatly enhances reconstruction if it is traumatized or burned. Up to $^{7}/_{8}$ of the auricle can be avulsed and successfully reimplanted using meticulous closure with careful realignment to maintain the contour of the auricle (11). A gentle supporting bandage is helpful for the 7 to 10 days after this type of repair.

Burns

The ear can be burned thermally, chemically, electrically, or by ultraviolet radiation. Moderate to severe pain occurs with first- and second-degree burns, but third-degree burns usually result in anesthesia or hypesthesia. Frequently a pseudomonal, streptococcal, or staphylococcal infection develops as a sequela of a burn. Vigorous cleaning is avoided initially, and a topical antibiotic ointment such as Silvadene is applied. Systemic antibiotics are given to patients with significant burns. Reconstruction of the ear after the most severe burns may be necessary (11).

Chemical burns should be treated with neutralization of the agent that produced the burn. With an intact eardrum the auricle and canal can be washed with dilute sodium hydroxide for an acidic burn, and with 2% acetic acid for an alkaline burn. Electrical burns can be quite deceiving on initial appearance, because tissue injury demarcates later and is proportional to the voltage. It is important to keep the ear clean while demarcation is taking place, and to protect the ear from further trauma. Once demarcation has occurred, the ear is treated as for other burns.

Frostbite

Frostbite, of course, results from exposure to severe cold weather (see Chapter 33). Early in the course of the injury local pallor and numbness develop, but on rewarming, edema, vesicles, and bullae develop and are associated with considerable pain. Treatment consists of thawing the ear quickly with gauze soaked in warm saline solution while avoiding rubbing the ear or subjecting it to any other trauma. Rapid rewarming can be extremely painful. Careful debridement should be used initially until the injury demarcates, after which it is treated as for burns, including a topical antibiotic ointment (11).

Nodular Chondrodermatitis

Another disorder that affects the auricle is nodular chondrodermatitis of the helix, characterized by a small (0.5 to 1.0 cm), smooth, painful nodule, typically with a crest at the superior helical rim. There may be a history of trauma, but often no antecedent injury. Pain is disproportionate to the appearance. When these lesions are seen it is important to rule out carcinoma and actinic keratosis. Intralesional corticosteroids can be used with success, although a simple wedge resection is often used for biopsy (12).

Relapsing Polychondritis

Auricular pain, erythema, and swelling are usually the result of infectious cellulitis; however, relapsing polychondritis is another cause of this symptom complex. It results from an autoimmune process that inflames and destroys cartilage, with the auricle and joint cartilage most often involved. Whites are primarily affected by this disorder, and symptoms are seen most frequently in patients 40 to 60 years old. Renal and cardiovascular involvement may be seen in a small percentage of patients. Treatment is based on nonsteroidal antiinflammatory drugs, corticosteroids, dapsone, and in severe cases, immunosuppressant therapy. Relapses are common (13).

Arteriovenous Malformations

Arteriovenous malformations are sometimes seen in the region of the auricle. These are congenital, spontaneous, or traumatic in origin and are manifested by localized pain with swelling and increased warmth over the area. Treatment consists of surgical excision after embolization, if the lesion is large.

Infections of the External Auditory Canal

External Otitis

External otitis is a common disorder associated with swimming, especially in fresh water, diving, and misuse of cotton swabs. It also has an increased incidence in the postpartum period and in psoriasis and other dermatoses. Typically, an initial itch is present, followed by ear pain that can be severe. The pain may be associated with chewing or opening of the mouth, secondary to the proximity of the temporomandibular joint. Examination reveals the skin of the ear canal to be red, swollen, and draining, and the pain might seem out of proportion to the findings on examination. Often the tympanic membrane cannot be well visualized secondary to the swelling, and the examination is uncomfortable to the patient. Grasping the auricle and moving it posteriorly causes pain. The most common causative organisms are *Pseudomonas* and *Staphylococcus* (14).

Treatment consists of thorough cleaning of the ear canal, which is best performed under an operating microscope. If cellulitis extends lateral to the meatus it should be treated with an antistaphylococcal oral antibiotic. It is sometimes necessary to place a porous wick in the external auditory canal to permit application of corticosteroid-containing antibiotic drops (Cortisporin otic suspension). Wicks should not remain in the external auditory canal for more than 48 hours, at which time the process is usually much improved and the eardrum can be visualized. It is important to follow these patients to the resolution of their symptoms and to rule out necrotizing or malignant external otitis in patients who are diabetics or immunocompromised (15).

Necrotizing External Otitis

Necrotizing external otitis is a life-threatening disorder that cannot be distinguished from diffuse external otitis on the basis of pain alone. It represents a progressive, intractable pseudomonal infection of the temporal bone. Patients with this disorder are often quite sick, can be chronically ill, and frequently are diabetics. Bone destruction and facial paralysis are frequent. Typical findings include granulation tissue in the ear canal, an elevated erythrocyte sedimentation rate, enhancement on ^{67}Ga scanning, and bone destruction on computed tomographic (CT) scan. Treatment should be carried out in a hospital with careful cleaning of the ear and systemic antibiotics effective against *Pseudomonas*, along with aggressive control of diabetes and other comorbid conditions. Surgery is reserved for poor resolution of the process. This problem has a significant mortality (16).

Bullous External Otitis

Bullous external otitis is characterized by sudden severe pain in one or both ears, with a dark red discharge from the ear. Examination shows hemorrhagic bullae on

the wall of the ear canal. This is a self-limiting problem that only lasts for several days and is probably caused by a virus or *Mycoplasma pneumoniae*. Treatment consists of ear canal cleaning and application of drops that contain a combination of a corticosteroid and an antibiotic.

Other Painful Disorders of the External Auditory Canal

Cholesteatoma

Cholesteatoma of the external auditory canal is an unusual problem that often follows surgical trauma or other injury to the bone of the external auditory canal. These patients may present with chronic dull pain in the ear secondary to focal invasion of squamous epithelium into the canal wall. The process continues until eradicated by surgery, which entails removal of all of the involved bone and reconstruction with a mastoidectomy cavity or skin graft (7).

Keratosis Obturans

Keratosis obturans is a disorder of obscure cause. It is characterized by acute severe pain in the ear secondary to large plugs of desquamated keratin. It often occurs bilaterally and is associated with bronchiectasis and sinusitis. Examination of the ear canals shows large plugs of keratin that can be removed as a cast of the lateral surface of the tympanic membrane and the external auditory canal, as well as bony remodeling of the ear canal. Treatment consists of external auditory canal debridement and close follow-up. This chronic disorder requires cleaning of the ear at regular intervals (17). Presently, no curative therapy exists for this condition.

Foreign Bodies

Foreign bodies are a frequent cause of pain in the ear. Foreign bodies are usually inserted by children or by mentally deficient individuals. Insects may fly or crawl into one or both ears. If the insect is alive, infusion of mineral oil or lidocaine solution into the ear canal can be used to float the insect or induce it to exit. If the insect is dead it can often be removed with forceps. Vegetable matter can swell within the ear canal, making removal difficult. A local anesthetic block of the ear canal can be used, but uncooperative patients might have to be given general anesthesia for removal.

Slag Metal Burns

Slag metal burns occur occasionally in people who work with molten metal. The burns are characterized by ear pain and poor healing within the external auditory canal. Tympanic membrane perforations caused by such burns are not intrinsically painful in a high percentage of patients, but they heal poorly and may require tympanoplasty.

Infections of the Tympanic Membrane, Middle Ear, and Mastoid

Bullous Myringitis

Bullous myringitis is a viral or *M. pneumoniae* infection of the tympanic membrane characterized by sudden excruciating ear pain that subsides rapidly after the blebs in the tympanic membrane are ruptured, either spontaneously or surgically. Treatment consists of application of eardrops and surgical rupture of the blebs. The disease is self-limiting even if no treatment is given (18).

Acute Otitis Media

Acute otitis media is an extremely common problem, especially in children. Nearly two-thirds of all children have at least one episode of acute otitis media and nearly one-third have three or more episodes (19). The problem can occur at any age, however, and remains a common problem even in adulthood. Risk factors include the winter season, bottle-feeding, smoke exposure, daycare attendance, cleft lip and palate abnormalities, and preceding upper respiratory infections. Symptoms might be poorly described by children, but they usually pull at the ear and have fever. Those old enough to articulate experience localized pain in the ear, caused by distension of the tympanic membrane. Often, the tympanic membrane perforates, and purulent discharge occurs, with prompt pain relief and consequent resolution of the problem. It should be noted that acute otitis media can progress to mastoiditis in patients who are treated inadequately. The most common organisms are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* (19).

Treatment of acute otitis media consists of administration of oral antibiotics (ampicillin, amoxicillin, cefaclor, erythromycin with sulfa, or Augmentin). Gram-negative sepsis must be considered in neonates, and a complete septic workup should be performed. Culture and sensitivity of purulent drainage are indicated in septic patients, in infants younger than 2 months old, and in those with poor resolution despite antibiotics (20,21).

Acute Mastoiditis

Acute mastoiditis is a destructive bacterial infection of the mastoid bone and air cell system, and although it is uncommon today, it remains a potentially serious condition. The classic presentation of acute mastoiditis includes a recent history of acute otitis media and an examination that identifies a displaced auricle and middle ear infection. However, not all patients experience a preceding episode of acute otitis media. Dull postauricular pain and ear drainage are the most common presenting symptoms. *Streptococcus pneumoniae* is the most commonly isolated organism. Initial therapy with parenteral antibiotics is appropriate, but a large percentage of patients need mastoid surgery (22,23).

Bezold Abscess

Bezold abscess is a complication of acute mastoiditis and is characterized by pain, tenderness, and swelling in the upper neck. It consists of lateral breakthrough of pus from the mastoid cortex, either directly or by way of a postauricular lymph node that is deep to the attachment of the sternocleidomastoid muscle to the mastoid bone. Patients are usually symptomatic from acute mastoiditis and can be quite ill. Bezold abscess may be discovered fortuitously when there is poor resolution of an acute mastoiditis that is treated with a simple mastoidectomy. Treatment of Bezold abscess consists of incision and drainage and exploration of the upper neck. The same antibiotics are used as for acute mastoiditis.

Chronic Otitis Media

Chronic otitis media is characterized by a nonhealing tympanic membrane perforation and chronic, recurrent ear drainage. The patient may have dull aching pain that is accentuated by intermittent infection of the middle ear and mastoid. Treatment consists of topical corticosteroid drops containing an antibiotic. Patients should be evaluated by a specialist to consider surgery for chronic otorrhea, cholesteatoma, or closure of the tympanic membrane perforation.

Chronic Mastoiditis

Chronic mastoiditis is associated with cholesteatoma and can be similar in symptoms to chronic otitis media. Sudden increase in local pain suggests complication of a cholesteatoma, such as lateral sinus thrombosis or intracranial abscess. Patients with chronic mastoiditis who develop a sudden increase in pain should therefore be carefully examined for evidence of such complications. The examination should include funduscopy, careful cranial nerve examination, and a CT scan (24,25). Proteus mirabilis, pseudomonal, and staphylococcal organisms are commonly found (26). Mortality secondary to complications of cholesteatoma ranges from 10% to 18% (26).

Otitic Hydrocephalus

Otitic hydrocephalus is a complication of cholesteatoma and chronic mastoiditis. These patients are typically being followed for chronic otitis media and suddenly develop headache, which can be unilateral or diffuse and associated with blurred vision, nausea, and vomiting, as a manifestation of increased intracranial pressure. Characteristically though, no ventricular dilatation is identified on CT imaging, but an associated lateral sinus thrombosis often is present. Treatment is focused on the management of the elevated cerebrospinal fluid pressure so as to prevent atrophy of the optic nerve from persistent papilledema. Serial lumbar punctures or placement of a lumbar drain effectively diminishes cerebrospinal fluid pressures over the several weeks usually required for the condition to run its course.

Mastoidectomy should be performed to manage the chronically draining ear (27,28).

Tumors of the Auricle and External Auditory Canal

Auricle

Tumors of the auricle and periauricular skin are common and notoriously difficult to control. Cutaneous malignancies that commonly occur in these sites are squamous cell and basal cell carcinoma, involving the parts of the auricle that are exposed to sunlight. Tumors of the auricle tend to produce symptoms early and do have a favorable prognosis when small. They are usually treated by a wedge resection and rarely require regional lymph node dissection. Radiation therapy can also be used as an alternative modality for these small auricular lesions. Mohs' surgery is an effective surgical technique for larger and more complex lesions (29).

External Auditory Canal

Tumors of the meatus and external auditory canal are uncommon and generally present with chronic ear drainage, which is often bloody. Examination reveals granulation tissue, polyp, or exposed bone within the external auditory canal. The tumors are usually squamous cell carcinomas. Pain can be persistent and gnawing but variable in intensity. Frequently, the initial presentation is consistent with an external otitis or chronic otitis media, and it is only with poor response to conventional therapy and a high index of suspicion leading to biopsy that the diagnosis is made. Treatment of tumors of the meatus and external auditory canal consists of surgical removal.

PAIN IN THE MIDFACE

Basic Considerations

The midface is composed of a series of air-containing cavities surrounded by bone and soft tissue. The maxillary, ethmoid, frontal, and sphenoid sinuses are all air-containing spaces surrounded by respiratory mucosa and bone. The nose is composed largely of soft tissue that hangs off a small bony skeleton. Sensation in this area is mediated predominantly via branches of the trigeminal nerve. The three major branches of the trigeminal nerve exit the skull through foramina that lie close to the midface structures. Consequently, sensory defects and pain patterns identified by the history and physical examination can localize lesions in this area.

Most disorders in this region cause only local pain, referred pain being rare, although dental and sinus lesions can cause referred otalgia. Most painful disorders of the nose are related to inflammation or distension of soft tissue. Pain in the sinuses is largely the result of compression of the mucosa onto unyielding bony margins.

Trauma

Nasal Trauma

The nose is frequently traumatized because of its prominent position on the face. The thin, paired nasal bony leaflets can be relatively easily displaced by blunt trauma. Bony fractures of the nose are almost invariably associated with epistaxis because of the close opposition of the well-vascularized periosteum and mucosa intranasally. Treatment of bony nasal displacements consists of closed reduction if obvious cosmetic deformity is noted, after swelling has subsided. During an approximately 2-week-long grace period, closed reduction can be performed. After this time open reduction is best.

Trauma to the cartilaginous portions of the nose is extremely common and can cause deflections and reduplication. These injuries can also be seen in neonates, who might have difficulty with nasal breathing. Closed manipulation is generally all that is required in such cases. The sequelae of nasal trauma are septal hematoma and abscess, which can be recognized by an intranasal bulging on either side of the septum that is generally bilateral. Usually, considerable nasal pain is associated with this condition, as is tenderness of the nasal tip on palpation. Treatment consists of an incision and drainage with appropriate intranasal packing.

Trauma to the Midface Skeleton

Trauma to the midface skeleton also frequently occurs, but requires more significant force than that required for nasal fracture. LeFort divided midfacial fractures into types I, II, and III, based on remarkable cadaveric studies he performed in the nineteenth century (30). Type I is a horizontal fracture just superior to the palate; type II is a triangular fracture from the glabella along the infraorbital rim, inferior to the zygoma; and type III includes the zygoma (Fig. 52-2). In practice these types are usually mixed.

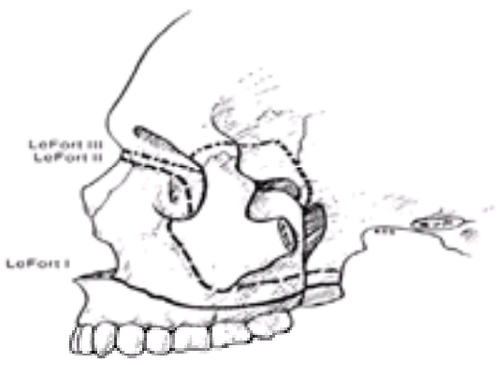

Figure 52-2. Sites of LeFort facial fractures.

Diagnosis is made on the basis of the history and physical examination, which reveals obvious disruption of the midfacial supports on traction. Treatment usually consists of open reduction and internal fixation with facial plating systems (31).

Infections of the Nose

Vestibulitis

Nasal vestibulitis is an infection caused by *Streptococcus* and *Staphylococcus* in the skin at the entrance to the nostril, often associated with folliculitis of the vibrissae. Differential diagnosis should include fissural cysts; these congenital remnants are often dental in origin but can present in the nasal vestibule.

Treatment consists of antibiotics and possible incision and drainage if abscess formation has occurred. Vigilance must be observed, as with any midfacial infection, that the infection does not spread posteriorly along the venous drainage and into the intracranial spaces. Therefore, the patient who does not rapidly respond to treatment should be admitted to the hospital for intravenous antibiotics.

Rhinitis

Rhinitis is an extremely common disorder of varying etiology, including viral, allergic, and nasal spray–induced reactions. It is usually associated with rhinorrhea and nasal stuffiness more than with pain. One variant that is associated with significant pain, however, is caused by the *Klebsiella ozaenae* organism. This type of rhinitis, known as *atrophic rhinitis*, presents with massive crusting of the nose and an extremely foul smell that can be difficult to eradicate. Treatment consists of local debridement and antibiotics.

Rhinoscleroma

Rhinoscleroma is an infectious disorder of the nose and sinuses caused by *Klebsiella rhinoscleromatis*. It is most often seen in people from the Middle East and Southeast Asia and is usually an indolent infectious process that can cause significant atrophy and deformity if left untreated (32). At times it presents with a picture consistent with that of sinusitis, and the associated symptoms and signs cannot be distinguished from those of sinusitis without a high index of suspicion and a biopsy of the granulation tissue. The biopsy shows the characteristic Mikulicz foam cells, with vacuolated cytoplasm. Treatment consists of antibiotics that include tetracycline and erythromycin. The infection sometimes proves difficult to eradicate.

Infections of the Sinuses

Acute Sinusitis

Sinusitis is a common problem that can be caused either by viral, bacterial, or fungal pathogens. It occurs most commonly in the maxillary antrum as a complication of a rhinovirus infection. Epidemiologic studies have indicated that 0.5% of all viral colds are complicated by sinusitis (33,34). Acute sinusitis is usually secondary to an obstruction of the sinus ostia, which normally allows pressure equalization and egress of the mucosal blanket from the sinus into the nose. Acute sinusitis has a bacteriologic spectrum similar to that of acute otitis media, *Streptococcus pneumoniae* and *Haemophilus influenzae* predominating.

Patients usually present early in the course of their disease with pain localized to the region of the affected sinus. An exception is patients with sphenoid sinusitis, who can present with pain at the vertex of the skull. Sinusitis pain is characteristically worse during the day and much better or wholly absent at night. This pain pattern is related to the normal nasal cycle of congestion and decongestion. In children, nasal congestion, cough, rhinorrhea, headache, and facial pain are the predominant symptoms (35).

Diagnosis can be made on physical examination by eliciting tenderness over the thinnest part of the bone of the involved sinus. Radiography (contrast-enhanced CT scan) is reserved for assessment of patients with possible complications of sinusitis.

Treatment consists of topical decongestants and systemic antibiotics. Ampicillin and amoxicillin are first-line drugs. A cephalosporin, erythromycin, and tetracycline can all be used to treat an acute sinusitis. Anaerobic bacteria also play a role in acute sinusitis but are more significant in chronic sinusitis. A poorly responsive sinusitis can therefore be treated with the addition of metronidazole hydrochloride (Flagyl), 250 to 750 mg three times a day orally. It is often advisable to continue antibiotic therapy for 14 to 21 days. In acute sinusitis, surgery is reserved for present or impending complication. This includes sinusitis localized in the sphenoid or frontal sinuses, which does not show definite signs of improving over a 24- to 48-hour period, and an ethmoid sinusitis associated with signs of orbital involvement. Complications of ethmoid sinusitis are more frequent in children but tend to be more serious in adults.

Chronic Sinusitis

Chronic sinusitis occurs secondary to obstruction of the osteomeatal complex. It consists of a symptom complex of dull, aching, gnawing facial pain, with periodic rhinorrhea. Patients often complain of a tired feeling in the ipsilateral eye. Diagnosis is made by history and is confirmed by CT scanning, which shows thickening of the sinus mucosa or opacification.

Because anaerobic bacteria are frequent causative agents, antibiotics for such infections should be used, and b-lactamase coverage should be considered. Current understanding of chronic sinus disease mandates that these infections be treated with prolonged courses of antibiotics. Additionally, a mucolytic agent, a topical nasal corticosteroid spray, and nasal irrigations are considered standard therapy in this setting, and a course of prednisone may augment antibiotic therapy considerably. Sinus surgery is appropriate for continued symptoms or suppurative complications.

Mucormycosis

Rhinocerebrophycomycosis, or mucormycosis, is an uncommon fungal infection that has a rapidly fatal course if treatment is delayed (36). It is characterized by the classic syndrome of diabetic ketoacidosis, unilateral blindness, ophthalmoplegia, and proptosis. The infection should be considered in any patient with sinusitis and diabetic ketoacidosis. Facial pain is typical early in the course of the disease, but it is not characteristic as the infection advances. Examination can show a black turbinate, although the turbinate might appear pale when seen early. These patients are often extremely ill and have signs of cerebrovascular thrombosis with meningocephalitis. Biopsy is usually required for making the diagnosis and shows invasive broad, branching nonseptate hyphae with hemorrhage and tissue infarction (37). Treatment consists of reversal of the acidosis, debridement of involved tissues, which might require an orbital exenteration, and the use of amphotericin B (36).

Complications of Sinus Disease

Mucocele and Mucopyocele

Mucoceles are the most common expanding lesions of the paranasal sinuses and usually arise from the frontal and ethmoidal sinuses (38). The most common symptoms are headache, double vision, and proptosis. The major diagnostic tool is CT scanning, which shows a smoothly marginated cyst and often reveals bony destruction. The usual treatment is surgical exenteration of the involved sinus.

Intracranial Disorders. Sinus infection can progress to intracranial involvement. Persistent headache, particularly one originally localized but that becomes more generalized, together with neurologic changes, mandates the ruling out of intracranial extension. This is best done with a contrast-enhanced CT scan (39).

Osteomyelitis. Frontal sinus osteomyelitis (Pott's disease) is a rare complication of frontal sinusitis. It is characterized by considerable local pain and a swollen erythematous forehead, with *peau d'orange* skin changes. Frequently, the ipsilateral eye is swollen, particularly the upper lid. Treatment consists of antibiotics and surgical drainage. Extensive osteomyelitic involvement of the anterior table of the frontal bone requires removal of this bone, with consequent cosmetic defect unless it is reconstructed. Intracranial involvement is a not infrequent accompaniment, and severe headache, fever, and dizziness, together with poor response to treatment, should prompt a contrast-enhanced CT scan (40).

Other Disorders

Epidemic Parotitis

Epidemic parotitis, or mumps, is a paramyxovirus infection, which is a common cause of pronounced unilateral or bilateral parotid swelling. It is associated with moderate to severe pain and frequently occurs in children and young adults. Occasionally, the submandibular gland is involved. Constitutional symptoms are common, including fever and malaise. Orchitis and oophoritis can also be seen. Uncomplicated mumps resolves within 2 weeks on supportive therapy only. Despite the administration of the mumps vaccine, mumps must still be considered, because the efficiency of the vaccine is between 75% and 90% (41).

Acute Parotitis

Acute suppurative parotitis most frequently occurs in the elderly. It is also known as *surgical parotitis* . *Staphylococcus aureus* is the most common pathogen associated with the condition (42). The clinical entity consists of unilateral pain and swelling in the region of the parotid gland, which is often doughy in consistency and can be enlarged. Pressure on the gland often produces excretion of pus from Stensen's duct. Predisposing factors include dehydration, malnutrition, oral tumors, sialolithiasis, and medications that diminish saliva.

Treatment consists of appropriate antibiotics and rehydration. Occasionally, the process leads to parotid or periparotid abscess, which requires surgical drainage by an experienced surgeon (43).

Sialolithiasis

Sialolithiasis can occur in any salivary gland but is most common in the submandibular gland. It is characterized by pain with meals and can produce swelling of the involved gland secondary to the backup of saliva and distension of the ductal system. Palpation of the involved gland is usually painful. Prolonged blockage can lead to an acute bacterial sialadenitis with constant pain and chronic dysfunction of the involved salivary gland. Ninety percent of submandibular gland stones are radiopaque, but only 10% of parotid gland stones are radiopaque. Once the stone has been identified it is removed with a surgical incision along the duct. Chronic changes might require surgical removal of the gland, which is more frequently necessary for the submandibular than for the parotid gland.

Wegener's Granulomatosis

Wegener's granulomatosis is a systemic vasculitis that often presents in the nose and produces associated manifestations in the sinus, lungs, and kidneys. The inflammatory reaction includes necrosis, granulomas, and vasculitis. A positive antinuclear cytoplasmic antigen finding strongly implicates Wegener's granulomatosis, and the diagnosis is made on biopsy, which shows vasculitis of midsized arterioles (44). Patients with Wegener's granulomatosis can present with nasal granulations, nasal-septal perforation, or pain from sinusitis. Treatment is principally medical, with corticosteroids and cyclophosphamide significantly improving the natural course of the disease (45).

Tumors

Cutaneous Malignancies

Most tumors of the nose and skin of the face are similar to cutaneous malignancies elsewhere in the body. Basal cell carcinoma is the most common, followed by squamous cell carcinoma and melanoma. The pain associated with these lesions is often secondary to associated infection or bone erosion. Cutaneous carcinomas of the midface are renowned for their tendency to burrow and skip, so that simple elliptic incisions of an obvious carcinoma are fraught with subsequent failures. Many tumors in this area can initially be treated by Moh's surgery followed by reconstruction (46,47).

Carcinoma of the Paranasal Sinuses

Squamous cell carcinoma, which is the most common type of sinus malignancy, occurs rather infrequently (48,49 and 50). It is most frequently seen in the maxillary sinus, followed by the ethmoid sinus. Early symptoms are identical to those of benign sinus disease, and a high index of suspicion is required for diagnosis. Approximately 70% of patients present with localized facial pain or swelling, and of these approximately 50% present with nasal obstruction and bloody drainage.

A patient who presents with a history of chronic unilateral bloody rhinorrhea, nasal obstruction, and facial pain should prompt suspicion of a squamous cell carcinoma of the sinus. Plain films often show an opacified sinus with bony destruction, and a CT scan is useful to delineate the size of the lesion, but biopsy is necessary for definitive diagnosis.

Treatment options include surgical excision, radiotherapy, or both. Unfortunately, patients tend to present late in the course of the disease, and surgery is not always feasible in those with large lesions.

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma has a high incidence in certain Asian populations (51,52). The most common presenting features are neck mass, retroorbital pain, or pain high and deep in the neck beneath the ear. These tumors may be related to Epstein-Barr virus and can be followed with early antigen and viral capsid antigen titers (53). Radiotherapy has been the traditional mode of treatment, but some information suggests markedly improved survival using concomitant chemotherapy and radiation therapy (54).

PAIN IN THE UPPER AERODIGESTIVE TRACT

In the following discussion, the upper aerodigestive tract is considered to consist of the larynx, pharynx, parapharyngeal space, and deep neck structures. The sensory nerve supply (including nociceptive fibers) of these structures is through the glossopharyngeal and vagus nerves (Fig. 52-3). Consequently, referred pain to the ear, also innervated by these cranial nerves, is a frequent accompaniment of disorders of the laryngeal and pharyngeal regions. Pain from the upper aerodigestive tract is poorly localized by the patient. For example, cricopharyngeal dysphagia can be a manifestation of gastroesophageal junction pathology. Therefore, the differential diagnosis of pain in the upper aerodigestive tract requires consideration of disorders of the esophagus and of the trachea and lungs, as well as glossopharyngeal and vagal neuralgia (see Chapter 47, Chapter 53, Chapter 62, and Chapter 63).

