CHAPTER 85

Antidepressants, Muscle Relaxants, and N-*Methyl-*D*-Aspartate Receptor Antagonists*

Mitchell B. Max and Ian H. Gilron

This chapter discusses the use of selected antidepressants, muscle relaxants, and *N*-methyl-d-aspartate (NMDA) antagonists for reducing pain. This particular grouping reflects the organization of previous editions, in which antidepressants, muscle relaxants, antianxiety agents, and neuroleptic drugs were presented under the heading of *psychotropic drugs*. We prefer to drop that term because research in animals and patients has shown that antidepressants and muscle relaxants can relieve pain in patients with normal mood by mechanisms having little to do with emotional processes. Neuroleptic agents are not addressed as a class because, with the exception of methotrimeprazine, a strongly sedative phenothiazine occasionally used to treat cancer patients who cannot tolerate the respiratory or gastrointestinal side effects of opioids (see Chapter 36), there is little evidence supporting their analgesic efficacy. The following pages focus on the pharmacologic principles of pain treatment; the diagnosis and treatment of emotional disorders associated with chronic pain are discussed in Chapter 26.

ANTIDEPRESSANTS

Apart from the opioids and the acetaminophen–nonsteroidal antiinflammatory drug group of analgesics, antidepressants are probably the most commonly prescribed class of drugs for the treatment of chronic pain. Their use for pain was first described by Lance and Curran (1), who carried out a placebo-controlled trial showing that amitriptyline reduced the severity of tension headache, and by Woodforde et al. (2), who described amitriptyline's apparently beneficial effect in a case series of patients with postherpetic neuralgia. These authors differed in their opinions of the relative importance of antidepressant and specific antinociceptive effects; Lance and Curran thought a vasodilator action, not a mood effect, accounted for benefit, whereas Woodforde et al. favored an antidepressant action. Taub and Collins (3) reported their clinical experience that a combination of amitriptyline and fluphenazine appeared to benefit patients with neuropathic pain, whereas amitriptyline alone had little effect. Watson et al. (4) carried out a placebo-controlled trial of amitriptyline that showed benefit in patients with postherpetic neuralgia who were free of depression or other psychiatric disorder. This study both undercut the rationale for Taub and Collins' antidepressant-phenothiazine combinations and provided support for the new hypothesis that potentiation of serotonin (5-HT) and norepinephrine (NE) pathways descending from brainstem to spinal cord might relieve pain (5).

Clinical Efficacy of Antidepressant Drugs for Pain Treatment

Benefit Varies According to Source of Pain

Tricyclic antidepressants, including amitriptyline, imipramine, nortriptyline, desipramine, clomipramine, and doxepin, block the reuptake of NE, 5-HT, or both at spinal dorsal horn synapses, potentially leading to increased inhibition of pain (see Chapter 4). One might expect that such an effect would reduce most types of chronic pain, but the pattern of results from more than 75 published controlled clinical trials shows a highly variable effect depending on the type of pain studied. Most of the published studies were reviewed in a formal metaanalysis by Onghena and Van Houdenhove (6) and a qualitative systematic review by Magni (7). Their conclusions, which have been confirmed by a smaller number of studies in the 1990s, are summarized in Table 85-1. The diagnostic categories are listed in order of decreasing effect size calculated by Onghena and Van Houdenhove. The effect size is the ratio of the mean reduction in pain determined in the study (relative to placebo) divided by the standard deviation of the pain reduction; it therefore reflects the certainty that some favorable effect occurred rather than the actual magnitude of the pain reduction. In this table and in the rest of the section, pain reduction is the only outcome variable discussed, because the published studies of antidepressants provide few data about changes in patients' physical functioning, return to work, and health care consumption.

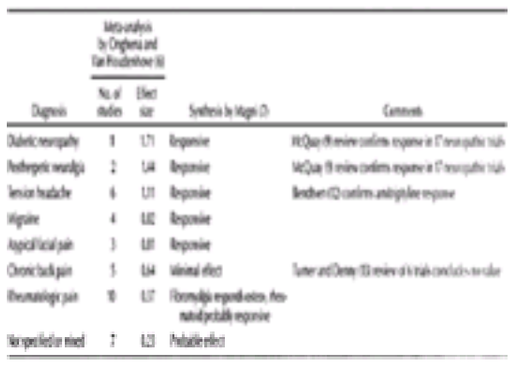

TABLE 85-1. Review of antidepressant analgesia

As of 1998, studies in diabetic neuropathy and postherpetic neuralgia offer the most convincing evidence for benefit. Only three of the 16 published studies relating to painful diabetic neuropathy and postherpetic neuralgia were included in the Onghena and Van Houdenhove metaanalysis (6), but subsequent reviews that include the more recent studies (8,9) confirm the top ranking of neuropathic pain. McQuay et al. (9), whose data summary (10) appears in Figure 85-1, calculated that approximately one in three patients obtains at least 50% relief from a tricyclic antidepressant above any placebo effects, an effect similar to that derived from their metaanalysis of the analgesic effects of anticonvulsants (11).

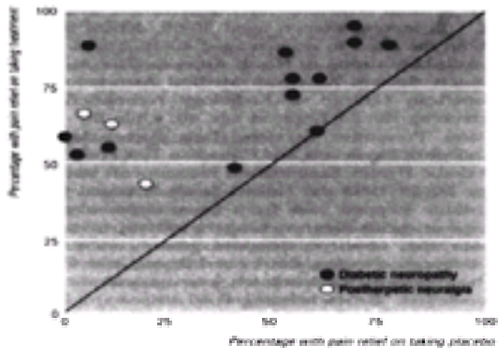

Figure 85-1. Effectiveness of tricyclic antidepressants in double-blind, placebo-controlled trials in diabetic neuropathy and postherpetic neuralgia. Each trial is represented by a data point. The percentage of patients in the trial with at least 50% reduction in pain on the antidepressant is plotted against the percentage with 50% reduction in pain on placebo. All except one of the points are above the diagonal line (zero-effect line) illustrating that antidepressants were superior to placebo in almost all the studies. (From McQuay HJ, RA Moore. Antidepressants and chronic pain. *BMJ* 1997;314:763–764, with permission.)

There is also relatively convincing evidence for the efficacy of tricyclic antidepressants in preventing tension and migraine headaches (see Table 85-1). The robust effects of amitriptyline in tension headache (but not of the selective 5-HT-reuptake blocker citalopram) were reconfirmed by Bendtsen et al. (12). Three studies suggested benefit of tricyclics in atypical facial pain. The finding of little clinical benefit of tricyclics in low back pain has been reinforced by another metaanalysis by Turner and Denny (13) and by a new study by Atkinson et al. (14) showing that nortriptyline, titrated to a plasma concentration of 50 to 150 ng per mL reduced pain by only approximately 10% relative to placebo, a benefit largely due to a strong effect in the subgroup of patients with definite nerve root injury and radicular pain. Results in rheumatologic pain differ according to diagnosis: Fibromyalgia has responded to low-dose amitriptyline in several studies, whereas results in osteo- and rheumatoid arthritis have been less impressive (7). Klein (15) reviewed five controlled trials of tricyclic antidepressants in irritable bowel syndrome and nonulcer dyspepsia and concluded that there was little evidence for efficacy.

In view of the widely differing results in various disease conditions and the paucity of controlled trials in any conditions apart from neuropathic pain, one must be cautious in making generalizations across disease conditions about the finer points of drug choice and prescribing. It may be useful to specifically examine the trials in neuropathic pain, because this is the disease category in which the largest number of trials has been done. Three groups, in Toronto, Odense, and Bethesda, have carried out the majority of these trials, using similar patient populations and methods, and have arrived at similar results.

In 15 of 16 studies of diabetic neuropathy and postherpetic neuralgia (see Fig. 85-1), at least one tricyclic antidepressant relieved pain significantly better than a placebo. The result was strengthened in many of these studies by demonstration of superiority to an “active placebo,” which mimicked antidepressant side effects (16,17,18 and 19) to another antidepressant (20,21 and 22) or to another active drug (23). This is important because patients' perceptions of side effects might bias them toward reporting pain relief, potentially imputing spurious efficacy to a drug with prominent side effects if compared only to an inert placebo.

Many of these neuropathic pain studies showed that a significant analgesic effect remained even when depressed patients were excluded from the analysis (17,19,24). Each of the research groups has prospectively assessed a number of different subtypes of pain and discomfort, expecting that antidepressants might relieve one type more than others, but no such selective effect was apparent. The antidepressants in these studies relieved brief, lancinating pains as well as constant pains (4,16,17) and allodynia as well as spontaneous pain (16,21). No differences have been discerned among the relief afforded various qualities of steady pain, such as burning, aching, sharp, or pressing pain (19,23), or between pain, paresthesia, and dysesthesia (24). The methodologic features of these studies make the positive results more convincing and are missing from many of the studies in other disease conditions.

Although the large majority of neuropathic pain trials were carried out in patients with either diabetic neuropathy or postherpetic neuralgia, single reports suggest that amitriptyline is superior to placebo in a poststroke central neuropathic pain (25) and a mixed group of nondiabetic peripheral neuropathies (26). However, in two trials in patients with human immunodeficiency virus–related painful neuropathies (27,28), amitriptyline's effect was small and did not significantly surpass placebo.

Which Neurochemical Actions of Antidepressants Correlate with Pain Relief?

Many of the controlled trials in neuropathic pain have examined whether relatively selective blockers of NE or 5-HT retain the pain-relieving effects of the mixed reuptake blockers amitriptyline and imipramine. Sindrup et al. (24) have shown that the time course of imipramine analgesia is consistent with the hypothesis that pain relief is mediated by blockade of monoamine reuptake. Careful preliminary studies of each patient's metabolic rate for imipramine allowed a high fixed dose to be given, rather than the cautious titration used by most investigators. Figure 85-2 shows that reductions in pain and other symptoms approached maximum values after 4 days of treatment, roughly paralleling the expected plasma drug concentrations.

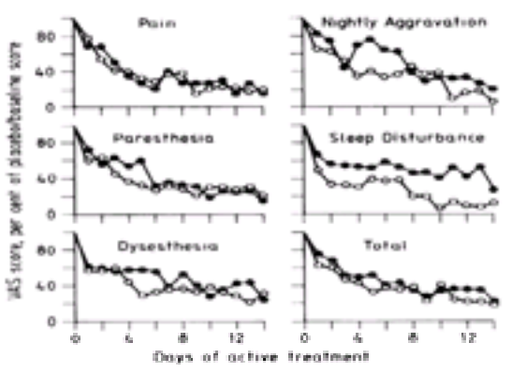

Figure 85-2. Onset of action of imipramine (*open circles*) and paroxetine (*filled circles*) in a study of patients with painful diabetic neuropathy. Both treatments were superior to placebo (not shown). Near-maximal reduction of pain (upper left) is evident as early as 4 to 6 days after beginning treatment with a fixed dose of imipramine determined by a prior dose-finding period. The time course of onset of pain relief parallels the expected time course of plasma antidepressant concentrations. These results are consistent with the hypothesis that a rapidly occurring drug effect, such as acute blockade of monoamine reuptake, directly mediates pain relief. (VAS, visual analog scale.) (From Sindrup SH, Gram LF, Brosen K, et al. The selective serotonin reuptake inhibitor paroxetine is effective in the treatment of diabetic neuropathy symptoms. *Pain* 1990;42:135–144, with permission.)

Several caveats must be raised about the assumptions of the selective monoamine reuptake blocker studies. First, because the concentrations of various antidepressants in human brain tissue and, in particular, at the relevant receptors, are not known, it is uncertain whether selective or complete blockade of central neural mechanisms is attained. As Richelson (29) has pointed out, explanations of comparative effects of antidepressants based on affinity constants are on firm ground only for peripheral tissues, where plasma drug concentrations are relevant. The use of radiolabeled NE- and 5-HT–receptor ligands in future brain imaging studies may allow direct assessment of effects of antidepressants at central monoaminergic synapses. A second caveat is that even if some of these drugs selectively affect reuptake of NE or 5-HT, the consequences do not remain confined to that monoamine system. In studies of depressed patients, Potter et al. (30) found that zimelidine and desipramine, selective blockers of 5-HT and NE reuptake, respectively, each produced similar alterations in the levels of CSF metabolites of both 5-HT and NE.

Taken as a whole, studies by the Bethesda, Odense, and Toronto groups suggest that the relatively “dirty” tricyclics, amitriptyline and imipramine, which block reuptake of both NE and 5-HT and also block H1, adrenergic, and cholinergic receptors, have the greatest efficacy, exceeding the relatively specific NE-reuptake blockers desipramine and maprotiline. Evidence supporting specific serotonin-reuptake inhibitors is the least impressive at the moment, although paroxetine and

citalopram relieved diabetic neuropathy in one study each (24,31).

After placebo-controlled studies of desipramine in both diabetic neuropathy (18) and postherpetic neuralgia (16) that showed analgesic effects similar in magnitude to those previously described with amitriptyline, the Bethesda group carried out a crossover comparison of amitriptyline (mean dose, 105 mg per day) to desipramine (111 mg per day) in 38 patients with diabetic neuropathy (19). To evaluate the efficacy of selective serotonin-reuptake blockade, they compared fluoxetine, 40 mg, to a benztropine active placebo in 46 diabetics in a comparison run concurrently with the amitriptyline-desipramine study. Figure 85-3 shows that amitriptyline and desipramine were each effective. The difference between the two drugs was not statistically significant. In contrast, fluoxetine was not significantly more effective than a placebo. The modest trend toward a fluoxetine effect apparent in Figure 85-3 disappeared when the 13 depressed patients were excluded from the analysis. There was no suggestion of an analgesic effect in patients with relatively high or low plasma concentrations of fluoxetine or its metabolite, norfluoxetine.

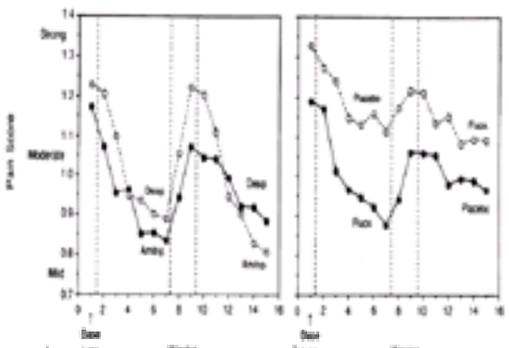

Figure 85-3. Intensity of pain caused by diabetic neuropathy during treatment with amitriptyline (*Amitrip.*) and desipramine (*Desip.*) in 38 patients **(A)** and during treatment with fluoxetine and placebo in 46 patients **(B)**. The mean weekly values of the descriptors of pain intensity are plotted; three of the actual descriptors used in the diary are shown in their equivalent positions on the ordinate. Each curve represents a single group receiving sequential treatments. The central vertical lines distinguish the two 6-week treatment periods from the intervening 2-week washout period. There was no statistically significant difference between the effects of amitriptyline and desipramine, but both were significantly more effective than placebo in the subgroup of patients who were randomized among all four possible treatments. There was no significant difference between the effects of fluoxetine (*Fluox.*) and placebo, and the modest trend favoring fluoxetine was due entirely to the data from the 13 depressed patients. (From Max MB, Lynch SA, Muir J, et al. Effects of desipramine, amitriptyline, and fluoxetine on pain in diabetic neuropathy. *N Engl J Med* 1992;326:1250–1256, with permission.)

This finding is consistent with Watson and Evans' (20) report from Toronto that the specific serotonin-reuptake blocker zimelidine was ineffective in patients with postherpetic neuralgia who responded to amitriptyline. It is possible that serotonin-reuptake blockade alone has a weak pain-relieving effect but enhances the pain-relieving effects of NE-reuptake blockade. This hypothesis would explain the trend toward greater effectiveness of amitriptyline, which inhibits 5-HT reuptake more strongly than does desipramine. Watson et al. (21) reported the similar result in postherpetic neuralgia that the selective NE-reuptake blocker maprotiline was less effective than amitriptyline.

Sindrup and his colleagues at Odense University (31) have reported results that agree in many respects with those of the other groups. Figure 85-4 combines the results from a number of their studies in patients with diabetic neuropathy. As reported by the other groups, the tricyclic antidepressants with “balanced inhibition” of 5-HT and NE reuptake, imipramine and clomipramine, appeared to be the most effective agents, and the selective NE-reuptake blocker desipramine was also effective (19,20 and 21). Mianserin, a nontricyclic antidepressant that does not block reuptake of either monoamine, did not relieve pain, also consistent with the monoamine hypothesis. Mianserin has strong antihistamine effects, suggesting that H1-receptor antagonism is not sufficient to relieve neuropathic pain. The difference between the groups' findings is that Sindrup et al. found that two different selective serotonin-reuptake inhibitors (SSRIs), paroxetine and citalopram, had at least some analgesic effects in groups of 20 and 15 patients, respectively. This contrasts with the flatly negative results in the 61 patients who were given fluoxetine or zimelidine by the other two groups. There were no obvious differences between the populations of diabetic neuropathy patients studied by Sindrup et al. (31) and Max (19), and the spectrum of receptor actions of fluoxetine, paroxetine, and citalopram is quite similar. Larger studies should be conducted to try to confirm the results of the Odense group. If the SSRIs produce some analgesia, albeit less than the mixed blockers, they will offer improved treatment for patients with fragile medical conditions, because these drugs cause no postural hypotension, cholinergic blockade, or heart block.

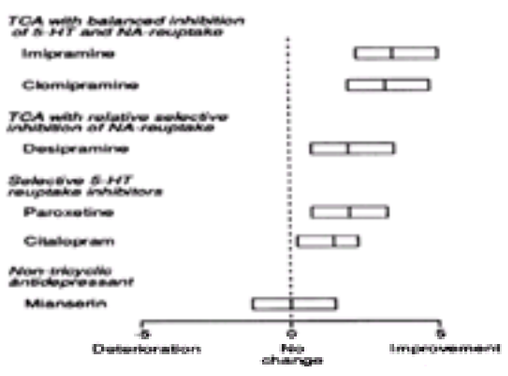

Figure 85-4. Effectiveness of various antidepressants on symptoms of diabetic neuropathy. Medians (*vertical lines*) and 95% confidence intervals (*boxes*) describe the differences between different antidepressants and placebo as measured by physician scoring of symptoms of pain and discomfort on a 0 to 10 scale. Data are drawn from a number of the studies by Sindrup et al. As in the studies by Max et al. (see Fig. 85-1) and Watson et al., a selective norepinephrine (*NE*)-reuptake inhibitor was effective, and drugs that inhibit both NE and serotonin (*5-HT*) reuptake appeared even more effective. The results shown here differ from findings of the latter two investigators in that the specific 5-HT-reuptake inhibitors, paroxetine and citalopram, showed a statistically significant analgesic effect. TCA, tricyclic antidepressant. (From Sindrup SH, Bjerre U, Dejgaard A, et al. The selective serotonin reuptake inhibitor citalopram relieves the symptoms of diabetic neuropathy. *Clin Pharmacol Ther* 1992;52:547–552, with permission.)

Several studies have also found that SSRIs were unimpressive in other conditions previously shown to respond to tricyclics. In a crossover study of 34 patients with tension-type headache, Bendtsen et al. (12) reported that amitriptyline, 75 mg per day, reduced the duration and frequency of headache pain by approximately 30%, whereas citalopram, 20 mg per day, had no significant effect. Norregaard et al. (32) reported no effect of citalopram, 20 or 40 mg per day, in fibromyalgia. In contrast, Rani et al. (33) reported that fluoxetine, 20 mg per day, was superior to placebo and similar to amitriptyline, 25 mg per day, in a small group of patients with a mixture of rheumatologic disorders, mostly low back pain and osteoarthritis.

Concentration-Response Relationship for Antidepressant-Mediated Analgesia

There have been few prospective dose-response studies of antidepressants for chronic pain. McQuay et al. (34) compared doses of 25, 50, and 75 mg per day of amitriptyline in a randomized, blinded crossover study in a group of patients with mixed chronic pain diagnoses. The 75-mg-per-day amitriptyline dose significantly surpassed 25 mg per day, which they had previously shown to be better than placebo (35), as had Sharav et al. (36) in facial pain and Goldenberg et al. (37) in fibromyalgia.

Sindrup et al. (38) studied imipramine in 15 patients with painful diabetic neuropathy (Fig. 85-5). Based on preliminary characterization of patients' imipramine metabolism, the investigators chose a series of doses between 25 and 350 mg per day that would ensure a maximum plasma concentration of imipramine and desipramine well above 400 nM per L (or approximately 120 ng per mL). Most patients received an ascending series of doses with 1 week of treatment at each dose;

dose reductions were included at various points in seven of 15 patients. In Figure 85-5A, patients' visual analog scores for pain are plotted against plasma tricyclic concentration; each line represents one patient. Figure 85-5B shows the cumulative number of patients who reached at least 95% of their maximal pain relief at a given plasma concentration. Most patients appeared to get optimal relief at or below 400 nM per L, a plasma concentration that required imipramine doses of 125 to 350 mg per day. Because of the great variability in both pharmacokinetics and the plasma tricyclic concentrations needed to obtain optimal response, Sindrup et al. (38) cautioned that one should not discontinue treatment because of an inadequate response to a standard dose such as 100 mg per day. Sharav et al. (36) prospectively compared high (mean dose, 129 mg per day) and low (23 mg per day) amitriptyline doses to placebo in a patients with facial pain of muscular or neuropathic etiology and reported a trend toward superiority of the higher dose that did not reach statistical significance. Watson (39) had reported seven cases of a “therapeutic window” for amitriptyline analgesia—that is, patients reporting pain relief that disappeared with further dose increase and reappeared with dose reduction. No other reports have confirmed this, however.

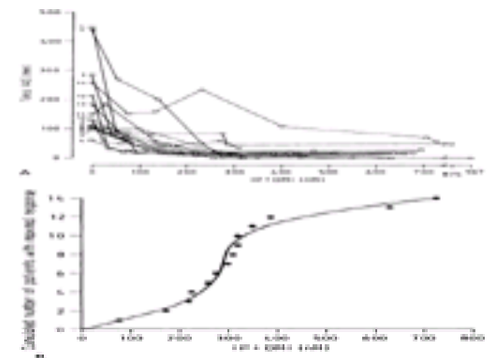

Figure 85-5. A prospective study of the imipramine (*IP*) concentration-response relationship in patients with painful diabetic neuropathy. **A:**Total neuropathy symptom scores (maximum possible score = 600) are plotted against plasma concentrations of IP plus its active metabolite desipramine (*DMI*). Each line represents a single patient, numbered 1 to 14 to the right of the *y* axis, and each circle represents IP treatment for 1 week at that particular dose level. Pain and other neuropathic symptoms declined progressively with higher plasma drug concentrations. **B:** Solid circles represent the cumulated number of patients experiencing more than 95% of maximal response [total visual analog scale (VAS) score at baseline – total VAS score during treatment] at or above various plasma concentrations of IP and DMI. Plasma concentrations higher than 400 nmol were sufficient to produce near-maximal responses in most patients. (From Sindrup SH, Gram LF, Skjold T, et al. Concentration-response relationship in imipramine treatment of diabetic neuropathy symptoms. *Clin Pharmacol Ther* 1990;47:509–515, with permission.)

Many other authors have attempted to correlate antidepressant dose and plasma concentrations with effects in studies in which each patient's dose was individually titrated based on pain relief, but no clear associations have been consistently replicated (40). Compared to prospective studies in which the dose or plasma concentration is randomized to several different levels, individual titration designs are very inefficient in elucidating the relationship of pain relief to dose, because dose is a dependent variable. For example, even if there were an underlying positive dose-response relationship in the population, this fact might be obscured because patients who obtain significant relief might have their titration stopped at a low dose, whereas patients who continue to have large amounts of pain would usually be pushed up to high doses.

Genetic Variability in Metabolism of Tricyclic Antidepressants and Dose-Concentration Relationships

A crucial issue to bear in mind is that there is extraordinary variation in plasma concentrations among patients receiving the same dose because of genetic polymorphism in CYP2D6, the cytochrome P450 enzyme that oxidizes and inactivates all of the tricyclic antidepressants (41,42 and 43). Seven percent to 10% of Caucasians and 1% of Asians have mutations in both copies of the 2D6 gene. Such patients get drug levels more than tenfold higher than average and are termed *poor metabolizers*. Most patients (*extensive metabolizers*) have two normal copies of the gene, but many patients have intermediate levels of metabolism due to mutations of one gene or minimally disruptive mutations of both genes, and occasional patients (*ultra-rapid metabolizers*) have multiple copies of intact genes. Some commonly prescribed drugs, including fluoxetine, paroxetine, and quinidine, powerfully inhibit the function of the 2D6 enzyme, converting extensive metabolizers into poor metabolizers, leading to as much as a tenfold elevation of levels of tricyclics and other drugs metabolized by the 2D6 enzyme, including dextromethorphan, mexiletine, and a variety of other antiarrhythmics, antipsychotics, b-adrenergic blockers, and other drugs (42). Figure 85-6 shows the amount of increase in plasma desipramine levels produced by the addition of various SSRIs in a number of published studies (44). Fluoxetine and paroxetine have powerful effects that could cause serious toxicity in patients concurrently treated with tricyclics, but other SSRIs such as sertraline, citalopram, fluvoxamine, and venlafaxine have smaller effects that would less often be clinically significant. Fluoxetine is unique among the antidepressants in that 2D6 inhibition may persist for 1 month after fluoxetine is stopped because of the 7- to 15-day elimination half-life of the active metabolite norfluoxetine. Antidepressants are involved in several other drug-drug interactions that may be important for practice. For example, the SSRI fluvoxamine inhibits several other cytochrome P450 enzymes, including 3A3/4, which can lead to moderate elevations in plasma levels of carbamazepine and benzodiazepines, and 1A2, leading to higher levels of theophylline.

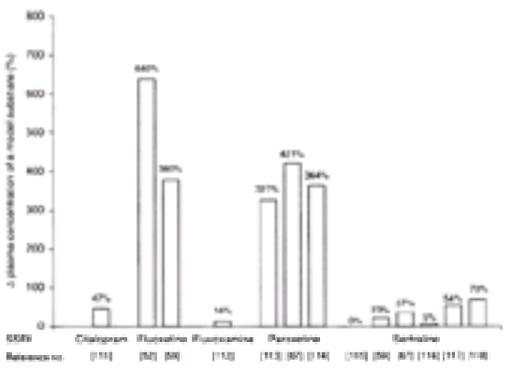

Figure 85-6. Mean increases in plasma desipramine or imipramine concentrations caused by the addition of various selective serotonin-reuptake inhibitors (*SSRIs*). Data from 13 published studies are summarized. Fluoxetine and paroxetine are powerful inhibitors of the cytochrome P450 2D6 enzyme and cause large elevations of plasma concentrations of tricyclic antidepressants. Citalopram, fluvoxamine, and sertraline are less likely to cause clinically significant elevations in tricyclic metabolism. [From Preskorn SH. Clinically relevant pharmacology of selective serotonin reuptake inhibitors: an overview with emphasis of pharmacokinetics and effects on oxidative drug metabolism. *Clin Pharmacokinet* 1997;32(Suppl 1):1–21, with permission.]

The variability in antidepressant metabolism has two implications for practice. First, the clinician must be familiar with the important drug interactions caused by antidepressants (41,42,44) and monitor patients closely when adding antidepressants to drugs likely to have metabolic interactions. Second, dose titration of these drugs must be individualized. Low starting doses of tricyclics (10 to 25 mg per day) are warranted to avoid serious toxicity in poor metabolizers, but one can fail to produce benefit in some patients who are extensive or ultra-rapid metabolizers unless one verifies, by checking a blood level, that clinically meaningful plasma concentrations have been achieved (e.g., at least 50 to 100 ng per mL for the commonly used tricyclic compounds).

Mechanisms of Clinical Pain Relief Produced by Antidepressants

Blockade of Norepinephrine and Serotonin Reuptake

As discussed above, the monoamine hypothesis has driven much of the clinical research with antidepressants, and the hypothesis that an increase of NE, and to a lesser extent 5-HT, is responsible for analgesia is consistent with most of the data. In animals, a variety of interventions that enhance spinal NE or 5-HT function reduce pain (45). The onset of clinical pain relief within a few days (see Fig. 85-2) is consistent with the monoamine reuptake hypothesis and differs from the delayed

response of major depression (46,47). Although the small number of studies in neuropathic pain with various SSRIs differ somewhat on whether these drugs produce modest or negligible analgesia, all of the studies agree that mixed NE/5-HT-reuptake blockers such as amitriptyline or imipramine are superior to more selective compounds, whereas mianserin, an antidepressant that does not block monoamine reuptake, was ineffective in diabetic neuropathy (22).

We believe that the monoamine hypothesis is still the most appealing explanation for antidepressant analgesia. If true, mixed NE/ 5-HT-reuptake blockers (e.g., venlafaxine), which lack many of the cardiovascular side effects of the tricyclics, should be useful clinical agents, but controlled studies with these agents have not been completed at the time of this writing.

Blockade of Sodium Channels

All of the tricyclic antidepressants block neuronal and cardiac sodium channels, and several groups have proposed that peripheral nerve sodium channel blockade is the main mechanism for analgesia (48,49). An appealing feature of this hypothesis is that neuropathic pain conditions appear to be the most sensitive to tricyclics, and these pains are thought to be mediated in large part by ectopic discharges in injured nerve sprouts and dorsal root ganglion cells that decrease with sodium channel blockers such as lidocaine (50).

This hypothesis faces several challenges, however. First, the differential effectiveness of various antidepressants needs to be explained. For example, fluoxetine was ineffective in treating diabetic neuropathy pain (19) and an animal model of neuropathic pain (48) but blocked neuronal sodium channels almost as effectively as drugs known to be effective in neuropathic pain, such as amitriptyline and desipramine (49). Second, the effectiveness of tricyclics in conditions such as headache and fibromyalgia needs to be explained in terms of sodium channel blockade. Ptacek (51) has speculated that common migraine may be caused by mutations in sodium, calcium, or other ion channels causing neuronal hyperexcitability, but there is no evidence for this as yet, let alone any evidence linking fibromyalgia or tension-type headache to abnormal sodium channel activity.

The sodium channel hypothesis for antidepressant analgesia generates some important predictions. One might expect that combinations of an antidepressant with another drug working through sodium channel blockade, such as mexiletine or carbamazepine, would be mechanistically redundant. Such combinations would not be clinically advantageous unless the combination reduced some toxicity of the components of the combination unrelated to sodium channel blockade. Also, one would expect other blockers of sodium channels that did not block monoamine reuptake to share the clinical effectiveness of antidepressants.

Antagonism of NMDA Glutamate Receptors

Eisenach and Gebhart (52) have shown that intrathecal amitriptyline produces analgesia that is mediated in part via blockade of NMDA receptors. This finding is not clinically relevant to systemic treatment with tricyclics, however, as the tissue concentrations reached with oral administration are several orders of magnitude lower than those achieved in the spinal cord with intrathecal administration. One can calculate from the affinity of amitriptyline for brain NMDA receptors (52) that clinically achieved concentrations would not block a substantial proportion of NMDA receptors.

Sympathetic Blockade

Esler (53) reported that intravenous injection of desipramine, 25 mg, reduced sympathetic efferent activity by approximately 90%. This may contribute to pain relief in patients with sympathetically maintained pain.

Effects on Visceral Nerve Fibers

Su and Gebhart (54) have reported that systemic administration of imipramine, desipramine, or clomipramine reduced by up to 80% the discharge of mechanosensitive afferents in response to noxious distension of the rat colon. This effect occurred after the central connections of the nerves had been severed and in the presence of antagonists of NE and 5-HT receptors. The authors speculated that this effect might be mediated by an action on the peripheral nerve receptor, perhaps involving peripheral opioid receptors and calcium channels. Despite this powerful effect in animal models of visceral pain, clinical investigators have been unimpressed with antidepressants in irritable bowel syndrome (15).

Effects on Mood

Although a major thrust of recent clinical research with antidepressants has been to establish analgesic effects distinct from effects on mood, experienced clinicians know that depressed patients with pain suffer less when their depression has been treated.

Adverse Effects of Antidepressant Drugs

Cardiovascular Effects

The most serious toxicities of tricyclic antidepressants occur in the cardiovascular system: postural hypotension, heart block, and arrhythmias. Postural hypotension is mediated through blockade of a-adrenergic receptors. It may occur in any age group but is most serious in elderly patients in whom syncope and falls are liable to lead to serious trauma. Ray et al. (55) reviewed a series of 1,400 patients with hip fracture and controls and estimated that prescribing tricyclic antidepressants or benzodiazepines to patients over the age of 65 triples the risk of hip fracture. This risk of antidepressant-related injury is increased even more in patients with volume depletion or congestive heart failure or patients who are receiving concurrent treatment with vasodilators. Nortriptyline and, to a lesser degree, doxepin probably have a lower incidence of postural hypotension compared to amitriptyline, desipramine, imipramine, and clomipramine (Table 85-2), which are equivalent in this regard (56).

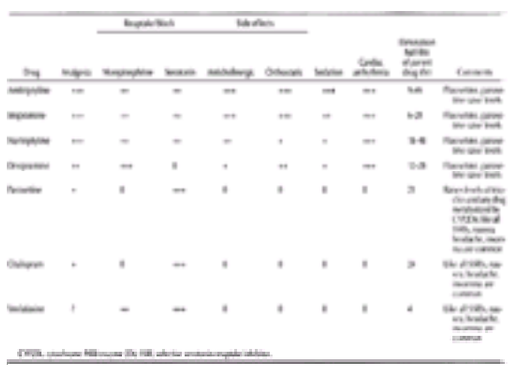

TABLE 85-2. Antidepressants commonly used to treat chronic pain

The tricyclics slow conduction throughout the heart and may be hazardous in patients with preexisting cardiac conduction disease, particularly bundle branch block (QRS >110 milliseconds) (56). A new concern has emerged following the finding in several large studies that chronic treatment of patients with ischemic heart disease with quinidine or moricizine increased the incidence of sudden death by stimulating the occurrence of complex ventricular arrhythmias. The cardiac electrophysiologic effects of tricyclic antidepressants are quite similar to quinidine and moricizine. One study has confirmed that treatment of depressed patients with ischemic heart disease with nortriptyline led to potentially dangerous sinus tachycardia or complex arrhythmias in 18% of patients, compared to only 2% of patients treated with paroxetine (57). There may even be a risk of treating elderly patients without obvious cardiac ischemia with tricyclic antidepressants, as silent ischemic events are common in this group. The SSRIs are free of all of these cardiovascular side effects, but unfortunately, they do not appear to be very effective for chronic pain. We hope that venlafaxinelike drugs will be more effective.

Five cases of desipramine-associated sudden death in children 8 to 12 years old were reported several years ago (58), raising the issue of whether desipramine or

tricyclic antidepressants in general are dangerous to children. Although extensive studies have revealed no more than minor changes in electrocardiography and pulse rate with desipramine or other tricyclics, experts recommend additional precautions when treating children with tricyclics, including taking an electrocardiogram before drug treatment, periodically during dose escalation, and after plasma drug concentrations to avoid overdose in slow metabolizers.

Sedation

Sedation, probably produced by blockade of H1 receptors, can be either a dose-limiting toxicity or a boon to patients with insomnia. Amitriptyline, imipramine, and doxepin are quite sedative, whereas nortriptyline is minimally sedative, and desipramine and the SSRIs often produce insomnia. Sedative effects usually decline after several weeks of treatment. As the half-lives of all of the tricyclics and SSRIs approximate 24 hours, one can time the administration of single or divided dose schedules to optimize the impact of sedative effects.

Anticholinergic Effects

Amitriptyline, imipramine, and doxepin produce strong anticholinergic effects, causing patients to complain of dry mouth, constipation, and urinary retention. Nortriptyline and desipramine are mildly anticholinergic, whereas the SSRIs lack these effects.

Weight Gain

Patients frequently report increased appetite and weight gain while on tricyclic antidepressants. Some clinicians feel that amitriptyline is a particular offender in this regard, but there are no controlled comparisons of the tricyclics. In contrast, the SSRIs cause anorexia and mild degrees of weight loss.

Sexual Dysfunction

The tricyclic antidepressants and SSRIs have all been reported to delay or prevent orgasm in both sexes (59). Studies of clomipramine, paroxetine, and fluoxetine have shown that this effect may prove beneficial in patients with premature ejaculation. This is thought to be due to enhanced 5-HT activity at central 5-HT $_2$ receptors that inhibit ejaculation. If these side effects interfere with sexual activity, the dose may be reduced, or intercourse should be timed to coincide with trough levels of drug.

Psychiatric Complications

Tricyclic antidepressants may trigger manic episodes in patients with bipolar disease. The major psychiatric risk of tricyclic treatment, however, is suicide; the many cardiovascular effects of tricyclics often lead to a lethal outcome of overdose. Psychiatric consultation should be considered before treating patients with severe depression, bipolar disease, or otherwise complicated psychiatric history.

Withdrawal Syndromes

Abrupt or gradual discontinuation of tricyclic antidepressants may trigger a number of symptoms, including nausea, vomiting, headache, malaise, sleep disturbance, akathisia, or paradoxical behavioral activation resulting in hypomanic symptoms (60). Withdrawal phenomena most commonly begin 24 to 48 hours after the last dose and may last up to 1 month.

When fluoxetine was introduced into general use, the lack of withdrawal symptoms led many clinicians to assume that other SSRIs would share that advantage. Experience with newer SSRIs has led to the conclusion, however, that it is only the long half-life of fluoxetine (2 to 4 days) and its active metabolite norfluoxetine (7 to 15 days) that minimizes withdrawal symptoms. All of the other SSRIs, with elimination half-lives near 24 hours, have been reported to cause symptoms such as dizziness, lethargy, paresthesias, nausea, vivid dreams, irritability, and depressed mood.

For both classes of antidepressants, withdrawal symptoms can be minimized by tapering the dose gradually and by raising the dose should symptoms be troublesome. In patients who develop unexplained symptoms during long-term antidepressant treatment, clinicians should consider the possibility that they have missed several doses, bringing on acute withdrawal.

Serotonin Syndrome

Combinations of antidepressants with certain other drugs may precipitate a “serotonin overload syndrome” characterized by myoclonus, hyperreflexia, tremor, increased muscle tone, fever, shivering, sweating, diarrhea, delirium, or coma (61,62 and 63). It is usually reversible if the responsible drugs are discontinued, but deaths have been reported. The most common precipitant has been combinations of monoamine reuptake inhibitors with SSRIs, tricyclics, venlafaxine, tryptophan, dextromethorphan, or serotonergic weight-loss agents such as fenfluramine or dexfenfluramine, but other combinations of drugs on this list, such as SSRIs plus tryptophan, dextromethorphan, or weight-loss agents have also triggered the syndrome.

Combinations of Antidepressants with Other Analgesic Drugs

Most analgesic clinical research to date has focused on the effects of single drugs and on the search to create substitutes with similar efficacy and fewer side effects. This search has met with limited success. In published clinical trials, a variety of different classes of drugs including antidepressants, gabapentin, mexiletine, opioids, and clonidine have rarely reduced chronic pain more than 20% to 25% relative to placebo, and as outlined above, antidepressants with narrower spectra of effects at receptors may be less effective or totally ineffective. Clinical researchers in other disease areas have successfully dealt with the same problem by developing combinations of drugs with additive or supra-additive therapeutic effects but differing side effects.

There have been very few rigorous studies of combinations of antidepressants with other analgesics. The only controlled study of the combination of an antidepressant with a phenothiazine showed no augmentation of pain relief when flupentixol, 3 mg per day, was added to amitriptyline in patients with idiopathic pain disorders (64). We advise against the use of antidepressant-phenothiazine combinations, particularly in view of the risk of tardive dyskinesia from the phenothiazine. Goldenberg et al. (37) compared the effects of amitriptyline plus naproxen to either drug alone or a placebo in patients with fibromyalgia and found little or no effect of naproxen alone or in combination. A number of animal studies have demonstrated augmentation of opioid analgesia by tricyclic antidepressants (65). Levine et al. (66) and Gordon et al. (67) have reported that pretreatment with 1 week of desipramine, 50 to 75 mg per day, augments postoperative morphine analgesia, but these studies did not examine whether analgesia was increased more than side effects or whether there was a pharmacokinetic interaction; other studies have failed to show augmentation of opioid analgesia by tricyclics (68,69). Studies of other drugs in combination with antidepressants would be of obvious interest. However, the design of these studies will be quite challenging, and investigators will need to take great care in characterizing their patient populations, assessing side effects as well as pain relief, and manipulating and monitoring plasma drug concentrations.

Treatment Recommendations

Choice of Antidepressant versus Other Classes of Drugs

In neuropathic pain, there is strong evidence for the efficacy of tricyclic antidepressants, but other drugs including gabapentin, opioids, and carbamazepine may provide similar degrees of relief. Choice of drug will depend on the ability of the patient to tolerate side effects of the various drugs and the urgency of the need for pain relief. In a patient with severe cancer-related neuropathic pain, for example, opioids may be the drug of first choice. In patients with ischemic heart disease or orthostatic hypotension, gabapentin would be preferable, as it is free of cardiovascular side effects. In the patient with insomnia or depression, the sedative and antidepressant effects of tricyclics would provide additional value. In headache, fibromyalgia, and atypical facial pain, tricyclics are considered first- line treatments.

Choice of Antidepressant

Table 85-2 compares the analgesic efficacy and side effects of antidepressants commonly considered in the treatment of pain. Broad-spectrum drugs such as amitriptyline, imipramine, and nortriptyline appear to have greater efficacy than selective NE- reuptake blockers or SSRIs. Although nortriptyline has been less

extensively studied in chronic pain than amitriptyline or imipramine, this is our drug of first choice because it blocks reuptake of both NE and 5-HT, causes little sedation, and causes less postural hypotension and fewer anticholinergic effects than the other broad-spectrum tricyclics. In a large clinical series and a controlled clinical trial in patients with postherpetic neuralgia, Watson and colleagues (70,71) showed virtually identical response rates of nortriptyline and amitriptyline. Desipramine is an alternative in patients who are unable to tolerate nortriptyline.

There are few positive controlled studies on which to base a recommendation of nontricyclic antidepressants. The two studies suggesting effectiveness of paroxetine and citalopram in diabetic neuropathy pain may favor the choice of these drugs for neuropathic pain, but there are few pharmacodynamic differences between these drugs and fluoxetine or sertraline. Similarly, a single study supports the use of mianserin in chronic gastrointestinal pain (72). If the monoamine hypothesis is accurate, venlafaxine may be an excellent analgesic drug, but there are no published controlled trials.

Dosing Regimens

1. Before starting tricyclic antidepressants, take a careful cardiovascular history and perform a baseline electrocardiogram. Consider whether other drugs the patient is taking affect the cytochrome P450 2D6 enzyme (examples include paroxetine, fluoxetine, and quinidine) or might potentiate orthostatic hypotension (diuretics, antihypertensives, nitrates).
2. Begin treatment with a dose of 25 mg per day in patients under 50 years of age or 10 mg per day in patients over 50. Give doses of sedative tricyclics at bedtime. If insomnia occurs, give the drug once in the morning or in divided doses.
3. Raise the dose by an increment similar to the starting dose every 3 to 4 days until the patient reports troublesome side effects, achieves satisfactory pain relief, or reaches a dose of 100 to 125 mg per day. (If treating major depression, higher doses are indicated. See Chapter 26.)
4. If no relief is achieved at 100 to 125 mg per day, determine the plasma level approximately 24 hours after the last dose. If this level is below the range of 50 to 100 ng per mL (for amitriptyline or imipramine, take the sum of the parent drug and its respective active metabolite, nortriptyline or desipramine), the patient may either be a rapid metabolizer or be poorly compliant. Consider raising the dose.

MUSCLE RELAXANTS

Nociception from muscle may play a role in several pain syndromes including tension-type headache (73), myofascial disorders (74), low back pain (75), acute musculoskeletal injury (76), and central nervous system (CNS) disorders associated with chronic spasticity (77). This section covers the heterogeneous group of skeletal muscle relaxant drugs (Table 85-3) that inhibit muscle tone and are often used in the treatment of these and other disorders (77,78,79,80 and 81). It is not always clear in these disorders that muscle is the primary source of pain or that these drugs work solely by relaxing muscles, but we think there is sufficient evidence to retain the rubric of “skeletal muscle relaxants” for now. The clinical information presented focuses on the management of acute muscle spasm because of the lack of rigorous data on the prevalence or response to treatment of chronic muscle spasm. This discussion does not include depolarizing or nondepolarizing muscle relaxants (e.g., succinylcholine, pancuronium), which are primarily used for paralysis during surgical anesthesia. Table 85-3 shows the pharmacologic classification and main indications for skeletal muscle relaxants.

Primary indication	Pharmacologic classification	Example (proprietary name)
Acute muscle spasm	Antihistamine	Orphenadrine (Norflex)
	Benzazole derivative	Chlorzoxazone (Parafon)
	Benzodiazepine	Diazepam (Valium)
	Carbamate esters	Methocarbamol (Robaxin)
		Carisoprodol (Soma)
	Methylpropanediamine derivative	Tolperisone (not marketed in North America) (Pratzel et al. [33])
	Tricyclic derivative	Cyclobenzaprine (Flexeril)
Chronic central nervous system spasticity	α-Adrenergic agonist	Tizanidine (Zanaflex)
	Benzodiazepine	Diazepam (Valium)
	GABA derivative	Baclofen (Lioresal)
	Peripherally acting	Dantrolene (Dantrium)
Fibromyalgia	Tricyclic derivative	Cyclobenzaprine (Flexeril)
Nocturnal leg cramps	Peripherally acting	Quinine (Quinamm)

TABLE 85-3. Classification of skeletal muscle relaxants

History of Skeletal Muscle Relaxants

Phenoxypropanediol (Antodyne), the prototypical skeletal muscle relaxant, was discovered in 1910 (82) followed by its derivative 3-*o*-toloxypropanediol (mephenesin) in 1946; mephenesin was shown to produce ascending paralysis in animals without sedation (83). Although mephenesin's short duration of action made its use in clinical practice extremely limited, experimental models used to study its effects have advanced our understanding of neural modulation of muscle tone (next section) leading to the development of a diverse group of skeletal muscle relaxants such as methocarbamol, cyclobenzaprine, baclofen, and tizanidine (82,84).

Neuromuscular Physiology

Segmental and Supraspinal Regulation of Muscle Tone

Figure 85-7 schematizes the neural regulation of muscle tone and possible sites of action of skeletal muscle relaxants (85,86 and 87). Skeletal muscles contain among their muscle fibers fusiform sensory muscle spindles (also called *intrafusal fibers*) that signal changes in muscle length. These sensory structures lie in parallel with ordinary (extrafusal) muscle fibers that normally contract to move or stabilize one or more joints.

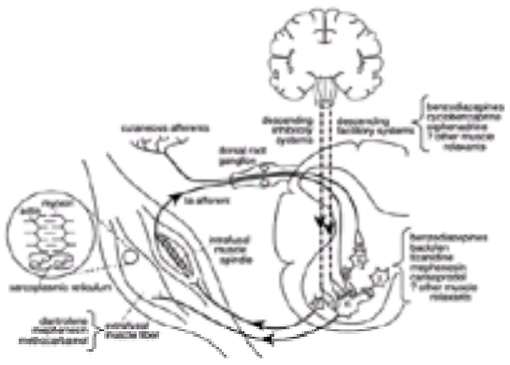

Figure 85-7. Neural regulation of muscle tone: possible sites of action of skeletal muscle relaxants. See text for details. (+, excitatory effect; –, inhibitory effect; a, alpha-motoneuron; Ca^{2+}, calcium ion; E, excitatory interneuron; g, gamma-motoneuron; I, inhibitory interneuron.)

Segmental Monosynaptic Reflex

When a muscle is stretched, the fibers in its muscle spindles also stretch, causing an increase in the frequency of neural discharges carried by Ia afferent nerve fibers. These Ia fibers enter and traverse the dorsal horn and terminate on alpha-motoneurons in the ventral horn, producing excitatory postsynaptic potentials, which promote contraction of the muscle from which the muscle spindle originated. Conversely, *decreases* in muscle length silence Ia nerve fiber activity, which results in a

decrease in muscle contraction. Therefore, the afferent activity from the muscle spindles serves as a negative feedback on changes in joint position.

On the efferent side, muscle spindles are innervated by small gamma-motoneurons that originate in the ventral horn of the spinal cord and travel together with the alpha-motoneurons that innervate extrafusal muscle fibers. These gamma-motoneurons (like alpha- motoneurons) release acetylcholine, which adjusts the sensitivity of the spindle such that it can regulate muscle tension over a wide range of muscle lengths. The adjustment of spindle sensitivity by gamma-motoneurons may be illustrated by explaining how an individual can carry a heavy pail of water. If we start by imagining the pail being carried with a relatively straight arm extending down from the shoulder, both intrafusal spindles and extrafusal muscle fibers in the biceps muscle are in a relative state of stretch. This stretch increases the input from Ia afferent fibers to promote biceps muscle contraction and thus maintain the pail in a steady position. If the individual wishes to flex the elbow and continue to carry the pail in this flexed position, he or she will generate a pattern of efferent motor impulses from alpha- and gamma-motoneurons that contract the extrafusal fibers and intrafusal fibers, respectively, of the biceps. The internal contraction of the biceps muscle spindle maintains tension on the Ia afferent receptor, which then fires to maintain the contraction of the extrafusal biceps fibers to keep the joint flexed. Without this increase in tension in the biceps muscle spindle, flexion of the elbow would result in decreased tension in the biceps muscle spindles, decreased Ia afferent activity, and difficulty keeping the arm in the desired degree of flexion.

Polysynaptic Reflexes

In the spinal cord, a complex network of excitatory and inhibitory interneurons mediates motor reflexes in response to deep and cutaneous stimulation. Such reflexes mediate ipsilateral flexion and contralateral extension in response to noxious stimuli to coordinate a protective or escape response. For example, after noxious stimulation of the left foot of an animal, ipsilateral flexion withdraws this foot from the stimulus and contralateral extension helps the animal escape from the stimulus. Impulses from cutaneous afferents travel through the dorsal horn of the spinal cord and terminate on excitatory interneurons, which in turn terminate on presynaptic terminals of the intrafusal Ia fiber to further promote its excitatory effect on the ventral horn alpha-motoneuron.

Supraspinal Regulation

Early electrophysiologic studies have identified inhibitory centers in the bulbar reticular formation (88) and facilitatory centers from several brain regions (89) that further regulate both corticospinal and reflex muscle activity. Alterations in both of these systems by “spasticity-producing” CNS diseases as well as by skeletal muscle relaxants may exert an important effect on the above described reflexes and on regular corticospinal muscle activity.

Neurotransmission in the Spinal Cord

Excitatory neurotransmitters proposed to play a major role in the modulation of movement in the spinal cord include excitatory amino acids such as glutamate and aspartate as well as neuropeptides such as substance P. These transmitters are released from the terminals of primary afferent fibers to mediate the above-mentioned reflexes as well as from excitatory interneurons to enhance motor tone at the spinal level (77). The major inhibitory spinal neurotransmitters are glycine and gamma-aminobutyric acid (GABA). Glycine is thought to be released by inhibitory interneurons, and GABA (from both supraspinal and interneuronal inputs) is thought to play a major role in presynaptic inhibition of motor neurons in the spinal cord (77). In addition to these inhibitory transmitters, supraspinal descending monoaminergic systems release the transmitters noradrenaline, dopamine, and 5-HT, which facilitate locomotion and reflex activity.

Pathophysiologic Mechanisms of Spasticity and Muscle Spasm

Disease or dysfunction of the above regulatory components of muscle tone may lead to acute reflex muscle spasm or chronic spasticity whose pathophysiology is poorly understood. In the case of spasticity (sometimes called *upper motor neuron syndrome*), lesions of descending pathways such as the corticospinal, vestibulospinal, or reticulospinal tracts may result in either excessive excitation or diminished inhibition of alpha-motoneurons at the spinal segmental level (85). In the case of acute muscle spasm, a peripheral injury or noxious stimulus may result in a reflex increase in muscle tone, either by the activation of segmental polysynaptic reflexes (described above), thus producing hyperexcitability of alpha- or gamma-motoneurons, or by the supraspinal activation of descending facilitatory systems that increase segmental muscle tone (90).

Sites and Mechanisms of Action

Site of Action

Skeletal muscle relaxants have been observed to act at several CNS sites important in the regulation of muscle tone. Due to this diversity of action, the relative importance of drug action at each of these sites remains unclear. Early studies suggested that the skeletal muscle relaxant mephenesin acted on excitatory spinal interneurons since it effectively inhibited polysynaptic reflex contractions while leaving monosynaptic reflexes unaffected (91). However, further studies of mephenesin demonstrated an effect on monosynaptic systems as well (92), and other studies showed that mephenesin and methocarbamol prolong the refractory period of skeletal muscle by a direct action on skeletal muscle fibers (93). Dantrolene, which is distinct in its mode of action from most other skeletal muscle relaxants, acts peripherally on skeletal muscle by inhibiting the release of calcium ions from the sarcoplasmic reticulum (77). Finally, it has been observed that higher doses of diazepam are needed to effectively suppress polysynaptic reflexes in animals after spinal transection in comparison with spinally intact animals (94). The interpretation of this finding has been that diazepam inhibits polysynaptic reflexes, in part, by acting in the brainstem to suppress a descending facilitatory system.

Neurotransmitter Mechanisms

Very little has been described about the effects of skeletal muscle relaxants such as cyclobenzaprine, methocarbamol, carisoprodol, and chlorzoxazone on neurotransmission. However, benzodiazepines such as diazepam are known to act by potentiating the postsynaptic effects of GABA in the CNS (85). Baclofen (parachlorophenyl GABA) is a lipophilic derivative of GABA that binds to $GABA_B$ but not to $GABA_A$ receptors and may exert its effect, in part, by inhibiting the evoked release of excitatory amino acids (e.g., glutamate) and substance P (77). Tizanidine, a newer antispasticity agent, is an a_2-adrenergic receptor agonist that may also act by decreasing spinal excitatory amino acid release (95).

Clinical Information

Evidence for Efficacy

Benzodiazepines. In addition to trials of benzodiazepines in conditions of muscle spasm (see Other Muscle Relaxants, later in this chapter), a general discussion about the use of benzodiazepines in pain management is warranted. In 1994, Dellemijn and Fields reviewed several controversies surrounding the use of benzodiazepines in the treatment of chronic pain. Although evidence exists to suggest that benzodiazepines may alleviate situational anxiety and thus be useful analgesic adjuvants in the setting of acute pain (96), their clinical utility in chronic pain management is somewhat controversial. In conditions where anxiety and muscle spasm potentiate each other, benzodiazepines may improve these two symptoms and interrupt this vicious cycle. However, benzodiazepines may worsen depression, which may further aggravate pain (97). Although controlled trials support the efficacy of benzodiazepines in certain disorders such as chronic tension headache (1,98) and temporomandibular joint dysfunction (99), benzodiazepines have been ineffective in controlled trials of postherpetic neuralgia (24) and other chronic nonmalignant pain syndromes (100).

Other Muscle Relaxants. In 1997, van Tulder et al. (101) conducted a systematic review of randomized controlled trials of common interventions used in the treatment of low back pain. Based on detailed trial assessment criteria including those of study population, interventions, treatment effect, and data presentation and analysis, this review identified 14 trials of muscle relaxants, eight of which were scored as high quality (i.e., greater than 50/100 on a methodologic assessment score). All five high-quality trials comparing muscle relaxants to a placebo reported a significant reduction in pain intensity with the muscle relaxant in comparison with placebo (102,103,104,105 and 106). Two of the three high-quality trials that compared different types of muscle relaxants showed no difference in pain intensity between those compared (107,108). Based on this analysis, it was concluded that there is strong evidence (i.e., multiple relevant, high-quality randomized controlled trials) that muscle relaxants are more effective than placebo for acute low back pain and that there is strong evidence that different types of muscle relaxants are equally efficacious for acute low back pain (101). Some of the studies showing subjective clinical improvement of low back pain also demonstrated that the muscle relaxant studied successfully decreased objective measures of muscle spasm (102,105,106). This evidence demonstrates that muscle relaxants actually alleviate reflex muscle spasm, which likely contributes to their pain-relieving effects.

The evidence of efficacy of muscle relaxants in the treatment of low back pain provides the rationale for using these drugs for other conditions such as cervical (109) and temporomandibular disorders (90,110). However, direct evidence of efficacy in these conditions is equivocal (111,112 and 113). Two clinical studies by Basmajian have looked at the clinical and electromyographic effects of muscle relaxants in the treatment of cervical muscle spasm (111,114). A double-blind comparative study of cyclobenzaprine, diazepam, and placebo included only ten patients being treated for neck spasm and showed that cyclobenzaprine produced significant clinical improvement in neck spasms compared to diazepam and placebo (111). Furthermore, the improvement noted with cyclobenzaprine was correlated with an augmentation of myoelectric activity measured by electromyography. A subsequent study comparing diazepam and phenobarbital to placebo in 40 patients with reflex cervical muscle spasm failed to show any clinical analgesic effects with either drug despite significant myoelectric augmentation (seen previously with improved clinical effects of cyclobenzaprine) with diazepam (114). This negative result was partially explained by the likelihood that in many cases pain was originating from other nonmuscular structures and thus was unaffected by pharmacologic muscle relaxation. Two other studies evaluating muscle relaxants in the treatment of temporomandibular dysfunction fail to support their efficacy in this condition. In 1960, Schwartz et al. (112) reported on a double-blind placebo-controlled study of carisoprodol in 34 patients with temporomandibular dysfunction syndrome showing no benefit with carisoprodol over placebo. A similar study of carisoprodol in 60 temporomandibular dysfunction patients by Gallardo et al. (113) failed to show any beneficial clinical effects. Again, these negative results may partially be explained by the heterogeneity of disease mechanisms, some of which give rise to pain of a nonmuscular origin. Table 85-4 shows several high-quality controlled trials of muscle relaxants in the treatment of acute back pain, neck pain, and orofacial pain.

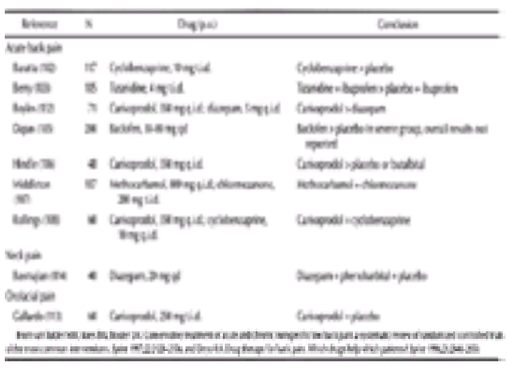

TABLE 85-4. Randomized controlled trials of skeletal muscle relaxants

Evidence for efficacy has been demonstrated for the muscle relaxants baclofen, dantrolene, and tizanidine in the treatment of spasticity secondary to upper motor neuron or spinal disorders (77,85,95). However, due to limited clinical evidence in the treatment of acute muscle spasm, these agents are not indicated for this use (115). Of relevance to the analgesic effects of centrally acting muscle relaxants, intrathecally administered baclofen, in addition to its effects on central spasticity (116), has been evaluated in a few small studies for analgesic effects in the treatment of pain related to central spasticity (117,118 and 119). Two small (n = 7 to 14) studies have demonstrated brief analgesia following acute intrathecal baclofen administration to patients with chronic neuropathic pain related to spinal cord injury (118,119). However, Loubser and Akman (117) studied *chronic* intrathecal baclofen administration in 16 patients with central spasticity and showed that although this resulted in a significant decrease in spasticity-related musculoskeletal pain, there was no change in neuropathic pain symptoms.

Indications

Table 85-5 outlines commonly used drugs that are indicated for the treatment of painful skeletal muscle spasm. Other muscle relaxant agents discussed in detail elsewhere (120,121) include chlorphenesin carbamate (Maolate), metaxalone (Skelaxin), and quinine (Quinamm). In addition to skeletal muscle spasm, cyclobenzaprine (Flexeril) is also indicated for the treatment of fibromyalgia (122).

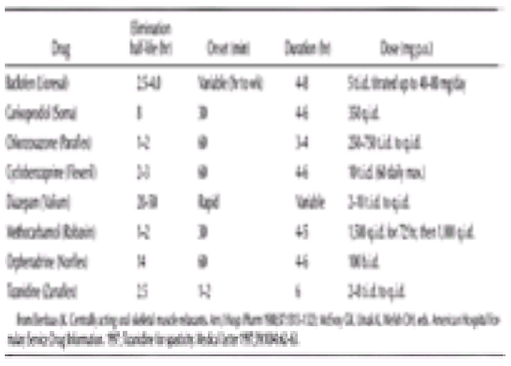

TABLE 85-5. Clinical pharmacology of commonly used skeletal muscle relaxants

Contraindications

Health professionals should consult individual drug product information prior to prescribing or recommending any of these medications. All drugs are contraindicated in patients with a known history of specific drug hypersensitivity. Carisoprodol (Soma), a muscle relaxant that becomes metabolized to the sedative anxiolytic drug meprobamate (Miltown), is contraindicated in patients with a history of acute intermittent porphyria or with a history of hypersensitivity to meprobamate. As a tricyclic antidepressant derivative, cyclobenzaprine (Flexeril) shares the toxic potential of these agents and is contraindicated in patients with hyperthyroidism, congestive heart failure, ischemic heart disease, cardiac arrhythmias, heart block, or other cardiac conduction disorders and in those at risk of a suicidal overdose. Also, cyclobenzaprine is contraindicated in patients receiving monoamine oxidase inhibitors and should not be used within 14 days after discontinuation of any of these agents (115).

Precautions

As all of these skeletal muscle relaxants are CNS depressants, caution should be used when administering these drugs concomitantly with other CNS depressants, including alcohol, so as to avoid additive depressant effects. Also, patients should be instructed that skeletal muscle relaxants may impair ability to perform hazardous activities requiring mental alertness or physical coordination such as operating machinery or driving a motor vehicle. Of relevance to other tricyclic compounds and other antidepressants, it should be noted that the cytochrome P450 2D6 enzyme isoform plays only a minor role in the metabolism of the tricyclic derivative cyclobenzaprine and thus should not be much of a concern regarding its clinical use (123). Skeletal muscle relaxants with anticholinergic adverse effects such as cyclobenzaprine and orphenadrine should be used with caution in conditions where these effects are undesirable such as urinary retention, angle-closure glaucoma, increased intraocular pressure, or concomitant administration of other anticholinergic drugs. Finally, due to the lack of established safety, skeletal muscle relaxants should not be used during pregnancy or lactation or in pediatric age groups unless the potential benefits outweigh the possible risks (115).

Techniques of Administration

Table 85-5 shows the recommended dose, elimination half-life, onset, and duration of action of several commonly used and orally administered skeletal muscle relaxants (120,121). Although these drugs all come in oral preparations, diazepam, methocarbamol, and orphenadrine are also prepared and approved for parenteral (intravenous or intramuscular) administration. Some of these drugs are also prepared and approved as drug combinations with other analgesics including

carisoprodol [with acetylsalicyclic acid (ASA) or with ASA/codeine], methocarbamol (with ASA or with acetaminophen), and orphenadrine (with ASA/caffeine) (115).

Complications

Adverse Effects

The most frequent adverse effects of benzodiazepines and other skeletal muscle relaxants are related to CNS depression and include drowsiness, dizziness, lightheadedness, and fatigue (120,124). Cyclobenzaprine and orphenadrine also produce anticholinergic adverse effects such as dry mouth, blurry vision, urinary retention, and constipation (115). Chlorzoxazone has been associated with a limited number of cases of serious hepatic toxicity presenting with abnormal liver function tests, cholestasis, and hepatic necrosis following 1 to 5 months of administration (125). This risk of liver toxicity might be worse with acetaminophen combinations (e.g., Parafon Forte). Given the similar efficacy of different muscle relaxants, the risk of hepatic toxicity with chlorzoxazone makes it an unfavorable choice.

Abuse Potential and Dependence

Benzodiazepines and other skeletal muscle relaxants have the potential for abuse (126,127). Preston et al. (128) conducted a behavioral study in adult male volunteers to evaluate the abuse potential of methocarbamol in comparison with lorazepam and placebo. Results from this study suggest that methocarbamol has some abuse potential at supratherapeutic doses that is less than that of lorazepam and is limited by dose-related side effects. Discontinuation of benzodiazepines after chronic use has been reported in several cases to produce a withdrawal syndrome characterized by autonomic hyperactivity resulting in tremulousness, sweating, insomnia, tachycardia, mild systolic hypertension, and rarely seizures (129). Carisoprodol (Soma), whose active metabolite is meprobamate, is thought to carry with it a risk of meprobamate dependence (130). Abrupt discontinuation of carisoprodol following chronic use (several days) at 100 mg per kg has been reported to result in mild withdrawal symptoms such as abdominal cramps, insomnia, chills, headache, and nausea (115). Furthermore, psychological dependence has been reported, albeit rarely, with chronic carisoprodol administration.

Conclusions

Skeletal muscle relaxants are a diverse group of pharmacologic agents that decrease skeletal muscle tone by promoting the inhibition of certain supraspinal and spinal motor neurons and, in some cases, through direct action on skeletal muscle. Strong evidence exists for the efficacy of skeletal muscle relaxants in the treatment of muscle spasm associated with acute low back pain as well as for the similar efficacy of different muscle relaxant agents in treating this condition. Carisoprodol is our first choice because of the several high-quality controlled trials showing superiority to placebo or other muscle relaxants and its favorable safety profile over several decades on the market. More research is necessary to demonstrate the efficacy of these agents in the treatment of other disorders such as tension headache, neck pain, and temporomandibular dysfunction. The most prominent and clinically relevant adverse effects of skeletal muscle relaxants are those related to dose-dependent, reversible CNS depression. The abuse potential of these drugs is a relative contraindication to use for periods longer than several weeks. Other than for short-term use in the treatment of acute muscle spasm, there is little evidence of a favorable risk-benefit profile to support the general use of benzodiazepines as adjuvant analgesics in chronic pain management.

ANTAGONISTS OF THE *N*-METHYL-D-ASPARTATE GLUTAMATE RECEPTOR

As discussed in Chapter 4, animal studies have shown that many of the plastic changes that pain causes in the CNS are mediated by glutamate receptors, which are classified into NMDA, alpha-amino-3-hydroxy-5-methyl-4-isoxazole proprionic acid/kainate, and metabotropic subclasses. A small number of controlled trials with NMDA-receptor antagonists have suggested efficacy in various chronic pain conditions. Because of the limited data from controlled studies of chronic dosing, we think it is premature to recommend the use of these drugs at this writing. However, because clinicians are already using NMDA antagonists in patients with refractory pain, we briefly discuss the clinical pharmacology of ketamine and dextromethorphan, the two NMDA-receptor antagonists for which multiple controlled trials suggest analgesic efficacy.

Ketamine

Ketamine has been used as an anesthetic agent for more than 3 decades (133), but interest in chronic administration for pain was only recently kindled by the recognition that at subanesthetic doses, its primary effect is blockade of the phencyclidine site in the ion channel associated with the NMDA receptor (134). A series of placebo-controlled trials [references in Stubhaug and Breivik (135)] have shown that brief infusions of ketamine reduce pain caused by postherpetic neuralgia, chronic trauma, amputation, spinal cord injury, fibromyalgia, surgery, and a variety of types of experimental pain and hyperalgesia, but at doses that often cause sedation and dissociative reactions. In surgical settings, anesthesiologists often coadminister benzodiazepines with ketamine to ameliorate or prevent recall of psychotomimetic reactions, but Krystal et al. (136) have shown that lorazepam worsens the sedative, attention-impairing, and amnestic effects of intravenous ketamine and only partially reverses ketamine-induced psychosis at doses that do not produce sleep.

Chronic subcutaneous infusion of ketamine appeared effective in several patients with postherpetic neuralgia (137), but subcutaneous induration prevented chronic treatment. Several case reports (138,139 and 140) describe benefit from chronic oral administration of ketamine—either the intravenous preparation is dissolved in juice or an oral suspension can be used. Doses were titrated to effect in each patient and ranged between 50 and 60 mg p.o. four to six times per day.

The pharmacokinetic profile of oral ketamine differs from intravenous ketamine in humans in that there is a prominent first-pass effect; the liver metabolizes more than 80% of the ingested drug to the active metabolite norketamine. There is little information about the long-term toxicity of oral ketamine. Case reports of possible serious toxicity describe hepatic damage (141), gastric ulcer (138), and memory impairment (142). In view of these concerns, chronic ketamine should only be given when standard measures have failed, under close medical supervision.

Dextromethorphan

Dextromethorphan, widely available as an over-the-counter cough remedy, has recently been recognized to block the ion channel associated with the NMDA receptor as does its primary metabolite, dextrorphan (143,144). Dextromethorphan is also an agonist at sigma-1 receptors and an antagonist at the transporter for FHT reuptake (61) and at ion-gated calcium channels (145). Steinberg et al. (146) measured dextromethorphan concentrations in brain tissue of neurosurgical patients pretreated with the drug. By comparing these with brain tissue levels affording neuroprotection in animal models of ischemia, they concluded that adequate blockade of NMDA receptors requires doses several times higher than the maximum antitussive dose of 120 mg per day.

Two randomized clinical trials (147,148) showed that chronic treatment with dextromethorphan at an average dose of 400 mg per day reduced pain in 31 patients with diabetic neuropathy to about 80% of the intensity reported by placebo-treated patients, a degree of pain relief approximating that shown in other studies of tricyclic antidepressants, mexiletine, and gabapentin. Side effects at this dose include dizziness, fatigue, and confusion, which were prominent during upward dose titration but mild after a maintenance dose was found. Patients with postherpetic neuralgia did not report pain relief in either study. A previous study (149) had not shown any analgesic effect at 81 mg per day.

Like the tricyclic antidepressants, dextromethorphan is primarily metabolized by the cytochrome P450 2D6 enzyme, whose multiple alleles cause great variability in drug concentrations achieved in different patients. Capon et al. (150) reported the median elimination half-life to be 2.4 hours in extensive metabolizers and 19.1 hours in poor metabolizers. In order to get uniformly high dextromethorphan plasma levels (and to solve the difficulty in obtaining a high-dose preparation of pure dextromethorphan) several groups have administered quinidine, 50 to 75 mg twice daily, along with dextromethorphan. This drug powerfully inhibits the 2D6 enzyme, converting extensive metabolizers to poor metabolizers and increasing plasma dextromethorphan by 20-fold (151). We would urge caution in using this drug combination for several reasons: (a) Quinidine has its own toxicities, including potentiation of cardiac arrhythmias and allergic reactions, although the doses sufficient to block 2D6 activity (50 to 75 mg twice daily) are much lower than the doses generally used to treat cardiac arrhythmias; (b) blood concentrations of any other drug metabolized by 2D6 will also rise precipitously, including tricyclic antidepressants, mexiletine, antipsychotics, and b-adrenergic blockers (42,43); and (c) the blockade of metabolism will greatly lower plasma and CNS levels of the active metabolite dextrorphan. It is possible that dextrorphan played an important role in the pain relief reported in the treatment of diabetic neuropathy with high-dose dextromethorphan (147). If so, these results would not carry over into treatment with a low-dose dextromethorphan-quinidine combination.

Because dextromethorphan increases the amount of 5-HT at central synapses, it may cause the potentially fatal serotonin syndrome when combined with other

serotonergic drugs, including paroxetine, fluoxetine, and monoamine oxidase inhibitors (61,62 and 63). Case reports have suggested that dextromethorphan may trigger mania in patients with bipolar affective disorder (152).

Other *N*-Methyl-D-Aspartate Receptor Antagonists

A single paper reports that a single intravenous infusion of amantadine temporarily reduced chronic postsurgical neuropathic pain (153). There are no chronic treatment studies with the commonly available oral form of this medication. Memantine, another NMDA channel blocker commonly used in Germany for the treatment of Parkinson's disease and Alzheimer's disease, is under study in acquired immunodeficiency syndrome–related neuropathy, diabetic neuropathy, and postherpetic neuralgia.

CHAPTER 86

Anticonvulsants and Local Anesthetic Drugs

Michael C. Rowbotham and Karin L. Petersen

Anticonvulsants and local anesthetic drugs have been used for decades to treat chronic pain. Sufficient basic and clinical scientific evidence has accrued to firmly establish anticonvulsants and local anesthetic drugs as specialized analgesics. Neither class of drug has clearly established analgesic efficacy for musculoskeletal, nociceptive, or idiopathic pain. However, both classes can dramatically relieve neuropathic pain.

Research in animals with experimental nerve injury and humans with chronic neuropathic pain has highlighted one clinically important mechanism for the production of neuropathic pain: ectopic impulse generation by damaged, dysfunctional primary sensory neurons and their axons. This abnormal, ectopic discharge can be suppressed by anticonvulsants and local anesthetics with sodium channel blocking effect at concentrations orders of magnitude lower than needed to block the propagation of action potentials in normal nerves (1,2). Because the process of ectopic impulse generation is far more sensitive to sodium channel blockade than is normal impulse conduction, these drugs can be given systemically or regionally without fatal toxicity from failure of normal nerve conduction. Anticonvulsants that do not block sodium channels, such as gabapentin, are also highly effective analgesic agents. Discerning the neuronal basis for the analgesic effect of these drugs has been the subject of much research.

In this chapter, anticonvulsants and systemic local anesthetics are discussed in the context of current concepts of the pathophysiology of neuropathic pain. First, the mechanisms behind neuropathic pain and ectopic neuronal activity are summarized, and the mechanisms by which membrane stabilizing drugs suppress ectopic firing are reviewed: (a) Na-channel blockade and (b) non–Na-channel blockade. Then, the clinical literature relating to their use and efficacy in the treatment of neuropathic pain is reviewed. Finally, the currently available anticonvulsants and systemic local anesthetic drugs are reviewed.

NEUROPATHIC PAIN AND ECTOPIC NEURONAL ACTIVITY

In teased axon recordings from dorsal roots in rats and rabbits with chronic nerve injury, Wall and Gutnick (3) and Kirk (4) demonstrated an increased level of ongoing discharge in afferent A and C fibers compared to normal intact dorsal root and dorsal root just after acute nerve section. Subsequent studies identified two principal sources of this activity: the nerve injury site (e.g., neuroma or nerve compression zone) (5,6; reviewed in 7) and the associated dorsal root ganglia (DRG) (8,9 and 10). In addition to spontaneous firing, ectopic discharge at both of these locations can be produced by gentle tapping and by a range of chemical stimuli. In contrast to the nerve injury site, the DRG have not yet been investigated as a potential source of ectopic firing in humans despite the strong experimental evidence in animals.

Ectopic neuronal activity contributes to pain in three ways. First, abnormal afferent barrages that propagate into the central nervous system (CNS) directly will elicit paraesthesias, dysesthesias, and pain. For example, continuous discharge in C fibers produces continuous sensations of burning pain, and intermittent spontaneous bursts in A-d or A-b fibers produce lancinating dysesthesias or paresthesias. Second, ectopic sites are abnormally likely to generate action potentials (single or prolonged bursts of neuronal activity) spontaneously and in response to gentle mechanical stimulation, sympathetic efferent activity, and circulating catecholamines. Third, abnormally increased afferent input via nociceptors can trigger and maintain “central sensitization.” Central neurons become sensitized in response to a brief but intense barrage of nociceptor input or sustained low-level nociceptor input (11). Once central neurons are sensitized, even innocuous mechanoreceptor stimulation from an area around the nerve injury is perceived as painful (12,13 and 14). This effect of ectopic firing in neuropathic pain is best illustrated under conditions in which a well-localized focus of abnormal neuronal discharge can be identified. Sheen and Chung (15), for example, severed the spinal nerve of DRG L-5 and L-6 in rats, creating a focus of ectopic discharge in the L-5 and L-6 neuromas and DRG. The result was behavioral signs of ongoing pain, presumably due to the ectopic firing, and allodynia in the hindlimb skin served by the neighboring L-4 root that was presumed to be due to central sensitization triggered by the ectopic firing. Blocking central propagation of the abnormal ectopic discharge by secondarily cutting the L-5 and L-6 dorsal roots eliminated the ongoing pain and normalized sensation in the L-4 territory.

Confirmatory evidence in humans has been gathered using the method of percutaneous microneurographic recording from single nerve fibers (16). Microneurography allows a direct comparison of neural discharge and sensation. A small number of such studies in patients with neuropathic pain have appeared (17,18,19,20 and 21). Spontaneous and evoked discharges were strikingly correlated with neuropathic paresthesias and pain. As reported by Cline and colleagues (17), patients who complained of burning pain and hyperalgesia had spontaneous activity in unmyelinated primary afferents. Nystrom and Hagbarth (19) documented ongoing discharge in the peroneal nerve in a lower extremity amputee. Their patient had ongoing phantom foot pain that was augmented by percussion of the neuroma. Each percussion elicited an intense burst of spike activity, mostly in slowly conducting axons. Local anesthetic block of the neuroma eliminated percussion-evoked neuronal activity and pain. In a patient with radicular pain after surgery for disk herniation, straight-leg lifting (Lasegue's sign) produced dysesthesias referred to the foot as well as ectopic impulse bursts in the sural nerve, the intensity of which waxed and waned in close correlation with the abnormal sensation (18).

There is some clinical evidence that large areas of touch-evoked allodynia are due to a state of central sensitization maintained by ectopic impulse generation from the area of most severe neuropathic pain. Rowbotham and Fields (22) reported dramatic shrinkage of the area of allodynia with local anesthetic skin infiltration of just the area of maximum pain in a small series of patients with postherpetic neuralgia. Gracely et al. (23) reported a patient whose painful scar near the knee was surrounded by touch-evoked allodynia extending up the thigh and down the calf. Local anesthetic block of the scar eliminated the extended allodynia as well as the scar pain for the duration of the block. The interpretation offered was that noxious input originating in the scar triggered a spinal central sensitization state that amplified, and rendered painful, A-b touch input from the thigh and calf. More difficult to explain are those rare patients in whom a brief infusion of systemic lidocaine will reproducibly relieve neuropathic pain for days or weeks.

CONTRIBUTION OF NA^+ CHANNEL BLOCKADE TO PAIN RELIEF

Na^+ channels are membrane proteins found in all nerve cells. Among many functions, Na^+ channels constitute a major component of the impulse-generating machinery. Impulse propagation along axons is critically dependent on the functioning of Na^+ channels. The development of ectopic hyperexcitability is thought to be due to remodeling of the local electrical properties of the axon membrane via changes in Na^+ channel distribution (7). The principal underlying mechanism appears to be the accumulation of excess voltage-sensitive Na^+ channels in terminal swellings of axonal sprouts in the region of injury and in patches of demyelination (24).

Research suggests that there may be ten or more different Na^+ channel subtypes. Na^+ channels are classified as tetrodotoxin (TTX)-sensitive or TTX-resistant based on the response to TTX, an extremely potent selective Na^+ channel blocker. TTX inhibits neuronal activity in animal neuropathic pain models by blocking

TTX-sensitive Na^+ channels in the injured nerve but also blocks TTX sensitive Na^+ channels throughout the nervous system. A TTX-resistant Na^+ channel named *PN3* (or alpha-SNS) has been identified. In contrast to previously identified Na^+ channels, PN3 is located only in the PNS on small neurons in the DRG (25). The PN3 Na^+ channel is suggested to be of specific importance to pain transmission. Experimental nerve damage leads to changes in PN3 expression in the DRG (26,27 and 28). Using immunolabeling, migration of PN3 Na^+ channels from the DRG to C and A-d fibers has been demonstrated, implying that ectopic neural activity after nerve injury may be due to a dynamic redistribution of pain-specific Na^+ channels. Developing an analgesic agent specifically targeting the PN3 Na^+ channel has potentially important implications, since clinical use of nonselective Na^+ channel blockers are limited by systemic side effects presumed due to actions on cardiac and CNS Na^+ channels.

A variety of anticonvulsant and local anesthetic drugs that suppress abnormal discharge originating at nerve injury sites and associated DRG act on Na^+ channels (29). These include the anticonvulsants carbamazepine, phenytoin, and lamotrigine (30,31); the antiarrhythmics mexiletine and tocainide (32); and lidocainelike local anesthetics (33). Each of these prevents the generation of spontaneous ectopic impulses at much lower concentrations than are required to block normal impulse propagation. Abram and Yaksh (34) compared the effect of systemic lidocaine in three rat pain models: the formalin test (which uses a chemical stimulus to produce a two-phase nociceptive response), partial ligation of the sciatic nerve (which produces neuropathic hyperalgesia), and normal paw withdrawal to noxious heat. Doses of lidocaine that markedly reduce neuropathic hyperalgesia leave the withdrawal latency to noxious heat in the normally innervated paw and both phases of the formalin unaffected. Higher doses of lidocaine reduce only the second phase of the formalin test, which is thought to be due, in part, to the development of central sensitization. In a study of rat sciatic neuromas by Chabal and colleagues (32), lidocaine, mexiletine, and tocainide abolished spontaneous activity and markedly suppressed the ability of gentle mechanical stimulation to evoke abnormal activity. Other studies in animal models of neuropathic pain demonstrate that systemic lidocaine sometimes relieves cutaneous hypersensitivity for a longer time than would be expected from the serum half-life of the drug (35). In sum, these results suggest the following rank ordering of lidocaine effects on pain: (a) Low plasma levels suppress ectopic impulse generation in chronically injured peripheral nerve; (b) higher levels suppress central sensitization and central neuronal hyperexcitability; (c) high levels have general analgesic effects; (d) very high levels are associated with seizure activity, cardiac arrhythmias, and cardiovascular collapse; and (e) supralethal systemic levels block normal axonal impulse conduction.

ANALGESIC EFFECTS INDEPENDENT OF NA^+ CHANNEL BLOCKADE

Some anticonvulsant drugs are highly effective in controlling pain but seem to do so without blocking Na^+ channels. Proposed mechanisms of analgesic actions for non-Na^+ channel blocking drugs revolve around effects on sensitized central neurons, such as direct or indirect inhibition of the release of excitatory amino acids, blockade of neuronal calcium channels, and augmentation of CNS inhibitory pathways via increasing GABA-ergic transmission.

The best example of an effective non-Na^+ channel blocking anticonvulsant is gabapentin, a lipophilic GABA analog. Two large multicenter clinical trials of gabapentin for neuropathic pain demonstrated efficacy (36,37). Gabapentin does not reduce acute nociceptive pain (38,39). However, gabapentin does reduce signs of central sensitization in animals after experimentally induced hyperalgesia and may do so by reducing the sensitization of dorsal horn sensory neurons (39,40 and 41). Furthermore, it has been demonstrated in animal models that gabapentin reduces hyperalgesia following experimental nerve injury (38,42). Despite intensive study, the basis for gabapentin analgesia remains uncertain. Gabapentin was developed as an analog to the neurotransmitter GABA but has since been shown not to interact with either $GABA_A$ or $GABA_B$ receptors [for review, see Taylor et al. (41)]. Since gabapentin is excreted unmetabolized, active metabolites cannot explain the analgesic effect in humans. GABA-ergic function could be potentiated without direct interaction with GABA sites by increasing the concentration of GABA in neuronal tissue through release of GABA from nerve terminals (43), enzyme effects, or decreased GABA breakdown (for review, see 41 and 44). Another possible mechanism is mobilization of intracellular GABA via gabapentin-sensitive transporters. However, the best evidence to date comes from studies rank-ordering effects of gabapentin and related drugs on a specific gabapentin-binding protein found in brain and spinal cord. The binding site, called a $_2$d, is a subunit of an N-type voltage-gated calcium channel found in high density in the cerebral cortex, superficial dorsal horn, cerebellum, and hippocampus (38,41,45). Studies in spinal cord dorsal horn preparations have found that gabapentin binding is primarily postsynaptic and is resistant to neonatal capsaicin treatment and rhizotomy. GABA itself has no activity at this binding site, but gabapentin analogs that bind to the a $_2$d-subunit do appear to have analgesic activity. At this time, it is not certain which, if any, of the suggested mechanisms may be relevant to the analgesic efficacy of gabapentin.

CLINICAL USE OF LOCAL ANESTHETICS, ANTIARRHYTHMICS, AND ANTICONVULSANTS IN TREATMENT OF CHRONIC PAIN

Systemic administration of local anesthetics for analgesia has a long history (46). Beginning in the 1930s, procaine and later lidocaine have been given systemically for a broad variety of painful conditions. More recently, analgesia from systemic local anesthetic administration has been established through prospective controlled studies in patients with painful diabetic neuropathy (47,48 and 49) and postherpetic neuralgia (50). In two large uncontrolled series, systemic local anesthetics were most often effective for patients with pain due to peripheral nerve injury (51,52). In contrast, the effect of systemic local anesthetic in acute nociceptive pain is less consistent. Cassuto et al. (53) reported significant analgesic efficacy for intravenous lidocaine in postoperative pain and Jonsson et al. (54) reported its efficacy for burn pain. However, other controlled studies have reported systemic local anesthetics to have minimal or no analgesic effectiveness for postoperative pain. The effect of lidocaine on human experimental pain models is modest (55,56). Other diagnostic groups for whom excellent responses to systemic local anesthetic administration have been reported anecdotally include cranial neuralgias, multiple sclerosis, adiposis dolorosa (57), cancer pain, thalamic pain, and arachnoiditis (1,58,59).

Currently, lidocaine infusions are used to either further explore the nature of the pain (55) or to predict response to an oral antiarrhythmic or anticonvulsant agent that also blocks sodium channels (60,61). Mexiletine is the only oral antiarrhythmic agent studied prospectively for comparative response after intravenous lidocaine in neuropathic pain patients.

Anticonvulsants are a broad category tied together only by their ability to suppress epileptic seizures. Anticonvulsants came into general use by neurologists for a variety of painful conditions once carbamazepine was demonstrated to have dramatic efficacy in the treatment of trigeminal neuralgia (62,63,64,65,66,67 and 68). Clinical experience suggests that they are most effective in conditions in which the pain has a lancinating component (i.e., a neuropathic quality) (69,70). This point has not been examined quantitatively, however, and the efficacy of anticonvulsant drugs such as valproic acid and gabapentin in migraine prophylaxis (65) is noteworthy. In addition, gabapentin has been used anecdotally for a broad range of chronic pain states extending well beyond peripheral neuropathic pain and headache to include atypical facial pain, complex regional pain syndromes, fibromyalgia, and central pain.

CHOOSING A DRUG

Table 86-1 lists usual doses, common side effects, and general precautions regarding the specific oral drugs reviewed in this chapter. For further detail on specific drugs, see the *Physicians' Desk Reference* (71) and reviews of epilepsy therapy by Brodie and Dichter (72) and Dichter and Brodie (73). For newer drugs, such as gabapentin and topiramate, reports of unusual adverse events are largely limited to patients with refractory seizures on multidrug regimens. Of the oral medications currently available, there is no specific rank-order validated by prospective, blinded, comparative studies of patients with chronic pain. Carbamazepine and gabapentin would appear to be the first choice drugs, followed by mexiletine and valproic acid. The other anticonvulsant, antiarrhythmic, and local anesthetic drugs described here are used primarily for treatment of neuropathic pain and have not been studied in large-scale, prospective controlled trials. Carbamazepine has been the traditional first-line anticonvulsant agent and is the only one the U.S. Food and Drug Administration has approved for management of pain (trigeminal neuralgia). The overall side effect profile of carbamazepine and the need for close monitoring of hematologic function are substantial drawbacks that make many pain clinicians reluctant to use this drug. At the present time in the United States, it appears that gabapentin is the anticonvulsant agent used most often for chronic pain. However, carbamazepine and gabapentin have very different mechanisms of action. Nonresponse to one agent probably has no predictive value for response to the other. For a patient with trigeminal neuralgia, the first choice will likely remain carbamazepine until proven otherwise. For all other chronic pain conditions, gabapentin is probably the first choice anticonvulsant because of demonstrated efficacy in large controlled clinical trials (postherpetic neuralgia, diabetic neuropathy, and migraine prophylaxis), anecdotal evidence for efficacy in a variety of other chronic pain states, ease of use, and its relatively benign adverse event profile. Dosing of most pain patients can be managed on clinical criteria alone. Blood levels are useful for monitoring compliance and toxicity. It is noteworthy that for carbamazepine up to 100% circadian variation in plasma levels have been demonstrated making interpretation of plasma levels difficult (74). Furthermore, published recommendation of plasma levels refers to seizure control, not pain control.

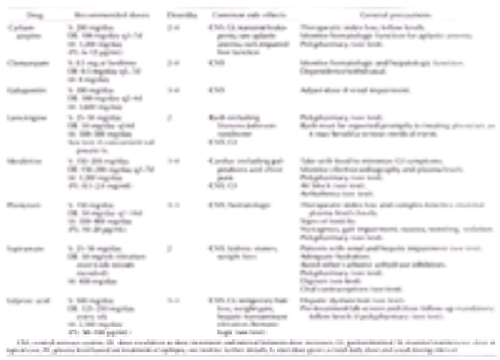

TABLE 86-1. Recommended total daily doses, number of daily doses, common side effects, and general precautions regarding the specific oral drugs reviewed in this chapter

Carbamazepine

Carbamazepine is the first-line drug for the treatment of trigeminal neuralgia and is the only anticonvulsant the U.S. Food and Drug Administration has approved for treatment of any neuropathic pain disorder. The primary mechanism of action underlying pain relief from carbamazepine is thought to be sodium channel blockade. In animal studies, carbamazepine reduces polysynaptic responses and posttetanic potentiation. Carbamazepine has not been thoroughly studied using current animal models of acute and chronic pain, but older studies showed a reduction in pain in cats subjected to repetitive infraorbital nerve stimulation. Like the local anesthetics lidocaine, mexiletine, and tocainide, carbamazepine reduces spontaneous activity in experimental neuromas (30). Controlled clinical trials with carbamazepine have produced mixed results. Success has been documented in trigeminal neuralgia and diabetic neuropathy but not in postherpetic neuralgia and central pain (69,75,76,77 and 78). Many other studies with carbamazepine in a variety of neuropathic pain disorders indicate efficacy but are small or uncontrolled, or both.

Side effects of sedation and unsteadiness can be prominent with carbamazepine, so therapy is best initiated with a very low dose of 100 mg twice daily. The dose should be increased in 100-mg increments every 7 days until either satisfactory relief is obtained or intolerance/toxicity appears. Only occasionally do total daily doses exceed 1,200 mg (divided t.i.d. or q.i.d.). For most patients, therapeutic plasma concentrations are between 6 and 12 mg per mL, although the occasional patient may require higher levels for stable pain control. In particular, trigeminal neuralgia patients may have exacerbations of pain requiring brief periods of higher than usual doses for control. Because of individual variation in the pharmacokinetics of carbamazepine and the fact that signs of toxicity appear near the upper end of the therapeutic range of plasma concentrations, it is important to carefully adjust the dose when initiating long-term therapy. Dose-related side effects include rash, fatigue, sedation, ataxia, vertigo, and blurred vision. Nausea and vomiting are also common. Rarely, rash may lead to erythema multiforme or Stevens-Johnson syndrome. A mild leukopenia occurs in approximately 10% of patients and persists in a quarter of these. Because of rare cases of irreversible aplastic anemia, approximately 1 in 15,000 persons exposed, regular monitoring of hematologic function is strongly recommended. Combinations of carbamazepine with other anticonvulsants, selective serotonin-reuptake inhibitor antidepressants, and oral contraceptives need careful monitoring because carbamazepine will affect blood levels of other drugs and vice versa.

Clonazepam

Clonazepam should be considered as a third-line drug for neuropathic pain. Unlike the other anticonvulsants reviewed here, clonazepam is structurally and pharmacologically related to the benzodiazepine family. There is only limited evidence for pain relief with other benzodiazepines (79) and strong evidence that benzodiazepines such as diazepam are not analgesic even when administered intravenously for up to 6 hours at a time (80). Max and coworkers (81) studied lorazepam, another benzodiazepine with anticonvulsant properties, in a double-blind crossover comparison with amitriptyline and placebo in patients with postherpetic neuralgia. Lorazepam was ineffective compared to amitriptyline. Other benzodiazepines with anticonvulsant activity, such as diazepam and lorazepam, have been specifically investigated in blinded clinical trials for neuropathic pain and found ineffective. The antiepileptic mechanism for clonazepam, although uncertain, is presumed to involve potentiation of inhibitory GABA neurotransmission. Reduction in pain intensity with clonazepam may be due to its antianxiety and antispasticity effects rather than to its anticonvulsant effect. Successful treatment of a variety of cranial neuralgias with clonazepam has been reported in uncontrolled studies that include a total of 46 trigeminal neuralgia patients and a small number suffering from sphenopalatine ganglion neuralgia, malignant skull base neuralgia, glossopharyngeal neuralgia, cluster headache, and phantom limb pain (82,83,84 and 85). Effective daily doses ranged from 3 to 8 mg.

The initial dose of clonazepam is usually 0.5 mg taken at bedtime. The dose is then titrated to effect by adding 0.5 mg every 5 to 7 days in a divided daily dose, two to four times per day. The maximum dose recommended for the treatment of epilepsy is 20 mg per day, but pain relief or intolerable side effects, usually sedation, should be apparent at doses below 8 mg per day. Clonazepam's elimination half-life is 18 to 39 hours. Catabolism is by first-order kinetics. Being a CNS depressant, acute toxicity of clonazepam may include confusion, somnolence, hypotension, and even coma. Patients should be warned that their ability to perform hazardous activities, such as driving, may be impaired. Transiently elevated serum aminotransferase and alkaline phosphatase, anemia, leukopenia, thrombocytopenia, and eosinophilia have all been reported. Periodic complete blood counts, platelet count, and liver function tests should be performed. Clonazepam should be discontinued with a gradual taper, as abrupt stoppage may result in severe withdrawal symptoms, including seizures. Because clonazepam is a benzodiazepine, patients with a history of substance abuse or alcoholism should be warned and monitored closely for signs of psychological dependence.

Gabapentin

The popularity of gabapentin for pain, likely exceeding that of all other anticonvulsants, appears to be due to ease of monitoring, a relatively low incidence of serious adverse events, and a perception of efficacy. Gabapentin was approved for marketing in the United States in 1995 as adjunctive therapy in the treatment of seizures.

Because of its apparently benign side effect profile and relative lack of drug interactions, gabapentin is currently entering widespread use for pain management. In some pain centers, gabapentin is being used as first-line therapy for all types of chronic pain. Several case reports and open-label clinical trials have reported analgesic efficacy of gabapentin in a variety of painful conditions (86,87). In a large retrospective review of charts, Rosenberg et al. (88) reported an analgesic effect of gabapentin in neuropathic pain, but not in low back pain. Two large, multicenter, double-blind, placebo-controlled clinical trials have demonstrated that gabapentin reduced pain from diabetic neuropathy (36) and postherpetic neuralgia (37). In another large study, gabapentin was reported effective for migraine prophylaxis (89).

Dosage recommendations for adults are a starting dose of 300 mg per day, increasing in 300-mg-per-day increments as tolerated up to total doses of 2,400 to 3,600 mg per day. Since gabapentin is absorbed via saturable active transport mechanism, four times daily dosing will produce higher blood levels than three times daily dosing. Because of the short half-life, doses should not be given more than 12 hours apart and discontinuation of the drug should be spread over 1 week (or longer). The dose must be adjusted in patients with renal failure, but no adjustment is necessary in patients with hepatic disorders because the drug is excreted unmetabolized. The most common side effects are related to CNS depression, such as dizziness, ataxia, and somnolence. Unlike carbamazepine, clinical trials do not indicate routine monitoring of clinical laboratory parameters is necessary for safe use of gabapentin, and gabapentin can be administered in addition to other antiepileptic drugs without concern of the serum concentration of gabapentin or other antiepileptics. Acute oral overdoses of up to 49 g have been reported without fatality.

Lamotrigine

Lamotrigine was approved for use as an add-on anticonvulsant in the treatment of partial seizures. Lamotrigine is similar to phenytoin and carbamazepine in blocking voltage-dependent sodium channels (90). Like other anticonvulsants suppressing ectopic impulse activity, central release of the excitatory transmitters glutamate and aspartate is reduced by suppressing abnormal peripheral input (91).

Animal data have demonstrated an analgesic effect of lamotrigine (38,92). In a study of postoperative pain, 200-mg single doses of lamotrigine reduced both postoperative pain and analgesic requirements (93). Large single doses of lamotrigine (300 mg) modestly suppressed pain during cold-pressor testing compared to placebo, but the effect was less than that observed with phenytoin and dihydrocodeine (94). So far, one double-blind, placebo-controlled study of the analgesic effect of lamotrigine has been published. In this small study, lamotrigine as an add-on therapy reduced daily pain in trigeminal neuralgia (95). Similar results have been

found in open trials of diabetic neuropathy (96) and trigeminal neuralgia (97). Furthermore, there are anecdotal reports of efficacy in both peripheral and central neuropathic pain conditions (98,99). In a placebo-controlled, double-blind trial, lamotrigine did not reduce migraine frequency (100).

Starting doses depend on other drugs being used concurrently, but standard recommendations suggest 50 mg per day for 2 weeks, then escalating to 100 mg per day, divided b.i.d. The dose can be escalated by 50 mg per day every 7 to 14 days to the usual maintenance dose of 300 to 500 mg per day, divided b.i.d. Lamotrigine is well absorbed from the gastrointestinal (GI) tract, with peak plasma levels in 1.5 to 5.0 hours. It is metabolized by glucuronidation and has a single-dose half-life of 24 hours. Unlike gabapentin, there are significant interactions of lamotrigine with other anticonvulsants. Concurrent use of carbamazepine and lamotrigine increases carbamazepine levels and can produce clinical toxicity. Valproate concentrations are decreased and lamotrigine half-life more than doubles when lamotrigine is used concurrently with valproic acid. Concurrent use of lamotrigine with phenobarbital, phenytoin, or primidone leads to shortening of the lamotrigine half-life because of induction of hepatic glucuronidation enzymes. Patients on concurrent valproate therapy require slower titration and should start on 25 mg every other day for 2 weeks, then 25 mg daily for 2 weeks, and then the dose can be escalated with 25 to 50 mg per day every 1 to 2 weeks to a maintenance dose of 100 to 150 mg per day, divided b.i.d.

Rash is the most common adverse effect, with up to 10% developing rash and 1 in 1,000 patients developing Stevens-Johnson syndrome (101). The incidence of rash is higher with fast dose escalation and when patients are on concurrent valproate. When lamotrigine treatment is started, the patients should be instructed that (a) rash may occur, (b) that it may herald a serious medical event, and (c) should rash occur, it must be reported promptly to their physician. Other adverse effects include dizziness, diplopia, ataxia, blurred vision, nausea, and vomiting.

Lidocaine (Intravenous)

Administration of lidocaine, and its predecessor procaine, by the intravenous route has been reported since the 1940s (46) to produce dramatic pain relief in some patients. Although pain relief lasting several days to weeks is reported in rare cases, patients should be warned that even when significant analgesia is reported, pain typically returns to baseline within 1 to 2 hours. The abrupt return of pain in some patients may be interpreted as a pain exacerbation above baseline severity. The protocol used at the University of California, San Francisco, Pain Management Center is to administer lidocaine intravenously at a dose of 5 mg per kg over 45 minutes, without a bolus. In patients with normal hepatic function, end-infusion blood levels are approximately 1 to 3 mg per mL, the low antiarrhythmic range for lidocaine. The infusion may be continued at the same rate for an additional 15 to 30 minutes if pain relief is incomplete. Side effects are mild, and cardiovascular changes are minimal. Alternative methods of delivering lidocaine intravenously may be used. For instance, Marchettini (55) successfully used a 60-second injection of 1.5 mg per kg as a test procedure. Others have used computer-controlled infusion pump systems to target and maintain stable plasma lidocaine concentrations (102,103).

After an intravenous bolus of 50 to 100 mg, lidocaine antiarrhythmic effects begin in 45 to 90 seconds and last 10 to 20 minutes. The terminal phase half-life of lidocaine is 1.5 to 2.0 hours. Approximately 90% of an intravenous lidocaine dose is rapidly metabolized by the liver. Although serious adverse effects are uncommon with the administration of parenteral lidocaine, continuous electrocardiographic, heart rate, and blood pressure monitoring is required, and resuscitative equipment must be immediately available. The procedure should be used with caution in patients with hepatic insufficiency, sinus bradycardia, and incomplete heart block. An increase in ventricular rate may occur in patients with atrial fibrillation. If an arrhythmia develops or prolongation of the PR interval or the QRS complex occurs, the infusion should be discontinued. Intravenous lidocaine is contraindicated in patients with known hypersensitivity to amide-type local anesthetics, Adams-Stokes syndrome, and severe heart block. The most common side effects, albeit transient and dose-dependent, are associated with intravenous lidocaine's CNS effects. These adverse effects include drowsiness, dizziness, tremulousness, euphoria, blurring of vision, paresthesias, and dysarthria. In the doses normally used, lidocaine is an anticonvulsant. At high blood levels, usually exceeding 10 mg per mL, lidocaine may cause seizures. If a patient is concurrently taking another local anesthetic antiarrhythmic, adverse effects could appear earlier in the infusion. Cimetidine and propranolol each may diminish the systemic clearance of lidocaine, resulting in higher plasma lidocaine levels.

Although there is good evidence that intravenous lidocaine reduces pain in a variety of disorders, its usefulness in chronic pain management remains unclear (51,52). In a few patients, relief from each administration is sufficiently long lasting that they prefer periodic intravenous lidocaine to daily oral medications. The response to intravenous lidocaine partially predicts response to oral local anesthetics for arrhythmia control (104). The evidence that the lidocaine infusion test is useful in predicting response to analogous oral medications is limited to one small, blinded prospective study (61). In that study, subjects received random-order, double-blind infusions of lidocaine, 2 mg per kg and 5 mg per kg, followed by 4 weeks of open-label mexiletine, up to 1,200 mg per day. Although the response to mexiletine was significantly correlated with the overall response to the two doses of lidocaine, some lidocaine nonresponders responded to mexiletine. Finally, a lidocaine infusion may serve as a control for systemic spread of lidocaine following a successful regional nerve block. Because many nerve blocks produce very high blood levels of local anesthetic for a brief period, equivalent pain relief from a systemic lidocaine infusion suggests that the nerve block relieved pain due to systemic spread of the lidocaine.

Mexiletine

Structurally similar to lidocaine, mexiletine is a local anesthetic and a class IB antiarrhythmic. A randomized, double-blind, placebo-controlled crossover study by Dejgard et al. (47) showed that mexiletine significantly reduced pain, dysesthesias, and paresthesias in patients with chronic painful diabetic neuropathy. A second blinded study showed mexiletine to be especially beneficial in those diabetic neuropathy patients with pain descriptors of stabbing, burning, heat, and formication (49). An intermediate dose of 450 mg per day was felt best overall. In open-label trials, mexiletine has been reported effective for a variety of painful neuropathies, poststroke pain, multiple sclerosis pain, and phantom pain (105,106).

The initial dose is 150 mg or 200 mg once per day with food. The dose is then increased as tolerated by one capsule every 3 to 7 days up to a ceiling of 1,200 mg total per day, divided into three to four doses. Electrocardiography and plasma levels should be monitored closely at the higher doses. Mexiletine plasma levels peak in 2 to 3 hours. The elimination half-life is 10 to 12 hours, but in patients with abnormal liver function it may exceed 25 hours. Therapeutic plasma levels for antiarrhythmic effects range from 0.5 to 2.0 mg per mL. Plasma levels of mexiletine may be reduced with concomitant therapy with phenytoin, rifampin, and phenobarbital; cimetidine therapy may result in elevated mexiletine levels. Mexiletine is contraindicated in patients with preexisting second- or third-degree atrioventricular blockade, but patients with first-degree atrioventricular block may be treated safely. Hypotension and bradycardia may occur with overdosage. Mexiletine may worsen arrhythmias, but uncommonly affects less serious arrhythmias, such as frequent premature beats and nonsustained ventricular tachycardia. In less than 10% of patients, mexiletine may cause palpitations and chest pain. In controlled studies, upper GI distress occurs in 40%, and tremor, lightheadedness, and incoordination each occur in about 10%. GI effects can be reduced by taking the medication with meals, an antacid, or Carafate. Ataxia and seizures are reported to occur in 2 of 1,000 patients. Dose-limiting sedation and dysequilibrium appear to be less of a problem than with carbamazepine.

Other Oral Local Anesthetic Antiarrhythmics: Tocainide and Flecainide

Flecainide may be worth considering as an alternative therapy for neuropathic pain (107) if the use of mexiletine is limited by side effects. The use of mexiletine is, however, much more extensive for pain management. A third oral local anesthetic– type antiarrhythmic, tocainide, had accumulated evidence for efficacy in animal studies and in a double-blind clinical trial in trigeminal neuralgia (108). However, its use has been severely restricted because of a higher than expected incidence of aplastic anemia, exceeding that for carbamazepine.

Phenytoin

Phenytoin was the first anticonvulsant to be specifically used in pain management, but it is now rarely used. Uncontrolled studies totaling 49 patients reported phenytoin to be effective in the treatment of trigeminal neuralgia (109). Double-blind, placebo- controlled studies have demonstrated analgesia with phenytoin in diabetic neuropathy (110) and Fabry's disease (a small fiber neuropathy) (111), although a small trial by Saudek et al. (112) failed to demonstrate analgesia in diabetic neuropathy. Phenytoin is available for parenteral administration and can be used in patients who are having severe and frequent attacks of trigeminal neuralgia (113). In such patients, intravenous administration of phenytoin may provide immediate relief. There are no studies comparing parenteral phenytoin and lidocaine to determine which would be more useful in stabilizing uncontrolled trigeminal neuralgia.

Therapy is usually initiated as 150 mg per day (dosed t.i.d.), and maximum daily doses rarely exceed 450 mg per day. Phenytoin has complex kinetics. Because phenytoin progressively interferes with its own disposition, it is easy to precipitate toxicity with even small increases in dose. Signs of toxicity include nystagmus, gait impairment, nausea and vomiting, and sedation. Cardiac conduction effects at very high blood levels can be life threatening. Coadministration of other drugs can

affect the plasma levels of phenytoin and result in neurotoxicity. Furthermore, phenytoin can induce the metabolism of other antiepileptic drugs.

Topiramate

Topiramate has been used for seizure disorders since 1996, but there are no published clinical trials on the effect of topiramate as an analgesic agent. Topiramate is a carbonic anhydrase inhibitor and has been shown to reduce neuronal activity by voltage- dependent blockade of Na^+ channels, enhancement of GABA at $GABA_A$ receptors, and antagonism of the kainate subtype of the glutamate receptors. Based on the mechanism of action, some analgesic efficacy seems probable, and topiramate is occasionally used in the treatment of chronic pain.

Treatment should be initiated with 25 to 50 mg per day followed by weekly titration of 50 mg to effective analgesic dose. A period of up to 6 weeks to reach maximal tolerated dose is recommended. Doses for pain equivalent to treatment of seizure disorders, 400 mg per day divided in two doses, appears logical. Clinical trials for epilepsy have used daily doses ranging from 200 to 1,000 mg (114,115). Monitoring of plasma concentrations is not mandatory. In patients with renal impairment, one-half of the usual dose is recommended, and in patients with hepatic impairment, topiramate should be administered with caution as clearance could be decreased. Tapering should be done gradually to minimize the potential of increased seizure frequency. Psychomotor slowing, somnolence, and fatigue are prominent, and patient acceptance is better with slow dose-titration regimens. Adequate hydration is recommended, since 1.5% of subjects in clinical trials developed kidney stones. For obvious reasons, other carbonic anhydrase inhibitors should not be administered concomitantly. Topiramate also has the unusual side effect of producing weight loss in a significant proportion of patients. This differentiates the topiramate from nearly all other medications used for pain control. In clinical trials, subjects lost an average of 1.7% to 7.2% body weight depending on dose. Weight loss peaked after 15 to 18 months of therapy with partial return to pretreatment weight thereafter (Ortho-McNeil Pharmaceutical Co., *unpublished data*, 1996). Topiramate has been shown to affect the serum levels of coadministered antiepileptic drugs, and therefore, with polypharmacy, monitoring of serum levels of coadministered drugs as well as of topiramate is required. Administration of topiramate to patients receiving digoxin requires careful monitoring of serum digoxin levels, since topiramate may reduce serum digoxin levels. Furthermore, the efficacy of oral contraceptives may be compromised by topiramate administration.

Valproic Acid

Valproic acid and divalproex sodium are structurally unrelated to any of the other anticonvulsants. Valproic acid is most often prescribed as divalproex sodium (Depakote), an equal combination of valproic acid and sodium valproate. Its analgesic mechanism of action is unknown, but valproic acid is known to increase GABA-ergic neurotransmission and increase brain GABA. Furthermore, excitatory amino acids in brain are reduced by valproic acid (116).

Valproic acid has proved useful in the prophylaxis of migraine in controlled clinical trials (for review, see 117). Limited data exist for the analgesic efficacy of valproate for neuropathic pain and other types of nonheadache pain. One study found no effect of valproate in central pain compared to placebo (118) (only amitriptyline has been reported effective for this condition). In an open- label study, Peiris et al. (119) reported partial or complete control of trigeminal neuralgia in nine of 20 patients with valproic acid in doses of up to 1,200 mg per day. No plasma level therapeutic range has been established for pain control with valproic acid. Similar to the treatment of seizures, the starting dose for the treatment of pain is 250 mg twice per day and the dose is gradually titrated to effect, with a recommended maximal dose in migraine prophylaxis at 1,000 mg per day. Valproate should not be administered to patients with hepatic dysfunction and should be discontinued if signs of dysfunction appear. Side effects and potentially serious toxicity have greatly limited the use of valproic acid for chronic pain. The combination of sedation, GI side effects, hair loss (usually reversible), abnormal liver function tests, potentially fatal hepatotoxicity, inhibition of platelet aggregation, and numerous other potential hematologic and nonhematologic effects makes pretreatment screening and close follow-up mandatory. When concomitant therapy is initiated, clinical status and plasma concentrations should be carefully monitored because changes in metabolization may affect the serum concentration of antiepileptics with polytherapy.

FUTURE DEVELOPMENT OF ANTICONVULSANTS AND LOCAL ANESTHETIC DRUGS

The dose-limiting side effects involved in the systemic use of Na^+ channel blockers include sedation, ataxia, vertigo, blurred vision, nausea, and vomiting. All are CNS effects. It is very often dizziness and loss of alertness that limit titrating to higher, and possibly more effective, analgesic doses. Another potential approach to avoiding dose-limiting CNS toxicity would be to produce a carbamazepine or lidocainelike agent in a form that preserves membrane-stabilizing properties of the parent drug but does not cross the blood–brain barrier. No such drug exists at present. Pharmacologic agents that block Na^+ channels by binding to the extracellular mouth of the channel are known and used widely in basic neuroscience research (e.g., TTX and saxitoxin). They differ from the local anesthetics and anticonvulsants, however, in that their potency does not depend on the firing rate of the neuron (i.e., they are not use-dependent blockers), but are highly toxic substances. Finally, mention should be made of the likelihood that the ectopic neural activity underlying neuropathic pain may be due to a dynamic redistribution of pain-specific Na^+ channels, Na^+ channel molecules subtly different from those present in low threshold afferents and those present in the heart and the brain. This difference might permit the creation of novel Na^+ channel blockers that selectively target and silence nociceptors. The success of drugs acting by mechanisms other than sodium channel blockade, most notably gabapentin, indicates much future potential for analgesic/anticonvulsant drugs.

CHAPTER 87

Topical Medications

Bradley S. Galer

BASIC INFORMATION

Topical medications (Table 87-1) are applied directly on the painful body area, where they penetrate the skin. A topical medication's site of activity is in the peripheral tissues, including soft tissue and peripheral nerve, directly underlying the site of application. Topical drugs, formulated as a gel, cream, liquid, or patch, should not produce any clinically significant systemic drug concentration.

	Topical	Transdermal
Application site	Skin: directly on painful skin	Skin: distant from painful region
Site of activity	Peripherally (soft tissue, nerve)	Systemically
Serum drug concentration	Insignificant	Necessary
Systemic side effects	No	Yes
Titration needed	No	Yes
Drug-drug interaction	No	Yes

TABLE 87-1. Topical versus transdermal drug delivery

Transdermal medications, on the other hand, are also applied directly to the skin, but the site of drug application can be distant from the area of pain (currently available transdermal drugs include fentanyl and clonidine). Transdermal drugs' sites of activity are not local but via a systemic effect. The medication of transdermal delivery systems is typically contained in a pooled reservoir within a patch, which is designed to push drug directly into the bloodstream. Therefore, unlike topical medication patches, a transdermal patch cannot be cut into different sizes.

Therefore, the key difference between topical and transdermal drug delivery systems is that a topical medication does not result in any clinically meaningful blood levels, whereas a transdermal drug must result in clinically effective serum concentrations for its clinical effect.

History

Applying medicinal substances directly on the skin is likely one of the oldest routes of administration. Ancient cultures ground herbs and plants into pastes for medical uses, including the treatment of pain. Over the past century, many tonics, gels, salves, and lotions have been sold as over-the-counter remedies for pain, although most have little to no scientific study to back their claims (e.g., “snake oils”). Many of these older topical medicinal products may in fact act only as counterirritants—that is, they produce a mild to moderate noxious stimulus that then suppresses the perception of the pain.

Only in the past few decades has the pharmaceutical industry begun to develop topical drugs for the treatment of pain with the aim of producing products with proven efficacy. However, even at the time of this writing, the commercial availability of topical pain medication with controlled clinical trial evidence of efficacy remains sparse. Yet, much development and clinical trial study are currently under way, with the promise of safe and effective topical drugs for the treatment of many acute and chronic painful conditions.

Theoretical Bases

Mechanisms of Action

Because topical drugs, by definition, must act locally on dysfunctional or damaged soft tissues or peripheral nerves, all abnormal pathophysiologic events within the periphery that generate or maintain pain are potential targets for these medications. In acute pain syndromes and arthritic conditions, topical drugs may play a role in reducing the inflammatory response and concurrent sensitization of nociceptors. In chronic neuropathic pain, abnormal neuronal activity generated by abnormal impulse generation secondary to upregulated sodium channels or a-adrenergic receptors is a potential target, as is the ongoing neurogenic inflammatory response.

Clinical Advantages

Theoretically, topical drugs' activity should be solely at a site of pain generation, unlike oral and other systemic drugs that first need to enter the bloodstream before they arrive at the necessary site of action. Therefore, because topical drugs do not result in any clinically significant serum levels, adverse reactions are limited to those produced by local reaction, such as allergy or skin rash. Most of the currently prescribed oral and transdermal medications for pain, both acute and chronic, are hampered by their systemic side effects. With nontopical agents, it is most often necessary to titrate the dosage to effect, either pain relief or intolerable side effect; unfortunately, the latter often occurs resulting in an aborted drug trial and the patient still suffering from pain.

Another advantage to topical agents is their lack of drug-drug interactions, again due to their lack of systemic activity. The potential for drug-drug interactions is common in many patients with chronic painful conditions, such as the elderly with arthritis or postherpetic neuralgia (PHN), and those suffering from painful neuropathies, such as diabetic and human immunodeficiency virus (HIV) patients.

When treating chronic pain conditions, treatment with oral agents requires slowly titrating the dose until either significant pain relief or intolerable side effects are reported by the patient—a time-consuming procedure that may take weeks or even months. The time to a noted effect with topical agents, on the other hand, usually is on the order of days. Thus, yet another advantage to topical drugs is the significant amount of time saved with no need to titrate the dose over several weeks or

more.

An additional important advantage of topical drugs is their ease of use. Patients either need to apply a liquid, cream, or gel several times a day or, with some preparations, apply a patch once or twice a day.

Clinical Information

Indicated Pain Conditions. Clinical conditions associated with pain in which a topical agent may have potential efficacy include both acute and chronic pain states. Acute pain conditions suitable for topical pharmacotherapeutic intervention include acute soft tissue injuries (e.g., sprains, strains, and contusions), postsurgical pain, and acute herpes zoster (shingles). Chronic nonmalignant pain states appropriate for topical drug treatment include arthritic conditions and chronic peripheral neuropathic pain conditions, such as PHN, diabetic polyneuropathy, HIV neuropathy, idiopathic neuropathy, complex regional pain syndromes, stump pain, and other neuroma pains.

Medication Classes. Currently only a few agents are commercially available for the treatment of pain, including nonsteroidal antiinflammatory agents, capsaicin, and local anesthetic agents. However, several new topical drugs—using different topical formulations, with a new active medication ingredient, or both—are actively being investigated (at the time of this writing), and it is hoped that they will prove efficacious in the not too distant future for the treatment of a variety of acute and chronic pain conditions.

Several different topical formulations may be available within the same medication class, which may differ significantly with regard to efficacy and side effect profile. Such different topical drugs in the same class may differ in several clinically significant ways, including (a) the actual active medication being delivered; (b) the topical vehicle formulation's ingredients, which affect skin penetration and drug delivery; and (c) the application form in which the drug is available, such as liquid, gel, salve, or patch/ plaster. Each of these three factors has vastly important relevance with regard to the topical drug's efficacy and adverse events (Table 87-2).

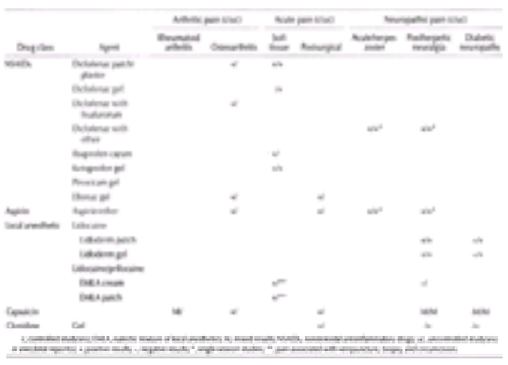

TABLE 87-2. Controlled and uncontrolled studies assessing the efficacy of topical drugs for the treatment of pain

DRUGS

Nonsteroidal Antiinflammatory Drugs

Of all of the drug classes, the nonsteroidal antiinflammatory drug (NSAID) class has the most studied and currently available different topical drug formulations that are commercially available or under investigation. Many different NSAIDs with vastly different vehicle formulations have been assessed in mostly acute pain syndromes and arthritic conditions.

Mechanism of Action

NSAIDs traditionally have been thought to have their primary mechanism of analgesic activity in the periphery, specifically via their inhibition of prostaglandin synthesis. However, a dissociation between the degree of pain relief of certain NSAIDs and their actual antiinflammatory effects suggests other important analgesic mechanisms of activity (1), including other peripheral effects, such as inhibition of the lipoxygenase pathway, inhibition of excitatory amino acids, and effects on G protein–mediated signal transduction (2).

Topical NSAIDs may also have direct effects on damaged and dysfunctional peripheral nerves. Topical NSAIDs theoretically could reduce primary afferent sensitization occurring as part of a localized abnormal neurogenic inflammatory response (3). An animal study of rabbit corneal nerve injury reported a significant reduction of abnormal neural activity and mechanosensitivity after application of topical diclofenac (4).

Clinical Trial Data

Acute Pain. Topical NSAID treatment has been studied for several clinical conditions associated with acute pain, including minor sports injury pain, postsurgical pain, and ophthalmic pain. A multicenter, randomized, double-blind, placebo-controlled study of acute sports injury pain found significant reductions of pain over a 2-week period with a diclofenac patch/plaster (5). An open-label study observed a 60% reduction in pain with this diclofenac patch/plaster in traumatic sport and overload injuries (6). Similar controlled studies in acute soft tissue injuries revealed significant reductions in pain over the first 48 hours with an ibuprofen cream (7) and over 7 days with ketoprofen gel (8). An open-label uncontrolled study comparing several different topical gels for acute soft tissue injury pain observed that diclofenac gel and ketoprofen gel were similar in efficacy, whereas piroxicam gel was less effective (9).

A double-blind comparative study assessed piroxicam gel applied preoperatively to patients undergoing an inguinal repair, local anesthetic inguinal block, and no treatment and reported that both the topical NSAID gel and the nerve block similarly reduced pain scores, time to first analgesic, and total opiate consumption as compared to the no-treatment group (10). Double- blind controlled studies have assessed topical NSAIDs for the treatment of acute pain associated with traumatic corneal abrasions and found significant reductions in pain (10,11 and 12). A study has also reported significant pain reduction with topical diclofenac treatment for postoperative pain associated with phototherapeutic keratectomy (13).

Arthritic Pain. A large randomized, multicenter, double-blind, 4-week study compared topical eltenac gel with oral diclofenac and placebo in patients with osteoarthritis of the knee and found that both active treatments were significantly better than placebo in reducing pain only in patients with severe symptoms, but that the number of gastrointestinal adverse reactions were three times higher in the oral NSAID group as compared to the topical NSAID group (14). Controlled studies demonstrated efficacy of a topical diclofenac in hyaluronan for the treatment of osteoarthritis (15,16 and 17). Placebo-controlled studies have reported significant reductions in pain with topical diclofenac plaster (patch) in patients with osteoarthritis of the knee (18), and inflammatory peri- and extraarticular rheumatologic diseases (19). After several days of diclofenac plaster application in patients with monolateral knee joint effusion, low levels of diclofenac were measurable in the synovial fluid without producing elevated serum levels (20). An open-label uncontrolled study reported topical flurbiprofen patches provided significantly better pain control as compared to oral diclofenac with significantly fewer gastrointestinal side effects after 2 weeks of treatment in patients with “soft-tissue rheumatism” (21).

Neuropathic Pain. A single-session, double-blind, cross-over study reported significant pain reduction for the treatment of both acute herpes zoster and PHN with a topical diclofenac/diethyl ether mixture with no significant side effects (22). This same study reported that an indomethacin/diethyl ether topical mixture was not superior to placebo in a single-session protocol. Another single- session study observed significant pain reduction in patients suffering from PHN with hydrous stupes (topical patches) containing indomethacin, ketoprofen, or flurbiprofen (23). However, no long-term efficacy studies with topical NSAIDs have been published for the treatment of either acute herpes zoster or PHN. No studies have assessed the use of topical NSAIDs for other peripheral neuropathic pain conditions.

Aspirin

Although no commercially produced form of topical aspirin is available at the time of this writing, several studies have reported the results of compounded formulations of topical aspirin for the treatment of pain associated with herpes zoster.

Mechanism of Action

Like the topical NSAIDs, topical aspirin may alleviate pain by affecting the inflammatory response and, at least theoretically, in neuropathic pain states by reducing neurogenic inflammation.

Neuropathic Pain

A double-blind, placebo-controlled, single-session clinical trial demonstrated statistically significant pain relief in patients with acute herpes zoster and PHN after application of a topical aspirin/diethyl mixture (24). In addition, several open-label studies have described pain reduction in PHN using topical mixtures of aspirin and chloroform or diethyl ether (25,26). No controlled study has assessed the long-term benefits and side effects with topical aspirin formulations.

Local Anesthetics

Over the past decade, two commercially produced forms of topical local anesthetics have extensively undergone the rigors of placebo-controlled clinical trials testing, Lidoderm gel and patches and EMLA (eutectic mixture of local anesthetics, 2.5% lidocaine and 2.5% prilocaine) cream and patch. To date, both products have proven efficacy for different clinical pain states, Lidoderm for peripheral neuropathic pains and EMLA for acute pains associated with invasive procedures, such as venipuncture. Other topical formulations of local anesthetics have also been reported for the treatment of acute pain states.

Mechanism of Action

Local anesthetic drugs applied topically are thought to provide pain relief by reducing ectopic discharges in superficial somatic nerves, which are damaged and dysfunctional in neuropathic pain states and are normally active in acute injuries, such as venipuncture. It is not necessary to produce a total anesthesia of the skin to produce clinically significant pain relief in chronic neuropathic pain states. Animal models of neuropathic pain have shown significant reductions in the abnormal tonic, evoked, and ectopic activity in damaged peripheral nerve with local anesthetic concentrations dramatically below that which blocks impulse conduction (27,28). In addition, a topical patch, such as the Lidoderm patch, has been shown to have an added benefit of protecting allodynic skin from direct mechanical stimulation and thereby of reducing an allodynic patient's pain (29,30).

Neuropathic Pain

A large multicenter, placebo-controlled, double-blind study reported significant pain relief with 4 weeks of lidocaine patch (Lidoderm) use in patients with long-standing PHN and mechanical allodynia (30). Another controlled trial in PHN, using an enriched enrollment crossover design, demonstrated that long-term lidocaine patch users (mean duration of patch use was 3.3 years; mean duration of PHN 7.3 years) preferred the lidocaine patch to the placebo patch, 78% versus 9% (p <.001) (31). In addition, several double-blind, placebo-controlled, single-session studies have reported Lidoderm, both the gel and patch formulations, to be effective in significantly reducing the pain of PHN without any significant side effects (32,33 and 34). Lidocaine serum levels after use of this gel and the patch formulation are an order of magnitude below antiarrhythmic serum levels and are thus very safe, even in patients with cardiac conditions (29,30,33).

A randomized controlled trial of topical lidocaine gel and patches for the treatment of painful diabetic neuropathy showed clinically significant reductions in pain with both the active and placebo treatments in the vast majority of subjects but no statistical difference between the two treatments (Galer BS, Gianis A, *unpublished results,*1988). Of interest, the vast majority of subjects in this study continue to use the lidocaine patch or gel in a compassionate use protocol with clinically meaningful reductions in pain, even if they responded to the placebo treatment in the controlled study. Anecdotal evidence also suggests this drug may be useful for the treatment of other peripheral neuropathic pains, such as idiopathic polyneuropathy, painful mononeuropathy, stump pain, reflex sympathetic dystrophy, and painful HIV neuropathy (35,36).

Long-term efficacy appears to be maintained for this new topical lidocaine preparation. PHN and diabetic neuropathy patients who have applied Lidoderm for several years report continued pain relief, with some patients noticing a decrease in the size of the painful region and others needing to apply the topical medication less and less frequently. No significant acute or chronic side effects have been observed.

The other commercially available formulation of topical local anesthetic, EMLA, has failed to demonstrate efficacy superior to placebo (37).

Acute Pain

Controlled studies have reported EMLA cream applied under an occlusive dressing for 60 minutes reduces pain associated with venipuncture (38,39), intramuscular saline injections (40), spinal needle insertion (41), excisional biopsy or curettage with electrosurgery of cutaneous lesions (42), and pain from circumcision in neonates (43). A patch impregnated with EMLA was also shown to reduce pain associated with a skin biopsy in children (44) and venipuncture pain in adults (45).

A controlled comparative study of volunteers undergoing intravenous catheterization reported that liposome-encapsulated tetracaine provided more effective pain relief than EMLA cream after 60 minutes' application time, although the tetracaine also caused more erythema than the EMLA (46). Topical proparacaine was shown in a double-blind study to reduce the pain after photorefractive keratectomy (47). A double-blind study reported equally effective pain reduction with the use of topical bupivacaine- adrenaline-cocaine and topical tetracaine-adrenaline-cocaine mixtures for pain associated with wound suturing (48). A double-blind study assessed the efficacy of topical local anesthetics for pain associated with suturing lacerations in children and concluded that topical prilocaine-phenylephrine plus tetracaine-phenylephrine (tetraphen) was as effective as topical tetracaine-adrenaline-cocaine (49).

Capsaicin

Mechanism of Action

Capsaicin is an over-the-counter drug composed of an extract of chili peppers. It has been postulated that capsaicin selectively stimulates and then depletes substance P from nociceptive primary afferents and thus may produce pain relief in certain chronic pain states. However, this physiologic activity has not been definitively proved to be the mechanism of action of currently available capsaicin products. An animal study of experimental polyarthritis has noted that pretreatment with capsaicin significantly attenuated joint swelling and radiologic and histologic measures of arthritic changes, suggesting that capsaicin may directly suppress inflammation (50). Moreover, capsaicin produces a counterirritant effect in a majority of patients by causing a mild to severe burning on application, which may also be a potential therapeutic pain mechanism. (Because of this commonly occurring burning on application, placebo-controlled trials of capsaicin should be interpreted with caution since both subject and researcher are unblinded when this occurs.)

Neuropathic Pain

Topical capsaicin has been studied in PHN and painful diabetic neuropathy with mixed results. In PHN, several studies have reported reductions in pain (51,52,53 and 54), whereas others have not (54). Similarly, controlled studies in painful diabetic neuropathy have also resulted in both negative and positive findings. A randomized controlled trial of 0.075% capsaicin in painful diabetic neuropathy showed no benefit (55). Another controlled study using 0.075% capsaicin in painful diabetic neuropathy reported improvement in pain with capsaicin, although an intent-to-treat analysis was not performed (56). A controlled trial using an active placebo (a topical substance that also produced burning on application but had no pain-relieving capabilities) reported no difference between capsaicin and this active placebo in patients with a variety of painful polyneuropathies (57). One small controlled study reported topical capsaicin reduced the pain of postmastectomy syndrome (58).

Unfortunately, currently available formulations of capsaicin have been disappointing clinically as an analgesic agent for all neuropathic pains (59). Currently, most

authorities rarely prescribe the drug for the treatment of neuropathic pain due to its overall poor efficacy and the high proportion of patients who complain of a worsening of their pain with drug application.

Arthritis Pain

Two controlled studies have demonstrated efficacy and safety for the use of topical capsaicin in the treatment of arthritis pain. A small double-blind, placebo-controlled study concluded that capsaicin significantly reduced hand pain from osteoarthritis but not pain from rheumatoid arthritis (60). However, a large double-blind study of arthritic knee pain reported significant pain relief in both rheumatoid arthritis and osteoarthritis, with more relief reported by rheumatoid arthritis subjects (61).

Clonidine

At the time of writing, no topical clonidine product is commercially available. However, a new formulation of a topical clonidine gel is being studied for a variety of neuropathic pain states.

Mechanism of Action

Clonidine is an a_2-adrenergic partial agonist. Alpha-2 receptors are autoreceptors located on the sympathetic nerves' terminals, which when activated inhibit their release of norepinephrine. Several lines of evidence suggest an abnormal adrenergic sensitivity in peripheral neuropathic pain states. For instance, locally infused adrenaline results in a worsening of pain and allodynia patients with reflex sympathetic dystrophy (62) and PHN (63). In addition, animal models of peripheral neuropathic pain have shown that injured neurons are sensitive to adrenergic activity, that is, an increase in ectopic impulse generation occurs in response to sympathetic agonists and to activation of postganglionic sympathetic efferent axons (64). Moreover, this adrenosensitivity appears to be an inherent property of the injured somatic peripheral nerve (65). Thus, application of clonidine topically may reduce release of norepinephrine from sympathetic nerve terminals, thereby alleviating the abnormal ectopic firing resulting from the dysfunctional nerve's adrenosensitivity, and, at least theoretically, result in clinically meaningful reductions in pain and allodynia.

Neuropathic Pains

No controlled studies have been performed using a topical form of clonidine, at the time of this writing. However, uncontrolled pilot studies have been performed assessing different concentrations of this new formulation of topical clonidine gel for the treatment of PHN, complex regional pain syndrome type I, and painful diabetic neuropathy. These open-label studies have observed improvement in pain and hyperalgesia in some patients (66). Controlled trials with topical clonidine gel are being planned.

One uncontrolled case series assessed the efficacy of transdermal clonidine patch (Catapres) in four patients with “sympathetically maintained pain” and two with “sympathetically independent pain” (67). This series observed that the patients with sympathetically maintained pain obtained complete relief of hyperalgesia only in the localized skin region under the patch but no change in the spontaneous ongoing pain, whereas no pain relief at all was noted by the two patients with sympathetically independent pain.

CONCLUSIONS

Theoretically, topical drugs have many clinically relevant advantages over other pharmacotherapeutic drug delivery systems, such as oral, transdermal, and intrathecally delivered drugs. By applying a drug directly to the skin, where it penetrates and acts directly at a site of pain generation without the need for systemic activity or invasive procedure, topical medications have the promise of producing pain relief with few side effects and little risk and cost. In the past, the question plaguing topical drug delivery has been whether clinically meaningful degrees of pain relief can be achieved with topical administration. Controlled clinical trials have demonstrated efficacy for a variety of topical drugs and topical formulations, such as NSAIDs' treatment of acute soft tissue injury and arthritis and topical local anesthetics' treatment of chronic peripheral neuropathic pains and acute pain associated with invasive procedures. The future looks bright for topical drug delivery, with many newer topical agents being studied for the treatment of both acute and chronic pain conditions. Because of their efficacy, safety, quick time of onset, and ease of use, topical medications should be considered first-line agents for the treatment of many pain states.

CHAPTER 88

Operant or Contingency Therapies

Wilbert E. Fordyce

This chapter concerns the use of contingency management (CM) procedures in the treatment of chronic pain. It builds on the overlapping topics discussed in Chapter 25, Chapter 89, and Chapter 109. *Contingency management* refers to a set of methods for helping patients and practitioners to change behavior. Although the terms *contingency management* and *operant conditioning* are essentially interchangeable, the former term fits more closely the focus of this chapter. CM is a method not for treating pain per se but rather for helping patients to modify pain behaviors and related activities or actions. CM can also be viewed as a method for rehabilitating pain patients by increasing functional performance in daily life. More detailed accounts of these concepts and procedures can be found in Fordyce (1), Sanders (2), and Baer (3).

A conceptual perspective underlying CM has been described by Brady (4, p. 31) as follows:

> . . . health related processes interact in profound and enduring ways with environmental circumstances and behavioral activities. . . . Conceptually, the roots of this behavioral perspective . . . can be identified with the fundamentals of environmentalism, which has two main features. The first of these is that knowledge comes from experience rather than from innate ideas, divine revelation, or any other obscure source. And the second holds that action is governed primarily by consequences rather than by instinct, reason, will, cognitions, beliefs, attitudes, or any of the myriad explanatory fictions that appear to have been created out of whole cloth by the magic of the human language.

This perspective is more extreme than the viewpoints I have expressed in Chapter 25; it is also narrower than that used elsewhere in this text.

This chapter presents principles of CM technology and then describes a format for its use. The applied elements address the use of behavioral principles in exercise and reactivation, managing analgesics and interpersonal interactions regarding pain and well behaviors.

OVERVIEW AND RELATION TO OTHER METHODS

Optimal treatment of chronic pain is a multimodal process. No single, narrowly based intervention is likely to bring about comprehensive and lasting change in long-established pain problems. This holds true whether the therapy involves surgery, medication, or such noninvasive modalities as ultrasound, traction, massage, CM, or cognitive-behavioral methods, the last two of which are somewhat complementary (see Chapter 89). The application of CM techniques to the modification of pain behavior and other associated behaviors should almost always be done in conjunction with other modalities. In particular, the effects of these procedures can be enhanced by addressing the profound misunderstandings patients often have about the nature of pain, the healing process, and the adverse effects of disuse and prolonged use of analgesics. The importance of responses of the world to pain behaviors makes it worthwhile to change these behaviors.

There is a synergistic relationship between CM methods and didactic or teaching methods. In chronic soft-tissue injury pain and some other pain problems, the symptom, pain behavior, often has become the problem: disability. CM is a technology that may be used to help change pain behavior—that is, change disability. The behaviors targeted for change are themselves influenced by anticipations. Anticipations can be viewed as meanings attached by patients to cues or stimuli encountered (i.e., the events expected to follow the cues or stimuli perceived). A patient anticipating adverse or painful consequences when using a body part or assuming a particular position is more likely to display pain behaviors, either before the action is undertaken to forestall anticipated pain and suffering or shortly thereafter. Thus, any intervention that helps to influence anticipations is relevant.

Information about pain, healing, and the effects of disuse is likely to influence what a patient anticipates. Information by itself, however, is rarely an effective way to change established behaviors. If it were, providing chronic pain patients with brochures or other materials that explain clearly the rapid nature of the healing process, the adverse effects of disuse, and how properly designed motion can promote healing would suffice to modify most pain behavior patterns. Of course, such an approach does not work any more than providing inveterate smokers with information about the adverse effects of smoking results in cessation of smoking. Relevant information can, however, promote a readiness to undertake treatment and reactivation (see Chapter 94).

Pain behaviors relating to body action are best altered by exercising and increasing activity. Cognitive components, including information, may facilitate change of pain behaviors but, in the case of chronic pain, are unlikely to be sufficient. Conversely, effectiveness of CM methods may be lessened considerably if a patient's readiness to participate is hampered by anticipating adverse consequences to becoming reactivated.

CM involves the use of environmental consequences in a studied way to help a person to modify behavior. It involves analyzing which environmental consequences support the strength or weakness of the behavior of interest and then changing those consequences to others that will support a different pattern of behavior. Cognitive-behavioral methods, while implicitly and often explicitly using systematic environmental contingencies as part of its treatment strategy, attach more focus on helping to modify patients' perceptions or labeling of sensations and, as a result, the behaviors to which they lead. Both approaches strive to make clear to patients and families that hurt and harm are not the same and that, once healing time has passed, using painful body parts is an important way to make them better. As noted, this is accomplished by providing information but also, more important, by providing for learning by doing.

CM and cognitive-behavioral methods clearly overlap and are sometimes indistinguishable. The labeling of sensations and perceptions and guided ways of seeking to change those has a particular relevance to recent onset or acute pain. A focus on environmental contingencies becomes more important in chronic pain.

TERMINOLOGY AND PRINCIPLES

The intent here is to describe methods by which CM can be applied to modification of pain behaviors. This is not an exhaustive review of CM technology. The level of detail provided should, however, be sufficient to permit clinical applications.

Three interlocking tenets form the foundation of CM. More complete accounts of what follows can be found in references 1, 2, and 5.

1. *Behavior* refers to specific actions or movements—not general classes of behavior and not thoughts or feelings;
2. Behavior is sensitive to consequences. Therefore, the rate or strength of a behavior tends to increase when followed by positive reinforcement or to decrease when followed by negative consequences or the absence of positive reinforcement.
3. There are no inherently reinforcing or nonreinforcing consequences. Reinforcing or nonreinforcing properties are defined by the particular past experience of the

person.

Behavior

Behavior refers to a specific action or pattern of activity elicited by a discrete stimulus or by a stimulus constellation such as cues present in a specific social setting. Behavior sequences occur or cease in response to environmental cues, which indicate the time and place of reinforcement, punishment, or extinction (absence of reinforcement) contingencies. Behaviors are considered strong if they occur frequently and weak if they are infrequent.

Specificity is essential in describing behaviors to be changed. For example, acting honestly is a general behavior; answering a particular question truthfully is specific. In the context of clinical pain, to say that a patient manifests pain behaviors is broad and vague. Limping, avoiding flexing forward, and asking for analgesics are specific behaviors that can be targeted for change.

One should first identify which specific behaviors are occurring excessively (e.g., reclining, taking medications, limping), too infrequently (e.g., walking, working, gardening), or not at all. Noting that a patient is “not moving enough” is too general. Noting that a patient walks less than 500 feet per day, avoids flexing forward, or is taking analgesics six or more times per day is more specific. (For more detailed discussion of behavior, see Chapter 25.)

Reinforcement

Definitions of what is or is not reinforcing for a person are empiric and circular. A reinforcing consequence is one that, when programmed to occur rapidly, contingent on, and systematically after the behavior of interest, increases the rate of the behavior it follows. Conversely, rate of a behavior is decreased by arranging that it no longer is followed by the consequence previously reinforcing it or by effectively reinforcing a behavior incompatible with it. Limping or grimacing, if followed systematically by special attention, sanctioned rest, or provision of analgesics, is likely to strengthen or increase in frequency. Limping or grimacing in relation to a healed injury if no longer followed systematically by those consequences is likely to diminish in strength or frequency of occurrence.

The strength of a behavior also tends to diminish if effective reinforcement becomes contingent on occurrence of a behavior incompatible with the one to be reduced. The difference between this approach and that of withdrawing reinforcement is illustrated by two very different methods for reducing excessive reclining in a deactivated pain patient. Suppose, for example, that a spouse tends to provide special supportive attention when the patient reclines at a time when, were there no pain problem, he or she would be active. Whatever the intent of the attention, the spouse is probably positively reinforcing reclining and that behavior may become more persistent. One method for applying CM-based methods for changing behavior—in this case, reclining—is to help the spouse to avoid being especially attentive when adverse reclining is occurring. If the spouse is an influential person to the patient, adverse reclining is likely to diminish. There is a different and often better way to go. It is usually easier to increase or accelerate a behavior than to decrease or decelerate it. Therefore, focusing on increasing walking, a behavior incompatible with reclining, may be more effective. The practitioner should see to it that positive reinforcement becomes contingent on walking. Walking is likely to increase and, conversely, reclining to decrease. A pain behavior is being reduced and reactivation is being facilitated.

Selection of Reinforcers

What consequences are likely to be reinforcing? This is determined not by some preordained state of affairs but by the particular history or experience of the person. Money, for example, is not always reinforcing to everyone or to an individual in every situation.

There is a straightforward answer to selection or determination of reinforcers that usually works and that one may program as consequences to help change behavior. Observation of what a person does frequently points to what is reinforcing. This is the Premack principle (6), the essence of which is that high strength behaviors may be used to reinforce low strength behaviors. By the nature of things, what a person does frequently is likely to occur because the activity is reinforcing. Similarly, what a person does infrequently is likely not to be reinforcing and may even be aversive. For a person who often reclines, rest is quite probably a potentially effective reinforcer. For a restless person, one who tends to keep moving, activity is likely to be reinforcing and rest aversive.

In treatment settings, rest, attention, and time out from aversive activities are all likely to be effective reinforcers and have the further advantage of being readily available and logistically simple to program. An example will illustrate application of the Premack principle. Let us assume that a given chronic low back pain patient reclines often and almost always avoids vigorous activity. We shall suppose that neuroanatomic or pathophysiologic reasons for not undertaking reactivation are no longer sufficient to warrant deactivation. For that patient, rest is likely to be reinforcing, perhaps also attention or pain behavior-contingent social regard. In addition, exercise or vigorous walking is, in his or her present deactivated state, probably aversive. Sanctioned time out from those activities is therefore also likely to be highly reinforcing. A detailed format for putting these circumstances together to promote reactivation is set forth later in this chapter.

Scheduling of Reinforcement

To be effective, reinforcement must occur promptly and be contingent on completion of the behavior it is designed to reinforce. For example, therapist approval withheld until the end of an hour-long physical therapy session is usually too long a delay. Patient performance should be closely monitored during early treatment sessions, and therapist response should be expeditiously expressed. Later, as progress occurs, therapists may be able to ease the level of monitoring and promptness of reinforcement.

Reinforcing each occurrence of a target behavior is known as *continuous reinforcement*; reinforcing only some occurrences of the behavior is known as *intermittent reinforcement*. Continuous reinforcement, although rarely fully attainable, is useful in early stages of a conditioning process to help “jump-start” the behavior.

Reducing the frequency of reinforcement is desirable and usually logistically necessary (1,5,7). Continuous reinforcement tends to lead to satiation and ultimate reduction in strength of the target behavior to the point of extinction. Intermittent reinforcement is more durable. The ratio between occurrence of the behavior and a reinforcing consequence should diminish as the behavior strengthens. This tends to occur in the natural order of events. For example, reinforcing an early and small number of repetitions of an exercise by therapist approval and attention yields a relatively high ratio of consequence to behavior. As numbers of repetitions increase with treatment, therapist response now occurs at a lower ratio of consequence to behavior. The ultimate goal is to provide the opportunity for naturally occurring reinforcing events in the patient's environment to begin to take over as consequences to help maintain treatment gains (7). Therapist fading of reinforcement frequency is an important prelude to that.

Units of Behavior (Movement Cycles)

What are the units of behavior to be measured? The basic unit is known as a *movement cycle*. A movement cycle is completed when the person is in a position to repeat it. In an exercise such as forward flexing, the movement cycle is to flex forward and then return to the upright position. In walking, it is moving one and then the other foot forward. Unless the person is beginning an exercise from an extremely reduced activity level, simple repetitions of an exercise will suffice (e.g., six pelvic tilts, four laps walked). The extremely deactivated patient may require a finer mesh of movement units or cycles in the initial stages of reactivation. Walking laps, for example, may begin with single steps between parallel bars or laps in the bars. As progress occurs, walking quotas can be shifted to meters walked outside the bars.

Punishment

Punishment is virtually never a desirable or effective way to help a person to change behavior for many reasons. There are ethical and moral principles involved. In addition, punishment, if severe enough, tends not to reduce behavior but to displace it in time and space only to occur on another occasion or in another place. The treatment relationship and readiness of the patient to respond to therapist direction and approval are compromised by punishment. A punishing therapist is likely soon to become an aversive stimulus, someone to be avoided or ignored.

Treatment Relationship

CM methods are not a substitute for a treatment relationship. The treatment relationship, including full informed consent and agreement as to objectives, is a prerequisite of all behavior change methods. During treatment, therapists should behave in ways that encourage undertaking some behaviors patients believe or fear will be harmful or, at the least, painful. Patients who are not confident that compliance with therapist instructions and directions will lead to beneficial effects likely will

fare poorly in treatment unless therapist encouragement and support prepare them to make the initial efforts. Because patients are initially unlikely to know that beneficial effects will follow treatment effort, they must view their therapists positively and have trust in them. Establishing patient trust and confidence in the therapist is at the core of treatment.

TREATMENT

Exercise

To take into account pain-related and other medical considerations and to bring to bear expertise regarding physical exercises, such exercises should be prescribed by an appropriately competent person. Most exercises occur in standard exercise facilities. The exercise of walking may require use of a different space.

Two commonly used exercises illustrate how to proceed: pelvic tilts and riding a fixed bicycle. First, the game plan should be explained fully and patient consent to proceed obtained. This explanation should describe determination of baselines, establishing quotas, and quota incrementing, as described below and listed in Table 88-1.

Baselines
Quotas
Quota incrementing
Quota failure

TABLE 88-1. Operant aspects of exercise

Baseline

Ask the patient to do pelvic tilts continuously “until pain, weakness, or fatigue cause you to want to stop. You decide when to stop.” Count and record number of repetitions, or in the case of riding the bicycle, distance ridden, for two to four trials separated by 30 minutes or more of rest, but more typically across 2 to 3 days. The average number of repetitions can be used as baseline. Always measure performance in numbers of repetitions or distance, never in time units.

Quotas

After baseline is defined, the assignment for each session is number of repetitions to be performed without interruption, as will have been explained at the outset of treatment. That is, rest or pause after each exercise assignment is contingent on achieving the quota.

Set an initial quota of approximately two-thirds or three-fourths of the number of repetitions—or distance ridden—averaged during baseline trials. The guiding principle is that initial quotas should be sufficiently below baseline levels to ensure success in early trials. This arranges that rest or time out from activity—which presently is probably aversive—becomes contingent on performance of the targeted behavior, namely, exercise.

Quota Incrementing. Quota incrementing is a therapist judgment call, but the incrementing plan should be determined after baselines have been defined and not on the basis of patient performance each session. It should be based on clinical judgment as to likelihood the patient can perform and adjusted further by number of therapy sessions available and by the anticipated therapy ceiling goal. For example, given a 4-week, once-daily session (20 sessions), if the baseline is nine and a reasonable end point is 25 repetitions, an increment schedule of one per session, starting with an initial quota of six, is usually adequate and reaches 25 one day early. If the therapist is confident of a more rapid incrementing rate, the schedule in the above example might be two each session. In the case of bicycle riding, the quota is distance ridden (e.g., in miles or tenths of a mile). Quotas should never exceed the therapist's reasonable expectation of the patient's ability to achieve but should be at the highest level commensurate with the therapist's confidence regarding achievement.

The working-to-quota mode provides the reinforcer of rest or time out from activity, enhanced further by therapist support and approval. It also illustrates applying the incompatible-response strategy. Reclining is decreased by increased activity level. In the example, time out from aversive activity as provided by the working-to-quota system and therapist response to performance serve as reinforcement. These may be augmented by patient awareness of progress. Having patients keep graphs recording performance is a way of enhancing this, although signs of progress are not always a potent reinforcement. The quota incrementing process should have been explained fully at the outset of the exercise program.

Quota Failure. Repeated failure to achieve quotas, assuming they have been reasonably set and there is no biomedical reason for failed performance, usually means the patient is more reinforced by rest or nonperformance than by progress. That in turn usually means that the situation to which the patient is destined to return has aversive qualities sufficient to deter success at treatment. There is no defensible reason for continuing treatment unless quotas begin to be achieved. Failures, except for an occasional lapse that is corrected by achieving the next quota, should be discussed in a forthright manner with the patient. If he or she cannot explain the failure(s) in acceptably logical terms, three options should be offered:

1. Terminate the program immediately.
2. Arrange a brief pause (e.g., one to three sessions) in incrementing rate, holding at the present level and then resuming the increment schedule with program continuation contingent on performance.
3. Continue with the increment schedule with continuation of the program contingent on meeting quotas.

It is important that patient performance be monitored rigorously. Failed quotas across several exercises or for several sessions require prompt intervention.

Speed Walking

Speed walking is an additional tool for helping to bring about reactivation and the maintenance of appropriate activity levels (Table 88-2). It is vitally important that a thorough medical clearance to engage in the speed walking program be obtained before proceeding. Conceptually, speed walking is an application of use of an incompatible response to diminish deactivation. It also can be thought of cognitively as seeking to establish patient self-perception as that of being a vigorous person, a condition somewhat incompatible with being disabled. An incidental but not infrequent by-product of speed walking is the reduction or elimination of limping, guarding, or knee-buckling during ambulation. Knee-buckling is sometimes observed to have become established as a conditioned form of guarding or protecting oneself from anticipated pain or weakness when the need to do so may have diminished or disappeared because of healing. Engaging in gradually incrementing speed in walking can be an effective method for overcoming that.

Course
Target speeds
Baseline pace
Graph results
Speed walking quota
Quota failures

TABLE 88-2. Speed walking

The objectives of the speed walking component to reactivation should be discussed thoroughly at the outset. Specifically, it should be made clear that the intent is not to establish a habit of walking rapidly; it is to help to learn by doing that it is safe to move with vigor. Achieving this will also demonstrate to family members and other interested persons that vigorous movement is a safe and effective way to further health and activity level, thereby favorably influencing their readiness to support return to normal activity levels. Target speeds should be indicated along with instruction not to strive to exceed those speeds beyond an incidental second or two.

1. Lay out a measured course (e.g., 50 meters per lap).
2. Target speeds (i.e., seconds elapsed during lap trials) should be identified. Unless there are specific medical or anatomic contraindications, 18 to 20 seconds for men and 20 to 22 seconds for women have been observed to be appropriate target speeds. The gender difference relates to typical leg length differences.

   It has also been observed that patients may compete with each other or with themselves to the point at which they begin attempting laps at a near-reckless pace. The objectives of speed walking will have been achieved by reaching the target speeds noted. Further reductions in elapsed time serve no good purpose and may expose the patient to some risk.
3. Instruct the patient to walk one lap at whatever pace he or she chooses. Explain further that the program objective will be to help him or her to walk a 50-meter lap in 18 to 20 seconds if male; 20 to 22 seconds if female. Time the lap, and repeat the process for two to three trials to establish a baseline of elapsed seconds. If target speeds occur during baseline trials, speed walking may be abandoned as unnecessary.
4. Prepare a graph with the ordinate in seconds extending from zero to whatever amount slightly exceeds baseline elapsed times. The abscissa should be of trials or treatment sessions. Draw a straight but diagonal quota line on the graph from 2 to 3 seconds above the highest baseline elapsed time to the target speed level (i.e., 20 or 22 seconds) at the point of anticipated number of speed walking sessions in the program for that patient. If more than one speed walking session is planned per day, the abscissa can be defined in terms of days of treatment.
5. Each speed walking trial should have a speed quota. That quota is defined as the number of elapsed seconds which, when recorded on the graph, reaches the highest possible point *beneath* the sloping line.
6. Quota failures at speed walking should be dealt with essentially as described above in relation to other exercises. That is, first reassess neuroanatomic and neurophysiologic factors to ensure those are not barriers to performance. Second, discuss with the patient why quota failures are occurring. If it is an incidental or capricious lapse, the program should continue as graphed with perhaps one or two repeat trials to achieve the quota. If there are repeated failures, program termination should be considered. Elimination of the speed walking component to treatment is a less desirable alternative.

Behavioral Management of Analgesics

This section is not concerned with decisions about whether to prescribe analgesics and, if so, which ones. It is concerned with using CM technology to reduce dependence or habituation (1,8,9). The methods described here are not needed for chronic pain patients presenting with little or no analgesic consumption.

Pain-related medications have often been prescribed on an as-needed basis. For recent onset and time-limited pain problems, the as-needed regimen is appropriate. Chronic pain is a different matter. Protracted use of narcotics can induce psychological or physiologic dependence, or both. CM methods are a straightforward way of dealing with this issue (Table 88-3). The procedure has come to be known as the *pain cocktail*. That is a method, not a commodity (1). Full description of the pain cocktail procedure should be provided and patient consent to proceed obtained.

1. Identify risk
2. Observe baseline consumption
3. Prepare initial pain cocktail
4. Deliver on time-contingent basis
5. Taper active ingredients
6. Discontinue when only vehicle
7. Open disclosure at all times

TABLE 88-3. Drug profile

1. Patients who are impaired by excessive opioid and sedative-hypnotic drug intake will almost certainly require an inpatient phase of treatment until medication ingestion has been significantly reduced, because it is essential to have close monitoring and control over access to drugs when they are inappropriately used. The patient is then instructed to take whatever analgesics are desired for 24 hours.
2. Determined by observation, not patient report, the type, frequency, and amount taken in a 24-hour period can be recorded. This may be repeated for a second or even third day, although this is infrequently required. The point is to determine what the patient presently requires or consumes. The 24-hour ingestion amount and average interval between is the baseline.
3. Prepare the initial pain cocktail. This consists of substituting an equivalent amount of methadone to the opioids that the patient has been taking, plus a color- and taste-masking vehicle—cherry syrup usually serves well—to total 10 mL (9). Other medications can be dealt with in a similar fashion by substituting a long-acting equivalent for short-acting drugs and then tapering.
4. Deliver the pain cocktail on a time-contingent basis around the clock. The interval should not be greater than observed baseline time intervals. An every 4 or 6 hours' schedule is common.
5. To diminish cognitive disarray from toxicity, reduce the active ingredient in the cocktail by 15% to 20% per day until the sensorium clears. When that point is reached, readjust the fading schedule to 20% a week. If no toxicity is demonstrated, the initial fading schedule can be 15% to 20% a week.
6. When the active ingredients have reached zero, indicate this to the patient and offer the option of discontinuing the cocktail or of continuing it for a few days before stopping.
7. Full and open disclosure of current levels of analgesics in the pain cocktail should be given to all patients who request it. This rarely proves to be any encumbrance to the fading program.

Social Reinforcement

Treatment Staff

The objectives here are twofold: to focus staff attention, responsiveness, and support on patient performance toward restoration of function and to minimize the extent to which professional staff actions are contingent on pain behaviors. To be nonresponsive is not to ignore a patient. It is to avoid letting approving behaviors occur.

Professionals interacting with the patient should be alert to encourage each increment in performance. Lavish praise and the like are usually inappropriate and ineffective. Straightforward acknowledgment of performance, given in positive tones, is helpful.

Patient expressions of pain behaviors should be responded to minimally. One does not ignore the patient. For example, maintain eye contact but let one's voice and facial expression remain neutral—not negative, but matter of fact.

Patient failures to achieve an exercise quota can be responded to in the same way. It often assists in putting the responsibility back where it belongs by adding the question “What do you think it means?”

Family

Family and significant others in the patient's social milieu will have evolved patterns of responding to pain behavior (1,10). These may be empathetic and socially supportive, neutral, or punitive and aversive. Family responsiveness often plays a role in helping to maintain a pain problem by pain behavior–contingent responses. It is essential, therefore, that initial evaluation of patients includes interviews with spouse or significant other to determine what if any problems may exist in this regard and to help set the stage for remediation.

Problems in patient–social milieu interactions regarding pain behaviors usually evolve because such responsiveness has become contingent on pain behaviors. It is a variation of “the squeaky wheel gets the grease.” Another form of environmental response to pain behaviors is admonishment of the patient to avoid activities that they feel might worsen the pain problem. In effect, they are punishing well behavior. These problems should be addressed. One or more meetings with spouse or significant other and a professional staff person usually suffice. The problem should be explained, and methods of remediation should be communicated as set forth above in regard to professional staff responsiveness.

Sometimes key persons in the milieu have developed resentment toward patient limitations in function and accompanying pain behaviors. This can be a complicated matter, reflecting long-standing relationship difficulties between patient and the other person(s). Sometimes aversive responsiveness to pain behaviors actually serves as reinforcement to those behaviors. The critical ramifications of these negatively toned interactions need to be studied by appropriately prepared professionals. If the problem is judged not to be entangled with long-standing relationship issues, it may suffice to have two to three meetings with the key person(s) to assist him or her in learning to focus on positive attainments by the patient, while becoming essentially nonresponsive to pain behaviors, as described above.

CM principles as described in this chapter are the foundation of multidisciplinary pain management and have been proven to be useful in the treatment of patients with chronic pain. Many other treatment strategies, both psychological and medical, also play an important role. Not all clinical psychology training programs provide adequate instruction in this form of therapy, whose principles must also be applied by physical and occupational therapists, nurses, and physicians.

CHAPTER 89

Cognitive-Behavioral Therapy for Chronic Pain

Judith A. Turner and Joan M. Romano

BASIC CONSIDERATIONS

History and Theoretical Basis

Behavioral therapies, emphasizing the promotion of adaptive behavior through the application of principles derived from learning theory, began to be developed in the 1950s (1,2). In contrast to psychodynamic psychotherapy, which seeks to change underlying personality processes presumed to cause maladaptive behaviors, behavioral therapies aim to modify maladaptive behaviors directly through the application of techniques based on learning theory principles (3). Maladaptive behaviors are assumed to be, to a considerable degree, acquired through learning experiences and to be modifiable through exposure to new learning experiences. Specific maladaptive behaviors and factors maintaining them are identified at treatment onset; specific, clearly defined treatment goals are set; and treatment is generally focused on the present and time-limited. Examples of behavioral therapies include systematic desensitization, assertiveness and social skills training, and operant conditioning. Fordyce (4) was a pioneer in the application of behavioral treatment approaches to chronic pain, which before the 1970s had been viewed generally as a strictly biomedical problem (see Chapter 25 and Chapter 88).

During the 1960s and 1970s, the importance of cognitive processes in emotional and behavioral problems gained increased attention. Cognitive processes (thoughts, attributions, beliefs, appraisals) were recognized as mediators of individuals' emotional and behavioral responses to environmental events. Rational-emotive therapy (5) was developed from a theory that assumes that emotional distress arises from faulty or irrational patterns of thinking. In rational-emotive therapy, the therapist assists the patient in determining external events and the associated thought patterns and underlying beliefs that give rise to negative emotions and then in altering irrational beliefs and thought patterns. Beck and his colleagues (6,7) developed a cognitive therapy that specifically targeted depression. This active, time-limited, structured therapy involves techniques designed to identify, reality test, and correct negative distortions in patients' views of themselves and their experiences. This therapy has been adapted for use with anxiety, anger, and other problems.

Cognitive-behavioral therapy (CBT) refers to an approach that combines cognitive therapy techniques with behavioral techniques such as relaxation training and assertiveness training. Meichenbaum (8) and others (9) emphasize a coping skills model— that is, teaching patients a variety of methods that can be applied across problems and situations. The reader interested in an overview of the historical development of cognitive theory and CBT in the field of psychotherapy should review Mahoney and Arnkoff (10).

Paralleling this increase in interest on the part of behavioral scientists in the cognitive aspects of behavior and behavior change has been increased recognition of the role that cognitive, affective, and behavioral factors play in the experience of pain. With this recognition has come an appreciation of the importance of examining the influences of psychological factors on an individual's pain experience and behavioral responses to pain and the potential for decreasing pain, suffering, and disability through cognitive and behavioral techniques. The rationale for applying CBT strategies to chronic pain problems is that learning new cognitive and behavioral responses to pain and to factors that can influence pain, such as stress, can give the individual a sense of control over pain; decrease negative emotions, thoughts, and beliefs related to the pain; decrease maladaptive behaviors; and increase adaptive behaviors. This, in turn, may reduce pain, suffering, and disability. These cognitive-behavioral techniques are typically incorporated as part of a broader comprehensive pain management approach.

Advantages and Disadvantages

The advantages of cognitive-behavioral techniques include their applicability to a broad range of clinical problems and pain syndromes and the fact that they have been proven efficacious in relatively brief group and individual treatment formats (e.g., six to 12 sessions), making them appealing in the current health care climate emphasizing low-cost, cost-effective, evidence-based treatments. One disadvantage is that CBT requires active patient participation and home practice. Not all patients are willing to expend the time and effort necessary to realize benefits. Another consideration is that specialized training is required to conduct CBT (e.g., graduate training in clinical psychology), and professionals skilled in the use of these methods may not be available in all settings. However, some highly structured CBT protocols can even be delivered by trained lay leaders (11).

CLINICAL CONSIDERATIONS

Indications and Contraindications

Any individual with a persistent pain problem potentially may benefit from CBT. The exact techniques applied are guided by the nature of the individual patient's problems. For example, a patient who tends to have many negatively distorted thoughts (e.g., “This pain is awful, and it will never get any better. I can't stand it—it is overwhelming.”) may benefit greatly from cognitive restructuring techniques (learning to identify and modify negatively distorted thoughts). A patient who tends to respond to stress with increased anxiety, muscle tension, and pain may benefit from learning a variety of stress management and relaxation techniques.

Several factors are likely to influence treatment success, particularly in chronic pain problems, and are worthy of empiric investigation. Patients who are not interested in CBT even after receiving information concerning the rationale for such an approach and what the therapy involves or who present for treatment only because they felt pressured to by an agency, such as a workers' compensation organization, or by a family member or physician, may be particularly challenging. However, such patients may become receptive to CBT if their physicians provide information and encouragement and if a working alliance between patient and CBT therapist is established so that the patient comes to perceive the therapy to be of potential benefit to him or her. Also, willingness to comply with and participate fully in a psychological treatment is likely to be minimal in patients who are convinced they have an organically based problem not influenced significantly by psychological factors. Attitudes of family members are also very important. Spouses who believe patients' pain is caused totally by biomedical factors and that psychological treatments are not relevant are unlikely to support treatment efforts and may undermine patient progress. Finally, the availability of personal, social, and environmental resources that can support treatment gains may well be critical in determining the long-term outcome.

Data are generally unavailable on particular factors that would predict positive or negative response to CBT for pain. In chronic pain problems complicated by factors such as chemical dependency, deactivation, compensation or litigation issues, or potent environmental reinforcers of pain behaviors, CBT alone may be insufficient to produce the desired patient outcomes. However, it may be useful as part of a more comprehensive multimodal treatment program that addresses a variety of important influences on the patient's pain and disability (see Chapter 11, Chapter 18, and Chapter 109).

Techniques

Although cognitive-behavioral therapies vary in goals and techniques, they share certain fundamental characteristics, including (a) the assumption that an individual's feelings and behaviors are influenced greatly by his or her thoughts (cognitions); (b) an emphasis on using active, structured techniques aimed at teaching patients

how to identify, monitor, and change maladaptive thoughts, feelings, and behaviors; (c) a focus on helping patients acquire skills in applying such techniques on their own to a variety of life problems; (d) a collaborative approach to therapy, in which the patient and therapist work as a team to help the patient learn and apply skills that are most relevant to the patient's unique situation; and (e) a relatively brief course of therapy.

The cognitive-behavioral therapist works from the premise that patients must be actively involved in learning to manage their own problems, including pain. Patients must have a clear rationale for the use of cognitive-behavioral techniques in dealing with their pain and be receptive to trying them. Many patients, understandably, are focused on obtaining a medical cure for their pain and fail to see the relevance of psychological approaches. Furthermore, some patients may interpret a referral to a psychologist as an indication that the physician believes their pain is “all in their head.” Patients may be provided several illustrations of ways CBT can be beneficial. One is that stress, which can stem from chronic pain and associated problems, as well as from other sources, can result in increased muscle tension, which in turn can produce increased pain. This serves as a rationale for relaxation and stress management training. Similarly, chronic pain can also be associated with feelings of anger or anxiety, which may also increase muscle tension and pain. It is helpful to emphasize to patients that the existence of such relationships does not imply that the sole cause of the patient's pain is stress or tension, but only that such processes can increase pain and suffering. It can also be stated to patients that chronic pain typically causes disruption in a number of important areas, including vocational functioning, marital and family relationships, and social and leisure activities. Such negative changes can in turn result in depression and anxiety, increased time available to focus on and worry about the pain, and decreased ability to cope with or tolerate the pain.

A simplified explanation of gate-control theory (12), emphasizing the importance of cognitive-evaluative and motivational-affective processes in the pain experience, can be very useful. It is important that patients recognize that pain is a subjective experience influenced by thoughts and feelings, as well as by nociceptive input. Many patients with chronic pain have never been told that an increase in their pain does not necessarily indicate that physical damage is occurring. Learning this, and being reassured that increased pain as they become more active does not indicate physical harm, can be extremely helpful in decreasing patients' activity avoidance and fear of movement. Patients also learn in CBT that, by recognizing and modifying maladaptive responses, regardless of the physical modalities being used to treat the pain and its organic causes, they can learn to better manage their pain and decrease suffering.

Cognitive-behavioral treatments are more likely to be successful if certain guidelines are followed (13,14):

- Organizing and presenting information in logical categories (e.g., diagnosis, treatment, expected results)
- Providing details of the treatment both verbally and in written form
- Tailoring instructions for each patient
- Presenting information gradually to avoid overwhelming patients
- Emphasizing the “how” rather than the “why” of treatment
- Assessing patients' understanding by asking them to describe what they will do after the session
- Providing a method by which patients can assess their performance of homework assignments
- Including patients' families in the treatment program
- Following up with patients to make sure they remember and understand the techniques
- Identifying obstacles to use of techniques and ways to overcome those obstacles

Two major types of CBT are cognitive restructuring and coping skills training. Each is described briefly in Table 89-1. Cognitive restructuring procedures and coping skills training overlap considerably; in practice, they reflect different emphases rather than completely different therapeutic modalities.

Type	Description	Example
Cognitive restructuring	Patients are taught to monitor and evaluate negative thoughts and to generate more accurate and adaptive cognitions.	A chronic pain patient who responds to increased pain by thinking, “I can't take this anymore” is taught to examine such thoughts and develop more accurate and adaptive ones; for example, “Is it really true that I can't deal with this? No, it may be difficult, but I've endured it before and can again.”
Coping skills training	Patients are provided a rationale for the use of techniques and then taught various skills for managing pain and stress.	
Relaxation		Physical and/or mental relaxation methods
Imagery		Imagining pleasant scenes
Coping self-statements		“Relax.” “I can cope.” “I can do something about my pain.” “It's not the end of the world.”

TABLE 89-1. Major types of cognitive-behavioral therapies

Cognitive Restructuring

Cognitive restructuring techniques, typified by rational-emotive therapy (5) and cognitive therapy (6), are used to teach patients to identify and modify maladaptive, negatively distorted thoughts that can lead to negative feelings such as depression, anxiety, and anger. Patients learn to examine objectively whether such thoughts are accurate and justified by evidence and to substitute more adaptive, evidence-based cognitions for negatively distorted thoughts. The term *restructuring* does not imply a literal change in any internal structure or process. However, it does serve to indicate that what is being learned is a method for examining and modifying one's thoughts about experiences and events that can be generalized across a number of situations. A somewhat similar approach, use of coping self-statements, is discussed in a later section, Adaptive Coping Self-Statements.

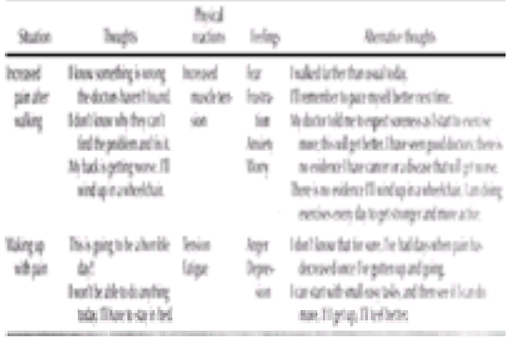
In using cognitive-behavioral techniques with chronic pain patients, establishing a plausible rationale for these interventions is critical, as many of these patients tend to reject psychological approaches to their problems. A simplified explanation of the gate-control theory of pain provides an excellent way to begin introducing the notion that psychological as well as physiologic factors may play a role in determining how pain is experienced. This concept can be made personally relevant to patients if the therapist helps them to identify factors that increase or decrease their experience of pain, discussing these in terms of opening or closing the “pain gate.” These factors may be classified as physical, emotional, and cognitive, as shown in Table 89-2.

Type of influence	Opens gate	Closes gate
Physical	Overexertion Muscle tension	Muscle relaxation Heat or ice Medication
Emotional	Anxiety Depression Anger	Happiness Mental relaxation
Cognitive	Worry Increased attention to pain Catastrophizing	Attention focus on something other than pain Coping self-statements

TABLE 89-2. Examples of influences on the pain gate

The next step in engaging a patient in CBT is helping him or her to recognize that emotional responses to pain are greatly influenced by one's thoughts. It can be helpful to delineate the components of a stressful situation through the use of a worksheet such as the one shown in Table 89-3. The therapist should emphasize that although we often cannot control or avoid distressing life events, we almost always can exert some control over how much suffering and life disruption such events

produce. Once patients understand these connections between thoughts and feelings, they are trained to identify their negative “automatic thoughts,” evaluate the accuracy of these thoughts, think of possible alternative appraisals, and counter negative thoughts with more positive or realistic cognitions. For example, suppose a patient experiences increased pain after walking some distance (the event) and then thinks to himself, “I know something is wrong that the doctors haven't found. This is going to get worse and I'll wind up in a wheelchair.” The usual consequences of such cognitions are anxiety, fear, and worry, and the patient may respond by avoiding activity. The consequences will be much less negative, however, if the patient thinks, “I walked much farther than usual today. I'll remember to pace myself better next time. My doctor told me to expect some soreness as I start to exercise more. It doesn't mean that I will wind up in a wheelchair. I am doing exercises every day so I can become stronger and more active.”



Situation	Thoughts	Physical reactions	Feelings	Alternative thoughts
Increased pain after walking	I know something is wrong. The doctors haven't found it. I don't know why they can't find the problem and fix it. My back is getting worse. I'll wind up in a wheelchair.	Increased muscle tension	Fear Frustration Anger Anxiety Worry	I walked farther than usual today. I'll remember to pace myself better next time. My doctor told me to expect soreness as I start to exercise more. She will get better. I have seen good doctors. There is no evidence I have cancer or a disease that is getting worse. There is no evidence I'll wind up in a wheelchair. I am doing exercises every day to get stronger and more active.
Waking up with pain	This is going to be a horrible day! I won't be able to do anything today. I'll have to stay in bed.	Tension Fatigue	Anger Depression	I don't know that for sure. I've had days when pain has decreased once I've gotten up and going. I can start with small easy tasks, and then see if I can do more. If I get up, I'll feel better.

TABLE 89-3. Template for identifying and countering negative thoughts

As a second example of this model, suppose that a patient has increased pain on awakening one day. Negative cognitions (e.g., “This is going to be a horrible day! I won't be able to do anything today. I'll have to stay in bed.”) are likely to result in anger and depression. On the other hand, the patient is likely to feel much less angry and depressed if he or she thinks, “I don't know that for sure. I've had days when pain has decreased once I've gotten up and going. I can start with small easy tasks, and then see if I can do more. If I get up, I'll feel better.”

Many chronic pain patients find it very difficult to recognize their negative automatic thoughts in response to increased pain or stress, and a number of sessions may be needed to develop this skill. It is often helpful to have patients “relive” a recent situation in which there was much pain, stress, anxiety, or depression, relating step by step what happened, how they were feeling, and what they were thinking. Patients typically need much help in fully describing their thoughts and feelings. They may say they simply felt anxious and had only one thought in a particular situation, when careful questioning may reveal several important additional feelings and thoughts. Each feeling described should be explainable by at least one thought. For example, if a patient says she felt angry in a certain situation but can give no thoughts that would lead to feelings of anger, the therapist should help the patient to reconstruct what thought was associated with that feeling. Similarly, if a patient describes a thought (e.g., “That was unfair.”) that would be associated with anger in most people but does not list that feeling, the therapist might point out that most people would feel angry if they thought that, and ask if the patient might not have had some negative emotional reaction at that time.

Between sessions, it is extremely useful to have patients record their thoughts and feelings during or immediately after situations in which they experience increased pain or stress. These records can be used during the following therapy session to provide examples for continued learning and practice of skills. It is important that patients learn to distinguish events, thoughts, and feelings. Many patients at first incorrectly record thoughts as events or feelings, feelings as thoughts, and so forth.

Only when patients can readily identify automatic thoughts and feelings should the therapist move on to instructing them in evaluating the accuracy of negative thoughts and generating alternative thoughts. In this process, the therapist and patient work together to examine whether negative thoughts are realistic and whether there may be other possible interpretations of the event or situation. The goal is not to persuade patients that their thinking is wrong but to help them examine the extent to which their negative thoughts are supported by evidence. For example, if a patient's thought is “I can't do anything any more because of this pain,” the therapist might ask, “Is it true that you can't do anything? Is there anything you can do despite the pain?” The therapist and patient might then go on to list what the patient is able to do, as well as what the patient can no longer do. They might also discuss the importance of activities that the patient cannot do and whether there are any ways the patient might be able to accomplish some of these activities despite the pain. Finally, the patient and therapist might design a homework assignment to test the patient's thoughts and assumptions and provide additional information for further discussion. As therapy progresses, core assumptions underlying negative thinking patterns may emerge, such as self-worth's being equated with ability to do certain types of work or activities. Addressing these core assumptions and themes with the techniques described here is an important component of CBT.

To summarize, the therapist aims to teach patients how to identify negative distorted thoughts, examine the accuracy of these thoughts, and generate more realistic and more adaptive ones. Thus, the focus is not on solving a particular problem but rather on learning a cognitive skill for dealing with negative thoughts and emotions. The goal is not to eliminate negative emotions, which are recognized to be a normal part of life, but rather to reduce the intensity of negative emotions that result from distorted cognitions about events and situations.

Coping Skills Treatments

Coping skills therapies aim to help patients develop a repertoire of skills for managing pain and stress. Although these skills often include cognitive restructuring, they also encompass other techniques, such as relaxation and distraction. Of the various specific coping procedures that have been taught in therapeutic situations, relaxation, imagery, and the generation of positive coping self-statements seem to be the most commonly used.

Relaxation and Imagery Techniques. A wide variety of relaxation methods exist; none has been proven more consistently effective than others when applied to chronic pain problems (see Chapter 92). It is often useful to teach patients several methods, so that patients may select the approach they find most useful. Daily practice of relaxation over several weeks appears to be necessary for realization of maximum benefits. Techniques that many patients with chronic pain find useful include progressively tensing and then relaxing major muscle groups (15), imagery (13), and deep breathing (13).

As with instruction in any cognitive or behavioral technique, the therapist should explain to patients why and how the procedure helps relieve stress, tension, and pain and emphasize the necessity of regular practice to develop skills and realize maximum benefits. Patients can be told that pain and other physical and psychological stressors often result in increased autonomic and emotional arousal and muscle tension. Muscle tension tends to spread to adjacent muscle groups and has the effect of further increasing pain. To illustrate this fact patients may be instructed to clench their fists and observe the impact on other muscles in their arms, shoulders, and jaws. The therapist then explains that relaxation is a very effective means of reducing the muscle tension, autonomic arousal, and negative emotional responses that make pain worse, thus breaking up a vicious cycle.

Relaxation and imagery methods are also helpful in diverting attention from pain, improving sleep (often disrupted in chronic pain syndromes), and giving patients a sense of control over pain. Furthermore, patients learn to monitor muscle tension in their bodies and to decrease tension before it mounts. Mentioning the effective use of relaxation and breathing techniques for labor pain may help enhance the credibility of this technique for patients.

Relaxation must be taught over a number of sessions—in our experience, at least six—for a patient to become proficient in its application. Ideally the patient and therapist meet once or twice a week, and the patient practices relaxation daily at home between sessions. An audiotape may be given to patients to use for home practice. The therapist observes the patient during the sessions to see how relaxed the patient is able to become and what body areas he or she has difficulty relaxing. During each session, some time should be spent discussing problems the patient has had in doing the home practice and in generating possible solutions. Typical problems include not being able to find time to practice and experiencing distracting thoughts while attempting to relax.

In our experience, there is no “right” protocol that patients must follow to relax fully; rather, the therapist and each patient should work together to develop a method tailored to the individual. After patients become proficient at being able to relax in a quiet, comfortable place, training can focus on generalizing relaxation skills to other settings and positions. The ultimate goal is for each patient to be able to achieve relaxation, without having to tense muscles, in any situation. As training

progresses, patients should find that they automatically notice tense muscles in daily situations and respond by relaxing.

Many techniques are helpful for enhancing relaxation: saying a word such as “calm” or “relax” silently to oneself, focusing on a pleasant image, and listening to music. Mental imagery can be used with muscle relaxation techniques as a procedure for decreasing pain. Again, numerous types of imagery have been described (16). Pain can be imagined as an object (e.g., a tight band) that can be manipulated to decrease discomfort, or the patient can imagine being in a pleasant place such as a meadow or a beach, to give just two examples. It is very important that the patient find an image that is highly involving, if possible using multiple (visual, auditory, tactile) senses. For example, if the image of walking on a beach is used, patients may be asked to imagine the colors of the sea, sand, and sky; the sounds of waves and birds; and the feelings of the warm sun and sand. Many patients are best able to work with images of actual situations they have experienced.

Adaptive Coping Self-Statements. The use of adaptive self-statements is another coping skill frequently taught. This involves teaching patients to cope with increased pain or stress by thinking adaptive thoughts (*self-statements*). Examples of coping statements are “I can deal with this,” “Focus on relaxing,” and “This tension is a cue to use my coping skills.” Although this technique is similar to the cognitive restructuring approaches described already, less emphasis is placed on acquiring a general method of examining and modifying cognitive processes than on learning a set of particular coping self-statements to be used in situations of pain and stress.

These techniques may be useful in coping with flare-ups or increases in pain associated with medical procedures or treatments. The patient may be given the rationale that anxiety and tension can increase discomfort and that the level of anxiety experienced is strongly influenced by what one says to oneself about the experience. Examples are useful in illustrating these points. Most patients can understand that certain thoughts (e.g., “I can't take this”; “This is unbearable.”) produce increased anxiety and focus on pain and suffering. A useful way to decrease this anxiety and tension is to respond to negative thoughts by substituting or countering with thoughts emphasizing the patient's ability to cope. Once the rationale has been established and the method demonstrated, it is useful to have the patient rehearse these techniques when imagining him- or herself in the painful situation. The patient is instructed to recognize the natural reactions of anxiety, muscular tension, and negative thoughts (e.g., “This is horrible”; “I can't stand this.”) and to then counter these thoughts with more positive ones (e.g., “This won't last long. I can handle it. Just relax.”).

Coping statements may be used in four different phases of coping with pain (13). In the first phase—preparing for the pain—such statements as “Think about what you can do to deal with this. Worrying will not help.” are used. In the second phase—confronting and handling the sensations—such statements as “Use the tension as a cue to relax. I can think of something pleasant.” are helpful as the pain begins to increase. The third phase—critical moments—involves feelings of intense pain or beliefs that one cannot deal with the pain. Statements such as “Just focus on a strategy for dealing with the pain. I can handle each moment as it comes with breathing and relaxation. I'll get through this.” are helpful in countering negative thoughts about one's ability to cope. In the final phase—reflections on how one did—the patient praises him- or herself for coping with the pain with statements such as “I handled that pretty well.” Patients may find it useful to keep a list of coping self-statements that they have found useful (e.g., “I can cope,” “Take some deep breaths and relax.”) on a card in their wallets.

Group Therapy. Group CBT is often an important component of pain treatment programs (see Chapter 109). Groups have the obvious advantage over individual sessions of enabling one therapist to work simultaneously with a number of patients. Another advantage of groups is that patients benefit from contact with and support and encouragement from others with similar experiences and problems. They may be more receptive to feedback and suggestions from other patients in the group than from the therapist. The group format also enables patients to role-play with a number of different people and observe others' role-playing.

Such sessions may be considered “psychoeducational” in nature. That is, educational approaches such as structured content and didactic teaching are combined with psychological techniques such as role-playing to teach coping skills that the patient can apply to current and future personal and interpersonal problems (17). Many groups start by providing information to patients about their pain condition (e.g., education about arthritis, temporomandibular disorders, low back pain, or complex regional pain syndromes). This may include current understanding about causes, role of diagnostic tests, various treatment options and the pros and cons of each, and what is known about the prognosis and natural history of the condition. The therapist may then go on to discuss the biopsychosocial model, the role cognitions and emotions play in pain, and the interrelationships among stress, tension, and pain. This may be tied into gate-control theory (12), and asking patients to generate a list of factors that “open” (e.g., tension, anxiety, worry, fear) and “close” (e.g., relaxation, attention diversion) the gate usually helps make these concepts more concrete and relevant to patients (see Table 89-2). Greater patient belief that such relationships are important in their pain problem and that the techniques to be taught can help them cope more effectively with stress and pain will create greater patient receptivity to therapy. Thus, it is important to cover these issues thoroughly with patients in the first few sessions. Visual aids, videos, and reading materials can help supplement the didactic content of the group.

Information provision alone may be insufficient to produce changes in patient behaviors and functional status (18,19 and 20). Thus, CBT groups include cognitive and behavioral techniques, in addition to education, to increase the likelihood of patient behavior change resulting in improved physical and psychosocial functioning. Typically, each patient develops specific individualized goals for behavior change as part of group CBT treatment. This could include goals such as increased physical activity (e.g., increasing daily walking time) or increased social or recreational activity (e.g., increased family recreation).

Group CBT typically consists of six to twelve 1- to 2-hour sessions, usually once a week for outpatients or once a day for patients in an inpatient or day treatment pain program. Sessions can cover diverse topics, such as stress management training, communication and assertiveness skills training, problem solving, cognitive restructuring techniques, sleep hygiene, coping with pain flare-ups, maintenance of gains and relapse prevention, conflict resolution, and anger management. Although the exact topics may vary according to the particular patient population and the total time available, the emphasis of all such sessions is on increasing the patient's sense that he or she can decrease pain, distress, disability, and other negative effects of pain by learning and using the techniques taught.

Size of groups may vary, but it is ideal to have at least six patients and no more than 10 patients in a group. The format is structured, with time allowed for education and skills instruction, practice, and rehearsal. It is also helpful, but not always possible, to include only patients with the same pain problem (e.g., low back pain or headaches) in a group, so that the group can receive education and other problem-specific content relevant to all members. Ideally, all patients in the group will be able to comprehend, read, and write the language in which the group is conducted, but it is possible to include patients without these skills by involving an interpreter or providing other special assistance. It is essential to screen patients before enrolling them in group CBT. Patients must be willing and able to attend the groups and receptive to taking an active role themselves in managing their pain. Patients who wish only to find a medical cure for their pain or who are quite angry or hostile may undermine other group members' progress and are not appropriate for group CBT.

Factors Affecting Treatment Outcomes

Compliance with Homework Assignments. There is evidence that the patients who most frequently use the cognitive-behavioral skills taught in CBT are those with the best long-term outcomes (21,22). Homework is usually required of patients in cognitive-behavioral treatment. This may consist of recording pain and mood ratings, recording thoughts and feelings in different situations, and practicing new techniques and behaviors. Noncompliance with such assignments frequently occurs. Therapists can use the following strategies to enhance compliance:

- Enlist the patient as a collaborator in setting up the assignment, incorporating his or her goals, suggestions, and feedback in designing the assignment, rather than giving the patient a standard, predetermined assignment.
- Start out with a very simple, easy assignment that the therapist and patient feel confident the patient can do; then progress gradually to more difficult and complex assignments.
- Suggest that the patient enlist the assistance of a spouse or family member. For example, the patient could ask his or her spouse to help prevent interruptions during his or her relaxation practice.
- Make sure the patient understands the homework assignment (what is to be done and the rationale) and believes it to be useful.
- Ask the patient what problems he or she anticipates might interfere with successfully completing the assignment, then generate ways of coping with such problems.
- Reinforce completion of homework assignments by attention and interest. If an assignment is not completed, work with the patient to understand why. Did the patient forget? Did the assignment seem too difficult? Once the reasons for not completing the assignment are understood, assignments may be modified to enhance the chances of successful completion in the future.

Maintenance of Gains and Preparing for Setbacks. An important component of treatment with all patients with chronic pain is discussion of ways to maintain the gains made in treatment and ways to cope with future setbacks or pain flare-ups. Several things may be done before setbacks occur to minimize the probability of their occurring and their negative impact. At the beginning of treatment, discussing the patient's expectations of treatment, what it can and cannot do, and the time frame for change is very important. Many patients have unrealistic hopes for rapid, complete pain relief, but they may not disclose these beliefs. Throughout treatment, the

therapist should work with the patient to identify obstacles and high-risk situations that might interfere with his or her practice and application of coping skills.

The therapist should tell patients, early in treatment, that setbacks (e.g., decreased rate of progress, periods of increased pain or depression) are quite likely to occur, both during and after treatment. Patients should be assured that setbacks during treatment can be very useful in providing information as well as an opportunity to practice newly learned coping skills. The therapist should encourage patients to share their negative thoughts about the treatment and to discuss setbacks, so that the reasons for them and various ways of handling them can be explored. One useful approach is to first review with patients their responses to increased pain before entering treatment in terms of their behaviors, emotions, thoughts, and physiologic reactions. These responses may include lying down; feeling depressed, anxious, and angry; thinking, “I can't stand this” or “I'll never get better”; and tensing up. These reactions may then be discussed in light of what patients have learned in the program about gate-control theory. These responses are likely to “open the pain gate” and thus contribute to the perpetuation of disability and pain. Although they are common and understandable responses to increased pain, they are not constructive coping strategies. A more adaptive coping plan consists of two components: ways to prepare for pain flare-ups and coping strategies to use at times of increased pain.

Patients may be best prepared to deal with flare-ups if they maintain realistic expectations regarding their occurrence. This means having neither an unrealistic belief that pain will never recur (which may set the patient up for severe disappointment and discouragement if a setback occurs) nor an overly pessimistic view that pain cannot be modified and the patient is unable to do anything to cope with it (which can lead to depression and failure to use techniques that have been taught). Advance preparation also involves keeping skills in stress management, communication, relaxation, exercise, and stretching well practiced. Skills that have not been used for some time are unlikely to work well in a crisis. As part of treatment, the therapist and patient should develop a list of red flags for setbacks—that is, situations or symptoms that in the past have been associated with increased pain or stress and indications that the patient is no longer engaging in practices that promote adaptive functioning (e.g., regular exercise, good sleep habits, application of stress management and communication skills). A specific plan of action for responding to such red flags should be written out. A typical plan includes coping self-statements (e.g., “I can cope with this,” “This is a good opportunity to use my skills.”), a relaxation exercise, and coping activities to engage in (e.g., taking a walk, stretching, working on a hobby), as well as a reevaluation of the patient's plan for maintaining adaptive behaviors such as exercise and stress management. It is useful to have the patient rehearse specific plans for dealing with pain flare-ups and other setbacks during CBT.

Keefe, Beaupré, and Gil (23) have described the application of Marlatt and Gordon's (24) four-step relapse prevention method to patients with chronic pain. The first step involves stopping and paying attention to the cues that a setback is occurring. The second step is to keep calm, using relaxation or other strategies. The third is to review the situation leading to the setback. The fourth is to make an immediate plan for implementing coping. The therapist and patient role-play how the patient might cope with setbacks.

Therapist Characteristics. Although many of the procedures described in this chapter appear relatively straightforward, therapists must be trained in their appropriate application. Typically, CBT therapists are doctorate-level clinical psychologists with postdoctoral training in pain management. Complex issues often arise during treatment, requiring considerable skill on the part of the therapist. These may include symptoms of major psychopathology, significant marital or family distress, issues related to workers' compensation and disability compensation systems, and persistent somatic focus and resistance to the use of psychological techniques. Whether or not such issues are salient, the importance of therapist style characteristics cannot be overemphasized. As with any psychotherapy, therapist warmth, empathy, respect for the patient, and attentiveness to the patient's goals and needs are important to the success of the treatment.

Results

Cognitive-behavioral strategies have been applied to a number of different chronic pain problems, including low back pain (25,26,27 and 28), headache (29), fibromyalgia (30,31 and 32), osteoarthritis (33,34), rheumatoid arthritis (RA) (35,36,37,38,39,40 and 41), ankylosing spondylitis (21), and temporomandibular disorders (42,43,44,45 and 46). Most multidisciplinary pain treatment programs incorporate cognitive-behavioral methods in addition to physical therapy and other modalities (see Chapter 109). A number of controlled trials have demonstrated the efficacy of CBTs in improving pain, depression, and physical disability in a variety of pain conditions [see reviews (47,48)].

Turner (49) conducted a metaanalysis of 14 randomized trials of cognitive and behavioral treatments for chronic low back pain published before April 1994. Compared with control conditions (waiting list or attention control group), cognitive-behavioral treatments were superior on posttreatment self-report measures of pain intensity, pain behavior, and functional disability, but not observed pain behavior or depression. However, most of the subjects in these studies were community volunteers, and, in general, they were not very depressed and did not show many pain behaviors before treatment. Thus there was little room for improvement on these dimensions. Studies that compared cognitive-behavioral treatments with control conditions at follow-ups were not available.

Turner (49) found six studies that compared cognitive or behavioral treatments with another treatment, such as physical therapy or standard medical care, for low back pain. In this metaanalysis, cognitive-behavioral treatments were found not to differ significantly from other treatments at either posttreatment or follow-up assessments on measures of pain, pain behavior, functional disability, and depression, although there was a trend toward a statistically significant posttreatment effect size in favor of CBT on a self-report measure of disability (the Sickness Impact Profile). Because only two to three studies used any one outcome measure and sample sizes were small, more studies are needed to resolve the question of the efficacy of CBT relative to other treatments for chronic low back pain problems.

Scheer et al. (50) reviewed randomized clinical trials of CBT interventions for subacute and chronic low back pain that assessed return to work and were published between 1975 and 1993. They found eight articles describing five studies that included or emphasized CBT for chronic lower back pain. They concluded that the data did not support the effectiveness of cognitive-behavioral strategies in affecting vocationally relevant outcomes, but that the majority of studies had significant methodologic limitations.

The Division of Clinical Psychology of the American Psychological Association published a list of empirically validated psychological treatments for various disorders, and this list included CBT for chronic pain (51). A National Institutes of Health Technology Assessment Conference Statement (52) concluded that there was moderate empirical support for the efficacy of CBT for chronic pain and that there was strong evidence for the efficacy of relaxation techniques and multimodal treatments for chronic pain problems. Also according to this statement, the data are not sufficient to conclude that one cognitive or behavioral technique is usually more effective than another for a given condition, although, for an individual patient, one approach may be more appropriate than another. The panel concluded that additional efficacy, effectiveness, and cost-effectiveness studies are needed, as are innovative methods of introducing psychosocial treatments into health care curricula and practice.

In a comprehensive review, Compas et al. (47) concluded that the literature supported the efficacy of CBT for rheumatic diseases. Compas et al. (47) found five studies that compared CBT to both attention control and standard medical treatments for rheumatic diseases. All five studies reported improvements in psychological functioning and three found significant pain reductions in patients who received CBT. One of the studies that failed to show overall improvements in pain (39) did find significant pain reduction at long-term follow-up in CBT participants who had shown high adherence to the practice of CBT techniques. The only study that found no improvement in outcome after CBT (53) used a sample of RA patients who had very active disease and demonstrated significant increases in measures of disease activity over the course of the study.

Compas et al. (47) also concluded that CBT was more effective than waiting list or education control conditions for patients with rheumatic diseases. In a study of ankylosing spondylitis patients, CBT was significantly more effective than a waiting-list control in reducing pain, anxiety, and psychophysiologic symptoms (21). In a study of RA patients, compared to an education control condition, CBT produced significant decreases in pain and joint inflammation (38).

Compas et al. (47) also reviewed the literature on CBT for chronic low back pain and for migraine headaches. They concluded that CBT was more effective than a waiting-list control in improving pain, activity level, and psychological functioning in patients with chronic low back pain. For migraine headache, however, they found no evidence that cognitive therapy or CBT enhances the benefits of biofeedback and relaxation training.

In a study examining the process of change in patients participating in a multidisciplinary pain treatment program, Jensen, Turner, and Romano (54) found that improved patient functioning was associated with changes in patient pain-related beliefs and cognitive coping strategy use, consistent with a cognitive-behavioral model. Some studies (26,27,42), but not all, have found continued improvement on outcome measures after the end of CBT for up to 1 year, perhaps as a result of patient application of skills learned in CBT.

Several investigators have examined whether involving family members enhances the efficacy of CBT. Radojevic et al. (40) randomly assigned 65 RA patients to four group treatment conditions: (a) CBT with family support, (b) CBT alone, (c) education with family support, and (d) a no-treatment control condition. Subjects in the

CBT with family support group attended the sessions with a family member. Patients were trained in cognitive pain coping and relaxation techniques, and the patient and family member were taught methods for prompting and reinforcing the use of learned pain control skills. Patients in the CBT alone condition received the same skills training, but no family member was involved. The CBT with family support condition was superior to all other conditions in reducing joint swelling at posttreatment. Both CBT conditions were effective in reducing joint pain at follow-up.

Keefe et al. (55) evaluated the efficacy of a spouse-assisted CBT intervention in managing osteoarthritic pain. Patients with osteoarthritic knee pain were randomly assigned to one of three conditions: (a) spouse-assisted CBT, (b) conventional CBT, or (c) an arthritis education/spouse support control condition. Patients in the spouse-assisted CBT condition attended sessions with their spouses in which they were trained in pain coping skills and in couples' skills (communication skills, behavioral rehearsal, problem solving, and maintenance training). At posttreatment, patients in the spouse-assisted CBT condition had lower levels of pain, psychological disability, and pain behavior and higher scores on measures of coping efforts, marital adjustment, and self-efficacy than did patients in the education-support control condition. These differences were statistically significant. Although there were no significant differences between spouse- assisted CBT and conventional CBT, there was a consistent pattern for patients in the spouse-assisted CBT condition to have the best outcome, conventional CBT the next best outcome, and education-support the poorest outcome.

Complications

Adverse effects of cognitive-behavioral therapies appear to be rare but have been reported. For example, some patients describe increased anxiety associated with the use of relaxation (56). However, because these treatments carry few if any serious risks, chronic pain patients who fail to respond initially to a particular technique may be given trials of other cognitive-behavioral strategies. Increased empiric study of these methods will provide data for specifying when these techniques are most appropriate and likely to be effective.

CONCLUSIONS

CBT is now considered an empirically validated treatment for chronic pain problems. Since the last edition of this book, substantial scientific evidence for the efficacy of CBT for diverse chronic pain problems has come from randomized clinical trials. However, it should be noted that CBT interventions are multimodal treatment packages that combine education about pain with training in a variety of cognitive and behavioral coping skills. There are few data concerning which components are necessary, sufficient, or most important. Furthermore, many experts have called attention to the need to match patients to treatments (45,47,57). For example, patients with greater physical and psychosocial dysfunction may require longer, more intensive, and more individualized treatments. Continued research may lead to the development of guidelines to assist clinicians in selecting the most cost-effective treatments for individual patients.

CBT has been largely applied to, and studied in, patients with long-standing chronic pain. Several investigators have suggested the potential value of providing CBT interventions to patients early in the course of their pain problem (42,49,57). Early intervention has the potential to increase patients' confidence that they can self-manage many symptoms, reduce unnecessary health care utilization, and decrease physical and psychological dysfunction.

This chapter has provided an overview of the rationale for the use of CBT with patients with chronic pain as well as a description of specific types of such interventions. Although the techniques may appear straightforward and easy to use, clinical acumen and experience are necessary for their successful application. Considerable patient investment in learning and applying the skills taught is important in producing a positive outcome, and this may be a barrier to their use with some patients. Nonetheless, there is now strong evidence that such interventions can be a very valuable treatment modality for many patients with chronic pain problems.

CHAPTER 90

Biofeedback Therapy for Chronic Pain Disorders

John G. Arena and Edward B. Blanchard

Biofeedback for chronic pain disorders is a biopsychosocial technique that has been in existence since the seminal work in 1970 of Budzynski, Stoyva, and Adler (1) with tension headache patients. The most concise definition of biofeedback is probably that of Olton and Noonberg (2, p. 4), who characterized it as “any technique which increases the ability of a person to control voluntarily physiological activities by providing information about those activities.” In reality, the process of clinical biofeedback training generally involves the use of a machine—now usually a computer—that allows a therapist to monitor the patient's bodily responses (generally surface muscle tension or surface skin temperature). Information concerning the patient' s physiologic responses are then relayed back to the patient, generally either through an auditory modality (a tone that increases or decreases on, for example, muscle tension increasing or decreasing), a visual modality (now usually a computer screen where, e.g., surface skin temperature is graphed on a second-by-second basis during each minute), or both. Through this physiologic feedback, patients learn how to control their bodily responses through mental activity. Figure 90-1 illustrates visual feedback provided through the use of a computer screen for a migraineur receiving hand surface temperature biofeedback.

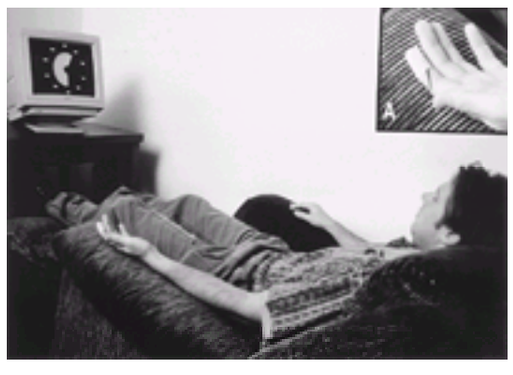

Figure 90-1. Visual feedback given through the use of a computer screen for a migraineur receiving hand surface temperature biofeedback. Inset A contains a close-up of the subject' s hand with the thermistor attached.

Two general theories underlie the use of biofeedback for most chronic pain disorders. The first is a direct psychophysiologic theory, which attributes the etiology or maintenance, or both, of the pain disorder to predominantly physical pathology that is corrected by biofeedback training. For example, it has traditionally been assumed that tension headache is caused by sustained contraction of skeletal muscles in the forehead, neck, and shoulder regions. Through the use of biofeedback, the patient learns to decrease muscle tension levels, leading to a decrease in headache activity. The second theory is predominantly psychological and postulates a relationship between situational stress and chronic pain (3). Through the use of biofeedback, the patient learns to decrease physiologic responses such as muscle tension levels or sympathetic nervous system activity, thereby leading to a decrease in overall stress levels, that, in turn, brings about a reduction in pain. Most clinicians subscribe to both theories, depending on the assessment of the individual patient.

Since the previous edition of this book (4), the literature on the use of biofeedback for pain disorders has grown exponentially. Every reference to biofeedback for pain management cannot be included in this chapter. We provide a review of the current literature for each of the major pain disorders for which biofeedback has been used, reviewing primarily the work published since the prior edition of this textbook and arriving at conclusions about efficacy that are consonant with contemporary research and clinical application.

Although biofeedback has been used for a wide variety of pain disorders, chronic headaches—both tension and vascular (migrainous) headache—have received the most attention in the literature. The quality of the published studies (i.e., controlled evaluations of efficacy) are highest for the treatment of headache. The use of biofeedback training for both tension headache and migraine headache has been endorsed by the Association for Applied Psychophysiology and Biofeedback and by the American Association for the Study of Headache. The American Psychological and Psychiatric Associations and the National Institutes of Health (5) have also provided endorsement for the use of biofeedback for these types of headaches in the context of comprehensive medical, psychological, and psychiatric care.

In view of these considerations, we devote a large portion of this chapter to biofeedback treatment of headache (see Chapter 48), with the remainder devoted to numerous other pain problems for which biofeedback has been used—predominantly lower back pain (LBP) and myofascial pain dysfunction (MPD) syndrome. Wherever possible, references to comprehensive reviews are included (6).

BIOFEEDBACK TREATMENT OF CHRONIC HEADACHE

Tension (Muscle Contraction) Headache

The phenomenology and pathophysiology of tension (muscle contraction) headache are described in Chapter 48 and are not repeated here.

Frontal Electromyographic Biofeedback

The initial report on biofeedback treatment for tension headache (1) described the procedure for frontal electromyographic (EMG) biofeedback, the standard paradigm to this day. It is important to note that the term *EMG* refers to surface electromyography, which uses noninvasive (surface) electrodes, is painless, and involves the pattern of many motor action potentials. In contrast, EMG when used as a diagnostic procedure involves invasive needle electrodes, looks at a single motor action potential, and is often quite painful.

The standard EMG biofeedback procedure for tension headache involves measuring the muscle tension in the forehead by placing electrodes approximately 2.5 cm over each eyebrow and another (ground) electrode in the center of the forehead. The signal is then electronically processed to provide the patient with information on changes in the electrical activity of the muscles on a moment-by-moment basis. Through this feedback, the patient learns how to relax the musculature of the face and scalp and how to detect early symptoms of increased muscle tension. For EMG biofeedback, the feedback signal is generally auditory and may consist of a tone that varies in pitch, a series of clicks that vary in frequency, or a similar system.

Before the electrodes are attached, the skin surface may be cleaned with a mild abrasive, followed by swabbing the forehead with an alcohol preparation. To insure

against infection, only disposable EMG electrodes with adhesive collars are used.

Treatment sessions usually last 30 to 50 minutes with 15 to 40 minutes of each session devoted to the actual feedback training. In our research (and in our clinical work), we have typically used the following format for biofeedback training sessions:

1. Attachment of electrodes and initial adaptation: 10 minutes.
2. In-session baseline, during which patients are asked to sit quietly with their eyes closed: 5 minutes.
3. Self-control 1, during which patients are asked to attempt to decrease their forehead muscle tension levels in the absence of the feedback signal: 3 minutes.
4. Feedback training, with the feedback signal available: 20 minutes.
5. Self-control 2, during which patients are asked to continue to decrease their forehead muscle tension levels in the absence of the feedback signal: 3 minutes.