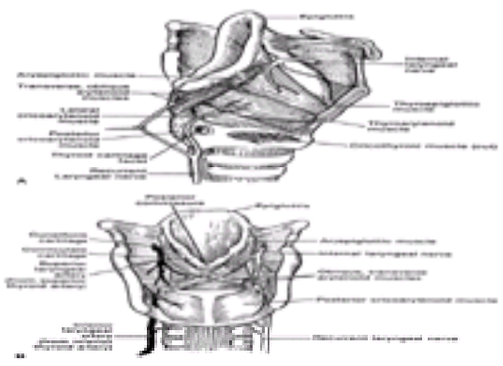

Figure 52-3. **A:** Lateral view of laryngeal muscles and nerves (half of thyroid cartilage and hyoid bone removed). **B:** Posterior view of laryngeal muscles, nerves, and arteries. Infections

Pharyngitis

Pharyngitis is an extremely common problem, characterized by sudden onset of sore throat, odynophagia, fever, pharyngeal exudate, and frequently cervical adenopathy. It is most common in childhood but can be seen in those of any age. Causes of pharyngitis include viruses (most commonly adenovirus), *Mycoplasma pneumoniae* , primary or secondary syphilis, tuberculosis (usually with laryngeal involvement), *Candida albicans* (especially in an immunosuppressed patient), b-hemolytic *Streptococcus* , *Gonococcus* , *Meningococcus* , and diphtheria. The latter infection presents with pseudomembranes that bleed with peeling and exudate that extends beyond the tonsils onto the soft palate and uvula (55). Vincent's angina is caused by an anaerobic infection. Symptoms and signs include pseudomembrane with a bleeding base, with a possible necrotic appearance to one tonsil. Agranulocytosis, leukemia, and malignancy are all associated with sore throat and should be ruled out in patients with pharyngitis that does not respond to therapy. Treatment consists of penicillin or erythromycin in allergic patients.

Peritonsillar Abscess

This abscess is a common clinical entity that often follows a tonsillitis episode. The common complaints are fever, painful swallowing, voice change, and ear pain. Common findings include a deviated uvula, a unilaterally medialized tonsil, and fullness of the soft palate on the affected side. The infection is generally polymicrobial

and may involve anaerobes. Incision and drainage and antibiotic therapy are the gold standard treatment.

Acute Epiglottitis

Acute epiglottitis is a rapidly progressive supraglottitis. It is especially common in children 2 to 7 years of age, but it can also be found in infants and adults. The condition begins with a sore throat, fever, and dysphagia, with drooling and exhaustion. Adults have a less fulminating course, but can have inspiratory stridor. History and the characteristic appearance of a child with fever, sitting straight up with head jutted forward, drooling, and gasping for air should cause the physician to be highly suspicious of this disorder. Lateral soft tissue radiography shows an enlarged epiglottis. Because of the danger to the airway, it is a surgical emergency requiring tracheal intubation or tracheotomy. It is most commonly caused by type B *Haemophilus influenzae* , although the Hib conjugate vaccine has dramatically reduced the incidence of Hib disease in the United States (56).

It is best to take the patient to an operating room for tracheal intubation, with tracheotomy reserved if intubation is unsuccessful (57). Examination of the oral pharynx is kept to a minimum before intubation because of the possibility of precipitating a severe laryngeal spasm. Chloramphenicol and ampicillin are given pending culture results. Usually, the edema resolves rapidly and the patient can be extubated in 2 or 3 days (57). This disorder rarely reoccurs.

Acute Laryngotracheobronchitis

Acute laryngotracheobronchitis, or croup, is an acute viral inflammation of the larynx and tracheobronchial tree that typically presents in children younger than 3 years of age in the middle of the night. This condition can follow an upper respiratory infection and tends to have a less fulminant course than supraglottitis. It can begin with a painful croupy cough, hoarseness, and a biphasic or inspiratory stridor with retraction, circumoral pallor, and cyanosis, indicating respiratory fatigue. Cervical soft tissue films are often all that is necessary to make the diagnosis in combination with the history and physical examination. Treatment consists of cold humidification, rest, hydration, oxygen therapy, racemic epinephrine, and antibiotics. Corticosteroids can be used but are often not necessary. Tracheotomy is reserved for patients with severe laryngeal edema.

Tuberculous Laryngitis

Tuberculous laryngitis is almost always secondary to pulmonary tuberculosis and is manifested by painful dysphagia, hoarseness, otalgia, dyspnea, and, later in the course, a cough. The most common site is the posterior larynx in the intraarytenoid fold, followed by the laryngeal surface of the epiglottis. Admission radiographs typically reveal evidence of pulmonary tuberculosis (58). Prognosis is good if treatment is begun early.

Deep Neck Infections

Deep neck infections occur in potential spaces defined by fascial planes (59). The most common causes are oropharyngeal and dental diseases, which allow microorganisms to enter deeper tissues through breaks in the mucosal barrier or by spread from lymphatic or hematogenous routes. Oral anaerobes are the most common bacteriologic offenders, *Streptococcus pyogenes* being the second most common type. Deep neck infections that originate from a cutaneous or parotid source are usually caused by *Staphylococcus* .

Parapharyngeal Space Abscess. The parapharyngeal space is pyramidal in shape, with the base at the skull and the apex at the hyoid bone, and lies just lateral to the peritonsillar space. The pterygoid plexus of veins, which provides major drainage for the midface, runs through the parapharyngeal space. It can be involved secondary to pharyngeal or central facial infections, especially in children. Abscess in the anterior compartment is manifested by trismus, medial displacement of the lateral pharyngeal wall, and retromandibular swelling. Oral intake can be impossible secondary to discomfort. Abscess in the posterior compartment of the parapharyngeal space is characterized by syncope, cranial nerve deficits, and sepsis after involvement of carotid sheath structures.

Retropharyngeal Space Abscess. Retropharyngeal space abscess is most commonly seen in young children because the lymph nodes in this area regress after infancy. The abscess in children is located near the posterior midline and causes pain, nuchal rigidity, dysphagia, and air hunger. Soft tissue films of the neck are helpful in identifying the bulging of the posterior pharyngeal wall. Manipulation of the abscess without airway protection is dangerous because of the possibility of rupture and aspiration of purulent material. Retropharyngeal abscess in adults is usually secondary to tuberculosis, trauma, a foreign body, or cervical spine surgery.

Diagnosis. The diagnosis of deep neck infections is based on physical findings coupled with a typical history of chills, fever, lethargy, and localized pain or tenderness. Brawny induration of the neck can be misleading and an underlying abscess must be ruled out. Neck films using a soft tissue technique are helpful for evaluating airway status and for diagnosing retropharyngeal or epiglottic disorders, as well as for demonstrating gas in the cervical soft tissues. Retropharyngeal thickness seen radiographically must be interpreted cautiously in children.

Treatment. Once identified, a deep neck infection can be treated with intravenous antibiotics and close observation for a short period of time, although it is strongly advised that surgical intervention be carried out whenever an abscess is suspected. Generous incision and drainage, copious irrigation, liberal use of drains, and close follow-up are mandatory to prevent significant morbidity and death (60).

Subacute Thyroiditis

Subacute thyroiditis is an acute self-limiting inflammation of the thyroid gland that often follows upper respiratory infection and is usually secondary to a coxsackievirus infection (61). This condition is characterized by pain in the thyroid region that is increased by swallowing or turning the head and that can radiate to the jaw, ear, and temporomandibular joint. Occasionally, dull pain is the chief complaint. Nervousness, palpitations, fatigue, and a fever can also be associated. Palpation of the thyroid reveals diffuse swelling, acute tenderness, and overlying erythematous skin. Thyroid function test results are normal, but the sedimentation rate is elevated. The treatment consists of analgesics and close follow-up of patients, who can become either hyperthyroid or hypothyroid after the inflammation resolves. Corticosteroids have been used in this condition, but do not shorten the course of the disease (62).

Other Infectious Processes

A number of inflammatory processes do not occur in the upper respiratory tract but, because of their close proximity, produce symptoms that suggest pharyngeal or laryngeal involvement. Patients with pertussis almost universally complain of sore throat in the early stages of the disease. Patients with pneumonias can present with pharyngeal pain.

Stevens-Johnson syndrome is characterized by high fever and vascular and bullous involvement of the oropharynx and skin. These lesions are usually hemorrhagic. Taking anything by mouth is extremely painful. The disorder is seen after patients have been given certain antibiotics, such as sulfa drugs, and it is occasionally fatal. Treatment is supportive and administration of corticosteroids (63).

Tumors

Ninety-five percent of tumors involving the larynx and hypopharynx are squamous cell carcinomas (64). Patients with primary tumors in the glottic larynx manifest hoarseness as an early symptom, but those with tumors in the hypopharynx do not show symptoms until the tumors become advanced. Symptoms depend on the location of the primary tumor, but ear pain in the absence of otic disease is a frequent symptom. Therefore, patients with otalgia in the absence of demonstrable cause should be followed closely to detect any upper aerodigestive tract tumor. Other presenting symptoms include dysphagia, aspiration, and airway compromise.

Tumors of the hypopharynx and supraglottis tend to metastasize to the neck in a high percentage of patients. Carcinomas of the glottis have a much lower rate of regional metastasis. Treatment includes chemotherapy, surgery, and radiation therapy. The choice of treatment depends on the size and location of the primary lesion and regional metastasis. Treatment protocols have changed constantly over the last 20 to 30 years, although organ preservation protocols are presently common.

In patients with persistent but undiagnosable facial pain, parapharyngeal space tumors must be suspected. The most common neoplasm in this area is the benign mixed parotid tumor (65). They usually present as asymptomatic masses. Malignant tumors in this region are usually either lymphosarcomas or malignant schwannomas, which produce constant ipsilateral facial ache or pain and eventually lead to total facial paralysis with flaccidity. The slow onset of the facial paralysis

caused by this condition contrasts with the prompt onset of Bell's palsy. Treatment is usually surgical using a cervical-parotid approach. Carcinomas that produce facial paralysis often have a poor prognosis (66).

Other Painful Disorders

Cricoarytenoid Arthritis

Cricoarytenoid arthritis is manifested by intermittent or constant pain with dysphagia, hoarseness, and dysphonia. It can be caused by rheumatoid arthritis, laryngeal trauma, and other arthritic conditions, but it can also consist of an isolated joint involvement without precise cause (67). Treatment depends on associated systemic manifestations and on the degree of vocal cord movement. Surgical arytenoidectomy or vocal cordotomy might be necessary to enhance the airway if bilateral involvement results in bilateral vocal cord immobility and glottic airway narrowing.

Dysphagia with unilateral otalgia, and possible airway compromise, can also be seen as a consequence of nasogastric intubation, particularly when the tube is placed in the midline as opposed to being placed on either side of the arytenoid cartilages. This can lead to arytenoid arthritis or postcricoid abscess, particularly in diabetics. Treatment consists of early recognition, removal of the nasogastric tube, and parenteral antibiotics.

Stylohyoid Syndrome

The stylohyoid syndrome, also known as Eagle's syndrome, is caused by a dystrophic calcification of the stylohyoid ligament and consists of cervicopharyngeal pain radiating to the ear and the neck pain during mandibular movement, twisting of the neck, or swallowing (68). The pain is stabbing in nature; it originates in the tonsil area and radiates to the ear and sometimes the base of the tongue. Pain is absent with the mouth closed, and no trigger points are present. An elongated styloid or cervical transverse process can also produce symptoms. Not all or even most calcified stylohyoid ligaments, however, cause symptoms. Treatment consists of surgical removal.

Hyoid Syndrome

Hyoid syndrome is characterized by pain in the lateral aspects of the neck and carotid triangle near the tip of the greater cornu of the hyoid bone (69). The pain is usually sudden and severe, especially with head turning or swallowing, and it is often referred to the ipsilateral ear. Between attacks, a chronic dull ache and foreign body sensation can be felt in the throat. Lateral movement of the hyoid causes pain. An elongated lateral extension of the hyoid can be seen on radiography. Treatment consists of surgical excision of the bone.

Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia is a rare cause of throat pain and otalgia that is characterized by radiating pain centered in the region of the tonsil, larynx, and tongue (see Chapter 47). The median age of onset is 64 years. Referred ear pain is the dominant complaint in this disorder. Treatment options include medical therapy such as carbamazepine (Tegretol), percutaneous neurolysis, and open surgical procedures.

Superior Laryngeal Neuralgia

Superior laryngeal neuralgia is similar to trigeminal and glossopharyngeal neuralgias and is characterized by paroxysms of severe, unilateral, lancinating pain radiating from the side of the thyroid cartilage or from the piriform sinus to the angle of the jaw, occasionally to the ear. The trigger zone is usually in the larynx, and attacks are precipitated by swallowing, yawning, sneezing, or by touching the skin over the hyoid bone. Block of the superior laryngeal nerve with local anesthetic produces complete pain relief and can be used as a diagnostic aid. It is also important to rule out laryngeal pathology as well as hyoid and glossopharyngeal neuralgias. Most patients obtain effective pain relief with Tegretol in a dosage of 200 mg daily, gradually increasing to 1,200 mg daily (70).

Carotidynia

Carotidynia is a self-limiting disorder characterized by intense pain in the region of the carotid artery, which is aggravated by palpation (71). Pain is localized to the lateral aspects of the neck, ear, and the angle of the jaw. It can be unilateral or bilateral, usually occurs in female subjects, can last a few days to a week, and is prone to spontaneous remission. Pain may be relieved by inhalation of 100% oxygen. It is important to rule out other pathologies including carcinoma, aneurysm, and inflammatory disorders of the lateral pharynx, salivary glands, and mandible.

CHAPTER 53

Pain Caused by Cancer of the Head and Neck

Douglas B. Villaret and Ernest A. Weymuller, Jr.

CANCER OF THE HEAD AND NECK

Physicians treating head and neck cancer patients become intimately aware of the many pressing concerns that affect these patients' quality of life and response to treatment. The first hurdle patients face is accepting the diagnosis of cancer, their initial reaction usually being shock and disbelief (1,2). During this time it is important that the oncologist and primary caregiver have empathy and respond to all questions, which frequently are asked multiple times either from difficulty assimilating the information or in the outside hope that a mistake has been made. This is of particular concern for cancers involving the head and neck as the patients not only realize their increased likelihood of death, but also the potential for functional and aesthetic impairment. In addition to the specter of pain, their self-image, socialization, and ability to perform such simple functions as swallowing and breathing may be impaired by the tumor itself as well as the treatment. This chapter focuses on pain as it relates to head and neck cancer. Additional information about cancer pain is contained in Chapter 35 and Chapter 36; palliative care is covered in Chapter 40.

Psychological and Emotional Issues

The response to pain is intimately related to the psychological state of the patient. One study evaluated the needs of newly diagnosed cancer patients (3). The most pressing concern noted was about their health, but they had additional concerns about family, adequate social support, and the financial burden that would be imposed on them. Most had symptoms of fatigue, a worried outlook, and occasional insomnia. Up to 40% of patients complained of pain, with 40% of this group reporting inadequate relief of their pain. Several therapeutic strategies designed to enhance the psychological well-being of patients have been shown to reduce their subjective response to pain (2,3,4 and 5). Ineffective coping strategies of head and neck cancer patients are helplessness and fatalism, which lead to increased difficulty in managing pain and incomplete resolution of many of the patients' concerns (6). Such patients often benefit from talking to a psychiatrist or counselor early in the course of their disease, an option that should be readily available to them.

Head and neck cancer patients are commonly perceived as having a poor overall physical and emotional health profile. This was addressed in a study comparing these patients to age-matched U.S. population norms using the Medical Outcomes Study Short-Form Health Survey (7). All head and neck cancer patients had significantly worse mental health scores on their pretreatment evaluations; both the younger and the more advanced stage patients also had a worse physical health component score. The posttreatment scores showed improvement in both the mental health scale and the bodily pain scale. Unfortunately, these patients do not completely recover their emotional well-being. Among patients who have no evidence of disease 7 to 11 years after intervention, 25% to 40% have clinical depression as defined by *Diagnostic and Statistical Manual*, third edition, criteria (4). In addition, head and neck cancer patients have an increased risk of suicide as compared with other cancer patients (8,9). The chronic usage of alcohol and tobacco in this population, as well as a prevalence of low socioeconomic status, low level of education, and poor social support may in part explain this increased psychological fragility (7,10,11). The treating physician must be aware of these factors and realize the direct effect of the psychological state on the patients' ability to cope with pain. The converse is also true: Inadequately controlled pain has a detrimental effect on the emotional well-being of the patient. Too often the psychosocial aspects of the patients' health are not addressed, ultimately delaying or preventing complete recovery from the disease (6).

Physical Issues

The physical deterioration seen in cancer patients also increases their perception of pain. The pathogenesis of squamous cell carcinoma of the head and neck, the most prevalent histologic diagnosis in this region, is associated with the synergistic effect of alcohol and tobacco abuse in 90% of aerodigestive tract tumors. The excessive use of these carcinogens contributes to a general anorexia (12). Compounding this problem, head and neck cancer patients frequently have bulky tumors that interfere with such homeostatic functions as deglutition and respiration. Subsequent nutritional depletion results in general malaise and depressed immune function, which precipitates intercurrent infections and negatively affects tumor growth control (13). With an increasing tumor burden, an increased production is seen of a lymphokine called tumor necrosis factor, formerly known as cachectin, which contributes directly to wasting (14). Additionally, the cosmetic stigmata of these cancers and their treatment often cause patients to seclude themselves (2,4). In conjunction with the previously mentioned poorer social support system, this may make gaining access to food a problem. This aspect of patient management must be treated aggressively not only to improve pain management, but also to improve the patients' quality of life and chance for survival.

Quality of Life

In dealing with patients who have advanced tumor burdens, it is important to remember that increased survival may not be a worthy goal if the quality of life achieved by potentially radical means suffers dramatically. In an article titled “Treatment of patients with stage IV cancer: do the ends justify the means?” Burns and colleagues report that 42% of the patients believed that “there was virtually no joy in life after treatment” (15). In a separate study, the quality of life in advanced stage oropharyngeal lesions was evaluated (16). A worsening of the overall quality of life score was seen at 6 months posttreatment, followed by a gradual return to baseline over the next 6 months. Chewing, swallowing, and shoulder dysfunction were the categories showing the largest decrease. Pain, as assessed by the patient, improved posttherapy in 67% of those patients undergoing surgery; a smaller percentage showed improvement in the radiotherapy arm. This study included patients in stages II through IV who were disease free at 1 year, a different population than in the study by Burns and colleagues, but it shows the resiliency of cancer patients and their ability to cope with their disease.

Symptom management in terminal head and neck cancer patients can also be difficult. Issues of dyspnea secondary to obstructing lesions are infrequent because of the liberal use of tracheostomies. However, dyspnea caused by chronic lung disease is quite common and usually indicates a need for supplemental oxygen (5). Nutritional deficiencies are common because of the various factors mentioned earlier. Pain control is often inadequate. A study by Talmi and colleagues evaluated both inpatient and home hospice patients with head and neck cancer (5). Close to 20% of patients complained of light to moderate pain, whereas 50% of the home care and 74% of the inpatients complained of severe to incapacitating pain when they were first evaluated by the hospice team. Using the World Health Organization Cancer Pain Relief Program, improvement in the severity of the pain reported was seen in all patients. This underscores the need for aggressive treatment of pain in cancer patients, as discussed in Chapter 36 and Chapter 40.

Global Pain Issues

Tumor-related pain was found to be a significant factor in the lives of 80% of patients with oral cavity and oropharyngeal cancer (17,18). In another study, opioids were required for pain relief in over 60% of patients with advanced head and neck carcinoma (19). The pain experienced by these patients can be classified as nociceptive or nonnociceptive. Nociceptive pain is brought about by direct stimulation of the free nerve endings (A-d and C fibers) and can be subclassified into direct

stimulation, referred pain, and nociceptive nerve pain (20). Nociceptive nerve pain is defined as pain in the distribution of a sensory nerve with evidence of an inflammatory or destructive process occurring along the course of the nerve. Nonnociceptive pain is that generated by abnormally excitable nerve endings, often found in neuromas, and may be significantly influenced by the psychological state of the patient. By definition, an absence of any type of pathologic process is required. This type of pain is often seen in patients after a neck dissection with no evidence of infection or recurrence. In a study involving 25 patients, 84% had nociceptive pain from tumor recurrence, and 16% had similar pain secondary to benign inflammation. Additionally, 24% also suffered from nonnociceptive pain after radical cervical lymphadenopathy (21).

As can be seen by the previous discussion, the perception and tolerance of pain in head and neck cancer patients are influenced by their psychological, emotional, and physical well-being. With the high rate of alcoholism, depression, and poor nutritional status in this population, it is difficult to care for all the needs of these patients. Yet, to adequately meet their pain and symptom requirements, all aspects of their health must be addressed.

Pathology and Symptoms and Signs

To treat pain caused by cancers of the head and neck effectively, it is essential to know the pathophysiology, especially the pattern of spread, and the symptoms and signs produced by cancers in various structures of the head and neck. The following is a brief consideration of this subject. A much more detailed discussion has been presented in Suen and Myers (22) and Thawley and colleagues (23), from which some of the following information is taken.

Oral Cavity

The oral cavity consists of the lips, floor of mouth, anterior two-thirds of the tongue, buccal mucosa, upper and lower alveolar ridges, hard palate, and retromolar trigone.

Lip. Cancer of the lip occurred in an estimated 3,190 patients in 1996 (24). Most (88%) of the tumors are squamous cell carcinomas, most (88% to 98%) occur on the lower lip, and the overall 5-year disease-specific survival is good at 91% (23). In contrast to all other aerodigestive carcinomas, it develops as a result of sun exposure and behaves like other cutaneous carcinomas.

Pattern of Spread. Squamous cell carcinoma starts at the vermilion of the lower lip and invades laterally into the adjacent skin and then the orbicular muscle. Advanced lesions invade the adjacent commissures of the lip and buccal mucosa, the skin and wet mucosa of the lip, the adjacent mandible, and eventually the mental nerve. The *lymphatic spread* is to the submental and submandibular nodes, with occasional spread of upper lip cancers to the parotid nodes. Cervical metastases occur in approximately 8% of patients with less than a 2-cm primary cancer, but occur 6% to 35% of the time in lesions that are larger (23).

Symptoms and Signs. Carcinoma of the lip usually presents as a nonhealing erythematous lesion on the lower lip that crusts. It is often an exophytic lesion that is nontender unless it ulcerates and becomes infected, at which time the pain is moderate to severe (22).

Floor of the Mouth. Most neoplasms of the floor of the mouth are squamous cell carcinomas, usually of moderate grade (25). Adenoid cystic and mucoepidermoid carcinomas account for approximately 5% of malignant tumors in this region.

Pattern of Spread. Approximately 90% of the neoplasms originate 2 cm from the anterior midline floor of the mouth and penetrate quite early beneath the mucosa into the sublingual gland, eventually reaching into the midline genioglossus and geniohyoid muscles. Extension toward the gingiva and periosteum of the mandible occurs early and frequently. Invasion of the mandible is usually a late manifestation. Posterior extension occurs into the muscles of the root of the tongue. *Lymphatic spread* is into the submandibular and subdigastric nodes.

Symptoms and Signs. Most small lesions are asymptomatic and erythematous with rolled edges. As the cancer progresses, it can restrict the mobility of the tongue by direct invasion of muscle or the hypoglossal nerve. Pain or paresthesia is a manifestation of deep infiltration to either the mental or lingual nerves, or direct invasion of the mandible (22).

Oral Tongue. More than 95% of oral tongue lesions are squamous cell carcinomas, usually well differentiated (22). Verrucous carcinomas and minor salivary gland tumors are quite uncommon. The latter also carry a worse prognosis stage for stage than other sites in the oral cavity (26).

Pattern of Spread. Almost all oral tongue squamous cell carcinomas occur on the lateral and undersurface of the tongue and tend to remain in the tongue until quite large. Advanced lesions in the anterior third of the tongue invade the floor of the mouth and root of the tongue, producing ulceration and fixation. Middle third lesions invade the musculature of the tongue and later invade the lateral floor of the mouth, whereas posterior lesions grow into the musculature of the tongue, floor of the mouth, anterior tonsillar pillar, base of the tongue, and glossotonsillar sulcus.

Symptoms and Signs. Initially, the tongue is mildly irritated, and pain occurs only during eating or drinking. As ulceration and infection develop, local pain becomes progressively worse and is frequently referred to the external ear canal. Extensive infiltration of the muscle of the tongue affects speech and deglutition. The mouth of the patient with advanced lesions has a fetid odor. Pain that was initially minimal becomes more severe as ulceration and compression of the lingual and mental nerves produce pain in the tongue and teeth and referred pain to the ear.

Buccal Mucosa. The incidence of squamous cell carcinoma arising out of an area of leukoplakia is highest in the buccal mucosa. Verrucous carcinoma can occur in this area and can be difficult to diagnose. Smokeless tobacco is often the etiologic agent (22).

Pattern of Spread. Almost all squamous cell carcinomas in this region originate along the occlusal plane. Early lesions are usually discrete, elevated tumors that are often exophytic; as they enlarge, however, they penetrate the underlying muscles and eventually penetrate to the skin (25). Peripheral growth occurs into the gingivobuccal gutters and eventually into the gingiva and underlying bone. Posterior growth invades the pterygoid muscles, and superior extension involves the alveolar ridge and palate. *Lymphatic spread* is usually to the submandibular nodes, but occasionally the periparotid or superior deep jugular nodes are involved first.

Symptoms and Signs. Early leukoplakic lesions are asymptomatic and produce the sensation of a lump that is felt with the tongue. Pain is minimal, even when the lesion becomes large, unless it extends posteriorly into the lingual and dental nerves in which case pain becomes moderate to severe and often is referred to the ear. As the tumor spreads posteriorly, it often invades the pterygoid muscles causing trismus and poor oral intake. Parotitis is possible when Stensen's duct becomes involved with the tumor.

Alveolar Ridge, Retromolar Trigone, and Hard Palate. Carcinomas arising from the upper and lower gingiva, including the retromolar trigone, frequently invade the mandible. The most common location is in the posterior third of the mandibular dental arch (22). Almost all of these tumors are squamous cell in origin. Primary squamous cell carcinoma of the hard palate is quite unusual, with most hard palate neoplasms being minor salivary gland tumors. Epidermoid carcinoma can occur within the body of the mandible or maxilla (intraalveolar epidermoid carcinoma), arising from odontogenic epithelium trapped during embryonic development.

Pattern of Spread. Squamous cell carcinomas of the lower gum invade the periosteum and adjacent buccal mucosa and floor of the mouth (25). Low-grade slow-growing lesions tend to produce atrophy of the adjacent bone, whereas moderate- to high- grade lesions invade the bone directly or through recently opened dental sockets. *Lymphatic spread* is to the upper deep jugular nodes (22).

Most carcinomas of the upper gum and hard palate originate in the gingiva and spread secondarily to the soft palate, buccal mucosa, nasal cavity, and maxilla (22). The maxillary antrum is invaded quite late, unless recent extractions have provided an open pathway.

Lesions from the small area of the retromolar trigone spread early to the adjacent buccal mucosa, anterior tonsillar pillar, tongue, and maxilla (22). Posterior spread occurs early into the pterygomandibular space and the medial pterygoid muscle, whereas posterolateral spread occurs into the buccinator muscle and fat pad (25). *Lymphatic spread* is to the upper deep jugular lymph nodes.

Symptoms and Signs The patient usually presents first to the dentist with dental pain, loose teeth or ill-fitting dentures, or a sore that does not heal (25). Mild pain and intermittent bleeding occur when the lesion is traumatized. Invasion into the mandible can involve the inferior alveolar nerve and produce neuralgia, paresthesia, and

anesthesia of the lower lip. Retromolar trigone lesions that involve the lingual and inferior dental nerves cause local pain and pain referred to the external auditory canal and preauricular area. Invasion of the pterygoid muscle produces trismus and severe pain. Erosion through the hard palate eventually produces either oronasal or oroantral fistulas.