The two self-control conditions are included to determine whether generalization of the biofeedback response has occurred. Generalization involves preparing the patient to, or determining whether the patient can, carry the learning that may have occurred during the biofeedback session into the“real world.” If the patient can decrease muscle tension without any feedback before the biofeedback condition (self-control 1 condition), then the clinician can assume that between-session generalization has occurred. If the patient can decrease muscle tension without any feedback following the biofeedback condition (self-control 2 condition), then the clinician can assume that within-session generalization has occurred.

There are other methods clinicians use to train for generalization of the biofeedback response. For example, in an attempt to make the office biofeedback training simulate real world situations, many clinicians initially train patients on a recliner; then, once they have mastered the rudiments of biofeedback in this extremely comfortable chair, they progress to, sequentially, a less comfortable office chair (with arms), an uncomfortable office chair (without arms), and, lastly, the standing position. Finally, giving the patient homework assignments to practice the biofeedback response in the real world is a routine way of preparing him or her for generalization.

It is important to note that clinicians vary tremendously in their biofeedback procedures, depending on personal style, training, and the type of patient seen. For example, the biofeedback portion of the session may be decreased significantly in length for patients who have poor concentration abilities or expanded if the patient has had a breakthrough in learning the biofeedback response in the latter minutes of the biofeedback session. Other clinicians choose not to include self-control conditions or choose to vary the length of the adaptation and baseline periods.

Although there is a large body of research on the use of EMG biofeedback alone as a treatment for tension-type headache, in clinical practice some form of relaxation training, usually an abbreviated version of Jacobson' s progressive muscle relaxation (see Chapter 92), is routinely added as an adjunct to the biofeedback treatment. It is common clinical practice to give the patient an audiocassette of the relaxation induction to guide home practice. Patients are asked to practice the relaxation on a daily basis.

The direct experimental comparisons of frontal EMG biofeedback and relaxation training have usually shown no advantage for one over the other. A sequential comparison by Blanchard and colleagues (7) showed a significant advantage for combining the two modalities over either one alone.

Published reports have used from five to 16 treatment sessions. We recommend planning at least ten to 12 sessions on a once- or twice-weekly basis. Some of our patients have required as many as 24 sessions.

Electrode Placement

Although the vast majority of published reports use the forehead or frontal electrode placement, there is some controversy about this point. This is perhaps because the Task Force Report of the Biofeedback Society of America, in their influential position paper on tension headache (8), strongly implied that frontal placement was the gold standard for biofeedback with tension headache sufferers, making no mention of other site placements. In the standard placement, the active electrodes are centered above each eye, approximately 2.5 cm above the eyebrow. A ground electrode is typically placed midway between them, as illustrated in Figure 90-2. With this very wide placement, muscle activity is detected not only in the forehead, but probably also from the rest of the face, scalp, and neck, down to the clavicle (9).

Figure 90-2. Frontal electromyographic electrode placement.

Some writers (10,11) have advocated attaching electrodes to other sites, such as the back of the neck or temporalis area, especially if the patient localizes his or her pain there. However, three of the four studies that compared biofeedback training from different sites between subjects found no advantage of one cite over the other (12,13 and 14). Arena and his colleagues (15) have published the only systematic comparison of a trapezius (neck and shoulder region) versus frontal EMG biofeedback training regimen with tension headache patients. They found clinically significant (50% or greater) decreases in overall headache activity in 50% of subjects in the frontal biofeedback group versus 100% in the trapezius biofeedback group. The trapezius biofeedback group was more effective in obtaining significant clinical improvement than the frontal biofeedback group. Thus, there is some limited support for the use of an upper trapezius electrode placement with tension headache patients. Figure 90-3 illustrates the upper trapezius electrode site placement.

Figure 90-3. Upper trapezius electromyographic electrode placement.

Outcome Results

A convenient way of reporting outcome is the average proportion or fraction of a sample of tension-type headache patients who achieve a clinically significant reduction in headache activity, as documented by the daily headache diary. For EMG biofeedback, this value ranges from 45% to 60% (16). When EMG biofeedback and relaxation are combined, the average improves to 70% to 75% (7).

Vascular Headache

There are two different forms of vascular headaches: migraine headache and cluster headache. More detail on these diagnoses and their treatment is provided in Chapter 48 and is not repeated here.

Biofeedback has not proved to be especially useful with cluster headache. In the largest case series, Blanchard and colleagues (17) reported that only two of 11 (18%) patients showed even modest improvements (some headaches less severe, some cluster bouts shortened, a few headaches aborted) over a 30-month follow-up after a 22-session regimen of relaxation training and thermal biofeedback.

Two related but somewhat different vascular headache populations have been the objects of an extensive research literature: those with only migraine headache, both with and without aura, and those who suffer from both migraine and tension-type headaches. The latter have been less studied.

Thermal Biofeedback

The initial systematic report on the thermal biofeedback treatment of migraine headache by Sargent and colleagues (18) described successful results when patients were taught to warm their hands with the assistance of biofeedback. Their treatment protocol, and many that have followed, included training in a meditative, self-instructional form of relaxation known as *autogenic training* (19).

Treatment sessions routinely follow the same temporal format described earlier for frontal EMG biofeedback. A temperature- sensitive probe, usually a thermistor, is attached to a fingertip (usually the ventral surface of the index finger of the nondominant hand) with care being exercised not to create a tourniquet or inhibit circulation to this phalange. The feedback signal can be auditory or visual. When patients are allowed to sample both, approximately 80% choose a visual display.

The patient should be in a relaxed position with care taken to keep the thermistor away from chair arm surfaces or other body surfaces. The room should be 72° to 75°F. It is very difficult for the patient to learn and emit the response in a cold room.

Patients are told that they must relax and *allow* their hands to become warm, rather than trying to force them to become warm. Effortful striving seems to hamper learning. Passive volition seems to work best. The autogenic phrases related to relaxation, heaviness, and warmth are taught at early sessions as one strategy.

The feedback portion of a session should be 15 to 20 minutes. From eight to 16 sessions have been described. We find a majority of patients begin to show good volitional control by about the seventh or eighth session. Some clinicians advocate training patients to a certain hand temperature criterion, 95°F or more. Patients are asked to practice regularly at home with electronic home trainers (cost of $50 and up) or simple alcohol-in-glass thermometers (approximately $1).

The mechanism by which thermal biofeedback benefits migraine headaches is unclear (20). It probably involves a diminution of peripheral sympathetic activity. Regular practice seems to have a prophylactic effect.

Outcome Results—Migraine

For patients with pure migraine headache, thermal biofeedback (with or without adjunctive autogenic training) leads to clinically significant improvement in 40% to 55% of cases (5,7,16). A systematic course of relaxation training seems to help. In one study, cognitive therapy added to the thermal biofeedback and relaxation did not improve outcome on a group basis (21).

Thermal biofeedback has been shown to be especially helpful with pediatric migraine headache (youth ages 8 to 17). In this population, success rates are usually in the 65% to 75% range. A quantitative review by Hermann and colleagues (22) showed thermal biofeedback to be on a par with the best prophylactic medication. Treatment sessions should be shorter overall with the younger population.

Outcome Results—Combined Migraine and Tension-Type Headache

For patients with both kinds of the primary benign headache disorders (migraine and tension-type), the results with thermal biofeedback alone (or with autogenic training) are a bit lower, averaging 30% to 45% success (5,16). Relaxation training alone leads to 20% to 25% success. The best outcomes have resulted from the combination of thermal biofeedback and relaxation training (again some form of progressive muscle relaxation) (7,16). Results show 50% to 55% success rates. Thus, we recommend a combination of the two treatments for these headache patients.

BIOFEEDBACK TRAINING FOR LOW BACK PAIN

LBP is a complex clinical pain syndrome that is frequently treated with a number of modalities (see Chapter 76). Estimates are that 13 million Americans are permanently disabled as a result of chronic LBP (23). Only EMG biofeedback has been used with this population, and the training procedures are similar to those described for tension headache. Figure 90-4 illustrates a bilateral paraspinal EMG biofeedback placement.

Figure 90-4. Paraspinal electromyographic electrode placement.

A number of theories concern the relationship between muscle tension and chronic LBP (24,25). These can be broken down into two major models:

1. The biomechanical theory, in which the EMG levels of the paraspinal muscles of the back are lower than normal, or there is a left-right asymmetry in the back, in which case the EMG activity on one side of the back musculature is abnormally lower or higher than the other side. This is presumed to be due to some mechanical or physical pathology, including tumor or infection, trauma, abnormal gait, or poor posture (2).
2. The stress-causality or psychosocial stressor theory, in which back pain is presumed to be due to increased paraspinal muscle activity caused by ineffective stress coping skills (25).

There is limited evidence to support either of these two theories (24,25 and 26). With LBP patients, biofeedback has been used as a general relaxation and stress reduction technique, as well as to specifically correct muscle tension abnormalities. Typically, paraspinal electrode placements have been used, but a number of

studies use forehead placements.

Although biofeedback is used extensively in comprehensive pain treatment programs (see Chapter 11), only a few studies have examined the efficacy of biofeedback alone in the treatment of back pain. We review here only those studies that have used biofeedback as the primary mode of treatment. For an in-depth, although somewhat dated, review of biofeedback for chronic LBP, see Sherman and Arena (27).

Previously, we detailed the methodologic limitations of many of the biofeedback studies in the treatment of LBP (27). These include small sample sizes; failure to describe the instrumentation and biofeedback procedures sufficiently to allow replication of the research; and the lack of clearly defined LBP diagnostic categories (many studies simply combine all subjects into a single diagnostic group), explicit inclusion and exclusion criteria (many studies combine both chronic and acute subjects), adequate control groups, pain diaries, and multiple outcome measures. The first section of Table 90-1 outlines the research conducted on LBP since the previous version of this chapter (28,29,30,31 and 32). Wherever possible, the overall percentage of improvement in the biofeedback condition is given; if this is not available, the percentage of subjects who achieved clinical improvement (arbitrarily defined by the authors as 50% or greater reduction in pain levels) is presented. As can be seen from this table, only three LBP biofeedback studies with a sample size of 15 or greater have been published since the prior version of this chapter.

TABLE 90-1. Biofeedback for chronic lower back pain (LBP)

Bush, Ditto, and Feuerstein (28) randomly assigned 66 LBP subjects to one of three groups: paraspinal biofeedback, psychological placebo, or wait list control. Regardless of treatment, all groups showed significant reductions in pain, anxiety, depression, and EMG following treatment and at 3-month follow-up. This well-designed study suffers primarily from a lack of clearly defined diagnostic groups—subjects simply had a“diagnosis of LBP without major physical findings” (pp. 309, 310)—and from reporting no usable outcome data, as numeric data such as pre- and post-treatment means on pain measures were not given.

Stukey, Jacobs, and Goldfarb (32) randomly assigned 24 chronic LBP subjects into one of three treatment conditions: EMG biofeedback (upper trapezius and paraspinal), relaxation training, or placebo. They found that relaxation therapy was superior to EMG biofeedback and placebo in decreasing mean reported pain intensity levels following a function test during which a physical therapist evaluated eight movements the patient performed. They also found relaxation, in comparison to the other groups, to decrease significantly upper trapezius levels, increase activities of daily living (as rated by a physical therapist), and increase subjective relaxation ratings. Unfortunately, this study suffered from some serious methodologic limitations. First, and most important, there are no clinically relevant measures of pain outcome, such as a pain diary recorded over some length of time. Instead, the pain outcome measure is a single snapshot in time. Second, chronic back pain sufferers with multiple diagnoses were combined, and there is no way for the reader to determine whether diagnoses were evenly distributed among the three groups. Finally, there were no measures of medication reduction, and eight subjects per group limits the generalizability of the study' s results.

Newton-John, Spence, and Schotte (30) assigned 44 chronic well-functioning LBP subjects to a cognitive-behavior therapy, EMG biofeedback to the erector spinae muscles, or wait list control group. At posttreatment, significant improvements in pain intensity, perceived level of disability, and adaptive beliefs about pain and levels of depression were found for both active treatment groups but not the wait list controls. The two treatment groups did not significantly differ from each other. Results were maintained or improved at 6-month follow-up. This, also, is a well-designed study that suffers only from a lack of clearly defined diagnostic groups—subjects simply had a diagnosis of“non-malignant lower back pain” (p. 692).

Several studies since the last edition of this chapter have examined the efficacy of EMG biofeedback in patients with multiple pain sites or have used heterogeneous populations (e.g., a mixture of patients with localized low back, upper back, neck, or shoulder pain). The second portion of Table 90-1 outlines these studies (33,34,35 and 36). Two of these studies are clearly superior to the others and deserve special mention.

Flor and Birbaumer (35) had 78 subjects who suffered from chronic musculoskeletal pain (57 low back and 21 temporomandibular joint dysfunction) randomly assigned into one of three groups: EMG biofeedback to the site of the pain (“back or jaw”), cognitive-behavior therapy, or conservative medical treatment. Results at posttreatment showed reductions in pain levels for all three groups, with only the reduction for the biofeedback group being statistically significant. At both 6- and 24-month follow-up, the EMG biofeedback group was significantly superior to both the cognitive-behavior therapy and conservative medical treatment groups on such measures as emotional distress and pain-related use of the health care system. On pain severity, it was superior to the cognitive-behavior therapy group at 6-month follow-up and superior at both 6- and 24-month follow-up to the conservative medical treatment group. Unfortunately, no separate results for LBP versus temporomandibular joint pain were provided, and even within the LBP subjects there was a mixture of various etiologies and diagnoses. This study is important, however, because it demonstrated that biofeedback was superior to“the best presently available medical interventions” (p. 655).

Spence and colleagues (36) randomly assigned 45 patients with chronic neck, shoulder, and upper extremity pain into one of four groups: EMG biofeedback to various muscle sites, relaxation therapy, combination therapy, or a wait list control. Immediately following treatment, subjects in the three active treatment groups showed significantly lower pain levels in comparison to the wait list controls. At 6-month follow-up, pain measures continued to decline and there were no differences between the three active treatment groups. This is a well-designed study that does not suffer from any significant methodologic limitation, other than separate results for the various diagnoses not being presented.

As we have previously concluded (4,27), biofeedback appears to hold promise as a clinically useful technique in the treatment of patients with back pain. Although we believe that optimal clinical improvement is clearly obtained when biofeedback is used within the context of a comprehensive, multidisciplinary pain management program [see Turk and Okifuji (37) for an excellent review of the advantages of such pain programs], the cumulative weight of the evidence, from studies outlined in both this and an earlier version of this chapter, suggest that EMG biofeedback is likely to be helpful, as a single therapy, in the treatment of musculoskeletal LBP.

However, many of the concerns that we have previously outlined (4,27) remain valid. First, only two studies have directly compared biofeedback to relaxation therapy, and both of these studies were significantly flawed so as to limit definitive conclusions. Direct comparisons of biofeedback to relaxation therapy are clearly needed. Second, although more studies are including follow-ups, longer (at least 1 year) and larger-scale (at least 50 per group) follow-up studies are required. Third, evaluations of treatments based on diagnosis (i.e., the cause of the pain) should be conducted. Fourth, comparisons of various biofeedback treatment procedures, such as paraspinal versus frontal electrode placement, or training while supine versus training while standing, are necessary. Finally, further evaluations of patient characteristics predictive of outcome, such as sex, race, chronicity, psychopathology, and psychophysiologic reactivity, are needed.

BIOFEEDBACK TREATMENT OF MYOFASCIAL PAIN DYSFUNCTION SYNDROME

MPD syndrome, also known as *temporomandibular joint syndrome*, is considered a subtype of craniomandibular dysfunction that is caused by hyperactivity of the masticatory muscles (see Chapter 49). It is characterized by diffuse pain in the muscles of mastication, mastication muscle tenderness, and joint sounds and limitations. Although disagreement exists as to the cause of the hyperactivity (e.g., occlusal problems vs. psychological stress), several researchers have examined the use of EMG biofeedback as a treatment, which can provide relief by teaching patients to relax the muscles of the jaw. Consistent with the logic of this approach, the most common electrode placement is on the masseter muscle (Fig. 90-5), although frontal muscle placements have also been used. Excellent overviews of the treatment of MPD syndrome are available (38,39).

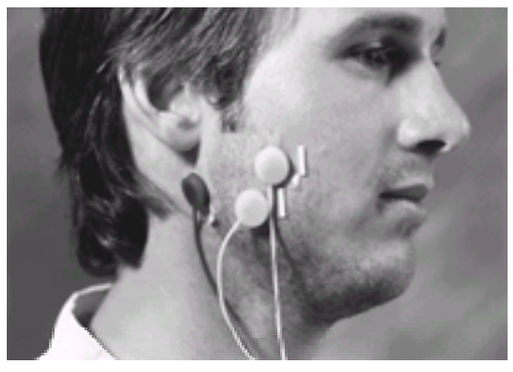

Figure 90-5. Masseter electromyographic electrode placement.

A summary of the literature on biofeedback therapy for MPD syndrome published since the last edition of this chapter is presented in Table 90-2 (40,41,42,43,44,45,46,47 and 48). Wherever possible, the percentage of improvement in the biofeedback conditions is given; if this is not available, the percentage of subjects who achieved clinical improvement (arbitrarily defined by the authors as 50% or greater reduction in pain levels) is presented.

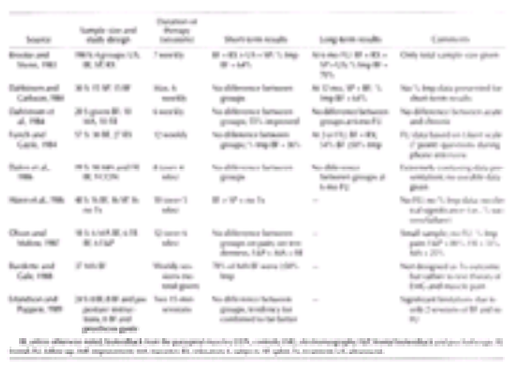

TABLE 90-2. Biofeedback for myofascial pain dysfunction syndrome

Two studies (40,41) compared biofeedback to a no-treatment control group. Using a combination of frontal and masseter biofeedback, Dalen and his colleagues (40) found no differences in pain between the control and biofeedback groups, both immediately after treatment and at 6-month follow-up, with both groups reported to improve significantly. This study, however, is significantly flawed, with no usable outcome data being presented, making it impossible to judge the actual percentages of improvement in both groups. In addition, no explanation was given as to why the no-treatment control group improved. The second study (41) found masseter biofeedback to be significantly better than no treatment, but, like the Dalen study (40), no usable outcome data were presented and, in addition, no follow-up was conducted.

Two studies (42,43) directly compared masseter biofeedback to relaxation therapy. Unfortunately, the relaxation procedure was not described at all in the Brooke and Stenn (42) study and only briefly described as a cognitive-type (i.e., focus on muscles and let them go) procedure in the other (43). Both studies at follow-up, however, found no difference between the two procedures.

Only two studies (44,45) have directly compared masseter and frontal biofeedback, finding no differences in outcome between the two placements. As in the headache literature (49,50 and 51), there was no relationship between ability to control one' s muscle tension and degree of improvement from biofeedback (40,41,46,47). Studies that have combined biofeedback with other treatments (45,48), although flawed, have found tendencies for the combined treatment to be superior to biofeedback alone. Studies that have compared biofeedback to more traditional medical procedures, such as occlusal splints, have found biofeedback to be equal or superior to the traditional medical intervention (41,42,44,48).

Finally, three glaring observations stand out regarding Table 90-2. First, although the majority of the studies have significant limitations, when taken as a whole they appear to be quite impressive in support of the efficacy of EMG biofeedback for MPD syndrome. Second, the four most recent studies all failed to provide any follow-up, but, when follow-up was presented, short-term results were sustained or improved. Finally, and most troubling, no MPD syndrome study of biofeedback as a treatment in and of itself has been published since 1989. Given these earlier positive results, this observation is somewhat perplexing.

The studies presented in Table 90-2, taken in conjunction with the studies detailed in the previous edition of this chapter, strongly suggest that EMG biofeedback is a clinically useful technique in the treatment of MPD syndrome. Biofeedback appears to produce improvement in a significant number of patients and is at least as effective as traditional dental treatments such as occlusal splint therapy.

Deficiencies in the research on biofeedback treatment for MPD syndrome are similar to those discussed in the section on LBP. Large-scale outcome studies, comparing (a) masseter versus frontal versus temporalis placement sites, (b) biofeedback versus relaxation, (c) biofeedback versus traditional dental strategies, and (d) biofeedback in conjunction with other treatments versus traditional dental strategies. The latter approach has been used by Turk and his colleagues (52,53 and 54) in a number of methodologically elegant studies. In these studies, not included in Table 90-2 due to the lack of a biofeedback-only condition, various combinations of biofeedback, stress management training, and intraoral appliances are used, with results showing strong support for combined treatments. Finally, lack of long-term follow-ups, or for that matter, any follow-up at all, is a serious limitation that needs to be corrected. Four of the nine studies reviewed had no follow-up, and three of the five that did contain follow-up were for only 6 months.

BIOFEEDBACK TREATMENT OF OTHER CHRONIC PAIN DISORDERS

Biofeedback has been used with numerous other chronic pain syndromes—so many, in fact, that we cannot hope to review all of them here. Rather, we summarize what we feel are the most interesting areas for clinicians and researchers, including most areas for which a substantial literature exists, as well as some areas for which, although promising, there is a paucity of treatment studies.

The thermal biofeedback treatment of Raynaud' s disease has a well-documented efficacy, with most studies showing a reduction in vasospastic attacks of 80% or more [see (55) for an excellent review of this literature]. Similarly, the work from Blanchard' s laboratory on irritable bowel syndrome [see (56) for a review] has repeatedly demonstrated the effectiveness of a treatment package that includes thermal biofeedback.

Along a similar vein, the biofeedback literature on treatment of constipation pain, especially in children, is both impressive and growing. Here, three studies particularly stand out. Benninga and colleagues (57) gave 29 children who suffered from constipation and encopresis an average of five sessions of EMG biofeedback of the external anal sphincter. At 6 weeks, 55% were symptom-free. Another group of investigators (58) placed 13 children who suffered from constipation into a standard medical care group, while another group of 13 children were placed in an EMG biofeedback (of the external anal sphincter—one to six sessions) plus standard medical care group. At 16-month follow-up, all children were significantly improved, with the biofeedback plus standard medical care group significantly more improved than the standard medical care only group.

One large-scale study, however, does not support the efficacy of EMG biofeedback for constipation pain. In a procedure similar to Cox et al. (58), Van der Plas and colleagues (59) placed 94 children who suffered from constipation into a standard medical care group, while another group of 98 children were placed in a

five-session EMG biofeedback (of the external anal sphincter) plus standard medical care group. At 18-month follow-up, over one-half the children in both groups were significantly improved, with no significant difference between the two groups. In spite of this large-scale study suggesting no advantage to the inclusion of EMG biofeedback to conventional medical care, we believe there is sufficient evidence to conclude that EMG biofeedback is a useful technique in treating the pain of both adult and childhood constipation, especially when the patient has proven refractory to standard medical care.

In addition to constipation pain, a growing body of evidence now exists in the colorectal literature for the efficacy of biofeedback for pain, especially for intractable rectal pain (60,61,62,63 and 64), with one study showing a 75% decrease in pain levels and 88% of patients no longer requiring pain medications (64). One interesting study (60) demonstrated that the use of EMG biofeedback reduces additional surgery for solitary rectal ulcer by 73%.

An extremely interesting and well-designed initial study using EMG biofeedback for the treatment of vulvar vestibulitis was conducted by Glazer and his colleagues (65). Vulvar vestibulitis causes extreme pain in the vulva and pain during sexual intercourse. In this study, 33 women with vulvar vestibulitis were given a portable EMG biofeedback unit and instructions on how to conduct daily, at-home biofeedback-assisted pelvic floor muscle rehabilitation exercises. After an average of 16 weeks of training, pain decreased in an average of 83% and 79% of patients resumed intercourse. It appears that large-scale, controlled EMG biofeedback studies would now be appropriate in the treatment of this painful gynecologic condition.

Fibromyalgia is a type of nonarticular, noninflammatory rheumatism that is characterized by diffuse pain, sleep disturbance, tenderness, and functional impairment. A number of studies have examined the efficacy of EMG biofeedback in the treatment of fibromyalgia (66,67,68,69 and 70), all concluding that EMG biofeedback is useful in reducing fibromyalgic pain (see Chapter 30). Given the relatively promising results, it appears that, here too, large-scale, controlled EMG biofeedback studies would now be appropriate.

Finally, thermal biofeedback has been shown to have some usefulness in reducing the pain of reflex sympathetic dystrophy (see Chapter 20) (71,72). For example, Grunert and his colleagues (71) found that a combination of thermal biofeedback, relaxation therapy, and supportive psychotherapy significantly reduced reflex sympathetic dystrophy pain by 48%. These results were maintained at 1-year follow-up, with 14 of 20 patients returning to work. For any clinician working with such extremely refractory pain patients, these results are indeed persuasive. Once again, it appears that large-scale, controlled studies need to be conducted.

CONCLUSIONS

Biofeedback has been demonstrated to be a useful clinical tool in the treatment of a variety of chronic pain states. Headache and LBP have been the best studied, probably because of their prevalence. Further research should be undertaken to identify patient factors that predict the successful use of this treatment strategy. Applications to other types of chronic pain should also be tested in a rigorous fashion. The technology required to use biofeedback is of low cost; there are few, if any, complications of this treatment; and it is applicable to patients with many diagnoses. Biofeedback deserves a more generalized usage in the treatment of chronic pain.

CHAPTER 91

Hypnosis

Joseph Barber

It is both dramatic and compelling to observe the tranquil face of a patient undergoing a painful medical procedure with no anesthetic except the patient's ability to dissociate from pain. It is equally poignant to observe a patient's relief from the pain of an injury or disease—relief created not by analgesic medications, but by the psychological capacity to dissociate from pain and suffering. One wonders how this can be possible. There has been so much nonsense written about hypnosis and so many unwarranted claims that it may be difficult for the reader to have a receptive mind. In this chapter, I include information gained from rigorous laboratory and clinical research and I have not included claims or allegations that are not supported by such evidence.

Hypnosis is a condition characterized by a markedly increased receptivity to suggestion, resulting in the possibility for dramatic modification of perception and memory. Price and Barrell (1) have identified five elements common to the hypnotic experience:

- Feeling of well-being
- Absorbed and sustained focus of attention
- Absence of judging, monitoring, and censoring
- Lack of orientation toward time, location, and sense of self
- Experience of one's own responses as automatic

Note that nothing in this description suggests that a patient has been rendered powerless by the hypnotic condition. The integrity of personality and character remains unchanged. An individual who is ordinarily vulnerable to the influence of others will continue to be vulnerable in the hypnotic circumstance. Similarly, an individual who is not ordinarily vulnerable to influence will continue to be invulnerable while hypnotized. For this reason, the effective clinician remains mindful of the need to support and encourage a hypnotized patient, to engage the patient's motivation for relief. Although apparently miracle cures occur often enough to maintain the superstitious illusion of hypnotic power, it is not likely that a clinician can successfully suggest to a hypnotized patient that his or her symptoms will suddenly vanish. Rather, hypnotic suggestions can be used as psychological leverage to enhance the effectiveness of a clinical intervention. In the therapeutic examples offered later in the chapter, the reader will notice that the clinician's acknowledgment of the patient's complexity—for instance, his or her pessimism, skepticism or unrealistic expectation, and, especially, of the pain's meaning to the patient—is reflected in the subtlety and complexity of the suggestions.

With the advent of contemporary anesthetics, of course, hypnotic analgesia is seldom needed in the operating room. However, the patient with chronic or recurrent acute pain who has not responded to curative or palliative intervention may benefit from the appropriate application of hypnotic techniques for pain management.

The first objective when introducing the domain of hypnosis is to acknowledge the healthy skepticism of the reader. Laboratory and clinical research has highlighted the value of hypnotic procedures as both primary and adjunctive clinical interventions. This chapter focuses on how these interventions, as well as interventions involving nonhypnotic suggestion, can be used in the clinical management of acute or chronic pain, and is organized in three parts: (a) basic considerations, including a brief historical overview of hypnosis and suggestion and current theoretical explanations of the action of this intervention; (b)technical considerations, with brief discussion of patient selection issues and of the most common hypnotic techniques used; and (c) clinical applications, including a brief summary of results obtained in various acute and recurrent pain conditions.

For more detailed accounts of how to apply hypnotic techniques and of the relevant supporting research, the reader may refer to Barber (2), Barber and Adrian (3), Fromm and Nash (4), Hilgard and Hilgard (5), Hilgard and LeBaron (6), Lynn and Rhue (7), and Price (8).

BASIC CONSIDERATIONS

History

Hypnosis is a troublesome word, because popular accounts nearly always convey wrong-headed ideas, many of which involve claims of powerful influence and magical effect. A persistent image associated with hypnosis is that of a man with a penetrating gaze mysteriously compelling someone (usually an attractive young woman) to behave in dramatically uncharacteristic ways. This impression has its roots in the early history of hypnosis, which, unfortunately, was often an amalgam of mysticism, magic, and hokum. Although the eighteenth-century physician Franz Anton Mesmer (1734–1815) initiated the development of what has become the domain of clinical hypnosis, his theory of action was a mistaken one (that it involved the transfer of magnetic fluid from the clinician to the patient), and his fascination with the drama of the process was a distraction from its psychological essence.

The Societé Royale in Paris created the Franklin Commission, a panel of eminent scientists chaired by Benjamin Franklin, to investigate experimentally Mesmer's claims of magnetism. The investigative work of the commission was historic for two reasons: It was perhaps the first instance of formal psychological experimentation, and the experimental results ultimately led to the concepts of hypnosis and suggestion.

The subsequent development of the theory and practice of hypnosis in the nineteenth century was primarily focused on its medical application, most notably pain relief, but in 1843, the English physician James Braid documented the importance of the psychological responsiveness of the patient (in contrast to the power of the hypnotist, a myth that exists even today). He observed how a suggested idea could dramatically alter the patient's experience. Braid coined the term *hypnotism*. This was an unfortunate choice, since it connotes a condition of sleep, although the hypnotic experience is not associated with sleep; rather, it is a state of deep absorption in a suggested experience.

In 1850, James Esdaile (9), an English surgeon working in India, successfully used hypnotic methods to induce anesthesia for a series of major surgical cases. This practical development was met with disbelief but also hope, since it meant the end to the routine agony (and associated morbidity) of surgery. Since Esdaile's report, there have been numerous accounts of surgery performed with hypnotic suggestion as the only anesthetic. Almost simultaneous with these initial reports of hypnoanesthesia, however, was the announcement of the successful use of chloroform in the operating room, which led to a waning of interest in the use of hypnoanesthesia.

Toward the end of the nineteenth century, and into the early years of the twentieth century, the focus of clinicians interested in hypnotic phenomena was its

psychiatric application in the treatment of hysteria and dissociation. Except for reports of the use of hypnotic methods in battlefield hospitals, there were no significant developments in the use of hypnotic methods for the relief of pain until the late 1950s, with the work of Ernest and Josephine Hilgard.

After securing his reputation as a premier scholar of human learning Ernest Hilgard established the Hypnosis Laboratory at Stanford University in 1957. For the next 3 decades, that laboratory was a fountainhead of hypnosis research, including especially the investigation of hypnotic analgesia (5,6,10,11,12,13,14,15,16 and 17). At the same time, Martin Orne (18,19), directing the Unit for Experimental Psychiatry at the University of Pennsylvania, also began to conduct hypnosis research, including the investigation of hypnotic analgesia. These pioneering efforts were the basis for subsequent research that has led to the richness of theory and research informing our contemporary understanding of hypnotic analgesia.

Theoretical Bases: Anatomy, Physiology, and Psychology

Because hypnosis is often mistakenly thought of as a magical or occult phenomenon, it is worth remembering that hypnotic phenomena are, in fact, psychological in nature and fundamentally explicable by psychological theory and principles. As Kihlstrom (20) reminds us, “Nothing about hypnosis changes the way the mind works.” How, then, are we to understand phenomena that cut across the spectrum of experience, including amnesia, analgesia, and hallucination? Although there remains the challenge of explaining hypnotic phenomena within a single, integrated psychological theory, over the past 20 years, two primary explanatory schema have risen to prominence: Ernest Hilgard's neodissociation theory, with variations suggested by Bowers (21,22 and 23), Kihlstrom (20,24), and Woody (25,26), and variants of a sociocognitive theory that is primarily the work of Theodore Barber (27), Coe and Sarbin (28), Spanos (29), Kirsch (30,31), and Lynn (7).

Neodissociation Theory

Dissociation theory dates from the late nineteenth century and offers an account of various psychopathologies, most notably hysterical disorders, and provides the essential concept of “a division between two streams of consciousness . . . with only one of these streams accessible” to conscious awareness (20, p. 187). Hypnotic suggestion is effective in both the alteration of symptoms (e.g., sensory alterations, such as blindness, deafness, and anesthesias, as well as motor symptoms, such as paralysis and mutism) of hysterical patients as well as in the creation of similar symptoms among normal human subjects. Consequently, there seems to be a logical connection between dissociative processes and hypnotic processes. Building on the dissociation theory proposed by psychiatrist Pierre Janet (32) nearly a century earlier, Ernest Hilgard offered a neodissociation interpretation of hypnotic analgesia (14). The neodissociation perspective reflects the recognition that some behaviors are not consciously intended, initiated, or controlled. “Dissociated control” (21,33) in everyday life is particularly well revealed in various mental lapses but is the basis for hypnotic responsiveness as well: “Such dissociated control of thought and behavior depends on a hierarchical model of mind, which assumes . . . that different cognitive control systems can operate in relative independence of each other” (22, p. 135).

The neodissociation model proposes that the hypnotic process creates a temporary functional separation between certain cognitive control structures, resulting in the corollary separation of awareness. For example, Hilgard suggests that a hypnotized patient comfortably undergoing a painful procedure is able to do so because of the separation—the dissociation—between the cognitive structure(s) responsible for the appreciation of pain and the central control structure(s) responsible for the individual's conscious awareness. Because a central feature of all hypnotic phenomena is the felt sense of automaticity—that the thought or behavior occurs without effort or, perhaps, even of intention—Hilgard's explanation applies to all hypnotic phenomena, not only hypnotic analgesia. Moreover, his explanation also accounts for nonhypnotic dissociative processes. Recent brain imaging research (34) has yielded evidence for the alteration in brain activity that correlates with hypnotic analgesia and has been interpreted as evidence for the neodissociation model (8).

Sociocognitive Theories

It is well known that social psychological variables affect individual psychological variables in a variety of circumstances. Orne's classic research (35,36) demonstrated that hypnotic experience is not immune from the effects of social variables such as attention of the clinician, the environment, and past experiences. This recognition of the relevance of social psychology to the understanding of hypnotic processes has led some to propose that social variables are *primarily* relevant to this understanding (29). Spanos writes, “Thus, from my perspective, successful hypnotic responding to suggestions . . . reflects goal-directed actions by subjects who, in coordinated fashion, generate experiences and enact behaviors in order to meet what they tacitly understand to be the requirements of the test situation” (p. 325).

Variations of contemporary sociocognitive theory of hypnotic processes have been described by Spanos (29), Kirsch (30), and Kirsch and Lynn (31). Both the neodissociation theory of divided consciousness and sociocognitive theories focus on mechanisms that create alterations in awareness, but whereas neodissociation theories emphasize a temporary splitting (dissociating) of consciousness, sociocognitive theorists emphasize ordinary conscious processes; these do not include perceptions and cognitions that are out of ordinary awareness. Kirsch (30), for instance, theorizes that it is an individual's belief and expectation that determines the hypnotic experience: “Typical hypnotic responses can easily be altered by providing subjects with expectancy-altering information” (p. 451).

The sociocognitive view suggests, for example, that an individual's expectation of analgesia may be self-confirming, so that it is the anticipation itself that reduces the pain.

No one theory has fully accounted for the range of hypnotic phenomena, and all contemporary theories are necessarily tentative. It is likely that any successful theory that emerges will take into account social processes as well as an individual's psychological processes. Both the sociocognitive and neodissociation models each contribute to our understanding of hypnotic processes. However, the neodissociation perspective is supported by a substantial accumulation of data from both basic and clinical research (6,12,13,15,19,21,22,23,24,25,26,27,28,29,30,31,32,33,34,35,36,37,38,39,40,41,42,43,44 and 45). It is particularly clear from this research that hypnotic experience is commonly experienced as automatic and involuntary—and that lack of awareness of certain thoughts or behaviors is central to the experience—a finding that contradicts a central tenet of sociocognitive theory, which is that hypnotized individuals are experiencing no more than what they expect and intend to experience. The neodissociation perspective appears to offer the most parsimonious psychological explanation of hypnotic analgesia and has sufficient empirical support to warrant both our tentative confidence and further exploration (8,25,26,46,47).

Psychophysical and Neurophysiologic Investigations

Psychophysical and neurophysiologic evidence also supports the neodissociation perspective. In reviewing this evidence, Price (8,48) has identified three components that underlie the processes suggested by Hilgard: (a) selective reduction of the affective dimension of pain, (b) reductions in sensory pain by mechanisms that divert pain from conscious awareness once nociceptive information has reached higher centers, and (c) inhibition of pain signals at the spinal level.

Kiernan et al. (40) demonstrated the dissociative quality of hypnotic analgesia and were the first to suggest the role of inhibitory spinal mechanisms in hypnotic analgesia, identifying specific spinal afferent activity associated with hypnotic analgesia. Rainville et al. (43) investigated cerebral blood flow changes that varied with onset and offset of hypnotic analgesia, and reported that their “results provide a new description of the neurobiological basis of hypnosis by demonstrating a specific pattern of cerebral activation underlying the multiple cognitive processes involved in this intervention.” Rainville et al. (34) have extended these findings, offering further evidence for the neurophysiologic correlates of hypnotic analgesia. This evidence constitutes yet more support for the neodissociation model.

Evidence for endorphin involvement in analgesia, including acupuncture analgesia (49), led to the hypothesis of a similar role in hypnotic analgesia. Several investigations, however, have not supported this hypothesis (49,50,51 and 52). In fact, no evidence has been developed to associate particular neurotransmitters with hypnotic analgesia. Sternbach (53), for example, did not find evidence to support his hypothesis for the involvement of acetylcholines in hypnotic analgesia.

TECHNICAL CONSIDERATIONS

Hypnotic Responsiveness

Scientific observation of hypnotic phenomena over the past 200 years has differed on several counts, but one observation most investigators agree on is that—as with all psychological variables—there are individual differences in response. It is well known that, as with any treatment, patients differ in the degree to which they respond to hypnotic treatment (5,6). “Who can be hypnotized?” is a commonly asked question. The question particularly relevant to the clinician considering its use with a patient is, “Under what conditions can hypnotic methods be used to reduce a particular patient's suffering?”

Research has explored this question and determined that variables such as age, intelligence, and personality do not predict hypnotic responsiveness (5). The only

personality trait that has been shown to significantly correlate with responsiveness is imaginative absorption—an individual's capacity to have a temporary experience of believing in imaginary perceptions (54).

Experimental investigations intended to identify predictors of hypnotic responsiveness (also referred to variably as *hypnotic susceptibility* and *hypnotizability*) have yielded differing results. In the typical study, hypnotic responsiveness is measured by reference to an individual's performance on a standardized test. Such a test creates the opportunity to respond to a hypnotic induction and to several suggestions for classic hypnotic behaviors (e.g., analgesia, amnesia, and hallucination). The number of behaviors the individual demonstrates then becomes the numeric measure of hypnotic responsiveness. Hilgard and Morgan (15), for example, demonstrated that the correlation between such measures and an individual's ability to hypnotically reduce experimental pain is significant ($r = 0.50$); this accounts for only 25% of the variance. However, they also reported that 44% of individuals whose responsiveness scores were low were able to reduce their pain by 10% or more.

> This means that the relation between reduction and hypnotic responsiveness is probabilistic, with a greater probability of successful pain reduction for those highly responsive to hypnotic suggestions. The data do not mean that those unresponsive to hypnotic suggestion as measured by the scales, have no possibility of help through suggestion. (5, p. 68)

A preponderance of laboratory evidence clearly supports the idea that hypnotic responsiveness is a relatively stable trait and that only a minority of individuals can achieve clinically significant hypnotic analgesia (5,6,10,11,13). However, the issue is not as clear as this may suggest, for there is also evidence that there may be other variables that determine clinical effectiveness of hypnotic treatment (55,56,57,58,59,60,61 and 62). We can infer from these investigations that variables inherent in the clinical context (including the clinician-patient relationship and the patient's felt need for relief) may engender responsiveness to hypnotic treatment in individuals whose responsiveness scores are measurably low. The laboratory research of Gfeller et al. (61) in particular confirmed the clinical lore that the clinical relationship is a primary determinant of responsiveness.

Gfeller and his colleagues (61) compared a low-interpersonal-training treatment with a treatment designed to augment rapport with the trainer and diminish resistance to responding. Following the intervention, 50% of previously unresponsive subjects tested as being highly responsive to hypnotic suggestion. Practice-alone control subjects' performance was stable across testing. The importance of rapport was demonstrated by rapport ratings paralleling group differences in hypnotic responding.

One explanation for the disparity in research findings, at least with respect to the analgesic capacity of those individuals with low responsiveness to hypnotic suggestion, might be that those with high responsiveness are better able to reduce the sensory-discriminative component of pain, whereas those with low responsiveness are sufficiently able to reduce the motivational-affective component (62). For example, it may be that low responders are not capable of dissociating from the sensory-discriminative component but are able to reinterpret the experience, thereby reducing the motivational-affective component. If these two components are not independently measured, it is entirely possible that some patients' measures reflect the sensory component, whereas others' reflect the affective component. This distinction may be particularly salient between the hypnosis laboratory (where pain measures tend to emphasize the sensory component by asking how intense the sensation is) and the clinic (where pain measures tend to emphasize the affective component, since it is suffering that brings the patient to the clinic).

It is also worth considering that reporting bias may well play a role in the discrepancy between findings in the laboratory and the clinic (see Chapter 24). In general, the clinical literature reports hypnotic suggestion to be more effective as an analgesic than one would predict from the experimental reports. Part of the explanation for this discrepancy may be found in the difference in motivation between laboratory subjects and clinical patients. Experimental subjects are significantly less motivated to experience a hypnotic effect than are patients who are seeking relief from suffering. There are also significant differences in the behavior (and motivation) of experimenters and clinicians. Experimental protocols usually require rigid adherence to a well-operationalized, standardized induction and set of suggestions. Rarely is the purpose of an experiment the search for optimum hypnotic effect. However, that is precisely what is involved in the clinical situation. Effective clinical use of hypnotic suggestion requires an individualized approach. Rarely is a standardized set of procedures followed, and the clinician, normally focused only on doing what is effective, may vary or repeat procedures until success is obtained. Although this may lead to successful clinical outcomes, it is usually impossible to assess the causal link between treatment and results (see Chapter 81).

Moreover, as Diamond (60) suggests, the relationship between the clinician and patient is a powerful determiner of the hypnotic effect (or any clinical effect). The relationship between an experimenter and subject is significantly less personal (sometimes the hypnotic induction is even conveyed by a tape recorder) than the well-developed, intimate, and more potent relationship of a concerned clinician and a patient in pain. Whatever the explanation for the disparity of reported hypnotic effect between experimental and clinical contexts, it is clear that clinical success with hypnotic suggestion requires innovative, personalized, clinically sophisticated procedures. It is difficult to compare such procedures with well-controlled experimental procedures. So, for the moment, the complex question of hypnotic responsiveness remains an open one.

Advantages and Disadvantages

The therapeutic goals in the treatment of acute or recurrent pain are the reduction of suffering and return to good function. Hypnotic methods may be suitable to both goals. The primary advantage of hypnotic intervention is that, in a given case, it may be effective when no other treatments have been. It is less invasive than medical pain management interventions, and it does not produce side effects, such as somnolence or motor retardation, as opioid medications may. Moreover, because suggestions can include those that encourage a healthy outlook and expectation for recovery, the clinician may expect that, in addition to analgesic effects, successful hypnotic intervention will also facilitate the patient's development of an optimistic and salutary outlook.

Unlike other pain management interventions that are done to the patient, hypnotic methods require the active psychological engagement with and involvement of the patient. So, in the case of a patient who may be ambivalent about achieving symptom reduction (as in the case of a patient for whom there are financial disincentives for rehabilitation), this ambivalence may result in only intermittent or temporary response or in a lack of treatment responsiveness altogether. Adequate evaluation before treatment will identify such ambivalence, and treatment plans can be guided by this information.

A distinct advantage of hypnotic methods of pain management is the potential for long-term effectiveness. In this connection, the importance of using posthypnotic suggestions is discussed later, under Extending Relief.

CLINICAL APPLICATIONS

Indications and Contraindications

A patient who suffers acute, recurrent, or chronic pain may be a likely candidate for hypnotic treatment if the following contraindications are not present:

- Disincentive for relief (e.g., financial or social reward for continued suffering)
- Intellectual impairment (characterized by an inability to attend and to learn)
- Psychological impairment (characterized by blurring of psychological boundaries, poor reality orientation, severe depression)

Because hypnotic treatment can cause radical alterations in cognitions and behavior—with a concomitant experience of nonvolitionality—concern is sometimes expressed that hypnotic techniques can be harmful. Much effort has been made to settle the question of whether hypnosis can cause an individual to behave in ways that would be harmful. Even though there has been no reliable documentation of an instance of harm coming to an individual as a result of clinical hypnotic intervention, this concern is often raised because of the occasionally harmful consequences of the antics performed by subjects of nightclub hypnotists. Whereas the behavior demonstrated in such acts can be explained without reference to hypnosis (e.g., group pressure and compliance with demand characteristics), there is still reason to believe that the psychological changes that can be produced by hypnotic intervention are sufficiently powerful to warrant its use only by trained clinicians. Hypnotic treatments, like any other clinical tool, can be misapplied, resulting in harm. This is a good reason to carefully train clinicians; it is not, however, a good reason to avoid the use of effective clinical tools.

Hypnotic methods can be harmful when

- The clinician does not have an adequate understanding of the patient's psychological needs and capacities. However, adequate training can prepare the clinician to respond appropriately to the patient.
- The patient's capacity for coping with deep absorption in fantasy, or with intense emotional contact with the clinician, is insufficient. However, the clinician can be prepared for this by adequate evaluation before treatment, through the use of both standard clinical interview and formal assessment instruments, such as

the Minnesota Multiphasic Personality Inventory-2, the Symptom Check List 90, and perhaps one of the depression inventories (e.g., the Beck Depression inventory), which can inform the clinician about the patient's psychological health. The Tellegen Absorption Scale allows the clinician to infer how readily the patient may respond to hypnotic intervention, since this requires imaginative absorption.

The experience of being hypnotized is generally innocuous and often pleasant. Yet, hypnotic treatment should only be undertaken by someone with sufficient clinical skills, including knowledge of psychological phenomena and psychopathology. Because hypnotic techniques can be applied across several areas of clinical expertise, it might be a temptation for a clinician trained in one area to use hypnotherapy to treat a patient whose problem would otherwise lie outside the clinician's training. For example, a psychologist may be well trained to treat a patient's pain, if the patient has already had an adequate medical evaluation and the psychologist is mindful of the medical aspects of the patient's condition. It would not be appropriate for the psychologist to treat a patient's pain without proper medical collaboration. Similarly, a gynecologist may be properly trained to hypnotically treat a patient's pelvic pain, but it would be inappropriate to treat the patient's psychosexual dysfunction with hypnotherapy. If the patient's pelvic pain is associated with psychological factors, it is best for the gynecologist to refer the case to someone with appropriate psychological training. One should only treat a problem one is trained to treat. If one is also trained in the use of hypnotic methods for such a problem, those methods will probably enhance the treatment. Training in hypnotic methods, alone, however, is not an alternative for adequate clinical training in general.

Techniques

Since hypnotic treatment requires the patient's cooperation and responsiveness, it is helpful for the clinician to observe how the patient responds. For example, ordinary suggestions made to a patient about sitting comfortably provide an important opportunity to observe how the patient responds. For example, how literal or confluent is the response? How at ease is the patient? This is not a hypnotic response, but it may offer a clue to subsequent responses. Moreover, this reminds us that suggestions alone—in the absence of a hypnotic experience—can substantially augment clinical effectiveness, through promoting patient comfort and confidence, and by promoting healthy expectations.

The manner in which the clinician introduces the topic of hypnotic treatment to the patient may either augment or diminish the patient's subsequent responses. The word *hypnosis* tends to have such unhelpful connotations for most people, and it probably does not convey an accurate idea of the treatment intended by the clinician. So it may be most helpful to discuss the treatment without reference to the word *hypnosis.* Rather, the treatment can be described in more operational terms, thus obviating the use of the word altogether. The intention is not to obfuscate or deceive, but, rather, to communicate clearly. Of course, if the patient uses the word *hypnosis*, the best response probably requires use of the word, as well. If a patient has had prior experience with hypnotic treatment—especially if the experience was satisfying—this experience can be used.

Following are some examples of what might be said to introduce the topic of hypnotic treatment, using operational terms:

- “You probably know that the relationship between mind and body is a powerful one. Would you like me to show you how to use the power of your imagination to help you feel better?”
- “Let's use your ability to fantasize, now, to help you feel better.”
- “Mental imagery can be very helpful in retraining your nervous system so that the nerves that carry the useless information about your pain will do so less and less in the future.”
- “Your ability to become deeply absorbed by your imagination can be really helpful to you now. Will you close your eyes right now, and take a very deep, very relaxing breath, so you can begin to notice how really relaxed your mind can become?”

Each example is intended to convey to the patient that he or she possesses the means to increase comfort. The clinician who uses such “nonhypnotic” language to introduce hypnotic treatment should remember subsequently to use language that is consistent with this introduction.

The three fundamental elements of hypnotic treatment are induction, therapeutic suggestions, and suggestions to end the hypnotic experience.

Induction

Hypnotic induction is the facilitation of the patient's alteration in consciousness from ordinary wakefulness to a state of imaginative absorption that supports the acceptance of clinical suggestions. The goal of the induction is to engage the patient's capacity to dissociate. Although there are a few classic induction techniques, in truth, the clinician is free to create whatever induction will most readily facilitate the patient's experience of trust, security, and interest in what the clinician is saying. Instruction in the technique of induction is well beyond the scope of this chapter. However, the literature is replete with such instruction (2,3,5,6,5364,65,66,67,68,69 and 70). In the context of this chapter, however, we can explore the ideas that make up an effective hypnotic induction.

Because hypnotic treatment requires the active involvement of the patient's imagination, the first goal of the clinician about to embark on hypnotic induction is that of engaging the patient's interested attention. It may be that the clinical context itself—and the patient's wish to be relieved of suffering—will be sufficiently interesting.

The second goal is to help the patient to focus his or her attention—to reduce the range of attention—and then to direct that attention inward, at which point the patient's imagination can begin to emerge as the agent of the ensuing hypnotic process. (At this point, suggesting that the patient close his or her eyes has the virtue of both eliciting a cooperative, voluntary response from the patient as well as eliminating visual sources of distraction—and offering another opportunity to observe how the patient responds to a suggestion.)

The final goal of the induction process is that of dissociation. Dissociation distinguishes the hypnotic experience from the nonhypnotic. Many adults and most children are able to develop a hypnotic experience with little or no facilitation by the clinician (6,70,71 and 72). In such cases, the clinician can function best by acting as a guide.

The following is an example of a hypnotic induction. It has been abbreviated for purposes of highlighting the essential suggestions (which, in practice, may often be repeated for emphasis).

1. Engaging the patient's interest and attention: “Are you ready to begin learning how to use your imagination to see if you can feel better?”
2. Focusing attention and turning it inward: “Close your eyes and take a very deep, very comfortable breath and, now, hold it . . . hold it. . . . That's fine. Now, let it all the way out, and just notice how easily can feel yourself sink down into a place of very deep quiet and relaxation.”
3. Dissociation: “As you become more and more aware that each breath contributes to a greater sense of comfort and ease, you might have already noticed that the sounds around you . . . all the sounds you can hear . . . are sounds that can become more and more a part of your experience of comfort and relaxation . . . with nothing to bother you, and nothing to disturb you.”

Therapeutic Suggestions

Once the patient is experiencing dissociation, suggestions can be offered to reach the therapeutic goal. Posthypnotic suggestions are discussed later in the chapter, but it is at this stage of treatment that they may be communicated. It is helpful to the clinician to know if the patient is responding to suggestions. Since the analgesic response takes place only in the patient's imagination and is essentially invisible to the clinician, suggestions for other, overt behaviors may be helpful, simply to assess the patient's responsiveness. Examples of therapeutic suggestions are given later in the chapter.

Suggestions to End the Hypnotic Experience

Once therapeutic suggestions, including posthypnotic ones, have been given, the hypnotic experience can be brought to an end. (In the case of immobile patients, e.g., patients in a burn ward, this may not be necessary.) Normally, the clinician suggests that the patient will, after the experience, feel alert, rested, curious about the outcome, and so on. For example, “So now, I'd like you to take one or two very deep, very refreshing, very energizing breaths. As you open your eyes, notice how easy it is for you to so quickly feel alert and refreshed. Almost like waking from a very refreshing nap.”

Strategies for Creating Hypnotic Analgesia

Just as there is an almost limitless range for creating a hypnotic induction, so, too, the patient's capacity for developing hypnotic analgesia may be accessed by a variety of suggestive strategies. When developing the treatment plan and considering which strategy to use, the clinician should be clear about the goal. In an acute context, for example, the goal may be simply to facilitate the patient's comfort during the acute period. In the context of treating recurrent pain, however, the clinician might keep in mind that the goal is to facilitate a reduction of suffering on the part of the patient with a concomitant return to good function (except, of course, in the case of patients with terminal illness). So, although the clinician may elect to follow one of the classic strategies described that follow, optimal effectiveness may depend on creativeness guided by the clinician's understanding of the patient's individual needs (e.g., autonomy or dependence, firmness or gentleness, clarity or ambiguity). For instance, does the patient feel more at ease if the clinician relates as an equal partner in the treatment or as an authority? Does the patient respond more readily if the intervention is approached as skills training or as an experience of altered consciousness? To what extent is the patient ambivalent about experiencing a reduction in pain? What consequences might the clinician expect if the patient feels less pain and suffering? Should the reduction in pain be suggested to be immediate or to occur at a later time? These are a few of the many questions the clinician will consider during the ongoing observation and growing understanding of the patient.

Acute Pain

For the immobile patient—one undergoing a painful procedure, is status postoperative, or is incapacitated by disease or injury—activity and full orientation to the environment are not important. Suggestions for dissociation from severe pain (and, too, from the unpleasantness of the circumstance), and can yield substantial levels of comfort (73,74). Since the clinical purpose here is to reduce the patient's suffering, the nature of the pain is irrelevant. What is crucial is the patient's understanding and expectation about pain. In other words, the meaning of the pain is what distinguishes the intervention from one patient to the next. Patients suffering from postoperative pain, postburn pain, dental pain, labor pain, and acute pain from other medical procedures may all benefit from hypnotic intervention. For more detailed instruction in the treatment of acute pain, the reader is referred to descriptions of treatment of labor pain (74), postburn pain (75), dental pain (56,76), and pain from medical procedures (77).

Here is an example of a suggestion intended to produce such dissociation for a postoperative patient:

> You don't have to stay here in bed, conscious of all the work, all the noise, that goes on here in the hospital. Would you enjoy a kind of vacation from this room?
>
> Wouldn't it be pleasant to imagine gently floating through the window and out into the beautiful blue sky of this sun-filled day? And to just float on, to wherever you'd like to be? Almost like living a favorite daydream . . . just enjoying going wherever you'd like to go, being wherever you'd like to be, leaving your body here in the room to be taken care of. Your mind, your imagination, can take you far away, if you'd like, to a holiday from discomfort, a holiday from boredom, to really enjoy yourself.

Chronic Pain Syndromes

Because hypnotic processes take place at the highest level of neural organization, the nature, quality, and location of pain are not essential determinants of success (as it would be, e.g., with a local anesthetic acting on peripheral nerves). That is, there is no strategy unique to treatment of osteoarthritic pain of the knee rather than the elbow, or of causalgic pain of the arm or of the leg, or of neuropathy of the face or of the foot. Hypnotic treatment can be effectively applied to any pain syndrome, so long as pain relief is in the patient's interest.

What is relevant about the choosing strategies for treating various pain syndromes is the phenomenology of the pain. That is, how the patient experiences the pain and what the pain means to the patient are crucial to effective treatment. Does the pain worsen with activity (as might be the case with, e.g., osteoarthritis)? Does the pain worsen with certain mood states? Is the patient's life threatened by the pain? Is the patient's sense of self threatened by the pain? Does the pain remind the patient of the trauma that caused the pain? Does the patient think someone else is responsible for causing the pain (as might be the case with a patient injured by a drunk driver)? If so, does the patient feel victimized by the injury or illness? Does the pain mean to the patient that life can no longer be happy, satisfying, or meaningful? Does the pain mean that the patient can no longer enjoy certain activities? Does the pain mean that the patient expects increasing disability and death? Will the patient receive compensation only so long as there is pain? The answer to these questions will guide the clinician's interventions.

Interim Strategies

Ordinarily, the patient suffering recurring pain has had prior experiences of treatment failure, so the clinician may find it helpful to use temporary interventions to accommodate the patient's pessimistic expectation and belief about pain relief. Once the patient has experienced what may be initially implausible—that is, the modulation of intransigent pain—more ambitious clinical goals may then be set. The following are examples of some initial treatment strategies.

Sensory Substitution. Just as one's imagination can alter the perceived intensity of pain, so it can also alter the perceived sensory quality, resulting in a reinterpretation of sensations that may be more tolerable. A sensation of intolerable burning, for instance, can be substituted by a sensation of cold. The substituted sensation does not necessarily have to be pleasant, but only more tolerable than the original sensation. Substituting a sensation is probably not the ultimate clinical goal, but it has the following advantages:

- The patient knows the pain is still present (e.g., so the cancer patient can be assured that the persisting cancer will continue to receive proper medical attention) and can monitor its progress, thus retaining a sense of control over the condition (78).
- The substitute sensation is not particularly pleasant, so its presence may seem more plausible to the patient than a pleasurable sensation.
- Because the patient does not lose financial and social incentives (because the pain still persists), this interim strategy may be a means for negotiating with the patient further treatment goals that might involve the loss of some or all such incentives.

The following is an example of suggestions for sensory substitution:

> Those sharp sensations in your shoulder, the ones you describe as “like a knife blade,” are very likely to begin to feel peculiarly different in a little while. I'm not sure exactly how they will begin to feel. It might seem, at first as if the sharpness just becomes more and more dull . . . as if the sensation is less deep, maybe. Or, maybe you have already begun to notice that the steadiness of the sensations has begun to change . . . as if they seem to come in waves now . . . strange, not altogether pleasant waves of dull pressure.

Displacement of Pain. Displacement of pain from one area of the body to another is yet another example of a perceived modulation. It can be useful both to render an intolerable pain more tolerable as well as to embolden a patient to experience fuller relief. Displacement may be particularly appropriate when the pain is well localized and primarily intolerable because of its location. Midline pain, for instance, is less tolerable than pain located more peripherally.

> You have probably already noticed that the pain moves, sometimes, just a little, sometimes surprisingly . . . and you might begin to notice, as I talk with you, that the movement seems to become more noticeable . . . and that it moves in an almost circular way, like an outward spiral. Spiraling outward, always spiraling outward, sometimes so slowly it's almost as if it isn't happening. If you pay attention to that movement, though, you might notice that the feeling seems to be moving out of the center of your belly, spiraling ever outward; almost as if it's reaching, reaching . . . so curious, so odd, yet farther and farther from the center of your belly.

Diminution of Intensity or Affect. Most of us have had the experience of being able, by using our imagination, to modulate a perceptual experience. Sometimes we feel a change in the intensity of the perception, and sometimes we notice a change in how we feel about the perception, and sometimes our experience is that both components have changed.

The hypnotic experience makes it possible for an individual to modulate the perception of pain, sometimes only a little, and sometimes to a dramatic degree. Here is an example of a suggestion that might be made to a patient to reduce the sensory component of pain:

> You remember that you have rated the intensity of the painful feeling as a “7.” Picture in your mind an image of that “7.” Do you see it? That's fine. The number you see is the number you feel. And the number you feel is going to become smaller and smaller. Now, notice, as you watch that “7” very closely,

watch how it begins to change. Notice how curiously the sharp angles of the “7” begin to soften, to become a gentle curve. . . . Tell me when you begin to first notice that the “7” has become a “6.”

[The patient has reported seeing the “6.”]

That's fine. . . . Now, as we continue, notice how the loop of the “6” begins to separate and, ever so slowly, becomes. . . . What number do you see now?

[The patient reports a “5.”]

That's fine. And tell me, now, do you feel the same or different than when we began?

This conversation can proceed, with the clinician continuing to guide the patient to an experience of continually lower intensity pain.

The same suggestions could focus on the affective component, rather than the sensory. In this case, reduction of the sensory component is not an issue. All that matters is that the sensations are not perceived to be unpleasant or bothersome, so that the patient does not suffer (independent of the intensity of sensation).

Examples of Strategies for Treating Chronic Pain Syndromes

Cancer Pain. Although some cancer patients experience pain of the disease itself, much of the pain associated with cancer is a result of clinical procedures (78). Such procedural pain can be treated as described previously, under Acute Pain.

The significant feature of cancer pain that requires the clinician's awareness is the meaning of the pain to the patient. Cancer pain threatens the patient's sense of safety and security. Some patients report feeling a particular dread of “being eaten” by the cancer. The pain of cancer may be both as much a source of anxiety and fear as it is actual sensory pain. As with treatment of other syndromes, the treatment of the pain associated with cancer requires that hypnotic suggestions encompass the patient's own sense of the pain. For instance, does the patient equate pain with death? Does the patient have a vivid sense that the cancer is consuming him or her? Sometimes, patients are reluctant to become fully unaware of the pain of cancer because they experience it as a way to monitor the progress of the disease. The clinician will be more effective if it is clear how the patient experiences his or her pain.

Headache. Although the etiology of headache is complex and varied (see Chapter 48), I simplify the problem for purposes of this chapter by collapsing the many headache categories to the following few, which encompass most of the headaches likely to be treated by hypnotic methods: migraine headache, muscular tension headache, cluster headache, and posttraumatic headache.

Headache pain is often less easy for a patient to tolerate than pain located elsewhere because it seems so central to awareness. It may be helpful, then, to “co-opt” the pain by incorporating it into the suggestions for hypnotic induction—so that the patient does not have to struggle to resist the pain to pay attention to the clinician. Here is an example of suggestions that might be used when employing such a strategy:

As you listen to the sound of my voice, notice that the sensations of aching [or pressure or whatever the patient experiences] can be almost at the very center of your awareness. You can hear my voice and pay attention to those sensations. As you do, nothing else seems to matter. Everything else just fades away. You hear my voice, you understand my words, you feel the sensations in your head, and nothing else matters.

And notice how curiously those sensations seem to change as I speak. You might notice that they seem to fade, momentarily, with each word. Or you might notice that they seem to move, almost in a spiral, each time I speak. I don't know exactly how you'll notice those sensations change, but I hope you can be interested and curious to notice. . . .

Also, it may be helpful to treat the patient when the headache is not present, using posthypnotic suggestions to intervene when the pain subsequently recurs (see Posthypnotic Suggestion, later in this chapter). This is a crucial factor when treating migraine pain. Ordinarily, the pain of a migraine is sufficiently debilitating that a patient cannot tolerate hypnotic treatment during a migraine episode. Migraines are treated most effectively by posthypnotic treatment. When a patient is not in pain, hypnotic suggestions may use prodromal signs as posthypnotic cues that then result in the posthypnotic experience of aborting the headache before it begins. This strategy, in modified form, is also effective for patients whose migraines are not accompanied by an aura. A more detailed exploration of this procedure can be found elsewhere (2).

Neuropathic Pain. The pain of facial neuropathy or of the various peripheral neuropathies can be approached in a number of ways, using the principles above. Here is an example of suggestions that might be given to a patient with facial neuropathic pain:

It is so curious that those painful feelings in your face are going to begin to change. I'd like you to be particularly alert to the ways they feel different in the future. For instance, you might notice that, the instant you feel the sensation of electricity just below your eye, in the very next instant it will feel more like a strange sort of touching sensation . . . almost as if someone is moving a feather across your face.

Or, you might notice that the painful sensation seems to “want to start,” but just can't get started. As if those feelings are becoming weaker and weaker. And soon it will be very difficult to feel them at all.

Or, you might notice that you have learned a kind of control over the painful feelings in your face. The next time you feel one, you can take a very deep breath, hold it for a moment, and then, as you let it all the way out, you notice that you are also letting the pain all the way out . . . almost as if you are breathing it out. And you can continue to breathe it out, with every breath, so that you feel better and better. And you can enjoy discovering just how much difference you can make to how well you feel.

Musculoskeletal Pain. The most effective treatment of recurring musculoskeletal pain is likely to be a combination of antiinflammatory medication, physical therapy, and strengthening exercise. Except for the relief of acute pain, and perhaps to facilitate the patient's compliance with nonhypnotic treatment, it may be that there is no appropriate role for hypnotic treatment of musculoskeletal pain.

Phantom Limb Pain. Phantom limb pain can be particularly vexing, to both patient and clinician alike, both because its etiology remains mysterious and its treatment variably successful. Hypnotic treatment may contribute to the patient's pain relief, especially if, in addition to suggestions for analgesia, suggestions are also focused on the patient's sense of loss and how to accommodate to the loss—to make peace—with respect to the amputation. It can be especially effective to help the patient experience the phantom limb as comfortable (e.g., the limb is no longer twisted or crushed or otherwise in pain). Subsequently, suggestions may be given for lessening of any awareness of the limb.

Extending Pain Relief

Just as the temporary relief of a local anesthetic is likely not to be a satisfactory clinical result for the patient with recurring pain, so the relief a patient may feel during the hypnotic treatment is also not sufficient. Once temporary relief has been achieved, then, it becomes necessary to extend the duration further, so the patient may feel more comfortable at work, at play, while awake, and while asleep.

Posthypnotic Suggestion. The unique and significant role played by posthypnotic suggestions in the effective management of pain has been explored in greater detail elsewhere (5). In this chapter, I describe the utility of posthypnotic suggestions and offer a model for their use to extend hypnotic pain relief, for it is through the application of posthypnotic suggestions that the practical and clinically meaningful relief of pain is most readily accomplished.

Although we await a satisfactory theory of action of posthypnotic analgesia, the following is an explanatory schema that serves as a first attempt (79):

1. Hypnotic suggestions (and their subsequent repetition) result in the dissociation of noxious perceptions, reducing the sensory and/or affective components of pain.

2. Over time, this analgesia results in neural reorganization (80) so that pain responses are replaced by new, nonpainful responses that are developed in response to painful stimuli so they no longer produce suffering.
3. The hypnotic effect is greatly facilitated by the clinical relationship.

As every clinician knows, the reality of the therapeutic enterprise does not break down neatly into the principles described above. However, in formulating treatment from those principles—of promoting a trusting therapeutic relationship and an openness to new learning—two components may be identified: The simultaneous communication to the patient of certain ideas and the use of posthypnotic suggestion. These ideas include the following:

- An initial empathic joining with the patient's hopelessness while suggesting a paradoxic hopefulness
- An extension of the patient's usual experience of being controlled by the onset of pain by suggesting the subsequent reduction of pain will also be out of the patient's control.

An example might be as follows:

> You've had such frustration, you must find it almost impossible to believe that anything can help your pain. It must be very hard to believe that I can help you. So it can be a very interesting, maybe very pleasing surprise when you begin to notice that you really are feeling better.

The attitude that seems to be helpful in supporting therapeutic effect is similar to that associated with 12-step programs: Abandon your inflexible belief in total personal control and relinquish your usual attitude of either unreasonable hopelessness or hopefulness.

Occasional subsequent reversals in the course of the patient's life (e.g., emotional trauma, reinjury, progression of disease) can markedly reduce the patient's continued pain relief. However, if subsequent treatment takes into account the meaning of the reversals, improvement may once again be reestablished.

Patients who successfully experience significant pain reduction tend to focus on those experiences and to minimize occasional failures, partly by incorporating the clinician's own optimism and partly by virtue of their own optimistic qualities. This optimism is supported by clinical success, which is why effective hypnotic treatment usually progresses stepwise, built initially on occasional noticeable differences in the pain, yet also acknowledging the patient's experience of not being able to reduce the pain.

Posthypnotic suggestion for analgesia uses the patient's fear of being unable to control the pain, and yet of wishing that pain would be relieved. The clinician hopes that this attitude will facilitate the development of a therapeutic relationship that capitalizes on the patient's pleasant early memories of being well cared for and needs for nurturing, thereby empowering the clinical intervention. Although suggestions must necessarily be highly idiosyncratic, responding to the patient's needs and expectations, the following may serve to illustrate suggestions:

> I wonder if you'll feel surprised, later today. . . . I don't know what time, later today, of course . . . maybe at 10 of 4 . . . or maybe at 4 of 10. . . . I really don't know what time it will be . . . that you will have the opportunity to suddenly notice that you're feeling better than you expected to feel.
>
> I don't know, though . . . it might not actually be the time on the clock . . . maybe it will have to do with what you are doing at the time . . . maybe you'll be turning the pages of a magazine . . . or sipping from a cup . . . or turning to catch a glimpse of color going by. . . . I don't know what you'll be doing later today when you have the opportunity to suddenly notice that you're feeling better than you expected to feel.

Self-Hypnotic Management. Another means for extending the duration of relief is by teaching the patient how to use self-hypnotic techniques. Self-hypnosis requires the patient to take the initiative to take time out from his or her day, to settle in comfortably, and to provide suggestions for inducing the hypnotic experience, followed by therapeutic suggestions. Most patients seem able to learn self-hypnotic techniques, although, as with most processes of personal development, this may involve complications. A patient's interest in learning self-hypnotic techniques and willingness to use them provide a valuable index of his or her motivation for actively participating in recovery, as well as a means of assessing broader psychological issues, such as attitude toward pain and readiness for self-care. If not effectively assessed, these attitudes may become an obstacle to therapeutic success.

It is sometimes the case that, even when experiencing hypnotic analgesia, some patients are resistant to initiating and maintaining such treatment for themselves. A common issue that emerges when such resistance is addressed is the patient's preference for being taken care of by the clinician, rather than initiating self-care. Most people enjoy being nurtured and cared for by someone else, and hypnotic treatment is likely to evoke this preference. The pleasure of being nurtured can be threatened by what may be perceived as the demand for self-care. Exploration of a patient's reluctance to use self-hypnosis may reveal that

- Although hypnotic analgesia is a relief, self-hypnotic training and treatment may feel emotionally empty and, therefore, aversive.
- Hypnotic treatment may recall a patient's earlier experiences of nurturing and care, so self-hypnotic training may feel like abandonment.
- Hypnotic treatment feels virtually effortless, but self-hypnotic treatment may feel unpleasantly effortful.

A patient's experience of self-hypnotic training as both effortful as well as abandonment by the clinician may be sufficient to lead to avoidance of learning self-hypnotic techniques. When a patient's motivation for learning self-hypnosis has been established, however, a number of techniques are available (81). A simple technique involves the use of a posthypnotic suggestion. For example, the clinician might say

> Whenever you want to feel this kind of comfort and well-being, all you have to do is sit back in a chair, a sofa, or a bed and take a very deep, very satisfying breath . . . and hold it, hold it. Then, as you let it all the way out, these feelings of comfort and well-being automatically come washing over you, just like water in a hot tub, with nothing to bother you and nothing to disturb you.

Self-hypnotic methods involve learning a skill; as with other skills, competence improves with practice. Sometimes it is helpful to make an audiotape for the patient to use at home as a practice aid, although it is also helpful to emphasize to the patient that the development of this skill (and the consequently increased duration of pain relief) requires a substantial commitment of time and effort.

As a patient's improving condition permits greater independence from treatment, less frequent treatment is necessary. At this point, clinical follow-up becomes increasingly important. Sometimes, substantial time passes during which a patient successfully maintains pain relief. Then, for a variety of reasons, he or she may find such pain management difficult. At such times, a “booster” treatment may be all that is necessary to return the patient to independent functioning. It may also be useful to help the patient identify the antecedents to the present difficulty in using self-hypnosis, so future coping will be more effective. Sometimes, of course, with a worsening medical condition, more intensive treatment may become necessary.

Results

Self-Reported Pain

Hypnotic treatment can be expected to reduce a patient's subjective report (and experience) of pain and suffering. Use of a Visual Analogue Scale simplifies the patient's task of reliably reporting both the sensory-discriminative and the affective-motivational components of pain. There is tremendous variation in both the latency and degree of reported pain relief. Some patients report relief following the first treatment, whereas others do not report relief until undergoing several treatments. Similarly, the duration of relief may be initially highly variable. The clinician can help the patient to tolerate this initial variability to capitalize on the improvement it represents, and to develop more stable and durable pain relief.

Functional Status

The clinician's interventions need to be focused on rehabilitation since this, not merely analgesia, is the clinical goal. Patients successfully treated for acute recurrent and chronic pain can be expected to return to good function, subject to the physical limitations of their condition.

Return to Work

If a patient's pain is substantially reduced by hypnotic intervention, the patient can be expected to return to work. Symptomatic relief is unlikely in patients for whom the opportunity to return to work is unappealing. Patients whose coping strategies include self-hypnotic skills learn to integrate them into their daily work lives.

Complications

Hypnotic methods are not without risks that, although rare, may include complications as the result of accelerated transference, acting out, disorientation, hysterical manifestations (e.g., paralysis), and memory contamination (82). As is evident from this list, these risks are more likely to be associated with the use of hypnotic methods in psychotherapy and less likely in the context of pain management.

If the therapeutic goals are not aligned with the patient's perceived self-interest, then complications are likely to arise from any treatment, including hypnotic treatment. Although there is no evidence that the hypnotic experience is itself harmful, if the patient is severely depressed, psychotic, or pathologically irresponsible, complications to hypnotic treatment may arise (82). An adequate medical and psychological evaluation will be likely to alert the clinician to potential complications, and adequate clinical training will prepare the clinician who confronts such complications (83).

CONCLUSIONS

Hypnotic intervention can be effective for the palliative treatment of a wide range of acute and recurring painful conditions. Medical treatment of pain is evolving with an increasing understanding of the role of psychological processes in pain modulation. Hypnotic treatment is also evolving, and with a greater emphasis on active participation by the patient, primarily through greater utilization of self- and posthypnotic strategies (8,79,81). As research and clinical techniques develop further, the unscientific attitudes identified with the earlier history of hypnosis should become increasingly rare, and clinical effectiveness will become increasingly common.

CHAPTER 92

*Relaxation and Imagery Techniques**

Karen L. Syrjala

Relaxation with imagery (R&I) is one of the most widely used methods for nonpharmacologic relief of pain. A form of R&I is nearly always a component of multidimensional chronic pain treatment. R&I also is effective with acute and cancer pain problems, as discussed in Chapter 9 and Chapter 36.

Numerous techniques and terms are used within the rubric of R&I, including progressive muscle (tense-release) relaxation, autogenic relaxation, imagery, visualization, and meditation. Although it is possible to describe separately the relaxation method and the imagery method, in practice, nearly all relaxation incorporates a form of imaging, whereas nearly all imagery begins with a form of relaxation. Consequently, the clinician needs to understand and be able to use both components. Relaxation is used to pull focus away from pain and to induce a physical state of decreased muscle tension, as well as decreased autonomic and affective arousal. In theory, this state is inconsistent with the usual pain experience and, in itself, may reduce pain perception. Imagery provides a directly competing cognitive focus, which can block perception of pain during total concentration on imagery. After imagery is completed, pain reduction may continue through a shift in cognitive interpretation of nociceptive signals or through more direct neurochemical mechanisms. Both relaxation and imagery disrupt the pain-dysfunction feedback loop by increasing patient focus on feelings of well-being, thereby decreasing the focus on pain, as well as the tension, anxiety, depression, and inactivity related to pain.

As is described in this chapter, R&I has been shown to be effective in the treatment of chronic low back pain, cancer pain, rheumatoid arthritis, childbirth, and acutely painful procedures. Headache and temporomandibular disorder (TMD) pain have been treated successfully with relaxation alone or combined with imagery. This chapter first considers some basic information, including a historical perspective of R&I techniques, theoretical bases including physiologic effects, and advantages and disadvantages of the methods. I then detail clinical methods and efficacy, as well as possible complications that a clinician should be prepared to manage. For further details on the application of specific approaches, the reader is referred to several books with useful information for professionals (1,2,3,4 and 5). In addition, Bernstein and Borkovec (6) have written a manual for training professionals in progressive relaxation. For reviews of research or practice of R&I, see articles by Fernandez and Turk (7), Keefe and Caldwell (8), McCaffrey and Beebe (9), the NIH Technology Assessment Panel (10), Syrjala and Abrams (11), Syrjala and Roth-Roemer (12), Turner and Romano (13), Vessey and Carlson (14), and Wallace (15).

With the increased public attention to self-help and alternative therapies, bookstores are full of books and audiotapes instructing patients in how to use imagery on their own. With a review of these, clinicians will find several that they can recommend for patient use, along with professional care, in treatment of specific pain problems. As an example, Davis et al. (16) have a relaxation workbook designed for patient use. *Books and audiotapes should not be considered adequate treatment alone. Most patients require initial professional assistance to adapt methods to their individual needs* (17,18). *Tapes alone can bias patients against trying R&I with a professional, since they believe "it doesn't work for me."*

BASIC INFORMATION

History

Relaxation was in use by the 1930s as a technique for reducing tension and anxiety. Progressive muscle relaxation (PMR) was introduced by Jacobson (1), who found that by extensive practice with systematic tensing and releasing of muscle groups, anxious patients could learn to discriminate the resulting sensations and produce an experience of deep relaxation. Wolpe (19) modified the procedure into a program that could be completed in six 20-minute training sessions with twice-daily home practice. He then incorporated relaxation into his systematic desensitization therapy for phobias, reasoning that relaxation would provide a response incompatible with fear. The relaxed state was paired with gradual exposure to the feared stimulus. The patient first imagined the exposure while relaxing and then actually confronted the feared object in real life. This method of treatment for phobias is still used today.

Autogenic training (AT) originated with a Berlin psychiatrist, Johannes H. Schultz, and was popularized in North America by Luthe (20). AT does not require tensing of muscles but instead consists of turning attention to each muscle group in turn, suggesting sensations of heaviness and warmth. After progression through the muscle groups, attention is turned to slowing the heart rate, developing a regular respiration pattern, and finally regulating the viscera and cooling the forehead. The objective of AT is autonomic regulation as well as muscle relaxation. In its passive concentration, AT resembles meditation. In its content it incorporates the use of imagery, although these images are limited and intentionally repetitive.

Benson (2) has described the relaxation response as a form of meditation without the religious or lifestyle connotations of transcendental meditation, Zen, or yoga. In the two most tested meditation strategies, the relaxation response and mindfulness meditation, patients are taught awareness in the moment, without judgment. Procedures vary, but awareness can focus on breathing, a phrase, or on a detached observation (for extended details of how to implement meditation, see references 3,5, and 21).

Although relaxation began as a treatment for anxiety, from the time that behavioral psychologists began working with pain patients, R&I techniques have been a key element of standard treatment (4). A sequential combination of PMR and AT is most frequently taught, with deep breathing and guided imagery often incorporated. Although not technically included in any of the original versions of relaxation already mentioned, deep breathing can be the first step toward helping patients focus attention before proceeding with further relaxation. Guided imagery serves as a distraction technique and, more important, as an effective means of introducing alternative thoughts, images, or ways to perceive pain. As such, the imagery component can be critical to the success of relaxation as a pain relief tool (7).

Theoretical Bases

The mechanisms through which R&I reduces pain are still under debate, except for consensus on the obvious mechanisms of tension relief and altered sympathetic arousal (10). Little is known about brain physiologic changes in response to relaxation, but more is known about peripheral physiologic change. Even brief PMR training has produced significant reductions in heart rate, respiratory rate, and electromyographic (EMG) forearm muscle tension (22). Furthermore, during relaxation, physiologic changes have been greater than those observed during hypnosis for systems not under voluntary control (e.g., heart rate and tonic muscle tension). Other documented physiologic responses to relaxation include decreases in oxygen consumption, blood pressure, and serum lactic acid levels; increases in skin resistance; and alterations in blood flow (23). Investigators have found that plasma norepinephrine levels either increase or do not change after relaxation (24). It has been hypothesized that these peripheral changes, which indicate a decreased arousal of the sympathetic nervous system, are related to decreased end-organ responsiveness to norepinephrine (23).

Reduced sympathetic activity after relaxation does not fully explain the pain reductions found in a substantial number of conditions (13,25,26 and 27). In tension headaches and TMD pain, the reduction in reported pain may be due, at least in part, to muscle relaxation effects and decreased sympathetic arousal, although not all studies have shown this. Altered blood flow may account for some of the effect with migraine headache. Other physiologic and cortical processes almost certainly are involved in accomplishing the pain relief reported with imagery in some acute and chronic pain conditions.

Measured brain responses to relaxation include increased electroencephalogram alpha and theta waves (23), but research has confirmed few other brain activity changes. One theory holds that relaxation and meditation result in a shift in hemispheric dominance, with greater activation of centers in the right hemisphere, although this is unproven (23). Another hypothesis speculates that pain relief is a function of changes in catecholamines, endorphins, or other neurochemical systems (10). Some data suggest that a spinal–thalamic–frontal cortex–anterior cingulate pathway influences subjective response to pain, whereas a spinal–thalamic–somatosensory cortex pathway influences pain sensation. Pain signals may be modulated through a descending pathway that involves the periaqueductal gray. At the dorsal spinal cord, serotonin and norepinephrine appear to play important roles in sensory modulation. Although these mechanisms have been hypothesized for some time, they remain difficult to test.

Advantages

R&I has three primary advantages over the similar but more complex techniques of biofeedback and hypnosis (see Chapter 90 and Chapter 91): (a) Patients can be trained in the use of the skills with relative ease; (b) no special equipment or extensive training of the therapist is required; and (c) patients readily accept R&I techniques, whereas they are more likely to reject hypnosis (28).

Although it can be difficult to predict who will benefit from R&I, the lack of serious complications and the relative ease and low cost with which it can be tried make this a method with minimal risks. Unlike the practice of hypnosis, R&I is essentially a skill that can be learned; it does not depend to any extent on the responsiveness of the patient. If a patient is unable to visualize images, PMR can be taught with potential benefit, and methods can be adapted to the particular capabilities and preferences of a patient. Thus, the flexibility within the method leaves room for adaptation to a wide variety of styles or needs. Expectations of patients tend to be more realistic than for hypnosis, which tends to evoke a wish for a ”magic cure,” higher expectations, and higher levels of fear of loss of control.

Disadvantages

R&I requires the participation of the patient. To optimize benefit, patients must practice outside the trainer's office. Although self-control is one of its appeals to patients, lack of practice is one of the greatest problems in its use. Further disadvantages follow as corollaries to R&I's advantages. These include the lack of implied magic cure that can be hoped for with either a medical intervention or hypnosis. Ease of use and lack of cost can be associated in patients' minds with lower expected efficacy. The effects of R&I may not be immediately apparent but can accumulate over time, thus requiring not only practice but also patience. R&I are subjective experiences not unlike pain; as such, their effects can be difficult to measure and confidence in their benefits may be low. Finally, for most conditions, R&I is not, alone, an adequate treatment for pain, but must be considered a complementary method used in combination with appropriate medical treatment.

CLINICAL INFORMATION

Indications

Indications for treating pain vary with the type of pain and the condition of the patient. Relaxation is recommended for any patient for whom tension is a significant cause of pain or for whom tension and fear may be augmenting the pain problem. In acute pain situations such as childbirth, trauma, or procedural pain, R&I may be combined with medication and other distraction strategies that decrease a focus on discomfort and speed the passage of time. Relaxation is clearly indicated in the treatment of tension, migraine, and cluster headaches and in TMD pain. In other chronic conditions and in cancer pain, clinical trials have indicated that R&I and meditation reduce pain (11,18,26,29). With the limitations of time in the current medical practice environment, R&I is most strongly recommended for patients who have chronic conditions that cannot be adequately relieved with medical intervention alone. In addition, patients will benefit from R&I training if they must regularly repeat acutely painful situations because fear and phobias can increase over time with exposure to these stimuli.

Contraindications

Contraindications are few and usually relate more to the mental status and characteristics of the patient than to the pain condition itself. Pain or sedation that prevents a patient from focusing attention, or a delirium that disrupts cognition, needs to be treated with other methods until concentration is possible. Then, briefer images with a short relaxation component can permit participation by a patient who otherwise could not sustain the mental effort needed for more extended training. Sometimes these patients feel ease of intense discomfort by combining images with physical massage or pressure on a part of the body (shoulder, hand, lower arm or calf muscles) that is not in pain. Of course, clinicians must be cautious and should consider having someone else in the room if they decide that physical touch with imagery is needed to help a patient with pain that cannot be relieved with medical methods alone.

Certainly religious objections, intense fear of loss of control, or resistance to trying the method for any reason should be respected. Skepticism is not a reason to withhold treatment if the patient is willing to give the technique a valid try—clinicians can encourage a healthy skepticism and empirical testing attitude. Similarly, patients who ask for biological explanations for why mental strategies might work usually respond well to information about physiologic mechanisms behind R&I. These patients also may do best with PMR in the beginning because this helps to enhance awareness of physical changes that occur as the body relaxes. The same is true for patients who seem out of touch with their bodies and unaware of tension or for patients who are action-oriented ”doers not thinkers.”

Intense anxiety or preoccupation that prohibits focus on imagery must be attended to pharmacologically or with discussion before beginning R&I. Because anxiety can increase during imagery, the clinician should assess a highly anxious patient and ensure that emotional expression is tolerable. Usually these patients need to express thoughts and feelings first. Then the clinician can reevaluate the patient's ability to focus. Ability to engage in a discussion of places that the patient enjoys should indicate adequate ability to participate in imagery.

Two additional circumstances can complicate the use of R&I: One is the patient who is feeling very out of control; the other is the patient who has a strong need to be in control. For patients who feel completely out of control of their experience and environment, a clinician can appropriately take charge of the situation and let patients know the clinician is going to ensure their safety while there. Clinicians need to convey to patients that the situation is manageable and the pain can be relieved. If these messages seem to reassure and calm the patient, the clinician should be able to move into imagery. For patients who give indications that they must be in control, clinicians will want to assess whether these patients might respond best to permissive, indirect imagery versus more structured PMR methods. PMR helps in this situation because patients can be told exactly what steps the clinician will take. Generally patients feel safest with PMR because it is clear that patients control their own responses. Alternatively, if imagery is used, the clinician can encourage patients to select as many features as possible and can incorporate options and permission to have other thoughts or experiences during the imagery. Another strategy is to have patients tell the clinician what they see, feel, hear, and do in their imagery, with the clinician asking questions rather than leading the imagery process.

Techniques

Preparation of the Patient

Relaxation may be learned and practiced by virtually anyone. The techniques can be taught by those who have had relatively limited training, but clinicians should be aware of and prepared to handle possible complications. Before relaxation training begins, the clinician should explain to pain patients the rationale for the particular procedure being used. Many patients view relaxation as irrelevant to their pain problem or even as an indication that the doctor thinks the pain is ”just tension” or ”all in my head.” Most patients are helped in their disbelief by a brief discussion of the gate control theory of pain, hypothesized neuroendocrine effects, and the feedback loop between pain and tension or fear. Patients can also be told that relaxation training is harmless and, if nothing else, will leave the patient feeling relaxed. The clinician can then suggest that the procedure be tried as an ”experiment,” with nothing to lose. This approach is preferable to promising patients dramatic pain relief because this rarely occurs initially. Patients also need to understand that R&I is a skill, like learning to read. Benefits take time to reach their peak, and daily home practice is necessary to become adept at the procedure and to maintain benefits. Audiotapes can be helpful in supporting home practice.

To prevent surprises and help patients feel secure, clinicians should describe the basic steps involved in the technique and estimate the length of time required to

complete the procedure. Although increased comfort can be achieved in as little as 5 minutes, deep relaxation requires at least 20 minutes for new practitioners and may continue for up to 45 minutes. Patients can be advised that they will likely be most comfortable with their eyes closed, although this is not mandatory, and that they are free to move at any time to make themselves more comfortable. Use of a reclining chair with a headrest is desirable, or patients can sit on the floor or a regular chair. They should not lie on a bed, unless the goal is rest for a sleep-deprived patient in pain. Lying on a bed tends to evoke falling asleep rather than completing the imagery. Unplugging the phone and minimizing other noises or disruptions are helpful. In hospital rooms this is not always possible. So it is helpful to add a statement such as ”and just allow any sounds around you to fade to the distance, part of the background that adds to your feeling of being in a different place, a place all your own right now.” Surprisingly, after imagery patients often indicate that they were unaware of any sounds or disruptions even though they may seem intrusive to the clinician.

Training Procedures

Deep breathing is the most rapidly learned of the relaxation techniques. Very little training is needed to obtain benefits. For patients in intense acute pain, deep breathing may be the most that they can accomplish. Controlled breathing also can be quite effective in capturing and holding a very distressed patient's attention and may be the first step toward using imagery to further distract the patient from the distress of the moment. I am aware of no reports on the usefulness of deep breathing in isolation from other strategies for pain control, although it is a component of many relaxation procedures that have been researched. One component that is often not stressed but can be quite valuable in relieving pain is making a sound while breathing, usually just emphasizing the sound of air leaving the lungs and mouth. Variations on this method are commonly used in childbirth preparation (30). Typical instructions for deep breathing are given in Table 92-1.

TABLE 92-1. Instructions for deep breathing [a]

PMR is the most routine of the techniques. Because it requires the patient to tense and release muscle groups, it provides the most feedback to the clinician (as well as the patient) on the participation of the patient. The tense-release format provides momentum from which the patient can achieve relaxation well below usual levels of tension relief. Before implementing this technique with a patient, the clinical investigator is urged to read the manual by Bernstein and Borkovec (6).

Autogenic relaxation is similar to PMR in that it progresses through the body, focusing attention on relaxing each area of the body in turn. Autogenics, however, does not require tensing muscles first. The focus is on imagining a feeling of warmth and heaviness in each area. Imagery may be inserted after completion of the relaxation phase or may be combined with the relaxation phrases. This technique is useful with patients who are quite fatigued and in general discomfort. The imagery component may relate only to feelings of warmth, heaviness, and sensations that accompany relaxation or may be augmented at length depending on the will and interest of patient and clinician.

Incorporating imagery into relaxation can greatly enhance efficacy as a pain relief tool (7,18,31). Imagery also increases the enjoyment of patients and therefore the likelihood that they will use the technique. Activating all the senses in the mind creates distraction as well as hypnosislike experiences of comfort, well-being, and mastery of a problem. For instance, patients can be asked to choose a place where they have felt most at ease or joyful, at a time when they were pain free. As patients recapture the familiar experience of a place with sight, sound, taste, smell, and touch, they also recapture the feelings of comfort. Clinicians can then suggest to patients that by imagining themselves in that place, patients can once again be comfortable and in control of how they feel. The content of images can vary greatly, from going to pleasant places to modifying the pain experience directly (11,32). More success in using imagery may be achieved by patients with greater ability to generate images and those who have a greater capacity to experience images as if they are real (33,34). Patients without these abilities may respond more to the relaxation component of R&I. Choice of images may be the most important factor in the success of imagery. Pain reduction is greater when patients can choose their images and when they make statements to themselves in the imagery that they are able to tolerate or modify the pain (34). Pleasantness may be more important to encouraging use of the imagery than in enhancing its effect on pain (35).

An alternative imagery strategy is more akin to meditation. This approach involves focusing on the pain rather than away from it and on picturing details of the pain location (36). There is some indication that for more extreme, unremitting types of pain such as with terminal cancer, focusing on the pain rather than away from it is more effective in achieving pain reduction (37). Table 92- 2 lists of some of the more commonly used imagery strategies for pain control. These can be incorporated into imagery of going to a favorite place or can be combined with deep breathing.

TABLE 92-2. Imagery options for pain controlstrategies

In execution, meditation most resembles deep breathing. Instead of focusing sequentially on each part of the body, meditation requires a cultivated ”detached observation” (3,5). Two similar approaches to meditation have been useful in medical settings. One involves repeating a phrase or word to oneself and is referred to as the *relaxation response* (2); the other is called *mindfulness meditation* (5,21). Mindfulness meditation is similar to the imagery approaches that transform painful sensation (36). Attention is focused not on changing pain perception but on insight developed from distinguishing all sensations as they occur moment by moment. Thoughts about pain are observed from the position of a neutral observer. Although relaxation response training is easy to implement, few data exist on its effectiveness as a pain reduction method. Mindfulness meditation has been shown to reduce pain in chronically ill patients (21,26). An experienced clinician is recommended as a trainer. Instructions for using the relaxation response and instructions for mindfulness meditation are detailed thoroughly in the Kabat-Zinn book (5).

Results

Comparisons have been made between R&I strategies and hypnosis or biofeedback, as well as between different relaxation techniques. Numerous studies have also tested packages of cognitive-behavioral skills training that have included a form of R&I. Each of these interventions, including hypnosis, biofeedback, and

cognitive-behavioral packages, elicits similar physiologic responses and subjective reductions in pain when compared with no treatment (13,18,23,25,27,31,38). In general, research results indicate that R&I demonstrates greater effect size than other strategies alone and that packages of cognitive-behavioral skills are not always superior to R&I alone (7,8,38). Hypnosis, biofeedback, and audiotaped relaxation are less effective than live PMR in achieving reductions in sympathetic arousal (22,39). An exception may be frontalis EMG levels, which have shown greater reductions with autogenic relaxation than with tense-release relaxation, although both approaches produce some decrease in EMG (40). This may be of some interest to clinicians choosing between relaxation techniques for the treatment of tension headache.

Much of the research on the effectiveness of relaxation alone for pain reduction has been conducted with tension headache patients. In general, the results of these studies suggest that relaxation is effective and that benefits are maintained at follow-up (13). Relaxation training alone appears to be a reasonable first step for headache sufferers, with the addition of biofeedback for those patients who are unsuccessful with relaxation alone (41). Similarly, research with TMD pain patients suggests that many can be treated successfully with relaxation alone, although some may benefit from the addition of biofeedback (42). With other conditions, relaxation is best implemented in combination with imagery. The next sections discuss efficacy of a single method of R&I within specific conditions, as this is how most clinical trials of the methods are tested.

Chronic Conditions

R&I is most often used as one element in a set of cognitive-behavioral treatments for chronic pain, rather than as an independent pain control technique. Research indicates that R&I can contribute to reduced pain levels, reduced medication use in a number of chronic conditions, and reduced disability, although the role of R&I versus other cognitive methods is not yet clear (27,38). The evidence for sustained improved function is less consistent but more often than not supports improvement in disability after treatment (27,38,43,44). Chapter 89, by Turner and Romano, presents a thorough review of the effectiveness of cognitive-behavioral strategies that usually include R&I.

Kabat-Zinn et al. (5,21,26) have used mindfulness meditation to successfully treat a variety of chronic problems, including pain located in the low back, neck, shoulder, arm, leg, face, head, chest, peripheral nerves, and multiple sites. Ten percent to 20% of patients refused to use this strategy for pain control. A majority (72%) of the patients who were willing to try were able to reduce their pain by 33% or more. In addition, improvement was noted in body image, activity, mood disturbance, and medication use. Compliance both during and after participation in the program was reported to be high. These results support the contention that meditation may have a generalized beneficial effect for chronic pain patients.

Headache. Tension headache research dominates the literature and generally reveals relaxation to be as effective or more effective than biofeedback (13,25,45,46). The same results have been found with migraine headache, although fewer studies are available. The most careful explorations into the relative roles of relaxation and biofeedback in relieving headache have been reported by Blanchard et al. (41,45,47) and Andrasik et al. (48) (see Chapter 90). In terms of both cost-effectiveness and success, the optimal therapy for tension, migraine, or mixed tension and migraine pain appears to be a two-step treatment beginning with PMR. For those patients who do not show substantial reduction in headache activity with PMR, the second step is instituted. For vascular headache patients, the second step is thermal biofeedback; for tension headache patients, frontalis EMG biofeedback is the second step. Blanchard et al. (49) found that with this two-step therapy 73% of tension headache patients and 52% of vascular headache patients were much improved. All groups improved with relaxation, with the tension headache patients improving the most. Among those patients who received biofeedback, the vascular headache patients responded most favorably.

Philips and Hunter (50) tested the effects of PMR versus PMR with calming imagery for tension headache patients. The two groups showed similar improvements in pain. The authors suggested that the addition of imagery produced a larger improvement in pain based on several outcome measures even though no individual measure showed significantly superior effects.

The superiority or equivalence of relaxation and biofeedback has not been supported by all research. LaCroix et al. (51), for instance, found that thermal biofeedback was superior to frontalis EMG feedback and relaxation for migraine patients, although all groups improved.

With regard to home practice, Andrasik et al. (48) reported that posttreatment practice was unrelated to maintenance of effects. It should be noted, however, that all patients in this study were provided with regular therapist visits.

Low Back Pain. Studies comparing relaxation with other techniques for low back pain indicate that relaxation is an effective treatment but that combining relaxation with other cognitive-behavioral strategies may be advantageous (see Chapter 89). Turner (29) compared PMR treatment with PMR plus additional cognitive-behavioral therapy or no treatment. The two treatment groups both reported reduced pain intensity and disability immediately after treatment and at 1.5- and 2-year follow-up. The cognitive-behavioral group, however, showed some superiority in maintaining treatment gains and in hours worked per week. A number of other studies by Turner et al. support the use of relaxation as one component of effective cognitive-behavioral treatment for chronic pain (13,27,29,38,54). McCauley et al. (52) compared PMR with hypnosis in the treatment of low back pain and found that both treatments were similarly effective and superior to a placebo EMG treatment. Sanders (53) compared single sessions of PMR, assertion training, reinforcement of activity, and ”functional pain-behavioral analysis training” in four low back pain patients. With the exception of functional analysis, each treatment differentially, but positively, affected medication use, pain ratings, and up time.

Additional research is needed on the relationship of component interventions to specific outcomes in the low back pain patient, even though these studies suggest that relaxation makes some contribution to favorable outcomes. In particular, research is needed that tests the efficacy of imagery combined with relaxation training for treatment of chronic conditions.

Temporomandibular Disorder Pain. The research on relaxation and cognitive-behavioral packages that include PMR for TMD pain supports the conclusion that relaxation is effective in reducing pain and is at least as successful as biofeedback, the most commonly compared treatment (54). Funch and Gale (42) reported that biofeedback and audiotaped relaxation training were equally effective in reducing TMD pain. Patients who were more successful with relaxation were generally younger, had experienced TMD pain for a shorter period of time, and reported other psychophysiologic disorders. Patients who were more successful with biofeedback tended to be older and married and had experienced pain for a longer period of time. The differential effect of relaxation and biofeedback with different patients also was found in a single-subject, multiple-baseline study by Moss et al. (55). In this study, relaxation with EMG feedback was most effective for three out of four patients tested. In the largest randomized controlled clinical treatment, Dworkin et al. (54) compared patients receiving usual treatment for TMD with patients receiving usual treatment plus a package of cognitive-behavioral skills that included relaxation training. The skills-trained group reported continued improvement over 12 months of follow-up and overall lower pain scores and a strong trend toward reduced pain interference with function.

Arthritis and Autoimmune Diseases. Evidence for the benefits of self-management strategies for coping with arthritis pain and dysfunction have been collecting over the last decade (56,57,58,59,60 and 61). As with other chronic pain clinical trials, benefits seem to continue or even to expand over time after treatment. Educational strategies that may or may not include relaxation exercises are widely used in arthritis and are cost-effective and pain relieving over and above the effect of medication treatment alone (8,58,62). Even more so than with low back pain and other chronic conditions, arthritis and autoimmune diseases are not treated with R&I alone, but rather with R&I as a component of educational and other cognitive skills training (8). Consequently, it is difficult to know to what extent R&I is an essential component of these techniques. There is no reason to believe that patients with arthritis pain or the patients with autoimmune diseases would respond differently than patients with other chronic illnesses such as low back pain or cancer, even though each disease has its own unique characteristics and therefore stressors to tax coping.

Cancer Pain. Cancer patients may experience acute treatment-related pain or chronic pain (see Chapter 35). The chronic pain may be stable (e.g., postmastectomy pain) or progressive (e.g., tumor invasion pain). Successful treatment depends to some extent on tailoring therapy to the type of pain. In clinical reports, relaxation with guided imagery, sometimes called *hypnosis*, is touted (63,64). However, there is little controlled research on the efficacy of R&I with adult cancer patients. As noted by Jay et al. (65), research on adult cancer patients has focused on chronic pain, whereas research on children with cancer has focused on acute procedural pain.

Spiegel and Bloom (66) provided group ”self-hypnosis” training to breast cancer patients and reported an additive analgesic effect of hypnosis, with smaller increases in pain and suffering over time. Syrjala et al. (31) provided three groups of bone marrow transplant patients with training in ”hypnosis,” cognitive-behavioral training including PMR, or support with no training. The group receiving hypnosis reported lower average levels of oral pain after chemoradiotherapy than the other two groups. In a second study, Syrjala and colleagues (18) tested R&I against three other groups: a standard treatment control, a supportive psychotherapy intervention, and a cognitive-behavioral package, which included R&I. Again, in this clinical trial R&I was the most effective treatment for pain, with cognitive-behavioral methods showing no mean additive effect over and above the R&I alone. There was an indication that some patients benefit from the cognitive-behavioral package who may

not have benefited from the R&I alone; however, power was not adequate to test this hypothesis. These data indicate a valuable role for imagery in helping cancer patients cope with pain and the need to individualize patient treatments.

Acute Conditions

Childbirth. Preparation for childbirth, which is now quite common, usually includes breathing exercises with a visual focus and sometimes includes formal relaxation training (see Chapter 71). As Tan (30) noted in his review, studies on the effectiveness of these strategies in reducing pain in childbirth are supportive but equivocal. Many of these studies do not include actual measures of pain levels in reporting favorable outcomes. Laboratory research has suggested that the attention-focusing component of preparation is more effective in reducing pain than is relaxation training (67) and that sensory transformation coping strategies are more effective than relaxation (68). Despite the equivocal data on pain reduction associated with childbirth preparation, the reduced distress resulting from such programs probably supports their continued use.

Acute Traumatic, Procedural, and Postoperative Pain. A number of sources confirm the benefits of relaxation training before various procedures and surgery. Only anecdotal evidence was found for the use of deep breathing, relaxation, and imagery during acute trauma, although hypnosis has been demonstrated effective during burn debridement (69). This is a difficult area to research because of the unpredictable availability of subjects and the wide variety of possible injuries. By and large, support for the use of these strategies in trauma situations must be extrapolated from research on other acute pain conditions.

Relaxation training before stressful procedures has been shown to be effective in reducing a number of measures of pain and distress. For example, patients trained in PMR and deep breathing before sigmoidoscopy rated themselves as less anxious and made fewer requests to stop the procedure than patients who were not trained in relaxation (70). Both relaxation and information have been reported to reduce heart rate and observer ratings of distress during endoscopy. Only relaxation also increased positive mood (71). Even greater effect was seen in a study of imagery/self-hypnosis during radiologic procedures. In this randomized clinical trial, patients receiving the active intervention reported less pain, used less analgesic medication, reported less anxiety, and had fewer procedural interruptions due to hemodynamic instability (72). In an interesting departure from using specialists to provide R&I to patients, Lang and colleagues (72,73) have trained radiology nurses and technicians to provide relaxation and imagery during painful procedures. Patients reported significantly lower pain scores, with a strong trend toward less drug use (73).

Laboratory and clinical studies have found that the effectiveness of relaxation training in acute situations may depend on the coping style of the patient. In the laboratory, it has been reported that patients who were more external in their ”locus of control” were better able to use relaxation training than were patients who were more internal—that is, saw themselves as the agent of control (74). During procedural discomfort, patients who reported that they preferred to avoid thinking about unpleasant things were helped more by relaxation than by information, whereas the reverse was true of the nonavoiders (71). In addition, patients who indicated that they were less independent benefited from both relaxation and information, whereas those who were more independent benefited from neither. Relaxation and information were not demonstrated to be harmful to patients who were not matched on intervention and coping style. Finally, with postoperative patients, Scott and Clum (75) found that brief relaxation training was profitable for those who had ”sensitizing” coping styles, but not for those who were avoiders. In sum, avoiders and ”external locus of control” patients may do particularly well with escape-oriented pleasant imagery, whereas other patients may respond well to all types of R&I.

Applications with Children

Research on the use of relaxation techniques with children is less extensive and well controlled than the research with adults. Lavigne et al. (76) and Vessey and Carlson (14) provide reviews of painful pediatric conditions and the interventions that have been successful. The terminology used in much of the published research is inconsistent. For example, treatments are interchangeably defined as active fantasy, guided imagery, breathing, hypnosis, relaxation, or imagery.

Children are generally able to participate in imagining as a distraction from pain or fantasy to modify the pain experience from approximately 5 years of age (14). Initially, imagery differs from play or active fantasy and storytelling only in its intention. I have found it particularly effective to use stuffed animals or soft puppets onto which the child can transfer the pain or the fear or anger that accompany pain. When left with the child, these toys become the transitional object with which the child can repeat the imagery when the clinician is not present. As children grow to adolescence, imagery and relaxation methods increasingly resemble those used with adults. However, adolescents and children are closer to fantasy than many adults and therefore require little or no time in relaxation and need to move to fantasy imagery more quickly. Adolescents respond well to imagery with themselves as heroes and the agents of change and success. Pain transformations can be included in these images of mastery.

In research with pediatric cancer patients, interventions have focused on procedure-related pain and distress (65,77,78 and 79). Effective treatments have included breathing and imagery, sometimes incorporated into a cognitive-behavioral package. Although numerous studies demonstrate that R&I can reduce distress related to procedures, and sometimes pain, increasingly we are seeing light sedation used for repeated invasive procedures such as lumbar punctures and bone marrow aspirations. Light sedation may be more effective than imagery at eliminating the distress and discomfort of these procedures, although relative risk, provider time requirements, and outcomes have not been formally studied.

A small number of case studies suggest that relaxation, particularly if coupled with imagery, can be effective in treating other pediatric pain problems. Distraction and breathing exercises have received some support as useful techniques for relieving pain during debridement for pediatric burn patients (76). Varni et al. (80) reported the successful use of relaxation and breathing to increase pain control in a 9-year-old with hemophilia. Unlike relaxation research with adults, which has focused on tension headache, pediatric research has focused on autogenic relaxation for migraine. This research clearly supports the use of autogenics for relief of migraine in younger populations (76).

Because children are usually easily engaged in active imagery, this component can be successfully introduced into most interventions with children in pain. Clinicians interested in the use of imagery are also referred to the literature on hypnosis, as many researchers using imagery with children commonly have termed their interventions ”hypnosis.”

Complications

Minor Problems

One of the advantages of relaxation techniques in comparison with more invasive therapies is the lack of lasting adverse side effects. Most complications are rare, are harmless, and can be handled with quick, matter-of-fact resolution of the problem. Muscle cramps can develop with PMR, in which case the patient can be asked to generate less tension in problem areas for shorter periods of time. If necessary, a pause can be taken while the patient massages cramped muscles. Unless the patient comments or appears uncomfortable, spasms should simply be ignored. Patients can be reassured that muscle spasms are common when people relax and occur in many people when they fall asleep. Movements are not uncommon but are generally not suggested unless they involve brief shifts to a more comfortable position. Talking and laughter usually stop if they are ignored. Alternatively, they can be casually acknowledged, such as ”and just notice that different feelings may come up and that's just fine, just a part of letting thoughts and feelings flow through your mind or body and away, leaving a feeling of being even more at ease.”

Because some patients experience intrusive thoughts as disruptive, they should be told ahead of time that such thoughts are to be expected. Suggest that as thoughts arise, they can be allowed to ”float through the mind, knowing that anything important will still remain later, but that right now there are no other things to focus on or to do but to let these normal thoughts just float away.”

If a patient falls asleep, the therapist might need to speak in a progressively louder voice until the patient is again awake. Patients who report falling asleep regularly during home practice should be instructed to practice earlier in the day and in a sitting position.

Problems Requiring Attention

Problems requiring the therapist to be more careful and attentive are infrequent. The more common difficulties and some solutions are described in Table 92-3. For certain patients, tension or pain can be localized in an area not sufficiently covered by the standard relaxation of body parts. TMD pain, as an example, benefits from exercises and relaxation targeted to that area (54). If residual tension remains, it is helpful to develop a tension or relaxation strategy that specifically targets the localized area. This might involve taking time after relaxing to go to any place in the body that continues to feel tight or uncomfortable, going to that place with the mind and watching while imagining breathing through that place in the body and noticing the changes in sensations. Sensory transformation imagery may be used to

expand on this experience.

TABLE 92-3. Problems and solutions encountered in clinical practice

Pain patients commonly have an initially greater awareness of the pain as attention is focused on internal states. In this case, patients can be instructed to observe the pain in a detached manner (similar to that just described previously). Usually the intensity will lessen. Alternatively, the clinician can move the patient's attention to another part of the body or to images away from the body.

Patients who have been particularly out of touch with body sensations can suddenly become aware of any number or type of strange, unfamiliar sensations while relaxing and focusing on the body. Patients might feel as though they are floating and disoriented to such an extent that they must open their eyes until they once again feel comfortable. If this sensation or others are frightening, the clinician will need to respond with reassurance. Other discomforting sensations can include tingling, nausea, lightheadedness, or a sense of losing control.

Patients who fear losing control require perhaps the greatest care in designing an appropriate intervention. These patients often respond initially to PMR because they are in control and the procedure feels most in their control. Telling them the process you plan to follow also helps to ease fears. Another strategy is to give these people choices of what they would like to try. With these patients, it is particularly important to include statements that they are in complete control of their experiences and what they choose to do, that at any time they can choose to change their experience or even to stop.

An increase in anxiety has been reported in some patients learning relaxation (81). In our experience, this occurs in approximately 2% of patients. Switching to a different relaxation (e.g., PMR) that more fully occupies the patient's attention may help reduce such anxiety. Discussion of the nature of the anxiety may reveal an alternative set of thoughts or images that can provide a more neutral focal point for the patient. Often patients feel some relief from expressing pent-up feelings. However, other patients may feel embarrassed or reluctant to try imagery again. This circumstance requires the use of clinical skills in deciding the best approach for each individual.

Sexual arousal can occur from the relaxation and perceived seduction of the setting. If treated matter of factly as similar to other normal intrusive thoughts, this usually resolves on its own (6).

Failure to practice relaxation strategies is by far the most common problem encountered in relaxation training. Clinicians can remind patients of other learning experiences, such as reading or biking, in which practice led to mastery. Discussion of changes in the home environment that would assist practice may also be helpful. Above all, clinicians must insist that practice is an important element of learning and using any relaxation technique successfully.

CONCLUSIONS

R&I techniques—including PMR, AT, deep breathing, imagery, and meditation—can be valuable in the treatment of both acute and chronic pain syndromes. The advantages of R&I include its relative cost-effectiveness and lack of lasting harmful side effects. Although the specific physiologic mechanisms through which R&I reduces pain have not been proven, relaxation reduces muscle tension, quiets the sympathetic nervous system, and provides a cognitive distraction from distress. R&I may also lead to neuroendocrine changes that inhibit pain perception.

For headache and TMD pain, relaxation appears to be the first treatment of choice, with biofeedback instituted for those patients who do not benefit from relaxation. For other chronic conditions, R&I may be as effective as biofeedback or any other packages of cognitive-behavioral skills. Furthermore, R&I is difficult to distinguish from hypnosis either in procedure or in effect. Similarly, with acute pain, R&I is as effective as other cognitive-behavioral approaches that have been studied.

There are no populations that should be excluded from using R&I, except for those with religious or other firm objections. Children and adults are equally adept at benefiting from the methods. Although R&I would rarely be used for painful conditions without considering appropriate medical treatments as well, R&I helps patients to be active participants in their health and should be considered whenever medical care alone is not adequate to alleviate pain.

The number of randomized, controlled clinical trials that demonstrate efficacy of R&I for many types of pain appear adequate to support a conclusion that this is an effective and cost-effective strategy for pain treatment. Challenges are to make this method less dependent on people with highly specialized expertise and to facilitate the incorporation of R&I into routine practice through training of nurses, technicians, and physicians providing front-line care. Other strategies are being tested that would combine video, printed, and audiotaped materials to patients who do not have access to experts or to provide these same types of materials through World Wide Web treatment groups. Matching patients to specific R&I techniques may also improve use. The survival of R&I as a pain strategy to combine with medical treatment may depend on these efforts to make R&I widely accessible. Another decade will tell whether R&I becomes a standard mode of treatment for those with pain or a rarely used relic from the self-help movement of the late twentieth century.

CHAPTER 93

Psychotherapy in the Management of Chronic Pain

Eldon R. Tunks and Harold Merskey

Psychotherapy has been defined as any form of treatment for mental illness, behavioral maladaptations, and other problems assumed to be of an emotional nature in which a therapist deliberately establishes a professional relationship with a patient for the purposes of removing, modifying, or retarding existing symptoms, or attenuating or reversing disturbed patterns of behavior, and of promoting positive personality growth and development (1). The relationship between the therapist and patient is an essential component of psychotherapy and can be summed up as follows (2):

- The doctor or therapist is concerned with the emotional problems of the patient.
- The doctor or therapist is able to relinquish the doctor's traditional controlling role.
- The doctor or therapist has the capacity to reflect on the emotional interaction between the patient and himself or herself and the courage to comment on it to promote insight and change.

The material in this chapter is presented in two major sections: (a) Basic Considerations, including a brief overview of the effectiveness of various psychotherapies, indications for their use with chronic pain patients, and factors influencing their success, and (b) Clinical Applications. The latter section describes and evaluates the main types of psychotherapies used in the management of patients with chronic pain. These include supportive, dynamic, family, and group psychotherapy. More detailed discussion of these and other topics related to psychotherapy and pain can be found elsewhere (3,4 and 5).

BASIC CONSIDERATIONS

Efficacy of Psychotherapy

Although an extensive literature exists concerning psychotherapy, assessing the efficacy of psychotherapy has proven difficult because of the plethora of psychotherapies and theoretical models and variables within psychotherapeutic techniques that are difficult to measure. An extensive review of the methodologic and efficacy issues in psychotherapy noted that the problem of defining and measuring effectiveness in psychotherapy plagues all schools of psychological treatment, whether they be behavioral, dynamic, group, milieu, or any other type (6). What can be demonstrated is that different psychotherapies appear to be effective for different purposes and that psychotherapy is clearly better than no psychotherapy or placebo treatment (6). The most significant problems in evaluating psychotherapeutic efficacy relate to four major issues:

1. Outcome measures are usually not built into the therapeutic technique, with the exception of behavioral and cognitive- behavioral therapies.
2. The treatment relationship is fundamental and not easily quantified, either in its degree of formation or in its impact.
3. Therapeutic outcome often involves subjective variables, including improvement in sense of self, feeling understood, and resolution of previously unresolved conflicts. These are very difficult to measure and even more difficult to compare among patients or therapies.
4. Many therapies, including psychodynamic, supportive, client-centered, interpersonal, family, and group psychotherapies, depend on the formation and exploration of relationships. The psychotherapeutic relationship itself is a process that unfolds between two active participants, in response to the patient's unique circumstances, so that the course of treatment may follow very different patterns from one patient to another. Therapy often occurs over longer periods of time, during which many sources of variance, cointervention, and other supportive professional relationships are likely to affect the outcome. For these reasons, it is difficult to construct adequate scientific designs for research on psychotherapy.

Each of the two major types of psychological treatments—behavioral therapy and insight-oriented psychotherapy—deals with an essential part of the individual. Behavioral therapies focus on an individual's actions, including his or her adaptive and healthy behaviors as well as those that relate to illness and maintain distress. It is reasonable to believe that a change in behavior will affect the experience of self and of illness (see Chapter 89). On the other hand, insight psychotherapy may be preferred by persons who are experiencing subjective distress (e.g., anxiety, depression, insecurity, worry about troubled relationships) and by persons who are more introspective or who perceive themselves as psychologically “ill.” They may wish to explore these feelings, and, at times, may need to work specifically on their understanding of the “origins” of their conflicts, on emotional reactions that they find puzzling, on their place in interpersonal relationships, and on resolution of conflicts, all as springboards to making change.

To help patients in a compassionate way, the therapist must consider behavior, feelings, and thoughts. Therefore, neither the behavioral therapies nor the psychotherapies can stand completely on their own. Each is complementary to the whole business of helping, and, in fact, good psychotherapists and good behavioral therapists resemble each other in the essential attributes that make them effective, whatever their theoretical leaning (7,8 and 9).

Efficacy of Psychotherapies in Management of Chronic Pain

There is abundant literature establishing the efficacy of multimodal pain management programs and of cognitive-behavioral therapy combined with rehabilitation in chronic pain management (10,11,12 and 13) (see Chapter 109). There is far less quality literature on the subject of (nonbehavioral) psychotherapy for chronic pain.

Education for patients (e.g., Back School) remains an important part of most multimodal pain clinics. Numerous controlled studies have examined the efficacy of patient education as a specific modality with respect to reduced pain or improved function. The outcomes of these studies have been combined in several metaanalyses and systematic reviews. Bigos et al. (12) found that educating patients reduced the use of medical resources, reduced apprehensiveness, and sped recovery, but there was no strong evidence on which to judge the efficacy of Back Schools. DiFabio (14) found that multimodal programs including patient education showed the greatest efficacy for treatment of pain and physical impairment and for education and compliance outcomes, whereas Back School alone did not demonstrate significant effect sizes compared with their respective comparison treatments. Cohen et al. (15), in their systematic review, found that of four quality studies of group education for chronic low back pain, only one showed a positive short-term effect in improved pain intensity. Gross et al. (16) found that patient education with or without associated medical or physical therapy for neck pain patients did not significantly alter pain outcomes.

A few studies have attempted to compare various forms of individual psychotherapies with control treatments. Pilowsky and Barrow (17) compared four conditions: amitriptyline plus individual psychotherapy, amitriptyline plus supportive therapy, placebo plus psychotherapy, and placebo plus supportive therapy. Although antidepressant use was associated with reduced time in pain and increased productivity, psychotherapy was associated with increased pain and increased productivity. Another study by Pilowsky et al. (18) comparing amitriptyline and cognitive therapy versus amitriptyline and supportive therapy was statistically inconclusive because of sample size and other design problems, but the impression was that at follow-up the amitriptyline plus cognitive therapy group did better with respect to pain but not in productivity. A controlled study of psychodynamic therapy versus supportive listening for irritable bowel syndrome came to the conclusion that dynamic therapy was superior in terms of pain, abdominal symptoms, and the limiting effect on the patient's life due to bowel symptoms (19). During the year after

treatment, the group receiving psychotherapy had a significantly reduced number of outpatient visits to the gastroenterology clinic compared with the year before treatment.

Although not a study of pain patients, a large study reported by Elkin et al. (20) compared four treatment conditions for depressed patients: interpersonal psychotherapy, cognitive behavioral therapy, imipramine plus clinical management, and placebo plus clinical management. Significant differences were found only for the subgroup who were more severely depressed and functionally impaired. Antidepressant treatment was most effective in the more depressed and functionally impaired patients, and interpersonal therapy and cognitive therapy were similar in efficacy and did better for the less impaired than for the more impaired depressed patients. Given that many chronic pain sufferers also suffer depression and pain sufferers seek psychotherapy because of psychological distress, these results also have relevance for pain patients with depression (see Chapter 26).

Person-centered counseling (a form of supportive psychotherapy pioneered by Carl Rogers) has been studied in the format of a low-intensity telephone-based counseling intervention for patients with systemic lupus erythematosus or rheumatoid arthritis (21). Patients were randomized to usual care or person-centered counseling. At 4 months, systemic lupus erythematosus patients (but not rheumatoid arthritis patients) receiving the counseling had improved significantly more on arthritis impact measurement scale scores representing psychological dysfunction but not on scores of pain, physical disability, or total scores.

Although family or couple intervention for chronic pain patients has been extensively reviewed (22,23 and 24), controlled studies of efficacy are uncommon. The review by Guthrie suggested that couple therapy should be a fruitful avenue to explore in treatment of patients with chronic functional symptoms but that the strength of the evidence is still disappointingly small (25). Saarijarvi et al. (26,27) randomized chronic low back patients to couple therapy or control conditions. At 12 months' follow-up, improved marital communication and psychological distress of male patients were associated with the couple therapy, but the therapy versus control groups were not significantly different in measures of self-reported pain, disability, or use of medical services.

With the exception of multimodal and cognitive behavioral therapies, group therapy for chronic pain has not yet been the subject of controlled studies. There is one possibly relevant study by Kashner et al. (28), in which patients with somatization disorders were randomized to group therapy or to control (no group therapy) conditions. Group therapy patients improved more on measures of physical function and mental health compared with control patients. The more group sessions attended, the greater the benefit in mental and general health measures. The annual health care charges decreased significantly more in the group therapy patients.

Indications for Psychotherapy with Pain Patients

The use of psychotherapy with chronic pain patients must be considered carefully. A psychotherapeutic approach that may be quite suitable and helpful for neurotic outpatients in a psychiatry department may be totally inappropriate and unworkable with patients with chronic pain. One of the special features of pain patients is that they suffer from a subjective state, which has been defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, and often described in terms of such damage (29). Chronic pain is probably the outstanding example of such a subjective condition, which can result from physical causes, psychological causes, or both. In theory, any treatment that might improve the subjective state could be considered for a patient in pain, whatever the initial cause of the illness. In practice, psychotherapy for pain is indicated in the following situations and conditions:

- The patient believes that there is a connection between his or her pain and associated psychological disorder.
  One might assume that psychotherapy would be appropriate when much or all of the pain seems to follow from a psychological disorder and without a major physical contribution. Not many such cases, however, are susceptible to symptom relief through psychotherapy alone. Indeed, patients who suffer pain associated only with somatization usually turn out to be unreceptive to insight-oriented psychotherapy, and many patients with pain due to lesions become emotionally distressed and benefit from psychotherapy.
  However, when the patient believes that there is a connection between the pain and psychological disorder, it usually indicates a readiness to benefit from psychotherapy, regardless of whether there is also a painful lesion.
- Patients who suffer multiple problems of pain and also psychological distress concurrently may benefit more if psychotherapy is added to the treatment program.
  There is clear evidence that chronic pain patients who attend specialty clinics have a higher loading on psychosocial risk factors (e.g., litigation, emotional impairment, poor work history, interference with daily activity by the pain problem, an increased tendency to use health care resources) than others (30,31). In these patients, the medical disorder is not the sole issue; they also have significant problems of dissatisfaction and emotional maladjustment, for which psychotherapy is potentially relevant. Psychotherapy may not provide significant symptomatic relief for the pain itself, but it may aid the individual in adjusting his or her human relationships, improves peace of mind, and often improves treatment adherence. As a result goal achievement and morale improve.
  In many cases of serious depression, antidepressant medication is more effective than psychotherapy, although it often appears that the addition of psychotherapy increases the efficacy of antidepressant therapy, particularly in chronic or resistant depressions (see Chapter 26).
- Patients with prolonged and severe physical illness but without evidence of premorbid predisposition to psychological illness may develop emotional changes in response to suffering. For them, supportive psychotherapy can be a useful part of treatment (see Supportive Psychotherapy).
- For people who suffer psychosocial problems attendant on chronic pain, psychotherapy, behavior therapy, or both may enable them to alter interpersonal relationships and behaviors. When the aim is primarily to change subjective distress related to troubled relationships, conflicts, losses, or a disturbed sense of self, psychotherapy is the treatment of choice.

Factors Affecting Psychotherapeutic Outcome

In psychotherapy for people with chronic pain, the requisites for success include certain nonspecific factors found in any psychologically oriented therapy and other factors that specifically relate to treatment of the chronic pain condition.

General Factors

The general factors essential for success with any type of psychological therapy include the following:

- The therapist and patient must be in therapeutic contact.
- A consistent therapeutic rationale must unite patient and therapist.
- Mutually agreed-on therapeutic goals must be established.
- There is an agreed focus for treatment.
- Structured therapeutic exercises should provide opportunities for new learning.
- There must be active participation by a motivated patient.
- This active participation in the therapeutic exercises promotes successful experiences, leading to a sense of mastery.
- Opportunities for application of the new learning to problem areas are created.
- There is a therapeutic relationship that acts as the context for this process.

For additional discussion of these points, see references 7,8 and 9.

Patient's Readiness for Psychotherapy

This readiness is variously described as “motivation” or “engagement” and consists of the patient's ability to agree on a focus for change, to be able to demonstrate in practice the willingness to make efforts to change, to be open to considering psychological factors, and to be able to demonstrate the acquisition of insight during therapeutic encounters.

Patients need a realistic explanation of what is expected of them during psychotherapy, of the potential benefits to be gained, as well as of the things that may be difficult or require patience. Obviously, the patient must be able participate willingly, without feeling coerced. Informed consent not only protects the patient and therapist alike, but it also promotes adherence and motivation.

Factors Specific to Chronic Pain Patients

In dealing with chronic pain patients, the psychotherapist must be aware of several additional requisites for success:

- The need to consider not only the presenting chief complaint but also the context of the patient's problems, whether at home or at work.
- The need for an extra degree of tolerance for negative attitudes of patients who may not be at first “psychologically minded” or willing to look at the emotional factors in their difficulties.
- A greater need for flexibility in therapeutic methods.
- Recognizing the possible involvement with a multidisciplinary team while appreciating the perspectives and difficulties experienced by colleagues who are not psychiatrists or psychologists, in handling patients who have a combination of physical and psychological disorders.
- Willingness to assume a more active therapeutic stance as teacher and guide, rather than the traditional neutral stance of the psychotherapist.
- Recognizing the need for clearly defined, goal-oriented, and solution-oriented methods in therapy while enlisting the patient actively in defining goals for treatment and for change.

In terms of this last requirement, much can be learned from behaviorists. Their approach involves offering a clearly defined therapeutic program, offering a clear description of how progress will be measured, and placing responsibility on patients for measuring their own progress consistently toward that outcome. These principles, which are central to the behavioral therapies, are not at all inconsistent with dynamic psychotherapies and will be beneficial when included in all types of psychotherapeutic practice.

CLINICAL APPLICATIONS

In this section, we discuss the major psychotherapies that have been used in the clinical management of chronic pain patients. These are supportive, dynamic, family, and group psychotherapy.

Supportive Psychotherapy

The most important and widespread form of psychotherapy—supportive psychotherapy—is knowingly and unknowingly used by specialists in psychological methods and by other health professionals. The trusting relationship with a physician, therapist, or clergyperson is the paradigm of this approach, which extends into every nook and cranny of professional work. One example is the trust that patients develop for their favorite doctor (“My doctor listens and takes the time to explain things”). Another example is the reliance on a social worker for help in filling out an application for benefits, with reassurance and advice, which then leads to attachment to that professional and to the advice provided. At a minimal level, supportive psychotherapy gives a patient the feeling that there is another person who shares the patient's concerns, is sympathetic, and will be happy when the patient feels better or concerned when there are reverses. At the very least, supportive psychotherapy provides companionship for the lonely and empathy for the isolated.

The theoretical basis for supportive psychotherapy emphasizes reality and the possibility and importance of making choices. Notwithstanding pain and adverse circumstances, it is possible for a patient to reduce disability and to increase the sense of well-being by thinking through the problems, setting objectives, drawing on his or her skills, and obtaining aid and advice from others. It assumes that people in distress are more likely to be able to successfully confront their problems in this way if they experience a sense of support from a helper who also assists them in organizing a problem-solving response. Although this theory is not psychologically esoteric and the practice is within the competence of most health care workers, formal psychological training and experience improve one's ability to provide effective supportive therapy. It is a professional activity and much more than mere hand-holding because improved adjustment and not just maintenance of the status quo are expected. Principles to guide effective practice are given below.

Treatment Strategy

The style of the therapist is that of both teacher and “coach.” Sometimes the task is to listen and help patients achieve their own stated goals. At other times it is to provide information and advice. Therapeutic sessions are not rigidly prescribed but are offered while educating patients to be prepared to generate their own objectives. Sessions may last from 0.5 to 1 hour, at intervals of every few days to every few weeks, depending on the patient's need. Termination of therapy depends on several factors, including the end of formal pain clinic treatment, the resolution of certain important psychological or social problems, or the desire to “try it on one's own.”

Supportive psychotherapy should be inherent in the management of every patient in an organized pain therapy program. The provision of a “case manager,” the practice of comprehensive evaluation and discussion in which patients are made to feel that their total situation is being considered, and the development of a confiding relationship with patients all provide a climate of support and encouragement. The most important motivator for change is the opinion and attitude of someone who is respected and liked.

Competent supportive therapy provides more than the incidental benefits of concern, expectation of improvement, and resourceful management of problems. In its complete form, it begins with an assessment of the life situations and problems of the patient and the personality and strengths of the individual; it evaluates the manner in which this individual has in the past characteristically preserved his or her psychological integrity and responsibilities in the face of adversity; and it proceeds according to a clearly defined rationale aimed at restoring that patient's emotional equilibrium. The rationale in supportive psychotherapy is usually to support and facilitate styles of problem solving that previously were successful for the patient and to assist the patient in developing new coping methods where necessary. The primary objectives of supportive psychotherapy are to restore a sense of confidence and to assist the patient in reorganizing coping skills in the most adaptive and psychologically economical fashion.

Formulating a Supportive Psychotherapy Intervention

The following questions will serve as a practical guide to the clinician in conducting supportive therapy:

What is the current problem?

How does the patient describe the chief sources of distress or worry?

What are the current ways that the patient uses to try to cope with (or avoid) these problems?

What are the patient's emotional strengths, problem-solving skills, and resources (family, work, social network) currently available to the patient? Have medical impairments (e.g., head injury, major depression) diminished these strengths?

What needs to change to restore psychological equilibrium?

What previously successful coping patterns did the patient use before this problem occurred?

What main objectives will help to resolve the problem or improve the sense of control?

What are the first priorities in beginning to resolve the problem or in achieving the first measure of control?

What additional external or psychotherapeutic support, structure, or assistance will be needed to help the patient to do these things?

What is the “game plan” to work through this problem?

How can one establish a confiding and encouraging relationship in which the patient can discuss worries, attitudes, and progress?

What are the frequency and duration of meetings, and how should “emergencies” be handled?

What “road map” will guide the patient in setting priorities, organizing solutions, and working through the problems, day by day, in a way that the patient will perceive

as successful and not overwhelming?

How will this work be brought to completion?

What has the patient learned, and what skills have been developed?

How will the patient make the transition from relying on the therapist to developing his or her own support system?

Has the patient had an adequate chance to “say good-bye,” to avoid feelings of being abandoned or rejected?

Dynamic Psychotherapy

As with supportive psychotherapy, in dynamic psychotherapy, the relationship is seen as being the most crucial factor. It is the relationship with the therapist that provides a context for the corrective emotional experience. The theory for dynamic psychotherapy is more complex, is based on concepts drawn from various original psychoanalytic frameworks, and involves the reorganization of thoughts and feelings through insights gained in the psychotherapeutic relationship. Psychodynamic approaches assume that the patient's inner conscious and unconscious thoughts, conflicts, and defenses are determinants of behavior and adjustment. Some central concepts of dynamic psychotherapy include the following:

- Certain properties of the mind, such as drive, need for mastery, conscience, and sense of self, are subject to modification by “making the unconscious conscious”—that is, by gaining insight.
- Each individual acquires by experiences during maturation a repertoire of patterns of feeling, believing, and behaving. These patterns are fundamental to both healthy (adaptive) and also to neurotic (maladaptive) styles of adjustment and eventually characterize an individual's personality.
- Current patterns of feeling and behaving in response to ongoing problems reflect solutions to problems that the individual has learned in the past in the course of previous relationships.
- Psychological equilibrium depends on having the psychological energy and mental strategies to maintain stability and to control negative feelings and conflicts. This can be improved through a therapeutic relationship with a psychotherapist.

Further descriptions of the psychodynamic perspective with respect to chronic pain can be found elsewhere (4,5,32,33 and 34).

Dynamic psychotherapy alone is not an appropriate treatment for the majority of chronic pain sufferers, although one might get that impression from some classic papers that deal with pain from a psychodynamic viewpoint (32,33). Psychodynamic therapy, however, is likely to be beneficial, especially in the subjective aspects of adjustment, when combined with other appropriate pain management modalities (35). Patients for whom dynamic psychotherapy is preferred usually (a) suffer a sense of psychological discomfort, (b) experience distress with regard to their key relationships, (c) perceive themselves as having changed for the worse, (d) may be perplexed by their own impulses or feelings, (e) experience difficulties because they perpetuate in their current relationships conflicts that they previously experienced with significant others during their maturation, (f) or demonstrate barriers (“resistance”) to therapeutic progress because of hidden motives about which they lack insight.

Treatment Strategy

With chronic pain patients, dynamic psychotherapy is often, but not always, short term—perhaps five to 20 sessions—and is focused on a few specific psychological issues (although patients sometimes may prefer a much more thorough exploration of issues that trouble their lives). Sessions are usually an hour long and are held at regular intervals. Sessions could be as often as twice per week, but weekly or semimonthly sessions are most common. In the majority of cases, this method of psychotherapy is one of several approaches that are offered concurrently, including even other psychological therapies. Dynamic psychotherapy is not, for example, incompatible with behavior therapies, vocational counseling, or medical treatments for pain.

Although dynamic psychotherapy explores hidden feelings and motives, it is unlikely that this therapy would lead to finding a purely “psychological cause” for chronic pain. The real benefits are an improved sense of self, reduced feelings of perplexity or conflict about one's own feelings or impulses, and a more comfortable (less distorted) relationship with significant others. All of this can be very helpful toward an individual's ability to cope with persistent pain. Dynamic psychotherapy requires specific training and is usually conducted by psychologists or psychiatrists.

Family Therapy

Chronic pain is such a disruptive problem that it is prone to affect a patient's family and not just the pain sufferer. Accordingly, it is prudent to involve family members right from the beginning in pain treatment programs. In some cases, psychotherapy of the marital or family unit is indicated as part of chronic pain management because of the influence of the family on the chronic pain disability. The importance of the family perspective in chronic pain has been discussed in other reports (4,22,23 and 24).

The intent of family therapy is not merely to search for conflict (as some families initially fear) but rather to consider both the assets and liabilities in a family's function, in an effort to help the family organize its communication and problem solving in the most satisfactory way.

Some family factors are especially important in cases of chronic pain. These include the role of family members as agents of pain behavior reinforcement (36,37), the value placed by the family on illness-related communications, and the degree of stability with which the family has absorbed the sick role (38).

Common indications for family therapy might include one or more of the following:

- Illness in a family member results in disturbances in family function.
- There is reason to believe that family dynamics may contribute to or perpetuate the patient's problem.
- The family is overwhelmed by multiple problems, in addition to having a member with chronic pain.
- The identified patient is a child.
- There are indications that the family is sufficiently motivated for a family therapy approach.
- The family can be mobilized therapeutically to influence the pain behavior or disability.

Treatment Strategy

Whereas dynamic psychotherapy focuses on psychodynamic factors and formative past experiences in understanding the present, family therapy is oriented to the here-and-now, considers the whole family as “the patient,” and concentrates on communication more than on introspection. In addition, the therapist takes an active stance in style of interventions. Family therapy takes place over a fewer number of sessions than dynamic psychotherapy, focuses on group and communication dynamics, and is more intensive in demands on both patients and therapist. A course of family therapy with chronic pain patients commonly consists of three to 20 sessions, but five or six sessions probably is most typical.

Group Therapy

Numerous types of group therapies have been used in chronic pain management, including educational groups (e.g., Back School), marital couples' groups, therapeutic milieu (on an admission ward), groups aimed at teaching special skills such as relaxation or assertiveness, and cognitive-behavioral groups in pain clinics. Discussions of group approaches for chronic pain patients have been published elsewhere (4,39,40). Among the important advantages of group therapy are that it provides the following:

- Group therapy economizes therapist time by allowing several patients to be treated simultaneously.
- Group therapy allows for the therapeutic influence of one patient on another, including vicarious learning and the motivating effect of shared goals.
- Group therapy permits certain conflicts and problems to be played out in a “safe environment,” avoiding destructive consequences and permitting learning of

more adaptive responses.
- The peer group has the potential of causing patients to feel supported and understood.
- The group permits a forum for an educational component of therapy.

The theoretical rationale of this approach is that people recreate their interpersonal conflicts and demonstrate their assumptions when they are in the context of a group. The group has a modulating effect on the behavior of each member, which the therapist can influence therapeutically.

Group Techniques for Chronic Pain Patients

The published evidence does not support the efficacy of group or education approaches used in isolation in treatment of chronic pain (12,13,14,15 and 16). This does not mean that group approaches are of no avail, but it indicates that group approaches should be used in conjunction with other modalities or comprehensive pain management.

The common reasons for including pain patients in group therapy are to provide a vehicle for the educative component of pain management, to increase patients' awareness of key psychological factors in their problems and treatment, to promote informed and motivated participation, especially in the case of comprehensive or inpatient pain management programs, and to provide a “normalizing” effect of a peer group and modeling of healthier ways of coping.

The educational component can be geared to providing accurate information about pain management, teaching coping strategies through example and role-playing and by sharing of experiences between patients, improving appropriate assertiveness, practicing coping skills, improving communication skills, reducing the sense of isolation, and providing social reinforcement of healthier behavior (40).

Treatment Strategy

The following are general guidelines for conducting group therapy with chronic pain patients:

- To be effective and manageable, a group should consist of at least four and not more than approximately 12 members.
- Psychiatric patients and chronic pain patients should not be included in the same group.
- Patients should be interviewed before their inclusion in the group to ensure that there is adequate motivation for the group and that the patients have realistic expectations regarding the time commitment, their active participation, the readiness for the “give-and- take” that will likely occur in the group discussions, and the likely benefits that will accrue.
- Patients who are paranoid or suspicious (using “projection”), who have florid “borderline traits” (e.g., self-injury, dissociation, and distortion), or who have antisocial traits should not be included in group therapy.
- The group should be structured to be relevant to the problems of chronic pain patients. In group therapy with psychiatric patients, it might be acceptable for the therapist to give little information beyond the initial introduction and to concentrate instead on group dynamics as they appear spontaneously. In pain clinic practice, however, a didactic component usually is necessary to resolve misconceptions and fears about pain and to deal with practical issues related to living with chronic pain. Coping techniques for pain control (e.g., relaxation, cognitive techniques such as imagery or self-talk for pain control) are often helpful and may be included in some sessions (see Chapter 89).
- An explicit set of norms is expected. These typically include not abusing medication or alcohol, being on time, not skipping sessions, minimizing illness behavior, keeping therapy “in the room,” and not imposing on copatients between sessions. Patients who later on prove disruptive to the group, who are not respectful of the needs of other group members, and who are not able to change their behavior after accurate feedback from the group should not be allowed to continue.
- When group therapy is part of a multimodal pain management program, opportunities should be provided for group discussion of emotional and adjustment issues that arise in the course of the rest of the pain management program.
- Care must be taken to accommodate for the fact that some pain patients have limited sitting tolerance. Hence, sessions should not last more than 1 hour, and opportunities to change position or find a comfortable chair should be afforded. However, therapists should not tolerate dramatic illness behavior such as lying on the floor or groaning, avoiding group participation through dramatic pain behavior, or leaving the room.

Pain management programs (day care or inpatient) typically have daily group sessions for the duration of the treatment program, often 3 to 8 weeks (see Chapter 109). Outpatient program groups may meet less frequently but over a longer duration.

CONCLUSIONS

The psychological dimension is always important in cases of chronic pain; however, no one psychological method can possibly address the full spectrum of therapeutic need. A variety of psychotherapeutic methods ought to be available as an integral component of the pain management effort. A flexible approach, drawing on supportive psychotherapy; education methods; cognitive- behavioral techniques; and occasionally specialized methods, such as dynamic, family, and group therapies, will permit each patient's needs to be addressed appropriately. Various psychological pain management techniques are presented in the other chapters of this section.

CHAPTER 94

Motivating the Pain Patient for Behavioral Change

Mark P. Jensen

Chronic pain rehabilitation, in contrast to cure, requires active patient involvement. After being evaluated by a pain clinician, chronic pain patients may be asked to increase, decrease, or maintain specific medications; initiate and maintain a program of regular exercise and activity; develop a plan for return to work; or learn and then regularly use specific pain management skills, such as relaxation or cognitive restructuring. Because so much of chronic pain rehabilitation depends on patient effort (self-management), patient motivation plays a vital role in chronic pain treatment.

When the clinician and patient agree on a course of treatment and the patient evidences a willingness to participate fully in this treatment, issues of patient motivation fade into the background. Treatment can proceed and both the patient and clinician can determine its effectiveness. However, problems arise when the clinician and the patient disagree on which intervention(s) to try next. For example, patients may hope for or expect “pain killers” or a surgery that will eliminate their pain, despite a clinician's reservations about either of these treatment options. Clinicians may believe that a course of active physical therapy or the development of a return-to-work plan will benefit the patient, whereas patients may not feel ready for either of these options “until the pain is taken care of.”

When clinicians and patients disagree about treatment, what can the clinician do? One option is to refuse to treat the patient and refer the patient back to his or her primary care provider or to another specialist. In this case, the patient misses an opportunity to try a treatment that the clinician believes will reduce the patient's pain and suffering. A second option is to insist that the patient try the recommended intervention despite the patient's reservations and resistance: “You must try this, it is your only option left.” This approach might work for some patients, especially when the treatment does not require sustained patient effort and is perceived as immediately helpful. Unfortunately, there are few chronic pain treatments that both (a) do not require sustained patient effort and (b) have immediate benefits (although the search for such a “magic bullet” goes on). A third option, and one that this chapter advocates, is for the clinician to spend time enlisting patient's motivation for and commitment to a treatment plan *before* offering treatment and then reinforcing and attending to motivation as treatment progresses.

This chapter is written for clinicians interested in learning more about this third option. The material is based largely on a set of therapeutic strategies developed by William Miller and his colleagues (1,2) that were designed to help individuals change addictive behaviors, and the interested reader is encouraged to read these sources for more detailed information about the motivational strategies described here.

The chapter has two major sections. In the first section, three key concepts underlying the use of motivational strategies are outlined. The second section reviews several specific clinician responses that (a) enhance patient motivation to consider new treatment approaches, (b) strengthen a commitment to a treatment plan, and (c) encourage continued participation in treatment and maintenance of any lifestyle changes made. Whenever possible, the discussions focus on how these concepts and strategies can be applied to behavior change, which is central to chronic pain rehabilitation.

KEY CONCEPTS OF MOTIVATIONAL STRATEGIES

For the pain clinician, three concepts about motivational approaches are especially important to understand. These include (a) viewing motivation as a probability of behavior change that can fluctuate considerably over time, (b) understanding the importance of the clinician's role for facilitating motivation to change, and (c) understanding behavior change as a multistage process. Each of these concepts is discussed in turn.

Motivation as a Probability

Traditionally, most clinicians have viewed motivation as something residing inside the patient. Lack of behavior change, or resistance to recommended treatment approaches, has been seen as an indication of a patient deficit in motivation: “This patient must not really want to get better if he or she refuses to accept my treatment plan.” An alternative view, and one that provides more hope that clinicians can influence patient motivation, is that motivation is “the probability that a person will enter into, continue, and adhere to a specific change strategy” (1). In this view, the probability that the patient will accept and adhere to treatment recommendations (e.g., “motivation”) depends, in large part, on the atmosphere in which treatment recommendations are made.

Creating an Atmosphere for Change

Pain clinicians sometimes take on the role of an expert to whom patients go to seek advice. In this role, the clinician, usually after a careful evaluation, gives the patient feedback and recommendations. The recommendations may include an offer of treatment (e.g., medication management, supervision of physical therapy, cognitive-behavioral therapy, skills training). The patient, in the role of a health care seeker, is expected to agree with the expert and then to follow through with the recommendations. As already discussed, this interaction often works when the patient agrees that the clinician's recommendations are sound and consistent with the patient's view of his or her pain. However, these roles work less well when the patient does not see how the treatment will help or believes that the treatment will make things worse. In this case the patient may feel that the evaluation was incomplete, that the clinician “did not listen to” or “does not understand” him or her, or that the clinician is incompetent. This can then create an adversarial relationship in which the clinician becomes frustrated with the patient for not accepting and following through with the treatment recommendations and the patient becomes frustrated with the clinician for his or her insensitivity or withholding a desired treatment that the patient believes could end his or her suffering. This scenario is not uncommon in chronic pain patient-clinician relationships.

An environment more conducive to change is one that recognizes patients' experiences, opinions, and feelings and communicates that recognition to the patient. Clinician responses that contribute to this environment differ markedly from the responses that would be expected from the traditional authoritative physician. They include, for example, asking open-ended questions, listening reflectively, affirming the patient, and summarizing (Table 94-1). The goal of these clinician responses is to create an atmosphere of trust and cooperation that helps set the stage for behavior change.

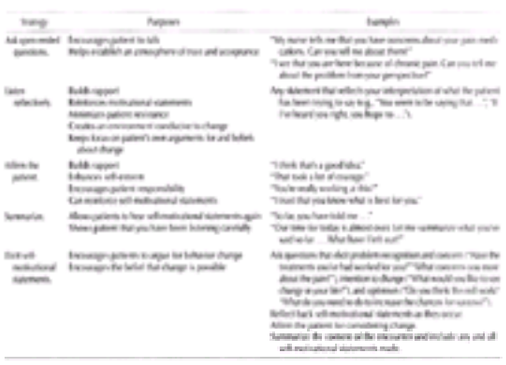

TABLE 94-1. Five strategies that enhance motivation to change

Rather than acting as an authority whose primary job it is to develop a list of treatment recommendations (at least in the initial encounter), motivational clinicians present themselves as coaches or teachers knowledgeable in a variety of pain self-management approaches. Clinicians concerned about motivation spend more time listening than they do talking, and much of what they say represents attempts to clarify and understand the patient's position. As described below, recommendations and advice, when made, are brief and are presented only when the patient has indicated a willingness to consider alternative approaches. Moreover, whenever possible, treatment recommendations are presented in the form of a "menu" of choices. A behavior change plan unique to the patient's own problem and situation is created in cooperation with the patient.

Although clinician responses that create an atmosphere of trust and cooperation help set the stage for behavior change, they would be ineffective without more specific responses that focus the patient's attention to the desirability of behavior change. Before these more specific responses can be described, a final concept needs to be explained: the concept of behavior change as a multistage process.

Behavior Change as a Multistage Process

Chronic pain patients usually see pain specialists because the strategies the patient is currently using to manage pain are not working. Although the patient may hope that the clinician will "find and fix" the problem, pain management ultimately depends more on what the patient does than on what is done to the patient. The primary purpose of motivational strategies is to increase the probability that the patient will engage in adaptive behavior change in the (near) future. That is, they will begin and fully participate in a specific treatment or try a new pain management approach. In order to facilitate this change, clinicians need to understand how change comes about. The most thorough model for behavior change has been developed by Prochaska and DiClemente (3), who have studied, in detail, the process of change from maladaptive (e.g., smoking) to adaptive (e.g., not smoking) health behaviors.

According to the model that Prochaska and DiClemente developed, adaptive behavior change involves five stages (Table 94-2). People who are not considering changing their behavior are in the *precontemplation* stage. Precontemplators see no need to change. They will show resistance when and if they feel coerced into changing some behavior that they do not view as a problem. Although precontemplator pain patients may suffer because of maladaptive coping strategies, they do not necessarily attribute their suffering to these maladaptive responses. Often, they blame their suffering on the pain itself. They may even view maladaptive responses (e.g., pain-contingent medication use and inactivity) as the "only" things that help. *Contemplation* is a stage in which a person acknowledges a need for change and may be considering making some change in the future. However, contemplators are not yet committed to change; they are in a constant state of weighing the pros and cons of altering their behavior. Contemplators might acknowledge that maladaptive coping responses create problems (e.g., side effects from medications, weakness, or perhaps even increased pain from inactivity) but may not see any other options for managing their pain. *Preparation* (also known as the *decision-making* or *determination* stage) involves both intent to make changes and taking some initial steps in the direction of change. Pain patients in the preparation stage express a willingness to try or learn a new approach to self-management of pain and problems associated with pain. Patients in the process of changing their behavior are in the *action* stage. Patients in the fifth stage, called *maintenance*, are making efforts to sustain the changes made in the action stage. Those unable to maintain the changes they have made are said to have relapsed. From this point, they may reenter the change cycle at any point (e.g., give up and become precontemplators or start right back in again at the action stage). People may, and often do, cycle through these stages several times before any change becomes permanent.

Stage	Description
Precontemplation	Patient sees no need to change current behavior.
	Patient will show resistance when asked or advised to change.
Contemplation	Patient feels ambivalent about change.
	Patient can identify both pros and cons of change.
Preparation	Patient has made the decision to try to change.
	Patient has made initial steps toward change.
Action	Patient is in the process of making concrete changes.
Maintenance	Patient is maintaining changes made in the action stage.

TABLE 94-2. Five stages of behavior change

There are some important characteristics about this stage model of change that influence how a clinician might think about and intervene with patients engaging in maladaptive pain coping behaviors, such as pain-contingent medication use, pain-contingent rest, or inactivity. First, the model predicts that people in different change stages should react differently to treatment, as a function of their change stage. For example, people in the preparation and action stages should be more likely than people in the precontemplation stage to benefit from treatments that require effort. Research supports this prediction, for both smoking cessation (4,5) and weight control treatment programs (6). One implication of this is *that not all patients are ready for treatments that require their own effort.* In fact, as described in more detail below, this model indicates that patients in different stages require different clinician responses to facilitate movement toward change.

SPECIFIC MOTIVATIONAL STRATEGIES

Given this background, we can now turn to the specific strategies that clinicians may use to create an atmosphere of change and develop a self-management plan that the patient can understand and accept. Motivational strategies can be organized into three types: those that generally enhance motivation for change and that should therefore be used for patients who are in the precontemplation or contemplation stages, those that strengthen the commitment for change and should be used in the preparation and action stages, and those that follow up on any treatment plan developed and that encourage maintenance of any changes made (1,2).

Strategies that Enhance Motivation for Behavior Change

Miller et al. (2) describe five specific strategies that can be used with patients in the precontemplation and contemplation stages to help guide them toward preparation and action. The first four, asking open-ended questions, listening reflectively, affirming the patient, and summarizing the interaction, all build rapport and contribute to an atmosphere for change. The fifth strategy, eliciting self-motivation statements, is unique to motivational approaches, and seeks to (a) support the patient's belief that change is possible and (b) encourage the patient to come up with his or her own reasons for change. Each of these strategies is described below and listed in Table 94-1.

Ask Open-Ended Questions

Open-ended questions are those that tend to elicit patients' concerns, ideas, and feelings. As such, they are an excellent strategy early in an encounter when the clinician seeks information about the patient's relationship with and commitment to the problem behavior. A good open-ended question is difficult to respond to with just a "yes" or "no." By encouraging the patient to express the problem in his or her own words, open-ended questions demonstrate that the clinician is interested in the patient's perspective on the problem. Two examples of open-ended questions are presented in Table 94-1.

In many cases, clinicians are limited to brief (e.g., 5- to 10-minute) encounters. Busy clinicians may therefore be concerned that asking open-ended questions would open a Pandora's box of (time-consuming) complaints, thereby turning a 10-minute encounter into an hour-long session. Some patients do require significant structure and limit setting to ensure that brief encounters remain brief. However, paradoxically, by initially giving patients a chance to air their primary concerns, patients may be more cooperative with the physician, increasing the efficiency of the encounter. Once patients feel heard they will feel less of a need to talk. They will also feel more understood and satisfied with the encounter. Moreover, knowledge of the patient's perspective of the problem may be helpful to enlist cooperation from the

patient for making the encounter even more efficient. For example, if time is starting to run out, the physician can say, “I'm sorry, but only 10 minutes were scheduled for your appointment today. To make sure we address [the important issue you raised earlier], I will need to ask you several questions and then discuss some treatment options with you. Is this alright, or would you rather make another appointment to do this?” The key here is not to use open-ended questions to encourage the patient to ramble for hours about anything that comes to the patient's mind. Rather, the clinician seeks to encourage the patient to communicate the primary problem(s) that need addressing from the patient's own perspective. Beginning the encounter with an open-ended question is an effective way for doing this.

Listen Reflectively

Reflective, or empathic, listening, as originally described by Rogers (7,8), provides a therapeutic environment that makes it easier for patients to consider making difficult behavior changes. This therapeutic strategy involves listening carefully to the patient and then reflecting back accurately what the patient has said. Reflective listening also acts to minimize patient resistance because it is more difficult to argue with someone seeking to understand you than with someone who is challenging you or lecturing you. Furthermore, and consistent with the goal of encouraging patients to convince themselves to engage in adaptive behaviors (see below), reflective listening keeps the patient talking and therefore increases the chances that the patient will say something that argues for behavior change.

Given the high volume of both verbal and nonverbal communication that can occur with every patient phrase, the clinician cannot hope to accurately reflect *everything* a patient says. Through careful selection of what to reflect back to the patient, reflective listening also may be used to emphasize and reinforce self-motivational statements (discussed further under Elicit Self-Motivational Statements).

Affirm the Patient

The clinician focusing on motivation seeks to affirm the patient at every opportunity. Affirmations, in the form of direct compliments and praise, are thought to provide a more positive environment for change by increasing rapport, enhancing patient self- esteem, encouraging patient responsibility, and reinforcing patient self-motivational statements (2). Affirming statements may be contrasted with reflective statements in that the former are sincere expressions of the *clinician's* positive responses to the patient (e.g., “I admire your courage”), whereas the latter consist of efforts to reflect the *patient's* concerns (e.g., “You really seem to be upset by this”).

Summarize

Toward the end of every patient encounter, even if that encounter was very brief, it is important to set aside a moment to summarize the basic content of the interaction. A summary serves an important opportunity for allowing patients to hear, yet again, any self-motivational statements they made during the encounter. However, it is also important to incorporate any concerns that the patient may have raised that indicate ambivalence about making a behavior change. This shows the patient that the clinician really listened.

A summary need not be lengthy. For example, after a 5-minute encounter that involved a patient's request for pain-contingent medications and a clinician's conclusion that complying with this request would not be helpful to the patient, the clinician could say

> “Even though we did not have much time to discuss treatment options for your pain, I think I have an initial understanding of the problem. You came today hoping that I would prescribe medications that you could take when you hurt as a way to ease the pain. I expressed some of my reservations about this approach. For example, despite using these in the past, you told me that the pain problem is not any better and in fact may be worse. You also expressed some worry about the effects of these medications on your concentration. I have found that patients do much better when they combine a taper of these medications with a regular exercise program. This is something that you seem willing to consider, although you still have some questions about how helpful this will be for you. Unfortunately, we did not have enough time today to address all your questions about this approach, and we agreed that I would see you again next week to discuss this option further.”

Elicit Self-Motivational Statements

Perhaps what sets the motivational strategies apart from other therapeutic approaches is the extent to which self-motivational statements are encouraged and reflected back to the patient. Self-motivational statements may be defined as arguments for behavior change (e.g., “It's time I did something about this”; “Okay, I'm ready to try something new”; “I can't go on like this anymore”). The strategies of asking open-ended questions, listening reflectively, affirming the patient, and summarizing, although basic to creating an atmosphere for change, would not effectively encourage change without a focus on eliciting self-motivational statements specifically.

The first step is to recognize self-motivational statements when they occur. Miller and Rollnick (1) describe four categories of self-motivational statements. Problem recognition statements indicate that the patient sees the problem behavior as having negative consequences (”I have gained weight mostly because of inactivity due to pain”; “Those pain killers make it so I can't work; you can't drive a truck and take those”). Expressions of concern indicate that the patient is upset or worried about his or her current situation (”I'm afraid I'm never going to get better”). Intention-to-change statements express an intention to make some change for the better or describe initial steps toward change (”I know I have to exercise”). Finally, statements that reflect optimism indicate that the patient believes he or she can be successful in making a positive change (”I think that if I take things a step at a time, I will be able to do this”). A primary goal of the clinician interested in a patient's motivation is to ask questions and make comments that elicit motivational statements like these and then (a) affirm the patient for making such statements (”That's a really good point; not all the people I work with recognize that”), (b) reflect these statements back throughout the interaction (e.g., during the session, “So you feel that . . .”), and (c) summarize them at least a third time at the end of the session.

Summary of Preliminary Strategies

The goal of the initial motivational strategies is to enhance motivation for behavior change—that is, to encourage movement from precontemplation to contemplation, and from contemplation to preparation. The strategies of asking open-ended questions, listening reflectively, affirming the patient, and summarizing all can be used to elicit and reinforce self-motivational statements. In this way, the clinician creates an environment in which the patient talks himself or herself into making positive behavior change. The assumption of this approach, supported by social science research, is that change will occur more rapidly when and if patients convince themselves that change is both necessary and possible than when clinicians try to convince patients of these things (9,10). These initial strategies should be used with precontemplators and contemplators until they enter, or are about to enter, the preparation and action stages. Rapid progression (e.g., within minutes) toward the preparation or action stages, as indicated by frequent self-motivational statements, suggests that the patient may be prepared to take action. At this point, the clinician should be ready to shift to the next set of strategies that strengthen commitment for behavior change. Slower progress suggests precontemplation and indicates that more time may be needed to enhance and build motivation for behavior change before the development of a treatment plan.

Strategies That Strengthen Commitment for Behavior Change

The timing of the switch from strategies that enhance or build motivation to change to strategies that elicit and strengthen a commitment to change is important. If the clinician switches strategies too early, the patient is likely to evidence resistance and progression to the action stage will be hindered. Fitting the motivational strategy to the patient, based on the stage of change, is essential to effective motivational enhancement. Six strategies that strengthen commitment to behavior change are listed in Table 94-3 and include the following: review of the consequences of behavior change, give advice, communicate free choice, develop a change plan, summarize, and ask for a commitment.

Strategy	Purposes	Examples
Review consequences of change.	Reminds patient that change has pros and cons. Allows patient to reinvent himself or herself of the reasons for changing.	"What do you think will happen if you were to . . . ?" "What are some of the benefits of changing?" "What are some of the costs of changing?"
Give advice.	Provides options. Influences action.	"I think you should . . . Does this make sense to you in your situation?" "Here are some options I think you should consider. Which of these makes the most sense to you?"
Communicate free choice.	Emphasizes that it is the patient's responsibility to decide on a plan. Encourages patient responsibility.	"How would you like to proceed?" "There are several ways we could go from here. What do you think?"
Develop a change plan.	Clarifies goals and change strategy. Fosters commitment to change.	"What, exactly, would you like to do at this point?" Consider using the change plan worksheet (see Fig. 94-1).
Summarize.	Allows patients to hear self-motivational statements again. Allows patients to hear and reaffirm change plan.	"Your major goals with this plan are to . . . and this will allow you to . . . Do I have that right?" "Let's review your plan to be sure I understand what you intended to do."
Ask for a commitment.	Clarifies patient's intent. Clarifies what patient is planning to do.	"Are you ready to commit yourself to doing this?"

TABLE 94-3. Six strategies that strengthen commitment to change

Review Consequences of Behavior Change

One effective way to strengthen commitment to change is to review with the patient the consequences of making the change versus not making the change. Most likely, the patient will realize that not making any changes means life as before. Such a life is unsatisfactory for many patients. An approach that elicits consequences of change is to ask the patient to review both the pros and cons of changing. More likely than not, much information about this would have already been reviewed earlier in the encounter or in previous encounters when self-motivational statements were elicited and discussed in detail with the patient. Patients may choose to list in two columns on a piece of paper the benefits and costs (or pros and cons) of different options. Such lists, as long as the contents are generated by patients and not "fed" to them by the clinician, and assuming that the benefits of behavior change outweigh the costs, should help strengthen the patient's motivation to change or maintain a behavior change plan.

For example, regular exercise should result in the patient's being more able to participate in activities that are important to him or her, such as child rearing, recreational activities, shopping, and household chores. On the other hand, documented improvement may lead to claim closure if a claims manager concludes that the patient now has enough strength and endurance to return to work. Both the positive and negative consequences of successful treatment should be acknowledged and discussed. However, as much as possible, discussions about the current and future *benefits* of the treatment plan should be emphasized and reiterated to enhance motivation before treatment and maintain motivation during treatment.

Give Advice

As patients with pain problems reach the preparation stage, they may ask for specific information and advice concerning how to proceed. One way to respond is to provide information based on personal experience or research and then ask a follow-up question concerning what the patient wishes to do. Whenever possible, offer a number of possible suggestions (a "menu") from which the patient might choose. This helps emphasize that it is the patient's responsibility to decide what specifically to do.

Giving advice can help increase motivation. However, some resistance to giving advice on the clinician's part may help to ensure that the patient is interested in hearing what is being suggested and not seeking to hear information with which he or she can argue. For example, a clinician might say, "I can tell you what I think might be best in your situation based on my experience with people who have problems like yours. However, I also believe that each person is different and that what is best for one person may not necessarily be best for another. That is why any decision about what you will do has to be up to you. I am here to support you in the development of a plan that *you* are interested in trying."

If the patient expresses the desire to know what you think might be best for him or her, especially after you communicate some resistance to providing advice, then short and clear advice statements are best (e.g., "I think you should maintain a regular exercise program"; or "I think you should give relaxation a trial. You might practice relaxation strategies 30 minutes a day for 1 month and then decide whether to continue."). In general, it is always a good idea to follow up any information and advice with questions that gauge the patient's response (e.g., "Does this make sense to you?" or "Do you have any questions about what I said?"). Such questions help to emphasize that it is the patient's responsibility to make a final decision as to what he or she is going to do next.

Communicate Free Choice

To maximize self-motivation and to facilitate the attribution of control to the patient, the clinician should provide frequent reminders of the patient's free choice in all aspects of his or her change plan. This can be difficult for some established pain treatment protocols that are not as successful when patients "pick and choose" which aspect and how much of the treatment they will do on any particular day. For example, in quota-based (i.e., non–pain-contingent as opposed to pain-contingent) reactivation programs, patients are asked to exercise to a specific and gradually increasing level (e.g., 10 minutes of aerobics or 12 partial sit-ups) every day no matter how good or bad the patient feels (11). Similarly, drug-tapering schedules are usually established ahead of time, and success is believed to depend in large part on patient adherence to the agreed-on tapering schedule. For treatments such as these that require a patient commitment to participating in the "whole" program, it is important to communicate the rationale behind the expectations and limitations of participation before offering the treatment to the patient. The patient's choice then becomes to participate or not participate in the treatment based on the established rules or requirements. However, to maximize motivation, it is important to provide as many treatment options for the patient as possible. Offering only a standard treatment plan for all patients would limit success. For example, in a quota-based exercise program, some choice can be provided regarding specific exercises ("Which activities are most important for you to become more able to tolerate?") or even the rate of increase ("If we go too slow, it may take too long to get where you need to be to feel better and do what you want to do. On the other hand, if we go too fast, meeting your quotas may be a challenge. Usually patients I see on an outpatient basis increase approximately 10% per week. What is most important is that you do increase a specific amount every week no matter how good or bad you feel. What rate of increase do you think makes sense for you given your goal of . . . ?").

Develop a Plan for Change

A primary goal of working with a patient in the preparation stage is to develop a behavior change plan to which patient can commit. Readiness to develop a plan may be initiated by the patient (e.g., "I'd like to get started on that exercise program we've been talking about"). It can also be effective for clinicians to raise the issue of plan development.

One strategy that the clinician might find useful to assist in the development of a plan for change is through the use of a change plan worksheet (CPW). This sheet can provide a structure for organizing the most important aspects of the patient's goals and reasons for making changes. It also provides the structure that may be used to develop a behavior change plan. The six questions addressed on the CPW are presented in Figure 94-1.

Change Plan Worksheet

The changes I want to make are: Date: _____

The most important reasons why I want to make these changes are:

The steps I plan to take in changing are:

The ways other people can help me are:
Person — Possible ways to help

I will know that my plan is working if:

Some things that could interfere with my plan are:

_____
Patient's Signature

Figure 94-1. Change plan worksheet. [Adapted from Miller WR, Zweben A, DiClemente CC, et al. *Motivational enhancement therapy manual: a clinical research guide*

for therapists treating individuals with alcohol abuse and dependence. (DHHS publication No. ADM 92-1894.) Rockville, MD: U.S. Government Printing Office, 1992.]

1. *"The changes I want to make are . . ."* Clear goals are important to effective behavior change plans. The goals should be identified by the patient as important. However, among individuals suffering from chronic benign pain, it would be wise to avoid listing "decrease pain" as a *primary* goal for several reasons. Although many patients identify this as a primary goal at the beginning of treatment, few adaptive behaviors that are in the patient's control have been shown to have a profound influence on chronic pain intensity in the short run. Moreover, two responses to pain that are thought by many clinicians to be maladaptive (pain-contingent use of opioid or sedative medications and pain-contingent rest) often have the short-term effect of decreasing pain experience. Thus, a primary goal of decreased pain, placed in a prominent position on the CPW, may actually work against long-term positive adaptation. Patients who insist on keeping pain reduction on the CPW (some may, and it is important to respect their ultimate choice) may be willing to consider "minimization of pain in the long run" as one of several goals. To the extent that the patient can identify goals over which he or she has some direct control (exercise, taking medications on a time-contingent bases and as prescribed, practicing adaptive pain coping strategies), there are more chances for success.
2. "*The most important reasons I want to make these changes are . . ."* Here is where the clinician or the patient can list the patient's review of the pros and cons of behavior change versus no behavior change. Be sure to emphasize those reasons for behavior change deemed most important to the patient. For example, some patients may want to exercise to have more endurance for playing with their grandchildren. Others may want to return to a particular job that requires a specific level of strength and endurance. Still others may be most motivated by a desire to lose weight. Identifying, discussing, and documenting how treatment adherence will make it more possible that the patient's own goals will be met will help enhance motivation.
3. "*The steps I plan to take in changing are . . ."* Under this heading, the ideas the patient has for making specific changes can be listed. Ideas initiated by the clinician may be included if the patient has endorsed these as his or her own. The more specific these plans are, the more helpful this section of the CPW will be to the patient. For example, stating "I will walk at a brisk pace for 2 minutes every day this week and increase by 2 minutes every week until I reach 20 minutes per day" is better than "I will try to walk some every day and try to do more each week." "I will practice relaxation every day for 1 hour for 1 month" is better than "I will try to relax more."
4. "*The ways other people can help me are . . ."* Pain clinicians have long recognized the importance of other people's responses to the patient as influencing patient functioning (11) (see Chapter 25). Discussing with the patient and someone close to the patient such as a spouse (if such a person is available) specific steps that the other person can take to assist the patient in making adaptive changes should increase the chances that such changes will actually occur.
5. "*I will know if my plan is working if . . .'* Because making adaptive changes to pain problems can be challenging, it is important to identify signposts that indicate the patient is moving in the right direction. Such signposts can act as potential reinforcers for the efforts made, even if the final goal has not yet been reached. Some goals—for example, reactivation— tend to result in *increased* pain and discomfort before the patient feels stronger. To the extent that such increase can be predicted, and even identified as a sign of progress (e.g., "Increased pain means that the muscles that need to be stronger are being challenged"), then the patient may be reassured rather than frightened. Specific signs of progress ("able to lift a bag of groceries," "able to drive for 15 minutes") toward the final goal ("able to grocery shop by myself") should also be included here.
6. "*Some things that could interfere with my plan are . . ."* To the extent that patients can identify specific problems they may encounter, and come up with plans for addressing these problems, then specific hurdles may be avoided altogether or at least more easily addressed.

Summarize

It is as important to summarize when strengthening a commitment to change as it was when building motivation to change. Patients have an opportunity to hear, yet again, their reasons for making change and their plan for change. The CPW, used by the clinician to keep track of the issues raised by the patient, may be used as a guide when summarizing. Changes offered by the patient during this summary should be incorporated into the CPW. The patient should get a copy of the CPW, and one should be included in his or her record.

Ask for a Commitment

The final strategy to use with patients when strengthening a commitment for behavior change is to ask them to commit to the plan they have outlined. Miller et al. (2) lists several issues worth exploring when obtaining a commitment. First, it is important to clarify what exactly the patient intends to do. This is a good time to review the CPW, beginning with the responses to the "steps I plan to take in changing are . . ." stem. Are the steps, as listed, actually what the patient intends to do? The other components of the CPW should also be reviewed at this time, including perceptions of the benefits of change and the costs of inaction and concerns about what might interfere with making the change and how to deal with these obstacles. After this review, simply ask the patient for a commitment to follow through with his or her plan: "Are you ready to commit yourself to this plan?" If so, then you can ask the patient to sign the CPW, give the patient a copy, and retain a copy for the patient's records.

If the patient does not feel ready to commit to a plan of action at this time, the clinician should ask the patient what he or she would like to do from here. Any pressure to "go ahead and try" some aspects of the plan (from the clinician) should be avoided. The patient may wish to think about the plan until the next visit or session. No patient should feel pushed into making a decision to change before he or she is feeling ready to do so, as this would likely result in more, rather than less, resistance to change in the long run.

Summary of Strategies That Strengthen a Commitment for Behavior Change

The strategies discussed above should be used with patients who are in the preparation or action stages. The primary purpose of these strategies is to develop a behavior change plan and obtain a commitment to this plan. The strategies that can help do this include the following: review consequences for behavior change, provide information and advice as requested, communicate free choice, assist the patient to develop a plan for change, summarize, and ask for a commitment. At this point, the patient should have a plan to make one or more specific behavior changes and should have expressed commitment to follow through on the plan. At the next encounter, interactions with the patient involve following up on the patient's efforts.

Follow-Through Strategies

Based on the premise that the most difficult obstacle to making adaptive behavior changes involves lack of motivation to change, and not a lack of information or skills, the first phases of motivational strategies might be considered the most difficult and challenging for the clinician. Once motivation to change has been developed and that motivation has been shaped into a clear plan of action and commitment to change, adaptive changes are more likely to occur. Follow-up and follow-through consist of only three basic strategies: reviewing progress, renewing motivation (if needed), and renewing commitment (if needed).

Reviewing Progress

The first thing to do in the follow-up session is to review the changes that have occurred, if any, since the last encounter. Review the specific commitment and plans made at the last encounter and explore the progress that was made toward the plan. Any and all approximations at progress should be praised. Although the occasional patient appears annoyed with praise (making it necessary for the clinician to provide alternative creative reinforcers), most people appreciate acknowledgment of and praise for their efforts. It is appropriate to express such praise in as dramatic a way as possible and for as long as the patient and encounter will tolerate.

Renew Motivation

An assessment of motivation to maintain change may include a review of the behavioral indicants of motivation (as reflected in what the patient has done since the last encounter), as well as the patient's responses to questions concerning reasons for making or maintaining changes. Any indications of a decrease in motivation to change can be met with the five strategies that enhance motivation described earlier (e.g., ask open-ended questions, listen reflectively, affirm the patient, summarize, elicit self-motivational statements).

Renew Commitment

Finally, the strategies used to strengthen a commitment for change (e.g., review consequences of behavior change, give advice, communicate free choice, develop a

plan for change) may be used to refine the CPW (if needed) and obtain a commitment to follow through on the new plan.

Problems with Motivational Strategies

Motivational enhancement strategies are not for everyone. Some clinicians are not comfortable with the basic approach of motivational strategies of encouraging patient choice and control over treatment. Some clinicians may not want to devote the time during encounters (which can sometimes be limited to no more than 5 minutes in some busy practices) eliciting patient concerns and providing treatment options and choices. For these clinicians, the strategies introduced in this chapter may be perceived as inefficient (1). Also, some patients may not want to be given choices and responsibility. These clinicians and patients may simply feel more comfortable with the more traditional clinician-patient roles that require the clinician to provide specific recommendations and expect the patient to follow through with those recommendations. Expecting all clinicians and patients to want to participate in the types of interactions described here is antithetical to the philosophy of the motivational approach.

What if motivational strategies do not work? Some clinicians may feel very comfortable with motivational strategies and may in fact already be using them to a large extent. Whether using these strategies for the first time or the thousandth time, they will not be effective for all patients in all situations. Most clinicians have worked with patients who continue to use maladaptive coping strategies for pain management *and* continue to refuse to consider alternative approaches. Some patients may appear motivated by what they say but show resistance through their (lack of) action. Such patients may become so annoyed with these motivational strategies and the lack of provision of what they see as more appropriate treatment(s) that they refuse to make or keep appointments. With such patients, I still seek to plant a seed of adaptive responding, even if only during a single encounter. For example, a clinician might say

> "In the little time we have had to get to know each other, I hope you understand that I respect your right to make all decisions about how you will handle this problem. You seem to be convinced that another surgery has the best chances of making you feel better, and surgery is not something that we offer. If at some time in the future you become interested in considering other approaches to managing your pain, I want you to know that we are here to help you do that."

A third problem concerning the application of motivational strategies to problems of pain management is the lack of controlled research specifying the relative adaptiveness of different pain coping responses. The motivational clinician seeks to encourage patients to avoid behaviors and coping responses that are maladaptive and and to use coping responses that are adaptive for that patient. Although there is little controversy regarding the need to change most of the problem behaviors to which motivational strategies have already been applied (e.g., smoking, problem drinking, heroin abuse, risk behaviors for contracting the human immunodeficiency virus), there remains controversy concerning the relative adaptiveness or maladaptiveness of specific behaviors related to pain problems. For example, although opioid medication use is strongly discouraged in some treatment programs (12), some clinicians believe that there is a place for opioid medications for some individuals suffering from chronic benign pain (13,14). Even physical exercise, which may be considered an essential component of multidisciplinary pain treatment (12), has not necessarily been shown to be important to short-term treatment effectiveness (15). Thus, clinicians do not always know which specific behaviors to discourage and which behaviors to encourage for a particular patient.

One reasonable approach to address this problem is to use motivation enhancement strategies to encourage behaviors that (a) are adaptive for most patients (in the experience of the clinician or based on the most recent research) and (b) the patient has not yet tried. Then, as the patient tries the new behavior or coping response, the clinician and patient can monitor changes in patient functioning to determine how helpful the new approach is.

CONCLUSIONS

The purpose of this chapter was to introduce pain clinicians to the motivational strategies outlined by Miller and his colleagues (1,2). These strategies have been applied to motivate individuals to change a number of specific problem behaviors, such as excessive drinking. They appear to translate well to the treatment of chronic pain problems, given the strong role that patient motivation plays in chronic pain treatment. Although the effectiveness of these strategies among chronic pain patients has not yet been tested empirically, support for their effectiveness for changing addictive behaviors is encouraging (1). Moreover, there is a growing interest in the applicability of motivational strategies for assisting individuals with chronic pain. For example, Kerns et al. (16) have published a measure of readiness to adopt a self-management approach to chronic pain based on Prochaska and DiClemente's (3) stages theory of change. This measure makes it now possible to test some basic hypotheses of the stage theory of change as it applies to change in chronic pain patients, so future research in this area can be anticipated.

CHAPTER 95

Orthopedic Management of Pain

Michael J. Moskal and Frederick A. Matsen III

Pain is a personal experience that cannot be observed directly (1), yet it is a common complaint of patients presenting to physicians. Effective *orthopedic* management of pain suggests an underlying mechanical etiology of pain. Many patients, however, only consult a physician because of their fear that they might have cancer or some other serious disease (2), and for these patients, reassurance can be beneficial as the sole treatment of minor musculoskeletal disorders such as contusions or musculotendinous strains.

Nonoperative therapy is not synonymous with conservative management. In some cases, such as adhesive capsulitis, surgical capsular releases may be more conservative than a closed manipulation (3). Orthopedic treatment in the management of patients with pain can be divided into general modalities that diminish swelling and inflammation and specific modalities that restore the basic tenets of a well-functioning musculoskeletal system: motion, stability, strength, and smoothness. We present a concise discussion of the various modalities used and their underlying basis for diminishing mechanical pain. Broad and simple categories follow to provide a general understanding of the indications and treatment rationales for various orthopedic maladies.

GENERAL MODALITIES

RICE

RICE is the classic mnemonic that represents the general modalities used to treat pain after an injury: *r*est, *i*ce, *c*ompression, and *e*levation. Injury causes damage to the soft tissues, muscle, and bone. Damaged blood vessels cause bleeding as well as local release of various tissue factors, such as histamine and bradykinins, that result in edema, swelling, and pain. RICE can be used any time after an injury but seem to be most effective when instituted within the first 24 to 48 hours after an acute injury.

Rest

Rest for musculoskeletal disorders has been recommended for hundreds of years (2,4) and is one of the mainstays of orthopedic treatment. Orthopaedic *rest* does not necessarily mean complete inactivity or immobility but rather *relative rest*. Waddell and colleagues (5) reviewed 18 trials of either “bed rest” or advice to “stay active” in the treatment of low back pain. They found consistently that bed rest was not an effective treatment for acute low back pain, and in fact, it delayed recovery. Atlas and Volinn (6) found that patients with acute low back pain who received a recommendation for 2 days of bed rest had significantly fewer days of work absence than those who received a recommendation of 7 days. *Relative rest* implies reduction of activity and avoidance of strain for a limited period. For example, a contusion of the quadriceps muscle results in swelling and hematoma formation. Vigorous muscle contraction immediately after injury would result in increased bleeding and therefore swelling and pain. Fu et al. (7) have recommended that to reduce pain and hematoma formation cryotherapy should be coupled with at least 48 hours of rest in both exhaustive and nonexhaustive types of exercises. After bleeding has subsided, gentle range of motion exercises of the hip and knee allow healing but diminish muscle fiber contracture. Lengthy periods of immobilization can lead to arthrofibrosis, joint stiffness, muscle atrophy, and cartilaginous malnutrition.

Orthotic devices such as thermoplastic splints can provide protective support after a destabilizing injury to a joint. The purpose of a brace is to assist, restrict, or simulate function (8). For example, stenosing tenosynovitis of the thumb often responds favorably to immobilization of the carpometacarpal and metacarpophalangeal joints of the thumb using a forearm-based thumb spica splint. Mild strains to the medial collateral ligament of the knee are treated by applying a functional brace that allows knee flexion and extension, as in walking, but protects the ligament from valgus and varus (side to side) stresses. Slings provide comfort after clavicle fractures and shoulder dislocations, allowing the shoulder girdle muscles to rest. Slings can aid in elevation of the hand after trauma. Removable forearm-based wrist splints are useful to prevent wrist flexion at night and diminish symptoms associated with median nerve compression at the wrist or to rest the wrist extensors in lateral epicondylitis.

Rest, slings, and orthoses are used as part of a rehabilitation effort rather than the sole form of treatment. For example, chronic use of lumbar corsets for low back pain can lead to increased trunk and pelvic muscular weakness, which can further predispose the patient to future episodes of back pain. Rest need not be synonymous with inactivity; rather, it may indicate protected activity so that the natural reparative mechanisms can predominate.

Ice

The application of cold, or cryotherapy, may be effective for acute trauma and also repetitive microtrauma that is part of many vocational and athletic endeavors (7). Ice may diminish pain and swelling and improve function. Speer demonstrated that patients using a cryotherapy device after major shoulder surgery may use fewer narcotics and have less pain (9). Cryotherapy slows metabolism and promotes local vasoconstriction of blood vessels reducing bleeding, swelling, and pain (10,11). The duration of ice application is limited by its potential harmful effects, such as thermal injury to skin and subcutaneous nerves as well as rebound hyperemia after the cooling elements are removed (12).

Compression

Compression bandage wrapping has been widely used to diminish bleeding and swelling. Compression-type bandages have also been used to treat nonspecific joint pains in the ankle, knee, wrist, and elbow. Again, as part of a global program, compression may be effective in improving comfort. However, care should be taken if this modality is used. Increased pressures within a limb caused by unyielding external compression such as a cast can lead to increasing pain and, potentially, neurovascular compromise. Improper application can reduce lymphatic return of the extremity distal to where the bandage was applied, causing distal swelling. This is commonly seen after application of a compression wrap (or cast) to the wrist after an injury. Venous and lymphatic return can be impaired if the wrap is placed too tightly just proximal to the metacarpophalangeal joints. Finger swelling and diminished range of motion can ensue and diminish comfort and function.

The effects of compression bandaging have been reviewed: Thorsson and colleagues (13) found that maximal compression bandaging within 5 minutes of a contusion

to a thigh or calf muscle did not significantly reduce the size of hematoma or significantly shorten the time to complete subjective recovery compared to rest and elevation. Compression may have other effects; for example, McNair et al. (14) found that normal subjects wearing a knee sleeve had better knee proprioception. They concluded that alterations in proprioception as a result of bracing may be partly responsible for the improvement in knee injury statistics reported in some studies. Although compression bandaging seems to improve comfort and function, it may not alter swelling after an acute injury (15). Its use should be tempered by its possible harmful side effects.

Elevation

Elevation encourages lymphatic and venous return and can reduce local blood flow to a limb, helping to diminish swelling. The benefits of elevation are easily recalled, as nearly everyone has suffered injuries and the subsequent throbbing if that limb becomes dependent. Elevation is contraindicated in the presence of ischemia or impending compartmental syndrome (16).

Local Injections

Judicious use of local anesthetic combined with corticosteroids can be useful in reducing inflammation and subsequent pain that have not responded to other modalities such as rest, stretching exercises, or both. For example, stretching exercises are the mainstay of treatment for a stiff shoulder. However, pain may significantly limit the patient's ability to participate in therapy. An injection may be beneficial to diminish inflammation and pain so that physical therapy can be performed. Steroid injections provide symptomatic relief and, used alone, do not alter the disease process (17). The potential for impaired healing (18) should be balanced against the potential gains from the antiinflammatory response. Although the maximal number of injections has not been elucidated experimentally and every patient circumstance is unique, we try to limit a patient to one or two injections. If a patient does not respond to one injection, it is unlikely that further injections will be beneficial.

Pharmacologic Therapy

Nonsteroidal antiinflammatory medications reduce pain and may have a protective effect after muscle injury (see Chapter 83). The efficacy of nonsteroidal antiinflammatory medications in the enhancement of healing, pain relief, return of function, and protective effect has been called into question (19,20 and 21). Most studies look at only a single pharmacologic agent, and it may not be appropriate to make broad-based conclusions about the different types of nonsteroidal antiinflammatory medications. These studies do demonstrate that use of these medications may not be appropriate for all patients. Newer nonnarcotic and more traditional narcotic medications may be more beneficial to improve comfort as the patient recuperates after an injury or surgery (22).

Ultimately, it is important to remember that there is a complex interplay between pain and function and that medications are only part of treatment. Thus, while antiinflammatory medications seem to help to diminish musculoskeletal pain and improve return of function, their use should be carefully weighed against possible adverse drug interactions and systemic side effects, as well as the possible unfavorable effect on healing. Medications of all types are discussed in greater detail in Chapter 83, Chapter 84, Chapter 85, Chapter 86 and Chapter 87.

PHYSICAL THERAPY

Physical and occupational therapy play an integral role in orthopedic care and orthopedic management of pain. Stretching and strengthening programs may be curative in some clinical situations. Good communication between therapist and orthopedist should exist so that a particular treatment algorithm can be monitored and optimized. Various modalities used in physical therapy are discussed in greater detail in the remaining chapters in this section.

Stretching and Strengthening

Pain causes a reflex inhibition of musculotendinous contraction as well as purposeful avoidance of painful behavior. The cycle of pain and disuse can lead to weakness and stiffness. Weak quadriceps muscles can magnify patellar maltracking; shoulder stiffness is often painful and functionally debilitating. Moffroid (23) has shown that the lack of endurance of the trunk muscles is an important factor in low back pain. A complex interaction exists between pain and activity. For instance, simply walking can improve the overall comfort and function in elderly people with chronic musculoskeletal pain (24). Although it is clear that walking did not alter the underlying degenerative arthritis, it did lessen pain.

Therapists can guide patients as they progress through the rehabilitation process. This does not necessarily mean that a patient must attend frequent sessions with a therapist. Rather, we have found that many patients do well with patient-conducted home therapy programs. After an initial session with a physical therapist who demonstrates and explains the rehabilitative process, the patient conducts the exercises on his or her own time.

Thermal Therapy

After an acute injury has subsided, heat and cold can be combined to augment performance and diminish pain. As implied above, cryotherapy is useful for acute and microtraumatic overuse-type injuries. Heat seems to be beneficial in pain reduction in various arthritides as well as before initiation of exercises such as strengthening and stretching. Oosterveld and Rasker (25) reviewed the literature concerning the treatment of arthritis with locally applied heat or cold. The temperatures of the skin, superficial and deeper tissues, and joint cavities do change based on locally applied heat or cold. Most studies report beneficial effects of heat and cold on pain, joint stiffness, grip strength, and joint function. However, *in vitro*, higher temperatures increase the breakdown of cartilage and other tissues that contain collagen (25,26 and 27).

Iontophoresis, Ultrasound, and Phonophoresis

A therapist may apply an electric current to the skin and thereby transmit drugs such as corticosteroids through the skin using electrical potentials. Iontophoresis transmits drugs to the epidermis, dermis, and deeper tissues and is dependent on structural and physiochemical properties of the administered drug and the resultant change in skin permeability (28). Ultrasound uses high-frequency acoustic energy in fluid-based mediums to impart thermal and mechanical effects. Used as a thermal modality, ultrasound is purported to increase local blood flow and decrease pain from muscle spasms and contusions. Phonophoresis combines ultrasound therapy with a drug such as an antiinflammatory medication (29). Most information regarding the rationale for the use of physical agents in pain management is based on tradition, data extrapolated from basic science research, and uncontrolled clinical trials. Further research is needed to establish clinical efficacy and to determine treatment parameters for the physical agents used (30,31).

Electrical Stimulation

Electrical stimulation has been used for years as pain relief and as an adjunct to muscle rehabilitation (32); its use has increased since the 1970s (see Chapter 98). Transcutaneous electrical stimulation has been used to treat pain related to a variety of conditions including the musculoskeletal, nervous, and vascular systems. The physiologic mechanisms by which pain is affected are not defined; local neural blockade, branch block in the dorsal horn, and activation of a central inhibitory system have all been postulated (33).

MECHANICS OF JOINT PAIN

Most nontraumatic joint pain is associated with at least one of four mechanical problems: stiffness, instability, weakness, and roughness.

Stiffness

Joint stiffness can be insidious in onset, or it can arise after major trauma or surgery. Joint stiffness is tolerated to different degrees by the various joints in the body. For example, limited range of motion of the interphalangeal joint of the thumb is often well tolerated, whereas shoulder stiffness is painful and limits many activities of daily living. Flexion contractures that often accompany minor arthritic changes of the knee are often well tolerated in most activities during the day; however, sleeping at night may be especially difficult because the knee does not extend fully. Joint stiffness can alter overall body mechanics and lead to pain elsewhere, as in hip

stiffness and back pain.

Treatment for stiffness begins by delineating the underlying pathophysiology and functional limitations. Elbow stiffness is commonly posttraumatic in nature and can be classified as intrinsic (e.g., due to intraarticular fractures and adhesions) or extrinsic (e.g., due to muscle scarring or burns). A stiff elbow might not be painful. Most activities of daily living can be performed with minor extension and flexion losses. An elbow that is painless and functional may require no treatment at all. Shoulder stiffness (e.g., due to adhesive capsulitis, idiopathic capsular fibrosis and contracture) may be painful and functionally limiting. Treatment may include a patient-conducted global stretching program, manipulation, or surgical release. Patients with diabetes or endocrine disorders such as hypothyroidism are more likely to require surgical intervention for their stiff shoulder. After regional anesthesia or general anesthesia with muscle paralysis, shoulder range of motion is determined and the firmness of the end points is assessed. Closed manipulation can be useful, but surgical capsular release may be needed to increase motion.

Instability

Pain associated with an acute dislocation of a joint is easily understood. Hip dislocations occur after high-energy trauma such as a fall from a height or a motor vehicle accident; capsular tearing, articular surface damage, and muscle bleeding are painful. Instability and pain can be associated with subtler instabilities such as subluxations.

Closed reduction is usually sufficient to manage an acute dislocation. Analgesia or anesthesia is used to make the patient more comfortable and to encourage relaxation of muscles in spasm, thereby lessening the forces necessary to achieve reduction. Some joints cannot be reduced by closed manipulation due to soft tissue or bony interposition. For example, the volar plate of a finger metacarpophalangeal joint can become interposed in the joint after certain dislocations. Attempts at reduction often tighten the soft tissues and possibly increase joint damage. A surgical reduction can address both bony and soft tissues after a dislocation. Stability after reduction is typically tenuous, and a protected joint mobilization program is often needed. Ligament reconstruction may be needed to restore stability and function. Figure 95-1 illustrates rupture and repair of the acromioclavicular and coracoclavicular ligaments caused by a fall on the shoulder during an athletic activity.

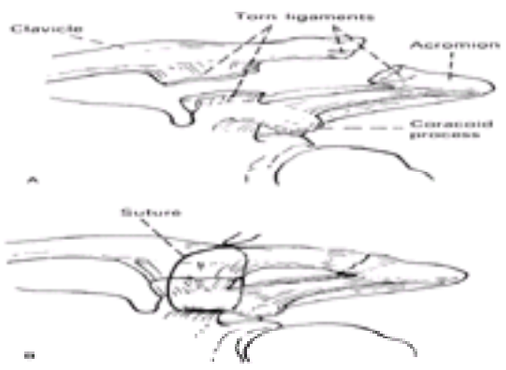

Figure 95-1. Ligament reconstruction. **A:** Third-degree acromioclavicular separation. In this injury, often sustained in landing on the shoulder after a fall while biking, skiing, playing football, or wrestling, the acromioclavicular and coracoclavicular ligaments can be torn. **B:** When substantial instability results, the torn ligaments are reconstructed by passing secure suture around the coracoid process and the clavicle. The bones are held in proximity while healing occurs.

Although not typically thought of in the context of stability, fractures can destabilize a limb, limiting its use. Proper alignment and stability after a fracture allow stable callous formation and healing. Malalignment can alter the forces on the joints above and below the fracture and therefore alter wear patterns and lead to pain. Closed manipulation after a fracture can restore alignment and stability (34,35). Good analgesia and muscle relaxation are essential components to minimize muscle spasm and achieve adequate reduction. Some fractures require surgical reduction followed by metallic fixation to enhance bony stability (Fig. 95-2). Stress fractures are multiple microfractures in a bone to due mechanical overloading that supersedes the body's normal reparative healing response. Stress fractures are commonly seen in the foot metatarsals after chronic rigorous activity, such as that experienced by military recruits in basic training. Decreased activity allows the fractures to heal as the body's healing response catches up. Regardless of treatment and fixation methods, the goals of fracture care are bony healing and restoration of function.

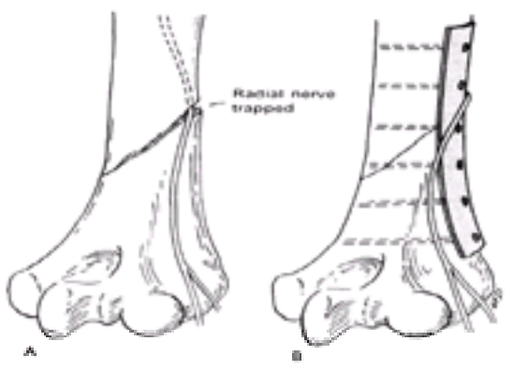

Figure 95-2. Open reduction and internal rotation of a distal humeral shaft fracture. Fractures of the distal humerus are not infrequently associated with radial nerve lesions. When the radial nerve is injured at the time of the fracture it is prudent to wait 6 to 12 weeks for nerve recovery. When the nerve is initially intact and then subsequently loses function during the process of reduction, however, it is possible that the nerve is trapped within the fracture **(A)**. If radial nerve function is acutely lost, open reduction and extraction of the nerve by internal fixation of the fracture, using a plate, is effective for protecting the nerve and permitting earlier return to function of the arm **(B)**.

Congenital, posttraumatic, or degenerative instabilities can be corrected in some situations by an osteotomy, or by cutting and realignment of the bone (35,36). For example, pediatric acetabular development of the hip joint requires concentric joint reaction forces and the biological plasticity of youth. Altered acetabular congruency with the femoral head due to either abnormal acetabular roof angles or femoral neck shaft angles can produce painful hip subluxations. In a child, an innominate osteotomy of the acetabulum and/or a varus osteotomy of the proximal femur can help to restore a more normal acetabulum configuration and hip joint stability, with return of comfort and function (37).

Weakness

Pain can reflexively diminish muscular power. Weakness itself does not necessarily cause pain. Rather, the causes and sequelae of weakness are often painful and have unique characteristics based on body location. Perry et al. (38) looked at postpolio patients with muscular weakness and noted that muscular substitutions for weak muscles placed increased demands on joints, ligaments, and muscles. They postulated that these increased abnormal forces might be responsible for pain and dysfunction. They suggested that treatment should consist of early identification of muscle overuse and ligamentous strain as well as lifestyle modification and bracing. Despite an intact muscular motor unit, strength and range of motion can be diminished due to tendinous pathology. Tendon function can be limited primarily by (a) diminished glide, (b) myotendinous unit contracture, and (c) rupture.

After an injury, such as surgery or a fracture in the area of tendons, bleeding can produce scar that limits tendon movement (glide). Active and passive range of motion is restricted, frequently causing pain at the limits of motion. For example, after phalangeal fracture, scar can form around the flexor and extensor tendons. If motion is ineffective in restoring normal flexibility and pull-through of the tendon, tenolysis might be required. In this procedure, the adhesions are sharply divided and the tendon is started on early motion to prevent restricting adhesions from reforming. If motion is limited in a particular position, the capsules of nearby joints may

contract in a shortened position, again limiting motion. In this case, the capsule would have to be released in addition to tenolysis.

Muscular contracture is often thought of as solely limiting power. Muscular contracture, however, can lead to pain and dysfunction in nearby anatomic locations. Ko et al. (39) found that patients with deltoid muscle contractures had a high prevalence of neck and shoulder girdle pain. After surgical release of the deltoid, pain in the neck and shoulder girdle resolved in 48 of 49 shoulders.

Partial or complete tendon ruptures can be painful as loads are applied to the tendon. Complete tendon ruptures can be treated by tendon repair, tendon advancement into bone, tendon grafting, and tenodesis. Patellar tendon ruptures can occur after a sudden eccentric (lengthening) force is applied across the knee joint, such as when a person missteps while walking over a curb. The large forces overcome the tensile strength of the tendon and it ruptures near the inferior pole of the patella or midtendon. Acutely, there is bleeding and an inflammatory response. Quadriceps muscle firing causes pain and cannot generate force to keep the knee straight. Tendon repair consists of direct repair for midsubstance tears, advancement into bone if the rupture is the patella or tendon grafting if there is major tendon loss or the muscle is chronically contracted and the tendon edges will not approximate. After the normal resting length of the muscle is restored and the local inflammatory response has subsided, comfort and function are restored. Finally, tenodesis can be used when it is difficult to restore normal tendon integrity; function can be at least partially restored by securing the ruptured end of the tendon. A classic example is tenodesis of the long head of the biceps to the proximal humerus after an intraarticular rupture.

Roughness

In general, roughness is the lack of smoothly gliding surfaces. The knee may be painful due to incongruous degenerated articular surfaces but also may be painful due to a torn meniscus that gets caught between the femur and tibia. The treatment of roughness is the restoration of smoothness. This restoration can range from a simple excision of a bony prominence to replacing the articular surfaces with artificial materials such as metal and plastic. In some situations decreasing the force across joints improves pain, whereas in others destruction is so severe that eliminating any motion, an arthrodesis, is the only surgical option.

In the forearm, bone from fracture callus can impede the movements of pronation and supination. A prominent olecranon process can prevent full extension of the elbow. Heterotopic bone in the forearm, about the hip, in the shoulder, or elsewhere can interfere with or prevent motion of the involved joint. Degenerative osteoarthritis of the knee frequently affects only the medial compartments. A high tibial osteotomy can realign the resulting varus configuration, shifting the load to the relatively unaffected lateral compartment. This type of reconstruction can restore comfort and function to the knee and avoid the potential problems of prosthetic arthroplasty (Fig. 95-3).

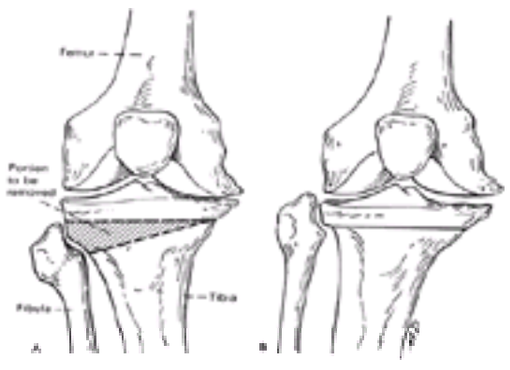

Figure 95-3. High tibial valgus osteotomy. **A:** Frequently, osteoarthritis selectively involves the medial compartment of the knee joint, which produces a progressive varus or bowlegged deformity of the leg in which the load is concentrated on the damaged medial side. A high tibial valgus osteotomy achieved by section of a laterally based wedge of the upper tibia can be a helpful therapeutic measure in this situation. **B:** When this wedge is removed and the dissection is closed, the varus deformity is eliminated and the load is transferred toward the relatively unscathed lateral compartment.

When damaged, menisci of the knee joint might require excision or repair. These menisci distribute forces across the knee and can be damaged by compressional or rotational loads across the knee, catching and tearing their substance. Torn and displaced meniscal fragments can cause pain and interfere with normal joint motion by catching between the femur and the tibia. Degenerative tears can also arise from wear and tear on the joint surface. Resection of the torn meniscus fragments can relieve the “catching” and pain but does not, however, restore normal function of the meniscus.

Arthrodesis, or joint fusion, is a common procedure for stopping the motion at a joint that has become destroyed, unstable, or both. For example, C-1 and C-2 vertebrae can become unstable because of rupture of the transverse ligament of the atlas in a patient with arthritis, jeopardizing the cervical cord at this level. Arthrodesis of these two vertebrae is the most effective way of preventing neurologic problems resulting from instability at this level. A shoulder that has become unstable from brachial plexus injury can be flail and render the rest of the upper extremity relatively useless (40). In such situations, function can be enhanced by fusing the humerus to the scapula in a position that favors use of the elbow, wrist, and hand (Fig. 95-4). Arthrodesis may be indicated for joints in which the functional loss is minimal yet pain relief is significant, as in arthritis of the distal interphalangeal joints.

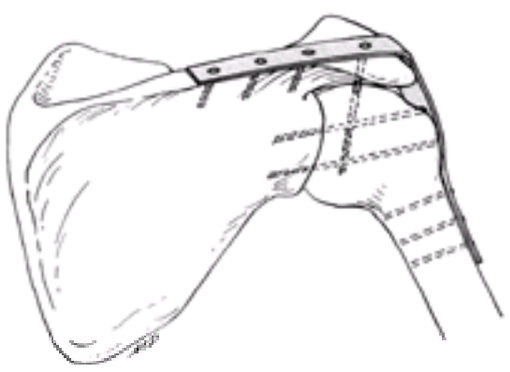

Figure 95-4. Arthrodesis of the shoulder joint. When the joint surface of the shoulder and the major muscles of the shoulder (the deltoid and rotator cuff) are substantially damaged beyond reconstruction or repair, comfort and some function can be restored by fusing the humeral head to the scapula. Here a contoured plate and screws are used to provide internal stability to the shoulder fusion. The shoulder is fused in a position that allows the hand to reach the front pocket, opposite axilla, and forehead. Motion is achieved by the scapulothoracic joint.

Biological arthroplasty procedures include resurfacing of the bone ends with fascia or dermis or a distraction-resection type of arthroplasty that allows the body to regenerate a new bearing surface. Resection arthroplasty is effective in certain circumstances, such as when the radiocapitellar joint is involved in rheumatoid arthritis of the elbow, where overall function is maintained. In an elbow with competent collateral ligaments, the radial head can be removed so that the rough surfaces of the capitellum and radial head do not articulate. The elbow remains stable due to the collateral ligaments and the articular surface of the ulnohumeral joint. Prosthetic arthroplasty involves the replacement of the damaged joint surfaces with Silastic or metal on polyethylene (41). Common examples include total arthroplasties of the hip, knee, shoulder, elbow, ankle, wrist, and fingers (Fig. 95-5). These new joint surfaces are anchored into position either by biological fixation (e.g., press fit, with or without tissue ingrowth) or by fixation enhancement with methylmethacrylate (bone cement). These procedures, by definition, eliminate the pain caused by rubbing of abnormal joint surfaces. Prosthetic arthroplasty is often of great benefit to the patient, but the procedure can fail because of infection, loosening, fracture, instability, or abnormal joint mechanics.

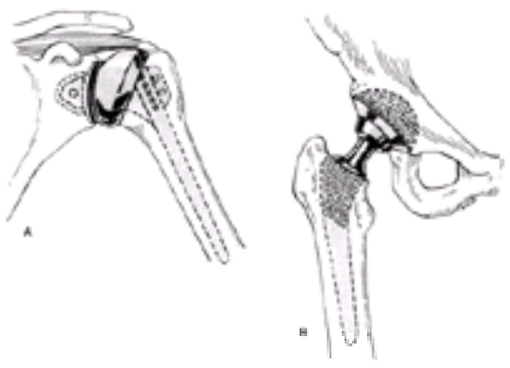

Figure 95-5. Joint replacement. **A:** Total shoulder arthroplasty. **B:** Total hip arthroplasty. In a shoulder replacement it is actually the articulating surfaces of the joints that are replaced. Stability and motion of the joint still depend on component position, joint reaction forces, and muscle integrity. Key elements in these procedures include accurate alignment of compartments, secure fixation of the components in the bone, and careful balancing of the ligaments and muscles about the joint.

Nonmechanical Pain

Pain unrelated to activity may be due to nerve dysfunction, trauma, or infection.