Oropharynx

The oropharynx includes four areas: the base of the tongue, tonsillar region (tonsillar fossa and tonsillar pillars), soft palate, and that portion of the pharyngeal wall between the level of the soft palate superiorly and the hyoid bone inferiorly, including the glossoepiglottic and glossopharyngeal folds. Squamous cell carcinomas of the oropharynx tend to be less differentiated and more aggressive than their oral cavity counterparts. They account for 83% to 95% of malignant lesions in this area. Lymphoma accounts for approximately 16% of tonsillar malignancies (an additional 6% being lymphoepitheliomas) and 1% to 2% of malignancies of the base of the tongue (27). The remainder of the lesions are minor salivary gland tumors. Approximately one-half of these are malignant, the two most common being mucoepidermoid and adenoid cystic carcinoma.

Base of Tongue

Pattern of Spread. Vallecular lesions spread along the mucosa to the lingual surface of the epiglottis, laterally along the pharyngoepiglottic fold, and then to the lateral pharyngeal wall and anterior wall of the piriform sinus. Lesions that begin on the lateral base of the tongue can invade the glossotonsillar sulcus and, from there, the tumor escapes into the soft palate or laterally into the neck. Advanced lesions tend to spread toward the larynx or oral tongue.

Symptoms and Signs. Most lesions of the small base of the tongue are asymptomatic and are rarely discovered until they are at least 2 cm. The earliest symptom of a lesion in the base of tongue is often a mild sore throat, with the patient sensing a lump in the back of the tongue or an asymptomatic neck mass. As enlargement occurs, the voice may become muffled or hoarse, with laryngeal involvement, dysphagia becomes more prominent, and referred otalgia via cranial nerves IX or X is common (23). Far advanced lesions affix the tongue and are associated with deep ulceration and necrosis, which produce severe pain and foul breath.

Tonsillar RegionPattern of Spread. Cancer of the anterior tonsillar pillar might consist of erythroplakic lesions early in its course, but can develop into a central ulcer, which eventually infiltrates the palatoglossus muscle. Superior medial spread occurs into the soft palate, the most posterior hard palate, and the maxillary gingiva. Anterolateral spread to the retromolar trigone is frequent, with later spread to the posterior gingival buccal sulcus and buccal mucosa. Invasion of the tongue is frequent. As these lesions advance, they adhere to the mandible and eventually invade the bone.

Lesions of the tonsillar fossa are most commonly found to be indurated and ulcerated with irregular margins. The next most common form is that of a lobulated, exophytic mass within the fossa, and least common is the deeply infiltrating ulcer (22). Invasion into the glossotonsillar sulcus and base of the tongue occurs in 41% to 80% of advanced cases (22). As the lesions advance they penetrate into the parapharyngeal space and gain access to the base of the skull superiorly, with consequent cranial nerve involvement. More advanced lesions invade the mandible, nasopharynx, and base of the tongue.

Lesions from the posterior tonsillar pillar either spread inferiorly along the palatopharyngeus muscle, pharyngoepiglottic fold, and posterior pharyngeal wall. Tonsillar fossa tumors are localized early, but later they spread to the tonsillar pillars and hard palate. Eventually, lateral spread penetrates into the superior constrictor muscle, with subsequent invasion of the pterygoid muscles and base of the skull, and occasionally with compression or invasion of cranial nerves into the parapharyngeal space. Lymphatic spread occurs early to the subdigastric nodes and then along the jugular chain. Cervical adenopathy is sometimes the only manifestation of a microscopic focus of cancer within the tonsil or tongue base.

Symptoms and Signs. The earliest symptom of lesions of the tonsillar region is a sore throat, usually aggravated by food or drink. Odynophagia and dysphagia cause 60% to 80% of the patients with tonsillar lesions to first seek medical attention (22). Ulceration causes local pain that is often referred to the ear. Advanced lesions invade the pterygoid or buccinator muscle or both and produce trismus and severe temporal pain. Invasion of the tongue eventually limits tongue mobility and, when accompanied by ulceration, causes severe pain through the lingual, inferior alveolar, or glossopharyngeal nerves.

Soft Palate

Pattern of Spread. Early mucosal lesions of the soft palate represent leukoplakia or carcinoma *in situ* , which progresses to invasive carcinoma. Often, multiple discrete areas are involved, known as *field-cancerization*. Spread occurs first to the tonsillar pillar and inferiorly to the tongue. Later growth penetrates to the superior constrictor muscles, with subsequent invasion of the medial pterygoid muscle and base of the skull and occasional compression or invasion of the cranial nerves in the parapharyngeal space. Superior growth extends into the nasopharynx.

Symptoms and Signs. The earliest symptom of a lesion of the soft palate is usually a mild sore throat aggravated by food or drink; it is not well localized. Often these tumors are asymptomatic and found by the clinician on routine examination of the oropharynx. An advanced lesion produces dysphagia, can cause voice change, and, if accompanied by destruction, perforation, or fixation of the soft palate, food and liquid are regurgitated into the nasopharynx. Lateral and superior spread to the nasopharynx and parapharyngeal space is associated with trismus or unilateral otitis media, moderate to severe temporal pain or headache, and occasional cranial nerve involvement, initiating along the palatine nerves.

Nasal Vestibule, Nasal Cavity, and Paranasal Sinuses

Tumors of the nasal vestibule, the anterior entrance to the nasal cavity, are considered separately from tumors of the nasal cavity because they are essentially skin cancer and have a different natural history (25). Eighty percent of neoplasms in the nasal vestibule, nasal cavity, and paranasal sinuses are squamous cell carcinoma. Adenocarcinoma of minor salivary gland origin tends to be more aggressive in the sinuses and contributes 6% to 17% of all tumors in this location (28). Malignant lymphoma and midline malignant reticulosis are seen in approximately 5% of patients (29). Other rare lesions include esthesioneuroblastoma (olfactory neuroblastoma), a malignant tumor that originates from the olfactory nerves, and a wide range of soft tissue and bone sarcomas, including chondrosarcoma, osteosarcoma, and Ewing's sarcoma. Delays in the diagnosis of these malignancies are common as the early symptoms mimic rhinosinusitis, the average time between onset of symptoms and definitive cancer diagnosis being 8 months (28).

Nasal Vestibule

Pattern of Spread. These lesions behave in a more indolent manner than their nasal cavity counterparts (30). Local growth is into the skin of the lip, laterally into the lower lateral cartilages of the nose, and medially into the septum. Nasal cavity obstruction is a late finding (29).

Symptoms and Signs. These lesions usually present with few symptoms other than a mass growing in the entrance of the nose, with crusting, scabbing, and occasionally minor bleeding. Pain is usually modest, even with destruction of the cartilage or involvement of the lip. Secondary infection can occur, in which case the nose is painful with manipulation.

Nasal Cavity

Pattern of Spread. The routes of spread are essentially the same for the various histologic lesions except for adenoid cystic tumors, which have a greater propensity for perineural spread (25). Lesions arising from the olfactory region invade the ethmoids, orbit, and anterior cranial fossa and frequently tend to destroy the septum; they can also invade the nasal bone to the skin. Lesions arising in the lateral wall of the nasal cavity invade the medial wall of the maxillary sinus, ethmoids, and orbit. Advanced lesions invade the nasopharynx and spheroid sinus. Some tumors follow the nasal nerves posteriorly and then superiorly toward the pterygopalatine ganglion and the pterygopalatine fossa, or along the maxillary branch of the trigeminal nerve (25).

Symptoms and Signs. Early symptoms of nasal cavity neoplasms are often confused with those of rhinosinusitis, except that the tumors are usually unilateral. Symptoms may include nasal airway obstruction, rhinorrhea, ipsilateral facial pain, and occasional referred otalgia, but even large sinonasal tumors may be surprisingly asymptomatic. The rhinorrhea can be mucoid, purulent, sanguinous, or clear (cerebrospinal fluid) (29). Late findings depend on the location of the tumor: Lesions arising in the olfactory region can cause unilateral or bilateral nasal expansion of the bridge of the nose and a submucosal mass can appear near the inner canthus and eventually ulcerate (25). Extension into the cranial cavity or ethmoid sinus is accompanied by a frontal headache. Invasion of the medial orbit produces

proptosis and diplopia.

Paranasal Sinuses

Most tumors of the paranasal sinuses originate within the maxillary sinus and are usually squamous cell carcinoma.

Pattern of Spread. Ohngren's line divides the maxillary sinus into anteroinferior and posterosuperior compartments. Less ominous lesions, those located anteroinferiorly, tend to invade through the lateral inferior wall or grow through dental sockets or anteriorly into the skin. Lesions of the posterior infrastructure can erode through the posterolateral wall and invade the pterygopalatine and infratemporal fossae. Tumors arising in the upper half (suprastructure) can invade superiorly into the orbit and laterally to the malar region and eventually ulcerate through the skin to produce an antrocutaneous fistula. Far advanced lesions can invade the temporal fossa and zygomatic bone. Suprastructural cancers that develop medially invade the nasal cavity, ethmoids, frontal sinus, lacrimal apparatus, and medial inferior orbit (29).

Tumors of the ethmoid and frontal sinuses are less common and tend to erode into the orbit, nasal cavity, and anterior cranial fossa. The sphenoid sinus is rarely the site of origin of carcinomas. They usually become evident by involving the cranial nerves in the cavernous sinus, including cranial nerves III, IV, and VI, and the ophthalmic and maxillary branches of the trigeminal nerve or the optic nerve. Lateral growth would invade the middle cranial fossa and anterior growth would be into the nasopharynx.

Symptoms and Signs. The symptoms and signs of tumors in the paranasal sinus depend on the structure invaded. Most patients have progressively moderate to severe local pain and neuralgia and cranial nerve palsies, as well as loose dentition or poorly fitting dentures. Visual disturbances such as proptosis, diplopia, and chemosis occur in advanced lesions when tumor breaches the periorbita. Compression or infiltration of the infraorbital nerve in the floor of the orbit can cause neuralgia, paresthesia, and hyperesthesia in the distribution of this nerve. Unilateral nasal obstruction, infection, and bleeding are common complaints with maxillary sinus tumors. Cancers developing in the medial suprastructure of the antrum present with nasal symptoms of discharge or bleeding, infraorbital pain, and displacement of the eye upward and laterally with proptosis, diplopia, and conjunctival edema. Cancer in the lateral suprastructure of the maxillary sinus produces a mass below the lateral canthus associated with pain, deviation of the eye medially and upward, chemosis, diplopia, and proptosis.

Lesions of the ethmoid sinus produce mild to moderate pain referred to the frontal and nasal area early in the course of the disease. Diplopia and proptosis also develop with invasion of the orbit. Neuralgia, paresthesia, and dysesthesia can develop over the distribution of some of the involved sensory nerves. Tumors of the sphenoid sinus frequently cause progressively severe head pain, headache, and cavernous sinus syndrome (cranial nerves III, IV, $V_{1,2}$, and VI).

Nasopharynx

Tumors of the nasopharynx are uncommon in the United States but are common in Southeast Asia, Greenland and Alaska, and parts of equatorial Africa. The nonkeratinizing forms (96%) are associated with elevated titers of Epstein-Barr virus. The various histologies include carcinoma (90%), lymphoma (5%), and miscellaneous (23).

Pattern of Spread. Tumors usually begin in the fossa of Rosenmuller and affect the adjacent eustachian tube orifice early. Inferior extension along the lateral pharyngeal wall and tonsillar pillars occurs in one-third of patients, and into or through the base of the skull (foramen lacerum) in 25% of patients; invasion of the posterior ethmoids, maxillary antrum, and orbit occurs fairly often. Cranial nerve involvement is frequent, most commonly being the maxillary and mandibular branches of the trigeminal nerve (23). Lateral extension into the pterygopalatine and infratemporal fossae may involve the lower four cranial nerves. Tumor can erode through the foramen ovale, foramen lacerum, and foramen spinosum, eventually reaching the cavernous sinus area and gaining access to cranial nerves II to VI. Metastasis to the neck nodes occurs with 80% to 90% of nasopharyngeal carcinoma, with occasional metastasis to the mental and occipital nodes (25).

Symptoms and Signs. The most common symptom of nasopharyngeal carcinoma is that of a painless unilateral metastatic cervical lymph node (22). Usually nasal obstruction, epistaxis, and serous otitis media are also seen. Some patients present with a mild sore throat, whereas many have facial pain in one or more of the three divisions of the trigeminal nerve, usually the mandibular. Pain in the scalp or the mastoid area may be related to involvement of a high jugular lymph node that has become fixed to the skull and spine. Posterior infiltration of the prevertebral muscles causes pain that is aggravated with lifting of the head and extension of the neck. Posterior orbital invasion usually produces proptosis. Trismus and temporal pain occur with invasion of the pterygoid region. Cranial nerve involvement occurs in 20% of patients (31).

Hypopharynx

The hypopharynx includes the pharyngeal walls from the level of the hyoid to the bottom of the cricoid cartilage, the piriform sinus, and the postcricoid pharynx. The larynx is intimately associated with this area, being anterior to the postcricoid space and medial to the piriform sinuses. Ninety-five percent of hypopharyngeal tumors are squamous cell carcinoma and are usually stage III or IV when diagnosed (32). Minor salivary gland tumors occur but are quite rare.

Pattern of Spread. Carcinomas of the posterior pharyngeal wall tend to remain on the posterior wall, grow up or down the wall, and infiltrate submucosally, often for distances over 10 mm. Skip lesions are also frequent in this area (23). As the lesion progresses the tumor bulges into the pharyngeal cavity and a ragged midline ulceration appears (25). The posterior tonsillar pillars can become involved with spread of the upper pillars, eventually reaching the palate. Advanced lesions tend to terminate inferiorly at the level of the arytenoids and can extend superiorly into the oropharynx. Prevertebral muscle invasion is a late finding.

Early tumors of the lateral pharyngeal wall are well-defined exophytic lesions but, as they advance, they tend to penetrate laterally through the constrictor muscle, thus entering the lateral pharyngeal space or the soft tissues of the neck. This may produce a palpable mass in the neck just below the hyoid that might be confused with an enlarged lymph node. The tumor can spread along the muscles of the pharynx that originate from the base of the skull to involve the eustachian tubes, styloid process, pterygomandibular raphe, and hyoid bone. The tumor can also course along cranial nerves IX and X and the sympathetic chain.

Early lesions of the piriform sinus are usually discrete and exophytic, particularly those high on the medial wall (25). Medial wall lesions can grow superficially along the epiglottic fold and arytenoids or invade directly into paraglottic space or posteriorly to the postcricoid region, again mostly by submucosal spread. Lesions arising on the lateral wall invade the posterior thyroid cartilage early, and later penetrate to invade the thyroid gland. They also tend to spread submucosally onto the posterior pharyngeal wall, which eventually becomes eroded and ulcerated. Advanced lesions of the piriform sinus invade all three walls, fix the larynx, involve the posterior pharyngeal wall, invade the thyroid cartilage and thyroid gland, and often escape into the soft tissues of the neck.

Early tumors of the postcricoid pharynx remain localized, particularly those on the posterior wall, and are difficult to diagnose. Lesions from the anterior wall tend to invade the posterior cricoarytenoid muscle and the cricoarytenoid cartilage. Perineural invasion of the recurrent laryngeal nerve is also seen. Advanced tumors eventually encircle the lumen.

Lymphatic spread of pharyngeal wall lesions terminates primarily in the jugular chain and the retropharyngeal node group and secondarily to the spinal accessory chain (23). Lesions of the hypopharynx spread mainly to the jugular chain, with 44% of patients having disease in the retropharyngeal nodes (22). Occult cervical metastases are seen in 50% to 80% of patients with hypopharyngeal cancer and are often bilateral (33). Clinically apparent disease in the neck can be as high as 75% for piriform fossa primaries (22).

Symptoms and Signs. These tumors are often asymptomatic until they reach a large size, accounting for the relatively late stage tumors found at initial diagnosis. Tumors localized to the lateral pharyngeal wall or the piriform sinus produce a unilateral sore throat, which is in contrast to an infectious sore throat that is usually bilateral. The pain is usually moderate but can become severe. Dysphagia, a sensation of a foreign body, referred otalgia, blood-streaked saliva, and voice changes occur later. Lesions of the posterior pharyngeal wall and piriform sinus can produce mild to moderate pain and dysphagia. Lesions of the apex of the piriform sinus or postcricoid area produce edema of the arytenoids and, if the mucous membrane is ulcerated, moderate pain is felt on swallowing. Involvement of the retropharyngeal nodes can produce pain in the neck with stiffness as well as pain radiating to the ipsilateral eye and forehead (23).

Salivary Glands

The parotid glands account for 80% of salivary gland tumors, with the submandibular gland contributing 10% to 20%, and the sublingual and minor salivary glands the remainder (23). Tumors of the major salivary glands account for 4.5% of all head and neck neoplasms (32). Among the major malignant tumors are low- and high-grade mucoepidermoid carcinoma, undifferentiated carcinoma, acinic cell carcinoma, squamous cell carcinoma, adenoid cystic carcinoma, adenocarcinoma, and malignant mixed tumors.

Pattern of Spread. Parotid malignancies infiltrate the remainder of the gland, invade cranial nerve VII, and spread along the nerve sheaths for some distance. They can invade the adjacent skin, adjacent muscles of mastication and facial expression, and the temporal bone and mandible. Extension from the deep lobe via the stylomandibular tunnel allows access to the parapharyngeal space. Malignant tumors of the submandibular gland invade the gland, fix the tumor to the adjacent mandible, and invade the hyoid bone and eventually the tongue, hypoglossal nerve, oral cavity, and oropharynx, with skin invasion occurring in advanced cases. Minor salivary gland tumors arising in the parapharyngeal space (prestyloid compartment) can extend medially to the oropharynx, superiorly to the skull base, posteriorly to the carotid sheath, anteriorly to the maxilla, and laterally to the mandible. High-grade malignancies metastasize 25% to the regional lymphatics, including the intraparotid, preauricular, and jugulodigastric nodes (22).

Symptoms and Signs. A great majority of patients present with a mass that is easily seen and felt in the parotid, associated with mild to moderate pain and pressure. Late findings include facial nerve palsy in 10% to 15% of tumors and dysphagia when the tumor is deep in the lobe. Once the parapharyngeal space is breached, cranial nerves IX through XII can become involved. When the tumor tracks along the auriculotemporal nerve it can extend to the base of the skull and involve the mandibular division of the trigeminal nerve, with consequent neuralgia. Temporal bone invasion causes otalgia and retroorbital pain.

Larynx

Cancer of the larynx affected 1.35% of patients in the total United States cancer population during the years 1985 through 1994 (32). Approximately 12,500 cases are newly diagnosed each year, making it the most common site for head and neck cancers (22). These tumors are found earlier than most other cancers because they cause hoarseness, which accounts for the fact that 61% are diagnosed as carcinoma *in situ* stage I or II (32). The larynx is subdivided into three distinct regions, each with varying natural histories: the supraglottis, glottis, and subglottis. Ninety-four percent of malignant tumors of the larynx arise from the surface epithelium and are therefore squamous cell carcinoma or one of its variants.

Pattern of Spread. Cancers of the supraglottis include those originating on the epiglottis, aryepiglottic folds, false vocal folds, arytenoids, and all but the floor of the ventricle. Most lesions are epiglottic in origin. Lesions of the suprahyoid epiglottis and aryepiglottic folds make up the marginal zone of the supraglottis and can have unhindered access to the abundant lymphatics of the pharynx via the pharyngoepiglottic fold, or can grow as an exophytic mass that does not invade outside its origin (22). Lesions of the infrahyoid epiglottis tend to produce irregular outgrowths of tumor nodules, with simultaneous invasion through the porous epiglottic cartilage into the preepiglottic space (23). Once in this space, the tumor can extend inferiorly to the anterior commissure, superiorly to the vallecula, or anteriorly through the thyroid cartilage or thyrohyoid membrane. False cord carcinomas are usually ulcerative and infiltrative and extend to the infrahyoid epiglottis. Advanced lesions can invade the thyroid, epiglottic, or cricoid cartilage and eventually invade the base of the tongue and pharyngeal wall. As evidenced by dye studies, a supraglottic compartment limits inferior extension to the glottis, but at a late stage tumors involve the anterior commissure and eventually have subglottic extension.

Most cancers of the vocal cords begin in the free margin and upper surface and are easily visible, with two-thirds usually confined to one cord. The four major barriers to spread are the conus elasticus, vocal ligament, anterior commissure, and thyroglottic ligament. As the lesions enlarge they extend to the thyroarytenoid muscle, fixing the cord; then to the vocal process of the arytenoid and laterally to the paraglottic space and thyroid cartilage. Superior extension encompasses the ventricle and false cord and remainder of the supraglottis. Advanced lesions eventually penetrate through the thyroid cartilage or thyrocricoid membrane into the neck and often invade the thyroid gland. Subglottic cancers, which are quite uncommon, usually involve the cricoid cartilage early, although the conus elasticus resists spread into the glottis. Further growth eventually invades the undersurface of the vocal cord, with consequent fixation of the cord, as well as inferior extension into the trachea. Lymphatic spread at the time of diagnosis of supraglottic cancer involves 25% to 75% of patients depending on stage; in 16% of these patients the metastases are bilateral. In glottic cancer the incidence of lymphatic spread at diagnosis is less than 5% for lesions confined locally (T_1), 5% to 10% for T_2 lesions, and 10% to 20% for T_3 and 25% to 40% for T_4 lesions (34,35 and 36).

Symptoms and Signs. Carcinoma arising in the glottis produces hoarseness at an early stage, whereas those arising in the supraglottis or subglottis do this only when the lesion is extensive. Advanced lesions produce pain of varying severity, sore throat, and airway obstruction. Sore throat and dysphagia are the most frequent initial symptoms with cancer of the supraglottic larynx, with odynophagia usually indicating spread to the hypopharynx (22). Mild to moderate pain is the most frequent initial symptom, often described as persistent irritation or sore throat associated with some difficulty in swallowing and the sensation of a lump in the throat. Cancer of the epiglottis does not produce symptoms until it becomes large, at which time it causes pain that is often referred to the ear (by way of the vagus nerve and auricular nerve of Arnold). Late symptoms include weight loss, foul breath, dyspnea, and aspiration.

Thyroid Gland (VIII-1)

Approximately 10,350 cases of thyroid cancer were reported per year in the United States from 1990 through 1994 (32). The 5- year disease-specific survival rate is 89.5% for all stages, with fewer than 1,200 patients dying per year of this disease. Most of the tumors are well differentiated and are either papillary carcinoma (80%) or follicular carcinoma (15%). Medullary carcinoma and poorly differentiated and anaplastic carcinoma form the rest, along with lymphoma (23). The prognosis for patients with papillary or follicular thyroid cancer is generally good, especially for women and those patients younger than 45 years of age.

Pattern of Spread. The spread of thyroid cancers depends on pathology. Low-grade well-differentiated papillary neoplasms tend to have multiple, discontiguous foci within the thyroid gland and to spread to the regional lymph nodes. Follicular neoplasms, on the other hand, tend to be localized within the gland and to spread by the hematogenous route. Medullary carcinoma, associated with multiple endocrine neoplasia syndromes 2a and 2b, most often spreads to the cervical lymph nodes and upper mediastinum. Anaplastic carcinoma is aggressive and spreads into all the local tissues (23).

Symptoms and Signs. Thyroid carcinoma is usually not painful and the initial presenting symptom is a small hard thyroid nodule. Because of the high incidence of thyroid nodules and the fact that only 5% to 20% of solitary thyroid nodules are cancerous, an accurate diagnosis is imperative (23). Factors in the history and physical examination that indicate a high probability of cancer include a history of previous external radiation therapy, relatively recent onset of a firm hard single nodule in the thyroid gland, and the presence of cervical lymphadenopathy. With progression of the disease, hoarseness is an ominous sign indicating recurrent laryngeal nerve involvement. Dysphagia and dyspnea occur, but often are present in large goiters as well. Rapid growth in a previously slow-growing nodule can herald the transformation into an anaplastic cancer.

Eye

The most important cancer of the eye among white adults is ocular melanoma. The annual incidence is 0.7 per 100,000 population in the United States, encompassing 79% of all noncutaneous melanomas (37). The prognosis depends on the size, histologic type, and presence of metastases: Overall disease-specific 15-year survival is 89%; when metastases are present the 5-year survival rate plummets to 10% (38,39). The most common intraocular tumor in children is retinoblastoma, which has a good prognosis unless the tumor escapes into the orbit (22). The most common orbital tumor in children is rhabdomyosarcoma, which accounts for 45% of all sarcomas in the head and neck. Other primary neoplasms of the orbit include adenoid cystic carcinoma and carcinoma ex pleomorphic, both from the lacrimal gland, and various soft tissue sarcomas. Secondary tumors from the skin (squamous cell and basal cell carcinoma) as well as the sinuses and nasopharynx also impinge on the orbit.

Pattern of Spread. The tumors from the lacrimal gland tend to have local and perineural spread along cranial nerves II, III, IV, V_1, and VI. Intraocular melanoma usually begins in the posterior choroid and either spreads laterally between the sclera and retina or pushes the retina anteriorly into the vitreous cavity (37). Other tumors have easy access from the orbit through the thin medial wall, lamina papyracea, to the ethmoid sinus or superiorly into the anterior cranial fossa.

Symptoms and Signs. The clinical symptoms and signs depend on the location and size of the tumor. Small lacrimal gland tumors can produce minimal visual disturbances, whereas large tumors produce pain, severe visual disturbances, and palsy of the cranial nerves within the orbital cavity. Orbital tumors produce proptosis, xerophthalmia, and ophthalmoplegia, with varying degrees of pain. Effective therapy produces a high rate of cure, and death usually occurs only with advanced cases that have been neglected. With small asymptomatic adenomas, appropriate workup and subsequent observation are the treatments of choice, particularly in elderly patients. If the lesion shows progression, particularly rapid growth, or an increase in size beyond 10 mm in diameter and 2 mm in elevation or the

lesion results in visual impairment, proton beam irradiation is the treatment of choice. Small melanomas produce visual changes in acuity, and large melanomas are indications for enucleation. A report from the Collaborative Ocular Melanoma Study Group failed to show a benefit to preenucleation radiation therapy for large orbital melanomas (40).

Cutaneous Cancer in the Head and Neck

The number of nonmelanoma skin cancer cases now numbers greater than 1 million per year in the United States, equal to that of all noncutaneous malignancies (41). Basal cell carcinoma, usually a slow-growing, indolent tumor, accounts for 25% of all human cancers with more than 85% being located on the face, scalp, or neck. They metastasize less than 0.1% of the time (23). Squamous cell carcinoma of the skin, however, makes up only 25% of the nonmelanoma skin cancer, but accounts for 75% of the mortality, with 2% of all patients who get squamous cell carcinoma of the skin dying of their disease.

The early stages of disease are marked by little or no pain, and appropriate surgical therapy cures the patient, but neglected tumors spread and can invade the underlying bone, ulcerate, and become necrotic. Some basal cell carcinomas of the head can erode through the skull and into the brain. These are usually associated with moderate to severe pain, and often have a foul odor (Fig. 53-1).

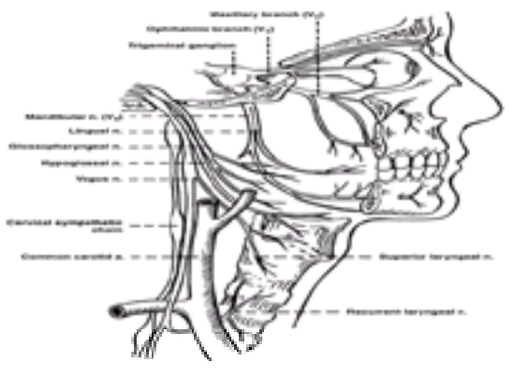

Figure 53-1. The course of the trigeminal, glossopharyngeal, vagal [with superior and recurrent laryngeal nerves (n.) shown], and cervical sympathetic chain is shown, illustrating the pathways of the nerves most commonly implicated in pain transmission from the head and neck. (Superficial cervical sensory nerves not shown.)