Neural Dysfunction

Neural function can be compromised by compression, stretching, scarring, or severance. In general, the return of function after an injury is affected by the specific nerve, age of the patient, and the location and type of injury. Recovery from an injury is improved if the patient is younger and the initial injury is less severe. For example, transection of the transverse carpal ligament for carpal tunnel decompression can result in diminished pain and improved grip strength and sensation. However, decompression of the median nerve at the wrist in an older patient with medical problems such as diabetes and longstanding compression may only halt the progression of further injury, and return of function is minimal. Spinal stenosis, narrowing of the spinal canal, or herniated disk may compress the spinal cord, a specific nerve root, or both. Disk excision does not beneficially alter the course of the degenerative process but is useful if significant pain or neurologic loss is present (37). Peripheral nerve compression syndromes are usually initially treated by behavioral modification such as splinting, local injections, and exercises as in thoracic outlet syndrome. If symptoms do not diminish with nonoperative treatment or if neural compromise is significant, progressive, or both, a surgical decompression such as section of the transverse carpal ligament in a carpal tunnel syndrome (Fig. 95-6) or ulnar nerve transfer for ulnar nerve compression at the elbow can be performed (42).

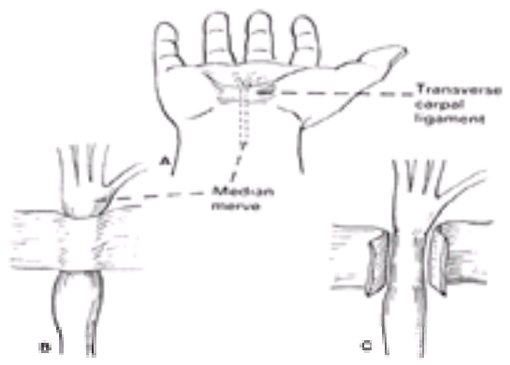

Figure 95-6. **A,B:** The median nerve is compressed at the wrist producing pain; hypesthesia in the thumb, index, and long fingers; and weakness of the thenar muscles. **C:** Symptoms can usually be ameliorated by section of the transverse carpal ligament.

Scar tissue is contractile in nature. Scarring about a nerve after an injury may produce pain and diminished function. Neurolysis removes scar from around the nerve. Patients should be carefully selected; surgery itself creates some bleeding and residual scar formation. Nerves that are divided can be repaired by direct suture repair, which attempts to align fascicles so that axons can regrow from the nerve cell body located proximal to the transection. Occasionally, cable grafts using nerves such as the sural nerve can be used to bridge segments of lost nerve.

Neoplasm and Infection

Benign, malignant, and metastatic bone lesions are painful due to a variety of reasons including chemicals produced by the tumor, structural instability, and local pressure. A more detailed discussion of this subject can be found elsewhere (17,18,19,20 and 21) and in the chapters on regional pain syndromes in this text (Chapter 46, Chapter 47, Chapter 48, Chapter 49, Chapter 50, Chapter 51, Chapter 52, Chapter 53, Chapter 54, Chapter 55, Chapter 56, Chapter 57, Chapter 58, Chapter 59, Chapter 60, Chapter 61, Chapter 62, Chapter 63, Chapter 64, Chapter 65, Chapter 66, Chapter 67, Chapter 68, Chapter 69, Chapter 70, Chapter 71, Chapter 72, Chapter 73, Chapter 74, Chapter 75, Chapter 76, Chapter 77, Chapter 78, Chapter 79 and Chapter 80). Surgery can diminish the “tumor load,” restore structural stability, and minimize compression due to space-occupying lesions. Surgical decompression can also help manage pain from infection.

Osteoid osteoma, a benign osteoblastic lesion with a typical well-demarcated nidus, undergoes intraosseous growth. Classically, the pain is worse at night and is temporarily relieved by aspirin. The tumor secretes prostaglandins and the aspirin may inhibit their formation. Although these tumors may eventually “burn out,” complete excision can result in the definitive elimination of the characteristic pain.

In osteomyelitis, systemically administered antibiotics cannot permeate the area of devitalized and devascularized bone, a sequestrum. Pain may be due to the local chemical milieu, compression of local structures, or structural instability. Generally, bone and purulent material must be completely excised to allow the body to eliminate the infection. If a substantial bony defect is present, stabilization may be required.

A benign bone tumor can cause pain due to its expansive growth characteristics or by destabilizing bone by replacing it with neoplastic cells. A large osteochondroma can cause local compression or roughness as surrounding tendons rub against it as its extraosseous expansion increases. Neoplasms such as giant cell tumors or fibrous dysplasia may weaken segments in bone and predispose to fracture. Giant cell tumors can be treated by removing all of the tumor tissue (43) and then filling the cavity with cancellous bone graft (44). Hopefully, the tumor will not recur and the bone graft will consolidate to restore bony integrity.

Chemotherapy and radiation therapy may be useful to kill neoplastic cells preferentially so that the tumor is more amenable to resection and/or to low the body to compensate to restore structural integrity. Combined chemotherapy and surgery have lowered the mortality rates in certain primary tumors (43,44). The incidence and prevalence of metastatic tumors are higher than those of primary tumors. Breast, prostate, thyroid, kidney, and lung cancers and other types of malignant tumors account for a large majority of tumors that metastasize to bone. Again, these tumors are painful because of structural compromise, chemical secretion, or local compression. The following are indications for orthopedic surgery in cases of skeletal metastasis (45): The tumor shows little or no sensitivity to radiotherapy or chemotherapy; the maximum dose of radiation has been applied and moderate to severe pain and instability are still present; pathologic fractures; and pain can be relieved and quality of life can be improved. Cancer pain management is discussed in detail in Chapter 35, Chapter 36 and Chapter 37.

Amputation

Indications for amputation of all or part of an extremity include malignant tumor, refractory infection, nonhealing ulcer, and untreatable ischemia (46). At times, amputation is indicated because of total loss of function of a part—for example, in a severe brachial plexus injury resulting in a flail arm below the shoulder. It is the paralysis of the limb, not the accompanying pain, that is the indication for amputation. Amputations usually heal, provided they are performed technically well and the flaps have adequate vascularity. Amputations are often not successful in the management of chronic pain (see Chapter 21).

CHAPTER 96

Basic Concepts in Biomechanics and Musculoskeletal Rehabilitation

Stuart E. Willick, Stanley A. Herring, and Joel M. Press

The human body is like a marionette: The puppet itself is analogous to the bones and joints of the human body, and the strings that attach to the puppet are analogous to the muscles and tendons that move the human skeleton. The puppeteer provides the neural input to the doll's musculoskeletal system. For the marionette to work properly, several specific mechanical properties of the doll must be in optimal working order. First, the length and tension of the strings must be correct. Second, all parts of the puppet and the puppeteer must have adequate strength and endurance to impart movement to the doll and prevent fatigue and breakdown from occurring over the course of repeated performances. Third, and perhaps most important, the puppeteer must manipulate the strings in a smooth, coordinated manner so that the movements of the doll are smooth and lifelike.

Those who fabricate marionettes work very hard to ensure that the doll is finely tuned. The joints of the doll must have low enough friction to allow easy movement, yet must be stable enough to prevent limbs from undergoing excessive displacement during more dramatic scenes. The string lengths must be exact, so that the puppet appears symmetric and the joints are allowed full range of motion. The strings must also have enough tensile strength to preclude breakage, yet they must also have the proper amount of elasticity so that the doll's movements are smooth. Finally, the puppeteer must practice many hours to perfect each movement, scene, and performance.

For the clinician intent on maximizing a patient's musculoskeletal health, the mechanical properties of a marionette may serve as a simple model by which to view human biomechanical functioning. A comprehensive musculoskeletal rehabilitation program begins with restoring soft tissue range of motion and flexibility, just as the puppeteer builds his or her doll with strings of adequate length and tension. Like a marionette, the human body also requires adequate strength and endurance to move body parts properly during single movements, as well as over the course of repetitive movements. And just like a marionette, humans need to have proper coordination and fluidity of movement for proper biomechanical functioning.

In the absence of acute trauma, such as fracture or dislocation, musculoskeletal pain is most often caused by or associated with alterations in proper biomechanics. Clinicians treating musculoskeletal pain should endeavor to improve their patients' biomechanics.

Whereas a puppet has no will and any repairs to faulty mechanics must be initiated by the puppet maker, a patient, if convinced the outcomes are worth the effort, can usually improve his or her own biomechanics through an appropriate home exercise program. Often, the assistance of a physical therapist is required to institute and facilitate the home exercise program. Patients also differ from puppets in that they need adequate nutrition for tissue healing.

By emphasizing biomechanical principles, the contents of this chapter represent a fundamental change from the customary emphasis on the use of physical therapy and physical modalities in treating musculoskeletal pain. Patients are often treated for musculoskeletal disorders with passive modalities such as hot packs, cold packs, massage, electrical stimulation, and deep heat. Unfortunately, these passive therapies are overused. While they certainly can play an important role in providing symptomatic relief of musculoskeletal pain, passive modalities should be used only as methods to facilitate *active* rehabilitation. The patient most needs to become actively involved in a therapeutic exercise program specifically designed to improve musculoskeletal functioning.

Musculoskeletal rehabilitation is a process whereby poor posture, muscle imbalances, and other biomechanical deficits are corrected using specific exercises to gain better static and dynamic control of the musculoskeletal system. The physical restoration process *may* involve passive therapeutic modalities to facilitate the exercise program. Clinicians treating musculoskeletal pain and dysfunction must identify and work to correct deficits in the patient's biomechanics.

This chapter introduces general concepts in clinical biomechanics that are crucial to the understanding of musculoskeletal rehabilitation. The first section, Basic Considerations, presents an overview of these biomechanical concepts. In the second section, Clinical Considerations, specific techniques used to treat musculoskeletal pain are reviewed. In keeping with the philosophy that *lasting* improvements in biomechanical functioning are due to exercise programs prescribed specifically for each patient's pain symptoms and biomechanical deficits, therapeutic exercise is emphasized; passive therapeutic modalities are given less attention. The concepts presented here can be applied to soft tissue injuries throughout the body. The diagnosis and treatment of specific injuries are covered in Part IV of this book.

BASIC CONSIDERATIONS

This section introduces basic concepts in musculoskeletal rehabilitation. Using specific examples, the importance of optimizing range of motion, strength, endurance, and neuromuscular control is reviewed. The role of muscle agonist/antagonist interactions and adverse neural tension (ANT) is included. There is a certain degree of overlap between the various biomechanical concepts that are presented. For example, although strength and endurance are related, they are presented separately because clinical pain syndromes related to deficits in strength differ from those related to deficits in endurance.

Range of Motion

Lack of adequate range of motion is probably the most common biomechanical deficit seen and one of the easiest to address. Deficits in range of motion can cause pain directly or may lead to pain elsewhere. An example of a range of motion deficit that causes pain directly occurs when electricians experience shoulder pain while doing overhead work because of limitations in glenohumeral forward flexion. An example of a range of motion deficit that leads to pain in a distant body segment occurs when electricians with limited glenohumeral forward flexion experience low back pain while performing overhead activities because they must increase their lumbar lordosis to compensate for the lack of shoulder elevation (Fig. 96-1). The compensatory increase in lumbar lordosis is an example of a maladaptive substitution pattern due to a biomechanical deficit (e.g., decreased latissimus dorsi length).

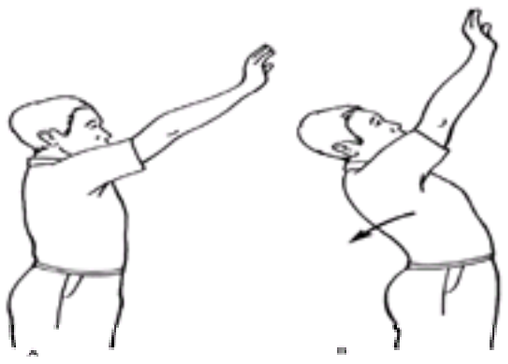

Figure 96-1. The individual with limited glenohumeral forward flexion **(A)** compensates with exaggerated lumbar lordosis during overhead activities **(B)**. This maladaptive substitution pattern can lead to low back pain.

The musculoskeletal clinician must have adequate examination skills to identify all range of motion limitations, decide which of these contribute most significantly to patients' symptoms, and implement appropriate therapies to correct the deficits. Range of motion restrictions can be due to shortening of muscle-tendon units, restrictions in joint capsule distensibility, ANT, or bone-on-bone contact at joint interfaces. The first three conditions are almost always amenable to specific stretching techniques. These are discussed under Clinical Considerations, later in this chapter. Range of motion deficits due to bone-on-bone contact are not improved with therapeutic exercise or physical modalities.

Strength

Deficits in strength do not always indicate that the patient has experienced a neurologic insult, a torn muscle or tendon, or prolonged bed rest. To those who perform manual muscle testing daily, it becomes readily apparent that few people in the general population have full strength in all muscle groups. Certainly, strength deficits occur with nerve injury, muscle or tendon tears, and prolonged inactivity. Strength deficits also occur in the absence of these conditions.

Two primary factors contribute to relative strength deficits in ambulatory patients without major nerve or muscle injury. The first might be considered a *relative disuse* weakness. In relative disuse, the body part is not immobilized but is infrequently used in a manner that develops strength. Triceps weakness in sedentary office workers is a good example of this. Although these individuals may be “pushing papers” all day long, they may go for decades without ever performing elbow extensions against enough resistance to prevent gradual weakness from developing. On manual muscle testing, they will likely earn an elbow extension grade of 4/5 to 5–/5. This relative weakness may never be symptomatic, unless the workload required in that individual's triceps muscle suddenly increases. This would occur, for example, if the person decided to build a deck onto the back of the house and began hammering for long periods.

Similarly, many of us do not maintain full strength in our hip extensors (especially for extension past the neutral position) or the muscles that help elevate the upper limbs, especially those that upwardly rotate the scapula. These simply are not movements that we do against resistance very often during routine activities of daily living. Mild strength deficits due to relative inactivity are frequently asymptomatic. They become symptomatic if the individual has a rapid increase in activity or if age-related changes such as loss of motor units or decreasing activity level further weaken muscle groups that already have mild strength deficits. Mild or relative weakness of the hip extensors and abductors has particular relevance in the setting of low back pain due to the functioning of the hip extensors and abductors as lumbopelvic stabilizers. Mild weakness of the scapular rotators has particular relevance in the setting of shoulder pain, due to the role of these muscles in overhead activities.

The second primary factor that contributes to relative strength deficits in ambulatory patients without major nerve or muscle injury is a process sometimes referred to as *muscle deeducation* (1). This is a process in which the individual fails to activate, or abnormally activates, a given muscle because of pain, fatigue, maladaptive biomechanics, or psychological reasons. Over time, the normal neuromuscular engram for the intended movement becomes harder to retrieve, and the neuromuscular control system has essentially “forgotten” the normal pattern of use for that muscle. Most often, muscle deeducation involves the patient losing the ability to fire a muscle with the correct timing, or strongly enough, for the movement intended. The patient adopts a maladaptive neuromuscular firing pattern and substitutes other muscles to perform the task. Sometimes the muscle deeducation process consists of the patient firing a muscle too strongly or losing the ability to relax the muscle appropriately.

An example of a patient substituting one muscle for another is the individual who preferentially fires hamstrings to perform hip extension, rather than using the strongest hip extensor, the gluteus maximus. If this maladaptive firing pattern continues over time, the gluteus maximus becomes deeducated and weak. This can result in poor pelvic control and secondary low back pain. The concept of muscle deeducation emphasizes the close interaction between neural control mechanisms and musculoskeletal function in the development of musculoskeletal pain.

A classic example of a patient losing the ability to appropriately relax a muscle is the individual who presents with unilateral upper back and posterior neck pain. This is often due to the patient holding the scapula in an elevated position. The levator scapulae and upper trapezius are short and tight, and there are pain and tenderness in these muscles. This hiked-shoulder posture is assumed when people work hunched over a desk or when they are tense. Some individuals do not bring the scapula back down to its normal position, and over time they “forget” how to relax the scapular elevators, and forget where their scapula should be normally positioned.

The clinician treating musculoskeletal pain must identify all strength deficits, decide which ones are clinically relevant to the patient's symptoms, and implement an appropriate rehabilitation plan to correct those deficits and reeducate muscles that have lost their normal patterns of firing.

Endurance

Deficits in endurance can exist in bone, muscle, tendon, ligament, and the nervous system. The concept of endurance is fairly self-explanatory. Biomechanically speaking, endurance is the ability of a tissue or body part to generate force, or withstand a force imparted to it, over an extended period or over repeated bouts of exercise (2). It is important to remember that endurance is different from strength. Deficits in endurance present differently than deficits in strength. Endurance is tested differently than strength, as shown in the following example.

A runner with L-5 nerve root irritation may complain of anterior leg pain after running a few miles. During a 2-month period, the pain has occurred at progressively shorter running distances. On manual muscle testing, he has 5/5 strength. When running, gait evaluation is performed on the treadmill; however, the patient begins to display high steppage gait, foot slap, and hip external rotation after 20 minutes. Strength is full, but there are severe endurance deficits in the ankle dorsiflexors due to the nerve irritation and subsequent impairments in normal neuromuscular recruitment. This example of neural fatigue emphasizes the importance of the interaction between the neurologic and musculoskeletal systems in many musculoskeletal pain syndromes.

Another example is that of a cafeteria worker who repetitively places large metal trays on an overhead shelf throughout an 8- hour shift. She may initially develop shoulder or back pain at the very end of the shift, which progresses to onset of pain at progressively earlier times during the day. Manual muscle testing in the shoulder girdle performed in the physician's office can be 5/5, but strength may drop to 4/5 after repetitively stressing the system. This indicates a deficit in muscular endurance contributing to a musculoskeletal pain syndrome.

The clinician treating musculoskeletal disorders sometimes needs to take the time to repetitively stress a muscle group to uncover endurance deficits. If endurance deficits are present and are felt to be clinically relevant to the patient's symptoms, the rehabilitation program must include endurance training.

Neuromuscular Control

Motor control is often overlooked in musculoskeletal rehabilitation. A muscle or muscle group may be quite strong, but if it does not fire at the appropriate time, it may as well not fire at all. Neuromuscular control is a combination of sensory feedback from the body part, pre–motor planning and motor execution (3,4). Impairments in

any of these pathways can lead to musculoskeletal dysfunction and pain. Normal neuromuscular control can be lost through injury or disuse and can be regained through appropriate retraining (5). For some movements, proper neuromuscular control is an easy task. For other movements, motor control requires practice.

For example, if you ask patients to fire their biceps muscles, they will be able to flex their elbows without any difficulty. But if you ask patients to fire their multifidus or lower trapezius muscles, they may not be able to do so even if you show them pictures of those muscles in an anatomy text and explain their actions (6,7). Multifidus and lower trapezius are under voluntary control just like biceps, but our ability to consciously use them to gain fine control over segmental spine motion and scapular rotation, respectively, is far less than our ability to consciously activate biceps to precisely flex the elbow. Specialized exercises can improve one's ability to execute fine control of the neuromusculoskeletal system.

When trying to gain fine motor control, one needs to maximize control of individual muscles and smoothly integrate the actions of different muscle groups in succession during dynamic activities (8,9 and 10). For example, when lifting an object, a person must first fire the foot and ankle muscles to stabilize the feet on the ground. Then one must fire the thigh muscles to stabilize the knee. Next, the hip girdle muscles must stabilize the pelvis before the spine extensors can elevate the torso. If the gluteus maximus fails to kick in before the erector spinae fires, the pelvis will remain anteriorly tilted and abnormal motion will occur in the lumbar spine.

Normal motor sequencing is a highly synchronized process that can easily break down. Several causes of deficits exist in neuromuscular control. One is a lesion in the motor pathways, either centrally or peripherally. This can be dramatic in obvious cases such as cerebellar lesions or cerebral palsy. Subtle nerve injury, however, can cause subtle loss of neuromuscular control. For example, mild irritation of the C-5 nerve root can cause abnormal firing patterns of the shoulder girdle muscles and result in upper back and shoulder pain (11). Mild irritation of the L-5 nerve root can cause abnormal firing patterns of ankle and lumbopelvic stabilizers and lead to ankle or lumbopelvic instability and pain. For optimal success, a comprehensive rehabilitation program addresses biomechanical deficits in both the musculoskeletal and neuromuscular systems.

Another cause of impairment in neuromuscular control is loss of sensory feedback from a body part. This can be dramatic in obvious cases such as occur with a lesion of the sensory portion of the internal capsule or severe vitamin B_{12} deficiency. More subtle loss of sensory feedback can also alter normal neuromuscular firing patterns, however. A common example of this is the inversion ankle sprain. One can strengthen the foot and ankle indefinitely, but if proprioception retraining is not added to the rehabilitation plan, the patient may have persistent ankle pain due to poor fine motor control of the ankle stabilizers (12,13). Proprioception and fine motor control training is crucial for many injuries involving the spine, knee, and shoulder, as well as the ankle (14,15,16,17,18,19 and 20).

The clinician must recognize deficits in neuromuscular control that may be contributing to the patient's musculoskeletal pain and implement a rehabilitation plan that includes correction of those deficits.

Muscle Balance and Agonist/Antagonist Interactions

Musculoskeletal pain and dysfunction are sometimes related to muscle imbalance and agonist/antagonist interactions. In its simplest form, muscle balance theory states that a strong, tight muscle group will reflexively inhibit the antagonist group (1,21). The clinical implications of such agonist/antagonist interactions are important. If a patient is having trouble strengthening a muscle group during a physical therapy program, simultaneous stretching of the antagonist muscle group may be necessary to facilitate strengthening of the target muscle group. Similarly, if the patient is not progressing with correcting range of motion deficits in a particular muscle group, the rehabilitation plan may need to include strengthening of the antagonist muscle group (22). This concept is best illustrated by the following common examples of muscle imbalance that are clinically associated with painful musculoskeletal dysfunction.

The first example is that of the patient with subacute or chronic posterior neck pain. This patient often presents with cervical hyperlordosis due to tightness of the long cervical extensors and weakness of the cervical flexors (23). Both of these biomechanical deficits need to be addressed to restore proper cervicothoracic posture and movement. Similarly, one contributor to abnormal motion at the patellofemoral joint, with subsequent patellofemoral arthralgia, is muscle imbalance in the structures that control the patella. Typical biomechanical deficits in this case are tightness of the laterally situated iliotibial band (ITB) and weakness of the medial thigh muscles, including hip adductors and vastus medialis obliques (24). In treatment, it is necessary to stretch the lateral patellar stabilizers and strengthen the medial patellar stabilizers to improve patellofemoral tracking.

Another common area of muscle imbalance is the shoulder girdle, where one frequently finds tightness of the strong anterior shoulder muscles, including pectoralis minor, pectoralis major, and latissimus dorsi, with associated inhibition and weakness of the posterior shoulder muscles, including middle and lower trapezius and rhomboids (25). This forward-rounded shoulder posture (Fig. 96-2) can be a cause of interscapular pain, rotator cuff pain secondary to abnormal scapular movement, and upper limb pain due to ANT in the brachial plexus.

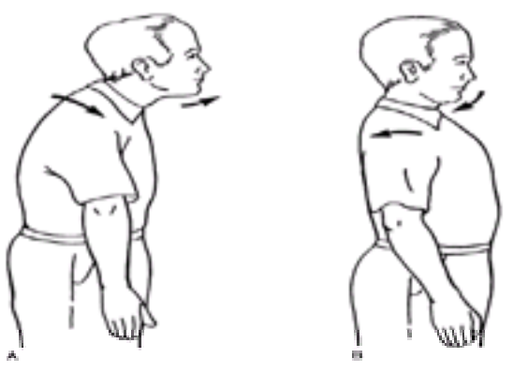

Figure 96-2. The forward-rounded shoulders posture offers a prime example of muscle imbalance that can lead to musculoskeletal dysfunction. The anterior shoulder muscles are tight and the neck and posterior shoulder muscles are put at mechanical disadvantage. **A:** Excessive cervicothoracic kyphosis necessitates a compensatory cervico-occipital extension to keep the eyes level. **B:** Posture rehabilitation includes stretching the anterior shoulder girdle, strengthening the scapular retractors, and chin tucks to improve cervicothoracic alignment.

Similar symptoms can be seen with imbalance between tight scapular elevators, principally levator scapulae and upper trapezius, and inhibited, weak scapular depressors, including lower trapezius and serratus anterior. This pattern of muscle imbalance causes the patient to have a shoulder-elevated posture and is also often seen in patients presenting with posterior neck and shoulder pain. The rehabilitation plan should include stretching of the tight muscle groups with simultaneous strengthening of their antagonists to restore normal muscle balance.

A fourth common site of muscle imbalance is the hip girdle, where tight hip flexors are often seen clinically with inhibited, weak hip extensors (1). Perhaps the most important clinical sequela of this type of muscle imbalance is not hip dysfunction *per se*. Instead, poor pelvic control by gluteus maximus results in an increase in anterior pelvic tilt, which leads to lumbar hyperlordosis and low back pain (26). The rehabilitation of low back pain almost always includes restoration of neutral lumbar posture. In this case, that would necessitate restoring full range of motion of the hip flexors as well as full strength of the hip extensors (27).

A few instances of agonist/antagonist interactions pose particularly troublesome problems for the neuromuscular control system. Consider again the relationship between the upper and lower trapezius. Working together, they couple forces to stabilize the scapula in a retracted and upwardly rotated position, a function crucial for all overhead activities. Yet, they also have antagonistic roles in that the upper trapezius is a scapular elevator while the lower trapezius is a scapular depressor. Such a complex relationship between two different parts of the same muscle, innervated by a single nerve, cannot always be accommodated by the neuromuscular control system and can result in scapulothoracic dyskinesis. In this case, the lower trapezius tends to become inhibited and weak.

An equally complex relationship exists between the tensor fascia lata and gluteus maximus, the two muscles that insert into and control the ITB. Working as agonists, the two muscles serve as hip abductors. Yet they are also antagonists in that the tensor fascia lata is a hip flexor and internal rotator, whereas the gluteus maximus is a hip extensor and external rotator. As in the above example, this can tax the resources of the neuromuscular control mechanisms that dictate appropriate firing patterns. In this example, the tensor fascia lata usually dominates, with the gluteus maximus becoming inhibited. If fine control of the ITB is lost, hip pain (trochanteric

bursopathy) or knee pain (ITB insertionopathy) can result.

Other examples exist where muscles serve paradoxic functions. The tibialis anterior and tibialis posterior (TP) work together to invert the foot and support the arch. Yet they are also antagonists in that the former is an ankle plantar flexor, whereas the latter is a dorsiflexor. At times, during normal walking gait, running gait, and going up or down stairs, both muscles must be active for dynamic arch support, but we need one or the other to stop firing because we need the action of its antagonist. Abnormal firing patterns of TP can lead to TP tendinopathy. Inhibition of either the tibialis anterior or TP can lead to arch collapse and foot pain.

Similarly, the extensor carpi radialis brevis (ECRB) and longus cooperate with the extensor carpi ulnaris to extend the wrist. But the ECRB is left in a quandary during wrist extension movements that require radial deviation, such as hitting a backhand in tennis, or repeatedly loading luggage onto a conveyer belt. At these moments, ECRB must fire to produce wrist extension and radial deviation. But the extensor carpi ulnaris, an ulnar deviator of the wrist, abandons its partner in wrist extension to allow radial deviation of the wrist to occur. This neuromuscular predicament impedes the ability of the wrist extensors to adequately concentrically generate or eccentrically absorb forces, and leads to ECRB overload (called *lateral epicondylopathy* or *tennis elbow*).

In each of the above examples of contradictory agonist/antagonist interactions, there exists a common, associated overuse injury such as rotator cuff tendinopathy due to scapulothoracic dyskinesis, ITB friction syndrome, posterior tibial tendinopathy, or forearm extensor tendinopathy.

The clinician must recognize muscle imbalances that contribute to the patient's musculoskeletal pain and implement a rehabilitation plan that restores proper balance by treating both the agonist and antagonist muscle groups involved. Neuromuscular control must be optimized through specific muscle education and training.

Neural Tension

Neural structures in the central nervous system (CNS) and peripheral nervous system (PNS) move when body parts move. Like muscles, tendons, and joint capsules, the connective tissue associated with the nervous system can lose its normal elasticity and range of motion. If symptomatic, this condition is called *adverse neural tension* (ANT). Alternative names include *adverse neurodynamic tension* or, sometimes, *dural tension*. ANT can be defined as abnormal physiologic or mechanical responses of the nervous system as its tissues are taken through a range of motion (28).

ANT is most commonly recognized as the condition that produces a positive straight-leg raise test. It is also commonly recognized as the entity that produces a positive Kernig's sign in a patient with meningitis. Less commonly recognized, however, is that ANT can exist in areas other than the lumbosacral roots that contribute to the sciatic nerve. Even in the absence of meningitis, it can exist in the spinal cord and the surrounding connective tissue, the cervical roots, brachial plexus, and peripheral nerves. ANT can cause range of motion restrictions, pain with movement, paresthesias in the distribution of the nerves affected, and diminished neuromuscular control.

Normal and abnormal movement of neural structures during movement of the musculoskeletal system has been partly characterized. The posterior part of the human spinal canal increases between 5 and 9 cm in length as the spine goes from full extension to full flexion (29,30 and 31). Thus, trunk and neck movement is associated with gliding movements of the spinal cord within the canal. The dura is connected to the bony and ligamentous structures of the spinal canal via the ligaments of Hoffman (32). Abnormal adhesions between the dura and surrounding structures may form, however, and have been implicated in enhancing pain consequent to disk herniations (33). Upper and lower limb movements also have mechanical consequences for the spinal cord and its roots (34). The median nerve elongates 20% as the upper limb moves from elbow and wrist flexion to full elbow and wrist extension (35). Further stretching of the nerve fibers in the brachial plexus is obtained by adding ipsilateral shoulder depression and contralateral cervical flexion (36).

The nervous system is linked to the musculoskeletal system in several ways. First, neural movement is mechanically coupled with musculoskeletal movement. Second, the nervous system is physiologically connected to the musculoskeletal system at the neuromuscular junction. Third, the nervous system itself can be considered to be in part a connective tissue. Myelin possesses elastic features that allow the myelin sheath to change conformation as nerves stretch, with opening of the clefts of Schmidt-Lantermann (37,38,39 and 40). The endoneurium, perineurium, and epineurium surrounding peripheral nerves all contain collagen (41), the common substrate of all connective tissue.

The connective tissues within peripheral nerves allow for the necessary gliding of adjacent fascicles against each other during limb movements, especially when the limb goes through its full range of motion. Also built into the neurodynamic system is an allowance for a considerable amount of motion between the peripheral nerve and the surrounding tissues in which it lies (35,42). Tunturi demonstrated the presence of elastin in the dura mater of dogs, suggesting that dura possesses the capability of distensibility (43).

Certain regions of the body exist in which the connective tissue of the nervous system is more abundant. For example, the fibular nerve (also called the *peroneal nerve*) has 17% more connective tissue associated with it as it passes around the fibular head than as it courses through the popliteal fossa (44). The amount of connective tissue in peripheral nerves ranges from 21% to 81%, with greater amounts present when the nerve passes a joint (45). The connective tissue elements associated with the CNS and PNS protect neural tissue from injury during gliding movements and compressive events.

The spinal nerve roots lie at the junction of the CNS and PNS and are at particular risk for mechanical stress and ANT for three reasons. The first is that the connective tissue covering the roots is at a transition between the CNS and PNS and is not as well developed as its more proximal or distal counterparts (46). Second, the spinal nerve roots are more tightly adherent to the walls of the intervertebral foramen than in other places (47,48). Third, stenosis of the intervertebral foramen, which can cause abnormal neural gliding, is a common occurrence.

Often, a close association exists between ANT and muscle tightness. A prime example of this is patients with lumbosacral nerve root tension who also have marked hamstring tightness. Both the nerve root and the muscle must be mobilized if normal biomechanics in the region are to be restored (49,50). ANT and muscle tightness often coexist and can easily be mistaken for one another. Careful physical examination is required to distinguish between the two.

Several special physical examination maneuvers that test for ANT in the spine and limbs are described later in the chapter. The clinician treating pain syndromes must be able to identify when ANT is contributing to the patient's symptoms and then implement an appropriate neural mobilization program.

Kinetic Chain Theory

Kinetic chain theory states that biomechanical deficits in one region can be responsible for symptoms in a distant body part. A corollary to kinetic chain theory is the concept of force distribution. A biomechanical system functions optimally when all its parts are able to absorb and generate forces appropriately. Loss of optimal function in one region of the kinetic chain may predispose to overload in another region. The following two examples illustrate this idea. First, if a volleyball player is generating inadequate hip extension or ankle plantar flexion moments during jumping, the athlete's quadriceps can become overloaded and patellar tendinopathy may result as the quadriceps is forced to compensate for the deficiencies of its kinetic chain partners. Second, if a golfer lacks adequate hip rotation, there will be a compensatory increase in lumbar axial rotation during the driving swing that may result in low back pain. Thus, the clinician must assess function in parts along the kinetic chain both proximal and distal to the painful area.

Kibler and colleagues (51,52 and 53) have eloquently synthesized a grand unifying theory of kinetic chain functioning. They describe how for any injury, there are five separate elements that make up the musculoskeletal injury complex that may be identified as contributing to the production or continuation of symptoms (Fig. 96-3). These elements include (a) the tissue injury complex—the actual area of anatomic disruption; (b) the clinical symptom complex—the group of symptoms the patient experiences, such as pain, stiffness, and impaired performance; (c) the functional biomechanical deficit—the set of muscle inflexibilities, weakness, and imbalance that cause inefficient mechanics; (d) the functional adaptation complex—the set of functional substitutions that the patient uses in an attempt to reduce pain and maintain performance; and (e) the tissue overload complex—the group of muscles and other soft tissue structures that are subject to overload injury secondary to the initial injury or maladaptive biomechanics, thus causing or prolonging symptoms. These five elements are often interactive and additive, setting up a vicious cycle of continuing musculoskeletal problems.

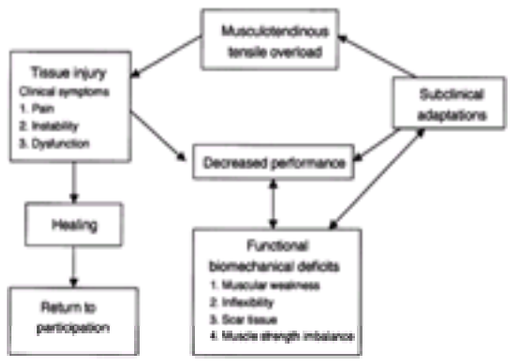

Figure 96-3. The vicious cycle: Tissue injury can lead to maladaptive biomechanical alterations, which in turn can lead to further tissue injury.

Prehabilitation and Posthabilitation

Prehabilitation refers to the process of identifying and correcting biomechanical deficits that might predispose individuals to musculoskeletal injury before they add stress to their musculoskeletal system by taking up a new sport, starting a new job, or otherwise increasing their activity level. The goal of prehabilitation is injury prevention. *Posthabilitation* refers to the process of ensuring that all relevant biomechanical deficits and maladaptive motor patterns are corrected, and remain corrected, after the patient becomes pain-free. It is important to remember that the absence of symptoms does not imply absence of pathology in the musculoskeletal system. The pain accompanying overuse injuries presents well after there are pathologic changes in the tissues and disappears before those tissues have fully healed. Therefore, the rehabilitation process must be comprehensive and continue after pain resolution. The goal of posthabilitation is prevention of injury recurrence.

Identifying Predisposing Factors

The astute musculoskeletal clinician searches for the reasons the patient developed an injury. In the case of acute trauma, the cause is obvious. In the case of soft tissue overload injuries, however, the clinician will need to look further. If the underlying precipitants of tissue overload are not addressed, the patient is at risk for recurrence.

Patient-Therapist Relationship

The relationship that the patient and therapist develop from their first session together and throughout treatment is crucial to the outcome of the rehabilitation process. The therapist must gain the trust of the patient and develop an exercise program that fits his or her musculoskeletal, cognitive, and psychological needs. Some patients require more information or more reassurance. Other self-motivated patients may simply need to be shown how to do their home exercise program correctly and require less attention from the therapist.

Regardless of the specific needs of the patient, the therapist and physician must empower the patient to become an active participant in the rehabilitation process. This is done by educating the patient about his or her particular musculoskeletal pathomechanics and ensuring that the patient is involved in a home exercise program designed to make lasting biomechanical improvements. It is the additional responsibility of the therapist to help motivate the patient to be conscientious about performing the exercises (see Chapter 94). Should the patient-therapist relationship hinder the rehabilitation process at any time, consideration should be given to having the therapist adopt different strategies for that particular patient or to changing therapists.

CLINICAL CONSIDERATIONS

Therapeutic Exercise

The musculoskeletal rehabilitation clinician uses therapeutic exercise like the cardiologist prescribes antihypertensive medication or the surgeon uses a scalpel. The goal of therapeutic exercise is to correct biomechanical deficits that are contributing to the patient's injury and restore and maintain normal structure-function relationships in the musculoskeletal system. Although it is appropriate for the exercise program to be overseen by a physician and therapist, patients should do the majority of exercises independently, either at home or in a gym setting. The importance of promoting patient independence in a home exercise program, with regular reevaluation and advancement of the rehabilitation program, is critical in our changing health care environment. The principal components of therapeutic exercise are flexibility, strength, and neuromuscular control training.

Flexibility Training

An individual's flexibility results from a combination of genetic factors (primarily collagen type) as well as musculoskeletal usage patterns. Injury and lack of use predispose to contracture of soft tissues. Potential benefits of flexibility training include increased range of motion, decreased risk of musculotendinous injuries, decreased soreness, and improved musculoskeletal performance (54,55). Several methods exist to improve flexibility. They include static stretching, ballistic stretching, contract-relax stretching, neural stretching, and manual mobilization. Each of these techniques is reviewed. Which technique to choose depends on the tissue to be stretched and the preferences of the physician, therapist, and patient.

Passive, Assisted Active, and Active Range of Motion. The terms *passive range of motion* (PROM), *active assisted range of motion* (AAROM), and *active range of motion* (AROM) refer to different levels of therapist and patient involvement in flexibility exercises (Table 96-1). PROM entails the therapist moving a joint through its range of motion with the patient maximally relaxed. The patient does not actively participate. PROM is often used in the early stages of rehabilitation and should be complemented with subsequent active participation by the patient. PROM is also used when the patient is unable to actively participate, for example, when trying to improve range of motion in a plegic limb. In AAROM, the patient actively moves the joint through its available range of motion as much as he or she is able, and then the therapist assists with overpressure at the end range of motion to make further gains in flexibility. AAROM is used when the patient is able to move the body part being targeted but not well enough at the end range of motion to improve flexibility. The goal of a progressive flexibility program is to enable the patient to perform the exercises independently. When possible, therefore, the patient should be advanced to AROM exercises without hands-on assistance from the therapist.

PROM	Passive range of motion
AAROM	Active assisted range of motion
AROM	Active range of motion

TABLE 96-1. Physical therapy categories

Static Stretching. In static stretching, the length of the muscle-tendon unit is slowly increased until the patient feels a mild to moderate pulling sensation in the belly of

the muscle being targeted. Sometimes the pulling sensation is felt at the musculotendinous junction or at the tendon-bone junction if there is overuse soreness or other pathology in these areas. If the patient feels pain or a severe pulling sensation, then the muscle-tendon unit is being overstretched and is at risk for injury. Severe discomfort during stretching is a signal that either the muscle should be relaxed by a few centimeters or a different stretch should be tried. During the course of a sustained static muscle stretch, the inverse myotatic stretch reflex is initiated, resulting in relaxation of the muscle (55,56). It is important to take advantage of this phenomenon by extending the stretch by a few degrees or centimeters every 10 seconds. Thus, “static” stretching is not truly static when appropriately performed. This slow, controlled method of stretching is generally considered the safest way to improve flexibility of muscle-tendon units.

Some debate exists over the optimum amount of time that a muscle should be placed on stretch to effect lasting elongation of the tissue. Most clinicians advocate that a stretch should be held for a minimum of 30 seconds (57); others prefer 120 seconds (58). Also, no clear guidelines exist on the frequency with which a muscle should be stretched to effect lasting elongation of the tissue. Generally, two or more stretches per day, each held for at least 30 seconds, are required to improve range of motion. Some prescriptions might call for stretching a muscle every 2 to 3 hours.

Ballistic Stretching. Ballistic stretching is a higher-level technique used to increase the length of the muscle-tendon unit. In ballistic stretching, the muscle is positioned near the end of its range of motion and then repetitively brought just past the point where it provides natural resistance. These repetitive “bouncing” motions can be low or high amplitude and low or high velocity. Repetitive low-velocity movements up to and just past the muscle's end range of motion are called *on-off stretching*. The primary advantage of ballistic stretching is that, when performed correctly, rapid and significant gains in flexibility can be achieved (59). The primary disadvantage is that it often requires the assistance of a qualified therapist or trainer. Another disadvantage is that the risk of over-stretching is greater than with static stretching. A session of ballistic stretching should be followed by static stretching of the target muscles.

Contract-Relax Technique. Contract-relax stretching is also considered a higher level stretching technique. Like ballistic stretching, the contract-relax technique has the potential to provide rapid gains in flexibility and it also often requires the intervention of a qualified therapist or trainer. This technique takes advantage of a period of muscle relaxation that follows muscle contraction. The patient firmly contracts the target muscle isometrically against resistance for approximately 5 seconds. Immediately following the contraction, the muscle is stretched. This contract-relax cycle can be repeated several times. Contract-relax stretching is sometimes referred to by the less descriptive term *proprioceptive neuromuscular facilitation* and is a form of the so-called muscle-energy stretching techniques.

Neural Tension Assessment and Mobilization. Restricted motion of neural elements can coexist and be interrelated with other soft tissue biomechanical deficits. Several reasons exist for this interrelationship. First, motion restrictions in the musculoskeletal system can cause secondary motion restrictions in the anatomically related neural elements. One example of this are tight, hypertrophied scalene muscles that restrict normal gliding of the brachial plexus as they pass out of the neck. Second, soft tissue edema or hematoma from acute trauma or chronic overuse can cause irritation of a nerve passing through the injured area. For example, sciatic ANT has been associated with repetitive hamstring strain (49,60). Third, primary nerve irritation, for example, from a discogenic inflammatory process, can cause abnormal neuromuscular control that leads to secondary biomechanical deficits in the muscles served by that nerve root. Thus, ANT is rarely seen in isolation and should not be treated in isolation from other biomechanical deficits.

Before adding neural mobilization to the rehabilitation program, the clinician must determine whether ANT is present and, if so, whether it is relevant to the patient's symptom complex. Several physical examination maneuvers can be performed that assess for ANT in the lower and upper limbs.

The best technique for assessing ANT in the lower limbs is the slump test (Fig. 96-4). The starting position for this test has the patient seated with hands placed behind the buttocks, palms up on the examination table. The patient then places the chin on his or her chest and slumps the torso forward. This motion draws the spinal cord cephalad (61). The examiner then sequentially extends the knee and dorsiflexes the ankle. These steps pull the lumbosacral nerve roots caudad (62,63). At each stage, the examiner asks the patient what he or she feels. If the maneuver reproduces the patient's usual leg pain, and having the patient extend the neck relieves symptoms, the test is considered positive for ANT. It is crucial that the geometric relationship between the thighs, pelvis, and thoracolumbar spine remains constant so as to avoid tensing and relaxing myofascial structures and thus better isolate movement in the neuraxis. A crossed slump test occurs when extending the asymptomatic leg reproduces pain in the patient's symptomatic leg. This is analogous to a crossed straight-leg test.

Figure 96-4. The slump test for adverse neural tension. Full spine flexion causes cephalad gliding of the spinal cord. Sequential knee extension and ankle dorsiflexion cause caudad gliding of the lumbosacral nerve roots. The examiner checks for reproduction of symptoms, side-to-side differences, and alleviation of symptoms with cervical extension.

The slump test is preferred over the better known straight-leg raise test for several reasons. First, the slump test is more sensitive because it adds cephalad gliding of the spinal cord, while the straight-leg raise maneuver only offers caudad gliding of the nerve roots. Second, the slump test adds specificity because neck flexion and extension help distinguish motion restrictions in neural tissue from other soft tissue inflexibilities. Using the standard straight-leg raise test, it is often difficult to distinguish between ANT and hamstring or gastrocnemius tightness. Both the straight-leg raise and the slump test can be modified to preferentially test tension in the peroneal/L-5 nerve fibers versus the tibial/S-1 fibers by inversion and plantar flexion of the foot (62).

The brachial plexus tension test is the upper limb homologue to the slump test. First, the cervical roots are pulled distally by sequential shoulder depression; shoulder abduction; and external rotation, forearm supination, and elbow, wrist, and finger extension. The examiner asks the patient what he or she feels at each stage. Reproduction of pain or paresthesias in the limb is considered a positive test. If the neck is side bent to the contralateral side, thus drawing the cervical cord away from the limb being tested, symptoms should be exacerbated. If the neck is side bent toward the ipsilateral side, symptoms should be alleviated (Fig. 96-5). Side-to-side comparisons should be done. The brachial plexus tension test was first described by Elvey (64) and has been subject to cadaveric and clinical verification (65).

Figure 96-5. The brachial plexus tension test: The examiner sequentially performs shoulder depression and abduction, forearm supination, wrist and finger extension, and elbow extension. After each movement, the patient is asked about symptom production. Contralateral cervical lateral flexion should increase limb symptoms, and

ipsilateral cervical lateral flexion should alleviate limb symptoms.

Brachial plexus tension testing maneuvers with median, ulnar, and radial nerve bias have been described (28). Because it can be difficult to differentiate between tightness in neural elements versus inflexibilities of myofascial structures along the kinetic chain, some clinicians refer to these physical examination maneuvers by the more generic term *upper limb tension tests* rather than brachial plexus tension tests. If the maneuvers reproduce neurologic symptoms, then the clinician can feel more confident that ANT is present.

The results of the neural tension maneuvers guide the initial neural mobilization maneuvers. The therapist instructs the patient to place the limb in the position where neural tension is first noted. Then the patient is instructed to slowly relax the limb a few degrees to a more comfortable position and then stretch a few degrees back toward the position of symptom reproduction. By gently repeating this maneuver with ever larger amplitudes, the connective tissues associated with the nerve gradually regain normal gliding motion.

Manual Joint Mobilization. Joint mobilization is a technique applied by a therapist to a spinal or peripheral joint in which an oscillatory movement is performed to restore full range of motion in the joint. Manual joint mobilizations differ fundamentally from the previous types of range of motion techniques discussed. Mobilizations are aimed at improving accessory movements rather than voluntary movements. Voluntary movements are movements that individuals can perform themselves, such as glenohumeral joint flexion, interphalangeal joint flexion, and lumbar flexion. In contrast, accessory movements are joint movements that individuals have no ability to perform and only occur passively. Examples of accessory joint movements include anterior-posterior gliding of the glenohumeral joint, interphalangeal joints, and individual vertebral segments. Accessory movements can be gliding, rolling, spinning, or compression/distraction motions of the joint. Joint mobilization maneuvers target range of motion restrictions in the joint and joint capsule itself, rather than the muscles that span the joint. Joint mobilizations can be diagnostic as well as therapeutic: They can help distinguish capsular versus muscular patterns of tightness.

Joint mobilizations are classified into four categories of increasing aggressiveness. Grade I mobilizations are small-amplitude movements performed in the middle of a joint's normal range of movement. Grade II mobilizations are large-amplitude movements performed within the free range of the joint but not moving into any resistance or stiffness. Grade I and II mobilizations can prevent further loss of joint range of motion but do not increase range of motion. They almost always precede grade III and IV maneuvers during a therapy session. Grade III joint mobilizations are large-amplitude movements performed up to the limit of the available joint range of motion. Grade IV mobilizations are small-amplitude movements performed at and just beyond the limit of the joint's range of motion. Manual joint mobilizations should only be performed by a therapist or clinician with advanced training in these techniques. Experienced manual therapists can mobilize virtually any joint in the body.

Common Stretching Errors. Probably the most common cause of ineffective stretching is not holding the stretch long enough or not performing it frequently enough. Improper technique is another common cause of ineffective stretching. Often individuals will fail to make gains in flexibility because the stretches target the single joint muscles in a muscle group, rather than the more important biarthrodial muscles. A prime example of this is the classic standing quadriceps stretch, which might address the vastus lateralis, vastus intermedius, and vastus medialis but neglects the rectus femoris, which crosses the hip joint as well as the knee joint (Fig. 96-6). Sometimes a stretching position inadvertently stretches tissues other than the target tissue. Finally, the flexibility program must address all the relevant structures contributing to the inflexibility. Joint capsule mobilization maneuvers alone will not be successful if the muscles crossing that joint are also tight. Similarly, muscle stretching alone will not be successful if an underlying motion restriction exists in neural structures. Carefully documenting an exercise history will help determine whether the exercises are being performed correctly.

Figure 96-6. A common error in quadriceps stretching is failure of the patient to stabilize the pelvis. The position shown here provides pelvic stabilization and greater stretch to all four of the quadriceps muscles.

Strength Training

Strength deficits often contribute to musculoskeletal pain. Strength deficits can cause pain in one of two main ways. First, a muscle can be a primary pain generator if it lacks adequate strength or endurance to perform a given task and therefore fatigues. Second, a muscle group lacking sufficient strength to properly control a joint may cause abnormal, painful motion in that joint. Many ways exist to improve muscle strength.

Exercise Prescription. A strength training prescription should include the patient's diagnosis, the muscles to be worked, the modality of strength training, the frequency, the number of repetitions per set and number of sets per workout, the intensity of the exercise, and precautions. Exercise prescriptions should be flexible. The clinician must reevaluate the patient at appropriate intervals and modify the program as necessary.

Specificity of Training Effects. Training effects tend to be very specific to the type of exercise performed. For example, strengthening the biceps in isolation does not increase triceps strength. Training for quick, explosive power does not improve endurance, and vice versa. Training muscle groups to generate force does not necessarily increase their ability to absorb force. Strength training for the lower limb does not improve balance unless it is done in a manner that challenges balance. Therefore, the goals of the rehabilitation program must be clear, and the prescription must be written to fulfill those goals.

Neural versus Muscular Mechanisms of Strength Gains. Physiologically, strength gains come about through neural and muscular mechanisms. It is well established that neural mechanisms play a significant role in strength gains during training. As early as 1967, researchers showed that rats on a training program improved muscle strength without a concomitant increase in muscle bulk (66). The ability of muscle to undergo strength gains without hypertrophy has been confirmed in humans (67,68). The mechanism of strength gains without muscle hypertrophy has been shown to be improved synchronization of motor unit firing. Neural mechanisms are more important than muscular mechanisms in the early stages of training, before muscle hypertrophy has had a chance to occur (67,68,69 and 70). Later in the course of a training program, muscular mechanisms predominate. The quantitative electrodiagnostic techniques used to investigate changes in neural synchronization during strength training have been shown to be reliable and sensitive (71,72 and 73) and continue to be used to investigate training effects on the neuromuscular system (74,75 and 76).

Static versus Dynamic Strength Training

Static Strength Training. Strength training can be broadly classified into static or dynamic exercises. Static strength training is more commonly referred to as *isometric exercise*. In isometric exercise, a muscle or group of muscles works against a resistance without any change in muscle length or joint angle. Isometric exercise is the strength training method of choice in the earliest stages of rehabilitating injured muscle, tendon, ligament, or joints. Isometric exercise offers the primary advantage of avoiding movement in painful or frail structures, while allowing strength gains to occur. Isometric exercise is used in patients with osteoarthritis, if putting joints through a range of motion may be painful or impossible. Isometric exercise is also used in the initial stages of the rehabilitation of strains and sprains and advanced

tendinosis, when movement of the injured structure puts it at risk for further injury.

Isometric exercise of any given muscle or muscle group should be varied in several ways. First, the joint angle should be varied. For example, in the earliest stages of rehabilitation for forearm extensor tendinopathy, the patient should be given a light hand weight to hold for a set amount of time with the wrist in a neutral position. Then the patient should statically hold the weight with the wrist in varying degrees of flexion and extension. The exercise should be gradually advanced by adding weight and by increasing the length of time of each repetition. The position should be held until mild to moderate fatigue develops in the target muscles.

Isometric exercises can be performed to either isolate a single muscle or work several segments of the kinetic chain simultaneously. In the rehabilitation of forearm extensor tendinopathy, for example, the wrist extensor strengthening can be done with the entire upper limb supported, except for the hand. Alternatively, the upper limb can be unsupported to simultaneously work the shoulder girdle. The latter method offers the advantage of working proximal parts of the kinetic chain, where relative weakness may have predisposed to distal overload. At appropriate times during the rehabilitation course, the patient's program should be advanced to short arc and then longer arc dynamic strengthening exercises.

Dynamic Strength Training. Dynamic exercises have various classifications. One can speak of concentric versus eccentric exercise, isokinetic versus isotonic exercise, closed kinetic chain versus open kinetic chain exercise, and plyometric exercise.

CONCENTRIC AND ECCENTRIC EXERCISE. *Concentric muscular contraction* refers to an action in which the muscle shortens to move a body segment. An example of concentric movement is shortening of the quadriceps muscle as one extends the knee while ascending stairs. An eccentric muscle contraction is one in which the muscle lengthens while resisting a force. An example of an eccentric movement is controlled lengthening of the quadriceps muscle as the knee flexes while descending stairs. The muscle has to lengthen to accommodate the normal mechanics of descent and also has to fire to prevent the knee from buckling. Eccentric exercise works muscles harder and is more likely to cause muscle overload than concentric exercise (77,78,79,80 and 81).

Frequently, strength training regimens include both concentric and eccentric exercise. When rehabilitating a particular injury, however, one should emphasize the movement that overloaded the structure in the first place. For example, if a furniture mover suddenly overloaded his elbow flexors by trying to stop a falling couch with his forearm, the initial strength retraining program should progress from gentle isometric exercises to slow, gentle eccentric elbow flexor exercises. In normal human movements, one often finds an eccentric contraction preceding a concentric contraction in the same muscle. This sequence of eccentric and concentric contractions forms a natural pattern called the *stretch-shortening cycle* (82).

ISOKINETIC AND ISOTONIC EXERCISE. In isokinetic exercise, the target muscle moves a joint through a range of motion at fixed angular velocity, but the torque generated by the movement may vary. This is accomplished with the use of specialized equipment that can be programmed to provide resistance to joint movement at any predetermined fixed rate, usually measured in degrees per second. Although isokinetic exercise is useful for quantifying strength for research purposes, or quantifying a patient's progress during the course of rehabilitation, it is a type of movement that is rarely performed during real-life activities (83). The applicability of isokinetic movements performed in the laboratory is further limited because of the dissociation between joint angular velocities and muscle shortening (84,85). Therefore, rehabilitation protocols should emphasize more functionally relevant exercises.

Isotonic muscle contraction refers to a muscle contracting through a range of motion while maintaining either a constant tension within the muscle or a constant torque applied against a resistance. Like isokinetic movements, isotonic movement is rarely reproduced during daily activities and is therefore more of an academic concept than a practical one.

CLOSED AND OPEN KINETIC CHAIN EXERCISE. *Closed kinetic chain exercise* refers to work done with the distal end of the limb fixed in space. *Open kinetic chain exercise* refers to work done with the distal end of the limb free in space. When a person does push- ups, for example, the hands are fixed on the floor, and the upper limbs function in a closed kinetic chain situation. When someone throws a baseball, however, the hand moves through space and the upper limb functions in an open chain fashion.

Advantages and disadvantages exist to both open and closed kinetic chain exercise. In general, if the movement to be trained is an open chain movement, such as lifting boxes, then the clinician should prescribe open kinetic chain exercises. Closed kinetic chain work is preferred when the patient needs to strengthen muscles that are primarily used in closed kinetic chain situations, for example, when strengthening knee and hip extensors in a postpolio patient who is having difficulty arising from a chair. Closed kinetic chain work offers several additional advantages over open kinetic chain exercise. Closed kinetic chain exercise promotes co-contraction of multiple muscles that cross a joint, thus providing greater joint stability. It also tends to work more segments of the kinetic chain, thus providing a more complete workout while also promoting improved sequencing of movements. Finally, closed kinetic chain work generally demands greater proprioceptive feedback than open kinetic chain exercise, thus improving this important sensory modality.

COMBINATION STRENGTHENING EXERCISES. A current trend exists to simultaneously work multiple muscle groups throughout the kinetic chain, rather than strengthen individual muscles in isolation. Two primary advantages exist to exercising multiple body parts at once. First, it is more time efficient. Second, most normal activities involve activating multiple muscle groups simultaneously or in sequence. Therefore, combination exercises are considered more functional than exercises that isolate individual muscles. An advanced form of combination exercise is plyometric exercise.

Plyometric exercise is a higher level dynamic form of exercise that can combine strength, endurance, power, balance, and agility training. Plyometric maneuvers simultaneously bring multiple muscle groups through a rapid stretch-shorten cycle. A simple example of lower body plyometric training is step jumping (Fig. 96-7). In this exercise, the hip extensors, knee extensors, and ankle plantar flexors rapidly fire concentrically. On landing, they fire eccentrically while lengthening. An example of upper body plyometric exercise could be throwing a basketball at a target while balancing on one leg. To avoid injury, an individual must attain an adequate baseline level of strength and flexibility before starting a plyometric training program.

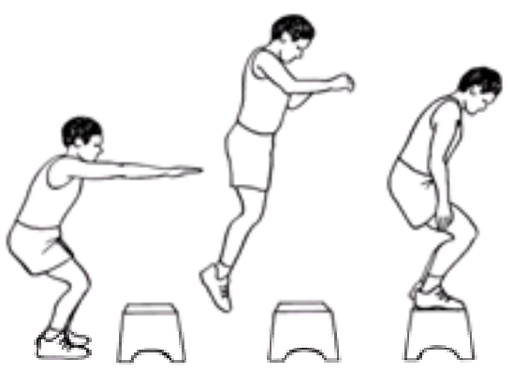

Figure 96-7. Lower body plyometric exercise: Step jumping builds strength, endurance, balance, and agility.

Manipulation

Manual manipulation of the musculoskeletal system dates back at least to the times of Hippocrates and Galen (86,87). After a long period of obscurity, manipulation reemerged at the end of the last century with the founding of osteopathy in 1874 (88) and chiropractic medicine in 1895 (87). Manipulation enjoys widespread popularity today, with an estimated 12 million Americans undergoing 90 to 120 million manipulations per year (89,90 and 91). Joint manipulation differs from joint mobilization in that manipulation employs low- amplitude high-velocity thrusts, while mobilization employs higher amplitude, low-velocity movements. Theoretically, if a manual therapist or chiropractor can improve a patient's joint alignment through manipulation, then biomechanics will also be improved (92,93 and 94).

Despite its popularity, the exact mechanism of action whereby manipulation alleviates pain remains unclear. Manipulation of the musculoskeletal system is postulated to have several beneficial effects. First, it is believed to help restore joint symmetry, particularly in reference to the spine (95,96 and 97). Second, it may aid in mechanical restoration of muscular and fascial range and ease of motion (98,99). Third, manipulative techniques have been theorized to induce sensory afference,

which may diminish pain through a gate theory effect (99,100 and 101). Fourth, some authors have postulated that manipulation increases endorphin release (92,97,99). These theories have not been subjected to rigorous scientific testing, however. Many believe that manipulation benefits patients primarily through a placebo effect (102).

In the past, many practitioners of manipulation have extended the benefits of this modality to areas beyond the musculoskeletal system, such as the endocrine, immune, and digestive systems (87). Such leaps in logic have led those in conventional medicine to question the practice of manipulation. Fortunately, a greater percentage of practitioners of manipulation now rely on this technique to restore structure-function relationships only in the musculoskeletal system.

Clearly, no current consensus exists on the mechanism whereby manipulation improves musculoskeletal function. Furthermore, there is no consensus on whether manipulation is beneficial at all, due to a lack of well-designed randomized controlled studies. One metaanalysis (103), two reviews (104,105), and two controlled clinical trials (106,107) indicate that manipulation decreases spine pain in selected populations, at least for short periods (e.g., less than 1 month). A review of randomized controlled trials found limited evidence that manipulation is better than placebo but not superior to other conservative measures for acute low back pain (108). The same review found strong evidence that manipulation is better than placebo and moderate evidence that it is better than analgesics, rest, and massage for chronic low back pain (108). Further study is needed to determine whether and how manipulation is effective.

Contraindications to high-velocity thrust manipulation include progressive neurologic impairment, unstable vertebral segments, severe osteoporosis, rheumatoid arthritis, bone or spinal cord tumors, spondyloarthropathy, bleeding diathesis, and poor manipulative skills. Risks are greater with cervical spine manipulations and include injury to nerve root, spinal cord, vertebral artery, and other soft tissue and osseous structures (109,110).

Spinal Traction

Like manipulation, spinal traction techniques date back to ancient times (111) and are widely used today, but are not universally accepted in conventional medicine circles. Also like manipulation, the literature on spinal traction is fraught with inconsistencies and methodologic flaws (108). Reviews of randomized clinical trials have failed to find proof of efficacy for spinal traction (108,112,113,114 and 115). However, numerous reports of positive results of traction exist (116,117,118,119,120,121 and 122), primarily in uncontrolled and/or nonrandomized clinical trials.

Proponents argue that if correctly performed, spinal traction can aid by widening the intervertebral foramina, decreasing intradisk pressure, allowing migration of herniated disk material back into place, decreasing facet joint friction, stretching paraspinal musculature, and straightening spinal curves, both in the lumbar (123,124 and 125) and cervical (126,127 and 128) regions. Three studies, two using epidurography (119,129) and one using computed tomography (122) to visualize disk herniations, have demonstrated reduction in disk prolapse following traction. Long-term maintenance of the reduction has not been demonstrated, however. In fact, disk material has been observed to return to its prolapsed state following traction therapy (129). It has been speculated, but not proven, that traction improves nutrition of the disk by decreasing intradisk pressure and facilitating imbibition (130). Traction has been advocated in the treatment of facet arthralgia and muscle spasm (131). Some argue that the primary benefit of traction is from immobilization rather than the traction itself (132).

Many ways exist to apply traction to the axial skeleton. Devices can be accommodated for use in a regular bed or hospital bed. There are also specially constructed, mechanical, single piece and split traction tables (133). Motorized and hydraulic traction tables are also available (132). A therapist can manually apply traction (88,134,135), although duration and force are more difficult to control when compared to mechanical or motorized traction. Some degree of traction can be obtained simply with positioning— for example, right side-lying on several pillows to provide left axial distraction. Autotraction is a technique that relies on patients' pulling their torsos cephalad with their arms, while the pelvis is fixed. Autotraction can be inexpensive and provides built-in protection against over-distraction because the patient controls the force applied. The patient's upper limb strength may be inadequate to generate the force necessary for distraction, however, and the time frame is limited by the patient's endurance (136,137). Furthermore, autotraction puts the patient at risk for shoulder injury. Some prefer gravity traction, in which the patient is suspended from a crossbar either in a fully inverted position or in an upright position. Both orientations provide distraction forces of approximately 50% body weight through the axial skeleton (138).

Traction devices can apply longitudinal, rotational, and side-bending forces. In addition to specifying the type of traction device used, traction prescriptions differ in terms of frequency of application, time per session, and force applied. No standardization of these parameters exists and prescriptions vary widely among practitioners.

Contraindications to traction are similar to those for high-velocity manipulation and include fracture, spine instability, osteoporosis, tumor, infection, pregnancy, hiatal hernia, and claustrophobia (139).

Physical Modalities

Physical modalities such as heat, cold, and electrical stimulation can be useful adjuncts to the physical restoration program. The primary goals of physical modalities are to decrease pain and inflammation to facilitate the exercise program. They should rarely, if ever, be used in isolation without an appropriate exercise program.

Heat

General Physiologic Effects of Heating Modalities. Many different heating modalities are available to raise the temperature in superficial and deep tissues. The physiologic effects of tissue heating can be broadly classified into hemodynamic, neuromuscular, joint and connective tissue, and analgesic effects.

The hemodynamic effects of tissue heating are related to increased blood flow. Forearm blood flow increases two- to threefold following application of heat (140). Vasodilation is postulated to speed healing of nonacute soft tissue injuries by increasing local metabolism and ingress of nutrients, leukocytes, and antibodies and increasing egress of breakdown products (141,142). Heat also increases nerve conduction velocities in most peripheral nerves (140,143). The clinical significance of this effect in musculoskeletal rehabilitation is unclear. A more relevant neuromuscular effect of tissue heating is the inhibition of group II muscle spindle fibers (144). Inhibition of spindle fibers can relax muscle and facilitate stretching.

Tissue heating facilitates stretching of muscle-tendon units by direct effects on connective tissue as well as by indirect effects via the muscle spindles. Lehmann and colleagues (145) showed that tendon distensibility increases with increasing temperature. They further showed that heat combined with stretching produced greater gains in tendon distensibility than heat or stretching alone. Heating superficial joints such as metacarpophalangeal joints can decrease stiffness in these structures and facilitate a stretching program (146).

Although heat is often used for its analgesic effect, the mechanism whereby heat reduces pain has not been clarified. Possible mechanisms include general relaxation effect, endorphin release, vasodilation causing washout of pain mediators, and vasodilation leading to a decrease in ischemic pain (147,148 and 149).

General Precautions for the Use of Heat. Heat use should be avoided in patients who are unable to provide feedback about their tissue temperature. This includes insensate patients and those whose cognitive condition impairs their ability to accurately warn the therapist of adverse effects—principally burns. Heat should also be avoided in patients with arterial insufficiency. The vasodilation produced can cause metabolic activity to exceed the ability of the arterial system to deliver oxygen to the area, resulting in tissue ischemia (141,150). Vasodilation can also result in increased bleeding in patients with a bleeding diathesis. Heat is contraindicated in acute musculoskeletal injury because it can increase acute hemorrhage and edema. Theoretical objections have been raised against the use of heat near tumors due to the fear of increased rate of tumor growth or hematogenous spread (149).

Superficial Heat. Heat may be transferred to body tissues by means of conduction, convection, or conversion. The first two are forms of superficial heat, while the last is used to heat deeper tissues. Superficial heat modalities are most useful for facilitating range of motion exercises in the hands and feet, where the target tendons and joints are superficial and not well protected by an insulating subcutaneous fat layer.

Hydrocollator packs, which transfer heat by conduction, are a commonly used modality to heat superficial tissues. They are made of silicon dioxide enclosed in canvas. These packs are heated to 65°C to 90°C and are applied to the skin over insulating towels for 20 to 30 minutes (151). Hydrocollator packs have been shown to raise tissue temperatures up to 3°C at a depth of 1 cm below the skin (152). The ability of Hydrocollator packs to significantly elevate the temperature of tissue deeper than 1 cm is questionable (152,153). Hot water packs, electrical heating pads, and chemical packs heat by convection. Hydrocollator packs have the advantage of offering greater temperature control than most of the convection modalities. Whirlpool and Hubbard tanks, however, provide superficial heat by

convection and offer very good temperature control. Heated water tanks should not exceed 40°C.

Perhaps the most common misapplication of superficial heating modalities occurs when it is used in an attempt to heat deep structures. Studies have shown that the modalities listed in this section do not raise the temperature in tissues deeper than the subcutaneous fat, which serves as an excellent insulator against heat (152,153).

Deep Heat

Ultrasound. Ultrasound is the safest and most commonly used of the deep heating modalities. Ultrasound employs sound waves above the frequency threshold of human hearing to heat deep tissues. The ultrasound frequencies used range from 0.8 to 1.0 MHz. Although ultrasound produces some nonthermal effects on biological tissues, such as streaming, microstreaming, cavitation, and standing waves, the effects of the nonthermal effects are not thought to be clinically significant (154,155,156 and 157). It is the thermal effects that are important.

The literature on the clinical benefits of ultrasound remains mixed. One group found no difference between exercise plus ultrasound and exercise plus sham ultrasound in a randomized, double-blind study in patients with lateral epicondylalgia, although both groups showed improvement over time (158). Similarly, ultrasound plus exercise showed no benefit over exercise alone in a randomized, double-blind, placebo-controlled study on patients with painful knee osteoarthritis (159). A review of the ultrasound literature concluded that most positive studies lacked adequate controls and that additional research was required to determine efficacy (148).

Shortwave and Microwave Diathermy. Ultrasound has largely replaced shortwave and microwave diathermy as the deep heating modality of choice. They are included here largely for historical reasons only.

Shortwave diathermy employs radio waves to heat deep tissues. The Federal Communications Commission has restricted medical use to specific frequencies and most shortwave diathermy machines in the United States operate at 27.12 MHz (160). Temperature elevations of 4°C to 6°C can be attained in muscle (161). Thermal effects tend to be greatest in water-poor tissues, however, and subcutaneous fat may be heated up to 15°C (162). Shortwave diathermy has been used to heat connective tissue in nearly every part of the body, including pelvic floor structures via transvaginal and transrectal application (163). Pulsed shortwave diathermy has produced statistically significant pain relief in patients with rotator cuff tendinopathy (164), neck pain (165), and other soft tissue injuries (166).

In addition to the general precautions of heat mentioned above, shortwave diathermy is also contraindicated in the setting of implants such as pacemakers, stimulators, surgical implants, contact lenses, and metallic intrauterine devices. Such devices can cause excessive heating to occur in the tissues immediately surrounding the implant. Additionally, shortwave diathermy can cause excessive bleeding if applied to the menstruating uterus. The safety of shortwave diathermy has not been established in those with immature skeletons and therefore is not recommended in the pediatric population.

Microwave diathermy differs from shortwave diathermy in that it employs electromagnetic radiation of much greater frequency. The Federal Communications Commission has approved microwave frequencies between 915 and 2,456 MHz for medical use. Lower frequencies penetrate to deep tissues better than higher frequencies (167,168). At 915 MHz, subcutaneous fat temperature may be increased 10°C to 15°C, with deep muscle temperature elevations of 3°C to 4°C at 2 to 4 cm below the skin (169).

The contraindications for other forms of deep heat application hold for microwave diathermy as well (see Fig. 96-1). Microwaves can produce cataracts, so both patients and therapists should wear protective goggles (170). Although human fetuses have been exposed to microwave diathermy without deleterious effects, the overall safety in fetuses and children has not been established and its use is therefore discouraged in pregnant women and young children. Because tissues with a high water content are selectively heated, application of microwave over fluid-filled cavities, cysts, or blisters can produce unacceptable local heating (171). The use of microwave diathermy has, however, been used to speed resolution of hematomas (172). Most clinicians feel that the presence of an acute inflammatory condition such as inflammatory arthritis is a contraindication to microwave diathermy (160). There are some reports, however, of improved patient comfort after application of microwave to rheumatoid joints (173,174).

Cryotherapy

Biological Effects. Cryotherapy has several benefits in the treatment of musculoskeletal pain. Its ability to slow nerve conduction (140,175,176 and 177) and produce local analgesia (178) is well known. It has also been shown to improve tendon distensibility (179) and modify muscle stretch reflexes (180,181,182,183 and 184). In combination, these effects can greatly facilitate a stretching program aimed at restoring full range of motion. Chilling a body part initially stimulates local reflexes to enhance sympathetic tone and produce vasoconstriction (185,186). Vasoconstriction reduces blood flow, slows local metabolism, and lessens swelling (187).

Technique. Ice packs, iced compression wraps, iced whirlpools, frozen steaks, and frozen bags of peas all work equally well in cooling body parts. The preferences of the therapist and patient usually determine the specific method of cryotherapy. Iced compression wraps offer a few advantages. Compression wraps help reduce swelling and can also add proprioceptive feedback for the individual who is exercising while icing (*cryokinetics*) or stretching while icing (*cryostretching*). Commercial products are available that are specifically designed for different body parts and that allow the individual to apply ice and compression simultaneously. These usually allow people to participate in other activities such as working or doing household chores because they do not have to fumble with a clumsy plastic bag of ice cubes. The recommended duration of cryotherapy is 20 to 30 minutes. This can be repeated up to once per hour. Longer periods of application increase the risk of local tissue damage and reactive hyperemia (188).

Precautions

The most common adverse reaction of cryotherapy is local tissue damage from overzealous icing. Skin burns, frostbite, and nerve injury can occur (189). Delayed tissue healing may occur if cryotherapy is used for extended periods, because of reduction in blood flow and slowing of local metabolism (190). Cryotherapy should be used judiciously or not at all in the extremities of patients with Raynaud's disease, cold urticaria, cryoglobulinemia, and atherosclerotic disease, because of the risk of inducing limb ischemia. As is true with heat therapy, cryotherapy is contraindicated in insensate patients who are unable to provide feedback on the status of the treated area. Properly applied ice treatments of less than 30 minutes in healthy individuals will not cause injury (178,184).

Functional Electrical Stimulation and Surface Electromyography

Transcutaneous electrical stimulation for the treatment of pain is discussed in Chapter 97. In the rehabilitation of muscle dysfunction, functional neuromuscular electrical stimulation (NMES) and surface electromyography (SEMG) are sometimes used to aid the muscle reeducation process. Muscles can become deeducated or lose their normal firing patterns for several reasons, including partial denervation, disuse from prolonged immobilization or bed rest, and maladaptive substitution patterns. Specialized muscle reeducation techniques are often useful after tendon transfers as well, when the muscle is being asked to fire in a new pattern (191). Electrical stimulation of muscle can help maintain muscle bulk during a period of disuse. It can also assist in the early stages of a muscle reeducation process, by giving the muscle a “jump start” (192,193 and 194). Once the patient feels the muscle firing with electrical stimulation, it is easier to start voluntarily firing the muscle. Feedback from the muscle can be transmitted to the patient using SEMG recordings. The patient can see the EMG signal recorded from the muscle undergoing reeducation and try to improve the firing pattern to make those tracings match a set of normal tracings. The use of SEMG as a biofeedback technique to help patients relax muscles that are overfiring is covered in Chapter 90.

The use of functional NMES/SEMG to help patients self-regulate the activity of motor units started in the 1960s (195,196 and 197). It has been used fairly extensively in the functional rehabilitation of stroke patients (198,199,200 and 201). In the nonstroke population, it has been used to reeducate muscles around the shoulder (202,203), forearm and hand (204,205 and 206), lumbar spine (207,208), and knee (209,210,211,212,213 and 214). As the benefits of functional NMES/SEMG become more widely appreciated, there will be greater elucidation of normal and abnormal firing patterns of muscle groups during dynamic activities.

Functional NMES is contraindicated in patients with pacemakers, local infection or malignancy, recent fracture or serious muscle/tendon disruption, local skin lesions, seizure disorder, and pregnancy (191).

Miscellaneous Physical Modalities

Numerous other physical modalities have been used through the millennia in the treatment of musculoskeletal pain ranging from aromatherapy to snake venom to healing touch. The majority of these alternative modalities are not discussed here due to a lack of scientific literature about their efficacy. Two less mainstream modalities that are becoming popular, vibration and low-energy laser therapy, warrant brief mention, however.

Vibration. A wide variety of vibration therapy products are commercially available. Physical therapists prefer models that operate with frequencies around 150 Hz and amplitudes around 1.5 mm (215,216 and 217). In uncontrolled studies, vibration therapy has been reported to be 70% successful in the treatment of sinusitis and musculoskeletal pain (218,219 and 220). These effects were not reversed by naloxone, suggesting that the mechanism of action did not involve stimulation of the natural opiate system (221).

French investigators have also reported success with vibratory stimulation in the treatment of chronic pain (222,223). In a prospective controlled study, Guieu and colleagues (223) found vibration to be more effective than sham treatment for short-term relief of chronic pain. Another arm of the same study found the combination of transcutaneous electrical nerve stimulation plus vibration to have additive effects for short-term relief of chronic pain (223). In a series of experiments, the same group of investigators has explored possible roles of vibratory stimulation in modulating the Met-enkephalin and substance P pathways via activation of large afferent nerve fibers (224,225,226,227 and 228). The definitive mechanism of action whereby vibration therapy reduces pain remains under investigation.

Low-Energy Laser. While low-energy laser treatments are available outside the United States for treating pain from osteoarthritis, back pain, headache, and neuritis, they are not yet approved for clinical use in this country. Energy levels used are usually in the range of 1 to 100 mW (229,230). Pain relief has been reported to be as high as 60% to 80% of subjects, although other investigators have found no benefit (229).

One double-blind controlled trial of low-energy laser versus sham treatment found it to be associated with decreased pain and improved grip strength in patients with lateral epicondylitis 4 weeks after treatment (231). Other randomized, placebo-controlled studies failed to find benefit from low-energy laser treatments in this condition (232,233) and in ankle sprains (234). A randomized, double-blind study evaluated the effect of low energy laser versus sham treatment on chronic low back pain. Both treatment groups were also placed on an exercise program. Both groups had a decrease in pain, but there was no difference between those who received laser treatments and those who received sham treatments (235).

The mechanism of action of low-energy laser remains unproven. Proponents of this modality report that it accelerates wound healing by stimulating DNA synthesis and collagen production and improves the function of damaged neurologic tissue (230). Further research is needed to definitively assess its efficacy and indications.

CONCLUSIONS

The goal of physical rehabilitation is to maximize the functioning of the patients' neuromusculoskeletal systems. Therapies are directed at correcting pertinent biomechanical deficits by restoring full, pain-free range of motion, adequate strength and endurance for the patients' desired activity levels, and proper neuromuscular control. The mainstay of treatment is therapeutic exercise. Most exercises can be done by the patient in a home exercise program after careful instruction by a therapist. Manual techniques by a specially trained therapist can be very helpful, especially in the early stages of the rehabilitation program. Patients' progress should be reevaluated at appropriate intervals, and their therapeutic exercise programs should be upgraded as needed. Therapeutic modalities such as ice and ultrasound can be helpful to facilitate the exercise program. The majority of the work in most successful programs is done by the patient, not the therapist.

CHAPTER 97

Acupuncture

Stephen H. Butler and C. Richard Chapman

Acupuncture is a therapeutic procedure in which small, solid needles are inserted into the skin at varying depths, typically penetrating the underlying musculature. This method, derived from practices in ancient Asian medicine, was essentially unknown to most physicians in the United States when the first edition of this book was written. Bonica (1) mentioned acupuncture as a form of local therapy and cited its use by Osler for treating various painful conditions during the latter part of the nineteenth century. Because of the publicity given to Chinese demonstrations of acupuncture pain control for surgery in the 1970s, acupuncture has since become familiar both to the medical community and to the lay public. Its practice remains controversial, but in more than 34 states in the United States and many other countries, nonphysician acupuncturists have won the right to practice their trade either independently or under the auspices of a licensed physician. In the United States, there are more than 10,000 licensed nonphysician acupuncturists, plus 3,000 physician acupuncturists, as well as at least that many additional physicians using various acupuncture- related techniques. More than 1 million patients per year are treated by these practitioners (2). In 1993, the U.S. Food and Drug Administration reported that more than $500 million was spent on acupuncture therapies.

Acupuncture is of interest to physicians concerned with pain management in day-to-day practice for two reasons: (a) It offers a comparatively safe alternative or complementary treatment to the prescription of medication for pain problems, and (b) patients often ask their physicians for advice on whether they should engage the services of an acupuncturist or for referral to an acupuncturist. It is therefore worthwhile to have a working knowledge of acupuncture techniques, the potential of this approach for pain management, the issues surrounding its putative mechanisms, and its limitations.

This chapter provides an overview of current clinical and scientific knowledge about acupuncture for pain therapy. We discuss the use of acupuncture for the control of acute and chronic pain rather than its possible use for the prevention of pain during surgery. Acupuncture pain control in the surgical setting, although now recognized as a valid phenomenon, is of little clinical importance in Western medical practice, and its adoption in the West is no longer at issue for surgical anesthesia. There are, however, interesting reports of intraoperative “electroacupuncture” having opioid-sparing effects in the postoperative period (3). Bonica (4) wrote a definitive report on the use of acupuncture for surgery. Surgical use is of interest only to the extent that it sheds light on the mechanism(s) of acupuncture therapy for pain prevention or relief. Acupuncture in the treatment of disease states is not discussed, as that subject is beyond the scope of this book.

In addressing acupuncture pain therapy, which is practiced widely in the United States, this chapter draws heavily on the research produced in this area since 1980, but, where appropriate, earlier studies are also considered. The National Institutes of Health (NIH) Office of Alternative Medicine has provided more than $2 million for research since its creation in 1993 (2). In November 1997, the NIH issued a consensus report after a panel reviewed the current literature. They acknowledged that evidence was strong for the use of acupuncture for nausea and vomiting associated with surgery and for post–dental surgery pain but that more research was necessary to support the claims for other areas of pain relief. The political and economic issues surrounding acupuncture may have significantly influenced both the panel's recommendations and the popular interpretation of the usefulness of acupuncture.

The ancient Chinese acupuncture medicine is noted only briefly, because this information is of little relevance and is available in copious detail elsewhere (5,6,7,8,9 and 10). For those interested in a recent translation of the Yellow Emperor's 2,300-year-old treatise on Asian medicine, a portion on low back pain is available in English (11). The purpose of this chapter is to provide interested physicians with a working knowledge of the field so that they can judge the potential utility of acupuncture techniques for specific pain management problems.

The Basic Considerations section includes the three basic types of acupuncture therapies for pain and the indications for these therapies, a brief description of how acupuncture is performed, and a broad review and evaluation of the scientific basis for the use of acupuncture for managing pain. The Summary reviews the current state of knowledge in this field. The use of acupuncture needles in the treatment of musculoskeletal pain syndromes is discussed in Chapter 28. This is the only current use of the technology at the University of Washington Pain Center; we do not make use of traditional Chinese acupuncture in the treatment of chronic pain.

Since the prior edition of this text in 1990, the literature has expanded. A Medline search revealed 788 abstracts from 1988 to 1998 covering all aspects of acupuncture for pain in both the clinical and basic domains. There continue to be major difficulties with the literature. Fifty percent of the citations are in Chinese or other non-English languages, the latter mostly from Eastern Europe. Often they are without abstracts, which makes evaluation impossible. The studies continue to lump traditional acupuncture, electroacupuncture, intramuscular stimulation, and a new designation, *pharmacologic acupuncture*, together as if they were interchangeable therapies. Much of the basic research is in anesthetized animals, usually receiving electrical stimulation through acupuncture points that supposedly correspond to those in humans. The results are then interpreted in a human patient context—a tremendous leap of faith that is rarely addressed in these studies or in reviews of the subject.

BASIC CONSIDERATIONS

Types of Acupuncture Therapies

Review of the current medical literature reveals that the term *acupuncture* can refer to at least four different interventions: classic acupuncture based on Chinese medicine, acupuncture as a form of trigger point therapy, acupuncture as a procedure for electrical stimulation, and pharmacologic acupuncture, in which substances as varied as water, opioids, herbal mixtures, and steroid extracts are injected at acupuncture points. The use of lasers instead of needles is also becoming popular, but there is little information on the scientific basis for this and it is, strictly speaking, not a puncture. These are distinctly different therapies, and each should be considered separately. Unfortunately, the basic and clinical research studies often gloss over some fundamental differences in these techniques. However, many studies point out that electrical stimulation of acupuncture needles, in any position, and transcutaneous electrical nerve stimulation (TENS) are indistinguishable from electroacupuncture at classic acupuncture points (9).

Classic Acupuncture

The first and best-known form of acupuncture is the practice of traditional methods according to the principles of ancient Chinese medicine (10,11 and 12). Taoist doctrine saw human health as existing within the tensions created by opposing forces in nature, the yin (dark, female) and the yang (light, male). Medical intervention carried out within this tradition was undertaken to balance opposing energy forces considered out of harmony. A concept of energy flow that combined circulation and neurologic function was fundamental to the practice of classic acupuncture. Vital life energy was thought to flow through a set of interconnected channels, called *meridians*, that followed a circadian rhythm (Fig. 97-1).

Figure 97-1. The practice of acupuncture derives from the principles of oriental medicine. The points that an acupuncturist stimulates by needle puncture follow a series of life force lines, or channels, called *meridians*. A vital life force, called *chi* (or sometimes *Qi*) flows through the channels. Chi flowing through meridians moves longitudinally, encircling the body. Essentially, the meridians are a closed system for the circulation of energy throughout the body. There are 12 main pairs of meridians (each is represented on both sides of the body) and two midline meridians on the ventral and dorsal midlines of the body. The meridians on the ventral surface are yin meridians; those on the dorsal surface are yang. The names of the meridians correspond to the various organs or functions for which they have a controlling influence. Excess, blockage, or deficiency of the flow of chi causes disease in the affected meridian distribution.

One of the internal organs was thought to be associated with each meridian, and the meridians are named according to organs. For example, the meridian for the gallbladder runs from the external canthus of the eye, back and forth along the skull, and down to the shoulders, from which it descends along the side of the body and ends at the fourth toe. It is a yang meridian—its function is balanced against that of its yin counterpart, the liver meridian. The latter runs from the great toe to the groin and into the chest, where it is said to disappear from the map of meridians because it courses deep into the body and has no surface representation. Diseases and discomforts such as pain were classified according to the meridians felt to be involved and according to whether they had a yin (cold, hypofunctional) or yang (hot, hyperfunctional) nature.

The meridians were said to be interconnected with the vital life energy, *chi*, flowing through them. Excesses or deficiencies in the flow of energy were said to cause pain, discomfort, hypo- or hyperfunction, and, with time, trophic changes. By inserting the needles strategically along individual meridians or at their junctures, the acupuncturist attempted to balance the flow of energy throughout the body.

Numerous variations on classic acupuncture exist. Among them is a system of ear acupuncture based on the belief that the pinna contains a map of acupuncture points representing the entire human body. Research on this type of diagnosis and therapy is expanding, but there are few controlled trials and those that have been undertaken have failed to yield supporting evidence (13). The many other embellishments of classic acupuncture are outside the scope of this chapter.

Today in Asia, many practitioners still use classic Asian medicine principles in the treatment of pain and disease states, and they are also popular in many parts of Europe, where they are used by physicians, nurses, and physical therapists as well as nonmedical practitioners. When Western physicians or other health care professionals practice traditional acupuncture it is often based on a cookbook approach in which a routine set of meridian points is used to treat each type of pain problem (5,6). This is neither bona fide Western nor Asian medicine, because classic practice in its pure form emphasizes the unique individual diagnosis of each patient.

Although these and other concepts of ancient medicine were exceptionally enlightened for their time (e.g., they conceived of circulation and certain basic principles of neurology), they are now primarily of historical interest to Western medicine. It is hardly surprising that much of the ancient folk medicine cannot be validated by modern science. For example, one organ postulated by the ancient Chinese to affect energy flow, the “triple heater,” is nonexistent. Similarly, meridians exist neither as anatomic structures nor as patterns of neurologic response. Whereas contemporary studies have shown that acupuncture points are often characterized by low electrical skin resistance and tenderness to palpation, these are also the characteristics of trigger points (see Chapter 28 and Chapter 29). The existence of correspondence between meridian pathways and patterns of referred pain or sensation produced by finger pressure at tender points/trigger points overlying muscle is not surprising and is well known to Western medicine (14,15 and 16). Such correspondences help to confirm that ancient Oriental therapists identified and treated conditions that are still observed and often undertreated today. They do not validate the notion that acupuncture has some special or mysterious origin that gives it an advantage over contemporary, scientifically based practices.

Variations of traditional medicine exist in a revised form in contemporary medicine in the Far East. For example, Japanese Ryodoraku treatment maintains most of the basic tenets of classic acupuncture, but the mechanism underlying treatment is considered to be the autonomic nervous system (17,18). Therapists attempt to balance sympathetic and parasympathetic functions of the autonomic nervous system and rely heavily on readings of electrical skin resistance at traditional meridian points for diagnosis. Meridians are considered to be patterns of autonomic activation. This and other hybrid therapies offer bridges between classic Asian medicine and modern science. Unfortunately, such possibilities remain in the realm of conjecture for want of scientific data to support the basic hypotheses.

It is difficult to justify the perpetuation of ancient folk medicine concepts, at least in their pure form, in contemporary medical practice, but the romance of ancient knowledge has gained a strong following among lay practitioners of folk medicine and among some physicians. It is strongly rooted in the culture of several major nations. In some industrialized countries, including Japan, Chinese medicine is taught in degree-granting institutions. Approximately one-sixth of the world's population relies occasionally on Chinese medicine.

Trigger Point Therapy

The second application of acupuncture is essentially neurologic and muscular. Degenerative changes in neural function related to stress, prior injury, and aging can upset the normal properties of skeletal muscle, as well as those of other tissues and organs, in subtle ways that might not be evident on conventional neurologic examination. Abnormal areas of skeletal musculature can be felt as tender, ropy strands or points associated with signs of excessive sympathetic activity (e.g., coldness, mild edema), pain on palpation, and general fatigue. Such points have been identified by Bonica (1,14), Travell and Simons (15), Sola (16), and others as *tender points* or *trigger points* that can be effectively treated by stimulation to achieve relief of persistent pain. Chapter 28 and Chapter 29 describe trigger points, their associated myofascial pain syndromes, and treatment of these syndromes.

When acupuncture needles are used to treat the tender points in muscle associated with chronic pain, acupuncture is nearly indistinguishable from trigger point therapy. The close relationship of trigger points as defined by Western medicine and acupuncture points as identified by ancient texts of Asian medicine has been addressed by Melzack (19) and Gunn (20). Although many trigger point therapists choose to inject local anesthetic or normal saline solution into tender areas, some use stimulation with an acupuncture needle at the same site. Many, like Sola, believe that trigger points are associated with sympathetic hyperactivity and that local chemical blockade of the trigger point eliminates the basic pathophysiology.

The possible mechanisms underlying trigger point therapy have been reviewed in depth by Travell and Simons (15) and Sola (16,21). We also postulate that such treatment may reverse the effects of chronic nerve damage, such as radiculopathy, on skeletal muscle (see Chapter 28). Pain of this type is almost invariably accompanied by prolonged muscle contractures, and pain relief is predicated on the release of painful contractures. These concepts and principles of treatment are not encompassed by traditional Chinese acupuncture theory or practice.

Electrical Stimulation Therapy

Electrical stimulation for pain relief might be as old as acupuncture itself. Records from the ancient Greeks and Romans indicated that fish such as the electric eel that could produce an electrical discharge were used to treat patients with pain. During prolonged surgeries in the early 1970s, Chinese acupuncturists found extended manual twirling with needles inefficient (and perhaps monotonous and tiring as well) and replaced this practice with electrical stimulation. In parallel, Western practitioners, inspired by the gate-control theory of Melzack and Wall (22), began to develop electrical stimulation therapies for pain control. This has led to the widespread use of TENS and the development of an industry in the United States (and other parts of the world) that manufactures TENS units. (TENS therapy for pain

is presented in Chapter 98.)

In an animal study, TENS and electroacupuncture were shown to have the same effects (23), and research in one area contributes information to the other. The two approaches have in common three sets of parameters for electrical therapy: (a) high-frequency, low- intensity stimulation (generally delivered at the area of painful focus); (b) low-frequency, high-intensity stimulation (typically delivered distal to the area of pain, perhaps at a classic acupuncture point); and (c) burst mode stimulation, in which brief bursts of high-frequency stimulation are given. These methods appear to have different effects in different situations. More detailed information on the parameters of choice for electrical therapy and the differential application of the three sets of parameters for selective pain problems is presented in Chapter 98.

Acupuncturists differ from TENS therapists in the use of needles rather than broad electrodes and in a tendency to use electrical therapy for systemic rather than local effects, although prominent exceptions to this rule are found. Because needles penetrate the skin and often underlying muscle, some therapists combine electrical and trigger point therapy.

Procedure

Classic Methods

The insertion of acupuncture needles is not technically demanding, but a surprising variety of techniques exists. Many claims have been made—but with no actual evidence—that different procedures of needle insertion produce different therapeutic results, and acupuncturists do not agree among themselves about optimal needle technique. Many classic therapists think it important to slant the needle either in the direction of assumed energy flow in the treated meridian or against the energy flow, and some use gold and silver needles for special purposes. In some cases, mugwort is pressed into a ball and attached to the top of the needle. The acupuncturist lights the herb after needle insertion, and the smoldering material gently heats the inserted needle. These practices and other exotic refinements related to classic theory are of no practical importance for Western medical application.

Modern Methods

Figure 97-2 demonstrates a typical procedure used by classic therapists for needle insertion. Individual therapists vary considerably in the way they manipulate the needle during insertion. Some use a lifting and twisting motion, others quickly insert it without rotation, and still others slowly penetrate the skin and underlying tissue. A few therapists penetrate only the skin and contend that no benefit is obtained by stimulating deeper tissues. Others argue that superficial and deep penetration are appropriate for different types of disorders. No right way exists, however, and patient comfort (or discomfort) is perhaps the most important criterion. Even this would be argued by the few acupuncturists who believe that stimulation of deep muscle and periosteum is of therapeutic benefit.

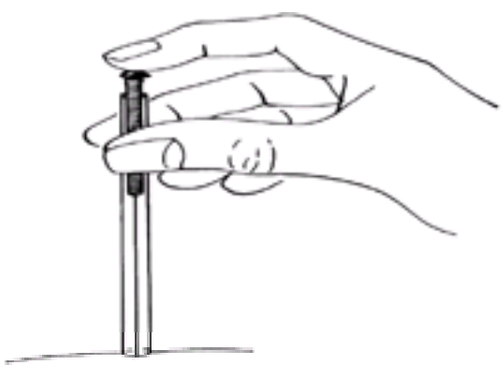

Figure 97-2. Classic acupuncture needle insertion techniques: the tapping method.

Students of acupuncture in China typically learn by inserting needles into themselves. This type of practice helps to ensure a technique that is minimally distressing to patients. Some physicians prefer to use needle guide tubes or devices that mount the needle in a guide cylinder equipped with a piston that taps the needle into place at the touch of a finger. Such methods help to minimize the distress of treatment and to maintain sterility. Figure 97-3 illustrates a Japanese needle system. Such equipment lends itself well to Western trigger point therapy, and we advocate the use of this type of instrument for dry needling as discussed in Chapter 28.

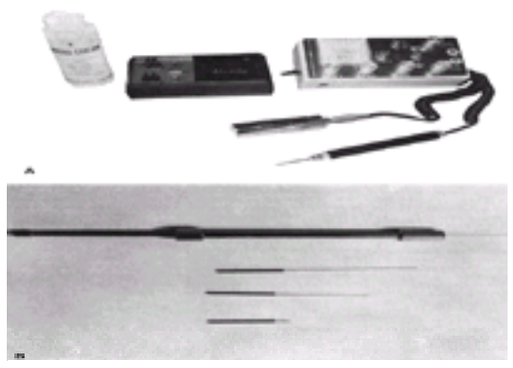

Figure 97-3. A needle system developed in Japan for acupuncture that is uniquely suited for trigger point therapy. **A:** Equipment to search for acupuncture points. From left to right: plastic container containing conducting cream, a battery pack, and a resistance meter with one lead (heavy upper) held by the patient and the other lead ending as a pencil point probe to detect acupuncture points. **B:** Three disposable acupuncture needles and a needle holder/plunger to assist in needle placement.

Chinese therapists emphasize the importance of *te chi* at the site of insertion: the underlying muscle appears to grab the needle and hold it firmly. The patient reports a concomitant feeling of heaviness or pressure or a deep ache where the needle is inserted. Trigger point therapists such as Sola (16) and Gunn et al. (24) have noted that the insertion of needles in muscle tissue that is not associated with a trigger point does not produce this response. In most classic practice the therapist does not remove the needle until the *te chi* has dissipated and the needle can be lifted from the tissue without effort.

The technique used by trigger point therapists for needle insertion has been borrowed from traditional acupuncture. Stainless steel acupuncture needles of varying lengths are commonly used. The length of the needle is dictated by the location of the point to be treated; deeper and thicker muscles require longer needles. A fine-gauge needle (30 gauge or less) with a pencil-point tip is believed to be less traumatic than the bevelled cutting edge of a hollow needle. The fine, flexible needle transmits the resistance and consistency of tissues penetrated, which adds a diagnostic component to the procedure.

The direction of needle insertion is generally perpendicular to the skin so as to penetrate the muscle zone of innervation. Tubular guides are used to facilitate skin penetration and to avoid touching the needle. We have used multiple needles for the several motor bands within a myotome belonging to both anterior and posterior primary rami that require treatment, but we now prefer the convenient use of only one needle in the plunger-type needle holder, which allows the same needle to be used at multiple loci.

Side Effects and Complications

Potential Complications

Acupuncture is a potential source of infection if sterile precautions are not taken. If an old, worn needle is used it can be broken during insertion and require surgical removal. In addition, improper needle insertion in the thorax or base of the neck can cause pneumothorax. The literature reveals a few cases in which patients have harmed themselves by inserting needles improperly (spinal cord injury in one instance), but few complications of acupuncture have been noted when performed by a trained physician. In the last 10 years, the literature has only ten citations related to complications, which list toxic shock with necrotizing fasciitis, bacterial meningitis, spinal cord injury, and pneumothorax. The safety of the technique compares favorably with the use of prescription medications, trigger point injections, and TENS.

The practice of acupuncture by nonphysicians is of growing concern to physicians as the use of acupuncture spreads. Most nonphysician practitioners are skilled and safe, but the possibility that serious problems might remain undiagnosed in patients under the care of nonphysicians is disquieting. Acupuncture can alleviate or mask symptoms that are of medical importance. This has been emphasized by the NIH consensus group as well as the need to standardize training and licensure. Therefore, the physician who has a patient who is also being seen by an acupuncturist should be certain that the patient has a thorough medical evaluation and should be alert to the fact that concomitant acupuncture treatment can affect or even suppress the symptoms with which the patient would normally present.

Precautions

It is essential to sterilize acupuncture needles and plungers by autoclave or gas because they could transmit hepatitis, human immunodeficiency virus, or other viral diseases. Alternatively, disposable needles for one-time use are preferable. Since repeated use weakens needles, the use of disposable needles minimizes greatly the possibility of breakage and retained needles. The skin should be cleansed with alcohol or another antiseptic at the site of treatment. The infectious complications of acupuncture therapy are minimal when sterile precautions and disposable needles are used. It is important to guard against pneumothorax when placing needles in the chest and shoulder areas, particularly when treating the parascapular and intercostal muscles. Treatment of the trapezius muscle requires particular caution because the patient might flinch with needle insertion, leading to inadvertent puncture of the apical pleura. When treating the paravertebral muscles, care should be taken to avoid excessively deep penetration that could injure the spinal cord. Vasovagal syncope responses are sometimes seen, typically when needles are inserted in the region of the brachial plexus, and it is good practice to have the patient lie down or sit in a supported position. The guidelines offered by Sola and Bonica in Chapter 29 and by Travell and Simons (15) for trigger point therapy are equally suitable for acupuncture.

Scientific Basis: Problems in Scientific Development

Traditional acupuncture is without a scientific basis (19). Modern research on acupuncture is a formidable undertaking, and work to date has been problematic at both the basic science and the clinical levels because scientific inquiry has not followed a logical progression. Just when the scientific community took interest in acupuncture in the mid-1970s, the raphe-spinal structures were identified as the mechanism subserving opioid analgesia and the enkephalins and endorphins were discovered. Many investigators rushed to hypothesize that endogenous opioids must be the mechanism of acupuncture pain control, and acupuncture research became caught up in the enthusiasm of endorphin researchers for linking all sorts of hitherto unexplainable phenomena to endogenous opioids (25,26,27 and 28). Over the last 20-plus years, the endorphin/opioid hypothesis has continued to intrigue acupuncture researchers. Of 46 articles reviewed that address this issue, 39 support the hypothesis for partial involvement and seven do not. Those in support all show only an incomplete effect and admit that this is not the whole story. All of this research interest in acupuncture in turn has led the scientific and clinical communities to engage for a time in backward reasoning: Acupuncture must be effective because so much work is being done to elucidate its mechanism(s). Proponents of acupuncture therapy have pointed proudly to animal studies that show links between acupuncture and endorphins, enkephalins, or dynorphins. The same animal models have been used to implicate all known structures in the ascending pain transmission systems from the spinal cord to the cerebral cortex as well as the descending inhibitory systems. Again, these effects are only partial and cannot be discriminated from the effects of noxious stimulation in studies that compare the two. Whether acupuncture analgesia in humans can be related meaningfully to effects seen in animals, many of whom are under the effects of general anesthesia for the studies, has not been considered. This unfortunate unsystematic progression has produced a knowledge base of limited value. To be fair, however, the problem of bias in research is not limited to the acupuncture field—it is well known in the philosophy of science. The tendency to be biased in interpreting scientific data that bear on clinical issues has been described (29), and “confirmation bias” of the sort demonstrated by some acupuncture researchers has been discussed by Greenwald and colleagues (30), Patel and colleagues (31), and Lewith and Vincent (32).

Unfortunately, the fundamental clinical research questions of whether acupuncture treatment can prevent or relieve acute and chronic pain are still inconclusively answered in spite of hundreds of studies over the past two decades. Indeed, many of the most basic questions remain unasked. As this review demonstrates, the literature is far from proving that acupuncture is effective in pain control. The American Medical Association reviewed this issue at its 1981 meeting and decided that insufficient evidence existed to conclude that acupuncture has any more effect on pain than a placebo or sham acupuncture (33). Sweet (34) was less kind, attacking acupuncture as essentially worthless. The issue has reemerged due to government pressure to scientifically assess alternative medicine. To address this issue, the NIH has founded a new department, and research funding has begun to flow. Clinical efficacy studies have, for the most part, been weak in design, measurement technology, and long-term follow-up. Consequently, it is still not known which acute and chronic pain problems, if any, can or cannot be helped by acupuncture.