Cancer of the Cranium and Brain

Primary Cancer of the Cranial Bones

Severe pain always accompanies primary cancer of the bone, the site of primary Ewing's sarcoma or osteosarcoma. Both types of cancers produce progressively severe pain in the lower jaw. Other tumors originating in the mandible include fibroosseous lesions (fibrous dysplasia, ossifying fibroma, and cementoossifying dysplasia), giant cell tumor, and ameloblastoma, but these do not cause pain unless secondary infection takes place or they have grown to such a size that the nociceptors in the periosteum are affected (37,42). Other primary bone tumors can originate in the calvarium or other cranial bones and produce pain that either is localized or referred as a headache. Occasionally, these produce neuralgia if one of the major divisions of the trigeminal nerve, the intermedius nerve of the facial or glossopharyngeal nerve, or the vagus nerve is compressed.

Primary and Metastatic Brain Tumors

The most common tumors in the cranial cavity are derived from the neuroepithelium, with glioblastoma being the most common, followed by astrocytoma (37,42). Worldwide, the incidence of primary intracranial tumors is estimated to be approximately 7.1 to 8.6 per 100,000 population, with the incidence of glioblastoma alone being in the 3.5 to 5.0 per 100,000 population range (43). Meningiomas, a benign but locally destructive tumor, account for approximately 20% of all intracranial neoplasms in men, but nearly double that for women (44). The 1995 Surveillance, Epidemiology, and End Results (SEER) of the National Cancer Institute (NCI) statistics show a 30% 5-year survival for all brain tumors (24). Glioblastomas are particularly aggressive, with the mean length of survival after diagnosis being 8 to 10 months (37). A bimodal age distribution occurs: Medulloblastoma and ependymomas account for the early peak seen in children (42). Seventy percent of the tumors in children are infratentorial, whereas the opposite is true in adults (37). Consequently, cortical or hemispheric lesions are seen with much greater frequency in the adult population, whereas most pediatric gliomas arise in the cerebellum, brainstem, and midbrain or thalamic region.

In 1978, Posner and Chernik found a 24% incidence of brain metastases in an autopsy study performed on patients dying from cancer (45). Other studies have shown that up to one-half of all intracranial neoplasms are metastases (42). The most common site that metastasizes to the brain is the lung, accounting for 36% to 40% of all such tumors (46,47 and 48). Breast carcinoma is next most frequent with 18% to 29%, followed by tumors from the gastrointestinal tract with 6.7% to 7.1% of the total. Head and neck cancers, reflecting their low percentage of all cancers, make up only 1.9% to 3.1% of all brain metastases. Once these tumors are diagnosed in the intracranial cavity, the median survival ranges from 10 to 14 months, with a 1-year survival rate of 44% to 55% with therapy (46).

Symptoms and Signs. Headache is the most frequent initial presenting symptom in most brain tumors (see Chapter 48). Although fewer than 1% of all headaches for which patients seek medical advice are attributable to tumor, more than 70% of patients with an intracranial neoplasm complain of moderate to severe headaches (46). It is usually mild and episodic early, but with time it increases in frequency, duration, and severity. The headache is usually bilateral and caused by increased intracranial pressure and has a typical temporal pattern: It is often worse in the morning, awakening the patient, and decreases in intensity during the day because of differences in the cerebrospinal fluid draining in the supine versus the upright position and the relative hypercapnia experienced during sleep. Often a regional correlation to the headache is found, especially with anterior or middle cranial fossa lesions causing supraorbital headaches via irritation of the ophthalmic branch of the trigeminal nerve (42). Occipital or posterior fossa lesions can cause occipital and posterior cervical pain and sometimes referred otalgia through irritation of cranial nerves IX and X. Many patients, however, complain of a diffuse headache that varies in location. The headache is aggravated by coughing and straining and is often associated with nausea. The most common sign of increased intracranial pressure from tumor is bilateral papilledema, occurring in greater than 50% of patients with brain tumors (42).

The second most common presenting sign of an intracranial neoplasm is a seizure. Approximately one-fourth of patients with a neuroepithelial tumor have a seizure as their presenting symptom. They are usually nongeneralized seizures, rather than grand mal, and eventually occur in one-third of these patients. Focal neurologic symptoms usually connote a fairly well-developed mass lesion. These include absence or sensory seizures or deficits in vision, hearing, smell, or motor function that occur in relation to specific tumor sites.

The most common presenting symptoms of brain metastases are headache in 55%, motor weakness in 40%, and behavioral changes in 31% (46). Most of the headaches are of the tension type, with some being classified as migraine. Other symptoms of metastases include ataxia and aphasia.

Tumors of the Base of the Skull

Until fairly recently, lesions in certain regions of the skull base were considered inaccessible, and as most are radioresistant, incurable. With new surgical approaches, skull base surgery has been refined, allowing extirpation of lesions without gross deformity. Anatomically, the skull base can be divided into four broad regions: anterior, anterolateral, middle, and posterior (22). The anterior cranial base is usually affected by squamous cell carcinoma, primarily by direct invasion from the paranasal sinuses. Juvenile nasal angiofibroma almost exclusively is found in adolescent boys; esthesioneuroblastoma, mucosal melanoma, lymphoma, and fibrous dysplasia can also be found here. The anterolateral area is most affected by the benign, but locally aggressive, meningiomas and those tumors that extend into the cavernous sinus. The middle cranial base, extending from the orbit to the mastoid, include tumors from the parotid gland, carcinomas from the skin, pinna and ear canal, jugular glomus tumors, jugular neurilemomas, temporal bone metastases, and nasopharyngeal carcinoma. The posterior cranial base harbors acoustic neurilemoma, chordoma, meningioma, and chondrosarcomas. A report on 30 patients with malignant anterior skull base lesions showed a 56% 5-year survival rate

(49).

Pattern of Spread. The skull base neoplasms tend to invade locally through the sinuses, the orbit, along the cranium, and perineurally into the foramina. Nasopharyngeal carcinoma is the exception, with its high rate of metastases to the cervical lymph nodes.

Symptoms and Signs. The manifestations of tumors at the skull base are dependent on their anatomic location. Anteriorly based neoplasms can exhibit nasal obstruction with rhinorrhea, epistaxis, anosmia, and occasionally cerebrospinal fluid rhinorrhea. Often, the tumor causes an obstructive sinusitis with congestion and pain. Orbital involvement produces proptosis, diplopia, epiphora, and eventually decreased visual acuity. Facial pain and swelling also often accompany these lesions. Patients with more posterior lesions often complain of headache, with signs of various cranial nerve dysfunction. One localizing measure is in the pattern of cranial nerve deficits that constitute particular syndromes (Table 53-1).

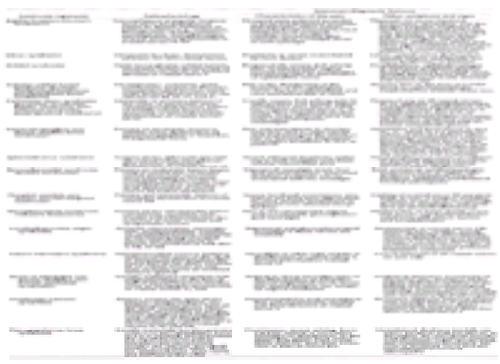

TABLE 53-1. Clinical syndromes caused by tumors involving the skull

MANAGEMENT OF CANCER-RELATED PAIN

Mechanisms of the Pain

The mechanisms by which head and neck cancer can cause pain include direct stimulation of nerve endings in the mucosa and submucosa, ulceration and infection, compression and involvement of sensory nerves, and bone invasion (20). Nonnociceptive pain is seen when nerve fibers exhibit abnormal excitability, as can be seen in the severed nerves after a neck dissection. Pain can also be caused by oncologic therapy.

Stimulation of Nerve Endings

Stimulation and sensitization of nociceptor nerve endings in the mucosa and submucosa are characteristics of the initial phases of cancer growth and can be considered to be mainly responsible for local burning sensation, superficial pain, and referred otalgia in exophytic or erosive lesions.

Ulceration and Infection

Most cancers that arise from the mucous membranes of the mouth and pharynx tend to ulcerate because of both central necrosis and microtrauma. Ulceration does not produce spontaneous pain. Pain is experienced after exposure to a local irritant agent such as alcohol or acid, onset of infection with expression of inflammatory mediators, and resultant inflammation. Movement markedly increases pain caused by ulceration, and its intensity varies from site to site. Exacerbation by functional activity is minimal in static regions such as the cheek, hard palate, nasal and paranasal cavities, and nasopharynx and is severe in dynamic structures such as the tongue, floor of the mouth, soft palate, and faucial arches.

Nerve Compression and Infiltration

An important cause of head and neck cancer pain is infiltration, compression, or both of one or more branches of the trigeminal, glossopharyngeal, or other sensory cranial nerves (see Fig. 53-1). Thus, tonsillar fossa tumors are frequently accompanied by pain that is at first mild and localized to the tonsil; as the tumor grows, however, pain becomes progressively more severe and spreads to the lateral wall of the pharynx and then to the entire area supplied by the glossopharyngeal nerve. In the initial stages the pain is somewhat sharp, but as it spreads it becomes more severe, continuous, persistent, dull, and aching and is accompanied by bouts of lancinating pain, referred otalgia, and generalized headache. Cancers of the maxillary antrum and upper jaw frequently produce pressure on branches of the maxillary nerve and consequent maxillary neuralgia, which is superimposed on the local pain caused by periosteal stretching and consequent stimulation of nociceptive endings.

As indicated in the preceding section, some tumors invade the pterygoid region and the infratemporal fossa and can involve the mandibular nerve or some of its branches to the muscles of mastication to produce neuralgia, trismus, and temporal pain. Tumors of the nasopharynx, oropharynx, or hypopharynx can compress and infiltrate branches of the glossopharyngeal and vagal nerves and produce neuralgia in their distribution, as well as localized pain.

Pain Caused by Bone Involvement

Bony involvement with squamous cell carcinoma of the head and neck usually occurs by direct extension of sinonasal, oral cavity, and oropharyngeal tumors into the adjacent bone of the maxilla, skull base, or mandible. A report by Troell and Terris found only a 5% rate of distant metastases to bone in a review of 97 consecutive patients with head and neck cancer (50). The pathogenesis of bone pain starts with stimulation of A-d mechanoreceptors and C nociceptors that are located mostly in the periosteum, but also in the marrow space along blood vessels and in the tendons (51). The inflammatory cytokines interleukin-1, interleukin-6, and tumor necrosis factor, as well as prostaglandins in the E series, mediate activation of the nociceptors (52). Interestingly, these same humoral factors are responsible for osteoclast activation and subsequent bone destruction. The mechanoreceptors are sensitive to stretching of the periosteum by movement around an eroded area (i.e., the mandible during mastication) or by an expanding (metastatic) lesion contained within an intact periosteal layer (53). Activation of nociceptors may also stimulate localized reflex muscle spasm resulting in increased traction and an increase in pain. This occurs more often in osteolytic bone, which produces more microfractures. For untreated tumors involving the mandible, local growth eventually involves the inferior alveolar nerve and produces numbness, rather than continued pain. This same phenomenon can be seen with involvement of other branches of the trigeminal nerve as well.

Distant metastases from squamous cell carcinoma to the long bones tend to be osteolytic and can produce painful, pathologic fractures. They present a unique management problem in that curative treatment is no longer a realistic goal (see Chapter 37). For solitary lesions, focal radiation can be delivered with significant reduction in pain (54). Hemibody irradiation may be used for multiple metastases, but myelosuppression often occurs. Clodronate, a second-generation bisphosphonate, effectively reduces both the hypercalcemia associated with bony metastases as well as the pain. Given either orally or parenterally, long-term usage does not impair mineralization of bone as etidronate does, and some evidence exists for impairment of growth of existing lesions and formation of new lesions (55). Radionuclides are also used with some efficacy for painful bony metastases. Strontium 89 has a positive effect on pain control in 70% of patients that can last up to 6 months (56). Rhenium 186 complexed to hydroxyethylidene diphosphonate is a newer compound with a shorter half-life (89 hours) than strontium. This compound is taken up in bone that has a high turnover rate and emits beta rays, damaging the adjacent tumor cells while providing some pain relief (57). Both of these compounds cause mild bone marrow suppression. Finally, narcotics and adjunctive analgesics as well as heat therapy, physical therapy, adequate rest (with joints extended rather than flexed), and warm, loose-fitting clothing must also be used for effective pain relief (58).

Pain as a Complication of Oncologic Therapy

Postoperative Pain Syndromes. Surgery followed by radiation for oncologic cure in patients with stage III or IV oropharyngeal cancer has the benefit of providing superior pain relief when compared with primary radiotherapy (16). However, neck dissection, particularly radical neck dissection, frequently causes postoperative

pain because of shoulder dysfunction and neuromas caused by the severing of small and large cervical sensory nerves. Neuromas can be followed by chronic, continuous, aching pain and associated bouts of lancinating pain in the distribution of the nerves.

Mucositis. Oral mucositis from head and neck cancer treatment (radiation, chemotherapy, or both) is usually moderate in severity and self-limiting, but it can be debilitating and dose-limiting, leading to a reduction in the amount of radiation or chemotherapy delivered, thus compromising tumor treatment (59). This topic is discussed in detail in Chapter 38. Patients receiving these treatments, especially chemotherapy, are often myelosuppressed; thus mucositis and ulceration can be portals of entry for endogenous oral bacteria and a significant source for sepsis (60). The oral cavity has been shown to be the source in 25% to 50% of immunocompromised patients with sepsis (61). Mucositis also limits oral intake. For those patients without gastrostomy tubes, an average weight loss of 5 kg has been shown to occur during the course of radiotherapy (62).

Mucositis develops through an initial increase in local cytokines, interleukin-1 and tumor necrosis factor-a being the two most predominant. These are generated by interstitial host lymphocytes reacting to the effect of the radiotherapy or chemotherapy on the proliferating cells in the oral mucosa, with subsequent loss of a significant portion of the dividing epithelial cells (63). Ulceration of the mucosa with potential bacteremia or sepsis occurs next, followed eventually by the healing phase. It is during the ulcerative phase that the lesions are most painful, oral intake is diminished, and the risk for sepsis is the highest (63).

Symptomatic treatment of oral mucositis is designed to reduce pain, prevent dehydration, and help increase oral intake. Oral mouthwashes are effective at decreasing the bacteriologic load and improving hydration, with some improvement in pain (59). One study indicates that saline is as effective as other mouthwashes including chlorhexidine and benzydamine (61). Other local remedies include topical analgesics, often put into Orabase ointment; an antihistamine in a coating agent (Benadryl in Kaopectate); and cytoprotectants such as sucralfate. Severe mucositis may require parenteral narcotics for symptomatic relief. Although these treatments give temporary relief, none hastens the resolution of the mucositis.

Prophylaxis for oral mucositis is an active subject of current clinical trials (60,61,64,65,66,67,68 and 69). Although none of these agents is the present standard of care, some of them show promise. Sucralfate has had mixed results in clinical trials aimed at reducing the severity and duration of oral mucositis. Although this drug acts both by increasing local prostaglandin concentration and as a mechanical barrier, a double-blind, randomized study failed to show any benefit over a placebo (69). Prostaglandin E_2 has been used topically, with two small, nonrandomized studies showing a decrease in the amount of mucositis after either radiotherapy or chemotherapy (70,71). Both granulocyte colony stimulating factor and granulocyte-macrophage colony stimulating factor have been used with some success (72,73). Nemunaitis and colleagues showed a significant reduction in grade 3 and 4 mucositis in patients undergoing intensive chemotherapy for a variety of lymphomas and leukemias (65). The additional advantage of these hematopoietic stimulating factors is that they increase the monocyte and neutrophil cell counts, thereby removing this as a treatment-limiting factor. Antibiotic lozenges containing amphotericin B, polymixin, and tobramycin have shown promise, with two studies yielding objective decrease in mucositis and a third showing a decrease in the amount of pain reported by the patients (62,68,74).

A new agent for the prophylactic treatment of oral mucositis is amifostine, an organic thiophosphate. It is a cytoprotectant that was initially developed by the military to be used as a possible radioprotectant for soldiers exposed to radioactive fallout. Normal cells selectively take up amifostine, which is converted into its active form by alkaline phosphatase (75). At present, this drug has been approved to reduce the nephrotoxicity of cisplatin chemotherapy (76). Buntzel and colleagues designed a randomized study of patients with stage III or IV head and neck cancer who would receive up to 60 Gy of radiation with 70 mg per m^2 of carboplatin with or without 500 mg of amifostine delivered immediately before the chemotherapy on days 1 through 5 and 21 through 25 of treatment (77). No grade 3 or 4 mucositis occurred in the amifostine arm, but 10 of 14 patients had grade 3 and 2 of 14 patients had grade 4 mucositis in the group that did not receive amifostine. Similar, although not as dramatic, efficacy has been seen in other trials (78,79).

A concern has been that amifostine would also decrease the effectiveness of the tumor therapy. In a study of 242 women with advanced ovarian cancer who were undergoing cytoreductive surgery with cyclophosphamide and cisplatin given as adjuvant treatment, not only were neutropenia, nephrotoxicity, and hospital stay all decreased, but a second-look laparotomy showed an increased tumor response rate from 65% to 75% (80). There appears to be promise for this drug at not only reducing mucositis, but also as a cytoprotectant for other organs. The drawbacks are that it has to be given intravenously, and that it often causes hypotension, nausea, and vomiting (81).

Postherpetic Neuralgia. In cancer patients, herpes zoster infection commonly occurs in the area of tumor pathology or in the port of previous radiation therapy (see Chapter 22). The true incidence of postherpetic neuralgia in patients with cancer is unknown, but it is more common in patients in whom the infection develops after the age of 50. A study comparing patients older than 50 years of age to a group younger than 30 noted a difference in the rate of postherpetic neuralgia, 3 months after the acute infection, of 32% (39% versus 7%, respectively) (82). This appears to be related to a functional decrease in the immune system, as evidenced by the high rate seen in individuals infected with human immunodeficiency virus (83). The pathophysiology of the pain is related to damage of the dorsal root ganglia and afferent nerves, decreasing the activation threshold. Atrophy of the affected dorsal horn has been found at autopsy in patients with postherpetic neuralgia (83). Generally, the patient experiences three types of pain: continuous burning pain in the area of sensory loss, painful dysesthesia, and intermittent shocklike lancinating pain. The abnormally discharging dorsal horn cells create an exaggerated response to light touch and temperature changes.

Acute herpes zoster can be alleviated by an anesthetic block of lidocaine with epinephrine in the involved ganglion. This can decrease pain as well as decrease the number of vesicles and hasten resolution (84). Oral antivirals have a beneficial effect on the duration of the zoster and its associated pain, with famciclovir and valacyclovir showing some superiority to acyclovir (83). Oral corticosteroids also lessen the pain of the acute outbreak, although no reduction in the rate of postherpetic neuralgia is noted with its use.

Treatment of postherpetic neuralgia of some months' duration is more difficult. Adrenergic receptor activation, especially with solutions containing epinephrine, causes a worsening of the pain, as opposed to the acute state (85). Attempts at pain control often involve topical anesthetics, narcotics, tricyclic antidepressants, and anticonvulsants. To prevent the occurrence of postherpetic neuralgia, valacyclovir has been shown to be superior to acyclovir in at least one large study, reducing persistent pain at 6 months (19% versus 26%) as well as decreasing the severity of the pain if therapy is instituted within 3 days of appearance of the rash (85).

Methods of Pain Control

Primary Oncologic Therapy

The fundamental method of managing patients with cancer pain is the use of oncologic therapy in the form of radiotherapy, surgery, or chemotherapy, alone or combined, to effect a cure or decrease the size of the tumor. Because the great majority of pain problems arises from a recurrence after previous treatments, it is necessary to consider every treatment not only as an isolated symptomatic measure for palliation, but also as part of a general therapeutic plan in which it must always be remembered that progression of the tumor and severity of the pain are usually related (86).

Surgery. Surgery is the principal modality for many small (T_1 and T_2) cancers of the head and neck. Smaller lesions in anatomic sites where surgical extirpation would disrupt important physiologic functions, such as the base of the tongue and larynx, are more often treated with primary irradiation. Larger (T_3 and T_4) lesions, unless treated under an organ-preserving protocol, are managed with a combination of surgery and radiotherapy. Depending on the site, stage, and nodal status, cure rates between 20% and 95% are achieved (23).

Surgical therapy of *unresectable* cancer for the alleviation of pain, especially nociceptive pain, is a widely accepted practice. Removing a bulky tumor that impinges on cranial nerves (most commonly the lingual, inferior alveolar, or glossopharyngeal nerve) and causes trismus by invasion of the muscles of mastication or infiltrates the cervical sensory nerves brings about a dramatic relief of pain (23). Even though the patient does not derive a survival benefit, the palliation derived from the procedure is worth the effort, as long as morbidity is minimized by preserving as much normal anatomy as possible. Attempts have been made at tumor, and therefore pain, control with the addition of intraoperative radiotherapy. In selected cases in which surgery can reduce tumor volume to a small residual area, a focused dose of electron irradiation is delivered. Because electrons have limited tissue penetrance, adjacent normal structures do not receive excessive doses. Some reports have demonstrated a small improvement in locoregional and pain control (87,88).

Pain is an important component of surgical cancer management. It is an aid to diagnosis both for primary and recurrent tumors. Acute pain in the newly diagnosed patient, especially referred otalgia, has been correlated with more advanced lesions and a worse outcome (89). New-onset pain in a cancer survivor often heralds a recurrence, and if heeded, may result in earlier diagnosis and improved survival. This is especially true for lesions recurring after primary irradiation alone, both at the local site and in the neck. Long-term survival in these patients is approximately 25% (90). Evidence that recurrent cancer does not necessarily equal a grave prognosis comes from a new staging system for maximally treated recurrent oral cavity and oropharyngeal lesions. Yeuh and colleagues could stratify between a high

of 88% and a low of 4.2% 1-year survivability for these cancers after appropriate secondary therapy (91). In treating recurrent cancers with surgery, however, the physician must always keep in mind the potential morbidity of the resection itself versus the prognosis of the patient. The appropriate treatment for the tumor is not always the appropriate treatment for the patient.

Surgical supportive care is an important adjunct in treating patients with advanced cancer. Nutritional support is important to these often-cachectic patients. Nasogastric tubes can be used from days to a few weeks, but the discomfort and potential alar necrosis often necessitates placement of a gastrostomy or jejunostomy tube. Airway distress is one of the most frightening experiences a patient can face. Alert clinicians should intervene whenever possible by placement of a tracheotomy tube before the situation becomes emergent. Bleeding is also fairly common in terminal patients. The most dramatic example of this is the carotid blowout. Patients most at risk for this have been previously irradiated and often have a salivary fistula in the neck. A sentinel bleed is common, and if correctly diagnosed, the blowout can be prevented by urgent ligation of the carotid and regional soft tissue coverage of the ligated vessel.

Radiotherapy. Radiotherapy as the sole therapeutic intervention is appropriate for many sites in the head and neck, especially for stage I or II lesions (see Chapter 37). The most radiosensitive tumors tend to be those that are of high pathologic grade (less differentiated) and located within Waldeyer's ring (the nasopharynx, tonsillar fossa, and base of tongue). Larger lesions can be treated by external beam radiation alone, but are more commonly radiated in conjunction with chemotherapy in an organ-preservation protocol or as an adjuvant to surgical resection. Standard therapy in the United States consists of 70 to 74 Gy to the primary site in daily fractions of 180 to 200 cGy (1). Some centers use hyperfractionation as their standard regimen, with doses of approximately 120 cGy twice a day.

Most painful tumors are improved by radiation, especially in those cases in which the tumor is cured. However, external beam therapy has a side-effect profile that does produce patient discomfort. Oral mucositis is a major source of pain during the treatment and sometimes causes treatment breaks and possibly decreased tumor control secondary to these interruptions. A study by Munro and Potter also showed a significant increase in fatigue and weakness, increasing from pretreatment to at least 4 weeks after the conclusion of therapy (92). Other side effects noted were odynophagia, dysphagia, xerostomia, and altered taste, all peaking during the course of radiation. Potential complications of radiotherapy include osteoradionecrosis, myelitis, cataracts, and encephalopathy. All of these complications are seen less frequently now that three-dimensional conformal planning is available for the lesions nearest to vital structures (1).

External beam radiotherapy is also used in the palliative setting. For those patients who have an unresectable tumor that is causing either pain or obstruction of the aerodigestive tract, radiation can be used to ameliorate the symptoms without undue toxicity if this form of therapy was not used to treat the initial lesion. Radiation is sometimes used even if the patient had received previous radiation, as long as the nearby normal tissues would not exceed the maximal tolerated doses. The specific radiation doses used for recurrent primaries or regional disease is largely empiric, as Hodsen and colleagues found in their exhaustive literature search: “The retrieved literature provides little information on either the frequency, degree or duration of symptomatic relief or the offsetting treatment toxicities that such radical management can produce for these patients, especially those not cured of their disease” (93). Other uses for radiotherapy include palliation of painful distant metastases. One article evaluated bone metastases, and gave a specific recommendation for a single dose of 800 cGy for pain control, as approximately 70% of patients had their symptoms improved (54). The ability to achieve results like this with a single dose is important because the median survival for the patients with bone metastases is 12 to 16 weeks, making short treatment time an important goal to improve the quality of life for these patients in their final days.

Chemotherapy. Chemotherapy has not been shown to be effective in prolonging survival in head and neck cancer in the adjuvant or neoadjuvant setting (see Chapter 37). Response to chemotherapy may be an indicator for response to radiation and is presently used in protocols to preserve the function of the larynx and base of tongue (94). In a previously untreated patient, response rates of 70% to 90% can be seen with neoadjuvant chemotherapy, yet no improvement in survival occurs (95). Some trials, however, have shown moderate improvement in locoregional control and disease-specific survival when the chemotherapy, usually a combination of cisplatin, fluorouracil, and hydroxyurea, is given concomitantly with radiotherapy (96,97 and 98). The Intergroup study 0099 showed a marked improvement in the 3-year overall survival in nasopharyngeal cancer (76% versus 46%) when they compared concomitant cisplatin plus fluorouracil with radiotherapy with radiotherapy alone (99). The combination treatment carries a higher price in the acute side effects, however, with oral mucositis and leukopenia being the major limitations to continuing treatment. Although the standard of care for nasopharyngeal carcinoma has changed, further studies are needed to confirm the results for the other sites in the head and neck.

In the palliative setting, the effect of chemotherapy is much less, with response rates between 15% and 40% in previously treated tumors and a life expectancy of approximately 6 months (unchanged by the addition of chemotherapy) (95,100). Methotrexate has been the standard palliative drug of choice for the past 25 years. In well-tolerated doses of 40 to 60 mg per m^2, the response rate usually is 30%, but again, survival rates are unaffected (95). Side effects are myelosuppression, mucositis, and diarrhea. Other single drugs and combinations have been used, but in these terminal patients, the response rates have not been improved and the side-effect profile is generally worse. For those patients who respond, the benefits can be great. With regression in tumor size, pain is diminished. Physiologic functions such as swallowing and speech can also be transiently improved, yielding a better quality of life in the preterminal setting.

Management of Pain during Oncologic Therapy. The point made in Chapter 35 and Chapter 36, which deserves reemphasis, is that patients undergoing oncologic therapy frequently have moderate to severe pain that persists primarily because an inadequate attempt has been made to control it. Most physicians recognize the importance of alleviating pain, but fears of overdosing or causing addiction persist. These concerns often cause pharmacologic undertreatment, but other avenues are available.

First, patients should be informed about the possible consequences of oncologic therapy without creating new fears and anxieties. This helps patients to mobilize coping skills that allow them to face the consequences of other therapy realistically and calmly. In addition, stress management techniques such as relaxation, hypnosis, and biofeedback enhance patients' ability to facilitate tolerance and adaptive functioning (see Chapter 88, Chapter 89, Chapter 90, Chapter 91, Chapter 92 and Chapter 93). These should be supplemented with some type of pharmacologic therapy. Patients with severe pain who are receiving oncologic therapy on an outpatient basis can be prescribed oral morphine either as a liquid every 4 hours or as slow-release morphine, given in doses that produce effective but perhaps not complete relief of pain.

Patients who are being treated in the hospital can be managed by patient-controlled analgesia with opioids or epidural opioids (see Chapter 84 and Chapter 103). If the pain is severe, temporary relief can be achieved by daily blocks of the gasserian ganglia or of one of the major branches of the trigeminal nerve. Another technique that can be used for this purpose alone or in combination with narcotics is transcutaneous electrical nerve stimulation, although this therapy tends to work better for chronic benign pain than for pain secondary to cancer (101). If oncologic therapy is effective in eliminating pain in patients who have been on narcotic therapy for several weeks, it is essential to taper the dose of narcotics over a 1-week period to obviate the abstinence syndrome.

Symptomatic Management of Pain

When oncologic therapy is ineffective in providing relief, the pain must be treated by one or more of the following: (a) systemic analgesics and adjuvant drugs; (b) psychological techniques of analgesia; (c) neurostimulating techniques; (d) regional analgesia with local anesthetics or neurolytic blocks; and (e) neuroablative surgical procedures. Because these techniques and methods are discussed in detail in Chapter 36 and in various sections of Part V, comments here are limited to discussion of issues especially relevant to cancer pain in the head and neck.

It is essential to evaluate the patient and the pain, as discussed in detail in Chapter 35. This requires a thorough history, particularly in regard to the characteristics of the pain at the time of onset, during its course, and at the time the patient is seen, and including previous diagnosis and therapies; a psychological and psychosocial evaluation; careful measurement of the multidimensional aspects of pain; a complete physical examination, especially a careful neurologic study; and appropriate radiologic and laboratory diagnostic tests.

Plain radiography is rarely used to evaluate head and neck tumors because it is often inadequate for assessing these lesions. CT and magnetic resonance imaging are considered to be the most useful diagnostic procedure in evaluating cancer of the head and neck. A CT with contrast is most often used to evaluate cervical nodal disease as well as laryngeal, paranasal sinus tumors and oral cavity tumors that invade bone. Magnetic resonance imaging is used to evaluate tumors in soft tissue such as the parapharyngeal space, base of tongue, and skull base tumors invading dura or brain. Other techniques include radionuclide bone imaging and positron emission scans for metabolically hyperactive lesions. Patients with primary metastatic brain tumors and leptomeningeal metastases require evaluation of the cerebrospinal fluid. Biopsy of the nasopharynx, sphenoid sinuses, or accessible bones might sometimes be necessary to establish the tumor diagnosis. Obviously, these measures should have been carried out before initiation of oncologic therapy, but it is the responsibility of the algologist to review the results carefully. If regional analgesia, either with local anesthetic or with neurolytic agents or a neuroablative procedure, is being considered, it is important to know the prognosis of the patient and the anticipated pattern of metastatic spread.

Selection of the procedure or combination of procedures for the relief of cancer pain in the head and neck requires consideration of the following: (a) the physical, mental, and psychological condition of the patient; (b) the type and stage of the oncologic process and the prognosis; (c) the mechanism, intensity, quality, and location of the pain; (d) the skill and knowledge of the health care personnel and the therapeutic modalities and resources available; and (e) most important, the opinions and feelings of the patient and family after they have been fully informed about the advantages, disadvantages, limitations, and complications associated with the various therapeutic procedures. In all circumstances it is essential to exploit psychological techniques as adjuncts to other therapies (e.g., in the form of relaxation training, hypnosis, or psychological support). Assuming that the patient is agreeable and other resources are available to carry out all the methods, this discussion is divided into two parts: patients in the intermediate stage of the disease who are in good condition, and patients with advanced or terminal cancer who have severe pain.

Pain in Intermediate Stage. Patients with the intermediate stage of the disease, who have not been relieved with oncologic therapy and who have mild to moderate pain, can be managed with systemic medications comprised of aspirin or other nonsteroidal antiinflammatory drugs and adjuvant drugs, as discussed in Chapter 83. This combination is usually effective in relieving mild to moderate pain and can be continued for months to years. Patients with the intermediate stage of disease with severe or excruciating pain, who have not been relieved by oncologic therapy or intensive, high-dose opioids and who are expected to live 6 months or more, are candidates for an ablative neurosurgical or neurolytic procedure to achieve prolonged pain relief.

Pain in the face or head within the distribution of the trigeminal nerve can be managed with trigeminal gangliolysis achieved with the thermocoagulation technique (see Chapter 105 and Chapter 107). This procedure produces analgesia with fewer postoperative sensory deficits and other disturbances than either retrogasserian rhizotomy or alcohol injection. Although a superb procedure for patients with tic douloureux, this operation can be used to relieve cancer pain (102). The results with malignancy are less favorable, probably because of progression of the disease. Thus, Siegfried and Broggi (103) reported on 20 cancer patients, all of whom obtained complete pain relief immediately after the operation, but the relief lasted only a few days in five patients and, at 1 month follow-up, six patients had recurrence of pain, although it was still much less intense. Among the 15 patients who survived to 3 months, 60% remained pain-free, whereas the other 40% had partial or no relief. Among the patients who survived to 12 months, the figures were 70% and 30%, respectively; among those who survived to 18 months the figures were 40% and 60%, respectively. In view of the fact that the gangliolysis can be repeated, it is surprising that this was not done in the patients who had recurrence of pain.

Percutaneous differential radiofrequency rhizotomy of the glossopharyngeal and the vagus nerves can be used for the relief of severe excruciating pain in the throat and larynx. Another neuroablative procedure involves rhizotomy through open operation. As discussed in Chapter 105 and Chapter 108, a retrosigmoid craniectomy allows the use of a supracerebellar approach for better visualization of the cranial nerves.

Patients who have more extensive pain require trigeminal rhizotomy as well as section of the nervus intermedius and perhaps of the glossopharyngeal nerve through a lateral approach combined with a supracerebellar approach to the trigeminal nerve. When the neoplastic disease is more extensive and is producing severe pain involving the sensory fibers of other cranial nerves, a posterior fossa craniectomy is performed to section the roots of cranial nerves VII, IX, and X and, if necessary, the sensory roots of the upper two or three cervical nerves. Side effects can be serious, with a 10% morbidity (meningitis, cerebrospinal fluid leak, severe ataxia, aspiration pneumonia), a 1% chance of a major intracranial bleed, and a 0.6% perioperative mortality (102). Because of this, its use should be limited to patients who are in good physical condition and who can tolerate the stress of general anesthesia and a major surgical intervention.

Severe Pain Caused by Advanced and Terminal Cancer. An attempt should be made to try to control the severe pain of advanced and terminal cancer with a combination of medications including potent narcotics, but, if the pain is severe or extremely severe, the degree of relief is usually less than optimal. In such patients the technique of percutaneous differential radiofrequency rhizotomy of the trigeminal or glossopharyngeal and vagal nerves should be used by a neurosurgeon skilled in these techniques. Another alternative is to use intraventricular morphine delivered by an Ommaya reservoir. Decreased tolerance to morphine occurs when delivered by this route. One study reports that 70% of patients describe their pain relief after receiving intraventricular morphine as very good to excellent, 20% as good, and 10% as poor (101). Another technique is to use deep brain stimulation by implanting electrodes in the periaqueductal and periventricular gray matter for nociceptive pain (104). Other neurosurgical ablative techniques that can be used for severe pain in the head are medullary trigeminal tractotomy, hypothalamotomy, and thalamotomy (Chapter 108 presents detailed results with the use of these techniques in cancer patients).

Unfortunately, these neurosurgical procedures are only performed in major medical centers. If neurosurgery is not an available option, but a skilled anesthesiologist is available, a neurolytic gasserian ganglion block should be considered; such a block is highly effective if the tumor involves structures supplied by the trigeminal nerve (Fig. 53-2, Fig. 53-3 and Fig. 53-4). Even if the pain is located in one of the major trigeminal divisions, it is preferable to carry out gasserian ganglion block at the onset to produce a widespread field of analgesia into which the cancer can spread without producing more pain subsequently. Although this entails the risk of neuroparalytic keratitis and corneal ulcer, effective relief of severe pain for patients with advanced cancer is considered to be worth such risk. Properly done, alcohol block of the gasserian ganglion produces pain relief in more than 80% of patients with advanced cancer pain in the anterior two-thirds of the head (84).

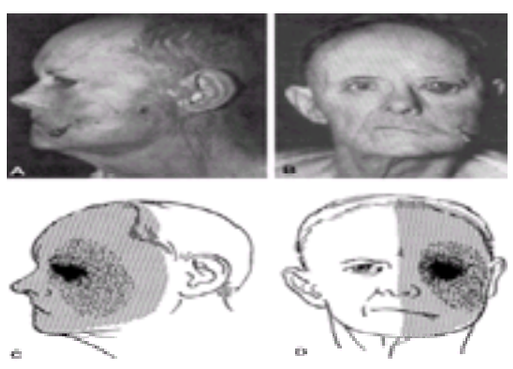

Figure 53-2. **A,B:** A 69-year-old patient with fibrosarcoma of the left orbit with invasion of the maxilla, which produced severe pain in the eye and ipsilateral side of the face, particularly the cheek. The pain became progressively worse and interfered with the patient's comfort despite administration of large doses of morphine. Gasserian block with 1 mL of alcohol produced complete relief of pain and permitted a gradual decrease of morphine until the patient could be made comfortable with codeine and aspirin. **C,D:** Sites of severe pain (*black*) and moderate pain (*stippled*), and the area of analgesia (*cross-hatchin* g) consequent to the neurolytic block.

Figure 53-3. Patient with advanced carcinoma of the orbit associated with severe pain that was relieved by gasserian ganglion block with alcohol. (Courtesy of Dr. José Madrid.)

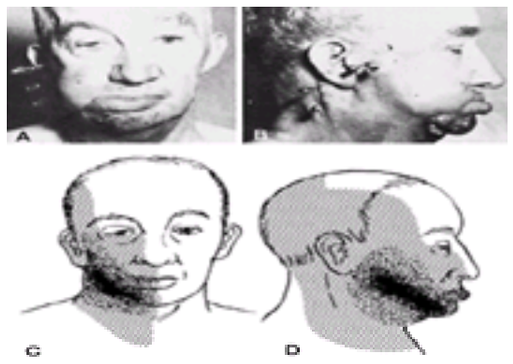

Figure 53-4. **A,B:** Patient with cancer of the tongue with invasion of the cheek, lower jaw, and chin. The severe pain was not relieved by intensive radiation therapy and large doses of narcotic analgesics but was relieved with alcohol block of the right maxillary and mandibular nerves and of the second and third cervical nerves. **C,D:** Sites of severe pain (*black*) and moderate pain (*stippled*), and the area of analgesia (*cross-hatching* in **C**) that persisted until the patient's death 4 months later.

In addition to the severe sharp somatic pain, some tumors of the face and head cause a burning discomfort that requires complementary neurolytic block of the cervical sympathetic chain. However, if the pain involves the structures supplied by the glossopharyngeal and vagus nerves, diagnostic and prognostic blocks of these nerves can be done, but neurolytic blocks should be avoided because they produce prolonged paralysis of the pharyngeal and laryngeal muscles.

Another alternative is neuroadenolysis of the pituitary gland, which involves injection of alcohol into the pituitary gland using a transsphenoid sinus route. This procedure has been alleged to produce effective pain relief in approximately 80% of patients with bone metastases. It produces total body pain relief by a mechanism theorized to include endorphins, as naloxone can block the effect (101). It is not commonly used at this time.

The pharmacologic approach is the mainstay of the management of pain in advanced cancer patients. This includes the analgesic ladder technique, developed and widely advocated by the Cancer Unit of the World Health Organization (see Chapter 36). Properly used, this method produces complete pain relief for moderate pain in almost every patient, and effective (although not complete) relief of severe pain in approximately 70% to 80% of the patients. Head and neck cancers and their treatments can lead to severe pain. It is imperative that all of those who treat such patients are attentive to the complaint of pain and prepared to strive for its relief.

CHAPTER 54

General Considerations of Pain in the Neck and Upper Limb

John J. Bonica, René Cailliet, and John D. Loeser

Disorders of the neck, shoulder, and upper limb are among the most frequent causes of pain, suffering, and disability. These painful disorders can be caused by infection or degenerative arthritic changes, trauma, or disease of one or more of various parts of the cervical spine, myofascial pain syndromes, neuropathic disorders, and many other causes. Knowledge of the causes, pathophysiology, and symptoms and signs is essential to establish a diagnosis and develop effective therapeutic strategies. The pain management physician should know the functional anatomy and biomechanics of the cervical spine and the anatomy and function of the cervical nerves, cervical plexus, brachial plexus, and their branches for proper interpretation of the patient's history and for performing meaningful general physical, neurologic, and orthopedic examinations.

This first chapter of Section B, like other chapters that introduce the management of pain in various regions of the body, provides a concise discussion of these various considerations. The information is presented in four major parts: basic aspects; description of the segmental and peripheral somatic nerve supplies and the sympathetic nerve supply to the neck and upper limb; summary of the assessment process in evaluating patients and their pain; and a table summarizing pain characteristics and other symptoms and signs in the neck and upper limb to help in making a differential diagnosis. More detailed information has been presented by Bland (1), Cailliet (2), and others (3,4).

BASIC CONSIDERATIONS

This first section discusses the clinically relevant aspects of the anatomy of the cervical spine, including a brief description of the vertebrae, joints, ligaments, and muscles that are attached to the cervical spine; mobility of the spine; and other points essential for understanding the pathophysiology of painful disorders of the neck and upper limb. The second part of this section describes the contents of the vertebral canal, spinal cord, rootlets and formation of the cervical nerves, and, finally, the cervical plexus and brachial plexus, their branches, and the structures they supply.

Anatomy and Biomechanics

Although the embryologic development of the three parts of the vertebral column is quite similar, the anatomy of the cervical spine has characteristics quite different from those of the thoracic and lumbar spines (Fig. 54-1). It allows positions and movements that are adapted to support and move the head and permits the sense organs to function within the head. The extent, direction, and variation of movement of this portion of the spine have the greatest range of any part of the spinal column. The cervical spine, which is both a structural static support of the head and a mobile kinetic mechanism, is an aggregate of seven vertebrae composing a flexible column held together by five intervertebral disks, 12 joints of Luschka, 14 hypophyseal joints, and a system of ligaments and muscles that allow its wide range of motion and mobility (see Fig. 54-1).

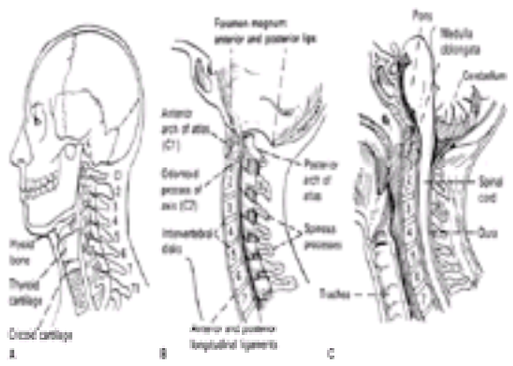

Figure 54-1. Anatomy of the cervical spine. **A:** Lateral view, showing landmarks of the spine, including the hyoid bone, thyroid and cricoid cartilages, and transverse and spinous processes. **B:** View of the skeletal portion of the lower skull and cervical spine. The skull and spinous processes are shown in sagittal section, whereas the vertebral bodies are shown as normal. **C:** Sagittal view of the cervical spine showing the relationship of the brainstem, medulla oblongata, foramen magnum, and spinal canal, containing the spinal cord. Normally, the lower portion of the medulla is outside and below the foramen magnum so that subluxation of the atlas on the axis, and compression of the lower brainstem, can occur by compression from the odontoid process, which moves posteriorly against the neuraxis. (Modified from Bland JH. *Disorders of the cervical spine: diagnosis and medical management*. Philadelphia: Saunders, 1987.)

Cervical Vertebrae

In contrast to the thoracic and lumbar spines, which are basically similar, the cervical spine has two unique units. These upper two segments, the occipitoatlantal unit [occiput of the skull and the atlas (C-1) and the atlantoaxial (C-1 to C-2) unit], form the upper portion, which has special characteristics. The lower five segments are constructed in a similar manner to the other spinal segments.

Upper Functional Units. The atlas (Fig. 54-2A) has no body and is composed of a solid ring of bone with two lateral pillars; the upper and lower surfaces are articulating facets (1,2 and 3). The short anterior arch articulates in a vertical plane with an odontoid process of the axis, whereas the longer posterior arch forms the posterior wall of the spinal canal. The upper facets are ellipsoid and are cupped to articulate with the occipital condyles, whereas the lower facets are round and concave, face laterally and downward, and articulate with the superior facets of the axis. The transverse processes of the atlas are longer than those of other vertebrae, each containing the transverse foramen for the vertebral artery, veins, and sympathetic plexus, and to which are attached powerful muscles that rotate the head.

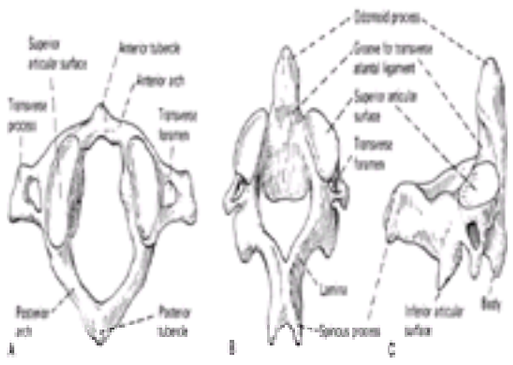

Figure 54-2. Anatomy of the atlas and axis. **A:**Superior view of the atlas. **B:** The axis viewed from a superior and posteroanterior aspect. **C:** Lateral view of the axis.

The axis (Fig. 54-2B and Fig. 54-2C) is composed of a small body from which the peglike odontoid process arises perpendicularly, acting as an eccentric pivot about which the atlas rotates (1,2 and 3). The anterior surface of the process has a facet articulating with the anterior arch of the atlas, and its posterior surface articulates with the transverse ligament (see Fig. 54-2C). The lateral masses have facets above and below, articulating with the atlas above and the C-3 vertebra below. The atlas has thick laminae (posterior arches) and a large bifid palpable spinous process. Its transverse processes are small, with tubercles at their tips, and have transverse foramina for the vertebral artery, veins, and vertebral (sympathetic) plexuses. Neither the atlas nor axis has pedicles or an intervertebral foramen, so the nerve roots of the first and second spinal nerves lie above and posterior to the articulating lateral masses of both vertebrae. This is in contrast to roots of the lower cervical nerves, which lie anterior to the apophyseal joint facets and traverse their respective intervertebral foramina.

Lower Functional Units. All the lower five cervical vertebrae have common characteristics: a body, two pedicles, two laminae, two vertebral arches, and a spinous process (Fig. 54-3). The vertebral arches arise from the posterolateral aspects of the bodies, giving rise to the pedicles, whose upper and lower surfaces are articulating facets of the zygapophyseal joints. The arches face the bodies at an angle of approximately 45 degrees, and the laminae arise from the pedicles and arch backward to meet in the midline, forming the bifid spinous processes that jut down. In front of the facets, the transverse processes arise laterally and project anteriorly and caudally; their upper surfaces are grooved and troughlike and contain the roots of the cervical spinal nerves. Each transverse process of C-3 to C-6 (but not C-7) has a foramen for the vertebral artery, plexus of veins, and vertebral (sympathetic) nerve or plexus. Each transverse process has an anterior and a posterior tubercle that serve as attachments for the scalene muscles. Adjacent bodies are united by the intervertebral disks, anterior and posterior longitudinal ligaments (PLLs), paired posteriorly placed zygapophyseal joints, ligamentum flavum, ligamentum nuchae, intertransverse ligament, and interspinous ligaments. The functional units of this lower portion of the cervical spine, as the lumbar units, consist of an anterior weight-bearing shock-absorbing portion and a posterior guiding-gliding section (5) (Fig. 54-4).

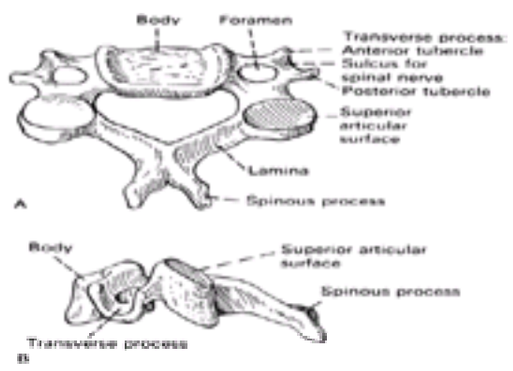

Figure 54-3. Typical cervical vertebra. **A:** View from above. **B:** View from the side. (Modified from Clemente CD, ed. *Gray's anatomy of the human body*. Philadelphia: Lea & Febiger, 1985.)

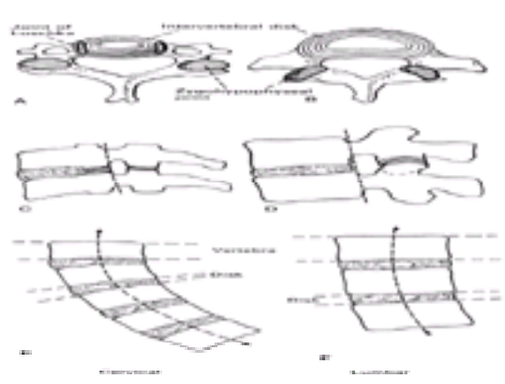

Figure 54-4. Comparative views of the cervical and lumbar functional units. **A:** Cross-section of the five joints of the cervical spine, which include an intervertebral disk, the paired uncovertebral (Luschka) joints, and the paired posterior articulations. **B:** Cross-section of the three joints of the lumbar spine, which include an intervertebral disk and the paired posterior articulations. **C,D:** Lateral views of the same vertebrae shown in **A** and **B**. The dashed lines divide the anterior supporting portion from the posterior gliding portion of each functional unit. **E,F:** Lateral views of the bodies of the vertebrae of the cervical and lumbar spines, depicting particularly the shapes of the intervertebral disks. Note that in the cervical region the anterior portion of the disk is larger (higher) than the posterior portion, whereas in the lumbar region the difference between the anterior and posterior portions is much less. (Modified from Cailliet R. *Neck and arm pain*, 2nd ed. Philadelphia: FA Davis, 1981.)

Anterior Portion. The anterior portion of the lower functional units is comprised of two vertebral bodies separated by the intervertebral disk, which is a self-contained fluid elastic system that absorbs shock, permits transient compression, and allows fluid displacement within its elastic container, thus permitting movement and distortion of the functional unit. The lower and upper plates of the disk are the end-plates of the vertebral bodies composed of articular hyaline cartilage in direct contact with, and adherent to, the underlying resilient bone of the vertebral bodies. These inflexible surfaces form the cephalad and caudad walls of the disk.

The outer wall of the disk, the annulus, is an intertwined fibroelastic mesh that encapsulates the gelatinous matrix of the disk, the nucleus pulposus. The annulus fibers are attached around the entire circumference of both upper and lower end-plates and intertwine in criss-cross oblique directions, thus permitting movement of one vertebra on the other in a *rocker* motion, in a rotary direction, and as a horizontal translatory motion (6) (Fig. 54-5). The nucleus pulposus, contained within the fibrous resilient wall of the annulus and between the floor and ceiling formed by the end-plates of the vertebrae, cannot be compressed, so any external force exerted on the area unit is transmitted undiminished to every unit area of the interior of the annulus. Fluid creates an intradisk pressure that forces the vertebrae apart and keeps the annulus fibers taut. Movement in any direction is permitted by some of the fibers' relaxing while the rest remain taut, thus maintaining intradisk pressure (see Fig. 54-5).

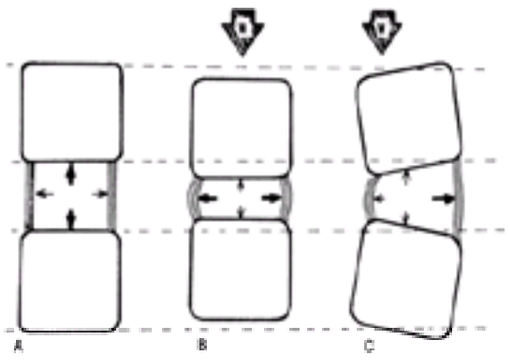

Figure 54-5. Schematic depiction of the hydraulic mechanism of the intervertebral disk. **A:** Normal disk at rest. The internal pressure is exerted in all directions, and the fibers of the annulus are taut. **B:** When the disk is compressed the fluid within the nucleus pulposus cannot compress, so the annulus must bulge. **C:** With flexion of the spine the fluid shifts within the intervertebral disk; the cubic contents remain the same but the fluid shift causes fibers of the anterior annulus to shorten and those of the posterior annulus to elongate. (W, weight.) (From Cailliet R. *Neck and arm pain*, 2nd ed. Philadelphia: FA Davis, 1981.)

The young or undamaged intervertebral disk has predominantly fibroelastic tissue, but aging or injury to the disk causes larger, less elastic fibers to replace the young, highly elastic collagen fibers; consequently, the older disk container is less elastic. The colloidal gel of the nucleus pulposus is a mucopolysaccharide that functions by its physicochemical action: It can imbibe external fluid and maintain its intrinsic water balance. The young disk contains 80% water but dehydrates with age and trauma, causing a decrease in the protein polysaccharide level and thus a decrease in the imbibitory property of the gel. Loss of the intradisk fluid and the decrease in annular elasticity results in a decrease in pressure. The intervertebral disk has a vascular supply that disappears after the second decade of life, and by the third decade the disk is virtually avascular (5), receiving its nutrition by diffusion of lymph and other fluids through the vertebral end- plates and through peripheral vessels of the annulus fibrosis. This is made possible by the alternating compression and relaxation of the elastic container, which acts like a sponge being squeezed and released, thus bringing lymph to the disk and allowing diffusion to occur.

The intervertebral disks make up approximately one-fourth the length of the entire spinal column. They dehydrate (shrink) consequent to weight bearing during the day and rehydrate during rest at night. Disks are relatively thicker in the cervical spine (thickest at C-6 to C-7), the ratio of disk to vertebral body height being 1:3 to 1:2 (1,2). Moreover, in contrast to the symmetric thickness of the annulus in the lumbar region, in the cervical spine the posterior portion is markedly thicker and broader than the remainder of the annulus (see Fig. 54-4), a factor that reinforces the disk at vital sites and protects adjacent nerves, blood vessels, and the spinal cord.

Another difference in the cervical spine is the vertical height of each disk. In the lumbar region the height is only slightly greater anteriorly than posteriorly, so that the upper and lower borders are essentially parallel. In the cervical spine the anterior vertical height of the disk is twice as great as that of the posterior height so that the disk viewed from the side is wedge shaped, a factor that increases the total curvature of the cervical spine (7).

The anterior portion of the cervical functional unit has several other structural differences from the anterior portion of the lumbar unit. Whereas the vertebral end-plates of the lumbar spine are flat and parallel and the nucleus is centrally located in the disk, in the cervical spine the vertebral cartilaginous plates are concave and convex, and the nucleus is located in the anterior portion of the disk (see Fig. 54-4A and Fig. 54-4B). The relationship of the end-plates and their shapes, in addition to the location of the nucleus, permits a rocking movement between the vertebrae in the lumbar region and a forward and backward gliding motion of adjacent vertebrae in the cervical region (6).

Another difference is the presence of the uncovertebral joints, also called the *joints of von Luschka* (3,8). These are not true joints and are absent at birth, appearing at approximately 10 to 20 years of age. They constitute bony projections that articulate on each other and form false joints, or pseudoarthroses. These are important in the function of the cervical spine and in the pathology of neck pain and cervical radiculopathy (1).