Animal, human laboratory, and clinical research studies are reviewed broadly in the remainder of this section. The purpose of these overviews is to summarize the scientific knowledge base.

Animal Studies

A comprehensive review of the large literature on animals cannot be undertaken here, and its relevance for the clinician concerned with pain patients is moot. It is important, however, that the clinician not be misled by claims of acupuncture zealots based on data from animal researchers. Although valuable, animal studies often shed little light on the effects of acupuncture on patient care for the reasons to be described.

Many animal investigations of acupuncture analgesia have been done, mainly with small animals, but a few have used dogs or horses (35,36,37 and 38). Stimulation is primarily electrical with very few animal studies using classic manual stimulation. Measurement of pain has been restricted mostly to reflex responses or to simple behavioral indicators, such as escape from a stimulus. Only a few studies have tried to define the nature of acupuncture analgesia in a controlled fashion; most have attempted to identify a mechanism. In general, investigators have inappropriately made strong and direct generalizations to humans from animal data without regard to species differences and to the limited relationship of animal laboratory algesimetry models to human chronic pain as seen in the clinical setting. The question of points and meridians in animals is also a problem. In some studies, electrical stimulation is done in muscles corresponding to muscles underlying human acupuncture points. Is this acupuncture? In others, researchers use charts of points created for specific animals. In many cases, those doing the needling (or stimulating) have no previous knowledge of traditional acupuncture or any experience in needling.

The results of animal studies are inconclusive as evidence for acupuncture mechanisms in humans, partly because parallel findings have emerged in the animal literature concerned with acupuncture analgesia and with stress-induced analgesia (39,40 and 41). These findings indicate species-specific responses to acupuncture. When animals are subjected to intensive stress, such as cold water immersion, fright, or painful stimulation, a major hypothalamic-pituitary axis response is produced that includes liberation of cortisols, adrenocorticotropin, and b-endorphin, among other substances. Consequently, stress as a physiologic response is characterized by reduced sensitivity to injury or other pain challenge. Such analgesia is typically reversed by the opioid antagonist naloxone (39). In small mammals, such as rabbits, response to a stressor can take extreme forms, which include total immobility. It is not surprising that studies to look at both ascending and descending neural systems involved in pain show widespread changes in animal models without any differences in the effects produced by other noxious stimulation (40).

Frightening a small animal can induce a state popularly called *animal hypnosis* (having nothing to do with human hypnosis), in which the animal is quickly rendered unconscious and insensible (42,43 and 44). The more severe the stress, the longer the immobility of the animal, and fear potentiates this immobility response. In nature, such animals are often carried off by a predator and left near its den for a later meal. The putative hypnotic state gives them a chance to feign death, effect a recovery, and escape at a later time. This can be demonstrated in the laboratory by simply throwing a rabbit onto its back; one can then carry out an apparently painless laparotomy (43).

Under certain stressful and threatening circumstances, animals in a laboratory setting can go in and out of a putative hypnotic state (44). Because acupuncture is not understood by animal subjects to be benign, the process of handling and painful stimulation with needles can induce a stress response unique to certain species. Support for this possibility was provided by Galeano and associates (45), who performed acupuncture in rabbits while taking care not to induce stress. Under these conditions, acupuncture analgesia could not be induced. Some studies separate animals in a study population as to responders or nonresponders. Thus, animals

might not be suitable models for human acupuncture analgesia.

Failure to acknowledge the parallels in animal hypnosis and acupuncture analgesia in animals has led to the emergence of a literature that is difficult to interpret. Thirty-nine of 46 abstracted articles on acupuncture analgesia mechanisms identified through computer search for the period 1979 to 1998 supported the hypothesis that acupuncture analgesia in animals is partially mediated by endorphins. In contrast, none of the human research studies addressing the endorphin hypothesis during this period provided positive outcomes.

Human Laboratory Studies

The effects of acupuncture (usually electric) on pain sensibility in normal human subjects have been studied in various laboratory settings. In general, human studies differ substantially from animal work for three reasons: (a) Volunteers are not stressed during testing, and every effort is made to ensure their comfort and satisfaction with the experiment; (b) the subjects understand the purpose of the experiment and appreciate the safety precautions taken on their behalf; and (c) more complex measures of pain are used. Pain threshold, pain tolerance, psychophysical stimulus-matching techniques, visual analogue judgments, performance in a sensory decision theory stimulus–judgment task, and brain-evoked potentials have all been used to evaluate the efficacy of acupuncture as an analgesic intervention. Pain has been induced in the laboratory by stimulating teeth or skin electrically, heating skin, immersing limbs in ice water, and applying a tourniquet. How these artificial pain states resemble chronic pain is, of course, unclear. They may be better models for acute states, such as postoperative or posttraumatic pain.

The literature on human studies is less extensive than that on animals but is of sufficient size and complexity to present a full review here. The areas in which the studies have yielded consensus merit comment, however, as does the experience of our laboratory in a long-term research program on acupuncture analgesia. Chapman and colleagues (46,47,48,49,50 and 51) stimulated the teeth of study subjects in repeated studies to create safe but noteworthy experimental pain and measured the effects of acupuncture on pain perception using both sensory decision theory techniques and brain-evoked potentials. Consistent observations by Chapman and others include the following findings. First, outcomes were generally positive although some investigators could not demonstrate alteration of pain perception with acupuncture stimulation (52). Although most studies controlled appropriately for expectancy and placebo effects, it was found that belief in the efficacy of acupuncture can play a role in the subjects' ratings of acupuncture pain control in the laboratory (53,54). In our laboratory we could observe reliable positive outcomes in a series of four sensory decision theory studies and four evoked-potential studies carried out over several years (46,47,48,49,50 and 51). The effect was not seen in every subject but was typically clear in approximately 75% of the volunteers in any given experiment.

Second, the effect obtained, although statistically significant, was usually small or even minor from a clinical perspective. In one study we observed that acupuncture analgesia was approximately equal to the effects of inhaling 33% nitrous oxide in oxygen (46). In another study we found that the effects of acupuncture were no stronger than those of TENS delivered at the same sites in the same way (47). Only in rare cases did we see a subject who appeared to become totally insensitive to laboratory pain during electrical acupuncture. Other investigators have reported similar findings (53,54 and 55). These results are strikingly inconsistent with the demonstrations of apparently total pain control in the surgical setting in China. Confounding variables in acupuncture used for surgery in China are the use of intravenous meperidine and local infiltration of local anesthetics to supplement the acupuncture as well as having quick, gentle surgeons. The human studies are similarly problematic for the hypothesis that endorphins mediate acupuncture analgesia, because the effect is small. If such stimulation produces an endorphin-mediated response of sufficient strength to permit surgery without pain, it should appear more formidable in the laboratory.

Third, in accordance with observations of Chinese surgeries, laboratory investigators found that the analgesia can be elicited either by stimulating the subject within the same dermatome used for the delivery of the painful stimulus or by stimulating a meridian point (48,56,57). The importance of piercing the acupuncture point with precision remains a moot issue. We found that successful demonstration of acupuncture analgesia for dental pain requires exacting care in placement of the needle at the *hoku* point in the hands (located between the thumb and the first finger and corresponding to the position of the first dorsal interosseous muscle), but others disagree that this is critical (20).

Finally, electrical acupuncture requires low-frequency intense electrical stimulation (58) and appears to be an all-or-none phenomenon. Andersson and colleagues (59) observed that the dental pain threshold could be altered only when the intensity of low-frequency electric stimulation was strong enough to elicit a pounding or throbbing sensation. We found that the evoked potential elicited by painful dental stimulation is reduced only when the acupuncture stimulation is at a level just below the subject's tolerance (49). It was not possible to demonstrate a dose-response effect by varying the intensity of acupuncture stimulation.

Two studies that have contributed uniquely to the laboratory literature merit comment. Chapman and colleagues (50) addressed the question of whether culture affects the response to acupuncture stimulation. Three groups of subjects were studied: non-Asian Americans, second-generation Japanese-Americans, and Japanese living in Japan. Subjects were required to discriminate several levels of painful dental stimulation in a sensory decision theory task. Detection, discrimination ability, and response bias were measured both in control conditions and during electric acupuncture. Acupuncture yielded small but significant analgesia in all three groups, and neither race nor culture significantly affected the amount of pain control observed. Other studies looked at this from a different viewpoint. A study by Kreitler et al. (60) showed that belief is highly correlated to pain relief with acupuncture and therefore there may be a strong bias in volunteer populations for laboratory research.

Price and associates (56) examined the effects of acupuncture on patients with chronic low back pain using a laboratory paradigm. They attempted to bridge laboratory experimentation and clinical pain control by testing patients with an experimental pain stimulus. A hand-held contact thermode was applied to the back and volar forearm of the subjects to deliver noxious heat stimuli. Patients rated both clinical pain and experimental pain under baseline conditions and again after acupuncture. Regardless of whether acupuncture was performed in the dermatomes involved in the back pain or at distant meridian points, both the clinical and experimental pains were reduced 1 to 2 hours after treatment for many patients. When patients were tested again several days after treatment, the therapeutic effect of the treatment on back pain remained but the effect on experimental pain was gone. This study needs to be replicated and extended before firm conclusions can be drawn about the use of experimental laboratory methods with patients, but it suggests that laboratory findings can provide valid evidence for the clinical application of acupuncture.

Berman et al. (61) reviewed the existing literature on acupuncture for low back pain and found that most studies were not well done. Of those that had a rigorous experimental design, only one-half had a statistically positive benefit for acupuncture that, again, highlights the point that the effects are not strong. A parallel study by Cherkin (62) looking at the comparison of the effects of acupuncture with conventional treatments (medication/exercise) emphasized the poor quality of the studies and that positive results were exaggerated beyond the clinical relevance on a statistical basis. The Price et al. study needs to be considered with these clinical observations in mind.

Whether human acupuncture analgesia is mediated by endorphins has been hotly contested (26,51). Some investigators have attempted to resolve the issue by measuring plasma endorphins in association with acupuncture therapy, but plasma-borne endorphins cannot cross the blood–brain barrier and therefore are not “functional” in opiate receptor pharmacology. The existence of significant parallels between peripheral and central endorphin changes is still uncertain (28). It is difficult to reach firm conclusions from the evidence on either side of this issue at present. It can be confidently stated, however, that the mechanisms of acupuncture appear to be neither singular nor simple. The complexity increases when these questions are raised at the clinical level. For example, we cannot be confident that the neuropharmacology of the chronic pain patient is the same as that of the normal person or of the elective surgery patient who might respond well when given acupuncture for surgical pain control. Endorphin levels in plasma or cerebrospinal fluid might simply be one part of a larger constellation of neuropharmacologic responses to disease, to chronic pain, or to their treatment(s); they do not necessarily offer the ultimate explanation for pain control during acupuncture.

Clinical Studies

Clinical investigation in the field of acupuncture has been undertaken primarily in the area of chronic pain, with few exceptions (e.g., the study of its effects on postoperative dental pain) (63,64). There is some enticing acute pain clinical research looking at blinded patients having electroacupuncture during a general anesthetic for surgery. Their postoperative opioid requirements were one-half those of the control although no other parameters were altered (3).

Clinical chronic pain research has been extremely difficult to carry out effectively for several reasons:

- Chronic pain is a complex problem that often has psychological dimensions as well as organic pathology.
- Chronic pain syndromes are sometimes complicated by previous surgeries, other failed therapies, or prescription drug abuse or dependency.
- Selection of reliable and valid outcome criteria is difficult, and outcomes are meaningful only when long-term follow-up is undertaken.
- Placebo controls are difficult and rarely used. They need to be coupled with nontreatment controls as well to look at the natural history of the problem being

treated.
- No standards are available for correct acupuncture therapy for a given problem, such as back pain.

The last point is particularly problematic. If a cookbook set of acupuncture treatment points is chosen arbitrarily for the target pain syndrome to conduct the study in a systematic fashion, the principles of Asian medicine are immediately violated. On the other hand, allowing acupuncturists to diagnose and treat each case individually produces a data set that is not amenable to rigorous analysis.

When these major obstacles have been overcome, the investigator must decide whether to use intrasegmental or extrasegmental (meridian) treatment strategies; whether to use electrical stimulation and, if so, what parameters; whether to use controls, such as treating patients at the “wrong” points; and how many treatments should be given. A more detailed discussion of these and other design issues in acupuncture research has been provided by Vincent and Richardson (10). These same criticisms are addressed by Thomas and Lundberg's (58) look specifically at low back pain. The two clinical studies mentioned above review these same complaints (61,62).

Two types of errors threaten the integrity of any treatment outcome study. The first produces a positive outcome when no real treatment effect exists in nature. Failure to control for placebo effects and unreliable measures and failure to undertake long-term follow-up can produce such outcomes. The second type is the failure to detect a treatment effect when one has occurred. Too few treatments, too small a sample size to achieve reasonable statistical power, inappropriate or insensitive measurement techniques, and failure to use a homogeneous group of patients can produce misleading negative data. These issues are discussed further in Chapter 82. An overview of the large and growing literature in this area reveals that all these errors have been made repeatedly (65). Lewith and Machin (66) have formally addressed the problem of insufficient sample size in the literature. Firm conclusions are therefore difficult to attain. It is clear, however, that acupuncture is not a panacea of sufficient strength to overcome all these problems and to demonstrate consistent and powerful effects on chronic pain.

In addition to small sample size, poor pain measurement has plagued studies of acupuncture therapy. The complexity of clinical pain measurement problems was discussed in detail by Syrjala and Chapman (67) and is presented in Chapter 15 of this volume. When pain is chronic, it is necessary to use both subjective and behavioral outcome indexes tailored to the clinical problem in question, and long-term follow-up must be carried out to determine whether lasting benefits have been obtained. The chances of spontaneous recovery from chronic pain are small by definition, but chronic pain patients can leave any given physician with the polite impression that they have been helped significantly and then go on to another in the never-ending search for a cure. When follow-up procedures such as postal or telephone inquiries about satisfaction with outcome are used, few data of value can be obtained. A rigorous review would dismiss most of the published reports on the basis of these criteria alone.

The earliest clinical studies were largely uncontrolled investigations of mixed groups of chronic pain patients (68). Some early studies used no pain measurement at all. The data consisted of scaled judgments by the therapists themselves. With time, study designs improved and more suitable but still insufficient pain measurement methods were introduced. The most thoroughly studied clinical problems have been headache and back pain.

A brief review of the field prior to 1976 was provided by Mendelson (68), and more recent reviews have been offered by Lewith and Machin (66), Lewith (65), Richardson and Vincent (69), Berman et al. (61), and Cherkin (62). The last three have provided the most comprehensive reviews to date, with particular emphasis on back pain, headache, and other musculoskeletal problems. They evaluated each of the studies critically on the basis of controls, measurement technology, and follow-up. All of the above investigators deserve credit for their attempts to extract information in a critical fashion from a weak and problematic body of literature. In addition, a few negative reports have been helpful in delimiting the range of effects of acupuncture. For example, Lewith and colleagues (70) concluded that acupuncture is ineffective for postherpetic neuralgia.

What conclusions, if any, can be drawn from the literature? In their review of the overall efficacy of acupuncture therapy, Lewith and Machin (66) concluded that a positive response is given by approximately 70% of chronic pain patients with the use of real acupuncture, whereas the positive rate for sham acupuncture controls is approximately 50% and for placebo approximately 30%. Lewith (65) reviewed the following in detail: six studies that compared acupuncture with conventional medical therapy, ten studies that compared acupuncture with random placement of needles, and two studies that compared acupuncture with placebo treatment. He concluded that acupuncture works to some degree in approximately 60% of patients with chronic pain, that the effects of acupuncture are greater than those of random needling or placebo treatment, and that acupuncture is as effective for musculoskeletal pain as other treatments such as physiotherapy or drugs. The more recent reports simply support these observations. Lewith (65) noted that acupuncture causes fewer adverse reactions than the use of opioid analgesics and antiinflammatory medications. Richardson and Vincent (69) found good evidence from controlled studies that acupuncture can provide effective short-term pain relief; the figures for effective relief range from 50% to 80% for both acute and chronic conditions. Long-range follow-up data are lacking, however, so little evidence has been found for the long-range benefits of acupuncture. Despite their positive broad conclusions, Richardson and Vincent (69) cautioned that the “placebogenic” qualities of acupuncture treatment might be greater than those of placebo treatments matched to drugs: Acupuncture in some cases might simply function as a more effective placebo than its so-called placebo control. Patel et al. (31) reviewed the literature by metaanalysis and concluded that most studies were biased, that there were other methodologic problems, and that no studies had statistical confirmation of a positive effect for acupuncture although the pooled results did. A more recent attempt to refocus clinical research and suggest methodology improvements in design was presented again by Lewith and Vincent (32). Hopefully, critical reviews will lead to an improvement in the quality of future research so a clearer picture will emerge with the recent resurgence of interest in acupuncture.

Overall, given the above reviews, acupuncture appears to have positive therapeutic benefit, but it falls far short of the claims of its zealous advocates who believe it to be uniquely powerful. How important is the lack of a rigorous scientific database? Most therapies in modern medicine, including many common surgical procedures, would appear weak if evaluated rigorously on the basis of the supporting literature—most medical practice is not derived from a systematic program of scientific research. Much has been demanded of acupuncture because it is basically a folk medicine from a health/disease concept very foreign to allopathic medicine and because strong claims have been made by its advocates.

SUMMARY AND CONCLUSIONS

More than two decades after its introduction on a large scale in the West, acupuncture remains a mystery and a point of controversy. It seems clear from the results of animal, human laboratory, and clinical studies that acupuncture stimulation (particularly electrical stimulation) can alter pain perception and relieve pains in clinical practice. The human laboratory and clinical studies are consistent, however, in showing that acupuncture stimulation offers no panacea. The effects seen are inevitably modest when large groups of subjects or patients are examined, and the collective outcomes clearly fail to support the exaggerated claims of many of the advocates of acupuncture made in the early 1970s. When the overlap of acupuncture therapy with trigger point treatment and electrical stimulation therapy is considered, it becomes questionable whether classic acupuncture merits its own identity as a therapeutic procedure in Western medical practice and research. This situation suggests a pragmatic solution to the question of how acupuncture should be regarded by the physician concerned with pain management. The following three principles are offered as guidelines.

First, acupuncture should be addressed, considered, and scientifically investigated as a method for hyperstimulation therapy, as advocated by Melzack and Wall (57) or, more specifically, as a treatment for conditions of neural degeneration/muscular pain as proposed in Chapter 28. It is not of value as a form of Chinese medicine. The practice of classical Chinese medicine is without a scientific foundation in Western medical practice, but acupuncture techniques can be beneficially used for the practice of electrical stimulation therapy, trigger point therapy, or both. Viewed in this framework, such techniques draw on a scientific rationale and on clinical databases in two or more areas. Acupuncture techniques, stripped of their mystique, offer a safe and inexpensive therapeutic alternative to writing prescriptions. They need to be regarded as an alternative form of medicine only when practiced by nonphysicians.

Practitioners interested in acupuncture therapy should broaden their focus to include TENS and trigger point therapy. TENS is relatively cheap after the initial investment in equipment and has the advantage of giving the patient control over the therapy. Trigger point therapy differs little from acupuncture when a dry needle technique or saline injection is used. Both can be relatively expensive, especially if unscrupulous practitioners arrange frequent visits over an indefinite period. Because the tips of acupuncture needles are not bevelled like those of injection needles, acupuncture is less traumatic to tissue, causes less minor bleeding, and may be somewhat less painful.

Second, the possibility that acupuncture stimulation might be related to an alteration of endorphin levels should be deemphasized in discussing such methods with patients and in considering whether a therapeutic trial with acupuncture is indicated for a given patient. The animal literature clearly shows an association of acupuncture stimulation to endorphins, but advocates of acupuncture appear to be confusing stress-induced analgesia in animals with the (presumed) stress-reducing therapy performed in a physician's office. The link of endorphin levels to chronic pain states is as yet uncertain and controversial, and it is not known whether any long-term benefit of treatment would accrue to a patient with chronic pain even if acupuncture treatment resulted in endorphin release for a short period. Future

findings could have a great impact on this conclusion. This statement is unchanged in the decade since the chapter in the second edition of this text was written, indicating that 788 citations have done little to alter our view.

Third, despite the problems and limitations of the clinical literature, it is clear that acupuncture offers little hope for a miracle cure for chronic pain problems. It is appropriate to advise patients that controlled outcome studies, although favorable, show limited and modest positive benefits of treatment overall and that insufficient information has been obtained to determine whether positive gains are lasting when pain is chronic. The literature does support claims that acupuncture is a low-risk treatment when properly performed; the cost of such treatment can be of greater concern to patients than safety since most insurance plans do not yet cover this treatment. Physicians should be alert to the possible suppression of important symptoms of disease when patients undergo acupuncture therapy for pain.

It is most unfortunate that, after more than two decades of research in this area, the literature does not permit firm conclusions to be reached about therapeutic efficacy that could be summarized in a book such as this for clinical referral guidelines. It seems clear that classically performed acupuncture remains an experimental therapy. The clinical problems for which it is and is not appropriate have only begun to be defined. It is unsettling that no consensus has emerged in regard to how acupuncture should be practiced, who are fitting patients, and how many treatments are needed. The old truism remains, however: The absence of evidence is not equivalent to the evidence of absence. Broadly speaking, acupuncture appears to help patients suffering with chronic pain, primarily musculoskeletal, and to do so at a rate greater than that of control treatments. Care must be taken when patients engage the services of nonphysician acupuncturists because symptoms of clinically significant disease might not be brought to proper medical attention. When properly practiced, acupuncture is quite safe, and it offers an alternative to the conventional, often ineffectual, treatments including invasive surgery, repeated nerve blocks, and prescription of analgesic and other medication for patients with persisting pain.

CHAPTER 98

Transcutaneous Electrical Nerve Stimulation

Charles Chabal

BASIC INFORMATION

History

For thousands of years and across all cultures, humans have used sensory and physical modalities to relieve pain. These modalities range from relatively pleasant counterstimulation, such as massage and heat treatment, to more severe counterirritation measures, such as cauterization, bloodletting (wet cupping), deep acupressure, and some forms of acupuncture. A review of the historical development of many of these ingenious folk medicine–based treatments is provided by Kane and Taub (1). Unfortunately, this history is marred by a number of treatments based on fraud and deception, while others have outcome measures that are difficult to separate from nonspecific treatment or placebo effects. Nevertheless, the unmistakable ability of counterstimulation and counterirritation to relieve pain for at least the duration of treatment is obvious to anyone who has taken a hot soak or shower to relieve aching muscles or placed his or her thumb under cold tap water after striking it with a hammer. The modern era of electrical stimulation of the skin for the relief of pain has an ancient heritage. In classical Greece, the electrogenic torpedo fish was imported from the Nile River and used to treat headaches and joint pains (1). In the Renaissance, electrostatic generators and Leyden jar condensers were used by physicians and charlatans alike to treat a wide array of ailments, including pain. When the electric battery was invented in the nineteenth century and the automobile spark coil at the turn of the century, a plethora of pain treatment devices were manufactured. Some of these were still used after World War II, but the dawn of the Sputnik era and solid-state miniaturized electronic circuits saw an explosion in the application of electrical stimulation for pain relief. This development was, of course, also facilitated by Melzack and Wall's gate theory, published in 1965. It should not, therefore, be surprising that science has at least provided a partial basis and explanation of the mechanisms and pathways involved in these pain-relieving treatments. This chapter focuses on the physiologic basis and mechanisms of transcutaneous electrical nerve stimulation (TENS) and applications in both acute and chronic pain conditions.

Theoretical Bases for Effect

All afferent nerve fibers seem to have the capacity to influence the activity of other afferent nerve fibers, mainly through mutual presynaptic inhibition (2). Based on results from animal experimentation as well as on clinical observations, Melzack and Wall (3) described, with later anatomic-histologic evidence from Kerr (4), a "gate" to sensory input. Located in the dorsal horn of the spinal cord, it is opened by activity in small-diameter nociceptive afferent nerve fibers that facilitate nociceptive transmission and closed by activity in large-diameter nonnociceptive mechanoreceptive nerve fibers, thereby reducing the transmission of nociceptive impulses. Although some aspects of the gate theory have been criticized (5), experimental and clinical evidence has supported the ability of both nonnoxious and noxious stimuli to temporarily inhibit transmission from small-diameter afferent nerve fibers to second-order neurons in the spinal cord.

If graded electrical stimuli are applied to a mixed nerve, whether buried in tissue or not, the first fibers to become activated are the large-diameter ones (6). It is thus possible to induce a substantial but nonpainful barrage of impulses selectively in large afferent fibers with a small, relatively uncomplicated current generator. The first clinical report using electrical stimulation to relieve chronic pain soon followed the publication of the gate theory (7). In fact, early research demonstrated, consistent with the gate theory, that other forms of peripheral stimulation such as vibration were very effective in reducing the perception of pain (8,9,10 and 11). The subsequent focus of research and commercial development on peripheral electrical stimuli in the form of TENS was largely related to the technological limitations and poor efficiencies of other applied peripheral forms of mechanical counterstimulation. Transcutaneous electrical stimulators are simple to build, highly portable, and relatively energy efficient. Mechanical vibratory stimulators are not.

The functional arrangement of large-diameter afferent fibers, mainly A-b fibers, is largely segmental and therefore requires that nonpainful counterstimulation, often in the form of paresthesias, be directed into the painful region of the body. In contrast, painful counterirritant therapies produce effects that are extrasegmental in nature and need not be applied directly to the painful region of the body. As a result of this neural organization, several different patterns of TENS stimulation have emerged. High TENS, also called *conventional TENS*, uses a nearly continuous high-frequency stimulation (60 to 100 Hz) and a relatively low-intensity current (10 to 30 mA). In conventional TENS, the electrodes are placed in the painful region of the body and the current is adjusted upwards until paresthesias are obtained. Some practitioners prefer increasing the intensity until mild muscle stimulation occurs. It is likely that the mechanism of action for conventional TENS involves gating of nociceptive fibers by stimulation of the large A-b afferents, as the effect appears to be resistant to the mu receptor antagonist, naloxone (12,13), and clinical success is correlated with the proper placement of the stimulating electrodes within the painful area of the body (14). In conventional TENS, increasing the intensity of stimulation by increasing stimulator pulse width, frequency of stimulation, or both will recruit more inhibitory pain fibers and theoretically increase the effect of TENS (15,16).

In contrast, low-frequency TENS, also called *acupuncturelike TENS*, uses burst patterns of 100 Hz in 1- to 2-Hz pulses at a high-intensity level (20 to 50 mA) or until a painful muscle twitch is elicited (7). Location of the stimulus is not necessarily limited to the painful region of the body, and the effects of low TENS are reversed by naloxone, suggesting that the effects are mediated through endogenous opioid receptor activity (12). Some studies have reported successful pain treatment with acupuncturelike TENS in patients who have not obtained pain relief with conventional TENS (17,18).

Experimental Evidence

There is solid evidence that the theoretical model of neuronal modulation within the spinal cord, demonstrated in the physiology laboratory, also occurs in humans. Using a human experimental pain model, TENS significantly increased the subjects' pain tolerance, with the effects most evident at higher stimulation frequencies (60 Hz) (19). Studies done under controlled conditions indicate that TENS, when applied over trigger points, reduces the report of pain associated with the trigger points. This effect is not due to local changes in trigger point sensitivity but is more likely related to central nervous system modulation (20). Better effects were obtained using conventional TENS (100 Hz); increasing efficacy was noted as the stimulation pulse width increased from 50 to 100 milliseconds at an intensity just at muscle stimulation threshold. Little effect was seen with acupuncturelike TENS (20). Indeed, patients often report that properly applied TENS produces an area of reduced skin sensitivity or numbness, consistent with the experimental findings.

The effectiveness of TENS in humans is further supported by a well-designed, well-controlled study in patients with low back pain of a variety of etiologies (21). Treatment sessions consisted of 30-minute experimental treatments twice a week for 10 consecutive weeks. In this study, conventional TENS (100 Hz and intensity set to produce a paresthesia) produced a significant reduction in pain over the short term when compared to placebo-TENS and a control group. The effect of TENS appeared cumulative and was present for up to 1 week after treatment was concluded. Similar results were not seen in the placebo-TENS or the control group. Consistent with experience from other analgesic trials, placebo-TENS also produced a significant reduction in some aspects of reported pain when compared to baseline measures, but the effects were statistically less than those produced by actual TENS treatment. There is also evidence that TENS may have effects apart

from simply gating nociceptive afferent impulses. In a number of studies, TENS has been shown to produce an increase in blood flow to the region of stimulation, indicating that the effect of TENS may not be limited to pain modulation (22,23 and 24). In conclusion, there is ample basic research that indicates neuronal modulation of nociceptive impulses occurs. There are also well-designed studies that indicate that TENS produces significant analgesia when compared to placebo treatments under short-term controlled conditions.

CLINICAL INFORMATION

Treatment of Acute Pain

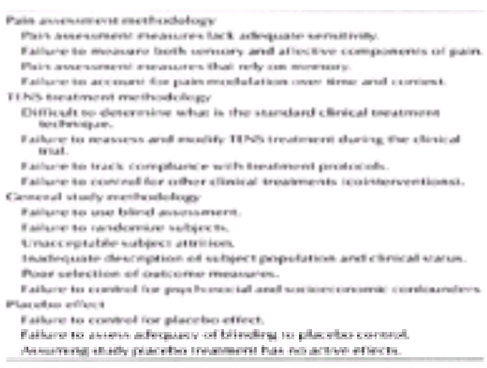
TENS has been used very successfully for the treatment of acute pain. A significant literature evaluates the effect of TENS in a number of acute pain conditions. Many of the studies have been done using well-designed methodology. TENS has been successfully used to treat postoperative pain after a variety of surgical procedures (25,26), after trauma such as a fractured rib (27), a variety of oral-facial pains (28,29), and the pain associated with parturition (30,31). Many studies have measured not only the effect of TENS on pain but have included other outcomes such as pain medication use, measures of respiratory function, and incidence of postoperative complications such as ileus and atelectasis. Ali et al. (32) examined pulmonary function in 40 patients after cholecystectomy. Patients treated with TENS had significantly improved vital capacities and functional residual volumes when compared to patients who had not received TENS or had received a placebo-TENS unit. Similar improvements in peak expiratory flow rates and arterial oxygen concentration have been associated with TENS use in patients with multiple rib fractures after trauma (27). Conventional TENS has also been shown to reduce pain and opioid analgesic use in patients after major intraabdominal procedures (33,34 and 35) and orthopedic procedures (36) and to enhance postoperative rehabilitation in orthopedic patients (37). Other studies, while confirming the reduction of postoperative opioid use, failed to demonstrate an improvement in pulmonary function (38).

TENS has also been used to treat pain associated with labor (31,39). In these controlled studies, TENS produced moderate to good relief of back and abdominal pain in the first stage of labor. Pain relief associated with later stages of labor seems to be less amenable to treatment with TENS. An additional concern in the later stages of labor is related to the potential for TENS to interfere with some aspects of fetal monitoring.

TENS use after trauma, in the early stages of labor, or in the postoperative period is effective at reducing pain and may improve some objective measures of function. While, in most cases, TENS alone is not adequate as the sole analgesic treatment, it should not be overlooked as an adjunctive treatment for acute pain. TENS, unlike drugs such as nonsteroidal antiinflammatory drugs (NSAIDs), is virtually free of complications yet may significantly reduce pain of the postoperative period.

Long-Term Treatment of Chronic Pain

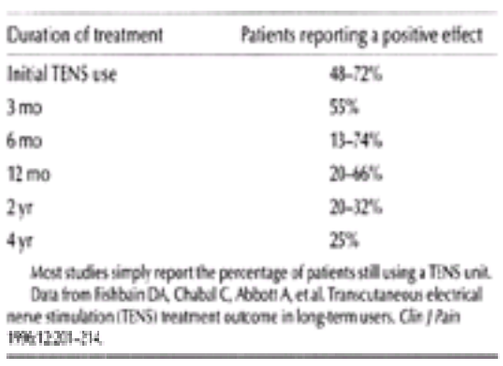
The effectiveness of TENS for the treatment of chronic pain is an area of controversy. The results have not been as consistent as laboratory-based or postoperative studies. The reasons for this controversy are multifactorial, related to a number of problems inherent in the design and execution of any complex clinical trial, and well discussed by Marchand et al. (21) and Deyo (40). In brief, outcome measures such as pain relief must be sensitive enough to detect small but clinically significant changes. For example, studies indicate that even powerful opioids produce only small changes in reported pain when used chronically in clinical pain trials, thus requiring very precise pain assessment techniques. In addition, any intervention has significant nonspecific effects including placebo; thus careful controls are an essential part of any study (see Chapter 81 and Chapter 82). The ability to design an active placebo control is particularly difficult in a treatment such as TENS that relies on the requirement of the patient to generate, with the TENS device, a distinct and sometimes strong paresthesia into the painful region of the body. Most trials use an inactive placebo-TENS device and suggest to the subject that he or she will feel a paresthesia from the placebo device. The suggestibility of subjects who endorse physiologically absent symptoms may produce a bias towards placebo-responding subjects and skew treatment groups. Alternatively, a placebo treatment may produce a real clinical effect resulting in confusing data. Table 98-1 summarizes a variety of experimental design issues that have often been inadequately addressed in long-term TENS outcome studies.



Pain assessment methodology
Pain assessment measures lack adequate sensitivity.
Failure to measure both sensory and affective components of pain.
Pain assessment measures that rely on memory.
Failure to account for pain modulation over time and context.
TENS treatment methodology
Difficult to determine what is the standard clinical treatment technique.
Failure to reassess and modify TENS treatment during the clinical trial.
Failure to track compliance with treatment protocols.
Failure to control for other clinical treatments (cointerventions).
General study methodology
Failure to use blind assessment.
Failure to randomize subjects.
Unacceptable subject attrition.
Inadequate description of subject population and clinical status.
Poor selection of outcome measures.
Failure to control for psychosocial and socioeconomic confounders.
Placebo effect
Failure to control for placebo effect.
Failure to assess adequacy of blinding to placebo control.
Assuming study placebo treatment has no active effects.

TABLE 98-1. Study design and methodologic considerations relevant to long-term transcutaneous electrical nerve stimulation (TENS) outcome trials

Over 600 articles on TENS have been published since 1970 (41). TENS has been reported as a successful treatment for a variety of neuralgias and neuropathic pain syndromes, peripheral vascular disease, chronic angina, and musculoskeletal pain. Long and Hagfors (42), Long (43), and Fishbain et al. (41) have provided comprehensive reviews of the long-term outcomes of TENS treatment. In 1991, Long (43) concluded that the literature indicated that TENS was an effective treatment for a pain from diverse etiologies, that TENS has a short-term benefit in about 50% of patients who suffer from chronic pain, that about 25% of patients will use TENS for many years, and that the effect of TENS cannot be explained simply as a placebo effect. The results from the review by Fishbain et al. are presented in Table 98-2. The compiled data indicate that a significant subset of TENS patients prescribed TENS continue to use their TENS unit for many months. From this set of studies it is difficult to conclude any impact on physical function, adjunctive medication use, or quality of life.



Duration of treatment	Patients reporting a positive effect
Initial TENS use	48–72%
3 mo	55%
6 mo	13–74%
12 mo	20–66%
2 yr	20–32%
4 yr	25%

Most studies simply report the percentage of patients still using a TENS unit.
Data from Fishbain DA, Chabal C, Abbott A, et al. Transcutaneous electrical nerve stimulation (TENS) treatment outcome in long-term users. Clin J Pain 1996;12:201–214.

TABLE 98-2. Synopsis of studies reporting the long-term use of transcutaneous electrical nerve stimulation (TENS) for chronic pain

A few long-term TENS studies have examined outcome variables other than pain relief. One study associated TENS use with increased socialization (19) and one with better sleep (44). Another study compared activity levels between a TENS treatment group and a non-TENS control group (45). The TENS treatment group showed a significant increase in activity as compared to the control group. There was no difference in analgesic medication use between the two groups at 1-year follow-up. A number of studies report that long-term TENS use helps reduce the consumption of pain medications (18,44,46,47 and 48). Most recently, in a survey of over 500 long-term TENS users, Fishbain et al. (41) reported that long-term TENS use was associated with a reduction in opioid analgesics, NSAIDs, sedative hypnotics, and steroid medications. These same patients also reported a significant reduction in pain's interference with work, home, and social activities; an increase in physical activity; and a reduction in use of physical occupational therapy resources. A cost outcome simulation done with these data at 6 months of TENS use

reported a significant reduction in the cost of pain-related medications and therapies associated with TENS use (49).

Perhaps one of the best designed studies on TENS use in chronic low back pain patients was reported by Deyo et al. (50). One hundred forty-five patients with chronic back pain (mean duration, 4.1 years) were divided into one of four experimental treatment groups: (a) daily TENS, (b) sham TENS, (c) TENS plus exercise, and (d) sham TENS plus exercise. Subjects were treated for 1 month. Both TENS and sham TENS treatment groups showed an improvement in pain outcomes. Exercise seemed to produce the greatest benefit, but by 2 months after the active study, most patients had discontinued their exercise program. The authors concluded that TENS had no greater benefit than placebo and that TENS added no benefit to exercise alone. The study has had a significant impact on the way many providers view TENS as a useful clinical treatment. However, the widespread extrapolation of these results to the realm of clinical care has been cautioned (51). An editorial in *The Lancet* offered a number of representative comments (52). The study maximized the effect of the placebo treatment; the relatively short study duration was not adequate to show an effect of active treatment; the treatment approach with active TENS was somewhat unconventional and not commonly used in clinical practice; and all treatment groups used hot packs and heating pads, which may have confounded the results of the study. Others have offered that pain assessment was done over short intervals and may not reliably measure true effects of treatment (21). In conclusion, a large body of literature evaluates long-term TENS use for the treatment of chronic pain, but valid conclusions are limited by a number of complex methodologic considerations (see Table 98-1). While TENS, like any other medical intervention, is associated with nonspecific effects, the numerous clinical reports of patients using TENS for many months indicate that for at least some patients, TENS is a useful treatment with effects that surpass those of placebo.

TECHNIQUES

Predictors of Use and Maximizing Effectiveness

Numerous studies attempt to predict success or failure of TENS therapy based on either patient characteristics or parameters of the TENS intervention, such as waveform and pulse duration. No patient physical predictors appear to be of substantial value. Nor do most of the technical considerations of the electrical impulses appear to have predictive value. Experience indicates that TENS has been used successfully in many different conditions. Depression, overwhelming psychosocial distress, and overt psychiatric problems increase the likelihood that TENS will be ineffective (53,54). In any of these instances, the underlying psychosocial problems need to be addressed and the patient must be making improvement prior to instituting TENS treatment.

Most experts endorse a TENS trial to evaluate the effectiveness of treatment prior to having the patient purchase a device (55). The optimal nature and duration of the trial are vague, usually depending on individual provider preference, and can range from 1 hour to several weeks and has changed over the years. In the past, some providers actually admitted patients to the hospital for such trials. In general, an evaluation is done in which a provider, often a physical therapist, uses a temporary spotting electrode to evaluate TENS electrode placement. This maneuver, based on the evidence that large-diameter afferent inhibition occurs at a segmental level, attempts to produce stimulation, most often paresthesias, in the region of the body that has pain. Experience from spinal cord stimulation supports the concept that for effective treatment to occur, one must be able to produce paresthesias in the anatomic region of pain. If this cannot be done, it is unlikely that conventional TENS will be of much benefit, and a trial of acupuncturelike TENS may be warranted. If after a period of successful treatment, a patient notes that his or her TENS no longer helps, it is usually worth reevaluation of the electrode placement to again maximize the effectiveness of the TENS treatment.

Patients should be educated and their expectations addressed prior to TENS treatment. They should be taught the theoretical basis of TENS treatment, that TENS effects are similar to those of a mild analgesic, and that pain will not usually be totally abolished with TENS use. They should be told to use the device at least several times per day, and alternative use strategies should be offered. Alternative use strategies include using the TENS only during particularly painful times such as riding in an automobile, only as a sleep aid, or to include TENS holidays, which may reduce tolerance to TENS effects. It is inappropriate to offer derogatory comments about TENS treatment or to use TENS treatment as an alternative to a more comprehensive approach in a patient with overwhelming psychosocial distress.

Technical Issues

Stimulator Selection

TENS stimulators are miniaturized current generators that produce a constant current and are usually powered by rechargeable batteries (Fig. 98-1). The constant current amplifier prevents surges in supplied current from changes in skin impedance. TENS devices now are approximately 10 × 5 × 3 cm. Further miniaturization would probably make the units, especially the controls, difficult for patients to handle. Stimulators have one or two separate output channels, the latter type being more versatile but also more expensive. The stimulation intensity and frequency are set by external dials, separate for each channel, and preferably linear with respect to output. A new version of a TENS unit has been approved for use (Fig. 98-2). This unit requires patients to turn the unit on and off by indicating their pain level on an electronic visual analogue scale. The device records patient use and treatment effects, which are later accessible to the health care provider (Empi Inc., Minneapolis, Minnesota).

Figure 98-1. Transcutaneous electrical nerve stimulation (TENS) unit with adjustments for impulse stimulation width, mode of stimulation, and rate of stimulation. Patients are taught how to adjust their own units to produce optimal pain relief. On the far left is a typical TENS electrode. On the near left is a temporary spotting electrode. The spotting electrode is used to locate the optimal placement of the conventional TENS electrode.

Figure 98-2. Transcutaneous electrical nerve stimulation (TENS) unit showing two stimulation channels with adjustment dials. The dials control the intensity of stimulation of the TENS unit. Patients are instructed to increase the intensity of stimulation until they feel paresthesias (conventional TENS) or until direct muscle contraction occurs (high-intensity TENS). The optimal stimulating parameters for any given patient are often determined by a series of trials and assessments.

Available stimulation modes should include single pulses between 30 and 100 Hz (variable) for conventional TENS and short trains of pulses that can be delivered at

a 1- to 2-Hz repetition rate for acupuncturelike TENS. In two-channel units, it is an advantage if the mode can be independently varied for each channel. Most patients prefer units with rechargeable batteries. For safety reasons, patients should not be able to treat themselves while a unit is being charged.

Stimulation Frequency

Most patients seem to prefer a stimulation frequency of 80 to 100 Hz with conventional TENS and 1 to 2 Hz with acupuncturelike TENS. To avoid unpleasant sensations from too high a stimulus intensity, stimulators with a burst mode should be used for acupuncturelike TENS to elicit muscle contractions. This burst may be a short impulse train of seven to ten pulses at a 100-Hz internal frequency applied to a 1- to 2-Hz repetition rate (17) (Fig. 98-3).

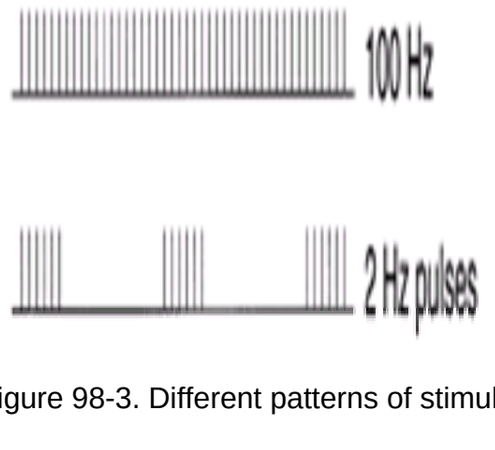


Figure 98-3. Different patterns of stimulation. **A:** Conventional transcutaneous electrical nerve stimulation (TENS). **B:** Acupuncturelike TENS.

Pulse Characteristics

For any type of nerve fiber, a strength versus duration curve can be plotted indicating which current intensity is needed to activate the fiber at a given stimulus duration. To elicit electrical paresthesia for the relief of pain, most patients prefer a pulse duration of 0.05 to 0.15 milliseconds, which is in the same range as that considered optimal for activation of large myelinated fibers in experimental situations (56). These and other experimental data strongly suggest that a monophasic square wave of 0.05 to 0.20 milliseconds is sufficient (and optimal) for both conventional and acupuncturelike TENS.

Biphasic pulses are not necessary to avoid polarizing phenomena due to the capacitive components of the skin. The current generator should be calibrated and be of the constant-current type, which compensates for the large variations occurring in the electrode-skin-electrode impedance. A current output of 50 mA per channel into a 2,000-W external load is necessary to activate deeply situated nerve bundles (e.g., the sciatic nerve), whereas superficially situated nerves in the facial region or distally in the extremities require less energy. Constant-voltage generators are less suitable, because the stimulation may be rendered ineffective if the impedance is unexpectedly high for a given output setting (57).

Electrodes

The electrodes are usually made of conductive rubber containing carbon and have a life span of 4 to 6 months in normal use. This material has a suitable internal resistance that produces an even current distribution over the electrode surface. The size of the electrodes—representing a compromise between the demand for current density and the risk of skin irritation—is usually 10 to 15 cm^2. Larger electrodes may be advantageous when distinct nerve bundles cannot be stimulated (e.g., with pain in the back or abdomen).

A thin layer of conductive gel is put between the electrode and the skin to facilitate contact. The electrodes are attached to the skin with hypoallergenic tape. A more expensive and short-lived alternative is self-adhesive electrodes made from conductive karaya rubber or synthetic substitutes, which eliminate the need for conductive gel and tape.

Selection of Treatment Parameters

Conventional TENS is the mode of choice in neuralgia, causalgia, and dull continuous pain referred to the skeleton (spine, joints, ribs) whether from arthrosis, cancer, or muscular origin. It should also be tried in central pain states. This mode of stimulation should always evoke electrical paresthesia in the painful area. Activation of most of the large afferent fibers requires an intensity two to three times that at the threshold for sensation, usually 10 to 30 mA with standard-size electrodes. Stimulus frequency should also be kept constant initially at 80 to 100 Hz. Later it can be varied according to the need and preference of the patient.

In some patients, the pathologic condition or previous treatment has destroyed the peripheral or central afferent pathways to the extent that a marked hypesthesia is present and electrical paresthesia cannot be elicited by conventional TENS. Acupuncturelike TENS should be tried whenever conventional TENS does not give satisfactory pain relief. In addition, it is the primary choice in projected pain such as radiculopathy (sciatica) and in deep pain such as in myalgia. A positive effect with this mode requires elicitation of forceful muscle contractions in the myotomes segmentally related to the painful area. Often, a stimulus strength three to five times that at the sensory threshold, commonly 15 to 30 mA, is required to produce muscle contractions. Stimulation must produce *visible* muscle contractions to be effective. The stimulation should be started with a set repetition rate (e.g., 1.5 Hz), and the patient is allowed only to modify it later after increased experience. If the stimulation causes discomfort before muscle contractions, the electrode positions should be adjusted slightly. The patient may feel muscle stiffness after the first few treatments, but this vanishes within a few days.

CONTRAINDICATIONS AND SIDE EFFECTS

TENS units should not be used in patients with cardiac pacemakers, as it is feared that the electrical impulses generated by the TENS unit will inhibit the function of the pacemaker. TENS electrodes should not be placed over the carotid arteries because of the risk of stimulating the carotid sinus reflex and causing bradycardia and hypotension. The most common and nearly only side effect of TENS is skin irritation under the sites of the stimulating electrodes. This is best resolved by changing the type of electrode, periodically moving the stimulation site, or using a different type of electrode gel.

CONCLUSIONS

Clinical TENS treatment is based on sound physiologic and experimental principles with strong support from a number of clinical studies. The positive effects of TENS are well defined in the acute pain setting but less clear-cut in the treatment of chronic pain conditions. Some of the confusion surrounding the role of TENS in treating chronic pain is due to the fact that TENS is not a powerful intervention. It is best described as a moderately effective, adjunctive analgesic on the order of an NSAID or very-low-dose opioid. Given these limitations, TENS is best viewed as a palliative component in a more comprehensive approach to chronic pain. However, TENS, unlike many analgesic medications, is totally free of side effects such as gastrointestinal distress, coagulopathies, and hepatic and renal toxicity. It is a useful component of comprehensive pain management.

CHAPTER 99

Peripheral Nerve Stimulation

Jan M. Gybels and Bart J. Nuttin

BASIC INFORMATION

History

Two periods can be distinguished in the history of chronic stimulation of peripheral nerves (PNs) for pain relief using implanted devices. A first period started in 1967, when Wall and Sweet (1), to test in humans the prediction of the gate-control theory, showed that PN stimulation (PNS) could produce hypalgesia and could cause temporary abolition of clinical chronic pain outlasting briefly the duration of the stimulation. There was some initial enthusiasm, but variable results and the lack of commercially available adequate electrodes reduced interest in PNS. Subsequent attention was directed mainly to the development of spinal cord stimulation (SCS). The 1980s saw a second period of development of PNS with the advent of improved equipment, particularly the introduction of flat electrodes with several contacts (Resume by Medtronic, Inc., Minneapolis, MN), better surgical techniques, and, in at least one series, improved outcome studies.

Mechanisms of Pain Relief by Peripheral Nerve Stimulation

The mechanisms of effective pain relief are uncertain and many theories have been proposed. We discuss the more accepted hypotheses only.

At the peripheral level, it has been demonstrated that electrical stimulation can induce a peripheral blockade of nociceptive afferents (2). In pathologic situations such as nerve injury, such a blockade might become particularly significant: Among the physiologic properties of experimentally produced neuromas, spontaneous ongoing activity in both A and C fiber afferents is a common feature. It has been shown that a short period of repetitive electrical stimulation of the nerve in which a neuroma has been produced at a strength above threshold for the single fiber under study may completely stop the ongoing discharge for several minutes (3).

The pain-suppressive effects of PNS have also been explained by central mechanisms. Most attention has been paid to inhibitory mechanisms in the dorsal horn. It is on the basis of this aspect of the gate-control theory that the modern era of PNS for pain relief was initiated (see Chapter 4). There is experimental evidence in the intact animal that prolonged inhibition of spinothalamic tract neurons can be obtained by PNS (4). This inhibition was also observed in spinalized animals, indicating that it must depend in part on spinal cord neural circuitry. The A-d fiber group was most important for producing this inhibition, although significant additional effects were also produced by activation of the A-ab and C fiber group (4). Both from an experimental and clinical point of view, there is clear evidence that PN lesions induce profound changes centrally that may themselves be instrumental in producing pain, but there are no data available on how those central changes are modulated by PNS. We know, however, from recent work that tactile allodynia in a rat model of mononeuropathy involves a gamma-aminobutyric acid (GABA)–ergic mechanism and that SCS may operate by upgrading the spinal GABA-ergic system. The potential of SCS for producing pain relief is dependent on the availability of responsive GABA-containing inhibitory interneurons (5). It has become increasingly clear that different pathophysiologic mechanisms are involved in painful sequelae of nerve injury, and therefore one cannot expect that PNS will influence these painful sequelae in a uniform way.

It is somewhat amazing that in recent years much has been learned about the pathophysiology of damaged PN (6) but that the influence of electrical stimulation of the nerve on these pathophysiologic mechanisms has not yet been examined.

Advantages versus Disadvantages

PNS is a method of pain relief that does not require damage to the nervous system. It is therefore more acceptable to most patients and their referring physicians than an ablative procedure. PNS permits stimulation of the involved nerve without spread of paresthesias to the opposite side of adjacent body regions. A major advantage of PNS over SCS is that with an epidural percutaneously placed electrode, delayed electrode migration is a possibility and paresthesias may change both in intensity and topography with movement of the spine. Especially with an electrode placement in the cervical spine, it may be difficult to overlap the painful area with paresthesias, particularly when the painful area is only a specific part of the hand or the foot. Direct application of an electrode to a PN obviates this problem.

Disadvantages of PNS versus SCS are the following:

- When the electrode is placed over a mixed nerve, paresthesias can be accompanied with movement, but with a correct placement and appropriate parameters of stimulation this is rare.
- Scarring can occur around the nerve, even leading to neuropraxia, but with current techniques this has become exceptional.
- PNS requires a formal surgical procedure to place the electrode on the nerve; this is somewhat more invasive than percutaneously placed SCS but not more so than using an electrode that requires a laminotomy.

CLINICAL INFORMATION

Patient Selection Criteria

Figure 99-1 represents a treatment algorithm for peripheral neuropathic pain as proposed by Levy at a consensus meeting in 1996 (7). In this algorithm, PNS is recommended for peripheral neuropathic pain when noninvasive treatment modalities have failed in a patient with neuropathic pain in the territory of a single proximal or mixed nerve, provided there is no psychologic contraindication and there is a favorable response to an appropriate screening test. Almost all authors agree that when a neuromodulation procedure is indicated, pain in the distribution of a single traumatized PN is the optimal indication for PNS (Table 99-1 and Table 99-2).

Figure 99-1. Treatment algorithm: peripheral neuropathic pain. (DBS, deep brain stimulation; DREZ, dorsal root entry zone lesions; IT MS, intrathecal morphine sulfate; PNS, peripheral nerve stimulation; SCS, spinal cord stimulation.) (Reproduced from Levy RM. Algorithms for treatment of neuropathic pain syndromes. In: North RB, Levy RM, eds. *Neurosurgical management of pain*. New York: Springer-Verlag, 1997:337–339, with permission.)

When transcutaneous stimulation of the nerve is not a feasible option (nerve too deep, patient too fat, or reaction of the skin to the applied material), temporary stimulation with an implanted electrode connected via percutaneous leads to an external stimulator is a useful method of providing the patient with a stimulation trial. This avoids the cost of an implanted receiver or pulse generator while the patient determines if good pain relief can be achieved. At a later date, the percutaneous leads can be removed and the electrode connected to either a radiofrequency (RF) coupled passive device or an implanted pulse generator. Externalized leads do increase the risk of infection.

The predictive value of a local anesthetic nerve block as a selection criterion has been advanced by some (1) but found ineffective by others (8). It is probably fair to state that although pain relief with nerve blockade does not ensure a good pain-relieving effect with PNS, continued pain despite a technically adequate nerve block makes it very unlikely that stimulation of the same nerve will be successful(9).

Implantation Technique

Different materials for chronic PNS in humans have been described, which can be either a fully implantable device or an RF-coupled system (Fig. 99-2). A permanent stimulator should be implanted only after a successful trial screening with an implanted electrode. Implantation of the electrode can be performed either under general, local, or wake-up anesthesia. Using one of the two latter types of anesthesia, in combination with intraoperative stimulation via the electrode, the position of the electrode in relation to the nerve may be optimized. No tourniquet is used. The electrode is implanted in close contact with the nerve (median, ulnar, radial, tibial, or common peroneal nerve or brachial plexus) proximal to the lesion (10).

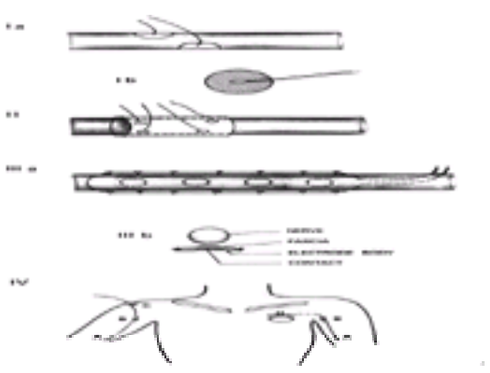

Figure 99-2. Different techniques for electrical stimulation of peripheral nerves in humans. **Ia:** Multicontact electrode directly sutured to the peripheral nerve (12). **Ib:** Platinum-iridium button electrode. **II:** Multiple-button cuff electrode (Avery Laboratories) (13). **IIIa:** On-point electrode Model 3987 (Medtronic, Inc.) sutured to the surrounding tissues underneath the nerve. A fascial flap is placed between the nerve and the electrode. **IIIb:** Transverse section through the nerve and the electrode at the level of an electrical contact. **IVA:** Electrode implant on median nerve. **IVB:** Connection between the electrode and the temporary percutaneous wires or the permanent extension cable. **IVC:** Percutaneous wires fixed to the skin with a suture. **IVD:** Implanted stimulation device.

If a plate electrode (On-point, see Fig. 99-2) is used, a fascial flap of 1 cm by 5 cm can be harvested (11). The fascial flap is sewn over the plate with multiple interrupted sutures, avoiding wrinkles. The flap prevents direct contact between the electrode and the nerve and can be compared with dura mater between electrode and spinal cord in SCS. In spite of the manufacturer's recommendation, it is not certain that this fascial flap is really necessary. The nerve is dissected free over a distance corresponding to the length of the electrode, with interruption of major vascular supply carefully avoided. The electrode itself is sutured to the surrounding tissues underneath the nerve.

A cuff electrode is usually not covered with fascia and the cuff diameter is adjusted to the nerve diameter. The authors have no experience in suturing the electrodes directly onto the nerve (12). Rubbing of the nerve against the electrode body as it progresses toward the extension cable should be prevented. Watching the nerve-electrode-complex during movement of the nearby joints before closure of the wound can point to traction on the electrode, which could potentially dislocate the contacts and/or injure the nerve.

A second incision is made proximal to the first incision above the nerve to allow space for the connector between the electrode and the percutaneous wires. In between both incisions the lead wire is placed in a subcutaneous tunnel. The percutaneous wires are also laid in a subcutaneous tunnel and leave the body at a distance from this second incision and also as far as possible away from the future subcutaneous tunnel for the permanent extension cable (see Fig. 99-2). The wires are connected to an external stimulator.

Implantation of a permanent pulse generator is usually done under general anesthesia but can also be performed under local. The percutaneous wires are removed and a permanent extension cable is connected to the electrode and is tunneled subcutaneously to a subcutaneous pocket, usually located in the infraclavicular region for the upper extremity or lower abdominal wall or lateral thigh for the lower extremity. There it is connected to the permanent power source, which can be either a fully implantable device or a radiofrequency coupled system. In the case of tibial nerve stimulation, the power source can be implanted subcutaneously in the lateral part of the thigh. If stimulation of the common peroneal nerve is considered, the stimulating device may be implanted just caudal to the iliac crest. It is important not to place the pulse generator or RF receiver over an osseous structure to avoid mechanical pain.

Results

Table 99-1 (8,9 and 10,13,14,15,16,17,18,19,20,21,22,23 and 24) summarizes the published results of PNS obtained with a permanent implant for the treatment of persistent pain. Most of the patients have suffered from chronic pain after a PN or root injury. The outcome (50% or more) pain relief is only approximately correct, as the different authors do not always report their results in this fashion, but obviously the criteria for “success,” “good” results, and “50% or more” pain relief are often inadequately specified (25). Most of the reports cited in this table present retrospective, uncontrolled, and incomplete data from a group of selected (and nonrandomized) patients. However, most of the data come from respected authors with a well-established reputation in the field of neurosurgical treatment of persistent pain. The absence of randomized clinical trials is not unique.

TABLE 99-1. Results of peripheral nerve stimulation

Of particular interest is the study of Hassenbusch et al. (24) because it is a prospective study of a consecutive series of 32 patients who were tested and of whom 30 (90%) were treated with an implanted PN stimulator.

Using clinical criteria, all patients were classified as having stage III reflex sympathetic dystrophy and according to the authors might be considered as having complex regional pain syndrome type II (see Chapter 20). Outcome criteria were quantified and included pain relief (spontaneous and evoked), physical changes (vasomotor tone, motor strength, trophic changes), and activity levels (employment, walking stairs, sleeping, eating). The most recent evaluation was conducted by a disinterested third party. Overall, 19 (63%) of 30 patients experienced good or fair relief on a consistent basis. Six (20%) of the 30 patients undergoing PNS placement returned to part-time or full- time work after being unemployed before stimulator implantation. Follow-up in these patients was 2.2 ± 0.6 years postimplantation.

In 1990, we published our results of treatment of pain due to nerve injury by electrical stimulation of the injured nerve (26). These results were obtained in 11 consecutive patients in whom a device was implanted between 1980 and 1987 and who were invited for follow-up examination in 1987.

The relevant clinical data at the time of operation are summarized in Table 99-2. The mean follow-up was 52 months (range 13 to 92). PNS was usually considered after a long period of unremitting and intractable pain.

TABLE 99-2. Long-term results of peripheral nerve stimulationpersonal series

After a successful trial with transcutaneous electrical nerve stimulation (TENS) applied to the involved nerve in cases one through ten, the procedure for stimulator implantation was carried out, usually under local anesthesia. A Silastic cuff with four electrode contact points (Avery) was wrapped carefully but not tightly round the nerve. In the 10 upper limb cases, the electrode was implanted at the level of the nerve trunk in the upper arm whereas, in the femoral nerve case, the electrode was implanted in the lesser pelvis— that is, always proximal to the site of the injury. The receiver (Avery) was placed in the subcutaneous tissue over the pectoral muscle or in the abdominal wall. The patients were able to control intensity and rate of stimulating current themselves. No specific instructions were given about the duration and frequency of use.

At the follow-up examination in 1987, the patients were asked to fill out a questionnaire. A visual analogue scale was used to quantify the intensity and degree of unpleasantness of the remaining pain, compared with the situation before the operation. The patients were asked about actual use of analgesics or other pain therapy, professional and daily activities, and modalities of use of the PNS device (intensity and rate of the current, frequency, and duration of use) and if the elicited paresthesias were still felt in the painful area. Clinical examination included sensory testing (cotton wool, pinprick, two-point discrimination, 128-Hz vibration, and joint position) without and during stimulation. In some patients quantitative testing for allodynia was performed during and without stimulation, as is shown in the following example. Patient 2 from Table 99-2 developed pain and allodynia in the stump and ulnar side of the left ring finger after an amputation of the distal phalanx of the left little finger. The patient's most important complaint was allodynia to thermal and mechanical stimulation. We ultimately treated her with an implanted PN stimulator, which she now has used for more than 12 years. She stimulates four to five times a day for 20 to 30 minutes and that completely relieves the pain and allodynia. The effects of nerve stimulation on the thermal and mechanical allodynia are shown in Figure 99-3.

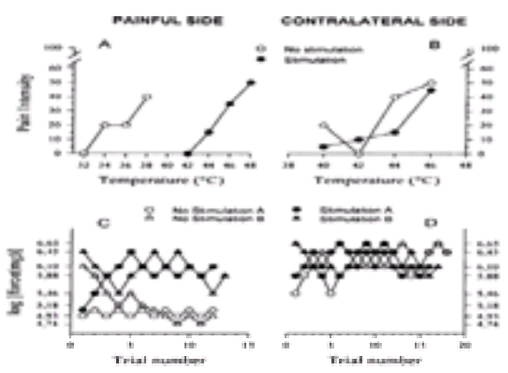

Figure 99-3. Effect of peripheral nerve stimulation (PNS) on allodynia to thermal and mechanical stimulation in a patient with neuropathic pain. The patient was tested twice, with an interval of 2 weeks, once with and once without PNS. In the no-stimulation session, the stimulator was turned off 24 hours before the start of the trial. Thermal and mechanical stimuli were applied in the ulnar region of the painful and contralateral hand. *Upper panel*: Response to thermal stimulation. The patient had to rate the painfulness of a series of ascending heat stimuli on a scale from 0 (no pain) to 100 (most intense pain imaginable). Each stimulus was presented three times. As shown, the patient had significantly lowered pain thresholds to thermal stimulation on the painful **(A)** compared with the contralateral **(B)** side. PNS completely abolished the allodynia on the painful side without affecting the thresholds at the contralateral side. *Lower panel*: Response to mechanical stimulation. A set of graded von Frey hairs was used. Filaments were applied in the painful and contralateral zone, and the patient had to indicate whether this evoked a painful sensation or not. In case the patient reported a pain sensation, a von Frey hair of a lower force was next applied; when the patient reported no pain, a von Frey hair one strength higher was taken. A double random staircase method was used (the suffixes A and B in the figures refer to the two staircases). In the figure, pain thresholds can be recognized by the sequence “ascending-descending.” As shown, the patient showed significantly lowered pain thresholds to mechanical stimulation in the painful **(C)** compared with the contralateral **(D)** hand. After PNS, the pain threshold at the painful side rose to the control values at the contralateral side. PNS had no effect on the threshold of the contralateral side **(D)**. (Reproduced from Kupers RC, Gybels JM. Evaluation of results of pain surgery. In: Gildenberg PL, Tasker

RR, eds. *Textbook of stereotactic and functional neurosurgery*. New York: McGraw-Hill, 1996:1311–1319, with permission.)

In nine of the 11 patients (see Table 99-2), the result was excellent: total pain relief in eight, almost total relief (70%) in one. None of these patients was receiving analgesics or other therapy, and all had returned to their normal professional situation, with the exception of one man. This patient was receiving lifelong workers' compensation with full pay after losing his right index finger in an accident during working hours, so he did not need to return to work, although he told us he could do so.

One patient (patient 8) is considered a moderate result. She reported pain relief of only 20% after PNS for ulnar nerve entrapment; before PNS she had three operations, during which neurolysis of the ulnar nerve was performed. However, with PNS she was able to return to work and abuse of tilidine (Valoron) was discontinued. Finally, one patient (patient 11) with femoral nerve injury after surgery for hip prosthesis reported no pain relief at all, and he suffered from motor activity in the quadriceps muscle during stimulation. However, in the first year after implantation, the result had been good. Reoperation and replacement of the electrode were performed without success. No other side effects or complications occurred.

For this chapter we have reevaluated the same patients 10 years later in 1997 (see Table 99-2). Using the same criteria, in 1997 the results were excellent in eight patients. The result remained a failure in one patient (patient 11). Two patients were lost to follow-up [patients 8 and 10, who in 1987 had a moderate (patient 8) and excellent (patient 10) result]. If we consider the two patients lost to follow- up to be failures, then 10 years after first evaluation we still have an excellent result in eight patients out of 11, which is 73%.

A most remarkable finding in our series of 11 patients, evaluated in 1987, was that all patients except one had to use the electrical stimulation progressively less frequently. In Figure 99-4, the duration of stimulation at latest follow-up in 1987, compared with the initial duration, is plotted logarithmically against time. The rate and intensity of the electrical current necessary to elicit paresthesias remained constant. At first, most of the patients used PNS continuously, some even during sleep. They gradually noted an “after effect”—that is, a pain-free interval after stopping the stimulation that increased with time. The return of the pain was gradual and stimulation was undertaken at that moment. Some patients reported that they had tried to delay stimulation when their pain started returning, but this resulted in a severe increase in the intensity of the pain. We stress that all this was found out by the patients themselves, without any suggestion from us. At the time of the last examination, some patients used the PNS less than half an hour every week.

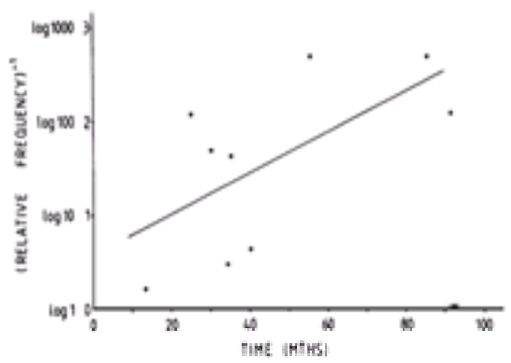

Figure 99-4. Inverse of relative frequency of use of peripheral nerve stimulation plotted against time. In the *x* axis, the follow-up period for the ten patients with good or moderate results is shown. In the *y* axis, a logarithmic scale is used for the inverse of the relative frequency of use at latest follow-up, compared with the initial use. With the least-squares method, a linear regression was performed with the nine patients who reported diminishing frequency of use. The equation of this straight line is $y = 0.022x + 0.55$. The correlation coefficient is 0.63. (Reproduced from Gybels JM, Van Calenbergh F. The treatment of pain due to peripheral nerve injury by electrical stimulation of the injured nerve. In: Lipton S, Tunks E, Zoppi M, eds. *Advances in pain research and therapy*. Vol 13. New York: Raven Press, 1990:217–222, with permission.)

At follow-up in 1997, most patients had to stimulate infrequently and some did not need to stimulate at all to remain pain free. It seems unlikely that with time the need to stimulate less can be attributed to a placebo effect or the “natural history.” None of the previous treatments had affected the pain syndrome, which had in all cases been unremitting before PNS. The time course of the effect was very similar in all patients and not related to the duration of the complaints before PNS. Some patients tried to delay stimulating when the pain reappeared, but this resulted in a further increased pain. In contrast to some studies, we found long-term and lasting good results in cases of neurogenic pain after nerve injury. Our success rate at more than 10 years' follow-up of at least 73% may be related to very careful patient selection: Only cases of neurogenic pain, preferably with injury to smaller, cutaneous branches in a well-defined nerve distribution, were operated on, and most of them only after a successful trial with transcutaneous electrical nerve stimulation was applied to the injured nerve.

Complications

In Table 99-1 is listed the complication rate as indicated by the different authors, ranging from 5% to 43%, with a mean of 18%. Complications include infection, idiosyncratic reaction to the implanted material, injury to the nerve as a consequence of implantation, scarring around the nerve, ischemia of the nerve (mostly reported with wrap-around electrodes that may have been too tightly fixed around the nerve), tenderness at the electrode or receiver site, repeat surgery for reposition of electrodes, and technical malfunctions of the stimulating equipment (mostly broken wires).

CONCLUSIONS

There is good clinical evidence that PNS may relieve certain forms of neurogenic pain. The indication for PNS is peripheral neuropathic pain in the territory of a single sensory or mixed nerve. Consequently, complex regional pain syndrome type II may be a good indication. A favorable response to appropriate screening tests is mandatory.

The following recommendations are made for the screening tests: (a) A preoperative percutaneous stimulation of the involved nerve must be done whenever possible, (b) a preoperative trial stimulation is useful for determining the distribution of the paresthesias and for the evaluation of eventual motor responses, and (c) when a preoperative trial stimulation cannot be performed, a post–electrode implant trial should be done before deciding to implant the stimulating device.

The predictive value of a preoperative evaluation of a local anesthetic nerve block has not been proven.

It is hoped that the companies making implanted electrical stimulators will develop appropriate electrodes for stimulation of PNs. The clinical experience thus far, although limited in numbers, is supportive of this strategy for the relief of pain secondary to nerve injury.

CHAPTER 100

Spinal Cord Stimulation

Björn A. Meyerson and Bengt Linderoth

BASIC CONSIDERATIONS

From a historical perspective, electrical spinal cord stimulation (SCS) is presumably the first example that chronic pain can be effectively managed by a method that evolved from the laboratory, and it was directly transferred to extensive clinical application. The first experiment in humans, based on the concept of the gate-control theory (1), was performed by Wall and Sweet (2), who inserted needle electrodes in themselves close to the infraorbital nerve and observed that low-intensity stimulation produced hypalgesia in the territory supplied by the nerve. The idea that antidromic activation of the large fibers of the dorsal columns (DCs) could activate the proposed gating mechanisms in the first relay of primary afferents mediating pain signals in the dorsal horn (DH) was first used by Shealy et al. (3), who launched what was then referred to as *DC stimulation*. Also at that time, transcutaneous electrical nerve stimulation (TENS) was introduced, but it was meant to be used merely to select patients for subsequent SCS treatment, as it was believed to have a predictive value for the outcome. Even today, it is general experience that a positive response to TENS augments the likelihood of a favorable response also to SCS, but no systematic studies demonstrating such relationship have been performed (see also reference 4). It should be noted that TENS did not become a treatment by its own until several years after its introduction. In a way, it is a paradox that SCS has become indispensable in the management of neuropathic pain, considering that it emerged as a clinical application of the gate-control theory. According to this theory, it is postulated that signals evoked by acute and noxious peripheral stimuli mediated by thin A-d and C fibers can be inhibited by the activation of large fiber afferents giving off collaterals to the neuronal pool in the DH that serves as a relay for the nociceptive impulses. Thus, on the basis of this hypothesis, SCS, as well as TENS, would be efficient in suppressing both acute and chronic pain of a nociceptive nature. To some extent, that might be true for TENS, although its efficacy in relieving pain in general has been challenged in recent studies (5,6). However, the paradox is still valid with regard to SCS, which is preferentially, or perhaps exclusively, effective for neuropathic forms of pain (e.g., see reference 7) and there is much evidence, although often of an anecdotal nature, that nociceptive forms of pain, both acute and chronic, are not directly influenced by SCS.

In the first decade after its introduction, SCS was extensively practiced and applied to a wide spectrum of pain diagnoses: It probably was used indiscriminately. The results at follow-up were poor and the method soon fell in disrepute. Therefore, in the late 1970s and the 1980s SCS was, at least in the United States, still used only in a few specialized pain centers. In Europe, SCS was not introduced until the early 1970s and then practiced to a very limited extent. The first European meeting devoted to SCS was organized in Freiburg (Germany) in 1974, and at that time there were only a few European publications in the field. No clear distinction was made between neuropathic and nociceptive forms of pain; there was, in fact, no general awareness of the distinctive features of the two types of pain. However, it was evident already in those days that the great majority of patients who were reported to have a favorable outcome suffered from what we now refer to as *neuropathic pain*.

In the last decade, there has been a growing awareness of the fact that SCS is a reasonably effective therapy for many patients suffering from neuropathic pain for which there is no alternative therapy. In fact, SCS is now in many pain centers regarded as a routine treatment. There are several reasons for this development, the principal one being that the indications have been more clearly identified. Improvement of equipment technology has also largely contributed to the better long-term results. The most important technical advancement was the introduction of percutaneous electrode implantation, thereby enabling trial stimulation, which is to date commonly recognized as an indispensable step in the selection of patients. The improved design of electrodes, leads, and receivers/stimulators has substantially decreased the incidence of reoperations for device failure. A further reason for the renewed interest in SCS is its application for other indications than neuropathic pain. By the late 1970s it was reported that the stimulation may produce peripheral vasodilatation (8,9), but it took almost a decade before its usefulness in treating pain associated with peripheral vascular disease (PVD) was recognized. This indication has now been widely accepted, although in practice adopted mostly in Europe. In later years, much interest has focused on the use of SCS for the management of therapy-resistant angina pectoris, first reported from Australia (10) and from Sweden (11). There are now numerous studies documenting that the success rate for this indication is exceptionally high and superior to what can be achieved when the treatment is applied for neuropathic pain.

It is estimated that each year approximately 14,000 SCS implantations are presently performed worldwide: virtually all in North America, the western part of Europe, and Australia. In Europe, the highest rates of SCS implantations per capita are recorded in Belgium, Holland, Sweden, Switzerland, Italy, and Spain. In many countries, problems with reimbursement constitute a major obstacle for the dissemination of SCS, but there is also a lack of knowledge and a great deal of skepticism toward its usefulness even among pain clinicians. A major concern is the cost of the device, and it was not until recently that cost-effectiveness analyses have demonstrated that SCS treatment, when applied for proper indications, may pay for itself within a relatively short period of time (see Cost-Effectiveness of Spinal Cord Stimulation).

Like most surgical interventions, SCS treatment hardly complies with the strict criteria for evidence-based medicine. The inherent nature of SCS precludes double-blind studies in the strict sense since the perception of paresthesias covering the painful area is a prerequisite for pain relief, and this is the case also in treating pain associated with PVD and angina pectoris. Moreover, it was not until recently that preliminary results of a strictly randomized study comparing the outcome of SCS with repeat operations in patients suffering from what is referred to as *failed back surgery syndrome* (FBSS) have been reported (12). It should also be admitted that there is a lack of conformity in the methods of assessing outcome and in the definition of pain diagnoses. Therefore, the results often do not permit pooling in order to make a general evaluation of the efficacy of SCS in a certain pain condition. Moreover, many of the pain diagnoses for which SCS has been tried are relatively uncommon and represented only by small groups of patients. To convince not only the medical community but also payors of the usefulness of SCS, there is a great need for conformity in the selection of patients both for trial stimulation and for permanent implantation as well as for protocols for outcome evaluation that take into account not only the degree of pain reduction but also the consequences for quality of life, functioning in daily living, working capacity, and so forth. Therefore, the efficacy and clinical usefulness have to be documented by well-designed prospective and randomized studies. Indications for SCS and guidelines for its implementation have been specified in two consensus documents (13,14) (for reviews, see references 15,16 and 17).

MODE OF ACTION

In spite of the widespread use of SCS for more than 25 years, the mechanisms involved in its pain-relieving effect are still poorly understood. It is surprising that most users of a treatment modality such as SCS, which is both time-consuming and expensive, do not seem to ask how and why a pain-relieving effect may be produced. The technical advancement of the stimulation device and of the implantation technique is in sharp contrast to the lack of stringent indications and of validated prognostic factors. No doubt, the improved technology has increased safety and reliability, but a better understanding of the physiologic and biochemical background would provide a more solid base for the selection of patients. It would also enable the development of methods for potentiating the efficacy of the treatment with

adjuvant pharmacotherapy [extensive reviews on the mode of action of SCS have been published (18,19,20 and 21)].

Neuropathic Pain

Neurophysiologic and Behavioral Studies

Over the years, a large number of theories have been advanced to explain how pain relief can be produced by SCS. Although the notion of segmental gate control cannot in its details explain the clinical effect of SCS, the general conceptualization of a delicate interplay between different types of afferent input to the DH of the spinal cord has had a tremendous impact on the understanding of pain processing and its modulation (see Chapter 3, Chapter 4 and Chapter 5).

It was reported already in the early literature that SCS does not seem to be effective in suppressing acute nociceptive pain (e.g., postoperative pain, chronic nociceptive pain, and experimentally induced nociceptive pain) (e.g., references 22,23). Nevertheless, in the 1970s and 1980s a number of animal experiments were performed with the aim of elucidating the mechanisms of SCS using acute, noxious stimuli (heat, pinch, pressure, electric stimuli, algogenic substances) (e.g., references 24,25 and 26). In these experiments it was possible to demonstrate that neuronal activation in the DH by peripheral noxious stimuli could be inhibited by concomitant stimulation of the DCs (e.g., references 27,28). It has generally been assumed that stimulation of the DCs gives rise to antidromic activation involving collaterals that in the DH, indirectly via interneurons or directly via pre- or postsynaptic activation, may inhibit second-order nociceptive neurons. However, it has also been argued that the effect may be exerted via antidromic activation of DC pathways originating from cells in DH lamina 3 to 4 (29). Of particular interest in this context is a study by Chandler et al. (30), who demonstrated that noxious activation of spinothalamic tract neurons, identified from the ventroposterior lateral thalamus during pinching, could be inhibited by DC stimulation. It was concluded that SCS preferentially inhibits high-threshold nociceptive-specific spinothalamic tract cells, rather than wide-dynamic-range neurons. It should be noted that at variance with the time course of therapeutic SCS-produced pain relief, DC stimulation as well as noxious peripheral stimuli were applied for short periods of time and the effects were present only concomitantly with the stimulation. There are but a few animal studies in which longer periods of post–SCS inhibition of nociceptive discharge has been recorded (up to 30 to 40 minutes) (31).

Although it is universally accepted that the presence of paresthesias, indicating the activation of the DC, is a prerequisite for pain relief, it has also been argued that the tingling and vibratory sensations are merely epiphenomena. The therapeutic effects should instead be exerted via the activation of other pathways than the DC. One possibility would be a conduction block of the spinothalamic fibers partly as a result of “collision” between impulses mediating pain and the activation produced by the SCS (32,33 and 34). However, this explanation seems less likely in view of the fact that therapeutic SCS is never perceived as painful, suggesting an activation of spinothalamic pathways, and the majority of the these fibers are thin and have a high activation threshold. Moreover, nociceptive transmission in the spinal cord is not blocked or substantially attenuated by SCS because the perception of acute or experimentally induced nociceptive pain is spared (23,35; see also reference 36). A strong support for the crucial role of the DC in SCS is the fact that the treatment always fails in patients suffering from pain associated with extensive deafferentation due to degeneration after an extensive peripheral nerve lesion or direct injury of the DC fibers.

Adjacent to the DC is the dorsolateral funiculus, which contains serotonergic and noradrenergic pathways known to mediate descending pain control (37). It is possible that SCS exerts at least part of its pain-suppressive effect by the activation of these pathways, although most of the fibers are relatively thin. In ongoing studies on rats with experimental mononeuropathy (see below), we have found that stimulation applied to the DC may have a moderate inhibitory effect on DH neurons in spite of an extensive lesion of the ipsilateral DC produced between the sites of stimulation and recording (38). This finding could be explained either by inadvertent activation of the adjacent dorsolateral funiculus or by the activation of a supraspinal negative feedback loop. Contradictory observations have been reported by, for example, Dubuisson (27), who recorded abolition of the inhibitory effect of SCS on nociceptive-specific DH neurons after section of the DC between the sites of stimulation and recording.

There are some studies suggesting that the SCS effect is at least partially dependent on supraspinal mechanisms. In a series of experiments, Saadé and his group (39) have shown that the inhibitory effect of SCS persisted after transection of the DC caudally to the stimulating electrode, whereas it was abolished by a DC lesion rostrally to the stimulation site. It has also been demonstrated that an activation of the DC can excite cells in the anterior pretectal nucleus, from which a profound analgesia by inhibition of nociceptive DH neurons may be produced (18). Furthermore, relatively short-lasting SCS produced a long-lasting inhibition of DH neurons and this effect was shown to be mediated via the dorsolateral funiculus.

A few experimental studies on SCS mechanisms have used the flexor reflex as a marker of a nociceptive event. The outcome of these studies has, however, been contradictory: The main C fiber–mediated components of the reflex were reported to be partially but consistently inhibited in some studies (39), whereas in others it was instead moderately facilitated (40).

Most of the studies referred to above have a limited clinical relevance due to the fact that they have been performed on intact animals and with the use of acute nociceptive peripheral stimulation. To mimic a type of neuropathic pain that often responds well to SCS, we have performed a series of studies on rats with mononeuropathy produced by partial injury of the sciatic nerve according to Bennett and Xie (41) or Seltzer et al. (42). These rats display an increased hypersensitivity to tactile stimulation (allodynia) of the nerve-lesioned hind paw. When studied in light anesthesia, the threshold of the electrically evoked flexor reflex is significantly lower in the nerve lesioned than in the intact, contralateral leg. SCS, applied with current parameters similar to those used in patients, significantly increased the abnormally low threshold selectively of the first component of the flexor reflex. This component appears with a latency of 12 milliseconds and represents the activation of A-b fibers. The late C fiber–mediated component of the reflex was not influenced by the SCS (43). This effect on the early flexor reflex component could be retained also after spinal cord transection rostrally to the site of the SCS, indicating that the selective effect on low-threshold afferent fiber functions may be present without the involvement of supraspinal mechanisms (44).

When rats with experimental mononeuropathy are subjected to SCS via an implanted electrode, the hypersensitivity to innocuous tactile stimulation of the nerve-lesioned hind paw may be suppressed (43). This effect outlasts a stimulation period of 20 to 30 minutes for up to 1 hour. It was reported in 1975 (23) that SCS may effectively suppress allodynia and hyperesthesia both to tactile and thermal stimuli in patients with peripheral nerve injury (Fig. 100-1). Thus, the experimental findings in our rat model of SCS are strikingly similar to what can be observed in patients. It is now well established that tactile allodynia is primarily mediated via A-b fibers (45,46), and on the basis of our experiments we have concluded that SCS seems to have a selective effect on the abnormal functioning of the spinal projection of these nerve fibers. In electrophysiologic experiments, it has also been found that SCS may effectively suppress the hyperexcitability of wide-dynamic-range neurons, manifested both by the presence of abnormal spontaneous discharge and enhanced responsiveness to peripheral, innocuous stimuli (47) (Fig. 100-2).

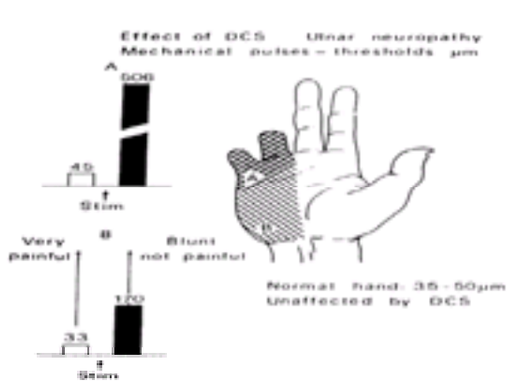

Figure 100-1. Records of thresholds to tactile stimuli (mechanical calibrated pulses) applied to a painful region of the hand after ulnar nerve injury. Before spinal cord stimulation (SCS) [dorsal column stimulation (DCS)] the thresholds were abnormally low and the stimuli perceived as very painful. After 20 minutes of SCS (“Stim”), which relieved the spontaneous pain, the thresholds were significantly elevated and the stimuli were perceived as blunt. Note that in the distal part of the hand and amputated fingers the thresholds became higher than in the intact hand disclosing a neuropathy in the form of hypesthesia. (From Linderoth B, Meyerson BA. Dorsal column stimulation: modulation of somatosensory and autonomic function. *Semin Neurosci* 1995;7:263–277.)

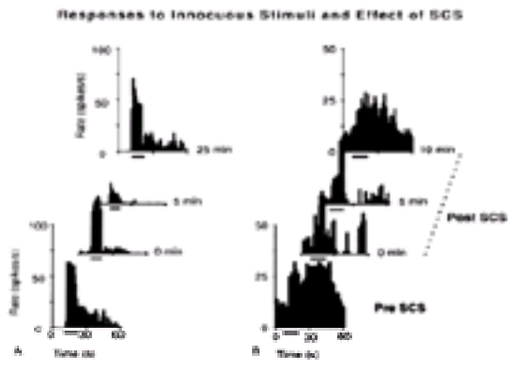

Figure 100-2. Peristimulus time histograms of press evoked responses in two dorsal horn neurons **(A,B)** in a rat with tactile allodynia after partial sciatic nerve injury before and after spinal cord stimulation (SCS). Responses before SCS are depicted in the bottom histograms. Time after cessation of SCS is shown to the right of each histogram. Bars under the histograms indicate the duration of innocuous pressure applied to the hind paw. Bin width = 1 second. (From Yakhnitsa V, Linderoth B, Meyerson BA. Effects of spinal cord stimulation on dorsal horn neuronal activity in a rat model of mononeuropathy. *Pain* 1999;79: 223–233, with permission.)

Neurochemical Mechanisms

Data from humans on biochemical correlates to SCS are sparse and partly contradictory. Several studies have been performed with cerebrospinal fluid analyses of neurotransmitters with a putative role in the effect of SCS (review, see reference 48). There are no solid data supporting the idea that the SCS effect involves endorphinergic mechanisms, and furthermore, no conclusion can be drawn about the possible role of monoamines. There is some evidence that substance P may play a role, as shown by an increased concentration in lumbar cerebrospinal fluid after SCS (49). Later experimental studies also showed a release of substance P, as well as of serotonin, in the DH by SCS (50).

In a 1985 study, Duggan and Foong reported that the SCS-induced inhibition of spinothalamic tract neurons could be counteracted by the gamma-aminobutyric acid ($GABA_A$) antagonist bicuculline (51). Later work has confirmed that SCS may produce a significant increase of GABA release, assessed by microdialysis in the DH of rats (52). In subsequent studies it was demonstrated that the DH release of GABA was significantly lower in rats displaying tactile allodynia after sciatic nerve injury than in intact animals. Moreover, SCS resulted in an increase of GABA release in animals that in preceding behavioral experiments had responded to SCS by a normalization of the withdrawal thresholds in the nerve-injured hind paw (53). In another microdialysis study, we have demonstrated that rats with nerve injury and tactile allodynia have an increased DH release of the excitatory amino acids glutamate and aspartate, and as a result of SCS this release is reduced concomitantly with an increased release of GABA (54). In behavioral studies, we have further observed that intrathecal administration of GABA or its agonists in nerve-injured rats markedly enhances the effect of SCS on tactile allodynia (55). A similar effect has been observed with intrathecal administration of adenosine in doses that by themselves were too small to influence the tactile allodynia in the hind paw (56,57). Figure 100-3 illustrates a simplified model of putative biochemical mechanisms involved in the pain-relieving effect of SCS. Our experimental studies further suggest that it would perhaps be possible to enhance the efficacy of SCS in patients by adjuvant pharmacological treatment. In fact, preliminary trials in patients have confirmed that intrathecal administration of baclofen may in some cases increase and prolong the suppression of pain after SCS (58). It should be emphasized, however, that a GABA-ergic mechanism is presumably only one of several biochemical correlates to the SCS effects.

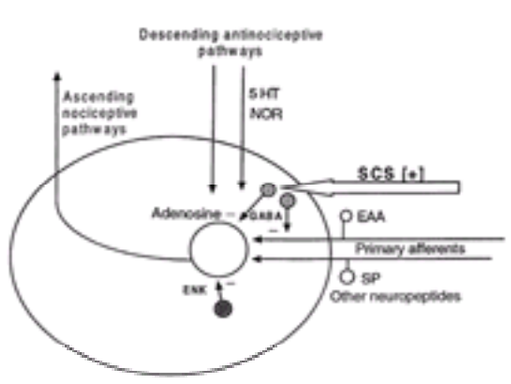

Figure 100-3. Schematic illustration of increased release of gamma-aminobutyric acid (GABA), resulting in a decrease of excitatory amino acid (glutamate and aspartate) (EAA) release in the dorsal horn after spinal cord stimulation (SCS) in nerve-lesioned rats with tactile allodynia. There is evidence that adenosine may play a role similar to that of GABA. (5-HT, serotonin; NOR, norepinephrine; SP, substance P). Pain in Peripheral Vascular Disease

The physiologic background to the vasodilatory effect of SCS, which conceivably is the main cause for the pain-relieving effect in PVD, is only partially understood and still a matter of controversy. Since the turn of the century, it has been known that peripheral vasodilatation can be induced by high-intensity stimulation, activating C fibers, of dorsal roots and peripheral nerves (59). This antidromically produced alteration of peripheral circulation has been demonstrated in many subsequent studies (60,61), and it is supposed to be caused by a release of vasoactive substances—for example, prostaglandins, substance P, and so forth—from perivascular nerve endings. However, there are several indications that the clinically used SCS stimulus parameters do not enable recruitment of thin, high-threshold C fibers.

As an alternative to the antidromic activation of thin afferent fibers it has been argued that such activation also of large afferents may result in the release of vasoactive substances. Interest has been focused on the possible role of stimulation-induced peripheral release of calcitonin gene–related peptide (62,63). Recent experiments have supplied further support for this idea (64).

Numerous studies have demonstrated a SCS-induced increase of peripheral blood flow, both in the macrocirculation (65,66 and 67) and the microcirculation (68,69).

It has been argued that the peripheral vasodilatation after SCS is secondary to a direct suppression of pain that in turn would result in a decreased sympathetic tone associated with a vasodilatory effect (discussion, see reference 70). This hypothesis has been partly based on experimental findings that SCS may induce direct inhibition of transmission of nociceptive impulses via the spinothalamic tract (71). However, these experiments used peripheral noxious stimulation and studied the effect of very short periods of SCS. Therefore, the experimental situation differs in relevant aspects from the clinical use of SCS. On the other hand, the deep aching ischemic pain is a nociceptive form of pain and it is difficult to explain how such pain can be influenced by SCS, considering the well-established fact that SCS otherwise is not effective for such pain. However, this contradiction may be resolved by the assumption that the suppression of ischemic pain is secondary to a primary effect on the peripheral ischemia. This idea is further supported by the fact that pain from ischemic ulcers, which are common in these patients, does not respond to SCS, whereas the deep resting and activity-related pain may be effectively alleviated (for further discussion, see references 21 and 70).

In recent years, there has been a growing support of the idea that the SCS effect in PVD is primarily due to a modulation of the autonomic system. The well-known beneficial, but often partial, effect of sympathectomy on peripheral circulation provides circumstantial support for this idea. In a study of peripheral blood flow, various autonomous reflexes, and cardiac activity in patients subjected to SCS, it was demonstrated that during stimulation there were a moderate decrease in heart rate and a partial suppression of sympathetic reflexes concomitant with an increase of the peripheral blood flow (72). To experimentally examine the hypothesis that attenuation of sympathetic activity is responsible for the SCS effect, we have performed a series of experimental studies in rats. These studies included cutting of the ventral roots, sectioning the sciatic nerve, and bilateral lumbar sympathectomy, and each of these procedures abolished the vasodilatory effect of SCS (73,74). The same result was obtained using the ganglion blocker hexamethonium or pretreatment with guanethidine. These studies, together with clinical observations, give

further support to the idea that the beneficial effect of SCS on peripheral microcirculation is primarily due to a decrease of vasoconstrictor sympathetic tone. It has also been shown that the vasoconstrictor activity modulated by SCS is exerted mainly via nicotine receptors in the ganglia and a $_1$-adrenoreceptors at the neuroeffector junction (75). It should be emphasized, however, that experimental data presently available have been derived from normal, intact animals and therefore the clinical relevance of the findings may be questioned.

Angina Pectoris

TENS was the first stimulation technique to be applied in intractable angina pectoris and was introduced by Mannheimer in the early 1980s (76,77). The outcome was remarkably promising. At that time, SCS was tried for ischemic pain in the lower extremities and it was quite natural to place the spinal electrode at the T-1 to T-2 level to induce paresthesias in the area where angina is experienced.

There are many reasons to believe that the beneficial effect of SCS on angina is due to an improved balance between coronary oxygen demand and supply. It has been difficult to prove that there is an increase of coronary blood flow during SCS, but a Dutch group has presented data indicating a redistribution of flow using positron emission tomography (78,79). There is a continuing debate whether the main antianginal effect in cases with radiologic normal coronary arteries is due to direct inhibition of nociceptive transmission (30) or mediated by a local redistribution of blood flow (80,81) or by a decrease in the coronary oxygen demand (82). The latter mechanisms could be the result of a depression of cardiac sympathetic activity (discussion, see reference 83), but one study lends no support to this idea (84). There is some evidence that stimulation-induced changes of cardiac blood is neurally mediated because TENS has been demonstrated to increase coronary flow in normal humans whereas it failed to do so in patients with transplanted— and denervated—hearts (85). Furthermore, it has been reported that endogenous opioids are released to the cardiac circulation during SCS and actually this could contribute to a local sympathetic suppression—if any (86,87).

Recent observations on SCS applied at the T-1 to T-2 level in the dog (88) have shown that stimulation with “clinical parameters” and at intensities 60% and 90% of the motor threshold results in depression of the activity in intrinsic cardiac neuronal systems. Especially after provocation of activity in these circuits by local occlusion of coronary blood flow, SCS significantly suppressed the increased activity in the intrinsic neurons. These observations suggest that SCS may, at least partially, limit ischemia by inhibiting the local neuronal circuits that otherwise could induce arrhythmias, leading to more generalized ischemic threats.

CLINICAL CONSIDERATIONS

Which Patients Can Be Considered for Spinal Cord Stimulation

Preoperative Evaluation

SCS, as other forms of electrical stimulation in pain treatment, requires an active participation of the patient as compared with pharmacotherapy. Because the stimulation equipment is to be handled by the patient himself or herself, at least a general understanding of the conditions for pain relief is desirable—for example, that true pain relief should be differentiated from a possibly masking effect of the stimulation-induced paresthesias; that high-intensity stimulation does not provide better pain relief (rather the contrary); and that stimulation, when used intermittently, generally does not have a prophylactic analgesic effect, at least not in neuropathic forms of pain. The patient should also be aware of the fact that a reduction of pain cannot be expected to be complete but instead partial; SCS almost never produces an all-or-none effect as compared with a nerve block. It is therefore important that the patient's expectations are realistic and that he or she accepts partial pain abolishment as a successful outcome.

To be able to use the SCS device properly and to understand the instructions, the patient must also have the ability to communicate and describe the characteristics of the pain both from a quantitative and a qualitative aspect. In some cases it may be important to differentiate between steady and evoked pain components because the former is generally more likely to respond to the treatment. For these reasons, language and cultural barriers may render successful SCS treatment almost impossible. In particular, a reliable evaluation of the outcome of trial stimulation can be very difficult. These special features of SCS, particularly when applied for neuropathic pain but maybe less so for PVD and angina pectoris, also imply heavy demands on the treating physician. Everyone who takes on the responsibility of subjecting patients to SCS treatment must be prepared to supply an almost lifelong continuing support because patients suitable for SCS typically suffer from a chronic multifactorial disease with pain as the major but not the only reason for their incapacity. Furthermore, in spite of the much-improved quality and reliability of the SCS equipment, device-related problems as well as side effects requiring local surgical interventions are not uncommon.

The implementation of SCS treatment requires a great deal of experience in the management of chronic pain patients in general. Therefore, the best results are achieved by centers with access to multidisciplinary pain expertise, where these treatments are performed on a regular basis. In a nationwide Belgian study, it was found that results reported from centers with limited experience—that is, a few patients (two to five) treated annually—were far less satisfactory than those obtained in major pain centers treating each year more than ten patients (89).

Like other forms of symptomatic pain treatment, it is mandatory to ascertain that all possible etiologic treatments have been exhausted before SCS is considered. This implies that the responsible physician must also critically evaluate the examinations on which the underlying disease diagnosis is based.

A further prerequisite for SCS treatment is a thorough pain analysis. Clinical experience, as documented in a large number of publications, indicates that SCS is predominantly, or exclusively, effective for neuropathic forms of chronic pain. (The beneficial effects on angina pectoris and pain associated with PVD are exceptions that are dealt with separately.) For this reason, the diagnosis of a neuropathic pain condition must be well established. Besides commonly used pain measures and descriptors (including, for example, pain drawing), a pain analysis may include also pharmacologic tests (e.g., see reference 90). It is of particular importance to establish the existence and relative importance of a neuropathic pain in so-called mixed pain conditions—that is, coexisting neuropathic and nociceptive pain components. A thorough neurologic examination, including a detailed analysis of cutaneous sensibility, is mandatory. Often quantitative sensory testing may be of much help in quantifying abnormalities of the cutaneous sensibility, which are common in cases of neuropathic pain (review, see reference 89). The following aspects of the pain analysis are particularly important, as they may relate to the SCS outcome:

- Distribution of pain (large or limited extension).
- Radiating versus trunk and midline components. The latter pain sites are more difficult to influence.
- Maximal pain intensity. Very severe, excruciating pain corresponding to 80 to 90 of a 100-mm visual analog scale (VAS) is less likely to respond.
- Variability of pain intensity. Pain corresponding to the lower portion of the pain intensity span is more likely to respond.
- Spontaneous, steady versus evoked pain components. Evoked pain components are less likely to respond.
- Character. Paroxysmal and shooting pains are less likely to respond than steady pain.
- External factors influencing the pain. Pain related to posture and load is less likely to benefit than pain worsened by changes of external temperature, in particular cold.
- Disturbance of cutaneous sensibility. Location and extension of hypo- and hyperphenomena should correspond to the distribution of stimulation-induced paresthesias. Preservation of large-fiber DC functions is a prerequisite for inducing paresthesias, and the presence of prominent hypesthesia may indicate a loss of such fibers.
- Effect of medication. Positive response to membrane stabilizers (intravenous lidocaine, mexiletine), antiepileptics (carbamazepine), clonazepam, tricyclics, and so forth suggests that the pain is neuropathic. Conversely, a marked pain reduction by analgesics, including opioids, increases the likelihood that the pain is nociceptive.
- A positive effect of TENS increases the likelihood of a positive SCS response, although a lack of response does not in any way preclude a beneficial SCS effect.
- Effect of sympathetic blocks has no predictive value.

It is strongly recommended that the pretreatment evaluation should include a psychological examination performed by a psychologist or a pain-oriented psychiatrist. It is well documented that psychological factors highly correlate to the outcome of SCS (89,92,93 and 94; discussion, see reference 15). The psychological examination may include also personality tests and aims at an analysis of the impact of the pain on functioning in daily activities, in the workplace, and in the family and with regard to quality of life in general. These measures must be well defined and documented so that they can be repeated at follow-up.

Furthermore, the psychological examination is performed also to exclude patients with major personality disorders, poor capacity to collaborate and to communicate their pain problems, drug-seeking behavior or abuse, and poor pain coping (“chronic pain behavior”). The fact that patients are on regular opioid medication does not in any way constitute an exclusion criterion, provided that this medication has provided a true analgesic effect and that there is no history of rapid escalation of doses,

suggesting tolerance, drug seeking, or both. Patients involved in litigation related to their pain condition should not be excluded for that reason only.

Indications and Results

Surgical treatments such as SCS are difficult to include in controlled, randomized double-blind studies. Thus far, SCS cannot be regarded as validated by evidence-based medicine. Moreover, the validity of many SCS studies can be challenged because only one or two facets of the many possible outcomes have been addressed. Thus, the treatment result is usually classified only with regard to the degree of pain relief assessed by the use of VAS. As a rule, an arbitrary degree of pain relief of more than 50% is regarded as good and 90% as an excellent result (discussion, see reference 95). Unfortunately, it is generally not reported whether the evaluation of pain relief is averaged over time, refers to the effect of stimulation at its best, or refers to the pain intensity generally present just after a stimulation session. The important issues of quality of life and functioning, the patient's global satisfaction, and employment status are rarely addressed. Some studies have simply grouped the patients as users or nonusers of the stimulation device, and in a long-term perspective this seemingly rather simple dichotomy may reflect the patient's global satisfaction and the clinical usefulness (96). The magnitude of a placebo response is completely unknown (see Chapter 81).