Another important difference is the character of the PLL. In the lumbar spine the PLL converges to a point in the caudal area and is incomplete posteriorly in the region of L-3 to S-1, thus inadequately reinforcing the lumbar disk. In the cervical spine the PLL is thick and broad and is complete across the posterior vertebral area; between the vertebrae it is double layered. This powerful reinforcement is a strong deterrent to any disk herniation or bulging, which could cause major peripheral nerve and spinal cord damage.

Posterior Portion. The posterior portion of the lower functional units in the cervical region has a posterior guiding-gliding action. It is composed of two vertebral arches, two transverse processes, a central posterior spinous process, and a paired articulation (2). The transverse processes and posterior spinous processes are bony sites of attachment of the neck muscles that move the spine and support the neck and head and are also sites of attachment for supporting ligaments. The posterior articulation, or *facet*, is comprised of two joints that are lined with synovium and are lubricated by synovial fluid within the joint capsule. They are called apophyseal or zygapophyseal in the sense of being outgrowths, but their articular cartilaginous surfaces classify them as true joints, thus able to undergo degenerative changes referred to as osteoarthritic joint changes. These facets are in opposition and placed in direction and degree of inclination so as to permit and guide the movement of the two adjacent vertebrae. Paired facets are similarly shaped and planed from the C-3 to the C-7 vertebrae, permitting similar movements between these paired joints that are different than those between the occipitoatlantal and atlantoaxial joints.

Ligaments of the Cervical Spine

The ligaments of the cervical spine are sufficiently resilient to control motion, thus aiding the support of the neck muscles, and are lax enough to permit a wide range of motion. Their resiliency is demonstrated by the protection they afford the spinal cord and the spinal nerves against the numerous stresses, strains, and trauma to which the neck is subjected. The head is heavy and eccentrically balanced on a relatively narrow elastic support. In its top-heavy balance it is repeatedly subjected to movement, positional changes, and various degrees of trauma. The ligaments and muscles bear the brunt of these stresses; the ligaments remain the sole support when the muscles are overused, fatigued, or ineffective in their function (Fig. 54-6).

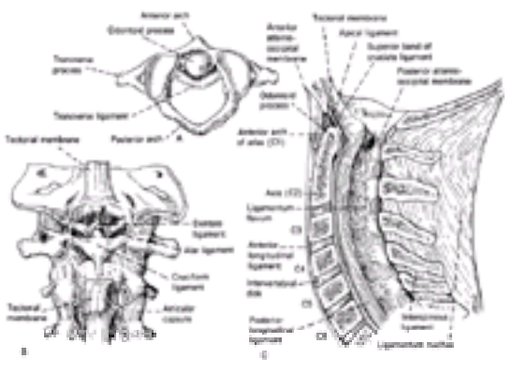

Figure 54-6. **A–C:** Ligaments of various parts of the cervical spine (see text for details). (Modified from Clemente CD, ed. *Gray's anatomy of the human body*. Philadelphia: Lea & Febiger, 1985:343–344; and from Netter FH. *CIBA collection of medical illustrations*. Vol 1. The nervous system. Summit, NJ: CIBA Pharmaceutical Products, 1983.)

Occipitovertebral Ligaments. The ligaments connecting the occiput to the atlas are extremely dense, broad, and strong and protect the entrance of the spinal cord through the foramen magnum into the skull while still permitting some 30 degrees of flexion and extension in a joint having no intervening disks or posterior

articulations (1,2 and 3). The following ligaments are some that connect the occiput with the atlas: (a) the apical ligament of the odontoid process (see Fig. 54-6C), a vestigial remnant attached to the peak of the odontoid process that runs to the anterior lip of the foramen magnum; (b) the alar ligaments (see Fig. 54-6B), which run on either side of the odontoid process to the margin of the foramen magnum, both enclosed in a sleeve or synovial membrane (these tough robust cords check atlantoaxial rotation); (c) the atlantooccipital membrane (see Fig. 54-6C), which extends upward from the anterior longitudinal ligament to connect the anterior margin of the foramen magnum with the anterior arch of the atlas; (d) the tectorial membrane (see Fig. 54-6B and Fig. 54-6C), a fan-shaped continuation of the PLL to the basiocciput whose fibers blend with the dura mater; and (e) the posterior atlantooccipital membrane (see Fig. 54-6C), which arches over the vertebral artery and is much thinner than the ligamenta flava or interspinous ligaments further down the cervical spine and also thinner than the anterior longitudinal ligaments and PLLs.

The stability of the atlantoaxial (C-1 to C-2) joint depends almost entirely on ligamentous structures and, of these, the transverse ligament (see Fig. 54-6A) is most important because it permits the atlas to move around the odontoid process. It is a taut resilient structure that maintains the normal relationship of the atlas on the axis; a tear of this transverse ligament has the same destabilizing effect as a fracture of the odontoid process (9).

Other Cervical Ligaments. In the rest of the cervical spine, from C-2 to C-7, the anterior longitudinal ligament and the PLL reinforce the disk annulus (see Fig. 54-6C). The anterior longitudinal ligament adheres tightly to the front of the vertebral bodies and blends loosely with the annulus as it crosses the disk spaces. The PLL is firmly bound to each disk, but is only loosely bound to the posterior concavity of the vertebral body. The PLL is double layered and reinforces the capsular ligaments; combined, they limit the degree of transverse sliding motion between vertebrae as well as limiting the extent of flexion and extension.

The ligamenta flava are strong elastic ligaments spanning the space between the laminae in pairs attached to the anterior inferior surface of the lamina above and to the posterior superior margin of the lamina below. They stretch laterally to the zygapophyseal joint and, in combination, they reinforce the latter's capsules. The ligamenta flava stretch under tension and retract and relax during undue bulging or folding in the normal state.

The interspinous ligaments (see Fig. 54-6C) are thin membranous structures that connect the adjoining spines. Their attachments extend from the root to the apex of each spinous process and are only slightly developed in the cervical spine. The ligamentum nuchae is a broad, firm, fibrous posterior ligament that attaches to the base of the skull around the foramen magnum and connects the tips of the posterior spinous processes as well as cervical vertebrae. Below C-7 it is replaced by the supraspinous ligaments, which are strong fibrous cords that connect the apices of the spine together from the C-7 vertebra to the sacrum.

Musculature of the Neck

The neck muscles can be divided into two major functional groups: those that flex and extend the head, the so-called capital movers, and those that flex and extend the cervical spine (2) (Fig. 54-7). The capital flexors are mainly the short recti and the longus capitis muscles, whereas the capital extensors are four short muscles extending from the base of the skull to the axis and atlas. These include the posterior rectus capitis minor and major and the obliquus superior and inferior capitis. The longissimus capitis, semispinalis capitis, and splenius capitis are longer muscles that also act as capital extensors when working together bilaterally (2).

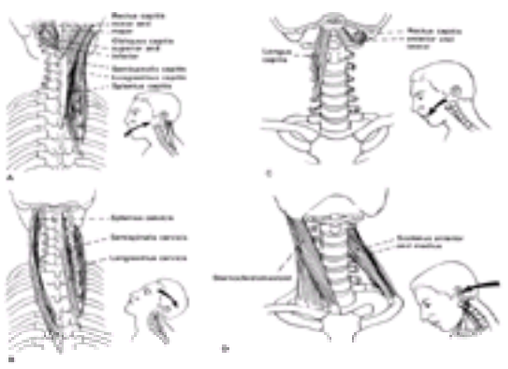

Figure 54-7. Musculature of the head and neck. **A:** The capital extensors attach on the skull and move the head on the neck. **B:** The cervical extensors originate from and attach on the cervical spine and alter the curvature of the spine. **C:** The capital flexors flex the head on the neck. **D:** The cervical flexors attach occlusively on the cervical vertebrae and have no significant functional attachment to the skull. (Modified from Clemente CD, ed. *Gray's anatomy of the human body*. Philadelphia: Lea & Febiger, 1985; and from Cailliet R. *Neck and arm pain*, 2nd ed. Philadelphia: FA Davis, 1981.)

The major flexors of the cervical spine consist of the scalenus anterior, scalenus medius, and scalenus posterior. These attach exclusively to the cervical vertebrae and have no significant functional attachment to the skull. The same applies to the cervical extensors, which include the splenius cervicis, longissimus cervicis, and semispinalis cervicis. The splenius cervicis, splenius capitis, longissimus capitis, and sternocleidomastoid of one side only act as rotators of the head. In addition, continuations of the total erector muscles of the vertebral column also affect movement of the neck. Most of the extensor musculature in the head and neck is at the atlantoaxial region and at the last two (C-6 to C-7 and T-1) articulations. These are the three major sites of stress. The bulk of the flexor musculature centers at the C-4 to C-5 space, implying that most flexion occurs here; it is also the site of maximum lordosis.

Mobility

The cervical spine moves in flexion, extension, lateral flexion, and rotation. The total of movements of the neck is the composite of all segmental movements that move synchronously, but the direction and degree of movement vary at different levels of the segmental spine. The greatest movement in terms of both range and amplitude occurs in the upper portion, between the skull and the C-3 vertebra. The major portion of flexion, extension, lateral movement, and rotation occurs between the skull and the atlas and between the atlas and the axis (2). Below the axis the extent of movement depends on ligamentous elasticity and on the distortion and depression of the intervertebral disk. Because the atlas functions principally with the occiput and the C-7 vertebra functions as a thoracic vertebra, neck movements are basically confined to five vertebrae.

Nodding, a movement of the head up and down in a sagittal plane, occurs between the occiput and atlas. Flexion occurs in a range of 10 degrees and extension in approximately 25 degrees (6,10,11), so that the head can move a total of 35 degrees in flexion and extension without any neck participation. All other movements between the skull and atlas are prevented by the direction of the opposing planes of the articular facets (2). In lateral flexion, and in rotation of the head and neck, the occiput and atlas move as one piece.

The greatest movement of the entire cervical spine occurs between the atlas and axis; between these two vertebrae as much as 90 degrees of rotation is possible from the extreme right to the extreme left (Fig. 54-8). This is one-half of the entire cervical spine rotation (normally 160 degrees) and occurs before any rotation is noted throughout the remainder of the cervical spine. Between the atlas and axis as much as 10 degrees of extension and 5 degrees of flexion are possible. The inferior facet of C-1 is flat and the opposing superior facet of C-2 is convex, so flexion and extension at the level occur as a rocker action of C-1 and C-2.

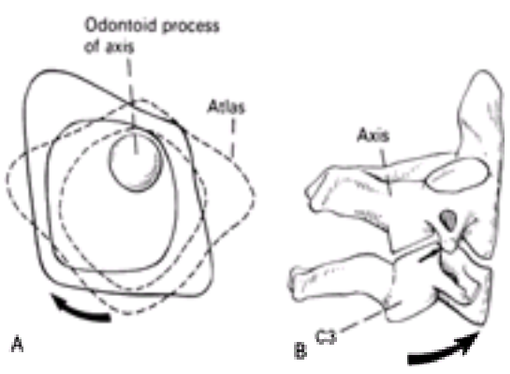

Figure 54-8. **A:** Rotation of the atlas about the odontoid process of the axis (C-1 around C-2). The dashed line shows the normal position of the atlas, whereas the solid line indicates rotation of 45 degrees to the right. **B:** Rotation of C-2 on C-3, which is limited by the mechanical locking of the articular structures. Note that the anterior tip of the upper articular process of C-3 impinges on the lateral margin of the foramen of the vertebral artery. (Modified from Cailliet R. *Neck and arm pain*, 2nd ed. Philadelphia: FA Davis, 1981.)

Rotation of the C-2 vertebra on the C-3 vertebra is mechanically limited by a bony locking mechanism in which the anterior tip of the upper articular process of C-3 impinges on the lateral process of the C-2 vertebra (see Fig. 54-8B). The locking mechanism prevents excessive rotation of the functioning unit and thus protects the vertebral artery and the emerging nerve roots in this specific intervertebral foraminal gutter (2). Movements of flexion and extension and lateral rotation are possible between C-2 and C- 7, flexion and extension occurring as a gliding movement of the upper on the lower vertebra. To permit this movement the disk distorts horizontally and compresses.

In forward flexion the intervertebral foramina become larger, whereas in extension they become smaller (Fig. 54-9). Moreover, in forward flexion the cervical canal lengthens, whereas in extension it shortens (Fig. 54-10). In lateral flexion or rotation the ipsilateral foramina decrease in size and the contralateral foramina enlarge (see Fig. 54-9). In a normal spine the degree of narrowing of the foramina is not enough to compress any tissues contained within the foramina, so that flexion, extension, and rotation of the head leave adequate room. In an abnormal spine, however, in which the vertebrae come closer together or in which movement is excessive, the foramina obviously can become constricted.

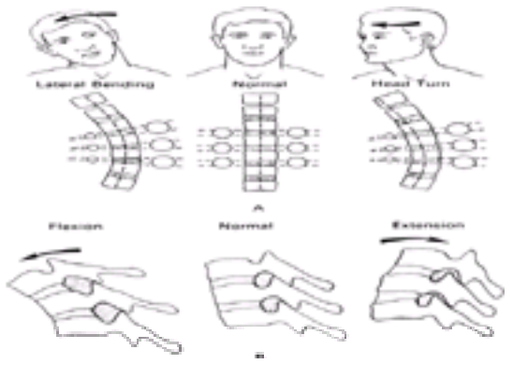

Figure 54-9. Changes in the size of the intervertebral foramina with movement of the neck. **A:** With lateral flexion and rotation of the head the foramina become smaller on the side of the head to which the head flexes laterally or rotates, and they are open on the opposite side. **B:** With forward flexion the intervertebral foramina become larger, whereas with extension they become smaller. (Modified from Cailliet R. *Neck and arm pain*, 2nd ed. Philadelphia: FA Davis, 1981.)

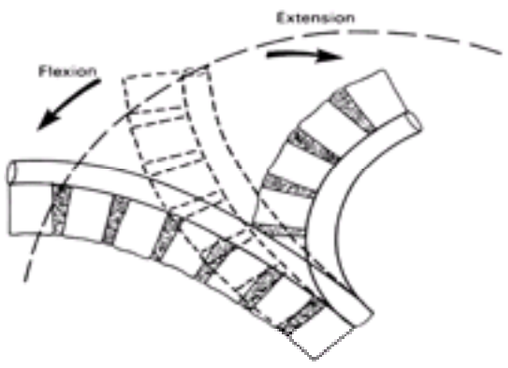

Figure 54-10. Schematic representation of the alteration of the length of the cervical spinal canal with movement from the normal position (*dashed lines*). In flexion the canal is longer and its anterior wall is shorter than its posterior wall, whereas in extension the total length of the canal is shorter, with the anterior wall being longer than the posterior wall. In the normal position both walls of the canal are equal in length. (Modified from Cailliet R. *Neck and arm pain*, 2nd ed. Philadelphia: FA Davis, 1981.)

These various movements affect the position of the structures within the cervical spine. On full forward flexion, in which the spine is concave forward, the anterior portions of the intervertebral disks are compressed and narrowed whereas the dorsal portions are widened and stretched: The anterior longitudinal ligament is slack whereas the PLL is stretched. The nucleus pulposus is dorsally displaced and the paired inferior articular facets of the vertebrae glide forward on the superior facets of the vertebrae below, with a forward slide displacement of the body of the upper vertebra on the body of the lower vertebra. The laminae and spinous processes are open fanwise, the ligamentum flava and interspinous ligaments stretch, and the posterior neck muscles are subjected to tension, with the muscles being the most powerful limiting force for flexion. Extension of the neck reverses these events; the limiting factors are tension on the anterior longitudinal ligament, the approximation and imbrication of the spinous processes, and the locking of the lower border of the lower articular facet and the lamina of T-1.

Vertebral Canal

The vertebral canal is triangular in transverse section. The posterior aspect of the vertebra and the disk constitute the base or anterior wall of the triangle, which is covered by the PLL; the pedicles in their transverse foramina contribute to this aspect (1,2). The other two sides of the triangle laterally and dorsolaterally are the inner aspects of the zygapophyseal joints, the laminae, and the ligamenta flava. The canal is funnel shaped, being widest at the atlas–axis level and narrowing to its smallest sagittal diameter at the posterior inferior edge of the body of C-5 and the lamina of C-6. The sagittal diameter of the vertebral canal in the cervical region varies; at the C-1 to C- 3 level it is approximately 21 mm (range, 16 to 30 mm), whereas at the C-4 to C-6 level it is approximately 18 mm (range, 14 to 23 mm); the transverse diameter at the C-4 to C-6 level is approximately 30 mm.

Spinal Cord

The spinal cord is suspended and cushioned in the subarachnoid space by the spinal fluid (see Fig. 54-1C). The anterior and posterior rootlets traverse the subarachnoid space *en route* to the inner part of the intervertebral foramina, where they join to form the anterior and posterior roots, respectively (see Fig. 54-12). The canal is fairly roomy to the level of C-3, where the cervical enlargement begins and extends to T-2 (1). The sagittal diameter of the cervical cord is approximately 11 mm at C-1, 10 mm at C- 2 to C-6, and 7 to 9 mm below C-6 (1). Its transverse diameters are greater than its sagittal diameters. The circumference at C-6 is approximately 48 mm (1). The cervical cord occupies approximately 40% of the canal, which is greater than at other levels of the spinal cord.

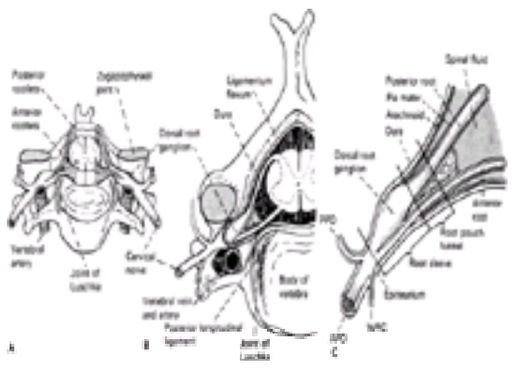

Figure 54-12. Transverse sections of the cervical spine. **A:** The spinal cord, and anterior and posterior rootlets join to form the spinal nerve. Note the relationship of the nerves to the Luschka and zygapophyseal joints and the two vertebral arteries, which pass through the transverse foramina and are located just anterior to the nerve. **B:** Cross-section of a cervical vertebra showing some details of the relationship of the posterior root to the lateral aspect of the ligamentum flavum, which covers the zygapophyseal joint just posterior to it. The anterior root and its dural covering are close to the lateral part of the posterior longitudinal ligaments and to the capsules of the joint of Luschka. The proximal portion of the dorsal root ganglion is in the outer portion of the intervertebral foramen, whereas the remainder is in the gutter of the transverse process. **C:** Detailed anatomy of a nerve root and its meningeal covering. Note the extent of the root pouch and root sleeve. Just distal to the joining of the anterior and posterior roots is the short spinal nerve covered by epineurium (the continuation of the dura), which promptly divides into the anterior primary division (APD) and posterior primary division (PPD) and gives off a white ramus communicantes (WRC). (**A** modified from Bland JH. *Disorders of the cervical spine: diagnosis and medical management*. Philadelphia: Saunders, 1987; **B** and **C** modified from Cailliet R. *Neck and arm pain*, 2nd ed. Philadelphia: FA Davis, 1981.)

With neck flexion the spinal cord and its dura elongate to their full normal lengths; the nerve rootlets and roots provide support within the limits of physiologic tension and occupy an uppermost position in the intervertebral foramina, actually contacting the undersurface of the pedicle. With extension the spinal cord shortens and the dura relaxes to assume a folded or corrugated appearance (*accordion pleats*) that encroaches on the cervical canal. In extension the nerve roots slacken, thus being more vertical to the cord, descending in the foramen and losing contact with the undersurface of the pedicle above (2). In extension the cord is thicker and the posterior inferior margin of the body of the vertebra is thicker than in flexion, but the intradural sagittal diameter is 2 to 3 mm less. Moreover, in extension, the vertebra above approximates the arch of the vertebra below, resulting in protrusion into the cervical canal. These factors cause the cord to have less play in extension than in flexion, a factor with important clinical implications.

The cervical enlargement of the spinal cord is thicker than the lumbar enlargement because it contains all the ascending and descending long tracts for the trunk and upper and lower limbs. The average length of the neuromere (each segment of the spinal cord) is 13 mm at the cervical region. The vertebrae and disks grow faster than the spinal cord during development, resulting in progressively greater discrepancy between the level of the neuromere and the vertebral level. In the lower cervical spine a given spinous process overlies the spinal cord segment located one below it numerically, so that the C-6 spinous process overlies the C-7 spinal cord segment. With increasing age the vertebrae and intravertebral disks lose height, and consequently the spinal cord lengthens relative to the vertebral canal.

Meninges. The meninges of the spinal cord consist of the tough dura mater, a loose-layered arachnoid, and the fine and delicate pia mater (see Fig. 54-12). The arachnoid and dura are separated by a capillary subdural space. As in other levels of the spinal column, the epidural space contains solid and liquid fat, loose areolar tissue, the internal vertebral venous plexus, the endings of the radicular arteries, which break up to contribute to the anterior spinal artery, and the two posterior spinal arteries. All these structures provide the spinal cord with some protection during movement and impact from external forces.

The dura mater is firmly attached to the foramen magnum and to the dorsal surfaces of the C-2 and C-3 vertebral bodies. The dentate ligaments, which are actually thickenings of the pia mater that exist between the anterior and posterior roots, attach the spinal cord laterally to the dural sheath. These dentate ligaments are usually coarse fibrous structures, although in some individuals they are delicate tissue slips whose physical properties may be causative factors in the pathogenesis of cervical myelopathy. These ligaments tense in flexion and become slack in extension, allowing extensive mobility of the cord (1).

Vertebral Arteries

The vertebral arteries deserve consideration here because they are linked with a number of cervical spine syndromes resulting from the unusual tortuous course of the vessels and their close relationship to the cervical nerves and cervical vertebrae (Fig. 54-11). These arteries are the first branches from the subclavian trunk that pass cephalad by coursing through the transverse foramina of C-6 to C-2, where they are directly in front of the cervical nerves and medial to the intertransverse muscles. Accompanying each artery are the vertebral plexus of veins and the vertebral nerve and plexus, which represent postganglionic sympathetic fibers originating in the stellate and intermediate cervical sympathetic ganglia. The course of the artery cephalad to C-2 is summarized in Figure 54-11. The vertebral arteries give off spinal branches that pass through the intervertebral foramina to supply ligaments, dura, and bone. These segmental arteries also communicate with the posterior and anterior spinal arteries, which are also branches of the vertebral arteries (see Fig. 54-11B). The vertebral sympathetic plexus surrounding the vertebral arteries gives off fibers that surround the various branches of the vertebral arteries. It supplies the artery itself as well as the basilar artery and circle of Willis and the branches derived from these vessels. These include the superior cerebellar and posterior cerebellar arteries and other structures within the cranial cavity (see Chapter 46 for details).

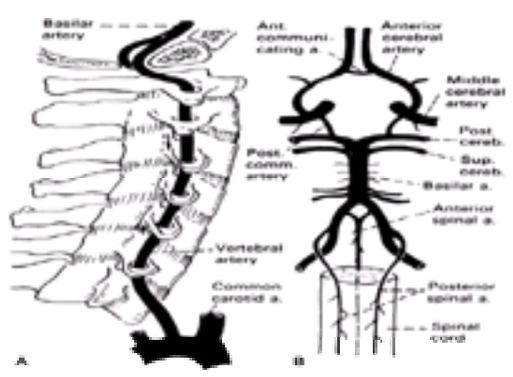

Figure 54-11. **A:** Lateral view of the cervical vertebrae depicting the course of the vertebral artery from C-6 to C-1 through bony ridges of the foramina transversaria. Note the double U-turn the artery makes from C-2 to C-1 in its posterior course around the lateral mass of the atlas. **B:** The two vertebral arteries join to form the basal arteries. Also shown is the circle of Willis. Note the origin of the anterior spinal artery and the two posterior spinal arteries from the two vertebral arteries.

Cervical Nerves

As discussed in Chapter 3 and Chapter 8 and depicted in Figure 8-1, each spinal nerve is composed of an anterior (ventral, predominantly motor) root and a posterior (dorsal, sensory) root. The posterior root, which is composed of the central processes of afferent neurons, breaks into 12 or more rootlets that attach in a linear series to the dorsolateral sulcus of the cord (see Fig. 54-12A). These sensory fibers enter Lissauer's tract and then plunge into the dorsal and ventral horns. The sensory rootlets peripherally converge into two bundles, the fasciculi radiculae, which in turn unite just proximal to the dorsal root ganglion. The anterior root arises from the ventrolateral sulcus of the cord by a smaller number and a less regular series of rootlets. Normally, the posterior root is three times thicker than the anterior root (except for C-1 and C-2) because of the much greater number of axons (see Fig. 54-12B).

Each rootlet is covered by pia mater and, as they come together to coalesce and form the dorsal and ventral roots, the rootlets become enclosed within a

funnel-shaped sac of the pia dura, the *root pouch*, which tapers toward the intervertebral foramen (see Fig. 54-12C). Within the spinal canal each root is separately enclosed in an arachnoid-dural sleeve, with each sleeve being separated by the interradicular septum. The dural root sleeves are attached to the bony margin of the intervertebral foramen, adhering more firmly with age and with the occurrence of pathologic processes such as osteoarthritis (1). As they pass through the short intervertebral foramen the anterior roots are in intimate contact with Luschka's joint and the annulus of the disk, which is covered by the lateral portion of the PLL. The dorsal (sensory) root lies close to the articular process and to the azoapophyseal joint capsule of adjacent vertebrae, factors that are significant in the pathogenesis of neuropathy (see Fig. 54-12B).

The roots normally occupy only one-fifth to one-fourth of the foramen (2). As each root passes distally beyond the foramen, it enters the *gutter* of the sulcus of the transverse process, where the arachnoid and dura blend with the nerve sheath. The arachnoid, and consequently the spinal fluid that envelops the nerve roots, ends at the outer part of the intervertebral foramen. The dura continues more distally, and at the point beyond the joining of the two roots into the formed spinal nerve it blends with the epineurium of the formed nerve. The epineurium continues as the epineural sheath of the brachial plexus and is firmly attached to the bony surface of the cervical spine, thus helping to prevent the nerves from being avulsed from the spinal cord during traction injury (12). The epineural sheath is also firmly attached to the transverse processes of the vertebra and to the fascial prolongation of the PLL, as well as to the fascia of the neck that surrounds the brachial plexus.

In the cervical region the intervertebral foramina open obliquely laterally and slightly anteriorly and inferiorly from 10 to 15 degrees downward. Their shape is like a figure eight and they are largest at the C-2 to C-3 level, becoming progressively smaller down to the C-6 to C-7 level. The average vertical diameter is 10 mm, and the transverse diameter is 5 mm. In addition to the nerve roots, the intervertebral foramina contain the spinal radicular arteries, intervertebral veins and plexuses, and extension of the epidural space, with loose areolar tissue and solid and liquid fat. These provide a protective cushion for the neural elements.

The dorsal root ganglia vary in location, with the upper two located above the vertebral arches and those of the lower cervical segments located partly within and partly distal to the intervertebral foramina in the gutter of the transverse processes, where they are close to the vertebral artery (Fig. 54-13).

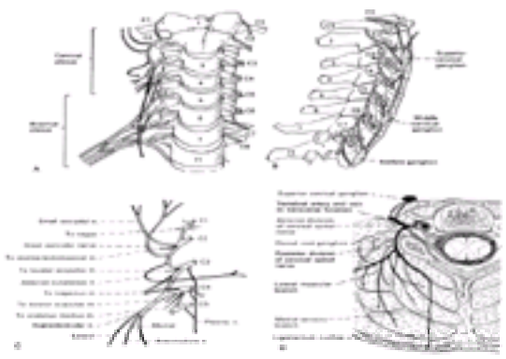

Figure 54-13. Cervical and first thoracic spinal nerves. **A:** Anterior view showing the formation of the cervical and brachial plexuses. **B:** Lateral view showing the course and relation of the cervical nerves and the cervical sympathetic chain. **C:** Origin and composition of the cervical plexus. **D:** Cross-section of the third cervical segment showing the course and distribution of the posterior primary division, with its medial branch passing posteriorly to supply the skin and subcutaneous structures and the lateral branch supplying the muscles. Also shown is a cross-section of the superior cervical ganglion and its connection to the nerve by the white ramus communicantes. Note the vertebral vessels just anterior to the nerve.