In some studies, the outcome measures include the patients' global evaluation of the usefulness of the treatment, changes in analgesic medication, and changes in functional ability (97). The patient's satisfaction may also be evaluated by asking whether he or she would again undergo the procedure of electrode implantation having experienced all that this implies (98). An example of a multifactorial outcome analysis, used by North et al. (98), is shown in Figure 100-4. Such composite outcome measures offer the opportunity to analyze in more detail the efficacy of the treatment. Variability in the different outcome measures renders a conclusive evaluation of the clinical usefulness difficult. A further problem with the evaluation of many SCS studies is that the outcome assessment may be based only on patients who have been permanently implanted; the total number of patients originally subjected to trial stimulation often is not reported. The exclusion of the primary nonresponders makes a global evaluation of the usefulness and efficacy of the treatment for a certain diagnosis virtually impossible. A minimal requirement for a reliable evaluation of the treatment outcome should be that the follow-up assessments are performed by a disinterested third party without the participation of the treating physician. This condition has rarely been fulfilled in SCS studies.

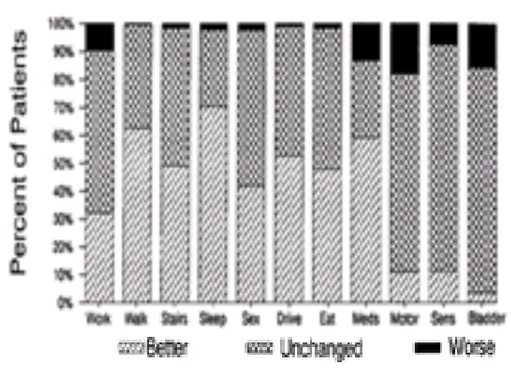

Figure 100-4. Changes of patients' ratings of their abilities to perform various activities in daily living related to impairment because of pain, ongoing medication, and neurologic deficits. The percentage of patients reporting gains, losses, or no change is represented in a stacked bar format. Data from a cohort of 171 permanently implanted patients with a mean follow-up of 7.1 years. (From North RB, Kidd DH, Zahurak M, et al. Spinal cord stimulation for chronic, intractable pain: experience over two decades. *Neurosurgery* 1993;32:384–395, with permission.)

An outcome measure of particular interest, not the least from an economic point of view, is a change in employment status. Contrary to expectations, there seems to be no obvious correlation between the degree of pain relief and work status, as reported in several studies (4,89,99,100). However, in one study reporting on patients with FBSS, 54% of the patients were able to work full-time after treatment, as compared with 41% before, and approximately 8% changed from part-time to full-time work (98). These results are in sharp contrast to what has otherwise been reported. Considering that the great majority of patients subjected to SCS are severely disabled and have long histories of chronic pain, it cannot be expected that many of them will be able to resume professional activities, particularly when unemployment is high.

In the evaluation and ranking of indications for SCS used for neuropathic pain, the shortcomings of the published studies discussed above must be taken into account. On the other hand, it should be noted that the relative efficacy of SCS, as shown in a large number of publications, for some common neuropathic pain diagnoses is surprisingly concordant (see also reference 101). Only those pain conditions for which the efficacy of SCS is well documented in larger series of patients are discussed. Numerous papers on SCS have been published since the early 1970s; we focus on studies performed in the last decade. In general, the principal indications have been for pain due to injury or disease in peripheral nerve or spinal roots. Occasionally, SCS may also be effective for pain of spinal origin, although the evidence for its efficacy on this indication is less well documented. The main indications are listed in Table 100-1.

TABLE 100-1. Indications

Neuropathic Pain

Pain Due to Peripheral Nerve Injury

Pain due to peripheral nerve injury is regarded by many to be the prime indication for SCS with the best chances of obtaining satisfactory and long-lasting pain relief (15,16,97,102,103). However, this view is not shared by others who have reported relatively modest results in such cases as compared with spinal root pain (98). Nerve injury associated with pain, both spontaneous and evoked, may follow trauma, surgery, entrapment, inflammation, and metabolic disorders. Often there is a combination of trauma and surgery, and it may sometimes be virtually impossible to identify the principal cause. This form of pain may occur as a result of both injury to one major nerve (e.g., ulnar nerve entrapment) and partial injury to distal nerve branches (e.g., incisional pain). Some nerve territories appear to be particularly vulnerable to surgical trauma, as evidenced by the fact that there is an overrepresentation of neuropathic pain conditions associated with some very commonly performed surgical interventions. A typical example is gynecologic surgery performed via a suprapubic incision (Pfannenstiel), which carries a considerable risk of resulting in a partial injury to the nerves supplying the groin (Table 100-2).

Pain location	Injured nerve(s)	Operation
Groin	Ilioinguinal	Herniectomy
	Iliohypogastric	Gynecologic surgery (Pfannenstiel)
	Genitofemoral	Appendectomy
Knee	Infrapatellar	Knee surgery (endoscopy)
	Saphenus	Varicose veins (stripping)
Ankle, foot dorsum	Superficial peroneal	Ankle joint surgery
Thoracic and abdominal wall	Intercostal	Thoracotomy
	Cutaneous abdominal	Mastectomy Renal surgery
Upper thorax, upper arm-axilla	Thoracobrachial	Mastectomy

TABLE 100-2. Examples of common postsurgical neuralgias likely to respond to spinal cord stimulation

A common but not unique feature of peripheral injury pain is the presence of disturbance of cutaneous sensibility. Often there is dysesthesia, allodynia, and hyperalgesia. These disturbances may have a tendency to spread outside the territory of the originally injured nerve(s). Occasionally, this progressive extension of cutaneous sensory disturbance may involve the entire upper or lower quadrant of the body; such conditions are for obvious reasons extremely incapacitating. This type of pain may fit the International Association for the Study of Pain criteria of complex regional pain syndrome (CRPS) type II (104). When the nerve injury pain is located in an extremity, or at least originates from a nerve injury in the hand or foot, it may be associated with signs of sympathetic dysfunction, and it may or may not be temporarily alleviated by sympathetic blocks, including regional block with guanethidine (105), and/or systemic administration of an a-adrenergic receptor antagonist (phentolamine) (106,107). CRPS type I affects the hand/arm or the foot/leg and is characterized by marked sensibility changes in the form of dysesthesia and allodynia, but there is no proven nerve injury.

Traumatic lesions of the brachial plexus may or may not be associated with injury of the cervical roots and may sometimes include root avulsion. It is important to establish whether the lesion is confined to peripheral preganglionic nerve structures or combined with root avulsion. In the latter case there is little chance that the pain may respond to SCS. It should be remembered that painful brachial plexopathy may occur also as a late sequela of radiation therapy; this form of pain may be effectively relieved by SCS.

In case of extensive peripheral nerve injury, the territory of the nerve may be markedly anesthetic. This may correspond to complete neuronal degeneration, comprising also the postganglionic portion of the sensory nerve root. In that situation there is often a lack of neuronal substrate in the DC, and it is not possible to induce paresthesias in the painful anesthetic region.

Pain after amputation, in the form of a phantom, is a most obvious example of pain due to complete deafferentation resulting from axotomy. In such conditions, it is sometimes not possible to produce paresthesias that cover the entire phantom and this is due to extensive degeneration of the corresponding DC fibers. This is one reason why patients with phantom pain sometimes do not respond favorably to SCS. However, for such pain, as well as stump pain, SCS should be considered as the first option of invasive treatment.

Postherpetic neuralgia is a form of nerve injury pain that is complex; it involves pathology of the ganglion cells as well as part of the spinal DH (see Chapter 22). Moreover, postherpetic neuralgia may present with a wide variety of sensibility disturbances. In general, the chance of a positive response to SCS is dependent on the integrity of large fiber functions; patients with signs of extensive deafferentation are less likely to respond.

The most extensive study, both with regard to number of cases and length of follow-up, on SCS in pain due to peripheral nerve injury is reported by Lazorthes et al. (97) (Table 100-3). This was a cooperative study from Toulouse and Zürich including 152 patients suffering from this type of pain. One hundred thirty-two patients were reported from Zürich with a positive long-term (2 to 20 years) result in 90% of the patients. The outcome was assessed not only with regard to the degree of pain relief but also to daily life functioning as well as to consumption of analgesics. Another relatively large study is that reported by Sanchez-Ledesma et al. (108). Out of 49 patients characterized as having “peripheral deafferentation pain,” 36 responded favorably to trial stimulation. They were followed for 5.5 years and reported substantial pain relief, 75%, in 57% of the patients. In a metaanalysis of 11 studies from the 1980s, pain due to peripheral nerve injury, often characterized as reflex sympathetic dystrophy or causalgia, was recorded to have favorable outcome from SCS in 70% of the patients originally subjected to trial stimulation (4; see also reference 109). Unfortunately, several of the studies had follow-ups shorter than 2 years. North et al. (98) reported that “peripheral pain syndromes” had a positive outcome of trial stimulation in 68% of the patients (n = 41), whereas Kumar et al. (100), in a series of 30 patients with pain associated with peripheral neuropathy, recorded no more than 14 who enjoyed long-term pain relief. In our own clinical practice, nerve injury pain remains the best indication for SCS, and a retrospective study revealed that 27 out of 38 patients with this form of pain were still dependent on regular use of their stimulators for up to 16 years (mean, 7 years) after implantation (96).

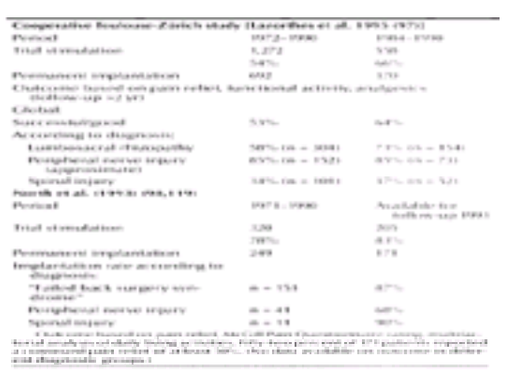

TABLE 100-3. Major spinal cord stimulation studies with long follow-ups (2-20 yr)

The most extensive series of patients with postamputation, stump/phantom pain is that of Krainick et al. (110), who reported on 64 patients with follow-ups of up to 5.5 years. At that time not more than 21% of the patients experienced pain relief of more than 50%. This is in contrast to the study by Lazorthes et al. (97), in which 13 patients out of 19 enjoyed good, long-term pain relief.

A beneficial effect of SCS in painful diabetic peripheral neuropathy has been demonstrated in a well-conducted study by Tesfaye et al. (110). Ten patients were in that series and six of them continued to note significant pain relief and used their stimulator as the sole pain treatment at 14 months' follow-up. It should be emphasized that in this study placebo stimulation was also used.

On the basis of available publications it is difficult to draw a general conclusion about the usefulness of SCS as treatment for postherpetic neuralgia because only small series of patients have been documented. It appears that the reported results are very contradictory; some studies have recorded relatively high rate of successes, whereas others have failed to obtain positive results in more than a few cases (4,108,112,113 and 114).

As concluded by Shetter in a review (17), it appears that the outcome of SCS for neuropathic pain of peripheral origin is equal and possibly superior to that for FBSS. However, it is difficult to draw any definite conclusions because the number of patients in each diagnostic category is small, and the lack of stringent diagnostic criteria makes a definite evaluation virtually impossible. Moreover, the new International Association for the Study of Pain terminology, CRPS type I and type II, will unfortunately make future retrospective metaanalyses of SCS treatment for pain after peripheral nerve injury even more difficult. The results of the two major up-to-date SCS studies are shown in Table 100-3.

Spinal Root Injury

In the majority of published series of patients subjected to SCS, lumbosacral rhizopathy is the most common indication and by many authors also regarded to be the best. This condition is often referred to in the literature as FBSS or *postlaminectomy syndrome*, which is a misnomer because it is neither a disease nor a pain diagnosis. Sometimes, the term *lumbosacral fibrosis* is used. In fact, these patients often present with a mixture of both nociceptive and neuropathic pain components. Although many of them have a history of surgery for disk herniation, the same form of mixed pain may occur spontaneously and often without any major pathology demonstrable by neuroradiologic and electrophysiologic examinations. Most authors contend that SCS predominantly influences the "radiating pain components," or "pain in the leg," conceivably corresponding to the neuropathic pain associated with lumbosacral rhizopathy. The differential effect of SCS in these conditions was first reported by Winkelmüller (115). It is widespread general experience that, at least with the usage of a single quadripolar lead electrode or a plate electrode, it is virtually impossible to produce paresthesias that cover midline and paravertebral parts of the lower back; the same applies to the neck, the thoracic back, the genitals, the perianal region, and the perineum (114,116). Thus, the selective effect of SCS on the rhizopathy-related pain also applies to the cervical region, and pain located in the neck with referred pain components into the back of the head, the shoulders, and the upper thoracic back can for the same reasons be expected not to respond (see also reference 16).

However, it has been argued that using a more complex configuration of electrodes such as dual 8-polar leads implanted in parallel may enable the production of paresthesias that also involve the midline regions of the back (117). It has further been claimed that such stimulation may also alleviate the pain in the low back region in spite of the fact that that pain presumably is of a predominantly nociceptive nature. It should be emphasized that there are no systematic studies addressing this issue, and thus, there are no robust data substantiating that SCS may effectively relieve pain confined to the lower part of the back.

In Table 100-4 are shown some SCS studies comprising a major portion of patients with lumbosacral rhizopathy ("low back pain"), and it appears that the long-term outcome is surprisingly concordant. Turner et al. (99) have performed a metaanalysis of publications (1967 to 1994) on SCS for chronic low back pain. The systematic literature synthesis resulted in 39 studies selected on detailed inclusion criteria. All these studies were case series, and no randomized trials could be retrieved. The majority of the studies presented data on the proportion of patients being permanently implanted after trial stimulation, and on average, 74% of the patients screened received stimulators. At follow-up (mean, 16 months), an average of 59% of patients had more than 50% pain relief. A few studies comprised follow-ups of up to 5 years with approximately the same outcome. It was concluded that the lack of randomized trials precluded conclusions concerning the effectiveness of SCS relative to other treatments, placebo, or no treatment. In an other prospective, multicenter study comprising 219 patients with "chronic back and extremity pain" subjected to trial stimulation 83% were permanently implanted. After 1 year's follow-up, 55% of the patients successfully "managed their pain" (118). In this context it should be noted that there is one prospective, randomized study, although still in progress, comparing the outcome of reoperation in patients suffering from FBSS (12). Preliminary results for the first 27 patients followed for more than 6 months showed a statistically significant advantage for SCS over reoperation.

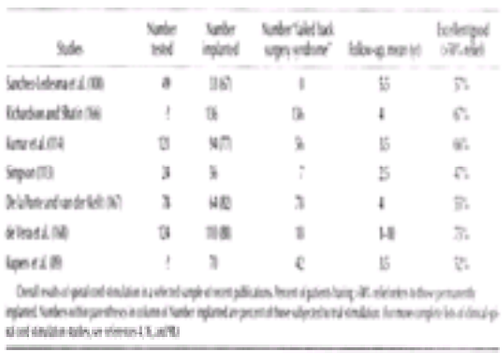

TABLE 100-4. Long-term results of spinal cord stimulation

One of the most detailed and well-performed studies is that of North et al. (98; see also reference 119), with a mean follow-up of 7 years (see Table 100-3). There were 153 patients with "postlaminectomy syndrome," and 87% of them received permanent electrode implants. It should be noticed that follow-up assessments were performed in this study by a "disinterested third party." In agreement with the commonly accepted standard for outcome assessment at least 50% pain relief was considered as a satisfactory result; also considered were the patient's global evaluation, functional gains in daily living, and medication and work status. It was concluded that approximately 50% of the patients could be classified as having a successful outcome. It should be emphasized that the patients with "FBSS" in that study were carefully selected because only those with a predominant radiating pain in the leg(s) were included.

Another extensive study with long-term follow-up and assessment of not only degree of pain relief but also daily life activities and medication is that of Lazorthes et al., referred to previously (97) (see Table 100-3). Data were collected for the period from 1972 to 1990; the total number of patients with "lumbosacral fibrosis" was 304, with a long-term (2 to 20 years) success rate of 58%. However, the results had improved over the years and in the late period 1984 to 1990 no less than approximately 70% enjoyed a favorable outcome.

There can be little doubt that lumbosacral rhizopathy (or FBSS) is a good indication for SCS treatment. In spite of the large number of publications, it is still difficult to precisely define the selection criteria. A major reason is that the patient materials are generally insufficiently presented and the relative severity of pain in the lower back and pain associated with rhizopathy are poorly described. There is in SCS outcome studies a great need for more detailed pain-related diagnoses based not only on pain history but also on thorough neurologic examination.

Spinal Cord Injury

In pain associated with disease or trauma affecting the spinal cord the results of SCS are generally disappointing (16,120). Examples are myelopathy of any etiology (e.g., tumor-related, stenosis, postmyelitis) and syringomyelia. However, partial spinal cord lesions, regardless of etiology, with some preservation of large fiber function may benefit from SCS. One example is pain in multiple sclerosis, as documented by Kumar et al. (114), who reported that seven of nine tested patients enjoyed useful relief, with a mean follow-up of 3 years. In one study, a cohort of 25 patients with spinal cord injury after trauma or surgery was subjected to SCS (121). Only those with incomplete lesions had a chance of obtaining some pain relief, but even in these the success rate was only 24%. In the largest series published, of a total of 101 patients followed for up to 20 years, 34% were considered to be successful (97) (see Table 100-3). A major problem is pain in complete spinal cord injury with extensive and total loss of motor and sensory functions below the injury level. That form of pain, which is a form of deafferentation pain and which is often felt in the lower extremities or trunk, does not respond to SCS. It is in these cases not possible to produce paresthesias in the painful part of the body conceivably because the DC fibers originating from below the injury have degenerated. In some patients, spinal cord injury pain may be present segmentally corresponding to the injury level, often in the transitional zone between partial sensory loss and normal sensibility. If the injury is located at the conus level, the pain may thus be felt in the legs corresponding to the root levels of the injury. Such pain is generally regarded to be a good indication (98). It should be noted that in many of the publications on SCS in spinal cord injury, information is rarely provided concerning either the completeness of the injury or the location of the pain (segmental or diffuse below the injury level). However, in view of what is now known to be at least a relative indication for SCS in these patients, it is reasonable to assume that patients reported to be successful refer to those with segmental pain or with significant preservation of DC fiber function.

Peripheral Vascular Disease

The application of SCS for treatment of pain associated with PVD was introduced by Cook and Weinstein in 1973 (8; see also reference 9), and they reported that together with the pain-relieving effect there was a tendency to a healing effect on ischemic ulcers. Their first reports, however, remained unnoticed for several years, and it was not until the mid-1980s that this new indication for SCS became recognized. In the following years, many studies confirmed the clinical usefulness of SCS in patients with ischemic pain due to disturbance of peripheral circulation, mostly in the lower limbs. Most of these studies were performed in a few European centers; SCS applied for PVD is still not commonly practiced in North America. One possible reason why the number of patients subjected to SCS on this indication is relatively small as compared with those treated for neuropathic pain is the skepticism among the vascular surgeons who are reluctant to refer their patients for this treatment. On the other hand, it has always been clearly stated that only patients for whom reconstructive surgery or pharmacologic treatments have been exhausted

should be considered as candidates for SCS treatment.

From the mid-1990s there has been a decreased interest in SCS treatment for PVD, and a major reason for this development might be that some recent controlled studies have failed to show convincingly positive results (122). On the other hand, these studies have included comparatively small groups of patients, and it is apparent that the patient materials have been heterogeneous. Moreover, it has to be remembered that insufficiency of the peripheral circulation is generally associated with a progressive underlying disease, and therefore, a possible beneficial effect of SCS can only exceptionally be expected on a long-term basis. On the other hand, the justification and usefulness of a treatment that is “palliative” and capable of providing efficient pain relief for several years cannot be disputed. At present, more stringent selection criteria are being defined and, it is hoped, will result in improved outcomes for SCS treatment in PVD in the future.

Indications and Clinical Results

It should be emphasized that SCS is indicated in conditions of PVD primarily because of pain. In the selection of patients, reference is generally made to the classification of Fontaine, and it is a universally accepted policy that the treatment should preferentially be applied only to patients in stage III. As evident from Table 100-5, the principal symptom in patients in this group is pain at rest, particularly in night, without signs of tissue involvement in the form of ulcers and gangrene. Patients in stage IV may be included, and there are several reports substantiating that ulcers smaller than 3 cm in diameter may heal. The main diagnoses have been arteriosclerosis and vasospastic disorders (e.g., Raynaud's disease, frostbite, and vasculopathy in scleroderma). Patients with Burger's disease also may respond (123,124). Arterial hypertension and diabetes have been claimed to correlate with a less favorable outcome (122,125), but other studies have in fact demonstrated better results in hypertensive patients (126,127). An important factor to be considered is the stability of the ischemic condition. Thus, patients with signs of a rapidly progressive disease and with a short history and manifest or impending gangrene should not be considered for treatment. Several of the patients who may be candidates for SCS due to PVD have previously been subjected to sympathectomy. It is generally agreed that this treatment does not preclude a beneficial effect of SCS.

Grade I	Arteriosclerosis with no symptoms
Grade II	Intermittent claudication with no symptoms at rest
	IIa Intermittent moderate claudication
	IIb Intermittent severe claudication
Grade III	Claudication + rest and night pain without tissue involvement
Grade IV	Grade III + tissue loss (ischemic ulceration, gangrene)
	IVa with local inflammation
	IVb with widespread inflammation

TABLE 100-5. The Fontaine classification of symptom severity in peripheral vascular disease

A number of methods for assessing the peripheral hemodynamics have been proposed both for the primary selection of patients and assessing the effect in the trial stimulation period. It appears that there is a good correlation between the clinical outcome and data on peripheral microcirculation obtained by measures of capillary density and flow velocity using intravital microscopy (128) as well as by measures of transcutaneous oxygen tension ($TcpO_2$) (124,126). Especially $TcpO_2$ seems to be an important predictor, and patients demonstrating a value between 10 and 30 mm Hg as measured on the foot dorsum preoperatively are more likely to have a satisfactory outcome with SCS than with conservative therapy (129,130). Augmentation of $TcpO_2$ values during the trial stimulation period is a positive prognostic sign. Thermography and laser Doppler flowmetry may also provide valuable information.

A review of the literature covering 20 publications from 1980 to 1989 on the long-term results of SCS in PVD showed that the proportion of patients with a successful outcome was 67% of those having been subjected to trial stimulation or for other reasons directly implanted (4). In the extensive review published by Simpson (15), “ischemic limb pain” is judged to be a condition with an exceptionally high success rate. In a cooperative study from 1986, 29 out of 36 permanently implanted patients still enjoyed effective pain relief after 25 months (67), and similar favorable outcomes have been reported in many other studies (112,125,128,131). Small ischemic ulcers have a tendency to heal as a result of the treatment. The SCS-induced peripheral vasodilation, which apparently may have a beneficial effect on ulcers, has raised the hope that the treatment may also result in limb salvage. Although such an outcome of SCS is still controversial, there are several reports in the literature that suggest that there is a decreased rate of amputation (122,124,125,128). A well-designed study using a matched control group has given further support to the hypothesis that amputation may be at least delayed (65; see also review, reference 132). Apart from the pain-relieving effect of SCS in PVD, there is a marked amelioration of claudication and walking distance increased, as reported in approximately 70% of the patients (see review, reference 16).

In 1977, Dooley claimed that vasospastic disorders would be a good indication for SCS (133). In a few studies, each reporting on relatively small numbers of patients, the favorable outcome of SCS applied for such conditions, including Raynaud's disease, has been confirmed (134,135 and 136). A positive effect has also been reported in frostbite, with relief of pain and healing of ulcers (137).

Angina Pectoris

Many patients suffering from disabling angina [New York Heart Academy (NYHA) classes III to IV] are elderly or suffer from concurrent disease, or both, making them unsuitable for major invasive procedures. Sometimes the coronary occlusions are too widespread or situated too distally to permit a successful surgical intervention. Furthermore, many patients suffer persistent, incapacitating angina even after successful bypass surgery or other interventions. In some patients with typical symptoms of angina, no obstruction of the cardiac circulation is demonstrable in the coronary angiogram. This is the so-called syndrome X, and it is debated whether the physiologic basis for the symptoms is “small vessel disease,” vasospasm, or some other disturbance difficult to demonstrate with available techniques. For these patients, classic medicine had little to offer beyond optimizing the pharmacotherapy (reviews, see references 79 and 138).

At first, SCS treatment for angina was met with skepticism, and it was feared that the stimulation would interfere with warning signals of a coronary infarction. However, numerous studies have subsequently demonstrated the effectiveness and safety of the method. Angina pectoris has in fact developed into the best indication for SCS, with a success rate above 80% (review, see reference 139). It is estimated that at present more than 1,000 SCS systems have been implanted for angina worldwide, of these approximately 500 in Sweden.

Patient Selection

Patients accepted for SCS should present with the following: (a) severe angina pectoris (NYHA classes III to IV); (b) significant coronary artery disease refractory to conventional treatment; (c) examinations that should demonstrate reversible myocardial ischemia; (d) or a diagnosis of syndrome X (small vessel disease). Pain alleviation with TENS may indicate a future positive response to SCS.

Exclusion Criteria

Exclusion criteria include (a) acute myocardial infarction; (b) other ongoing heart disease (e.g., peri/myocarditis); (c) low ability of cooperation or mental problems; (d) on-demand pacemaker (relative contraindication); and (e) magnetic resonance imaging investigation planned in the near future (relative contraindication).

The implanter should be aware that the SCS candidates often have been submitted to a thoracotomy, with subsequent pain problems of different etiology (e.g., postthoracotomy syndrome, intercostal neuralgia, psychogenic components).

Clinical Results

In general, 80% to 90% of the patients report significant pain relief, with reduced frequency of anginal attacks, diminished need for short-acting nitrates (but other medications often unchanged), fewer visits to the emergency room, and an enhanced quality of life (reviews, see references 78 and 135,136,137 and 138). There are many reports of stimulation-induced changes in various indices of coronary ischemia during workload, such as reduction of the ST segment depression in the electrocardiogram and alteration of cardiac lactate production to extraction paralleled by an increase in working capacity (78,82,142,143).

In the studies referred to previously, the multipolar electrode was often positioned with its center around T-1 to T-2. However, there is also a report of positive effects of SCS with the electrode tip at C-2 (144). That study comprised 23 angina patients followed for at least 3 months, and there was a decrease of anginal attacks from on average 124 per month to eight per month after surgery. The majority of the patients changed from NYHA angina class III to IV to class I after SCS.

Eliasson et al. (145) summarized results from 114 centers with a total of 517 patients with a mean follow-up of 23 months. The cardiovascular mortality was approximately 5% per year, and according to these authors there were no indications that SCS influences long-term mortality.

In one study, 104 patients with angina were randomized to SCS or to coronary artery bypass grafting (CABG) (146). Both groups experienced adequate symptom relief after the procedures and there were no significant differences. In the CABG group, the exercise capacity increased significantly and various indices of cardiac ischemia also changed positively. However, on an intention-to-treat basis, both the cardiovascular morbidity and the mortality rates were significantly lower in the SCS group. The conclusion was that SCS and CABG seem equivalent as to degree of symptom relief. However, it should be emphasized that considering the complications associated with bypass surgery, SCS is a favorable alternative, particularly for patients with increased risk of surgery.

Safety Aspects

In general, very few complications are reported with SCS therapy in angina (147,148). The most common is dislocation of the electrode, calling for reprogramming or open correction of position. There has been much concern about the hazardous issue of whether SCS may conceal critical coronary ischemia. Andersen et al. (149) reviewed 10 patients with SCS who sustained acute coronary infarction. In nine out of 10 patients (for the tenth, data are incomplete), this event was detected in spite of the stimulation therapy. Another question pertains to whether SCS may induce or aggravate arrhythmias. This has been investigated by Eliasson (83), who failed to demonstrate an arrhythmogenic effect of the SCS treatment.

METHODOLOGIC CONSIDERATIONS

Paresthesia Distribution

It is now universally recognized that it is a necessary, but not sufficient, precondition for effective pain relief that the stimulation-induced paresthesias cover the entire painful area. It is also generally believed that these paresthesias result from the activation of large, low-threshold fibers contained in the DC. This implies that in certain pain conditions associated with or due to degeneration of these fibers, there is a lack of neuronal substrate for the stimulation. The importance of the integrity of DC fibers has been emphasized by, among others, Sindou and coworkers, who rely on the presence of evoked potentials in response to peripheral stimulation of the painful area as a tool in screening candidates for SCS (150).

The notion that the effect of SCS is solely due to the activation of the DC has in recent years been challenged. Using a computerized model of the spinal canal and its content, it has in a series of publications been elegantly demonstrated that a stimulating electrode located in the epidural space may activate not only the DC fibers but also dorsal spinal roots and the root entry zone (e.g., 151,152) (Fig. 100-5A). Activation of the roots or the DC, or both, is dependent on the orientation of the fibers relative to the current field, the width of the dorsal subarachnoid compartment, and the electrode configuration.

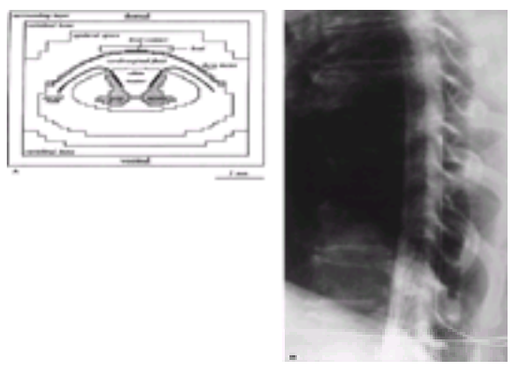

Figure 100-5. **A:** Computerized model of the spinal canal with its contents at the midcervical level. Note the proximity between the stimulating electrode ("lead contact") and the dorsal roots/root entry zone as well as the dorsal columns. (From Holsheimer J. Effectiveness of spinal cord stimulation in the management of chronic pain: analysis of technical drawbacks and solutions. *Neurosurgery* 1997;40:990–996, with permission.) **B:** Myelography of the thoracic region illustrating the wide subarachnoidal space and the wide space between the stimulating electrode and the dorsal aspect of the spinal cord.

The radiograph in Figure 100-5B illustrates the spatial relationship between the epidural electrode and the spinal cord at a thoracic level where the subarachnoid space is particularly wide. For obvious reasons, the activation of spinal roots will be associated with a segmental paresthesia distribution, whereas DC activation is likely to produce paresthesias in wider regions below the site of stimulation. However, it should be emphasized that the paresthesia distribution segmentally or in the trunk can often be influenced by varying the pulse duration. Thus, short pulses (50 to 150 microseconds) tend to evoke segmental sensations, whereas longer pulses (200 to 400 microseconds) are more likely to produce paresthesias with a wider spread in the trunk. In practice, it can be difficult to find the appropriate stimulation site from which paresthesias can be produced in the painful area. In thorough studies based on data derived from a large patient base, Barolat et al. (153) have provided guidelines for the optimal electrode placements for the induction of paresthesias in different parts of the body (see also reference 154).

Electrode Configuration

In 1972 to 1974, the first electrodes designed for percutaneous implantations were introduced (155,156 and 157) and these electrodes were monopolar and coupled as cathode with a separate anode plate or the case of the passive receiver as anode. Sometimes two such electrodes were used with the possibility of coupling either of them as cathode. Later, multipolar electrodes became available. There is now a great variability of electrodes available on the market (Fig. 100-6). The most commonly used electrode for percutaneous implantation is quadripolar, but octapolar ones are also available. The percutaneous electrodes have a tendency to dislocate and in order to maintain paresthesia distribution a quadripolar electrode in the form of a strip and implanted via a small laminotomy may be advantageous (Fig. 100-7). There is much evidence that quadripolar electrodes are far superior to monopolar or bipolar ones in controlling the paresthesia distribution. A new transverse tripolar electrode configuration has been introduced that may enable a better control in steering of the paresthesias by varying the coupling of the poles (158). This design has been partly developed on the basis of the computerized SCS model referred to previously.

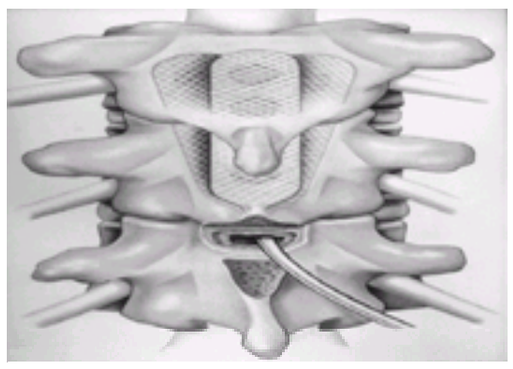

Figure 100-7. Schematic illustration of the technique for the introduction of a strip (plate) electrode. Note that angling of the strip to either side may enable activation of any specific part of the dorsal columns.

Surgical Technique

In the great majority of centers having experience with SCS treatment, a period of trial stimulation is considered mandatory before permanent receiver/stimulator implantation is decided (14). Trial stimulation is generally performed via a percutaneously implanted electrode. Disposable bipolar/multipolar electrodes for this purpose are available and with that type of electrode its proximal part is taped to the skin close to the percutaneous entry. It is also possible to use an electrode designed to be permanently implanted, with temporary connecting leads tunneled subcutaneously a short distance away from its spinal entry. Percutaneous electrode implantation should always be performed under local anesthesia and under fluoroscopic control to enable the placement at a site from where proper paresthesias can be induced. In principle, the same technique is used for implantation of electrodes both for trial and permanent stimulation.

In most centers, percutaneous electrode implantation is performed with the patient in a prone position. Although this position may appear comfortable for both the patient and the surgeon, it has the disadvantage that paresthesias, which in the perioperative test situation are adequately distributed, may change and no longer cover the painful area when the patient later tries the stimulation in a sitting or standing position. This problem can be avoided by performing the electrode implantation with the patient in a sitting position, which we have adopted as a routine procedure in neuropathic pain conditions. However, the sitting position is not advisable for implantation in patients with angina and cardiovascular disease.

The connection of the electrode to the receiver/fully implantable stimulator is preferentially performed under short-lasting general anesthesia or heavy sedation It is advisable to use prophylactic antibiotics in conjunction both with electrode and receiver/stimulator implantation.

Implantation of plate electrodes via a small laminotomy is generally performed under general anesthesia. Another option is to use propofol for anesthesia and awaken the patient for stimulation testing after the electrode has been positioned. However, some surgeons perform this procedure under local anesthesia only, which, however, is experienced as most uncomfortable by the patients, although it has the advantage of enabling perioperative trial stimulation. For implantation of such electrodes at mid- or lower thoracic levels, spinal anesthesia can be used, and in spite of complete anesthesia and paralysis of the lower part of the body, it is possible to induce paresthesias with stimulation at moderate intensity, thus avoiding the otherwise “blinded” electrode placement (159). It should be emphasized also that the final positioning of plate electrodes preferably is performed with fluoroscopic control.

There is a lack of conformity regarding the length of the trial period. In some centers, stimulation is applied for only a few days, whereas in others a period of several weeks is recommended. Regardless of the length of the trial period, it is advantageous that the patient is given the chance to evaluate the pain-relieving effect outside the hospital. The idea of trial stimulation is not only to assess the possible efficacy of the treatment, but also to minimize the influence of a placebo effect from being hospitalized and attended to. In some patients, the stimulation-induced paresthesias seem to have a purely masking or distracting effect, and the pain reappears immediately after turning off the stimulator. Although a continuous mode of stimulation is preferred by some patients, many use the stimulator intermittently. It is well known that a limited stimulation session, at least in patients with neuropathic pain, is generally followed by a poststimulatory pain relief lasting 1 to 2 hours (see also reference 119). In our experience, the presence of such a poststimulatory effect is a good indication that the stimulation has produced a “real” pain suppression, conceivably as a result of a protracted alteration of DH release of transmitter substances. Therefore, it is advisable to instruct the patient to apply stimulation intermittently for 30-minute periods and to assess the duration of a possible poststimulatory pain reduction using the VAS. This stimulation regimen should be applied at least for some days in the trial period and stimulator use ad libitum can be permitted during the rest of the period. A form that we have found to be very useful for assessing the SCS effect in the trial period is reproduced in Figure 100-8.

Form for Visual Analogue Scaling (VAS) of pain during trial stimulation

MARK THE LINE WITH A CROSS TO INDICATE PAIN INTENSITY JUST BEFORE STIMULATION

NO PAIN _____ WORST IMAGINABLE PAIN

SLIGHT MODERATE SEVERE

Stimulation started at: hrs Pain was felt to decrease at: hrs

Stimulation stopped at: hrs That is, after minutes of stimulation

MARK THE LINE WITH A CROSS TO INDICATE PAIN INTENSITY JUST AFTER STIMULATION

NO PAIN _____ WORST IMAGINABLE PAIN

SLIGHT MODERATE SEVERE

Pain started to reappear, or pain relief started to subside, at: hrs

I have taken analgesics/sedatives before next session of stimulation Yes / No

COMMENTS:

Figure 100-8. Form for visual analog scale evaluation of pain relief to be used primarily in the trial stimulation phase.

Trial stimulation in patients with pain due to PVD should be performed for at least 1 week. A beneficial effect of the stimulation in these cases is often not apparent until after many days. It is also recommended that these patients initially should use the stimulator almost continuously during the waking hours. The possible reason why there may be a delayed effect of the stimulation is that the pain relief presumably is the result of a reversal of peripheral ischemia with secondary metabolic changes in the tissue. It appears that these secondary effects of SCS may require some time to become apparent. In analyzing the outcome of the stimulation it is

important to differentiate the possible effects on resting and effort-related pain (claudication) and pain related to ulcers and gangrene because the latter pain cannot be expected to respond, at least not in the first weeks of the treatment. Although it is desirable that SCS-induced paresthesias cover the major part of the painful area, it seems that an effect on the peripheral vasculature can be achieved also in areas adjacent to the field of paresthesia distribution. Thus, it has been shown that an effect on the peripheral circulation, assessed by thermography and laser Doppler flowmetry, can be achieved also with stimulation just subthreshold to the production of paresthesias (*unpublished observation*; see also reference 70).

In patients subjected to SCS treatment for angina pectoris, the entire system, including the receiver/stimulator, is often implanted without a preceding period of trial stimulation. The reason why trial stimulation in these cases is not considered mandatory is that most of the patients have previously been subjected to TENS, which in these cases serves as a form of trial stimulation. Moreover, in well-selected patients with this diagnosis, the chances of a favorable outcome are exceptionally good. If uncertainty prevails whether pain confined to the thoracic wall or back is of cardiac ischemia origin, percutaneous trial stimulation is recommended.

After implantation of the receiver/stimulator patients may be free to use the stimulator at their own choice; there is no evidence indicating that continuous stimulation produces “fatigue” or “tolerance.” For angina, stimulation several hours daily at low intensity is recommended, with an increase to strong stimulation for a few minutes during anginal attacks or prophylactically during exercise. For patients who have implantable stimulators and who prefer continuous stimulation or stimulation for long and frequent periods, it is advisable to program the stimulator in a cycling fashion (e.g., 2 minutes on and 2 minutes off) to prolong battery life. The same applies in a situation in which high stimulus intensity is required to produce the paresthesias. For the same reason, the pulse duration and frequency should always be set at the lowest effective values. If excessive current is needed to obtain adequate paresthesias, a radiofrequency-coupled system should be chosen; otherwise, the life of the implanted pulse generator will be too short.

Complications and Side Effects

Serious complications with SCS treatment are rare. As with all surgery involving implantation of nonbiological material, there is a risk of infection. The most severe location of infection is, of course, in the spinal canal, where it may cause injury to the spinal cord. However, such events are very rare, whereas local infections at the site of the receiver/stimulator or in the back at the site of the connector between the connecting lead and the electrode are more common (5% to 10%) (e.g., 114,119). Local infections at these sites also may occur years after implantation presumably because of hematogenic bacterial spread. Needless to say, removing any SCS components from the region of infection is usually required, even when potent parenteral antibiotics are administered.

A word of caution is warranted concerning strip electrode implantation via a laminotomy in the cervical spine because in cases of severe spinal stenosis the introduction of the relatively stiff electrode plate in the epidural space carries the risk of producing spinal cord injury. The intraspinal introduction of the electrode with an obtuse angle should therefore be avoided.

Inadvertent dural puncture during percutaneous electrode implantation may result in long-lasting postpuncture headache. In case the electrode under these circumstances is introduced into the subarachnoid space, the stimulation threshold for inducing paresthesia is exceptionally low, and in such instances a subdural electrode location should always be suspected.

Many patients complain of local pain in the back at the site of the electrode connector. Therefore, care should be taken to place the connector deep in the paravertebral tissue and preferentially under the muscle fascia. It is also relatively common that the receiver/stimulator gives rise to local tenderness, particularly in lean patients with little subcutaneous fat. If the device is placed onto the lower chest, a lateral location may interfere with the patient's lying on that side in bed.

True reactions of rejection due to intolerance to the material of the implanted device are extremely rare. On the other hand, some patients tend to develop a fibrous reaction to the connecting cable that becomes palpable as a hard string, which may be mistaken as a sign that the cable is too short and stretched. Some patients subjected to SCS treatment present with marked signs of peripheral neuropathy extending into relatively large areas of the body. It seems that these patients have a general tendency of developing such abnormalities of cutaneous sensibility also following minor injury to the skin such as surgical incisions. Care should be taken to implant the receiver/stimulator as far away as possible from the painful neuropathic region. Nevertheless, local signs of neuropathy may occur in such patients as a result of the implantation of the SCS device (Fig. 100-9).

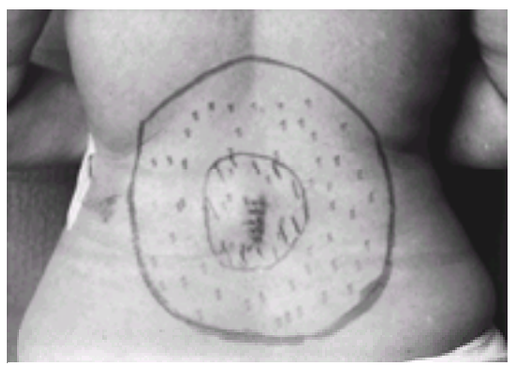

Figure 100-9. Signs of local neuropathy that developed, and persisted, as a result of the skin incision for permanent implantation of a spinal cord stimulation electrode. This patient was treated for a chronic pain condition originating from minor surgery in the knee with partial injury of the infrapatellar nerve. The inner circle denotes an area of marked tactile allodynia and the outer one the boundary of hyperalgesia (primary and secondary hyperalgesia, respectively).

By far, the most common complication requiring repeat surgery is a change of paresthesia distribution. In case of percutaneously implanted lead electrodes it is sometimes possible to visualize with x-ray a dislodgment of the electrode, but often it appears that the changed paresthesia distribution is caused by other factors—for example, a fibrous reaction around the electrode leading to an alteration of tissue impedance with a changed configuration of the current field. This is probably the reason why a similar phenomenon may occur also with strip electrodes. The incidence of replacement of electrodes is reported to be 25% to 30% in many studies (99), whereas in the long-term study by Lazorthes et al. (97), only 50 out of 692 patients were reoperated for that reason over a 20-year period.

The technology of the stimulation equipment has much improved in later years and considerably increased the reliability and safety. A major reason why repositioning of electrodes has become less common is the use of multipolar electrodes, with which it is possible by reprogramming to manipulate the distribution of paresthesias. Moreover, the access to handheld patient programmers has decreased the need to see patients for adjustment of the stimulation parameters. The marked decline of device-related failures with the use of multichannel electrodes has been elegantly demonstrated by North et al. (98) using Kaplan-Meier survival analysis.

COST-EFFECTIVENESS OF SPINAL CORD STIMULATION

SCS treatment implies relatively high health care cost; the device is expensive and the implantation procedure with trial stimulation, evaluation, programming, and so forth is time consuming. It should be recognized that in recent years, there is growing awareness that it is no longer possible to justify a treatment modality merely on the basis of personal experience and with regard to its efficacy from a strictly medical point of view. In fact, with tight regulations for reimbursement both in public health service and in relation to private insurance, it is demanded that the cost-effectiveness of any form of medical treatment must also be proven. The incidence and prevalence of disabling chronic pain are extremely high and represent a considerable portion of society's cost for health care. It is not until recent years that cost-effectiveness analyses of various treatment modalities have been performed, and with regard to SCS only a few studies are available. They are all focused on the treatment of low back/lumbosacral rhizopathy, or FBSS, comparing the estimated cost of long-term SCS treatment versus a mixture of other therapies including surgery. The very first study on that topic (160) demonstrated that the relatively high initial costs for equipment and hospital stay were more than compensated for by the considerable decrease of cost of medication and the ability to return to work, which in that study occurred in an exceptionally high proportion of the patients. In a study performed by the Health Technology Assessment Information Service (161), the 5-year cost ratio was analyzed for 100 FBSS patients treated with SCS versus another 100 subjected to alternative therapies. It was found that in comparison with repeat surgery with an efficacy of less than 80%, SCS was cost-effective. The costs for an SCS device is approximately the same as the cost for a spinal fusion procedure; however, the latter procedure is associated with much more extensive

rehabilitation and the cost for medication is considerably higher.

In one study, a thorough cost-effectiveness analysis was performed of SCS in the treatment of FBSS in the United States (162; see also reference 12). Reference was made to the tremendous costs that this condition represents to society, which in the United States are estimated to be at approximately $25 billion. It was also concluded that on the basis of available data it can be stated that a great majority of repeat surgery and other interventions for this condition are excessive and inappropriate (163). The analyses provided robust evidence that SCS treatment with a 56% efficacy will pay for itself within 2 to 3 years. If the analysis is based only on those presenting with a favorable outcome, the SCS treatment is paid for within 2.1 years by reducing the demand for other forms of medical care. It should be added that in this study, as well as in the Health Technology Assessment Information Service study referred to previously, the gains in pain relief and improvement of quality of life have not been economically evaluated. Another study reports that the application of SCS costs on average $3,660 per patient per year, and it is concluded that in spite of this relatively high cost, the cost-effectiveness compared favorably to other therapies with a high incidence of failure (164).

There are no data on the cost-effectiveness of SCS treatment in PVD; SCS applied for angina pectoris has been subjected to such a study by a Danish team (165). It was found that the SCS on this indication resulted in a considerable reduction of costs both for hospital and home care, amounting to a total savings of approximately $8,500 per year, per patient (1989 prices).

A problem with the cost-effectiveness analysis of a treatment such as SCS is that most data are based on costs in the United States, where doctors' fees and cost of hospitalization are considerably higher than in most other countries. Because the cost of the device is approximately the same in most countries, SCS treatment in many countries outside the United States presumably compares somewhat less favorably to alternative therapies.

CONCLUSIONS

SCS is not evidence based in the strict sense because of the paucity of prospective controlled studies. Moreover, due to the presence of paresthesias as a precondition for pain relief, double-blind study designs are not possible. Nevertheless, for more than two decades there have been numerous studies documenting its efficacy in the treatment of certain pain conditions that are otherwise notoriously difficult to manage. The facts that there is for most of these patients no alternative therapy that has not already been tried and that a referral for SCS treatment is often a last resort imply that controlled studies are in practice virtually impossible to perform. However, an analysis of the many studies available in the literature reveals that the results with regard to pain relief are surprisingly concordant. There has also been a tendency for the results to improve over the years; this development is largely due to advancement of device technology, the adoption of trial stimulation, and a more adequate selection of the patients based on differentiated pain analysis. The recognition of psychological factors as being of paramount importance for the long-term outcome is a further reason why the results are now more predictable.

Among experienced pain clinicians, there is a general agreement that SCS is an indispensable treatment modality for many patients with chronic neuropathic pain, particularly pain after lesions of peripheral nerves or spinal roots. There is no evidence that SCS may influence nociceptive forms of pain, and its effect on pain in PVD is conceivably secondary to the stimulation-induced peripheral vasodilatation.

The application of SCS in PVD is to date practiced to a relatively limited extent in spite of the favorable results reported in a large number of earlier studies. Pain in PVD is a condition that is particularly suitable for controlled studies because alternative treatments are available. To convince referring physicians of the usefulness of SCS in this condition, there is a great need for such studies with stringent inclusion criteria to ensure the homogeneity of the patient material.

SCS in intractable angina pectoris has not yet become an established treatment modality and is still practiced in only a few centers. However, much evidence has already accumulated that for well-selected cases SCS may result in a substantial reduction of both frequency and severity of anginal attacks in an exceptionally high proportion of patients.

SCS is a minimally invasive procedure that is well tolerated by patients and associated with very low risk of serious complications. The side effects are often trivial and can generally be overcome by minor surgical interventions or adjustment of stimulation parameters or electrode couplings.

SCS is presently underused and to promote its further dissemination, it should, to a larger extent, be practiced also outside the neurosurgical profession—that is, adopted by other pain specialists. On the other hand, it should be used only within a multidisciplinary pain team context in centers with extensive experience in managing difficult pain cases. SCS treatment is resource demanding, as it is time consuming and requires long-term, continuing doctor-patient contact and expensive equipment. However, studies indicate that SCS treatment is cost-effective.

The lack of a thorough understanding of the physiologic and biochemical mechanisms involved in the pain-relieving effect of SCS has hampered both its further dissemination and development. No doubt, there is a great need for continuing investigation of its mode of action, which would promote a more general acceptance and also make possible the development of strategies leading to enhancement of its efficacy.

CHAPTER 101

Brain Stimulation: Intracerebral and Motor Cortex Stimulation

Björn A. Meyerson and Bengt Linderoth

In the late 1970s a number of clinical studies provided evidence that intracerebral stimulation (ICS) (often referred to as *deep brain stimulation*) is a reliable method for the management of pain otherwise resistant to any therapeutic modality (1,2 and 3). However, many of the ensuing long-term follow-up studies failed to confirm the first optimistic reports, particularly with regard to the efficacy of the treatment for neuropathic forms of pain (4,5). On the other hand, some studies have established that long-lasting positive effects can be maintained with stimulation applied in the medial thalamus as treatment of nociceptive pain—for example, in conditions such as low back pain (6,7). Although ICS has been in use for more than two decades, there are still discordant opinions as to the indications, the preferred stimulation targets, incidence of tolerance and possible countermeasures, biochemical mechanisms involved, and so forth. Some years ago we undertook a limited inquiry to a number of established neurosurgeons with long experience in pain treatment. It became obvious that most of them had ceased to practice ICS because they only rarely found a good indication and considered the outcome unpredictable or had themselves often failed to obtain satisfactory results.

Considering the very few studies published in recent years, it is obvious that ICS presently is practiced only in a few centers. This gives the impression that the development of the method has come to a standstill and that no major progress leading to an improvement of the efficacy and reliability has been made. One reason why new data are sparse is that a novel and improved intracerebral electrode has not yet been approved by the U.S. Food and Drug Administration, implying that ICS in the United States has reverted to experimental status. The previous research protocol was discontinued in 1995. However, the new electrode, which is extensively used for ICS in movement disorders, is now freely available both in Europe and in Canada.

Although it appears that the majority of neurosurgeons involved in pain treatment have a skeptical attitude toward the usefulness of ICS for pain, a thorough analysis of several of the major studies with long follow-ups published in the last decade provides convincing evidence that this is a treatment modality that without good reason has fallen into disrepute. ICS can offer long-lasting and efficient pain relief for a relatively large proportion of patients for whom there is nothing else to offer. Even though it is an invasive procedure, it carries a relatively small risk of complications and side effects.

ICS has evolved along two lines, corresponding to the two major target regions for stimulation: the sensory thalamic nuclei (thalamic sensory nucleus, ventral posterior lateral thalamic nucleus) and the periaqueductal-periventricular gray region (PAG/PVG). Conceivably, stimulation in these two regions may influence pain by the activation of different mechanisms and/or systems. There is robust evidence that stimulation in the sensory thalamus is selectively effective for neuropathic, often referred to as *deafferentation*, pain, whereas PAG/PVG stimulation (in the following referred to as PVG when used in a clinical context) appears to affect preferentially nociceptive forms of pain. The distinction between these two principal types of pain is crucial for defining indications for ICS and for the choice of stimulation target. This makes the preoperative pain analysis of fundamental importance and, in fact, a prime precondition for optimizing the chances of a successful outcome.

In later years a novel mode of central nervous system stimulation has attracted much interest—that is, stimulation of the precentral motor area (Brodman 4) applied via a four-pole stimulating electrode placed epidurally. This treatment, which was introduced and pioneered by Tsubokawa et al. (8), has proven to be efficient particularly for central poststroke pain. This is a form of neuropathic pain that is notoriously difficult to manage, and it is not responsive to ICS in the sensory thalamus or the internal capsule. Moreover, motor cortex stimulation (MCS) appears to be a promising treatment for painful trigeminal neuropathy, including facial anesthesia dolorosa, and perhaps also for other forms of pain due to peripheral nerve injury (9,10).

INTRACEREBRAL STIMULATION

Basic Considerations

Sensory Thalamic Stimulation

The first trials with stimulation in the sensory thalamic nucleus, performed by Mazars et al. in the early 1960s (11,12), were based on the classic theory introduced 1911 by Head and Holmes (13). They had postulated that pain can occur as a result of insufficient activity in the epicritic (nonnociceptive) sensory system, and the idea with sensory thalamic stimulation was to restore the balance between the epicritic and protopathic (nociceptive) systems by artificial activation of the former. Basically, this idea appears to be very similar to the concept of the gate control. With the introduction of spinal cord stimulation, which was a direct clinical application of the gate-control theory, it was logical to consider the possibility of applying stimulation at a higher level in the lemniscal system—that is, at its second relay in the thalamus. It is unlikely that those who pioneered this new approach, Hosobuchi et al. (14) and Adams et al. (15), at that time were aware of the earlier experiences in Paris. It should be added, however, that some early attempts to relieve pain by stimulation in other intracerebral targets had been made [e.g., stimulation of the caudate nucleus by Ervin et al. (16) and the septal region by Heath and Mickle (17) and by Gol (18)].

Only a few experimental studies have sought to elucidate the mechanisms by which pain can be relieved by sensory thalamic stimulation. In view of the similarities between this form of stimulation and spinal cord stimulation (e.g., presence of paresthesias covering the painful area, time course of the pain-relieving effect, preferential effect on neuropathic forms of pain), it was natural to postulate the presence of supraspinal gating mechanisms. In fact, it was experimentally demonstrated that nociceptively evoked activity in the medial thalamus could be inhibited by stimulation of the dorsal columns (19). In experiments in monkeys, it has also been shown that stimulation in the ventrobasal complex of the thalamus can inhibit wide-dynamic-range spinothalamic neurones in the dorsal horn activated both by innocuous and noxious peripheral stimuli (20,21). It was further proposed that this inhibition may be due to antidromic activation of axons projecting to the sensory thalamus from pain-inhibiting relays in the brainstem. Activation of a thalamo-cortico-thalamic loop may also play a role. Furthermore, it has been demonstrated that stimulation of the sensory thalamus may modulate neuronal activity in the medial thalamus (center median and parafascicularis nuclei) evoked by peripheral noxious stimulation (22). On the other hand, sensory thalamic stimulation in the rat failed to attenuate the tail flick response as well as other measures of acute pain (23; discussion, see reference 24). There are hardly any data from experimental studies in patients subjected to sensory thalamic stimulation. Gybels et al. (25) reported that the paresthesias evoked by such stimulation had a masking effect on induced pain sensation in the threshold range, but that more intense induced pain was not attenuated. Similar observations were reported by Boëthius et al. (26).

There is much evidence that neuropathic pain, in particular central pain, leads to profound functional changes of the sensory thalamus. A series of crucial studies using microstimulation and recording in patients during stereotactic interventions has demonstrated that in patients with such pain the thalamic somatotopy is reorganized and there are marked signs of neural hyperexcitability and changes of response properties (27,28 and 29; review, see reference 2). Although stimulation in the somatosensory, as well as in the intralaminar nuclei, in patients undergoing surgery for movement disorders (Parkinson's disease) evokes only sensations of paresthesias, warmth, and cold, the same stimulation applied in patients with central pain often gives rise to a burning type of pain, usually referred to the painful region of the body. A pain-provoking effect of the stimulation appears to be more likely in patients presenting with peripheral signs of neuropathy in the form of allodynia and dysesthesia (30).

The clinical relevance of the animal experimental studies referred to previously may be questioned for the same reasons that apply to similar investigations performed to explore the physiologic mechanisms involved in spinal cord stimulation. Thus, these studies have used phasic noxious peripheral stimuli applied in intact animals,

under general anesthesia, and the effects observed were transient and short lasting. However, there is an electrophysiologic study performed using cats that apparently has been designed to mimic the condition of neuropathic pain (31). The animals were subjected to trigeminal deafferentation, resulting in increased spontaneous neuronal discharge in the spinal trigeminal nucleus. Stimulation, both of the sensory thalamus and the internal capsule, inhibited this deafferentation hyperactivity in approximately 40% of the neurons, and there was a long-lasting poststimulatory effect. Of particular interest is also a behavioral study by Kupers and Gybels (32) performed on a rat model of mononeuropathy. After a partial sciatic nerve-injury these animals display signs of neuropathy in the form of tactile hypersensitivity in the hind paw of the nerve-ligated leg. Stimulation applied to the sensory thalamus resulted in a marked suppression of this hypersensitivity that outlasted a 30-minute stimulation period by approximately 30 minutes. This study is of particular clinical relevance in view of the fact that in some patients undergoing sensory thalamic stimulation for neuropathic pain of peripheral origin, allodynia and dysesthesia can be markedly attenuated as well.

Stimulation of the posterior sensory limb of the internal capsule was introduced primarily for the treatment of central pain originating from lesions in the thalamus (15). Stimulation in this target gives rise to paresthesias indistinguishable from those evoked by sensory thalamic stimulation, suggesting that the same physiologic mechanisms are involved. On the other hand, it is apparent that the posterior limb of the internal capsule, comprising the sensory part, also contains fibers with motor function, because when stimulation is applied in this region, the stimulus parameters have to be carefully adjusted to avoid inducing muscular activation (33). For this reason, it cannot be excluded that the mechanisms involved in pain relief with capsular stimulation may also, at least partially, be similar to those underlying the pain-relieving effect of MCS (see later in this chapter).

Periaqueductal-Periventricular Stimulation

Stimulation of the PAG/PVG region has evolved from animal experiments and from observations during the course of stereotactic thalamic operations. In 1969, Reynolds (34) reported that stimulation of the periaqueductal gray matter in rats could produce a powerful analgesia and this observation was later confirmed in a large number of studies (23,35). These investigations marked a major breakthrough in modern pain research because they demonstrated for the first time the existence of an endogenous pain-controlling system. Later it was found that stimulation applied in the posterior part of the wall of the third ventricle, the periventricular gray region, also could produce analgesia (36,37). It has also been demonstrated that stimulation of the parafascicularis nucleus can excite a large population of PAG neurons similar to the excitation that may be induced by peripheral noxious stimulation. Moreover, these excited PAG neurons were found to project to the nucleus raphe magnus, a well-known relay for descending pain-inhibiting pathways (38). These findings are of particular clinical relevance because in patients the PVG area is often preferred to the PAG, where stimulation may induce unpleasant sensations of fear and anxiety. In humans, the site of stimulation in the PVG partly corresponds to nucleus endymalis and the medial part of parafascicularis (39) (Fig. 101-1).

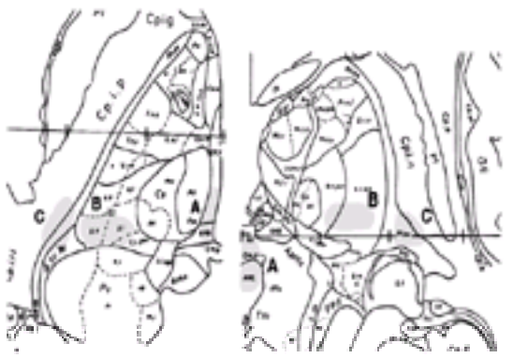

Figure 101-1. Approximate location and extent of stimulation susceptible regions in (A) the periventricular gray matter (PVG), (B) the sensory thalamic nuclei VPM/VPL, and (C) the internal capsule. Note that the PVG comprises the nucleus endymalis and at least part of the parafascicularis nucleus. The internal capsular target region is located in the most posterior and medial portion and comprises part of area triangularis and nucleus reticularis pulvinares (31). Left: Horizontal section 2 mm above the intercommissural plane. Right: Transversal section corresponding to the posterior commissure. Distances between marks on the horizontal lines in each figure represent 10 mm. (Adapted from Schaltenbrand G, Bailey P, eds. *Introduction to stereotaxis with an atlas of the human brain*. Stuttgart, Germany: Georg Thieme Verlag, 1959, with permission.)

Most of the experimental data on pain suppression by PAG/PVG stimulation may not be relevant for clinical applications. These experiments have been designed for the study of acute nociceptive events, and well-defined and reproducible pain-evoked reflexes such as tail flick and paw withdrawal on hot plate have been used. The relevance of nociceptive reflexes is debatable because the mechanisms underlying chronic pain are presumably different from those involved in acute nociception. There are several reports concerning the effect of PVG stimulation in patients with experimental pain induced by, for example, intense electrical stimulation, hot plate, or pinprick, but no attenuating effect could be demonstrated (40,41). However, there is one preliminary report that PVG stimulation may significantly increase the mechanical pain threshold as well as that for thermal nociception, both with regard to heat and cold pain (26). Furthermore, attenuation of pain perception using an ischemia test has been documented (42), although this is at variance with other reports (43).

There is but one experimental study that appears to be of particular clinical relevance because it has been performed on an animal model of chronic nociceptive pain (37,44). Rats that were rendered arthritic were subjected to stimulation in the periventricular area, which was found to suppress scratching and biting behaviors that were interpreted as signs of ongoing pain.

The demonstration that the analgesic effect of PAG/PVG stimulation in experimental animals is associated with the activation of the endogenous opioid system (45,46) suggested that a similar mechanism is involved in the clinical application of such stimulation. It has further been demonstrated that the central “opioid system” comprises not only the PAG/PVG area but also extends all the way from the arcuate to the raphe nuclei. It has been argued that stimulation anywhere along this system would have an analgesic effect, and in fact, several of these alternative stimulation targets have been explored (47). The involvement of opioid mechanisms was further supported by the observation that the stimulation-induced analgesia could be reversed with naloxone (48) and it was subsequently found that in patients stimulation produced an increased release of b-endorphin in the cerebrospinal fluid (49). In later studies, a direct relationship between the release of met-enkephalin and pain alleviation with PVG stimulation was demonstrated, whereas stimulation of the sensory thalamus failed to influence this release (50). The pain-relieving effect of PVG stimulation has also been found to be naloxone reversible (40). However, this is not a reproducible phenomenon in all patients (51,52), an observation that may relate to the finding that the dorsal part of the PAG area appears not to be associated with opioid-dependent mechanisms (53,54).

The development of tolerance to stimulation and the phenomenon of cross-tolerance between stimulation and the analgesic effect of exogenous opioids have been described (55). However, it appears that the incidence of tolerance development is maximal during the first 2 years and less common thereafter (56). There is evidence that the phenomenon of tolerance is perhaps not primarily related to the opioid system *per se,* but rather due to exhaustion of monoaminergic systems. The possible involvement also of serotonergic and noradrenergic mechanisms (57) has led to trials to counteract the development of tolerance by the administration of the precursor l-tryptophan (58), but the potency of this substance in restoring the pain-relieving effect of stimulation has not been confirmed. Moreover, serious side effects have been reported (7) (for further discussion on the physiologic background of PVG stimulation, see references 3 and 59.)

Clinical Considerations

Indications and Choice of Stimulation Target

In spite of having been in clinical use for more than two decades, ICS still cannot be regarded as an established treatment modality to be routinely applied. Therefore, it should be practiced only in centers with extensive experience in dealing with difficult pain problems and with a thorough knowledge of stereotactic procedures. It is a treatment approach that should be considered only when other less invasive therapies have failed. On the other hand, it might be that in some pain conditions ICS may compare favorably with intrathecal morphine infusion in a long-term perspective and particularly with regard to side effects.

There is much evidence indicating that stimulation applied to the sensory thalamus is effective only for pain identified as neuropathic. Therefore, the indications for this target are, in principle, the same as for spinal cord stimulation. Stimulation of the sensory thalamus is also indicated for similar pain conditions with supraspinal etiology, in particular pain originating from the trigeminal system. Some forms of neuropathic pain are associated with extensive degeneration of the primary afferent

fibers projecting in the dorsal columns, and these conditions are generally not amenable to spinal cord stimulation. Obvious examples are pain after spinal cord injury and pain after dorsal root avulsion or section. Patients with extensive peripheral nerve injury may present with profound deafferentation and the same may apply to postherpetic neuralgia. Other examples of deafferentation are phantom limb pain, trigeminal neuropathic pain, and facial anesthesia dolorosa. All these conditions may respond to sensory thalamic stimulation. There are reports also of patients with sensory thalamic stimulation applied for lumbosacral rhizopathy as part of the mixed condition of “low back pain” or “failed back surgery syndrome” (60).

In principle, the indications for sensory thalamic stimulation apply also to stimulation of the sensory limb of the internal capsule, albeit this target has been primarily used for the treatment of central poststroke pain (61,62). Such pain has, in a limited number of cases, also been reported to respond to stimulation in the sensory thalamus, but this is for obvious reasons not possible in the case of pain that originates from a thalamic lesion.

There is to date general agreement that PVG stimulation is mainly efficacious for pain characterized as nociceptive (in some studies referred as *somatogenic*). In practice, this often refers to what in the literature is described as “low back pain”—that is, pain confined to the lower part of the back and primarily originating from pathology in nonnervous tissues, such as muscles, joints, and ligaments. The syndrome of low back pain often represents a mixed form of pain comprising both nociceptive and neurogenic components. To identify and evaluate the relative importance of these components, a thorough pain analysis is mandatory for the proper selection of stimulation targets. Hosobuchi (60) has advocated the use of an intravenous morphine test that had proven to be helpful in predicting the possible responsiveness of the pain, or a pain component, to PVG stimulation. Although the reliability of such testing has been challenged on the grounds that some rare cases of neuropathic pain may respond to opioids, the test has in clinical practice been widely used and found to be helpful in differentiating nociceptive and neuropathic pain or pain components (63,64 and 65).

Notwithstanding, there are some patients with a definite diagnosis of neuropathic pain who have been reported to benefit from PVG stimulation (42).

Furthermore, there are a few reports of PVG stimulation applied in patients with chronic pancreatitis, ostitis, osteoporosis, and so forth, but the number of cases in each diagnostic group is too small to evaluate the usefulness of these indications. Previously, PVG stimulation was also applied to patients with cancer-related pain for which opioids provided insufficient relief or produced intolerable side effects (66). However, because of the advances in cancer pain treatment, ICS is no longer indicated for such pain.

Results of Clinical Studies

The outcome of major recent studies is summarized in Table 101-1 and Table 101-2. From these data, it appears that the efficacy of stimulation in either of the targets is quite variable, ranging from 30% to 80%. In a number of publications, the world literature on ICS has been summarized (6,7,24,67), and it appears that there is a tendency that somewhat better results are reported in studies from United States than from Europe. It should be noted, however, that there are hardly any publications originating from European centers in the last 10 years. Bendok and Levy (68) have performed a thorough metaanalysis of all studies including more than 15 patients. In 13 studies comprising 1,114 patients, the long-term good results varied between 19% and 79%. There was a clear tendency that the incidence of favorable overall results decreased during the first year, and for example, Richardson (3) reported a gradual reduction of good results with PVG stimulation, from 85% to 65%. The corresponding figures for the outcome of stimulation for neuropathic pain have been reported to be 61% and 30%, respectively (5).

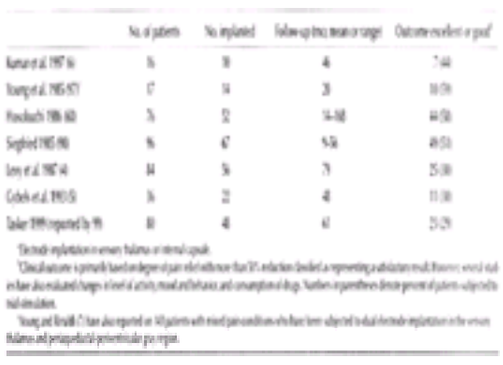

TABLE 101-1. Results of recent studies on intracerebral stimulation applied for neuropathic pain

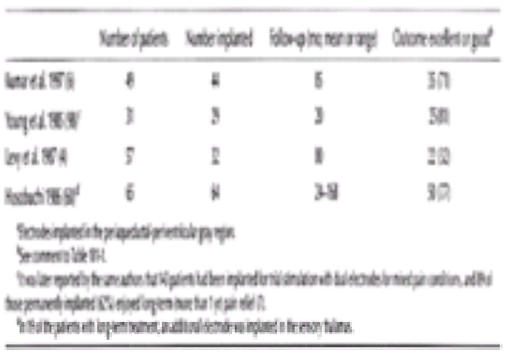

TABLE 101-2. Results of studies on intracerebral stimulation applied for nociceptive pain

The results of several of the major ICS studies with long-term follow-ups clearly show that the outcome is more favorable in patients with nociceptive than neuropathic forms of pain. Young and Rinaldi (7) reported 70% and 50% success rates for the two types of pain, respectively, and the corresponding figures in the above-mentioned metaanalysis were 61% and 42%. However, the difference with regard to neuropathic and nociceptive pain is at variance with the extensive study by Levy et al. (4), reporting that in patients with nociceptive pain subjected to PVG stimulation, a long-term favorable outcome was recorded only in 32% of those originally subjected to trial stimulation. In the most recent study it was concluded that low back pain is the best indication for ISC (6). With PVG stimulation, and in a few cases with dual electrodes (electrodes both in PVG and in sensory thalamus), 71% (35 out of 49 patients) reported excellent or good pain relief (more than 50%), considerable reduction of analgesic intake, and improvement in work tolerance. Apart from low back pain with or without radiating leg pain as a sign of lumbosacral rhizopathy necessitating dual-electrode implantation, the number of patients in each diagnostic group of neuropathic pain is too small to permit any definite conclusions concerning the efficacy of ICS. According to the metaanalysis referred to previously, it is apparent that PVG stimulation may be effective also for neuropathic pain, and in fact, no less than 23% of those having long-term success had been treated with stimulation in that target. The possibility that PVG may be efficacious also for neuropathic pain is further substantiated by the observation that pain relief may be accompanied by an objectively demonstrable suppression of peripheral signs of neuropathy in the form of allodynia and dysesthesia (69). On the other hand, sensory thalamic stimulation seems to be completely ineffective for nociceptive forms of pain. Some of the major studies provide data for the different types of neuropathic pain treated with sensory thalamic stimulation. However, it appears that the results are extremely variable and inconsistent, and, for example, anesthesia dolorosa is reported to respond favorably in many studies, whereas in others it is concluded that this diagnosis is a bad indication (2). In a group of 36 patients suffering from various forms of neuropathic pain (e.g., thalamic, cervical root avulsion, phantom, postherpetic) reported by Gybels et al. (5), 22 had a favorable short-term outcome, but only in 11 (30%) was the effect retained after 4 years' follow-up. The results in central pain, generally referred to as *thalamic pain*, as well as pain in spinal cord injury, indicate that these conditions have low probabilities of a favorable response. Conversely, the results in lumbosacral rhizopathy are reported to be successful in approximately 70% of the cases, although this diagnosis is reported separately from a low back syndrome only in a few studies.

Surgical Technique

Stereotactic electrode implantation should be performed under local anesthesia in order to enable communication about effects of intraoperative stimulation to ascertain correct positioning of the electrode. Target localization can be performed with the aid of ventriculography, computed tomography, or magnetic resonance imaging. Three types of electrodes suitable for ICS are available: a monopolar and two quadripolar electrodes with different spacing between the stimulating poles (Fig. 101-2). The quadripolar type of electrode is advantageous because it makes the placing of the electrodes with regard to depth less critical (for details concerning the technique for implanting and fixing the electrode, see the manufacturers' manuals). The connector to the percutaneous leads for trial stimulation as well as for the lead to the receiver/pulse-generator is preferably placed on the skull. To minimize protrusion from the connector it should preferentially be placed in a groove made with high-speed burr in the outer table of the skull. All patients require preoperative assessment of coagulation. Platelet-altering drugs such as nonsteroidal antiinflammatory drugs and aspirin must be discontinued.

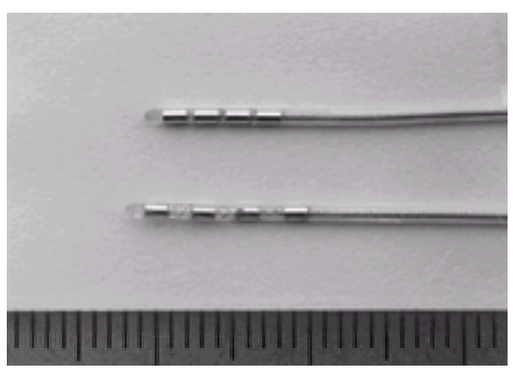

Figure 101-2. The two types of intracerebral stimulation electrodes presently available (Medtronic, Inc., Minneapolis, MN).

A prerequisite for obtaining pain relief with stimulation of the sensory thalamic nuclei is the elicitation of paresthesias in the painful area. To find the appropriate part of the sensory nucleus, the detailed atlas by Emmers and Tasker (70) is helpful. There is some evidence that stimulation in the basal part of the nucleus corresponding to the transitional zone of the medial lemniscus, where the threshold for evoking paresthesias is low, can be a more effective stimulation target than the nucleus itself (60).

The sensory thalamic nucleus is a comparatively large structure, whereas the PVG region in the medial diencephalic-mesencephalic junction zone, from where stimulation-produced pain relief is obtainable, is small. In particular, the mediolateral extension of the susceptible region, which does not exceed 2 to 3 mm, makes the electrode placement critical (39,60) (Fig. 101-3). The extreme precision that is required for implantation of electrodes in the PVG region, as well as the adjacent parts of this region being linked to both opioid and nonopioid mechanisms, accounts for some of the variability in the clinical results reported with this stimulation target.

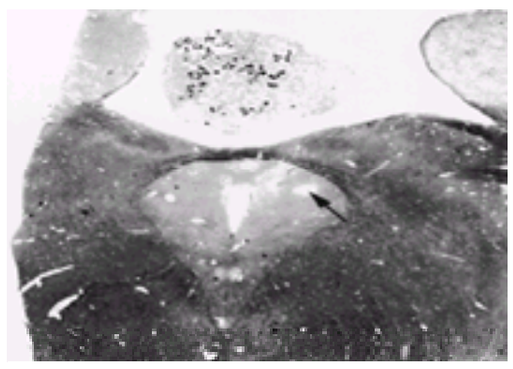

Figure 101-3. Autopsy specimen showing the uppermost part of the periaqueductal gray from a patient successfully treated with periaqueductal- periventricular gray region stimulation for visceral cancer-related pain. (*Arrow*, electrode tract.)

In contrast to stimulation of the sensory thalamic nucleus, PVG stimulation generally is performed with an intensity subthreshold to subjective sensations. At the onset of stimulation, however, patients generally report a pleasant feeling of warmth invading the trunk or the face, but this sensation does not necessarily imply that pain relief can be achieved. Even though stimulation is performed unilaterally, the evoked sensations have a symmetric, truncal distribution. Increased stimulation intensity may produce ocular oscillation and unpleasant sensations of fear, oppression, or anxiety. The approximate location and extent of the stimulation susceptible parts in the internal capsule, the sensory thalamus, and the periventricular region are depicted in Figure 101-1.

For details concerning stereotactic target localization and intraoperative stimulation and recording, the reader is referred to the paper by Tasker (71).

Stimulation Regimen

There are several reasons why trial stimulation should be performed for a period of at least 1 to 2 weeks. First, one has to ascertain that the electrode is correctly placed, as evidenced by the presence and distribution of paresthesias in case of sensory thalamic stimulation and of sensations of warmth and ocular movement (often diplopia) at higher intensity of stimulation in the PVG target. Second, a few patients perceive the stimulation-induced paresthesias as unpleasant or even painful (72). Third, the evaluation of the pain-relieving effect is, of course, necessary for the determination of whether to proceed to permanent implantation. It is a general experience that pain relief of less than 50% does not justify a permanent implantation. Of course, a few weeks' period of trial stimulation is not sufficient to eliminate the risk of a placebo effect (see Chapter 81). However, it is our experience that the presence of a poststimulatory pain-relieving effect lasting for at least 1 hour is suggestive of a true suppression of the pain rather than the result of placebo. It is therefore important to record in detail the time course of the stimulation effect. Fourth, different couplings of the stimulating poles should be tried to find the optimal combination. It should be noted that stimulation of the sensory thalamus should be applied with an intensity just suprathreshold for evoking paresthesias in the painful area. In the PVG target, pain relief may be obtained also with stimulus intensity subthreshold to any subjective sensations. This gives the opportunity, in this target, to use sham stimulation during the trial period, using, for example, an exhausted battery.

As a rule, stimulation of the sensory thalamus must be continued for 15 to 30 minutes to obtain pain relief. In general, the poststimulatory effect lasts for several hours and in exceptional cases it may persist for a considerably longer period of time. The patient should be allowed to choose the frequency that is perceived as the most comfortable (generally 40 to 70 Hz). It should be noted that the pulse duration may be critical for the paresthesia distribution and extension. Although it is a well-known phenomenon that the pain-relieving effect of sensory thalamic stimulation often tends to fade during the course of the first year, there is no evidence that there is a development of tolerance or fatigue that could be counteracted by restricting the use of the stimulator.

In the PVG region, the usual stimulation frequency is 30 Hz and the pulse duration 200 µsec. In this target there is at least some rationale for suspecting development of tolerance, and for that reason the patients are instructed not to stimulate themselves for longer than 20 to 25 minutes at one time and, if possible, not more than three or four times per 24 hours.

The great majority of patients reported in studies until the last 5 years have been implanted with a passive receiver, activated by an external radiofrequency-emitting generator. The fully implantable and programmable pulse generators presently available offer many advantages. However, it is important that the generators are programmed with a low maximal intensity and preferably also for limited periods of stimulation. Erroneous handling of the stimulator can lead to an inadvertently high stimulation intensity, which may produce unpleasant sensations with strong and almost painful paresthesias from the sensory thalamus and nausea, diplopia, and

anxiety from the PAG/PVG.

Complications and Side Effects

Serious surgical complications rarely occur with intracerebral implantation of electrodes. A survey of major studies reveals that hemorrhages have occurred in approximately 3% of the patients. A new design of ICS electrodes, now available, will presumably reduce the risk of producing intracerebral bleedings. Introduction of an electrode into the sensory thalamus may result in mild, local dysesthesia confined to the area corresponding to the part of the nucleus implanted, but this is generally a transitory side effect. Electrode implantation in the PAG/PVG may cause a slight but also transitory diplopia.

Infection at the receiver side or along the subcutaneous leads has been reported in some cases (approximately 3%), but the risk is minimized by the use of prophylactic antibiotics. Even though the trial stimulation period via percutaneous extension leads is often prolonged for several weeks or even months, only a few cases of intracranial infections have been reported. Otherwise, side effects related to the implanted material and equipment failures are similar to those with spinal cord stimulation (see Chapter 100).

Concluding Remarks

Similar to other invasive procedures, scientific criticism can be leveled against most studies on ICS as pain treatment. The lack of controlled studies, heavy influence from physician bias due to the lack of third-party evaluation, and no use of placebo stimulation (which would be possible at least with PVG stimulation) are all factors that preclude classification of ICS as evidence-based medicine. Moreover, the reported results are highly variable, ranging from 30% to 70% success, and the outcome measures are often relatively simplistic. Nevertheless, a thorough examination of the few recent publications with long-term results unequivocally reveals that a comparatively large proportion of patients with chronic pain who have failed to respond to any other treatment modality have enjoyed a useful and sustained alleviation of their pain. Although there are reasons to argue that the clinical data available to date “prohibit an objective appraisal of the clinical efficacy of deep brain stimulation,” as stated in a paper by Duncan et al. (24), we strongly believe that ICS should remain in the treatment armamentarium of a large pain center. It is most regrettable that medicolegal regulations in the United States in practice have deprived many patients of this therapy. It is true that the application of ICS requires considerable experience and expertise, but it should be emphasized that it is an invasive procedure that carries a relatively low risk of complications and side effects. The availability of a new type of electrodes designed to minimize the trauma to cerebral tissue can be expected to further reduce the incidence of serious complications because of intracerebral hemorrhages. Many patients who have benefited from ICS on a long-term basis suffer from pain in the lower part of the back, with or without signs of rhizopathy, and many of them may be candidates for long-term intraspinal morphine administration in case spinal cord stimulation has failed. Intraspinal morphine has gained in popularity in recent years, and there are a large number of reports substantiating its efficacy. However, many patients subjected to this therapy suffer serious side effects as well as the development of tolerance. We believe that for these patients ICS should be considered as an alternative therapeutic approach.

MOTOR CORTEX STIMULATION

Basic Considerations

As compared to stimulation of the sensory thalamus, and to some extent the sensory limb of the internal capsule, there seems to be little rationale for selecting the motor cortex strip (area 4) as a stimulation target for pain. MCS has been in use for approximately 8 years; however, the underlying mechanisms of its pain-relieving effect are poorly understood, and there are few experimental data pertaining to its mode of action.

At the International Association for the Study of Pain World Congress on Pain in 1990 in Adelaide, when Tsubokawa and collaborators (8) first reported on their clinical experience of MCS applied for central pain, there was also another report from the same group describing experiments in cats subjected to MCS (73). In these animals, thalamic neurons had been rendered hyperactive by spinothalamic tractotomy and it was demonstrated that stimulation of the motor, but not the sensory, cortex could suppress the increased neuronal spontaneous discharge. It should be noted, however, that Namba and Nishimoto (31) earlier had performed trigeminal denervation in cats, resulting in deafferentation hyperactivity in the spinal trigeminal nucleus. In their experiments, hyperactive wide-dynamic-range neurons could be inhibited by stimulation of *both* the sensory and of the motor cerebral cortex. It was further found that the activated corticofugal pathways were passing by the sensory limb of the internal capsule and the sensory thalamus. Because the latter two stimulation targets have since long been used for the management of certain forms of neuropathic pain, it is in this context relevant that MCS appears to be exclusively effective for such types of pain.

It has long been known that electrical stimulation of the sensory-motor cortex in rats, cats, and monkeys, not subjected to previous deafferentation, may produce presynaptic inhibition of spinal primary afferents and also of spinothalamic tract neurons (74,75,76 and 77).

In a neuroanatomic study using neuron labeling, the connections of the motor cortex were further examined with the purpose of exploring possible mechanisms involved in MCS (78). It was demonstrated that the motor cortex is reciprocally connected not only with the sensory cortex but also with a part of the sensory and posterior nuclei of the thalamus (for details concerning motor corticothalamic connections, see reference 79). Such connections have, in fact, been the basis for a theory advanced by Tsubokawa to explain the pain-relieving effect of MCS (80,81). It is hypothesized that pain after a cerebral lesion is the result of a deficient inhibitory pain control. Ortho- or antidromic activation of large-fiber reciprocal connections between the motor and sensory cortices by MCS would in turn activate nonnoxious fourth-order sensory neurons, giving rise to a restoration of the inhibitory pain control. Circumstantial evidence, compatible with Tsubokawa's hypothesis for neuronal activation, or synaptic events, in the cortex is provided by the finding that in a case of parietal cortex hypoperfusion, demonstrated with single photon emission computed tomography, MCS produced normalization of the regional cortical circulation (82). On the other hand, there are in the literature accounts of three patients, one reported by Peyron et al. (83) and two by Nguyen et al. (10), who benefited from MCS in spite of the fact that they presented with extensive parietal lobe infarctions involving also the sensory cortex. Moreover, in a positron emission tomography study, no cortical activation could be demonstrated in conjunction with MCS (83), and the same observation has been made by Hsieh et al. (84). Instead, a significant cerebral blood flow increase, reflecting augmented neuronal activity, was present in the ipsilateral thalamus, the cingulate gyrus, the orbitofrontal cortex, and the brainstem. It was concluded that the integrity of the somatosensory cortex and the lemniscal system does not seem to be a necessary condition for obtaining pain relief by MCS. These findings are thus at variance with Tsubokawa's theory. Instead, there is reason to believe that the thalamus, and presumably also the brainstem, is the main relay for pain control with MCS, and the fact that in one of the patients studied, somatosensory evoked potentials were clearly abnormal suggests that also the sensory thalamus is not necessarily involved. On the other hand, it is not yet clear how the thalamus and the brainstem as well as the cingulum may be activated by MCS without any signs of cerebral blood flow changes reflecting neuronal activity in the motor cortex. Moreover, there are several patients with extensive thalamic lesions who are reported to have benefited from MCS, although details on the extent and configuration of the lesions have not been published.

Clinical Considerations

Selection of Patients

There is substantial evidence indicating that MCS is efficacious only for certain forms of neuropathic pain, and no data suggest that it may influence nociceptive pain. The principal indications are central supraspinal pain and pain in trigeminal neuropathy. It should be remembered that MCS is still to be regarded as an advanced form of pain treatment that is not yet established as a routine, and it should be practiced only in major centers with extensive experience of the management of difficult pain conditions. Therefore, it is mandatory that all other less demanding and less invasive therapies should first have been tried. As with all forms of central nervous system stimulation for pain, MCS may be a lifelong therapy, and the continuity in the physician-patient relationship must be guaranteed. A mandatory requirement is that the patient has realistic expectations about the possible outcome and also is able to communicate and evaluate the possible effects. Otherwise, inclusion and exclusion criteria are very much the same as for spinal cord stimulation (see Chapter 100).

Particularly when applied for a central pain, the outcome of MCS is variable and there exist to date no reliable predictors. In a thorough study of patients with such pain, Yamamoto et al. (85) have used pharmacologic tests with the aim to relate the analgesic potency of barbiturate (thiamylal), morphine, and ketamine to the outcome of MCS. Thirty-nine poststroke pain patients with demonstrable thalamic or suprathalamic lesions were subjected to tests with these drugs administered intravenously. Definite pain reduction occurred in 21% of the patients with morphine, in 56% with thiamylal, and in 48% with ketamine. The responsiveness to the different drugs did not correlate to the site of the lesion. Conversely, there was a clear relationship between a positive outcome of the subsequent MCS treatment and thiamylal and ketamine sensitivity as well as morphine resistance. However, only 59% of the patients were responsive to thiamylal or ketamine, indicating that the predictive power of these pharmacologic tests is incomplete, although they may be of some help in selecting the patients.

It might be that the use of other drugs for testing may be useful in the selection of patients for MCS (86). For example, it has been reported that propofol at a low dose may alleviate poststroke pain (87), and the same seems to apply for intrathecal administration of baclofen (88).

There is an interesting report describing a patient with central pain in whom repetitive magnetic coil stimulation of the motor cortex for 30 minutes produced 30% pain relief. In that patient, subsequent long-term MCS proved to be effective, whereas another case failed to respond to both types of stimulation (89).

It has been described that focal transcranial magnetic stimulation integrated with frameless stereotactic technique enables a highly selective activation of individual muscles or groups of muscles (90). The preoperative application of this novel method of magnetic stimulation could be helpful.

The significance of the integrity of the corticospinal motor system in predicting the responsiveness to MCS has been emphasized in a study by Katayama et al. (91). Thus, it was found that in patients with central pain the long-term outcome was much more favorable in those with no or mild motor weakness than in those with more pronounced deficits. There was a similar relationship with regard to whether or not it was possible to induce muscle activation by high-intensity, low-frequency cortical stimulation.

Results

The most common indications for MCS are supraspinal pain after hemorrhage, infarction, or neurosurgery and painful trigeminal neuropathy, including facial anesthesia dolorosa. Occasional cases of pain after cervical root avulsion, pain in paraplegia or tetraplegia, as well as pain after peripheral nerve injury have been reported, but the number of patients with each of these diagnoses is too small to permit an evaluation. Both central pain and trigeminal neuropathy are otherwise notoriously difficult to manage (Fig. 101-4), and sensory thalamic or internal capsular stimulation rarely provide long-term beneficial results. Tsubokawa (80) in particular has emphasized that for central pain both these stimulation targets are effective in less than one-third of the patients, whereas MCS has a considerably better chance of success (2). The largest series of patients with central pain are those reported by Yamamoto et al. (85; see also references 80 and 92), Nguyen et al. (10), and Katayama et al. (91). As shown in Table 101-3, the overall positive results vary between approximately 45% and 75% of permanently implanted patients. An analysis of the patient materials reveals that there is no clear relationship between outcome and site of lesion. This implies that pain associated with a thalamic or suprathalamic lesion has an equally good chance of benefiting from the treatment. Also extensive lesions of the parietal cortex, comprising the sensory cortex, do not seem to preclude the possibility of a favorable outcome.

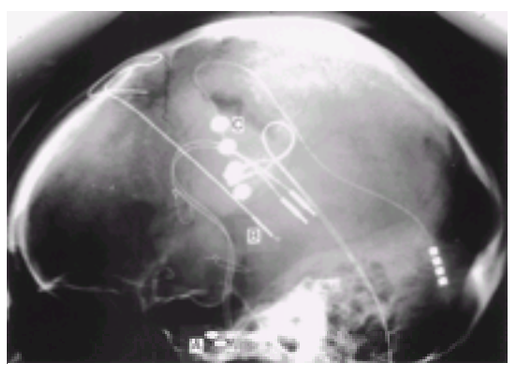

Figure 101-4. Radiograph of a patient suffering from trigeminal neuropathy with incapacitating chronic pain. This case illustrates that such pain may be extremely difficult to manage and that various invasive procedures may fail. This patient had been subjected first to stimulation of the gasserian ganglion (A) and then to sensory thalamic stimulation (B) as well as to stimulation of the spinal trigeminal tract (not illustrated). She has now for 7 years had a good, but not complete, pain relief with motor cortex stimulation (C).

	Number of patients trial/implanted	Follow-up (mo)	Number of patients with excellent or good outcome[a]	Average degree of pain relief
Tsubokawa et al. 1991 (80)[b]	110	24	51/80	>50%
Yamamoto et al. 1997 (85)	28	>12	13/46	>50%

[c] Wallenberg syndrome.

TABLE 101-3. Motor cortex stimulation for central poststroke pain

As apparent in Table 101-4, MCS applied for trigeminal neuropathy tends to provide somewhat better results than in cases of central pain. The alternative treatments in this condition are stimulation of the trigeminal ganglion/rootlets or sensory thalamic stimulation. It is a general experience that the former treatment, which is easier to perform from a technical point of view, does not provide a satisfactory outcome in more than approximately 40% of the patients, and besides, it is not applicable in cases of extensive deafferentation due to a retroganglionic lesion of the trigeminal nerve. Sensory thalamic stimulation often fails, at least in a long-term perspective. For these reasons it is probable that MCS will become the treatment of choice for trigeminal neuropathy.

	Number of patients trial/implanted	Follow-up (mo)	Number of patients with excellent or good outcome	Average degree of pain relief
Meyerson et al. 1993 (9)	5/6	6-30	3/5	>60%
Tasker et al. 1994 (96)	7/8	1-24	3/5	>50%
Nguyen et al. 1999 (10)[a]	12	27	8/11	>60%
Herregodts et al. 1999 (101)	17/15	18-24	8/11	>50%

[a] Two patients still enjoy excellent pain relief after 5–7 yr; in three patients the effect progressively diminished and eventually disappeared.
[b] Excellent/good outcome has also been reported in some case of three of patients with pain in paraplegia and in three out of four with pain of peripheral origin.

TABLE 101-4. Motor cortex stimulation for trigeminal neuropathy

Some patients with central pain report the presence of paroxysmal, shooting pain components besides the deep, aching, and sometimes burning type of spontaneous, continuous pain. It has been reported that also the former intermittent type of pain may be effectively alleviated by MCS (10).

A majority of patients with central pain as well as trigeminal neuropathy present also with various forms of evoked pain because of the presence of allodynia and

dysesthesia; in some cases there are also signs of hyperalgesia, often being more prominent in subcutaneous tissue than in the skin. In several studies, it has been reported that the evoked pain components may be markedly relieved by MCS. An example of this effect is shown in Figure 101-5, which illustrates the reduction of dysesthesiae and allodynia in parallel with the relief of spontaneous pain in a patient with severe trigeminal neuropathy. There was no relief with placebo stimulation (not illustrated), possibly because stimulation did not produce any subjective sensations and the patient was thus unaware of whether it was on or off.

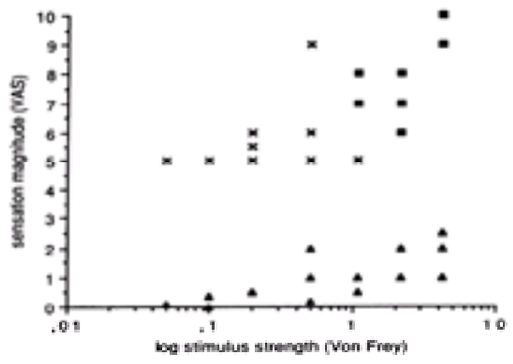

Figure 101-5. Effects of motor cortex stimulation on facial dysesthesia and allodynia assessed by von Frey filaments (stiffness expressed in grams of bending pressure on the abscissa) before and after a period of 30 minutes of stimulation. Note that the stimulation per se did not evoke any sensations. (Evoked pain: n, dysesthesia; x, allodynia before stimulation; s, sensation after stimulation.) Spontaneous pain: visual analog scale (VAS) 80/100 before and 20/100 after stimulation. [Reprinted from Meyerson BA, Lindblom U, Linderoth B, et al. Motor cortex stimulation as treatment of trigeminal neuropathic pain. *Acta Neurchir Suppl (Wien)* 1993;58:150–153, with permission.]

Surgical Technique

The crucial part of the implantation procedure is to localize not only the precentral motor gyrus but also to identify the appropriate portion of the gyrus according to its somatotopic organization. To ensure an optimal electrode position, one cannot rely on bony landmarks only. More sophisticated anatomic and functional means of localization must be used. For the purpose of identifying the central sulcus, Tsubokawa and collaborators, in their first report (8), described the use of preoperative examination with somatosensory-evoked potentials. The site where the N20 deflection of the response was phase-inverted into a positivity was marked on the skin of the skull and used as a point of reference for placing the burr hole and inserting the epidural electrode. An elegant method for anatomical identification and location of the motor cortex was introduced by Herregodts et al. (93,94). They produced preoperative three-dimensional magnetic resonance images of the cortical surface, and the location of the selected part of the precentral gyrus was identified in relation to the intersections of tubes, which were filled with magnetic resonance contrast–enhancing liquid, glued together as a net, and taped to the patient's head. In relation to this net the relative location of the chosen section of the motor gyrus was marked on the skin. This approach has been further developed by Nguyen et al. (10), who used a neuronavigator system enabling perioperative visualization and localization of the cortical gyri. It is recommended that craniotomy rather than only a burr hole be used for optimal positioning of the electrode, because it is then possible to further localize the central sulcus and motor cortex by both somatosensory-evoked potential recording and high-intensity, low-frequency stimulation, which produces peripheral muscle contraction. With this technique it has been possible to map the somatotopy of the motor cortex in detail, partly confirming the classic description by Penfield and Rasmussen (95) of the motor homunculus. It is also claimed that electrode placement via a craniotomy rather than a burr hole reduces the risk for epidural bleeding. Figure 101-6A is an example of the functional topography of the lower part of the motor gyrus and its spatial relationship to adjacent premotor gyri. The corresponding portion of the cerebral surface visualized with three-dimensional magnetic resonance imaging is depicted in Figure 101-6B.

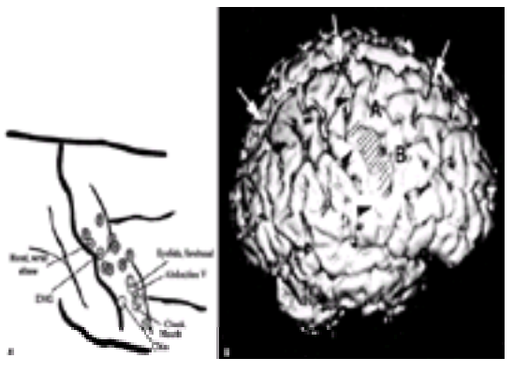

Figure 101-6. **A:** Somatotopic organization of the ventral part of the motor cortex according to Nguyen et al. (10). [Reprinted from Nguyen JP, Lefaucheur JP, Decq P, et al. Chronic motor cortex stimulation in the treatment of central and neuropathic pain. Correlations between clinical, electrophysiological and anatomical data. *Pain* 1999;82:245–250, with permission.] Circles denote sites where stimulation induced muscular activation in the hand (*dark gray*) and the face (*light gray*). (Abduction V, abduction ot the fifth finger; C, cheek; F, fingers; H, hand; M, mouth). **B:** A three-dimensional magnetic resonance image of the cortical surface where the approximate extent of the corresponding part of the motor gyrus, illustrated in the left figure, is striped. White arrows denote the interhemispheric fissure and the black arrowheads the central sulcus. *A* and *B* correspond to the superior and inferior frontal sulci, respectively. Note the location of these sulci in relation to the portion of the motor cortex representing muscular activation in the face and hand.

Many patients present with central pain that involves the entire side of the body but pain is perceived as most severe in the distal parts (face, hand, foot). Because MCS has to be applied strictly according to the somatotopic organization of the primary motor cortex it is not possible to cover the entire hemibody with one electrode strip. To enable suppression of pain in both foot and hand, a second electrode, connected to a separate pulse generator, must be used. To get access to the interhemispheric part of the motor cortex representing the lower extremity, the electrode must be positioned subdurally (83). However, the cortical representation of leg and foot is quite variable. In many patients it has been found to extend onto the medial part of the hemispheric convexity, implying that it may be possible to activate the leg-foot area by applying stimulation epidurally close to the midline [for a thorough discussion about motor cortex somatotopy, see Nguyen et al. (10) and Tsubokawa (81)].

There is no general agreement concerning the optimal orientation of the electrode strip. If oriented longitudinally onto the precentral gyrus (80), it is possible to activate a relatively large portion of the cortex. Others (10) apparently prefer placing the electrode perpendicularly to the central sulcus, with the stimulating pole onto the motor gyrus and one pole coupled as cathode and one pole as anode over the postcentral gyrus. This latter electrode orientation obviously makes the anterior-posterior placement less critical, although a much smaller section of the cortex can be activated and the location in the dorsoventral dimension must exactly fit to the somatotopy.

Complications and Side Effects

No serious complications associated with the implantation procedure or long-term application of MCS have been reported. As with all forms of implanted material there is a certain risk of local infection necessitating the removal of the system. Too few patients have presently been reported to permit an estimation of the infection incidence, but it is likely to be in the same order of magnitude as with spinal cord stimulation and ICS. Epidural hematoma, but without sequelae, has been reported to occur in a few patients. Several cases with stimulation-induced local pain at the site of the electrode have been described (10). This pain originates from the dura and it may be so troublesome that it necessitates a craniotomy and denervation of the dura by cutting and resuturing the part underlying the electrode.

In the trial stimulation phase (see later), when different stimulation parameters are explored, stimulation-induced seizures are relatively common. Of course, there is a fear that long-term stimulation could have a kindling-like effect, resulting in a state of epilepsy. No such case has been documented in the literature, but we have had

experience of one patient who, after 2 years of MCS treatment, developed an intractable epilepsy of the jacksonian type that persists after 4 years. However, it is not proven beyond doubt that the epilepsy was the result of MCS, *per se*, because it started shortly after an intervention for denervation of the dura because of unbearable local pain. The fits necessitated a reexploration that revealed a thin subdural clot measuring approximately 4 × 4 cm. At inspection no cortical lesion could be detected and the cortical surface had a normal appearance. The electrode was of course removed. Subsequent magnetic resonance imaging and positron emission tomography examinations have failed to reveal any local pathology that could account for the persisting daily motor fits. Because there is thus no definite proof that the stimulation was the principal cause for the development of epilepsy, we have not previously reported this case.

Stimulation Regimen

As with spinal cord stimulation and ICS, trial stimulation via percutaneous extension wires should always be performed during a period of at least 2 weeks. In most cases, trials with different stimulation parameters and electrode couplings are quite time consuming. It should be noted that the coupling of the stimulating poles can be very critical for obtaining relief of both spontaneous and evoked (allodynia, dysesthesia) pain in the entire painful region. This is especially the case if the electrode is positioned longitudinally over the precentral gyrus. The coupling appears to be particularly important in cases of facial pain, conceivably due to the extensive facial cortical representation and its strict somatotopic organization. This is illustrated in Figure 101-7, which shows a drawing made by a patient who suffered from severe and widespread trigeminal neuropathy.

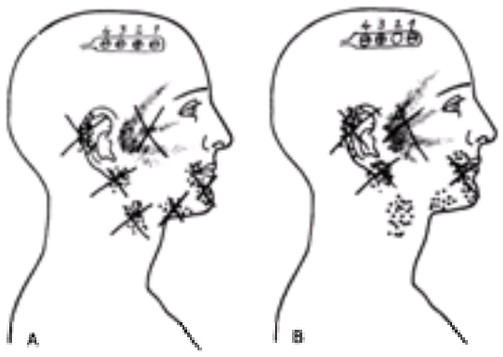

Figure 101-7. Drawings, made by a patient, showing the different areas of the face and neck where motor cortex stimulation, with different couplings of the stimulating poles of the electrode (shown in top of the figures), abolished spontaneous as well as evoked [allodynia (*dotted area*)] pain (*marked with crosses*). Note that stimulation with the electrode couplings indicated in **B**, as compared to those shown in **A**, failed to suppress ongoing pain and allodynia in two areas in the cheek region.