The two roots join just beyond the dorsal root ganglion to form the composite spinal nerve. The upper two cervical nerves pass laterally and slightly superiorly, with the first passing between the occiput and C-1 and the second passing between C-1 and C-2. The roots and formed nerves below the C-2 level course within the gutter of the transverse process in a lateral and downward direction and become more oblique with lower levels.

Immediately after emerging from the spinal canal each nerve receives one, two, or more gray rami communicantes from the cervical sympathetic ganglia. The superior cervical sympathetic ganglion contributes fibers to the upper four cervical spinal nerves, the middle and intermediate ganglia to the fifth and sixth nerves, and the inferior ganglion to the seventh and eighth nerves, whereas the first thoracic sends gray rami communicantes over to the eighth cervical and first thoracic nerves. Each cervical spinal nerve gives off a recurrent meningeal branch that returns to supply the coverings of the spinal cord.

At a point approximately 1 cm lateral to the foramen, just posterior to the vertebral artery, each nerve divides into the posterior and anterior primary divisions (Fig. 54-14; see Fig. 54-13). Except for C-1, the anterior divisions are much larger than the posterior divisions. Each cervical spinal nerve, like most spinal nerves, has motor fibers that supply specific muscles (myotomes) and sensory fibers that supply skin (dermatomes) and bones and ligaments (sclerotomes). The structures supplied by each cervical nerve and the first thoracic segments are summarized here (see Table 54-2,Table 54-3, and Table 54-4).

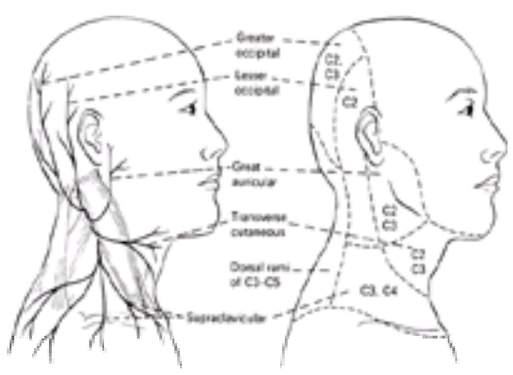

Figure 54-14. Cutaneous nerves derived from the cervical plexus (see text for details).

Muscle	Nerve supply	Muscle	Nerve supply
Capital flexors		Cervical spine extensors	
Rectus capitis anterior	C-1, C-2	Iliocostalis cervicis	C-4 to C-7
Rectus capitis lateralis	C-1, C-2	Longissimus cervicis	C-1 to C-6*
Longus capitis	C-1 to C-4	Semispinalis cervicis	C-1 to C-6*
		Multifidus	C-1 to S-1
Capital extensors			
Rectus capitis posterior major	C-1	Head rotators†	
Rectus capitis posterior minor	C-1	Sternocleidomastoid	Spinal accessory
Obliquus capitis superior	C-1	Splenius cervicis

TABLE 54-2. Nerve supply of muscles of the neck

Segment	Vertebrae	Joints	Ligaments
C-1	Periosteum and body of atlas	Atlantoaxial, medial, atlantoaxial, lateral, atlantoaxial	Alar, cruciform, apical dental, accessory atlantoaxial, articular capsules, medial, anterior atlantooccipital membranes, posterior atlantooccipital membrane
C-2	Periosteum and body of axis	Medial atlantoaxial, lateral atlantoaxial, intervertebral	Anterior longitudinal, atlantoaxial membranes, atlantoaxial, capsules, cruciform, nuchal
C-3	Periosteum and body of C-3 vertebra and dentin	Intervertebral, Luschka, uncovertebral, zygapophyseal	Anterior longitudinal, posterior longitudinal, capsular, nuchal
C-4	Periosteum and body of C-4 vertebra and dentin	Intervertebral, Luschka, uncovertebral, zygapophyseal	Anterior longitudinal, posterior longitudinal, capsular, ligamentum flavum, nuchal
C-5	Periosteum and body of C-5 vertebra and portions of humerus, scapula, and proximal ulna	Acromioclavicular, glenohumeral, Luschka, atlantoaxial, elbow, zygapophyseal, ulnocarpal	Anterior longitudinal, posterior longitudinal, capsular, nuchal, ligamentum flavum
C-6	Periosteum and body of C-6 vertebra and portions of humerus, radius, scapula, and first metacarpal bone	Glenohumeral, intervertebral, Luschka, elbow, zygapophyseal	Anterior longitudinal, posterior longitudinal, capsular, nuchal, ligamentum flavum
C-7	Periosteum and body of C-7 vertebra and portions of humerus, scapula, radius, and ulna	Elbow, Luschka, intervertebral, zygapophyseal	Anterior longitudinal, posterior longitudinal, nuchal, ligamentum flavum
C-8	Periosteum and body of C-8 vertebra and portions of humerus, ulna, carpal bones, and bones of hand and fifth fingers	Intervertebral, Luschka, zygapophyseal, elbow, wrist, hand	Supraspinous, interspinous, anterior longitudinal, posterior longitudinal
T-1	Periosteum and body of T-1 vertebra	Intervertebral, zygapophyseal, costovertebral, elbow, wrist, hand	Anterior longitudinal, posterior longitudinal, supraspinous, interspinous, ligamentum flavum

TABLE 54-3. Sclerotomal distribution pattern of the cervical and first thoracic nerves

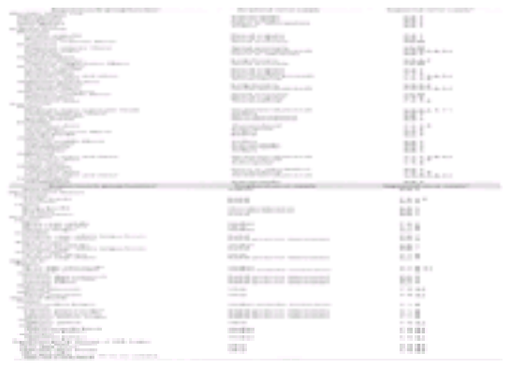

TABLE 54-4. Nerve supply of the muscles of the upper limbs

Posterior Primary Divisions. The posterior primary divisions leave the anterior division and pass posteriorly over the posterior portion of the transverse process around the articular pillar, as shown in Figure 54-13. All posterior primary divisions of the cervical nerves, with the exception of the first cervical nerve, divide into medial sensory and lateral muscular branches. The first cervical nerve, known as the suboccipital nerve, remains as one trunk and is distributed to the muscles of the suboccipital triangle. Sensory fibers of the C-1 nerve supply the periosteum and body of the atlas and occiput, atlantooccipital joint, medial and lateral atlantoaxial joints, and various ligaments around these joints. Occasionally, the C-1 nerve has a cutaneous branch that accompanies the occipital artery to the scalp and communicates with the greater and lesser occipital nerves. The lateral branches of the posterior primary divisions of the other cervical nerves supply the muscles of the posterior part of the neck, whereas the medial branches become superficial to supply the skin (see Fig. 54-13D). The medial branches of the posterior divisions of the second and third cervical nerves form the greater occipital and the third (least) occipital nerves.

Greater Occipital Nerve. The greater occipital nerve, which as noted previously is the medial (sensory) branch of the posterior division of the second cervical nerve, emerges between the posterior arch of the atlas and the lamina of the axis below the oblique inferior muscle, and then ascends obliquely on the latter muscle between it and the semispinalis muscle. It communicates with the third cervical nerve and gains the posterior part of the scalp by piercing the semispinalis and trapezius muscles near their attachment on the occipital bone in a position medial to the easily palpable occipital artery. There it gives off branches that supply the scalp over the vertex and top of the head and gives muscular branches to the semispinalis capitis.

Third (Least) Occipital Nerve. The third (least) occipital nerve arises from the medial sensory branch of the posterior division of the third cervical nerve, ascends in the same manner as the greater occipital nerve, and pierces the splenius capitis and trapezius just medial to the greater occipital nerve. It then ascends in the superficial fascia of the scalp to reach the vertex of the skull.

Anterior Primary Division. The anterior primary division of the cervical nerves passes laterally behind the vertebral artery and between the anterior and posterior intertransversalis muscles lying on the sulcus of the transverse processes of the vertebrae. The anterior rami of the upper four cervical nerves communicate with each other to form the cervical plexus, whereas the lower four cervical nerves and first thoracic nerve unite to form the brachial plexus.

Cervical Plexus

The cervical plexus is formed by the anterior primary divisions of the upper four cervical nerves. After emerging from the sulcus all the anterior trunks (except the first) divide into ascending and descending branches, forming a series of three loops. These loops are situated lateral to the vertebrae and anterior to the levator scapulae and scalenus medius muscles, and are covered by the sternocleidomastoid muscle. From these three loops two sets of branches, the deep and superficial, originate. The cervical plexus communicates with the vagus, hypoglossal, and accessory cranial nerves.

Deep Branches. The deep branches of the cervical plexus remain deep in the neck beneath the sternocleidomastoid muscle. One group of branches proceeds from beneath the muscle in a posterolateral direction toward the posterior triangle and is accordingly named the lateral (external) group. This group gives off muscular branches to the scalenus medius, sternocleidomastoid, trapezius, and levator scapulae muscles and several communicating branches that join the spinal accessory nerve. The other group of branches runs forward and medially toward the anterior triangle and is accordingly named the medial (internal) group. It gives off communicating filaments that join the vagus and the hypoglossal nerves, the descendens hypoglossi, and the superior cervical sympathetic ganglion. This medial group also sends muscular branches to the rectus capitis, lateralis, and anticus, longus capitis and longus colli muscles, and the diaphragm by way of the phrenic nerve. By means of the ansa hypoglossi it also supplies the thyrohyoid, geniohyoid, omohyoid, sternothyroid, and sternohyoid muscles (see Table 54-2).

Superficial (Cutaneous) Branches. The superficial branches of the cervical plexus constitute what is sometimes called the *superficial cervical plexus*. From their point of origin these branches proceed superficially to reach and pierce the deep fascia at approximately the middle of the sternocleidomastoid muscle, where they become subcutaneous. They then curve around the posterior border of the muscle and proceed in one of three general directions to supply the skin and superficial fascia of various parts of the head, neck, and shoulder (see Fig. 54-14).

Lesser Occipital Nerve. The lesser occipital nerve is derived from the anterior primary division of the second cervical nerve or from a loop derived from the second and third cervical nerves. It ascends along the sternocleidomastoid muscle, curving around its posterior border and, near the insertion of the muscle on the cranium, it perforates the deep fascia to continue cephalad along the side of the head, behind the ear, to supply the skin of this part of the scalp. This nerve communicates with the greater occipital and greater auricular nerves to contribute sensory fibers to the posterior part of the scalp. Through its auricular branch it supplies the upper and posterior part of the auricula and communicates with the mastoid branch of the great auricular nerve.

Great Auricular Nerve. The great auricular nerve, larger than the lesser occipital nerve, arises from the second and third cervical nerves, winds around the posterior border of the sternocleidomastoid, and, after perforating the deep fascia, ascends on the surface of that muscle deep to the platysma and divides into an anterior and posterior branch. The anterior (facial) branch is distributed to the skin of the face over the parotid gland and communicates with the facial nerve within the substance of the gland. The posterior (mastoid) branch supplies the skin over the mastoid process in back of the auricula, except its upper part. A filament of the nerve pierces the auricula to reach its lateral surface, where it becomes distributed to the lobule and lower part of the concha. This nerve communicates with the lesser occipital nerve, the auricular branch of the vagus nerve, and the posterior auricular branch of the facial nerve.

Anterior Cutaneous Nerve. The anterior cutaneous nerve arises from the second and third cervical nerves, bends around the posterior border of the sternocleidomastoid at its midportion, and then crosses the surface of the muscle obliquely as it runs horizontally anteriorly. It perforates the deep fascia, passing deep to the external jugular vein, pierces the platysma, and divides into ascending and descending branches. The ascending branches pass cranialward to the

submandibular region, pierce the platysma, and are distributed to the cranial, ventral, and lateral aspects of the neck. The descending branches pierce the platysma and are distributed to the skin of the anterolateral aspects of the neck as far as the sternum.

Supraclavicular Nerve. The supraclavicular nerve arises from the third and fourth cervical nerves (mainly the fourth) and, like the anterior cutaneous nerve, emerges from under the posterior border of the sternocleidomastoid, descends caudad, and divides into three groups of nerves: the medial, intermediate, and lateral supraclavicular nerves. These three groups pass caudad under cover of the investing deep fascia. Near the clavicle they perforate the fascia and platysma to supply the skin and superficial fascia of the clavicular region and the periosteum and bony structure of the clavicle.

The medial (anterior) supraclavicular nerves, also known as the *suprasternal nerves*, cross the external jugular vein, clavicular head of the sternocleidomastoid, and clavicle to supply the skin of the medial infraclavicular region as far as the midline, and laterally as far as the junction of the medial and middle third of the clavicle. They furnish one or two filaments of the sternoclavicular joint.

The intermediate (middle) supraclavicular nerves cross the clavicle and supply the skin over the pectoralis major as far as the second or third rib and communicate with the cutaneous branches of the second and third intercostal nerves.

The lateral (posterior) supraclavicular nerves, also known as the *supraacromial nerves*, pass obliquely across the outer surface of the trapezius and the acromion and supply the skin of the top and dorsal parts of the shoulder. The distribution of the supraclavicular nerves is depicted in Figure 54-14.

Brachial Plexus

The brachial plexus supplies all the motor and almost all the sensory functions of the upper extremity. It is formed by the union of the anterior primary divisions of the fifth, sixth, seventh, and eighth cervical nerves and first thoracic nerve and frequently receives small contributing branches from the anterior primary division of the fourth cervical and second thoracic nerves (Fig. 54-15). After these anterior primary divisions leave the posterior primary divisions outside of their respective intervertebral foramina, they proceed anterolaterally and inferiorly to occupy the interval between the anterior and middle scaleni muscles where they unite to form three trunks, thus initiating the formation of the plexus proper (see Fig. 54-15).

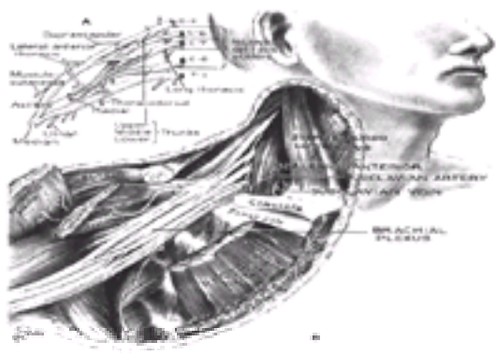

Figure 54-15. Anatomy of the brachial plexus. **A:** Schematic depiction of the brachial plexus. **B:** Relation of the roots of the brachial plexus to the scalene muscles showing the position of the plexus over the first rib and its course into the axilla.

The primary divisions of the fifth and sixth cervical nerves unite to form the upper trunk; the seventh primary division remains alone to become the middle trunk; the eighth cervical and first thoracic nerves unite to form the lower trunk. The three trunks emerge from the interscalenus space at the lower border of these muscles and continue in an anterolateral and inferior direction to converge toward the upper surface of the first rib, where they are closely grouped. At the lateral edge of the rib each trunk divides into anterior and posterior divisions, which pass beneath the midportion of the clavicle to enter the axilla through its apex.

These divisions, by which fibers of the trunk reassemble to gain the ventral and dorsal aspects of the limb, reunite within the axilla to form three cords named the lateral, medial, and posterior because of their relationship to the second part of the axillary artery (Table 54-1). The lateral cord is formed by the union of the anterior divisions of the upper and middle trunks, thus containing fibers derived from the fifth, sixth, and seventh cervical nerves; the medial cord is the continuation of the anterior division of the lower trunk, thus containing fibers derived from the eighth cervical and first thoracic nerves; the posterior cord is formed by the union of all the posterior divisions, thus containing fibers derived from all the nerves making up the plexus.

Structure	Nerve Levels
Branches of cervical nerves	
To phrenic nerve	C-5
To longus colli and scalenii muscles	C-5 to C-7
Branches from roots	
Dorsal scapular nerve	(C-4), C-5
Long thoracic nerve	C-5 to C-7
Branches from trunks (superior trunk)	
Nerve to subclavius	C-5, C-6
Suprascapular nerve	C-5, C-6
Posterior cord (origin chiefly all trunks)	C-5 to C-8, T-1
Branches	
Superior subscapular nerve	C-5, C-6
Inferior subscapular nerve	C-5, C-6
Thoracodorsal nerve	C-6 to C-8
Terminal branches	
Axillary	C-5, C-6
Radial	C-5 to C-8, T-1
Lateral cord (origin superior and middle trunks)	C-5 to C-7
Branches	
Anterior pectoral	C-5 to C-7
Terminal branches	
Musculocutaneous nerve	C-5 to C-7
Median nerve, lateral portion	C-6, C-7
Medial cord (origin inferior trunk)	C-8 to T-1
Branches	
Medial brachial cutaneous nerve	C-8 to T-1
Medial antibrachial cutaneous nerve	C-8 to T-1
Terminal branches	
Ulnar nerve (medial portion)	C-8 to T-1
Median nerve (medial portion)	C-8 to T-1

TABLE 54-1. Organization and branches of the brachial plexus

At the lateral border of the pectoralis minor the three cords break up to give rise to the peripheral nerves of the upper extremity: The lateral cord gives off the lateral head of the median nerve and the musculocutaneous nerve; the medial cord gives off the medial head of the median nerve, the ulnar, the medial antebrachial and brachial cutaneous nerves, and a branch to the intercostobrachial nerve; and the posterior cord terminates as the axillary and radial nerves. These peripheral nerves proceed to the arms, forearms, and hands.

In addition to the terminal branches constituting the peripheral nerves of the upper extremity, the brachial plexus issues other branches and receives communicating fibers. Immediately after their emergence from the intervertebral foramina, the anterior divisions of the cervical and first thoracic nerves receive postganglionic gray rami communicantes from the lower two-thirds of the cervical sympathetic chain and the uppermost thoracic sympathetic chain (described later in this chapter). The anterior divisions of the fifth, sixth, seventh, and eighth cervical nerves also send fibers to the longus colli and to the three scaleni muscles, whereas that of the fifth cervical nerve sends fibers to the phrenic nerve and gives off the dorsal scapular nerve, which supplies the rhomboidei and levator scapulae muscles. In addition, the anterior divisions of the fifth, sixth, and seventh cervical nerves contribute fibers to form the long thoracic nerve, which supplies the serratus anterior muscle (see Table 54-4).

The next set of branches is derived from the upper trunk, which gives off the suprascapular and the subclavius nerves, both of which contain fibers from the fifth and sixth cervical segments. The suprascapular nerve proceeds posteriorly to supply the supraspinatus and infraspinatus muscles and the shoulder joint, whereas the subclavius nerve supplies the subclavius muscle.

Within the axilla, in addition to the terminal branches, the lateral cord gives off the lateral anterior thoracic nerve, the medial cord gives off the medial anterior thoracic nerve, and the posterior cord gives off the upper and lower subscapular and thoracodorsal nerves. The anterior thoracic nerves supply the pectoralis major and minor,

the subscapular nerves supply the subscapular muscle and the teres major, and the thoracodorsal nerve supplies the latissimus dorsi. The following description of some of the major branches of the brachial plexus primarily concerns those that provide sensory innervation to various structures. (The distribution of the most important cutaneous nerves is depicted in Figure 54-19.)

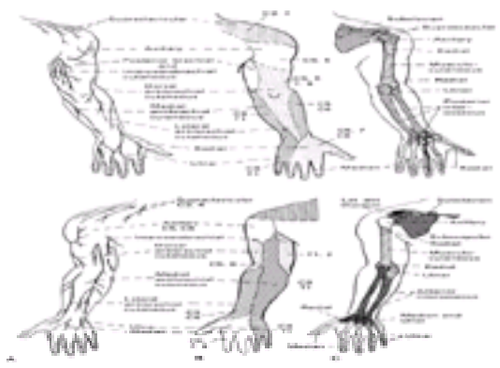

Figure 54-19. Peripheral nerve supply to the upper limb showing the anterior view (*above*) and posterior view (*below*). **A:** Various cutaneous nerves and their territories **(B)**. **C:** Nerve supply to the bones and joints.

Suprascapular Nerve. The suprascapular nerve contains sensory, motor, and sympathetic fibers that supply the supraspinatus and infraspinatus muscles, the shoulder joint, and some of the surrounding structures. Its component fibers are derived from the fourth, fifth, and sixth cervical segments and travel through the anterior primary divisions to reach the upper trunk of the brachial plexus, from which the formed suprascapular nerve emerges. It then proceeds laterally, posteriorly, and inferiorly beneath the posterior belly of the omohyoideus and trapezius muscles, but superficial to the plexus, to reach the superior border of the scapula (see Fig. 54-19). Here it passes through the suprascapular notch beneath the superior transverse scapular ligament and enters the supraspinatus fossa, where it gives off several branches to the supraspinatus muscle and an articular branch to the acromioclavicular and shoulder joints. It then courses around the spinoglenoid notch beneath the inferior transverse scapular ligament to end in the infraspinatus fossa, where it issues branches to the shoulder joint and its periarticular tissues and terminal branches to the infraspinatus muscle. It often gives off a minor cutaneous branch that supplies a small skin area at the apex of the shoulder.

Axillary Nerve. The axillary nerve is the last branch of the posterior cord of the brachial plexus before the latter becomes the radial nerve. It passes over the insertion of the subscapularis muscle dorsal to the axillary artery, crosses the teres minor, and leaves the axilla by passing through the quadrilateral space, where it divides into several branches. The posterior (lower) branch supplies the teres minor and the posterior part of the deltoid. It then pierces the deep fascia at the posterior border of the deltoid as the lateral brachial cutaneous nerves to supply the skin over the distal two-thirds of the posterior aspect of the muscle and over the adjacent head of the triceps brachii. The anterior (upper) branch winds around the surgical neck of the humerus under cover of the deltoid muscle as far as its anterior border to supply this muscle, and sends small cutaneous filaments to the skin covering its distal part. The articular branches of the axillary nerve leave the nerve near its origin and, in the quadrilateral space, supply the anterior and inferior parts of the capsule of the shoulder joint.

Musculocutaneous Nerve. As mentioned previously, the musculocutaneous nerve is derived from the lateral cord, pierces the coracobrachialis muscle, and, lying between the brachialis and the biceps brachii, crosses to the lateral surface of the arm. A short distance above the elbow, it pierces deep fascia lateral to the tendon of the biceps and continues into the forearm as the lateral antebrachial cutaneous nerve. During its course it gives off a branch to the coracobrachialis muscle, provides muscular branches to the biceps and brachialis, supplies an articular filament to the elbow joint, and gives off a branch to the humerus that enters the nutrient foramen with the artery (Fig. 54-16). The lateral antebrachial cutaneous nerve breaks into an anterior branch that supplies the skin over the radial half of the anterior surface and the skin over the thenar eminence. The dorsal (posterior) branch passes distally along the dorsal part of the radial surface of the arm, supplying the skin almost to the wrist and communicating with the dorsal antebrachial cutaneous nerve and superficial branch of the radial nerve.

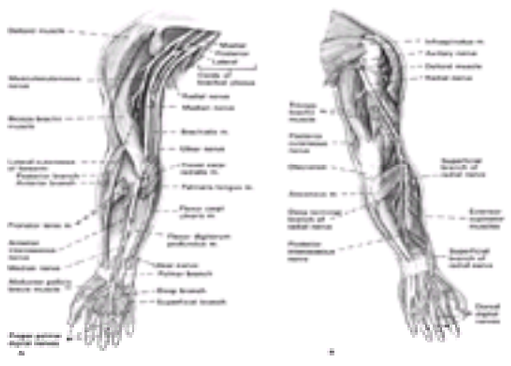

Figure 54-16. Anatomy of the median, ulnar, and radial nerves. Anterior view **(A)** and posterior view **(B)** of the upper limb showing the course of the three nerves and some of the muscles (m.) they supply.

Median Nerve. The median nerve is composed of fibers derived from the sixth, seventh, and eighth cervical nerves and first thoracic nerve and, in some cases, the fifth cervical segments. These fibers traverse the three trunks and their anterior divisions to reach the medial and lateral cords from which the nerve emerges by two heads, the medial head from the medial cord and the lateral head from the lateral cord. These two heads unite at the lower border of the pectoralis minor in the uppermost part of the arm to form the median nerve, which descends down the medial side of the arm in company with the brachial vessels, at first lying lateral to the artery and then medial to it after crossing it obliquely at approximately the middle of the humerus (see Fig. 54-16). At the bend of the elbow it is situated beneath the lacertus fibrosus medial to the artery and the tendon of the biceps and is separated from the elbow joint by the brachialis muscle.

The nerve then proceeds to the forearm, first passing between the two heads of the pronator teres and then between the flexor digitorum sublimis and the flexor digitorum profundus. It courses straight down the forearm, lying between these two muscles to come within 5 cm of the transverse carpal ligament, where it becomes more superficial and is situated between the flexor carpi radialis and the flexor digitorum sublimis posterolateral to the tendon of the palmaris longus. It then passes dorsal to the transverse carpal ligament and into the palm of the hand, where it terminates as muscular branches to the first and second lumbricales, abductor pollicis brevis, opponens pollicis, and superficial head of the flexor pollicis brevis, and as cutaneous branches to the radial two-thirds of the palm and the dorsal aspects of the second, third, and fourth fingers.

At the elbow the median nerve gives off articular branches to the elbow joint and at the forearm it gives off muscular branches to all the pronators and flexor muscles of the forearm, except the flexor carpi ulnaris and the ulnar half of the flexor digitorum profundus, and a palmar cutaneous branch, which pierces the volar carpal ligament, descends across the transverse carpal ligament, and is distributed to a small area of skin on the radial side of the palm. The median nerve supplies filaments to the median artery and its branches (see Segmental and Peripheral Nerve Supplies to the Neck and Upper Limbs, later in this chapter). It also gives articular osseous branches to the wrist and fingers.

Ulnar Nerve. The ulnar nerve supplies the muscles and some of the skin and bones of the ulnar side of the forearm and hand (see Fig. 54-16). The component fibers are derived from the eighth cervical and first thoracic segments and pass through the lower trunk and its anterior division and through the medial cord, from which the nerve arises just medial to the axillary artery. After emerging from the cord at the lower border of the pectoralis minor it descends on the medial side of the arm in front of the triceps muscles, medial to the brachial artery as far as the middle of the arm. Here it pierces the medial intermuscular septum to pass into the posterior compartment of the arm together with the superior ulnar collateral artery. It continues its descent on the medial head of the triceps into a groove between the medial epicondyle and the olecranon, where it is superficially situated and lies immediately beneath the skin and deep fascia; thus, it is easily palpable and accessible to the

anesthetizing needle.

The ulnar nerve then passes between the two heads of the flexor carpi ulnaris to gain the forearm and descend toward the wrist, lying between the flexor digitorum profundus and flexor carpi ulnaris on the medial side of the ulnar artery. During its course in the forearm it gives off branches to the flexor carpi ulnaris and to the ulnar half of the flexor digitorum profundus. At a point approximately 5 cm above the wrist it gives off the palmar cutaneous branch, which ends in the skin of the palm, and a dorsal cutaneous branch, which passes posteriorly to supply the skin of the dorsal surface of the wrist, hand, little finger, and ulnar half of the ring finger. The ulnar nerve then proceeds distally by passing superficial to the transverse carpal ligament, lateral to the pisiform bone, and posteromedial to the ulnar artery, finally reaching the palm, where it ends by dividing into the superficial and deep terminal branches. The superficial branch supplies the skin over the ulnar side of the hand, little finger, and ulnar side of the ring finger, whereas the deep terminal branch supplies the adductor pollicis, interossei, third and fourth lumbricales, deep head of the flexor pollicis brevis, palmaris brevis, and abductor, opponens, and flexor digiti quinti muscles.

The ulnar nerve gives off articular branches to the elbow, wrist and finger joints, vascular filaments that supply the ulnar vessels and their termination, and filaments to bones that supply the medial condyle of the humerus, the medial half of the upper extremity of the ulna, the bones of the little and ring fingers, and contributes to the innervation of the carpal bones.

Radial Nerve. The radial or musculospiral nerve is the largest peripheral nerve derived from the brachial plexus. Its component fibers arise from the fifth, sixth, seventh, and eighth cervical and first thoracic spinal segments, traverse through the three trunks and their posterior divisions, and finally unite within the posterior cord to form the nerve (Fig. 54-17; see Fig. 54-16). Because of its relative size, the radial nerve is often considered as the direct continuation of the posterior cord. From its point of origin at the lower border of the pectoralis minor, the radial nerve descends laterally and inferiorly behind the third part of the axillary artery and the upper part of the brachial artery and in front of the tendons of the latissimus dorsi and teres major. At the lower border of these tendons it turns posteriorly and proceeds distally in a spiral fashion around the humerus within the musculospiral groove between the medial and lateral heads of the triceps muscle. While within the groove it gives off the dorsal antebrachial cutaneous nerve, which supplies the dorsal aspect of the forearm. The radial nerve descends within the groove to a point approximately 10 cm above the external condyle of the humerus, where it pierces the lateral intermuscular septum and enters a cleft between the brachialis and brachioradialis muscles. Within these muscles it continues its descent, first on the anterior aspect of the humerus and then in front of the elbow joint.

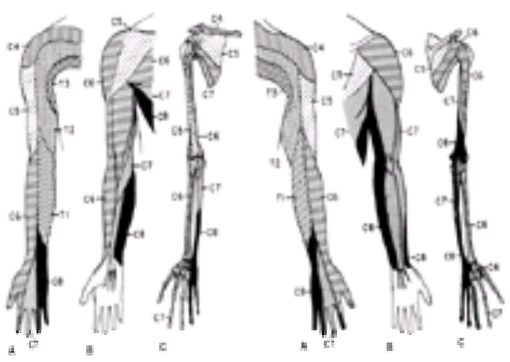

Figure 54-17. Segmental nerve supply to the upper limb showing the anterior view (*left*) and posterior view (*right*). **A:** Dermatomes. **B:** Myotomes. **C:** Sclerotomes.

The nerve then enters the substance of the supinator brevis where it divides into superficial and deep posterior branches, often called the dorsal interosseous nerve. The deep branch passes posteriorly through the substance of the supinator brevis muscle to wind around the lateral side of the radius and become situated between the superficial and deep layers of the extensor muscles on the posterior aspect of the forearm, to which it supplies numerous filaments. It continues its descent and finally reaches the dorsal aspect of the wrist and hand, where it presents a ganglioform enlargement from which filaments are distributed to the ligaments, articulations, and bones of the wrist.

The superficial branch, often considered to be the continuation of the radial nerve and so named, proceeds along the anterior aspect of the forearm beneath the brachioradialis muscle to reach the lateral (radial) side of the radial artery approximately 5 cm distal to the elbow. It continues its descent in this relation to a point approximately 7 cm proximal to the wrist, where it diverges from the artery, passes posteriorly beneath the tendon of the brachioradialis, pierces the deep fascia, and divides into lateral and medial branches. The lateral branch supplies the skin of the radial side and ball of the thumb, whereas the medial branch communicates with a branch of the lateral antebrachial cutaneous nerve and the dorsal branch of the ulnar nerve and supplies the radial two-thirds of the dorsal surface of the hand and thumb and the index, middle, and ring fingers.

In addition to these branches, the radial nerve gives off the posterior brachial cutaneous nerve that arises in the axilla and supplies the back of the arm; muscular branches that supply the triceps, anconeus, brachialis, and brachioradialis muscles; articular branches to the elbow, wrist and finger joints; filaments to bones, including part of the humerus, radius, ulna, and carpal bones; and vascular filaments that supply part of the axillary, brachial, and radial arteries and veins.

SEGMENTAL AND PERIPHERAL NERVE SUPPLIES TO THE NECK AND UPPER LIMBS

This section summarizes the segmental and peripheral nerve supplies to various structures in the neck, shoulders, and upper limbs. In addition, detailed descriptions of the sympathetic nerve supply to the vessels of the upper limbs are presented. Table 54-2 lists the myotomal distribution to the muscles in the neck. Table 54-3 lists the sclerotomal distribution of the first cervical to the first thoracic nerves, and Table 54-4 lists the peripheral and segmental nerve supplies to the muscles of the upper limbs. Figure 54-17 depicts the segmental nerve supply to the upper limb. Figure 54-18 depicts the dermatomal distribution of the upper four cervical nerves, and Figure 54-19 illustrates the peripheral nerve supply to the upper limbs.

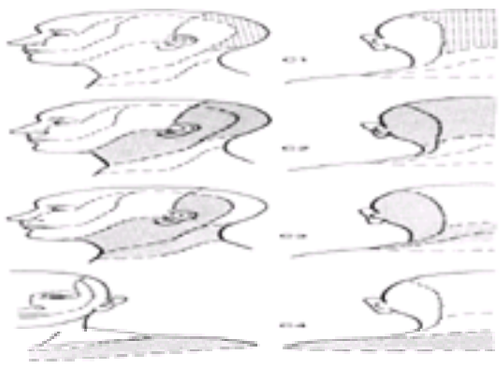

Figure 54-18. Dermatomes of the neck and head derived from the upper four cervical nerves.

Anatomy and Physiology of Sympathetic Nerves

Sympathetic Nerve Supply to Upper Limbs

The sympathetic nerve supply to the upper limbs begins with preganglionic cell bodies located in the anterolateral horn of the spinal cord at the second to eighth thoracic spinal cord segments (Fig. 54-20). In a small percentage of individuals the uppermost preganglionic cell bodies are located in the first thoracic and, in rare cases, the eighth cervical ramus, whereas the lowermost can be in the ninth or tenth, or in rare cases the seventh spinal segment (13,14,15,16 and 17). The axons of

these neurons pass through the anterior roots and white rami communicantes and thus reach the sympathetic trunk. They then ascend within the sympathetic trunk and end and synapse with postganglionic neurons primarily in the second and first and inferior cervical (stellate) ganglia, often in the intermediate and middle cervical ganglia, and in some individuals in the third thoracic ganglion. It has been shown that the second thoracic ganglion contains the greatest number of synaptic connections for the upper limb (18,19 and 20). Afferent fibers from the vessels of the upper limb enter the spinal cord through the first, second, and third thoracic, and even the fourth thoracic dorsal roots (17,18).

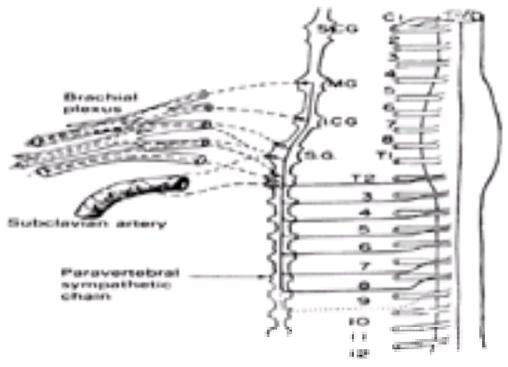

Figure 54-20. Schematic depiction of the origins and courses of preganglionic sympathetic neurons destined to supply the upper limbs. Note that the axons of the preganglionic neurons, which are located in spinal segments T-2 to T-8 (and occasionally T-9), pass through the anterior root as white rami communicantes and from there to the paravertebral sympathetic chain, where they ascend and synapse with postganglionic fibers primarily in the second thoracic, stellate, and intermediate and middle cervical ganglia, and occasionally in the third cervical ganglion (not shown). Some of the postganglionic fibers pass directly to the subclavian artery, but most pass as gray rami communicantes to the roots of the brachial plexus. (From Bonica JJ. *Clinical application of diagnostic and therapeutic nerve block*s. Springfield, IL: Charles C Thomas, 1959.)

Some postganglionic neurons pass directly from the sympathetic trunk as vascular filaments to the subclavian artery and to some of its branches. The principal bulk of postganglionic fibers, however, form the gray rami communicantes that connect the sympathetic trunk to the fifth, sixth, seventh, and eighth cervical nerves and first thoracic spinal nerve, the anterior divisions of which form the brachial plexus. Every one of these nerves receives one or more gray rami communicantes, with the middle and the intermediate cervical ganglia giving one set of gray rami communicantes to the fifth and another to the sixth cervical nerves; the stellate ganglion gives one or two gray rami communicantes to the sixth cervical nerves, two gray rami communicantes to the seventh cervical nerve, and three each to the eighth cervical and first thoracic nerves (Fig. 54-21). According to Sunderland (19), the postganglionic fibers do not travel as distinct bundles in the trunk of the brachial plexus, but are widely dispersed in the components of the plexus, especially where it crosses the first rib.

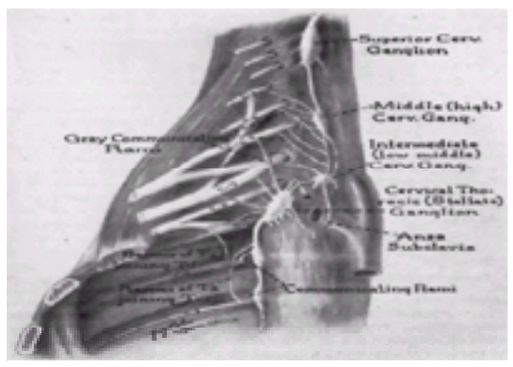

Figure 54-21. Distribution of gray rami communicantes from the cervical and upper thoracic sympathetic ganglia to the roots of the cervical and brachial plexus. Note that postganglionic fibers from T-3 ganglion pass to the third thoracic spinal nerve and from there to the second spinal nerve, and that gray rami communicantes from the second thoracic ganglion pass to the second thoracic spinal nerve and from there to the first thoracic nerve. These nerves constitute a pathway of sympathetic nerves to the brachial plexus that bypass the stellate ganglion and the intermediate and middle cervical ganglia. (From Moore DC. *Stellate ganglion block*. Springfield, IL: Charles C Thomas, 1954.)

In addition, in a significant number of people, an intrathoracic somatic branch arising from the second thoracic spinal nerve joins the first thoracic spinal nerve, which of course takes part in the formation of the brachial plexus. This intrathoracic branch is almost always joined by proximal gray rami communicantes carrying postganglionic fibers that arise in the second thoracic sympathetic ganglion, possibly in lower ganglia, and distal white ramus communicantes (15,20) (see Fig. 54-21). In some individuals a branch also arises from the third thoracic spinal nerve and passes to the second spinal nerve. This second intrathoracic nerve, which also contains preganglionic sympathetic fibers that arise from the third thoracic ganglion, joins the second thoracic spinal nerve proximal to the branch sent by the latter nerve to the first thoracic nerve. Thus, it is apparent that these inconstant preganglionic and postganglionic sympathetic pathways, known as *Kuntz's nerves* (17,20), pass to the lower part of the brachial plexus without passing through the stellate ganglion, a fact of critical importance in attempting complete sympathetic denervation of the upper extremity as previously practiced by Leriche (21). Thus, a pure stellectomy or local anesthetic block limited to the stellate ganglion does not produce complete sympathetic denervation of the upper limbs. In such cases it is also essential to block or resect the second and third thoracic ganglia to denervate the limb completely. Moreover, because all the fibers to the upper limbs pass through the second and occasionally the third thoracic ganglia, they are the key relay stations that can be blocked by small amounts of neurolytic agents or resected surgically to produce sympathetic denervation of the extremity (17,22,23).

Innervation of Blood Vessels, Sweat Glands, and Erector Pilae Muscles. The blood vessels, sweat glands, and erector pilae muscles of the upper extremities receive their innervation by sympathetic fibers that reach them either directly from the sympathetic trunk or indirectly from the peripheral nerves. The subclavian artery, axillary artery, and proximal portion of the brachial artery are supplied by sympathetic postganglionic fibers derived directly from the sympathetic trunk. The lower two-thirds of the brachial artery and all its branches are supplied by sympathetic fibers conveyed peripheralward by the brachial plexus and its constituent nerves, particularly the median, radial, and ulnar nerves. These are distributed to various blood vessels at irregular intervals, with most distal vessels having a greater number of sympathetic fibers than the more proximal ones. These vascular fibers have the same distribution as the nerves that convey them peripheralward, and, in the forearm, their distribution is sharply demarcated into the ulnar, median, and radial zones. The sympathetic supply to the major blood vessels of the upper limbs is depicted in Figure 54-22 and described in detail here. What is said about the arteries applies to the analogous veins.

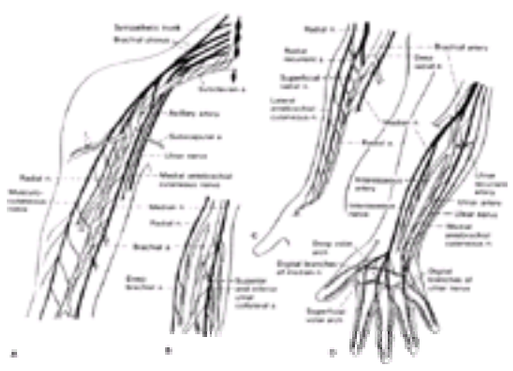

Figure 54-22. **A–D:** Sympathetic nerve supply to the arteries in the upper limbs.

Innervation of the Subclavian Artery and Its Branches. As previously mentioned, the subclavian artery and its branches receive postganglionic fibers directly from the sympathetic trunk, primarily the stellate and middle cervical ganglia. On reaching the artery these fibers form a plexiform network known as the subclavian arterial plexus and subsidiary plexuses, which surround the major branches of the artery. Some of these fibers extend to and surround the axillary artery and the upper third of the brachial artery. These arteries also receive vascular branches from the ansa subclavia and from the paravertebral ganglia, which pass to the seventh and eighth cervical nerves and thence through the lower trunk of the brachial plexus, and a vascular branch from the phrenic nerve. These various contributions form the anterolateral and posterolateral subclavian sympathetic plexuses (nerves) that supply the postscalenic portion of the subclavian artery and contain both sympathetic and sensory fibers.

Vessels of Axilla and Arm

Innervation of the Axillary Artery and Its Branches. The axillary artery is supplied by sympathetic and sensory fibers of a nerve from the posterior cord of the brachial plexus and by extension of the subclavian arterial plexus. The nerve supplied by the brachial plexus travels along the posterior wall of the axillary artery and splits into a twig for the anterior wall of this artery, a second branch for the circumflex scapular artery, and a third branch for the subscapular arteries. The proximal part of the posterior humoral circumflex artery receives a nerve that has a common origin with that of the upper third of the brachial artery. Hovelacque (24) described the axillary artery as being supplied by several nerves: The brachial plexus innervates the upper two-thirds, and the radial circumflex nerve and occasionally the musculocutaneous nerve supply the lower third of this blood vessel (see Fig. 54-22A). In addition, the axillary plexus receives filaments from the pectoral ansa.

Innervation of the Brachial Artery. Various anatomic descriptions indicate that principal vascular nerves containing sympathetic and sensory fibers that supply the brachial artery traverse the medial and lateral cords of the brachial plexus, but accompany the peripheral nerves in a variable manner before they reach the wall of the blood vessels. Pick (17,18), an outstanding authority on the nerve supply to the upper limbs, found that the nerve supply to the brachial artery was meager and distinctly segmental in nature.

The upper third of the brachial artery is innervated by the same nerve from the posterior cord of the brachial plexus (i.e., the radial nerve) that also supplies the posterior humoral circumflex artery, and also by filaments derived from the median and musculocutaneous nerves (see Fig. 54-22A) (18,25). The middle third is innervated by filaments derived from the musculocutaneous and median nerves (24). In some instances it is supplied by a new nerve that has a double root of origin, one from the ulnar and another from the radial nerves (see Fig. 54-22B) (17). The branch from the radial nerve also supplies the profunda brachii artery. The lower third of the brachial artery receives three nervelets from the musculocutaneous nerve and some filaments from the median nerve, which also issues a twig to the superior and inferior ulnar collateral arteries and, in addition, sends other filaments that supply the inferior ulnar collateral artery and the brachial artery in the cubital fossa (see Fig. 54-22B) (17).

Vessels of the Forearm and Hand. The arteries and veins in the forearm and in those of the hand, especially the fingers, receive the richest and most complex sympathetic and sensory nerve supplies (Fig. 54-22C and Fig. 54-22D). In the forearm the major arteries and veins receive fine sympathetic and sensory fibers from the medial, radial, and ulnar nerves and also from the antebrachial cutaneous nerves. These fine fibers take off from the parent nerve trunks at irregular intervals and are embedded in connective tissue. Moreover, these are supplied at much more frequent intervals than those in the proximal vessels. They run nearly parallel to each other from the nerve to the vessels. In the forearm and hand the distribution of these vascular sensory and sympathetic fibers is demarcated into ulnar, medial, and radial zones.

Innervation of the Radial Artery. The sympathetic and sensory nerve supplies to the proximal third of the radial artery consist of one branch from the median nerve and two small filaments from the lateral antebrachial cutaneous nerves (17,18). One of the latter filaments also innervates the radial recurrent artery, which also receives filaments from the deep branch of the radial nerve peripherally. Most investigators (13,15,17,18,24) have found no nerve supply to the middle third of the radial artery, whereas the distal third is innervated by one filament from the superficial branch of the radial nerve and by eight individual twigs from the lateral antebrachial cutaneous nerves. Some (14,15,17,18,24) have described vascular nerves to the radial artery supplied by the musculocutaneous and superficial ramus of the radial nerve and by the main stems of the radial and median nerves (see Fig. 54-22C).

Innervation of the Ulnar Artery. Pick (17,18) described the sympathetic and sensory nerve supply to the ulnar artery as follows. The upper third of the ulnar artery and the ulnar recurrent artery are innervated by filaments from the muscular branch of the median nerve; the middle third of the ulnar artery is supplied by a strong branch of the ulnar nerve; and the distal third of the ulnar artery receives three separate branches from the ulnar nerve and a distinct ramus from the medial antebrachial cutaneous nerve. The volar interosseous artery is supplied by five nervelets from the volar interosseous nerve (see Fig. 54-22D).

Innervation of the Arteries of the Hand. Pick (17,18) also described the innervation of the arteries of the hand. The deep volar arterial arch is supplied by two filaments from the ramus profundus of the ulnar nerve. The superficial volar arterial arch has a rich nerve supply, with nearly a dozen twigs or loops from the common digital branches of the median and ulnar nerves. Each proper digital artery is given 3 to 12 or more individual twigs from its accompanying nerve. This nerve supply to the arteries corresponds to the nerve supply to the skin (see Fig. 54-22D).

Distribution of Nerve Fibers in Vessel Walls. The slender filaments containing sympathetic and sensory fibers enter the adventitia of the vessels to become the intrinsic nerves of the arteries and veins (15). At the outer part of the adventitia of the vessels they form the outer or adventitial plexus. Some of the fibers run longitudinally in the adventitia for short distances with most fibers running distally, but some also run in the opposite (cephalad) direction. * These fibers, which are both myelinated and unmyelinated, form bundles that seem to be arranged with the vasa vasorum so as to afford convenient pathways for the bundles to pass through the adventitial tissue.

From the adventitial plexus, bundles of nerve fibers, chiefly unmyelinated, approach the surface of the media of the artery (and veins) and form a plexus on its surface, the so-called border plexus. From this plexus small bundles and individual small fibers penetrate to the superficial zone of the media to form a plexus, the so-called muscular plexus. The latter is sufficient to account for the innervation of the entire musculature (15). The nerve fibers in the media form dense intricate plexuses that cover the entire coat and extend between muscle fibers, so that they circulate throughout the entire layer.

Degeneration studies indicate that the nerves at the surface and within the media are predominantly sympathetic, whereas those in the adventitia are predominantly afferent (15). The sympathetic fibers that supply the vessels of the skin, subcutaneous tissue, and other somatic structures, except the muscle, make synaptic connections with a-adrenergic receptors, whereas those that supply vessels to skeletal muscles make synaptic connections with b-adrenergic receptors.

The terminations of afferent fibers that supply vessels are either naked or encapsulated. The naked terminations can consist of small terminal branches that end in a treelike fashion or in brushlike endings, primarily in the adventitia. The encapsulated terminations end in pacinian corpuscles or in the end-bulb of Krause (15). Although some have suggested that naked nerve endings of unmyelinated C fibers enter into the intima of the arteries and veins, many investigators dispute this notion (15). It has been suggested that, if they do exist, some of these fibers are chemoreceptors, whereas others are thermal receptors or mechanoreceptors.

Some unmyelinated nerve fibers intimately associated with capillaries have been demonstrated (15). Degeneration studies indicate that these are sympathetic fibers but, because the walls of capillaries contain no contractile tissue comparable with that found in the muscles of arteries and veins, the function of these fibers is not clear.

Physiologic Aspects

The sympathetic fibers contain both vasoconstrictor and vasodilator fibers. The largest arteries, such as the subclavian and axillary arteries and the proximal portion of the brachial artery, have few or no vasomotor fibers, but the arterial trees distal to these have vasomotor fibers, with the distal vessels having more than the proximal ones. When sympathetic hyperactivity occurs, provoked by anxiety, fear, apprehension, or exposure to cold, vasoconstrictor fiber activity predominates. Similarly, loss of blood provokes a change in baroreceptor activity, with consequent stimulation of centers in the hypothalamus and thus of vasoconstrictor fibers. Increase in adrenalin secretion by the adrenal gland causes stimulation of b-adrenergic receptors located in blood vessels that supply muscles of the limbs. This results in a slight increase in systolic blood pressure (a result of the inotropic and chronotropic effects of adrenalin) and a marked decrease in diastolic pressure (because of marked vasodilation of these vessels), with consequent decrease in the mean arterial pressure. Increased secretion of noradrenalin or injection of as little

as 15 µg of adrenalin as an intravenous bolus causes increases in both the systolic and diastolic pressures and consequently in the arterial blood pressure (26).

Block of vasoconstrictor fibers causes dilation of blood vessels to the extremity because tonic impulses that normally are connected to the vessels in a more or less constant stream to maintain the musculature in a state of tonus are removed. The dilation of the arterioles and smaller arteries and veins is not complete, however, because the muscles of these vessels have an intrinsic vasomotor tone. This intrinsic vasomotor tone can be completely eliminated by direct vasomotor paralysis produced by histamine, kinins, local anesthetics applied to the blood vessels, or administration of halothane or other systemic agents that directly paralyze the muscles of these vessels.

The existence of vasodilator fibers in sympathetic nerves has been amply demonstrated in experimental animals and in humans (15). Thus, it has been shown that, when the extremities of normal subjects are naturally cool, vasodilation in response to warming the body becomes evident in the fingers earlier than in the toes and indeed, in some instances, vasodilation can fail to occur in the feet. This delayed response in the toes as compared with the fingers has been attributed not to a difference in time but to a difference in the intensity of the vasomotor relaxation in the upper and in the lower extremities. Warming of the body elicits complete relaxation of the vessels in the upper limbs but only incomplete relaxation of the vessels in the lower limbs. This increase in skin temperature of the hands in response to warming of the body depends on the responsiveness of the arteriovenous anastomoses in the distal parts of the fingers to changes in body temperature. These anastomoses constrict as the body is cooled and dilate as the body temperature increases.

Experiments in humans have also demonstrated that the vasodilation involved in warming the hands is effected through the sympathetic nerves. This is suggested by the fact that warming of the body does not elicit similar responses in hands deprived of the sympathetic innervation. Moreover, studies have shown that this is an active process, and not the result of inhibition of vasoconstrictor impulse activity. Such studies have suggested that vasodilator fibers exist in sympathetic nerves, but this remains controversial. On the other hand, parasympathetic cholinergic vasodilator fibers do exist and innervate the arteries of the external genitalia (penis, clitoris, and labia minora), which markedly dilate during sexual arousal. Parasympathetic vasodilator fibers also supply the pial arteries of the brain.

EVALUATION OF THE PATIENT

Diagnosis of pain limited to the neck or shoulder or to other parts of the upper limb or the entire limb requires a thorough history, physical and neurologic examination, psychosocial evaluation, and, not infrequently, imaging studies and special laboratory tests. Because these aspects of the evaluation are discussed in detail in Chapter 12, only specific relevant points are emphasized here. Usually, the physician already has information available about the age, occupation, race, culture, marital status, and other demographic factors and can proceed to obtain a thorough history.

History

In obtaining the history, it is first essential to evaluate the characteristics of the pain at onset, during the interval since onset, and at the present time, when the pain was first felt, and the nature of the precipitating factor (5). Characteristics of the pain include the type of onset (sudden or gradual), distribution (local or widespread), quality (sharp, dull aching, or burning), intensity (mild, moderate, severe, or excruciating), time-intensity curve (same throughout the day or better or worse in the morning, afternoon, evening, or night), and duration. Were there associated symptoms and signs (numbness, weakness)? What relieved the pain, and what made it worse? The patient should be asked these questions in regard to the course of the pain and currently. What treatment has been received, and what are the results? What has been the effect of the pain on the patient's activities (at work or during leisure time)? How long during the day has the patient been required to rest in bed or to be active?

Localized pain is usually caused by disorders of joints, muscles, and bones; segmental pain is caused by lesions of nerves or nerve roots (intraspinal, vertebral, or paravertebral); and pain with peripheral nerve distribution is caused by lesions of the cervical or the brachial plexus or its branches. A sharp bright quality of the pain indicates a cutaneous or neurologic origin, a burning diffuse pain suggests a vascular origin, and a deep aching pain indicates a muscular, bone, or joint origin. Brief, sharp lancinating pain brought on by coughing or sneezing suggests radiculalgia, which can have many causes; continuous, deep, dull, aching pain aggravated by motion of the neck or extremities is usually of musculoskeletal origin; continuous, diffuse, burning pain associated with hyperalgesia and thermohyperesthesia suggests reflex sympathetic dystrophy of the upper limb; and a diffuse, aching or burning discomfort modified by dependency or elevation suggests peripheral vascular disease. Pain and stiffness on arising suggest a myofascial disorder, pain worsening at night suggests bone involvement, and pain worsening during the latter part of the day after hours of work suggests a musculoskeletal disorder.

Psychosocial Evaluation

History of the pain is followed by a psychosocial evaluation and medical and family histories (27). Detailed information should be obtained about psychological, emotional, and sociologic issues, such as past and current relations with the spouse and family and friends; history regarding the present and former use of tobacco, alcohol, and drugs; and the role of environmental factors and other issues (mentioned in Chapter 12 and discussed in detail in Chapter 16). The past medical history should elicit information about previous injuries, characteristics of the pain associated with the injury, treatment used, and results obtained, as well as other medical disorders the patient has had that might have some relationship to the present problem. Information about the health of the parents and siblings, and whether they have suffered frequent painful disorders and disabilities, should be ascertained.

As emphasized in Chapter 12, the physician has an unequaled opportunity during the taking of the history to develop rapport with the patient and also to study the patient as a whole: the manner, attitude, behavior, and emotional reactions, tone of voice, bearing, facial expression, posture, movements, gait, position of the head, and curvature of the neck. The patient who is slumped in the chair and bobbing the head about while talking, or gesturing with the head and neck, is likely not to have pathology of the cervical spine as a cause of the pain. The examiner should observe the patient as he or she walks in, noting how the head is held and how naturally and rhythmically the head and neck move with body movements. Similarly, the movement of the upper limb as the patient walks, sits, or gesticulates should be observed.

Physical and Special Examinations