There is in the literature discordant information concerning the presence of stimulation-induced subjective sensations. Thus, Tsubokawa et al. (80) maintain that most patients experience faint tingling sensations. Conversely, most other studies report that stimulation is generally not accompanied by any sensations (9,10).

A pain-relieving effect is generally reported after 5 to 10 minutes of stimulation, and a further pain suppression is achieved during the subsequent 10 to 15 minutes. Complete abolition of the pain is exceptional. There is generally a poststimulation effect that may last for several hours. Most patients to date are treated with fully implantable pulse generators (ITREL 2 or 3; Medtronic) that are programmed for continuous stimulation or in a cycle mode with short intervals, 3 minutes on and 3 minutes off (10), or longer periods of stimulation, 30 minutes on and 3 hours off (96). In most studies, the stimulus intensity is generally set at a value corresponding to approximately 80% of that required to induce peripheral muscle contraction, assessed by stimulation applied at low frequency, and this implies that the voltage may be highly variable (2 to 7 V). It appears that the other parameters are not critical and stimulation both with high and relatively low frequency (40 to 130 Hz) and different pulse durations (60 to 350 µsec) have been reported to be effective.

Concluding Remarks

MCS must be regarded as a treatment modality under development; it cannot yet be recommended for a routine use. There is evidence that it has an approximately 50% chance of providing partial pain alleviation (more than 50%) of central supraspinal (poststroke) pain. Its efficacy seems to be somewhat better in painful trigeminal neuropathy (presumably including also anesthesia dolorosa), with an approximately 70% to 80% success rate. The positioning of the electrode is critical and should be performed with the aid of computed tomography or magnetic resonance visualization of the precentral gyrus and intraoperative electrophysiologic control. Optimal stimulation parameters remain to be assessed. Although no serious side effects have been reported, the possible risk of producing permanent focal epilepsy cannot be neglected. Because stimulation of the motor cortex as a rule is not accompanied by subjective sensations, it is for the first time possible to assess the effect of neurostimulation for pain using a double-blind procedure. In view of the promising results obtained in the treatment of pain conditions for which there is otherwise little to offer, a systematic exploration of the possible efficacy of the MCS for other likewise difficult pain conditions, such as pain of spinal origin and cervical root avulsion, is warranted.

CONCLUSIONS

Direct electric stimulation of the brain (ICS and MCS), although not generally providing complete pain relief, still offers therapeutic possibilities in painful conditions for which standard treatment modalities have been exhausted. These procedures deserve to be parts of the armamentarium of major pain treatment centers. MCS seems to be promising, particularly in view of the possibility of offering an efficient treatment for patients suffering from central or trigeminal neuropathic pain.

CHAPTER 102

Regional Anesthesia with Local Anesthetics

F. Peter Buckley

This chapter discusses techniques that use local anesthetics (LAs) to interrupt neural conduction, most importantly afferent, but in some circumstances efferent, in the treatment of pain of a variety of sources. *Regional anesthesia* (RA) is chosen as a convenient descriptive phrase for these techniques, rather than more precise but cumbersome phrases such as *regional neural blockade*. It must also be acknowledged that these techniques may also be classified as anesthetic techniques, as they are not selective for neural transmission of nociceptive traffic. They interrupt both afferent and efferent neural conduction.

The techniques described in this chapter are illustrated in figures with technical descriptions detailed in the legends. This chapter is not intended as a definitive technical manual for those practicing RA and anesthesia. Rather the objective is to present the physician who is treating patients in pain but is not familiar with RA with some sense of what the techniques entail and their indications, contraindications, benefits, and risks. This approach is consistent with Dr. Bonica's long-held, oft-repeated belief that physicians treating patients with pain should have a broad-based knowledge of all therapeutic procedures used to treat pain, the better to treat and serve the suffering patient (1,2,3,4,5,6 and 7).

BASIC CONSIDERATIONS

Rationale for Use

RA is effective in managing patients with pain because it interrupts nociceptive input at its source or transmission of nociceptive information in afferent nerves. RA may also interrupt the afferent limb of abnormal reflex mechanisms, which contribute to the pathogenesis of some pain syndromes. RA can also interrupt the conduction of efferent sympathetic neural traffic that contributes to postoperative or posttraumatic pain and some chronic pain syndromes that possess a sympathetic component [e.g., complex regional pain syndromes (CRPS)]. Interruption of efferent sympathetic traffic also increases peripheral blood flow in circumstances of decreased flow, such as limb ischemia.

LAs are somewhat selective in interrupting neural traffic. Neural traffic in small nerve fibers and unmyelinated nerve fibers, such as A-d and C fibers, respectively, may be interrupted with low concentrations of LA, with only modest effects on larger myelinated fibers, which are predominantly efferent. Thus a nerve block may produce an analgesic, but not particularly paretic, body part. However, the use of higher concentrations of LA will result in interruption of all afferent and efferent neural traffic producing an analgesic and paretic body part, a situation that may be of therapeutic benefit in some circumstances (e.g., when neurally mediated muscle spasm is part of a pain syndrome).

The duration of the analgesic affect of an RA technique varies depending on the drug used (e.g., of brief duration with procaine, of much longer duration with bupivacaine). The duration of effect of the drug is determined by the drug's physicochemical characteristics and by the presence of vasoconstrictors that impede absorption of the drug into the vascular system and away from the site of action. In some pain states the duration of analgesia may outlast, by hours or days, the transient pharmacologic effect of the LA. In these pain states, afferent input may be activating or maintaining central neural processes that produce “central pain.” Interruption of the afferent input may quiet these processes (8,9,10 and 11).

Indications

RA can be used as a diagnostic, prognostic, or therapeutic tool, or as a combination of these.

Diagnostic Blocks

Diagnostic blocks can help with the following:

- Determine the anatomic source of pain: Pain from trigger points, neuromata, or painful joints may be eliminated by local infiltration. Peripheral nerve blocks may distinguish between a peripheral and central source of nociception.
- Determine nociceptive pathways: Via selective blocks, the anatomic pathways of a nociceptive process can be explored.
- Differentiate local from referred pain: Pain in proximal structures can produce pain referred to distal structures (e.g., hip disease may present as knee pain); RA of the knee will help determine the nociceptive source.
- Differentiate somatic from visceral pain: For example, pain of the trunk may be of somatic or visceral origin. Blockade of the intercostal nerves will interrupt the trunk wall somatic afferents without affecting the visceral afferents.
- Determine the sympathetic nervous system contribution to some pains: The sympathetic nervous system may contribute to, or be responsible for, a variety of pain syndromes (see Chapter 3, Chapter 4, Chapter 20) (12,13). Careful, precise sympathetic blockade may help to refine the diagnosis, be therapeutic, or both.
- Determine whether a painful deformity (e.g., in a limb) is caused by neurally mediated muscle spasm or by fixed deformities: Deafferentation and deefferentation (producing a paretic limb) will permit these distinctions to be drawn.
- Differentiate peripheral from central pain: Some pain syndromes may result from either a peripheral process or a central (spinal cord or brain process). Blockade of peripheral nerves may aid in the distinction of these two processes.
- Determine the role of nociceptive processes in complex pain syndromes: The pathophysiology of complex pain syndromes, particularly those of long duration,

may involve processes other than nociception alone. Regional block may aid in determining the role and extent of nociception in these syndromes.

Prognostic Blocks

These may be done to afford the patient and the physician the opportunity to observe the pain relief, sensory deficits, and other possible effects of a nerve block, as a prelude to a procedure that could produce a longer benefit than that afforded by an LA nerve block. Examples are a celiac plexus block in a patient with upper abdominal pain from a pancreatic tumor before a neurodestructive block or peripheral nerve blocks before consideration for dorsal rhizotomies or ganglionectomies. In these latter circumstances, it is unwise to proceed to a neurodestructive procedure on the basis of the result of a single block as there may be powerful placebo effects in operation. Several prognostic blocks, with LAs of differing duration of action, perhaps performed with the patient blind to the possible duration of effect, or the use of a continuous LA technique, may aid in the accuracy of prognostic blocks.

Prophylactic Blocks

Various nerve blocks may be used to ablate or diminish pain from trauma or surgery and these may exert an influence that transcends the duration of the blocks. There is evidence that epidural blocks maintained through the perioperative period may influence the incidence of postamputation phantom limb pain (14). In some postoperative pain studies, there is evidence that the single application of an LA block, before the patient experiences trauma or undergoes surgery, results not only in a diminution in pain during the period of efficacy of the block but also in an improvement in pain relief for prolonged periods beyond the efficacy of the block. This has been termed *preemptive analgesia*. Metaanalysis of the results of multiple studies of preemptive analgesia in postoperative pain are not strongly supportive of its clinical significance (15).

Therapeutic Blocks

Nerve blocks appropriate to the site of injury can diminish or ablate much of the pain following some operations or trauma. Single-shot nerve blocks such as brachial plexus blocks provide such relief for the duration of the LA's action. The duration of pain relief may be extended by days or weeks by using techniques that apply LA continuously to neural structures. The continuous techniques may be achieved by placing catheters alongside peripheral nerves (brachial plexus) or the epidural space or other spaces (e.g., interpleural space) and continuously infusing LA. The efficacy of continuous epidural LA techniques is greatly enhanced by the inclusion of low doses of opioid in the infused mixture (see Chapter 84).

In some chronic pain syndromes, nerve blocks may be efficacious in disorders involving the sympathetic nervous system (e.g., limb ischemia). In some circumstances (e.g., CRPS), regional blocks may be directly clinically efficacious and also provide analgesia to permit the application of mobilization techniques, which are an important component of therapy.

Principles of Application

RA has a useful and definitive role to play in the management of pain. However, for their optimal use, these techniques must be applied in the appropriate circumstances, in the appropriate manner, by an appropriately skilled practitioner, as propounded by Dr. Bonica (16,17,18 and 19).

The Physician

There are several requirements of the physician:

- While technical knowledge and expertise are crucial, it is also important that the physician have a thorough understanding of pain syndromes, their evaluation, possible treatments, and the side effects and complications of the possible treatments.
- Detailed knowledge of the anatomic basis of the procedure.
- Detailed knowledge of the side effects and complications of the procedure and the preparedness and skill to deal with them should they arise.
- Technical excellence and gentleness in performing the procedure. Patients with pain problems are poor subjects on whom to learn nerve blocks.
- A clear understanding of what to expect from the procedure.

Patient Assessment

The physician must be willing to fully evaluate the patient and the pain problem in order to be able to decide if a procedure is warranted, and if so, which procedure (see Chapter 12, Chapter 16). Before evaluating the patient, it is often appropriate to have patients keep pain diaries, which are patient-kept records of pain levels, activity levels, sleep, and other relevant symptoms. In the office, elements of the evaluation include the following:

- History from the patient and records with particular emphasis on the pain, its type, distribution, exacerbating and relieving factors, including drugs. Records may include pain diaries.
- Physical examination, with the emphasis on neurologic examination, particularly of the affected area.
- Review of available investigations and obtaining other investigations if necessary.
- Scrutinizing pain measurement tools such as a visual analog scale and pain evaluation questionnaires such as the McGill and the Minnesota Multiphasic Personality Inventory.
- Psychological or psychiatric evaluation.

The information derived from the evaluation enables the physician to decide whether any regional analgesic technique may be helpful in the evaluation, management, or both, of the patient's pain problem.

Communication with the Patient

When a regional analgesic technique is being contemplated, it is imperative that the physician tell the patient what is being advised, for what purpose (diagnostic, therapeutic, prognostic etc.), what to expect from the block (short-term and long-term), and how many blocks are advised. The physician should also discuss the risks and side effects of the procedure, what will be done to minimize the risks, and what will be done to maximize patient comfort. The patient should sign an informed consent form, which details the procedure and its risks.

Performing the Blocks

The procedures should be performed with the knowledge of the anatomy of the relevant region in mind and with an accent on avoiding complications. The use of needle placement aids, such as peripheral nerve stimulators, fluoroscopy with or without contrast medium, or ultrasound, is advised. For prognostic and diagnostic blocks, it is advisable to accurately place very small amounts (2 to 3 mL) of LA on the target nerve to produce the desired block without overspill of LA onto other structures. Repeating the block on two to three occasions with LA of varying durations of action or using a continuous technique may also provide useful information and patient experience. For therapeutic blocks, accurate placement is essential but there is more latitude about the choice of volume of LA. LAs of longer duration of action are most appropriate.

Efforts should be made to minimize patient discomfort during the procedure. This may be accomplished by the systemic use of modest doses of short-acting opioids (fentanyl, alfentanil, remifentanil) and sedatives (thiopentone, midazolam, propofol), although these have the potential to cause sedation and analgesia that may complicate the accurate assessment of analgesic efficacy with diagnostic or prognostic blocks. Good procedural technique and the use of small needles and liberal use of locally injected LA will contribute to patient comfort.

Assessment of Results of a Block

At intervals subsequent to the block, its physiologic effects and its pain-relieving effects should be ascertained. For obvious reasons, the block should be shown to be technically satisfactory. For somatic nerve blocks, sensory deficits to stimuli (light touch, scratch, pinprick, pinch) and motor deficits (weakness, reflex impairment)

should be sought and should be consistent with the anticipated effect of the block. For sympathetic blocks of the limbs, tests include increases in skin temperature, impairment of sweating, and skin conductance. For diagnostic or prognostic sympathetic blocks, it is important to test somatic sensory modalities, as LA may spill over onto somatic nerves and hence influence outcome and interpretation.

Provided that a block is technically satisfactory, its effect on pain and other pathophysiology should be observed and recorded. This observation and recording initially should be done in the clinic and then should be continued after the patient is discharged. The patient or relatives should record pain levels on a pain scoring sheet that categorizes pain levels and type of pain and block effects (numbness, weakness) for the next few hours and days. Duration of physiologic effect of the block and its correlation with duration of pain relief are important. With technically satisfactory blocks of the correct target, one expects duration of pain relief to be consistent with the duration of action of the LA used. A duration of pain relief shorter than that expected implies technical imperfection, that the wrong peripheral target was chosen, or that the neural source of pain is proximal to the site of the block. A duration of pain relief longer than expected implies a potential placebo effect or that the block interrupts self-sustaining neurophysiologic processes that can cause pain. Because of the uncertainties of interpretation of effects of the diagnostic or prognostic blocks, *it is advisable to perform the blocks with LAs of differing durations on several*(*usually about three*)*occasions before reaching conclusions about the effect of the blocks on the neural targets and the pain complaint*.

Limitations of Neural Blockade

Nerve blocks produced either by a single dose of LA or maintained by an infusion of LA through a percutaneous catheter are effective in relieving postoperative or posttraumatic pain. Because the damaged tissue may encompass many dermatomes, it is often necessary to also provide supplementary analgesia with opioid or nonopioid analgesics.

When used as diagnostic and prognostic entities, the limitations of nerve blocks should be borne in mind. In certain patients, provided technical and observational excellence is used, they are a useful addition to the available diagnostic and prognostic tools.

In patients with complex, chronic, and disabling pain problems, nerve blocks have a limited role. Blocks can be helpful as a way of jump-starting a pain management/reduction program but should be used in the context of a more comprehensive treatment program (see Chapter 11). Neurophysiologic and nociceptive abnormalities are only part of the etiology of these patients' pain and pain complaints, which also often have environmental, psychological, cultural, and disuse components. These latter components must be addressed if therapy is to be successful. Even in pain problems where the predominant initial etiology is probably neurophysiologic (e.g., CRPS), by the time a few weeks or months have passed other pathologies may be part of the pain syndrome (e.g., muscle contractures and weakness). These pathologies require specific therapy, which cannot be supplied by nerve blocks alone.

Pharmacology of Local Anesthetics

Safe and effective use of regional anesthetic blocks with LA requires a thorough knowledge of the pharmacology and properties of LA drugs. Table 102-1 lists important characteristics of commonly used LAs.

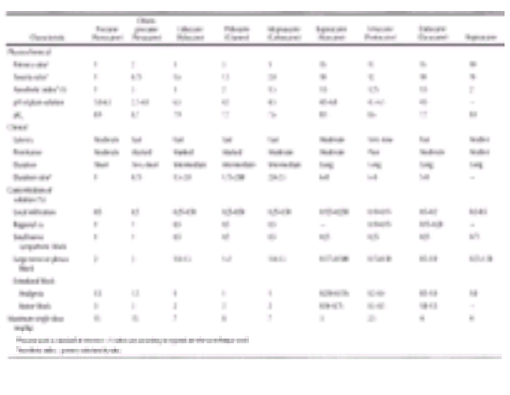

TABLE 102-1. Pharmacologic and clinical characteristics of local anesthetics

LAs produce temporary impairment of conduction of neural impulses by reversibly blocking nerve sodium conductance channels and maintaining the nerve in a polarized state. To achieve this effect, sufficient drug must be applied to the nerve membrane to produce a drug concentration that produces block; when the nerve concentration of drug falls, nerve function resumes. For *in vitro* studies of single nerve fibers in a nerve bath, sufficient drug to produce a block equates to drug concentration. When the drug is removed from the bath, the drug level in the nerve falls and nerve conduction resumes.

In the *in vivo* use of LAs, ingress to, and egress of, LA from the nerve, and the resulting onset and fading of neural block, are more complex. A number of pharmacologic and physiologic factors are at play (see Table 102-1) (20):

- Nerve size: To produce a block of a given nerve, the drug must penetrate the epineurium and perineurium to achieve a blocking concentration in the nerve and its fibers. Small nerve fibers (C, A-d, preganglionic sympathetic B) are blocked with low concentrations of drug; larger fibers (A-b and A-a) require higher concentrations. Small nerves (e.g., digital nerves: 1 to 2 mm in diameter) may be blocked with small volumes of low concentrations of LA (e.g., 1 to 2 mL of 0.5% lidocaine). Large nerves (e.g., sciatic nerves: 10 to 15 mm in diameter) require larger volumes of more concentrated LA (e.g., 12 to 20 mL of 1.0% to 1.5% lidocaine).
- Potency: Potency is an *in vitro* derived measure, confirmed by clinical studies, of the concentration of drug necessary to produce a block. Note that as potency increases there is a tendency for toxicity to increase, also expressed as anesthetic index of potency/toxicity.
- Drug pH and pK_a: To maintain product stability, most manufacturers of LAs formulate drugs at a low pH (4.5 to 6.0). However, the pK_a of most commercial LAs is between 7.0 and 8.0, and at that pH, the majority of drug is present as the ionized water-soluble form, as opposed to the unionized fat-soluble form.
- Penetrance: Drug penetrance (the perceived ability of the drug to cross barriers—a desirable property) is a function of the unionized form. Commercial drug must be alkalinized in the body for maximal effect (commercial drug may be alkalinized by the judicious addition of bicarbonate— *vide infra*). Penetrance roughly parallels the fat solubility of the drug.
- Latency: Latency is the relative speed with which the drug penetrates biological membranes *en route* to its target. Penetrance roughly parallels fat solubility and is influenced by pH.
- Duration: Duration is the time during which the drug produces its effect on the nerve. Duration roughly correlates with fat solubility and is also influenced by the mass of drug placed on the nerve (a bigger mass of drug takes longer to be removed from the site of action by the circulation).
- Blood flow at the site of injection: When LA is injected, it immediately begins to be absorbed by the circulation, distributed systemically, metabolized, and excreted. The quicker the LA is absorbed, the less stays at the site of injection to block nerve conduction. A block will, therefore, be of shorter duration. Different sites of drug deposition have differing blood flows: LA injected into areas with high blood flow such as the epidural space, will be absorbed more quickly and have shorter durations of effect than LA injected into areas with lesser blood flows such as the sciatic nerve.
- Inclusion of a vasoconstrictor in the injected solution: Most LAs produce vasodilation, enhancing circulatory absorption. Blood flow to a site of LA injection may be temporarily reduced, for about an hour, by the inclusion of a vasoconstrictor (commonly epinephrine 1:200,000, 5 µg per mL; lesser concentrations in children and the elderly) in the LA solution. The inclusion of epinephrine will tend to speed onset of LA block, reduce peak systemic blood levels of LA, and prolong the duration of effect of short- and medium-duration LAs (e.g., lidocaine, mepivacaine). Epinephrine has only a minimal effect on duration of block with longer-acting LAs (e.g., bupivacaine, ropivacaine) but does reduce peak systemic blood levels of drug.
- Alkalinizing LA: Most commercial LAs have a pH much below the pK_a of the drug and the majority of the drug exists in the ionized moiety. Raising the solution pH increases the concentration of the unionized moiety, which is believed to penetrate nerves more completely, leading to a faster onset and longer duration of effect. Raising the pH of lidocaine by carbonation has produced mixed results (21,22), but alkalinization of bupivacaine with bicarbonate may produce a faster onset and longer duration of effect (23,24).
- Attempted prolongation of LA effect: A number of agents have been mixed with LAs in the hope of prolonging duration of effect. Low-molecular-weight dextran has produced conflicting results (25,26,27,28,29 and 30), but high-molecular-weight dextran may produce a prolongation of effect (31,32) by alkalinization of the

solution. Substances that act as depot release agents for LA are under development and investigation. When bupivacaine is associated with liposomes, duration of epidural analgesia may be prolonged twofold, with less motor block when compared to plain bupivacaine (33). Similar effects may be produced in peripheral nerve blocks by the association of bupivacaine with biodegradable polymer microspheres (34).

Preliminary Considerations

Before any regional anesthetic procedure, other than minor procedures in which a minimal amount of LA is used, steps should be taken to ensure that the procedure can be carried out safely and effectively and that logistic issues concerned with safe discharge of the patient home are assured.

Nil per Os, Evaluation, and Consent

The patient should have an empty stomach to minimize the risks of nausea, vomiting, or regurgitation of stomach contents, and their potential pulmonary aspiration, either during the procedure or if complications occur. In practice this means no solid food for at least 8 hours and no clear liquids for at least 4 hours before the procedure.

Arrangements should be in place for the patient to be transported home by a responsible caregiver and for the patient to have access to a caregiver for 12 to 24 hours after the procedure.

The site and side of pain should be confirmed, the painful area should be reexamined, and the current presence of pain should be ascertained. It is pointless to perform diagnostic or prognostic blocks in the absence of pain.

The reason for the procedure, the steps of the procedure, and what the patient should expect to experience should be discussed. The expected outcome of the procedure, the duration of effect, and the incidence of common complications should be discussed. Based on these discussions, a written informed consent, witnessed by another adult, should be obtained.

Procedure Room and Equipment

The procedure should be performed in a room of sufficient size to accommodate the patient, stretcher, monitoring equipment, fluoroscope, and any other necessary equipment.

Regional anesthetic blocks have predictable effects on, and an incidence of complications affecting, the cardiovascular, respiratory, and central nervous systems. Hence, monitors capable of detecting these effects and complications, and equipment to deal with them, should be readily available. A means of ventilating a patient with 100% oxygen with a bag and mask, or via an endotracheal tube, and suction should be available. Airway management equipment and appropriate drugs to deal with procedure complications and resuscitation should be readily at hand (Fig. 102-1). There should be easy access to a “code cart” with drugs and equipment (e.g., defibrillator) required to manage a cardiac arrest.

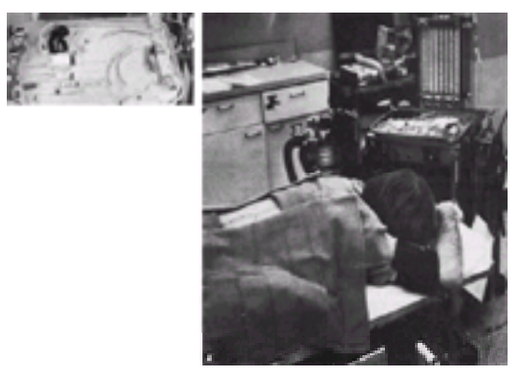

Figure 102-1. **A:** Position of patient for bilateral celiac plexus block. An anesthesia machine, resuscitation equipment, and drugs are next to the patient, ready for immediate use. **B:** Close-up of the tray on top of the machine. The tray contains ampules and syringes for administering epinephrine, ephedrine, diazepam (Valium), thiopental (Pentothal), and succinylcholine; behind these are different sizes of oropharyngeal and nasopharyngeal airways (left). The tray also contains a Macintosh laryngoscope, two endotracheal tubes, a Magill forceps for guiding tubes into the trachea, and a syringe for inflating the cuff of the endotracheal tube (right). The anesthesia machine is not necessary as long as equipment is available for immediate administration of oxygen and for carrying out assisted or artificial ventilation. Note: The patient has an intravenous catheter in a vein of the right hand and a continuous infusion of fluid for the prompt injection of resuscitative drugs if reaction occurs.

The person performing the procedure should be assisted by a staff member who is familiar with the procedures, the equipment and its use, and emergency management. This individual should also assist in patient positioning, comfort, and any emergencies that arise.

Patient Safety, Comfort, and Monitoring

Other than for minor procedures using minimal LA, all patients should have an intravenous line placed and kept patent by a slow fluid infusion (see Fig. 102-1). This assures access for the rapid administration of fluids and drugs (sedative, analgesic, resuscitation) should these be necessary.

Before any premedicant drugs are administered, the patient's vital signs should be obtained. The patient's vital signs should be monitored either continuously (electrocardiography and pulse oximetry) or at frequent intervals [blood pressure (BP) every 3 to 5 minutes], throughout the procedure.

Many patients are apprehensive, anxious, scared, or even frankly terrified of procedures such as nerve blocks. Hence, premedication with modest doses of short-acting opioid analgesics or sedatives should be routinely considered. Typical drug and doses are analgesic (fentanyl, 0.5 to 1.0 µg per kg i.v.) and sedative (midazolam, 10 to 20 µg per kg i.v.; thiopental, 1.0 to 1.5 mg per kg i.v.; propofol, 0.25 to 0.50 mg per kg). Lesser doses are appropriate in the older, smaller, and sicker patients. Premedication may be relatively contraindicated in circumstances where the drugs' central effects might impair the patient's subjective interpretation of the effects of the procedure (e.g., diagnostic or prognostic blocks). However, the short duration of effect of these drugs makes this of lesser concern than with longer-acting drugs. All sedative and analgesic drugs cause respiratory depression to some degree; patients receiving these drugs should be given supplemental oxygen.

Block Equipment and Drugs

Preservative-free LA drugs should be used for regional blocks, as this formulation has a higher pH and because the presence of a preservative may increase the risk for neural damage. Any epinephrine used should be added to the drug at the time of the block—commercial LA solutions with epinephrine have very low pH and contain preservative. The commonly used concentration of epinephrine used in regional blocks is 1:200,000 (5 µg per mL), although the concentration should be reduced to 1:400,000 (2.5 µg per mL) in the elderly and the young and when large volumes of dilute solution are used.

Needles should be of appropriate diameter and length—2.5 cm, 25 to 30 gauge for skin infiltration, 22 gauge for peripheral nerve blocks, 25 to 27 gauge for lumbar puncture for subarachnoid blocks (SABs), and various specialized epidural needles for epidural blocks. Short-bevel needles are advised for peripheral nerve blocks as these are believed to put the nerve at a lower risk of damage (35).

Accurate Location of Nerve Block Targets

RA requires that the LA is placed directly and correctly onto the intended neural target by placing the injecting needle close to or on the neural target. The classical approach to identifying correct needle placement is to gently probe the nerve with the tip of the needle. This maneuver produces a paresthesia in the area of the somatic distribution of the nerve. Once a paresthesia is produced, the needle is held steady and LA is injected. This technique has limitations. Probing some nerves (e.g., autonomic nerves) will not produce a paresthesia. There is evidence that producing paresthesia may increase the incidence of post–nerve block symptoms of neural damage (36). To avoid producing paresthesia and to help ensure accurate needle and drug placement, a number of different aides may be used. The use of aides to confirm correct needle placement and drug deposition is no substitute for detailed understanding of the anatomic and technical aspects of the block.

When blocking a mixed motor/sensory nerve, locating the nerve can be made easier by using an insulated needle connected to a peripheral nerve stimulator. By passing a current down the needle, the motor fibers in the nerve are stimulated, producing a twitch in the muscles supplied by that mixed nerve. This stimulation is usually not painful, as motor fibers are fired at lower current intensity than sensory fibers. Some patients may be alarmed at the uncontrolled twitching, and it is sensible policy to describe this in the preprocedure discussion. Characteristically, a stimulus frequency of 1 to 2 Hz (one to two stimuli per second), at a current strength of 1 mA, is used to advance the needle close to the nerve. Once a satisfactory muscle twitch is produced, the current intensity is reduced to 0.4 to 0.5 mA and the needle manipulated closer to the nerve, as evidenced by a maximal muscle twitch at the lower current intensity. A well-defined muscle twitch at this low current intensity implies that the needle is within a few millimeters of the nerve and LA is injected.

Radiography, fluoroscopy, and ultrasound are useful aids when accurate placement of the block is important (e.g., in diagnostic or prognostic blocks). These aids are particularly helpful when blocking pure sensory nerves, where the only other aid for accuracy is to probe the nerve with the needle and produce a paresthesia, or sympathetic nerve blocks where neither motor stimulation nor paresthesia is available as an aid. Preliminary injection of contrast media with radiographic visualization before the injection of LA can help confirm accuracy of needle placement and the potential spread of the LA. In addition, a permanent radiograph is an objective record of some of the details of the performance of the block.

Contraindications

Absolute contraindications to nerve blocks are as follows:

- A patient who is unwilling to accept the block or who does not sign an informed consent form.
- A patient who has a true allergy to the drugs used. True allergy to the ester LAs (procaine, tetracaine, chloroprocaine) is not uncommon, particularly as they share common allergenic features with sulfonamide antibiotics. However, these drugs are relatively rarely used. True allergy to the amide LAs (lidocaine, bupivacaine, ropivacaine) occurs but is exceedingly rare. Nonetheless, many patients report being told that they have an allergy to LAs, as manifest by side effects associated with the use of LAs, most frequently in dentistry. These effects are often not true allergy; rather they are often tachycardia or arrhythmias associated with the rapid absorption of epinephrine (1:100,000 epinephrine, 10 µg per mL, is commonly used in dentistry) or a vasovagal or psychogenic effect associated with an injection.
- Infection at the site of injection.
- Questionable blood clotting status.

Relative contraindications to nerve blocks are as follows:

- A clinical situation where a block may conceal the development of an untoward complication (e.g., a dense prolonged peripheral nerve block in a limb with a recent fracture which is at risk of a compartment syndrome).
- Debilitated, ill, and hypovolemic patients in whom the effects to the block, either of the injected agent or from a sympathectomy from the block, may produce an unacceptable degree of cardiovascular compromise.

Side Effects and Complications

RA is not a risk- and complication-free enterprise. To detect complications, patients should receive vigilant and continuous physiologic monitoring (electrocardiography, BP, pulse oximetry, staying in verbal contact with the patient to detect changes on sensorium, level of consciousness, and any unusual psychic phenomena) during and subsequent to the block. In addition, delayed complications (e.g., pneumothorax) should be sought. It is essential that the patient has an intravenous line *in situ* and that the drugs and equipment that might be needed to deal with complications are kept close at hand.

The complications that can arise can be categorized as follows:

- Systemic effects of the LA and its injection
- Physiologic effects of the procedure
- Inadvertent damage to nonneural structures
- Inadvertent damage to neural structures
- Systemic effects of the LA and its injection
- Psychogenic reactions

These commonly occur when little or no LA has been injected and may range from common scenarios such as a vasovagal episode to a panic episode. Treatment is symptomatic.

Epinephrine Effect

Rapid absorption of epinephrine in the LA solution, or the inadvertent intravascular injection of a small amount of the solution, can produce predictable epinephrine effects: tachycardia, hypertension, palpitations, pallor, shakiness. These must be distinguished from a potential toxic effect of the LA (*vide infra*). If the effects are minor, reassurance of the patient may suffice. If the effects are severe, or if they produce adverse cardiovascular system (CVS) effects in patients with CVS disease, hypertension should be treated with vasodilators (labetalol, 5 to 10 mg) and tachycardia with beta blockade (esmolol, 5 mg; metoprolol 2.5 to 5.0 mg).

Allergic Reactions

Allergy to the ester LAs (procaine, tetracaine, chloroprocaine) is known and probably occurs with cross sensitivity with sulfonamides. Allergy to amide LAs is rare. The physiologic consequences and treatment are as with any allergic reaction.

Effects of High, Toxic Blood Levels of Local Anesthetic

LAs have direct toxic effects on a number of body systems, most importantly the central nervous system (CNS) and the CVS. These CNS and CVS effects become increasingly pronounced as blood levels of LA rise. The effects and the clinical symptoms associated with rising blood levels of LA are depicted in Table 102-2.

Plasma concentration (µg/mL)	Effect
1–5	Analgesia
5–10	Lightheadedness
	Tinnitus
	Numbness of tongue
10–15	Seizures
	Unconsciousness
15–25	Coma
	Respiratory arrest
>25	Cardiovascular depression

TABLE 102-2. Systemic effects of lidocaine

High, or quickly rising, blood levels of LA can occur for a number of reasons: inadvertent intravascular injection of LA, unusually rapid absorption of LA, the use of an excessive amount of LA with normal absorption. The clinical circumstances influence how quickly blood levels of LA will rise; following an inadvertent intravascular injection, blood levels of LA will rise more rapidly than following injection of an excessive amount of drug. Irrespective of the circumstance, the end result is the same, rising or high blood levels of LA, which produce toxic effects.

To guard against the development of toxic CNS and CVS effects, the doses of LA should be kept within advised limits (see Table 102-1). To detect, and hence guard against, an inadvertent intravascular injection of LA, a number of practical maneuvers can be used. The needle should be aspirated frequently, after each 5 mL of injectate, to ensure no bloody return. A “test dose” of 3 to 4 mL of a mixture of LA plus 1:200,000 epinephrine (i.e., 15 µg epinephrine) may be injected as the first dose. If injected intravascularly, this mixture will, with a high degree of probability, cause a brief and transient (2 to 3 minutes) rise in the heart rate of 20 to 25 beats per minute and a rise in systolic BP of 20 to 30 points detected by continuous monitoring, due to the beta and alpha effects of the included epinephrine (37). This effect is significantly blunted if the patient is taking drugs that block the b-adrenergic effects of epinephrine. This technique was originally developed to detect inadvertent intravascular injections in epidural analgesia, but it may be used in other regional techniques.

A rising, or high, blood level of LA can be detected by monitoring the patient for the CNS symptoms described in Figure 102-2 and Table 102-2. This monitoring can only effectively occur in a patient who is fairly awake and lucid; hence, the use of sedation should be judicious. The classical sequence of events for LA toxicity with lidocaine, for example, is for severe CNS effects (convulsions) to occur at lower blood levels of LA (50% to 75%) than cause serious CVS effects. The hypoxia that may accompany a convulsion may exacerbate any direct CVS toxic effect. However, the sequence of CNS toxicity preceding CVS toxicity may not occur with bupivacaine, which can cause significant myocardial depression and cardiac arrhythmias at blood levels of LA that cause only modest CNS toxic effects (38).

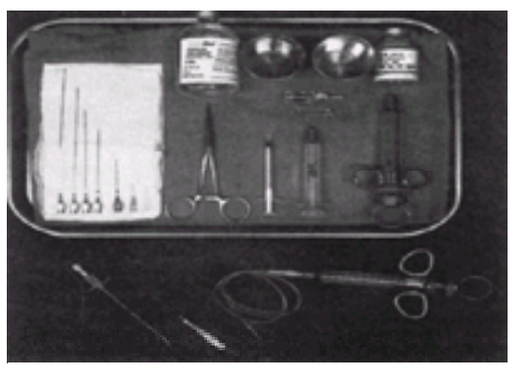

Figure 102-2. Equipment for regional analgesia and anesthesia. On the sponge are five 22-gauge security needles of different lengths, from left to right: 15 cm, 12 cm, 10 cm, 8 cm, and 5 cm. On the far right is a 25-gauge, 1.5-cm disposable needle. Hemostatic forceps for grasping sponges when applying antiseptic solution to the skin, a 1-mL tuberculin syringe for measuring epinephrine solution, a 2-mL Luer-Lok syringe for injection of small volumes of local anesthetics and for aspiration tests, and a 10-mL Luer-Lok control syringe used for most regional anesthetic blocks (because it facilitates aspiration and other maneuvers performed with one hand) are all shown to the right of the sponge. Above the syringes are a safety pin for skin testing and a 1-mL ampule containing 1 mg of epinephrine (1:1,000 concentration). A bottle of saline solution, a container for mixing the saline with local anesthetic solution to any desired concentration, a container for the antiseptic solution, and a bottle of local anesthetic are seen at the back of the tray. Below the tray, a Tuohy needle with a catheter threaded through it and a syringe for local anesthetic are shown. The injecting needle is attached to the syringe by a flexible extension tube, which prevents the transference of aberrant movements of the syringe to the needle, thereby reducing the chance of the needle moving away from the target. The tubing set is used for relatively superficial blocks in which the depth of the needle insertion is so shallow that it does not afford any stability (e.g., interscalene and axillary blocks) and for femoral sheath block.

If, during the course of injection of LA, the patient begins to manifest symptoms or signs of LA toxicity, steps must be taken to minimize the toxic effects of the LA immediately:

- Assistance should be immediately enlisted or summoned.
- The injection should be stopped.
- Oxygen (100%) via a bag and mask should be commenced immediately. This will ensure a store of oxygen in the patient's lungs should the toxicity proceed to convulsions. If the patient's oxygen saturation, judged from pulse oximetry, falls below 90%, positive pressure ventilation should be commenced. There is some evidence that hyperventilation, by producing hypocarbia, increases the threshold for convulsions.
- A small, anticonvulsant, dose of thiopental (50 to 100 mg) should be administered.
- Cardiovascular parameters should be closely monitored and adverse effects treated: hypotension with fluids and pressors (ephedrine, 5 to 10 mg), hypertension with vasodilators (labetalol, 5 to 10 mg), and tachycardia with beta blockers (esmolol, 5 mg; metoprolol, 2.5 to 5.0 mg).

These measures will often abort progressive LA toxicity. However, if the toxicity appears to be proceeding toward convulsions (agitation, limb jerking, loss of consciousness), further measures are necessary:

- Positive pressure ventilation with oxygen to ensure an oxygen saturation of greater than 90%.
- If ventilation is difficult, or if the patient convulses, muscle paralysis with 50 to 100 mg of succinylcholine should be used to ensure adequate ventilation.
- Cardiovascular monitoring and treatment of adverse CVS effects should continue.

Physiologic Effects of the Procedure

Expected Effects. Regional blocks with LA produce blocks of both somatic and sympathetic nerves and will produce the expected physiologic effects of neural paralysis. Somatic nerve blocks of nerves that maintain vital functions may produce physiologic impairments (e.g., phrenic nerve block causing respiratory impairment). Sympathetic nerve blocks, or intraspinal sympathectomies, such as may occur with epidural or SABs, can produce significant hypotension.

Unanticipated Effects. Many nerve blocks are performed in areas closely adjacent to other neural structures. Appropriately applied LA for a particular block may spill over to affect adjacent neural structures, producing unanticipated effects (e.g., interscalene brachial plexus blocks result in a high incidence of both cervical sympathectomy and phrenic nerve block). LAs may also be inadvertently deposited at unintended sites, producing unanticipated effects (e.g., inadvertent epidural or subarachnoid placement of LA, producing epidural or SABs, with thoracic paravertebral or intercostal blocks). Complications of this nature are described in the text for individual nerve blocks. Patients receiving regional blocks should be monitored closely for these adverse effects, which should be treated early and vigorously.

Damage to Adjacent Nonneural Structures

The needles used for regional blocks have the potential to pierce and damage structures adjacent to the site of the block. This complication can be minimized by careful technique and the use of aids such as fluoroscopy. Particular nerve blocks are associated with an incidence of such complications, even in expert hands (e.g., pneumothorax following intercostal nerve block or supraclavicular brachial plexus block). The complications associated with particular nerve blocks are discussed in the text.

The potential exists in all nerve blocks for the block needle to pierce a blood vessel and produce bleeding or a hematoma. In patients with normal clotting mechanisms, it is rare for such bleeding and hematomata to produce significant sequelae. Patients who have abnormal clotting mechanisms, either as a consequence

of disease or because they are receiving anticoagulant drugs, and receive nerve blocks are at significant risk of significant sequelae. The sequelae may be bleeding, to the extent that a patient becomes hypovolemic, or a hematoma that causes pressure effects on surrounding structures. This latter is of particular concern in epidural or SABs where hematomata of small size may lead to paraparesis and paraplegia (39). Hence, the presence of abnormal clotting mechanism is a strong relative contraindication to the use of RA.

In contemporary analgesic practice, continuous epidural analgesia with LAs and possibly opioids is commonly used for the control of postoperative pain following painful major operations (intraabdominal, intrathoracic, major orthopedic). The significant incidence of deep vein thrombosis (DVT) after such operations may be much reduced by the use of either low-dose heparin or its analogs [low-molecular- weight heparin (LMWH)]. The concurrent use of regional techniques in patients receiving such DVT prophylaxis is controversial. The concurrent use of epidural analgesia and heparin in complex management regimens (block placed before the institution of and terminated after the cessation of anticoagulation; postponement of the procedure if a bloody puncture occurs; monitoring the degree of anticoagulation) has been reported to have a low incidence of intraspinal hematomata (40). Nonetheless, intraspinal hematomata occur with a variety of regimens (41). LWMH appears to be a different matter, perhaps because there appears to be no reliable way to judge its degree of effect. There have been a number in the reports from the United States of epidural hematomata resulting in severe neurologic sequelae (42) and leading to the U.S. Food and Drug Administration's publishing warnings about the concurrent use of RA and LMWH. The concurrent use of LMWH and RA in Europe has not produced a similar incidence of complications, perhaps as a consequence of smaller doses of LMWH resulting in lesser degrees of clotting impairment (43). Ironically, the use of continuous epidural analgesic techniques using LA also produces a significant reduction in the incidence of postoperative DVT, possibly to the extent of the reduction produced by anticoagulant techniques (44). If an intraspinal hematoma producing neurologic sequelae is suspected, appropriate investigations (magnetic resonance imaging/computed tomography) and neurosurgical consultation should be rapidly obtained. If a hematoma causing neurologic sequelae has occurred, the faster it is decompressed, the greater the degree of eventual recovery.

Inadvertent Damage to Neural Structures

Placing needles close to nerves and injecting LA onto those nerves is associated with a definite but small incidence of neural complications ranging from minor paresthesia to severe nerve damage. The damage may be due to direct nerve trauma by needle or catheter, either accidental, or as a consequence of seeking paresthesia (36,45). It may be due to direct drug effects, inclusion of preservatives in the solution, or inclusion of epinephrine in the solution (46,47). It may be due to neuronal ischemia for a variety of causes. Precise data on the incidence of neural damage after nerve blocks alone are scarce. Much of the literature on nerve injuries is derived from the literature on anesthesia for operative surgery in which the majority of peripheral nerve injuries is not RA related (41). The quoted range of incidences of neural damage after epidural analgesia ranges from 1:11,000 (48) to 1:1,000 (49) with preexisting spinal column pathology being a risk factor.

LOCAL APPLICATIONS OF REGIONAL ANALGESIA

The infiltration of LAs into various body structures and their topical application onto mucous membranes are simple and frequently used techniques in the management of pain. For convenience, the use of these techniques is first considered for acute painful problems and then for chronic pain syndromes.

Local Infiltration

Acute Pain

Postoperative Pain. Local infiltration of a dilute solution of a long-acting LA (e.g., 0.125% to 0.250% bupivacaine) for orthopedic soft tissue procedures (50) and superficial operations such as excision of breast lumps (51) and inguinal hernia (52) produces effective postoperative pain relief for 8 to 12 hours, with a consequent significant decrease in the total amount of systemic analgesic required. Injection of LA through catheters with multiple openings, placed in the wound at operation, can provide even longer pain relief (53,54) (Fig. 102-3). Although such a procedure relieves abdominal or chest wall somatic pain, it usually needs to be supplemented by appropriate doses of nonsteroidal antiinflammatory drugs and opioids to relieve the visceral pain.

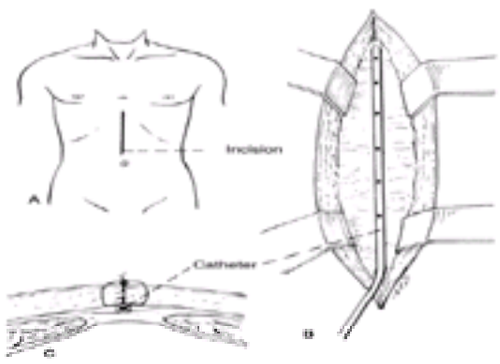

Figure 102-3. Postoperative analgesia after a midline incision **(A)** in the upper abdomen. **B:** Just before closing the wound, a catheter with multiple holes (*black*) is placed with its proximal end connected to the hub of a needle that fits into the catheter. The hub is kept sterile between injections of boluses of local anesthetic. **C:** Cross section of the abdominal wall showing the position of the catheter. Injection of a bolus of 10 to 15 mL of 0.25% bupivacaine with epinephrine results in diffusion of the drug to the surrounding structures, thus producing analgesia of the anterior abdominal wall adjacent to the incision.

Postoperative Joint Pain. Acute pain following intraarticular operations can be effectively relieved by the installation of 20 to 30 mL of LA, common bupivacaine, into the joint cavity before the joint closure. This technique is particularly effective for arthroscopic knee operations (55).

Acute Bursitis. Painful acute subacromial, subcapsular, prepatellar, and trochanteric bursitis can be promptly relieved with LA infiltration. The bursa should be infiltrated with 8 to 10 mL of dilute solution (e.g., 0.25%) of bupivacaine with epinephrine, with the addition of 40 mg of methylprednisolone (Depo-Medrol). Pain relief occurs in 10 to 15 minutes and can last 8 hours, and not infrequently 12 hours, after which pain returns and is often intense. The patient should therefore be given systemic nonopioid or opioid analgesics to manage the postblock pain. Several injections are frequently necessary. If the effusion of a joint is pronounced, frequent aspiration is indicated.

Tendinitis. The most frequent types of tendinitis include bicipital tendinitis, lateral epicondylitis (tennis elbow), medial epicondylitis (golfer's elbow), and supraspinatus (rotator cuff) tendinitis, often associated with subacromial bursitis (Chapter 58). Infiltration of these structures with 0.25% bupivacaine provides prompt relief of pain for 8 to 12 hours (Fig. 102-4). A long-acting steroid compound can be included in the solution for the first injection, but most orthopedic surgeons avoid repeated use because of the possible myotoxic effects and delayed sequelae (e.g., Cushing's syndrome) from the use of steroids. The inclusion of steroid in the LA for the first injection produces prolonged pain relief for 1 to 3 or 4 weeks. LA infiltration can be repeated several times until permanent relief is achieved.

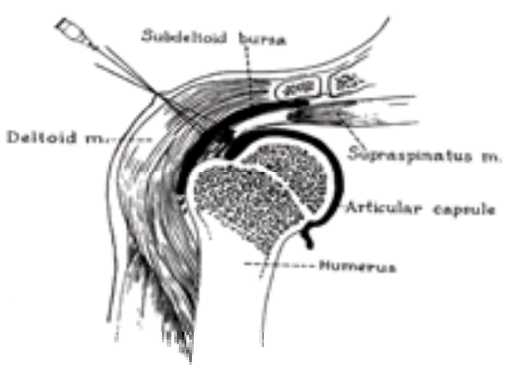

Figure 102-4. This frontal section of the shoulder region illustrates injection technique for treatment of supraspinatus tendinitis and subacromial bursitis. Note the calcium deposit in the supraspinatus tendon.

In some patients, the steroid causes a burning pain in the site of injection 24 to 48 hours after the procedure. As with other LA injections into bursa or tendon, patients may experience postblock pain, which should be managed with systemic analgesics.

Muscle Spasm. Muscle spasm with consequent severe pain can develop after injury in various locations, particularly in the low back. Muscle spasm can also be caused by poor posture or deformity of the spine (1). In all such cases, LA infiltration with a dilute solution (e.g., 0.125% bupivacaine) into the entire muscle causes prompt relief of the pain and muscle spasm that can last 8 to 12 hours. The injection should be followed by the application of heat, massage, and corrective exercises, as indicated.

Infiltration of an LA into a muscle can also be used as a diagnostic and therapeutic procedure in the rare cases of pyriformis or scalenus anticus syndrome.

Chronic Pain

Painful Scars. It is unusual for a whole scar to be painful but “trigger points” may be found in a scar. These can be associated with hyperesthesia and radiation of the pain along dermatomes from the scar. Infiltration of the scar with a dilute solution of bupivacaine (e.g., 0.25%) on about six occasions at 3- to 5-day intervals may produce persistent relief. If pain relief does not persist following a series of injections of LA, transcutaneous electrical nerve stimulation should be tried. If this fails, consideration should be given to injection of 1 mL of alcohol into the specific trigger points, which is said to produce a high incidence of success (56).

Neuromata. Neuromata can develop in nerves idiopathically, due to nerve entrapment, subsequent to traumatic nerve section or after surgery or amputation. Infiltration of the neuroma with an LA is a useful diagnostic procedure for determining whether the pain is arising from the neuroma. Moreover, injection of a solution containing an LA (without adrenalin) and a depot corticosteroid such as methylprednisolone (Depo-Medrol) into the neuroma can suppress the spontaneous ectopic discharges that are probably producing pain and paresthesia. Experimental studies have shown that the steroid stabilizes the nerve membrane for 2 weeks or longer (57). Therefore, patients with painful neuromata can be given a trial with this combination at 1- to 2-week intervals for the first month and at 2- to 3-month intervals thereafter. The management of patients with this type of pain is discussed in detail in Chapter 21.

Myofascial Syndromes with Trigger Points. One of the most effective clinical applications of infiltration of LA, with or without steroids, is in the management of myofascial pain syndromes with trigger points. Trigger points can develop in almost every muscle in the body, as well as in tendons and ligaments, producing local and referred pain, tenderness, reflex muscle spasm, and other signs and symptoms. In some patients, such trigger points can be in the vicinity of classic acupuncture points (58). Repeated injections of trigger points with an LA alone or combined with steroid or with saline solution usually produce permanent relief of pain and eliminate the other signs and symptoms (59) (see Chapter 29).

Arthritis. An intraarticular injection of a dilute solution of LA alone or in combination with steroids is also indicated as a diagnostic and therapeutic procedure in patients with pain of chronic arthritis involving major joints in the limbs or spine (Fig. 102-5 and Fig. 102-6). It has been suggested that injection of corticosteroids into tender spots along the nerves supplying an osteoarthritic joint produces much better relief of pain than intrasynovial injection of steroids (60,61). The inclusion of 0.125% bupivacaine with the steroid eliminates the postinjection burning pain.

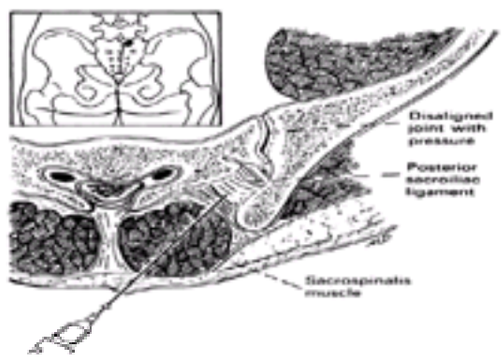

Figure 102-5. Injecting the ligaments of the right sacroiliac joint, which is shown subluxated. Inset: The skin wheal (*black dot*) used to anesthetize the skin for insertion of a larger needle is made in the midline at the level of the posterior superior spines of the ilium. The needle is inserted toward the affected side to make an angle of 45 degrees with the midsagittal section. Once the point is in the ligament, the LA is injected. Then an attempt is made to advance the needle into the subluxated joint, where 3 to 5 mL of solution is injected.

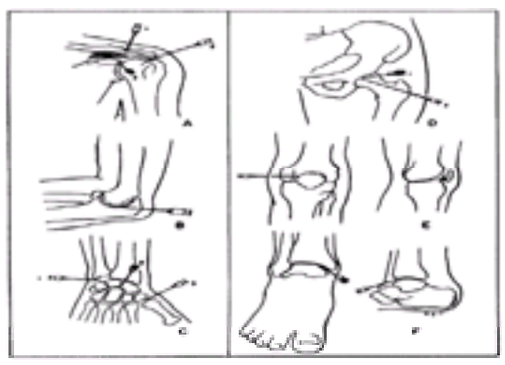

Figure 102-6. Intraarticular injection of various joints. **A:** Techniques for injecting part of the shoulder using a 22- or 25-gauge, 5-cm needle: the acromioclavicular joint (1), the supraspinatus tendon for treatment of tendinitis (2), and the scapulohumeral joint (3). **B:** Injecting the elbow (humeroulnar) joint. **C:** Intraarticular injection of the wrist: ulnar approach (1), dorsal approach (2), and injection into the carpometacarpal joint of the thumb (3). **D:** Injection of the left hip joint by the anterior (1) and lateral (2) approaches. Note the direction of the shaft of the needle to the bone. When inserted just anterior to the greater trochanter in a sagittal direction and pointed toward the middle of Poupart's ligament, the needle point slides anterior to the periosteum and enters the joint space anteriorly near the upper reflection of the synovial sac. **E:** Injecting the knee joint: anterior and lateral views. After a skin wheal is made on the anteromedial surface of the knee, 1 to 2 cm from the medial border of the patella, a needle is inserted in a lateral and slightly posterior direction, in a line, with the goal of sliding it between the posterior surface of the patella and the patellar groove of the femur. Synovial fluid can be aspirated as soon as the joint cavity is entered. **F:** Injecting the ankle joint: anterior and lateral views. (Reprinted from Bonica JJ. *Clinical applications of diagnostic and therapeutic nerve blocks.* Springfield, IL: Charles C Thomas Publisher, 1959, with permission.)

Facet Syndrome. Intraarticular injection of LAs into the facet joint in the lumbar, thoracic, and cervical regions (Fig. 102-7) has been used as an important diagnostic procedure. Although *facet syndrome* (a term first used in 1933 for diseases of the zygapophyseal joints) (62) as a cause of back pain remains controversial, it is believed that precise injection of the joint can be a valuable diagnostic tool in indicating whether pathophysiologic changes in the joint are a source of pain (63). The value of steroid injection into the facet joint as a therapeutic measure is also controversial; some clinicians have reported persistent relief of pain for at least 6 months in two- thirds of the patients, while others have reported relief in only 25% of patients. Moreover, a number of studies have suggested that this procedure or block of

the medial branch of the posterior primary divisions that provide articular branches to the zygapophyseal joints above and below the nerve can be used diagnostically. Figure 102-7 depicts both the intraarticular injection technique and block of the medial branch of the posterior primary division in the lumbar and cervical regions.

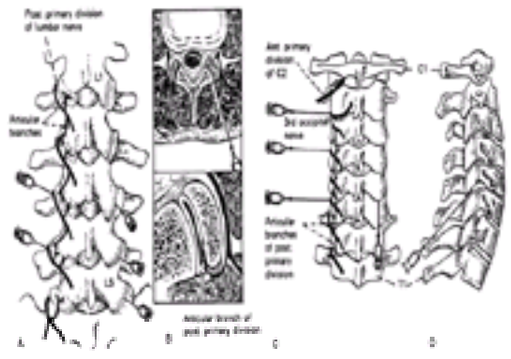

Figure 102-7. Local injection to relieve pain resulting from pathology of a facet joint in the lumbar region **(A,B)** and the cervical spine **(C,D)**. **A:** Posterior view of the lumbar spine depicting the approach for blocking the medial branch of the posterior primary division of the lumbar spinal nerves (left) and the intraarticular zygapophyseal joint (right). Each medial branch sends articular filaments to adjacent facet joints so that each joint is supplied by two (and sometimes three) adjacent nerves, which must be blocked to interrupt sensory fibers to the particular joint. **B:** Cross section of lumbar spine indicates the direction of the needle (top) and insertion of the bevel of the needle into the joint (bottom). **C:** Posterior view of the cervical spine depicting the approach for blocking the medial branches of the posterior primary divisions of the cervical nerves (left) and the direction of the needle for penetrating the zygapophyseal joint on the right. **D:** Lateral view of the cervical spine showing the course of a needle into the cavity of the right C-5–6 zygapophyseal joint. (Modified from Bogduk N. Back pain: zygapophyseal blocks and epidural steroids. In: Cousins MJ, Bridenbaugh PO, eds. *Neural blockade in clinical anesthesia and management of pain,* 2nd ed. Philadelphia: JB Lippincott Co, 1988.)

Topical Application

Topical application of an LA, either in solution or in paste form, is used to provide temporary relief of severe excruciating pain of the mucous membranes in the mouth, throat, and often the bladder. The most frequently used agents are 2% to 4% lidocaine, 4% to 6% cocaine, and 30% benzocaine solution to produce topical mucosal analgesia. For skin, analgesia jellies or creams such as eutectic mixture of local anesthetic (EMLA), a mixture of 2% lidocaine and 2% prilocaine; 2.5% to 5.0% lidocaine; and 4% tetracaine produce effective skin analgesia and may be useful in the management of some chronic pain problems such as postherpetic neuralgia (PHN) (see Chapter 22 and Chapter 87). Because topical anesthetic solutions are absorbed rapidly from the vascular mucous membranes, the amount applied must be carefully measured and limited to a total dose of one-third to one-half of the total dose shown in Table 102-1. Ointments are used to relieve the pain of mucositis in cancer patients receiving chemotherapy, rectal suppositories are used for anal or rectal pain, and jellies or creams are used for pain in the urethra or urinary bladder.

BLOCK OF SPINAL NERVES

Outside the spinal canal, the spinal nerves can be blocked in the paravertebral region or at points along their course (Fig. 102-8). Such procedures are usually done to interrupt nociceptive pathways in the management of severe acute or chronic pain, to block somatomotor nerves to relieve pain of muscle spasm, or to block sympathetic nerve fibers.

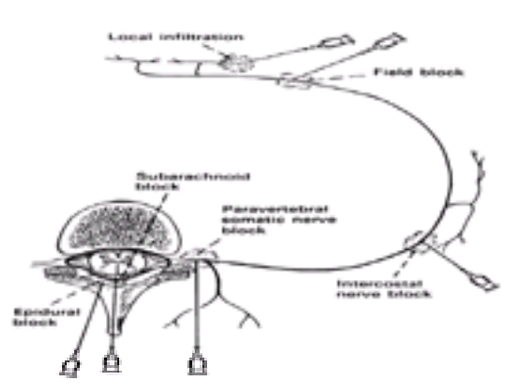

Figure 102-8. Various sites at which a typical (thoracic) spinal nerve can be blocked.

Cervical Spinal Nerves

The origin, course, and distribution of the cervical spinal nerves are described in Chapter 46 and depicted in Figure 102-9. These nerves may be involved in transmitting nociceptive information from the neck and upper limb and consequently are candidates for diagnostic/prognostic and therapeutic nerve blocks. The nerves can be blocked as they exit from the intervertebral foramina or distal to the vertebral column.

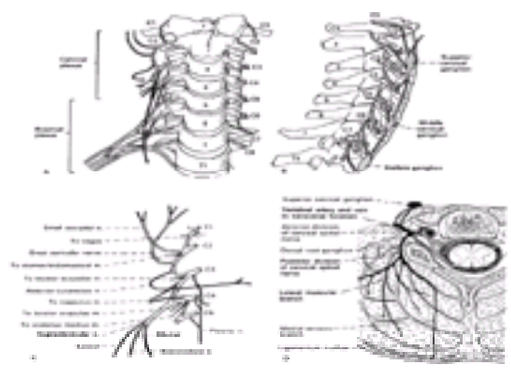

Figure 102-9. Anatomy of the cervical nerves. **A:** Anterior view. **B:** Side view. **C:** Plan of the cervical plexus showing its origin from the anterior primary division of the upper four cervical spinal nerves and its main branches. **D:** Schematic representation of a transverse section in the neck showing the relationship of the formed nerve to various structures. Each nerve passes distally within the sulcus of each transverse process. The posterior tubercle of the transverse process is larger and more superficial, and therefore is more easily palpable, than the anterior tubercle. The vertebral artery is just anterior to the formed nerve.

Paravertebral Block

Indications. Paravertebral block of the cervical nerves may be used diagnostically to identify the specific nerve segment(s) in patients with segmental neuralgia caused by herniated intervertebral disk, osteophytes, root sleeve fibrosis, or paravertebral lesions, such as tumor or aneurysm. The blocks may be used

prognostically in patients with cancer pain who are scheduled to have neurolytic or neuroablative interruption of nociceptive pathways. The technique is useful for the temporary relief of pain resulting from musculoskeletal pathology or for the manipulation of a painful or frozen shoulder joint.

Technique. The cervical nerves exit the spinal canal passing laterally within the sulcus of the transverse processes. Each transverse process has a small anterior tubercle and a larger and more superficial posterior tubercle, which is easily palpable in the average individual (see Fig. 102-9). The nerves can be blocked as they lie within the sulcus in the transverse process, most commonly using a lateral approach (Fig. 102-10) or a posterior approach. The lateral approach can be used to block all the cervical nerves except the C-8 nerve. To block the C-8 nerve, an intracutaneous wheal of LA is made in the skin overlying the transverse process of the C-7 vertebra. The needle is directed caudad and slightly mesiad and advanced slowly until contact with the nerve is made, indicated by eliciting paresthesia in its distribution.

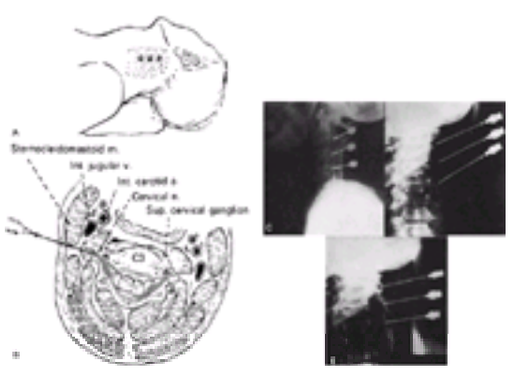

Figure 102-10. Lateral paravertebral block of the cervical nerves. **A:** Position of the patient. **B:** Cross section of the C-3 vertebra with the needle in place. The patient's head is turned to the opposite side, and a small pillow is placed under the upper portion of the thoracic spine and neck to make the transverse processes of the cervical vertebrae more prominent. The posterior tubercles of the transverse processes of the C-3–7 vertebrae usually can be easily palpated, but this can be difficult in an obese patient. A line is drawn between the tip of the mastoid process and Chassaignac's (C-6 posterior) tubercle, which is the most superficial and most easily felt. The second line is drawn 0.5 cm posterior to the first. Because the transverse process of the second is difficult to palpate, it is usually located 1.5 cm caudad to the tip of the mastoid process on the second line. The tip of the transverse process of each subsequent vertebra is generally 1.5 cm caudad to the tip of the preceding transverse process. In a very tall or long-necked (or both) patient, the distance between adjacent transverse processes can be 1.7 cm, and even as much as 2 cm.
After identifying the tip of the transverse process of the nerve or nerves that are to be blocked, the skin is prepared with an antiseptic solution. After 1 minute, the excess is removed and an intracutaneous wheal is produced over the transverse process containing the nerve to be injected. With the fingers of the left hand immobilizing the skin, a 5-cm, 22-gauge needle is inserted medially and slightly caudad and advanced until the nerve or the transverse process is contacted, usually at a depth of 2.5 to 3.0 cm (but possibly as deep as 4 or 5 cm in an obese patient). For diagnostic purposes, the nerve can be identified by eliciting gentle paresthesia or by using a nerve stimulator. If doubt exists, the nerve can be identified by lateral **(C)** and anteroposterior **(D)** radiographs. If the point of the needle is on the nerve (not *inside*), 2 mL of local anesthetic is sufficient to produce block without involving adjacent segments. If the procedure is done for therapeutic purposes, which require block of several nerves, a needle can be inserted for each segment to be blocked and 2 to 3 mL of solution injected. Alternatively, one needle can be inserted into the middle of the various segments to be blocked and 5 to 8 mL of solution injected. **E:** Anteroposterior radiograph taken 5 seconds after injecting 5 mL of 35% Diodrast solution through the middle needle. Note the wide diffusion of fluid.

The more technically difficult posterior approach is used in patients in whom the lateral approach is contraindicated (Fig. 102-11). Because some patients already have a neuropathy, care must be exercised to avoid further damage to the nerve. Moreover, because nerve blocks are primarily used for diagnostic purposes, and because of the close proximity to other nerves, the use of small volumes of LA is advised. To identify a specific nerve, either paresthesia can be elicited *gently* or a peripheral nerve stimulator can be used.

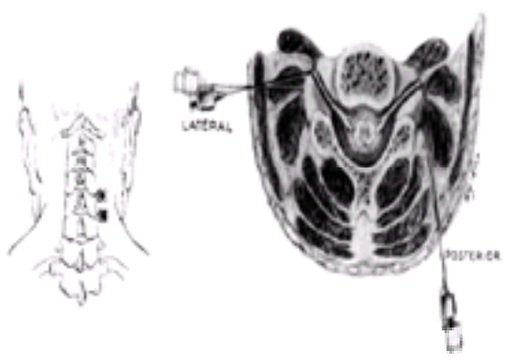

Figure 102-11. Paravertebral block of one or more cervical nerves by the posterior approach. After identification of the transverse process or of the processes that contain the nerves to be blocked, a line is drawn posterior to the midline with an indelible pen or marker. The patient is placed prone with a pillow under the chest, and the neck is flexed. After preparing the field, an intracutaneous wheal is made 3 cm from the midline on the marked line that is at the same cross-sectional level as the transverse process of the vertebra. An 8-cm, 22-gauge needle is inserted perpendicular to the skin and advanced anteriorly and slightly medially until the articular pillar is contacted, whereupon the needle marker previously threaded on the needle is placed flush with the skin. The needle is withdrawn until its point is in the subcutaneous tissue and redirected slightly more laterally so that its point is 1 cm lateral to the point of the first contact, as indicated by the needle marker. The marker is placed 1 cm from the skin, and the needle is slowly advanced until contact with the nerve is made, as indicated by paresthesia. For diagnostic purposes it is essential to elicit paresthesia; it might be necessary to make several insertions, directing the needle slightly more cephalad or caudad. It is also advisable to take radiographs. Paresthesia is not necessary for therapeutic purposes, but the point of the needle must be in the paravertebral space, which communicates freely in the cervical region and permits the anesthetic solution to diffuse easily to adjacent levels. The volume of local anesthetic is 2 to 3 mL for each segment or 8 to 10 mL for three or four segments.

Complications. Paravertebral block in the cervical, thoracic, lumbar, and sacral regions is associated with the risk of inadvertent subarachnoid, subdural, or epidural injection. In the cervical region, these complications may result in respiratory compromise because of phrenic nerve block or, in the case of a subarachnoid injection, because of rapid diffusion of the drug to the respiratory center. Inadvertent injection of LA into the vertebral artery, which runs in close proximity to the intervertebral foramina, is a definite complication of these blocks. Because the drug is delivered directly to the hindbrain, an intravertebral artery injection of very small amounts of LA (0.5 to 1.0 mL) will produce CNS toxicity (loss of consciousness, apnea, convulsions). Respiratory compromise and CNS toxicity should be treated *promptly* with artificial ventilation and support of circulation until the LA drug is redistributed and biotransformed. Other complications include cervical sympathetic block, with development of Horner's syndrome, involvement of the superior or recurrent laryngeal nerve, and even the trunk of the vagus. Because of the risk of respiratory compromise from either recurrent laryngeal and/or phrenic nerve block, it is advisable to perform cervical paravertebral blocks unilaterally at any one session.

Occipital Nerve Block

Indications. Block of the greater and third occipital nerve can be used as a diagnostic, prognostic, or therapeutic measure in managing patients with occipital headache, neuralgia, and other painful conditions in the posterior portion of the head.

Technique. The greater occipital nerve is usually blocked just above the superior nuchal line, 2.5 to 3.0 cm lateral to the external occipital protuberance (Fig. 102-12).

If it is difficult to contact the nerve and elicit paresthesia, 5 mL of LA can be injected on the medial side of the artery, 2 mm superficial to the skull.

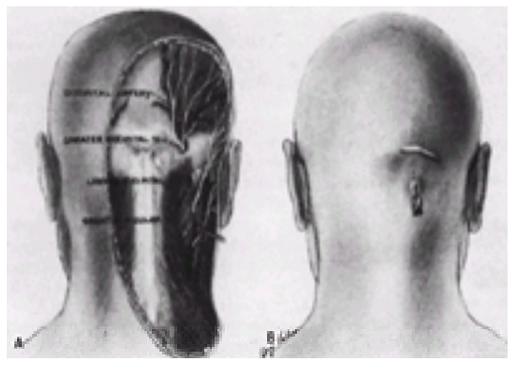

Figure 102-12. Occipital nerve block. **A:** Anatomy of the greater and lesser occipital nerves: The greater occipital nerve is 2.5 to 3.0 cm lateral to the external occipital protuberance and just medial to the occipital artery, which serves as the most reliable landmark for blocking of this nerve. The third occipital nerve, which is not shown, is usually located medial to the greater occipital nerve, while the lesser occipital nerve is located about 2.5 cm lateral to the artery. **B:** Occipital nerve block: The greater and third occipital nerves are usually blocked just above the superior nuchal line at a point medial to the occipital artery, which is easily palpated. After a thorough cleansing of the hair and scalp with an antiseptic solution, a 5-cm, 25-gauge needle attached to a 5-mL syringe filled with local anesthetic is introduced about 1 cm below the level of the target and directed anteriorly and slightly superiorly, directing its point just medial to the artery. Contact with the nerve elicits paresthesia along its course, whereupon 1 mL of local anesthetic is injected if the procedure is being done for diagnostic purposes or 2 to 3 mL of solution is injected for therapeutic purposes. Anesthesia of the scalp in the distribution of the greater and third occipital nerves develops within 5 to 10 minutes. If the procedure is repeated for therapeutic purposes, and it is difficult to elicit paresthesia, 5 mL of local anesthetic is injected on the medial side of the artery 2 mm superficial to the skull. The lesser occipital nerve can be blocked about 2.5 cm lateral to the site of the greater occipital nerve block. If all three nerves need to be blocked with a single injection for therapeutic purposes, a simple technique involves subcutaneous injection of local anesthetic along the elevation of skin across the scalp above the needle shown in **B**.

Complications. Complications are rare. Inadvertent intraarterial injection is usually inconsequential because of the small volume of LA injected.

Phrenic Nerve Block

Indications. Phrenic nerve block may be used diagnostically in patients with shoulder pain believed to be caused by irritation of the diaphragm. It can also be useful in the diagnosis or treatment of patients with intractable hiccups, in whom unilateral block is done to determine whether the condition involves one or both halves of the diaphragm.

Technique. The primary root of the phrenic nerve is the C-4 nerve, but it also receives fibers from the C-3 and C-5 cervical nerves. These join at the lateral border of the anterior scalenus muscles; the nerve then courses caudad on the anterior surface of the muscle and enters the chest (see Chapter 60). Block of the phrenic nerve is best achieved by depositing 5 to 10 mL of solution onto the anterior surface of the scalenus anticus muscle, approximately 3 cm above the clavicle (Fig. 102-13). Localization of the nerve may be assisted by the use of a peripheral nerve stimulator, which will produce an easily discernible diaphragmatic twitch. Because of the risk of respiratory compromise from diaphragmatic paresis, it is advisable to perform only unilateral phrenic nerve block at one session.

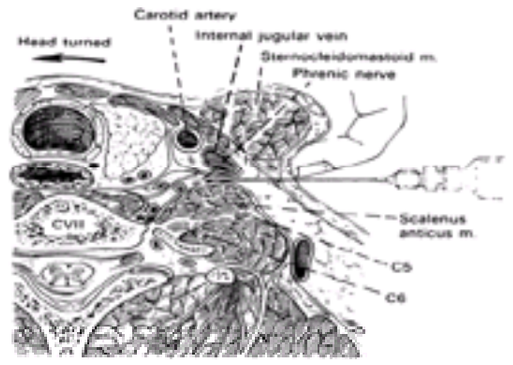

Figure 102-13. Blocking the phrenic nerve. The cross section at the level of the C-7 vertebra shows the position of the phrenic nerve anterior to the fascia of the scalenus anticus muscle, with the point of the needle just touching the nerve. This procedure is best accomplished by having the patient in the supine position with the head turned to the opposite side. The posterior border of the sternocleidomastoid is identified 3 cm above the clavicle by having the patient lift the head while it is turned to the opposite side and by hooking the physician's index finger around the posterior border of the muscle. A wheal is made at this point; a short-beveled 5-cm, 22-gauge needle is introduced through the wheal in a medial direction and guided with the finger of the left hand so that it passes posterior to the border of the sternocleidomastoid muscle. If the short-beveled needle is advanced slowly and carefully, one can better appreciate piercing of the superficial fascia. Injection of 3 to 5 mL of solution is usually sufficient for complete block.

Complications. Respiratory compromise, especially in patients who have preexisting respiratory disease, may result from hemidiaphragmatic paresis. Inadvertent injections of even small amounts of LA into the carotid or vertebral arteries will result in CNS toxicity (see above). Inadvertent intravenous injection into internal jugular or other veins may result in systemic toxicity.

Brachial Plexus Block

Indications

Diagnostic Block. Brachial plexus block can be used as a diagnostic procedure in causalgia, CRPS, phantom limb pain, and other types of postamputation pain. It can also be used to differentiate pain of peripheral neuralgia from pain of more central origin (e.g., brachial plexus avulsion). Because all sympathetic fibers to the hand and forearm are carried within the brachial plexus, block of the plexus can help confirm completeness of an upper extremity LA or surgical sympathectomy.

Brachial plexus block can be used diagnostically in patients with arm pain and joint deformities due to either guarding and muscle spasm caused by pain or to fixed lesions of joints or muscles. In the former case the block will permit passive range of movement, whereas in the latter the deformity will remain fixed. In patients with a fixed deformity of the arm, repeated plexus brachial blocks may assist in mobilization.

Prophylactic Block. Brachial plexus block for upper limb surgery delays the onset of postoperative pain and the time for the first postoperative request for analgesics and significantly reduces the amount of postoperative pain incidence (64). Studies that will be cited in Section F in connection with epidural analgesia provide reason to believe that continuous brachial plexus block instituted and maintained for 3 days before amputation may reduce the incidence of postamputation phantom limb pain.

Therapeutic Block. Brachial plexus block may provide temporary pain relief in patients with acute pain following trauma or surgery and in patients with vascular compromise due to arteriolar spasm or an embolus. Continuous brachial plexus block, providing both pain relief and a sympathectomy, is useful in patients who have

undergone reimplantation of a severed portion of an upper limb and in patients in whom the blood supply to the extremities is compromised.

Technique. The anatomy of the brachial plexus is summarized in Chapter 54 and depicted in Figure 102-14 and Figure 102-15. A number of brachial plexus block techniques have been described; the most commonly used are the supraclavicular (65) (Fig. 102-16), interscalene (66) (Fig. 102-17), and axillary approaches (67) (Fig. 102-18). In early RA practice, the supraclavicular technique was favored because it placed the LA in the plexus at a point where the plexus was closely compressed as it passed over the first rib and produced central and distal distribution of the drug and a reliable block. However, because the point of LA injection is close to the dome of the pleura, this technique carries a significant incidence of pneumothorax. Interscalene block, in which the LA is deposited on the plexus at a more central point, at about the level of C-6, has a much lower incidence of pneumothorax and is more commonly used for pain in the upper dermatomes of the brachial plexus. Interscalene block does not usually produce analgesia in the two lower roots of the plexus (C-8, T-1). The axillary block poses the least risk of serious neurologic or pulmonary complications but, unless large volumes are used, the branches of the plexus given off above the first rib tend not to be blocked.

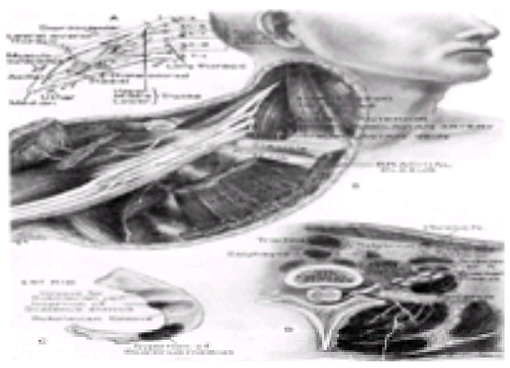

Figure 102-14. **A:** Schematic depiction of the makeup of the brachial plexus. **B:** Anatomy of the brachial plexus: The brachial plexus extends from the interval between the anterior and medial scalenus muscles to the lateral border of the pectoralis muscle. The three trunks emerge from the interscalene space at the lower border of these muscles and continue anterolaterally and inferiorly to converge toward the upper surface of the first rib, where they are closely grouped and thus accessible to injection of local anesthetic. In the posterior triangle of the neck, the plexus is located superficially and is covered by the superficial fascia, platysma, and deep fascia. At the lateral edge of the rib, each trunk divides into anterior and posterior divisions, which pass beneath the midportion of the clavicle to enter the axilla through its apex. Over the first rib, the subclavian artery, lying immediately anteromedial to the plexus, is also superficial, thus affording a palpable landmark to the plexus. Throughout their course, the brachial plexus and the subclavian artery are enclosed in a fascial sheath that extends from the anterior and middle scaleni muscles as far as the lower part of the axilla and the upper part of the arm (see Fig. 102-15). This sheath forms a relatively avascular enclosed space into which a local anesthetic solution can be injected, thus resulting in prolonged neural blockade (see Fig. 102-15). **C:** Superior view of first rib showing the subclavian groove, on which the brachial plexus and subclavian artery rest. **D:** Semidiagrammatic cross section to show relationships of the plexus, muscles, blood vessels, and apex of lung.

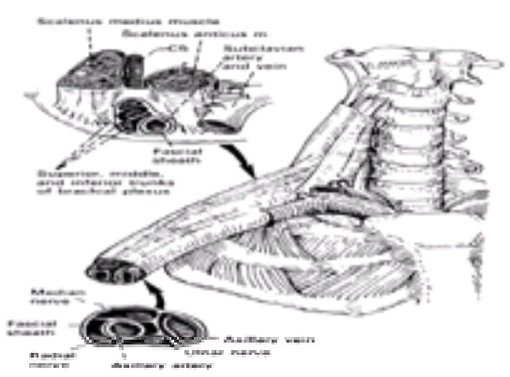

Figure 102-15. The brachial and axillary neurovascular sheath. The sheath is a lateral prolongation of the prevertebral fascial layer that encloses the roots of the brachial plexus and the scalenus anticus and medius to form a vertical tube, continuing laterally to enclose the brachial plexus and subclavian artery. In its position above the first rib, the subclavian vein is not enclosed in this sheath (upper inset) but, more distally, it is covered by a thin fascial sheath that tends to fuse with the larger neurovascular sheath. Lower inset: Cross section in lower part of the axilla showing the relationships of the three major nerves derived from the brachial plexus to the axillary artery and axillary vein. Small fascial septa subdivide the main sheath to enclose each of these structures, which might constitute a fascial barrier to the diffusion of local anesthetic. (Modified from Thompson GE, Rorie DK. Functional anatomy of the brachial plexus sheaths. *Anesthesiology* 1983;59:117–122.)

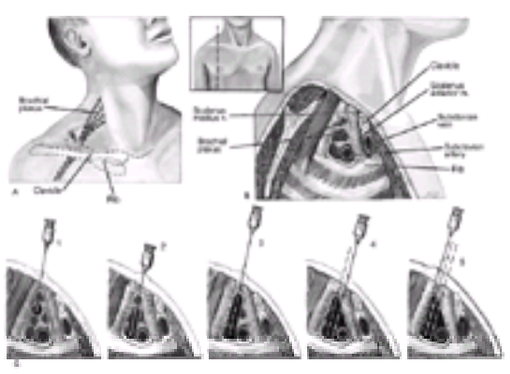

Figure 102-16. Brachial plexus block by the supraclavicular approach using the Bonica three-needle insertion technique. **A:** Anterior schematic showing the position of the plexus and direction of the needle. **B:** Parasagittal section (inset: *dashed line*) showing the subclavian artery and brachial plexus surrounded by a sheath derived from the fascia of the scalenus anticus and scalenus medius muscles. **C:** Injection of local anesthetic solution (*black*) for each of three insertions. After informing the patient about the pr ocedure and requesting that the patient promptly signal any feeling of paresthesia, the two ends of the clavicle are identified and the subclavian artery is palpated. The field is prepared, and a skin wheal is formed about 1 cm above the midpoint of the clavicle, just posterior to the palpable subclavian artery. A 5- or 8-cm (depending on the size of the patient), 22-gauge needle attached to a 10-mL Luer-Lok control syringe filled with local anesthetic solution is inserted in a caudad and slightly dorsad and mesiad direction **(A)** until paresthesia is elicited, whereupon the needle is arrested and aspiration is carried out in two planes; if negative, 3 to 4 mL of local anesthetic solution is injected. The needle is then carefully advanced until the upper surface of the first rib is contacted (*1*). After injecting 2 to 3 mL on the rib, the remainder of the 10 mL of solution is injected as the needle is withdrawn between the first rib and the superficial fascia (*2*). To avoid accidental intravenous injection, the needle should be withdrawn in a stepwise fashion and aspiration done before the injection of 1 to 2 mL of solution (*3*). When the point of the needle is in the subcutaneous tissue, the skin is moved 1 cm anteriorly and then advanced so that the shaft of the needle is parallel to the first insertion, and the same procedure is repeated (*4*). Following the second step, with the needle point again subcutaneous, the skin is moved 2 cm posteriorly (i.e., 1 cm posterior to the first insertion), the needle is advanced with its shaft parallel to that in the first two steps, and the procedure is repeated (*5*). By injecting 10 mL of solution through each of these three insertions, a wall of anesthesia is created within the entire fascial sheath (*black*) containing the neuromuscular bundle through which the plexus passes.

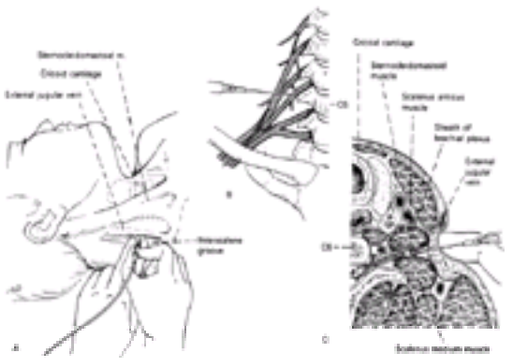

Figure 102-17. Interscalene block of the brachial plexus. **A:** The patient lies supine with the head on a pillow and rotated to the opposite side. The interscalene groove is identified by asking the patient to lift the head, which places the scaleni muscles in tension. The insertion point is determined by drawing a line that extends laterally from the cricoid cartilage to intersect the interscalene groove at the level of the transverse process of C-6. After formation of a skin wheal, and with the second and third fingers of the left hand palpating the interscalene groove, a 3- or 5-cm, 23- or 25-gauge, short- beveled needle is inserted in a medial and slightly caudad direction toward the sulcus of the C-6 transverse process. **B:** The needle is advanced slowly for 1.5 to 2.0 cm until paresthesia is elicited; this indicates contact with a nerve, which is usually the C-7 root of the plexus. **C:** Cross section at level of C-6 vertebra showing the bevel of the needle approaching the nerve, which is located between the anterior and middle scalenus muscles. The 30 to 40 mL of local anesthetic solution injected diffuses cephalad, caudad, and laterally to block the roots, trunks, and divisions of the brachial plexus and often the roots of the cervical plexus. Although this volume of solution can be injected by adapting a 10-mL Luer-Lok syringe directly to the hub of the needle, it is best to attach a length of tubing to the needle hub with its proximal end adapted to a 50-mL syringe containing the local anesthetic (as shown in **A**). To avoid unintentional intravenous or subarachnoid injection, attempts at aspiration are made before and after injection of 1 to 2 mL of solution and repeated frequently as the entire volume of the solution is injected. For a continuous technique, an 18- or 20-gauge intravenous catheter is similarly introduced, the stylet removed, and the catheter taped into place with its hub connected to a 10- to 15-cm length of tubing attached to the syringe containing the local anesthetic. Repeated injections of 20 to 30 mL of 0.250% to 0.375% bupivacaine every 6 hours, or an infusion of 0.25% bupivacaine at a rate of 6 to 12 mL per hour, produce continuous blockade.

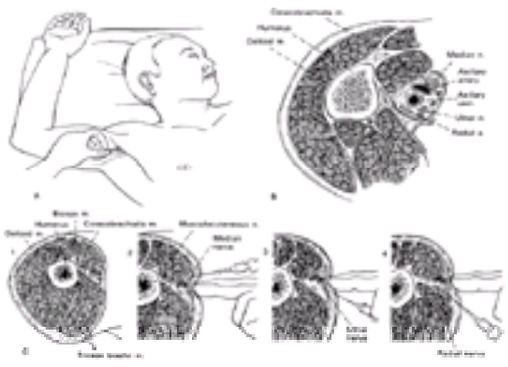

Figure 102-18. Axillary block of the brachial plexus. **A:** The patient is supine with the arm abducted to 90 degrees and rotated externally. **B:** Cross section of the upper part of the axilla showing the relation of the nerves to the axillary vessels. The axillary artery is palpated and traced as far as possible proximally within the axilla, ideally to the pectoralis major muscle. After appropriate preparation of the skin, a skin wheal is formed over the artery and a 3- or 5-cm, 23- or 25-gauge, short-beveled needle (attached to tubing connected to an anesthetic-filled syringe; not shown) is inserted through the wheal. The shaft of the needle should be at a 45-degree angle with the medial aspect of the arm **(A)**, directing its point cephalad toward the apex of the axilla and advancing it slowly. A short-beveled needle can be felt to penetrate the sheath, within which lie the lower portion of the axillary artery and the four major nerves of the plexus. Penetration of the fascial sheath is felt as a “click,” after which the needle is advanced 1 to 2 mm to ensure that the bevel is within the fascial sheath. Elicitation of paresthesia obviously indicates contact with one of the major nerves. Injection of 30 to 40 mL of solution while pressure is placed firmly on the neurovascular bundle and its surrounding sheath below the needle enhances diffusion of the solution proximally so as to involve all the branches of the brachial plexus, except those that leave it above the first rib. **C:** Some physicians prefer to elicit paresthesia and inject each of the three major nerves at the uppermost part of the arm at the beginning of the brachial artery (*1*). After identifying the artery, an intracutaneous wheal is formed just medial to the artery. A 5-cm, 25-gauge, short-beveled needle attached to a 10-mL Luer-Lok control syringe containing the local anesthetic solution is inserted through the wheal, and the skin is moved anteriorly about 0.5 cm. While palpating the artery with the second and third fingers of one hand, with the other hand the needle is advanced laterally through the fascial sheath, which can be felt. The needle is advanced another 2 or 3 mm until contact with the median nerve produces paresthesia in its distribution (*2*). Injection of 2 to 3 mL of solution is sufficient to anesthetize the nerve. For block of the ulnar nerve, the maneuver is repeated except, after inserting the needle through the wheal, the skin is moved posteriorly 0.5 cm and advanced until contact with the ulnar nerve elicits paresthesia in its distribution (*3*). To reach the radial nerve, which is posterolateral to the artery, the needle must be inserted 0.5 cm posterior to the point of injection of the ulnar nerve, with the needle passing posterior to the ulnar nerve in a lateral and slightly anterior direction (*4*). At this level, the musculocutaneous nerve has passed laterally and is in the substance of the coracobrachialis muscle. To block this nerve, it is necessary to insert the needle 0.5 cm anteriorly to where the median nerve is located and to advance the needle laterally into the substance of the muscle, in which 5 mL of solution is usually sufficient to diffuse and block the nerve. For a continuous technique, a 5-cm, 18-gauge intravenous catheter is introduced through an opening in the anesthetized skin that has been made with a larger sharp needle. The catheter is directed at an angle of 30 degrees with the skin in a central direction toward the apex of the axilla. Once the tip of the catheter pierces the sheath containing the neurovascular bundle, it is advanced about 2 cm along the side of the artery, the stylet is removed, the solution is injected, and the catheter is fixed firmly in place. Subsequent injections are repeated as necessary.

Regardless of which one of the three techniques is used, a common feature is that the LA is deposited within the fascial sheath surrounding the brachial plexus (see Fig. 102-15). Provided that an adequate volume of drug (30 to 40 mL in an adult) is injected into the sheath, it tends to spread longitudinally within the sheath to affect all components of the brachial plexus. Circumferential spread might not be as reliable, particularly with a small volume of solution (68).

For diagnostic purposes, 1% lidocaine produces a 2- to 4-hour block. For therapeutic purposes, 0.250% to 0.375% bupivacaine with epinephrine produces analgesia and sympathetic block for 8 to 12 hours. In a significant proportion of patients, the use of a higher concentration (e.g., 0.5%) of bupivacaine produces a prolonged block of up to 16 to 24 hours' duration.

Techniques to produce a continuous brachial plexus block have been described for the supraclavicular (69), interscalene (70), and auxiliary routes (71,72). The plexus is located by paresthesia or loss of resistance or with the assistance of a nerve stimulator. A catheter is passed either directly into the fascial sheath or after initial dilatation of the sheath with a few milliliters of LA, or a guidewire can be passed into the sheath and a catheter passed over the guidewire (73). The catheter is fixed in place either with sutures or transparent adherent dressings. Analgesia can be maintained with periodic injections of 20 to 30 mL of 0.25% bupivacaine every 6 hours or by a continuous infusion with an infusion pump delivering 0.25% bupivacaine at a rate of 6 to 12 mL per hour. With the use of these techniques, the resulting blood levels of drug have been reported to be near toxic limits (74,75). Such catheters have been left in for considerable periods of time, up to a week, with few or no complications (73).

Complications. Complications of the use of interscalene block include epidural, subdural, or subarachnoid block; inadvertent intravertebral artery or intravenous injection; block of the sympathetic and recurrent laryngeal nerves; and a 70% to 90% incidence of phrenic nerve block. Complications of the use of the supraclavicular route include phrenic nerve block, cervical sympathetic block, and, perhaps the most serious, pneumothorax with an incidence of between 0.5% and 6.0% (65). Complications of the use of the axillary route include intravascular injection, with a seizure incidence of 1.5% reported in some series (36,45), and axillary artery damage. Minor neurologic damage has been reported to occur in up to 3% of patients (36,45), but average incidence is likely lower (76).

Suprascapular Nerve Block

Indications. The suprascapular nerve, a branch of the brachial plexus, is the major sensory nerve supply to the shoulder joint. Suprascapular nerve block is useful for

the management of severe pain caused by bursitis, periarthritis, or arthritis if these conditions are not amenable to intraarticular and periarticular injection of LA and steroids.

Technique. The anatomy of the suprascapular nerve is described in Chapter 54. It springs from the C-4, C-5, and C-6 contributions to the upper trunk of the brachial plexus from which the formed suprascapular nerve emerges. It then proceeds laterally, posteriorly, and inferiorly beneath the omohyoideus and trapezius muscles, but superficial to the plexus, to reach the superior border of the scapula, where it passes through the suprascapular notch beneath the superior transverse scapular ligament to enter the supraspinatus fossa (Fig. 102-19A).

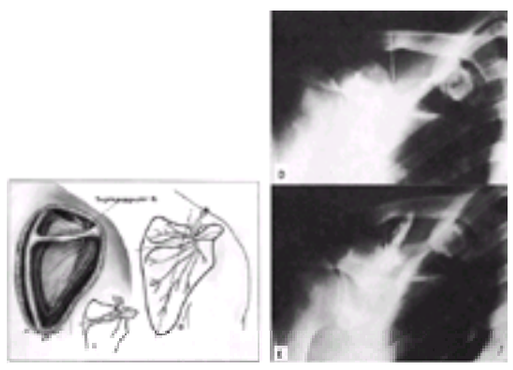

Figure 102-19. Suprascapular nerve block. **A:** Anatomy of the suprascapular nerve. **B:** Needle placement: After identifying the spine of the scapula, a line is drawn on the skin overlying it, with another line bisecting the inferior angle of the scapula (*dashed lines*). The outer triangle formed by the two intersecting lines is bisected and a wheal is formed on this line, about 1.5 cm from the angle. An 8-cm, 22-gauge needle is introduced through this wheal so that its shaft is directed anteriorly and slightly caudad and mesiad to make contact with the supraspinatus fossa just lateral to the suprascapular notch. The needle is withdrawn until its point is in the subcutaneous tissue and reintroduced so that its point is directed 5 mm medial to the point of first contact. Advancing the needle in this direction usually causes its point to enter the notch, make contact with the nerve, and elicit paresthesia. **C:** If the second insertion fails to produce paresthesia, a third or fourth insertion is made in search of the notch. Usually 3 to 5 mL of a local anesthetic solution produces block of the nerve. The radiographs show the point of the needle in the suprascapular notch before **(D)** and after **(E)** injection of 3 mL of 30% Diodrast. Note the diffusion of the dye.

The technique for suprascapular nerve block is described in Figure 102-19B, Figure 102-19C, Figure 102-19D and Figure 102-19E. This is usually a relatively simple block, but it is sometimes difficult to contact the nerve. Fluoroscopy or a peripheral nerve stimulator can be used to aid in placement of the needle.

Complications. Side effects include paralysis of the supraspinatus and infraspinatus muscles, producing transient disability. The most serious complication is pneumothorax occurring from the needle passing the upper border of the scapula into the chest wall, pleura, and lung.

Block of Median, Ulnar, and Radial Nerves

Indications. Block of the median, ulnar, or radial nerves at the elbow is useful as a diagnostic or prognostic tool in patients with pain in the distribution of each specific nerve. This procedure can also be used to produce a sympathetic block in the region supplied by each nerve. Block of the median or ulnar nerve, or both, at the level of the wrist can also be used for the same purpose.

Technique. The technique for blocking these nerves is described in Figure 102-20. Because the procedure entails approaching the nerve with the shaft of the needle at an angle that is perpendicular to the nerve, it is possible to impale the nerve with the needle against the underlying bone. It is essential to avoid nerve damage by using a fine (25-gauge), short-beveled needle and to elicit paresthesia gently or use a nerve stimulator. Usually 5 mL of 1% lidocaine or 0.25% bupivacaine is sufficient to block each nerve.

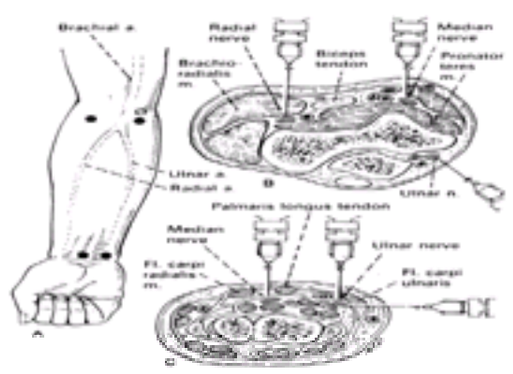

Figure 102-20. **A:** Sites of blocking of the major nerves at the elbow and wrist. (*Open circle*, brachial artery; *solid circle*, points.) **B:** Cross section of the arm at the elbow. The median nerve is medial to the brachial artery and is at a point midway between the medial epicondyle and the medial edge of the biceps tendon. To block the radial nerve, the needle is introduced 1 cm lateral to the lateral edge of the biceps tendon and advanced posteriorly. The ulnar nerve can usually be palpated just medial to the ulnar artery. Care must be exercised to use a fine needle with a short bevel to avoid damage to the nerve or eliciting paresthesia. **C:** Cross section of the arm at the wrist with needles in place to block the median and ulnar nerves. For median nerve block, a skin wheal is made between the tendons of the palmaris longus and the flexor carpi radialis. A 3-cm, 25-gauge needle is introduced perpendicular to the skin and advanced posteriorly until the nerve is contacted and paresthesia is elicited. For ulnar nerve block, the wheal is made just lateral (radial) to the tendon of the flexor carpi ulnaris and medial to the palpable ulnar artery. A 3-cm, 25-gauge needle is introduced perpendicular to the skin and directed posteriorly until the nerve is contacted. The ulnar nerve can also be blocked by a median approach, but care must be taken so that the needle is inserted just posterior to the posterior edge of the flexor carpi ulnaris tendon and advanced laterally until paresthesia is elicited.

Complications. In addition to possible nerve damage, other complications include inadvertent intravenous injection but, because the total amount of drug administered with each injection is small, this should not cause any systemic toxicity.

Thoracic Spinal Nerves

The thoracic spinal nerves transmit nociceptive information from the chest and abdomen and therefore are good sites for diagnostic, prognostic, prophylactic, or therapeutic procedures for various painful disorders involving these structures. Paravertebral blocks are performed as the nerve exits the intervertebral foramen and blocks the anterior and posterior primary divisions and the rami communicantes, which contain autonomic fibers from and to the thoracic and abdominal viscera. The anterior primary division of the thoracic nerve, the intercostal nerve, can be blocked at various sites along its course.

Paravertebral Block

Indications. Paravertebral block of the thoracic spinal nerves is helpful in painful disorders of the thoracic spine, thoracic cage, and abdominal wall. Because this block includes the recurrent nerve that supplies the vertebrae and meninges, it is helpful to determine the nociceptive pathways in patients with segmental neuralgia caused by vertebral pathology. Unless a prolonged block (3 to 5 days) can be achieved, its value in predicting the effects of neurolytic block of thoracic nerves or surgical

rhizotomy is questionable.

Paravertebral block can be used therapeutically to treat acute herpes zoster (77,78), rib fractures, and postoperative thoracotomy pain (79). This procedure has also been used to manage patients with chronic postthoracotomy and posttraumatic pain.

Repeated injections can be used for surgical or traumatic injuries to the chest wall or upper abdomen, or a catheter can be placed in the paravertebral space (80). The injection of an appropriate volume of LA through the catheter produces a block of two or three segments.

Technique. The anatomy of the thoracic spinal nerve is described in detail in Chapter 60 and is shown in Figure 102-21 and Figure 102-22. In the classic technique, the needle is inserted 4 to 5 cm lateral to the spinous process and advanced anteriorly and medially at a 45-degree angle to the midsagittal plane. When the needle strikes the appropriate transverse process, it is withdrawn until subcutaneous and then readvanced so that it passes inferior to the transverse process until its tip reaches the nerve. Using this approach, the needle traverses a concavity that contains the posterior border of the lung, thus risking pneumothorax. Moreover, if the needle is passed further, the intervertebral foramen might be entered, with consequent puncture of the dura and even of the spinal cord.

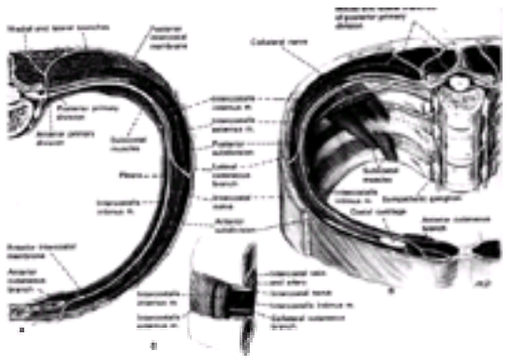

Figure 102-21. Anatomy of the thoracic spinal nerve. **A:** Superior view of the intercostal space. **B:** Anterior view of the chest. **C:** Cut section of two adjacent ribs. Note that the nerve exits through the intervertebral foramen to reach the paravertebral region, where it promptly divides into the posterior and anterior primary divisions. The anterior primary division, which becomes an intercostal nerve, proceeds between the posterior intercostal membrane and the endothoracic fascia and adjacent pleura. At the angle of the rib, it is located between the subcostal muscles and the internal intercostal muscle, and just distal to that it is situated between the intercostalis intimus and the internal intercostal muscles. The lateral cutaneous branch leaves the parent nerve near the angle of the rib. Note in **B** the relation of the intercostal nerves and their branches and these structures and the thoracic sympathetic chain; **C** shows the direction of fibers of the intercostal muscles and the position of the intercostal vessels and nerves. (Modified from Netter FH. *The CIBA collection of medical illustrations.* Vol 7, Respiratory system. West Caldwell, NJ: Ciba Pharmaceutica, 1979:11.)

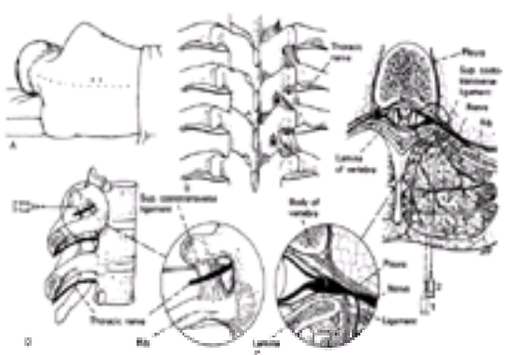

Figure 102-22. Thoracic paravertebral somatic nerve block. **A:** Position of the patient for block on the right side. Because placement of the needle depends on the relationship between the tips of the spinous processes and the laminae, it is essential to identify each spinous process and to mark it with an indelible pen or marker. After sterilizing the skin, a skin wheal is formed 1.5 cm lateral to the tip of the spinous process of the vertebra above. For block of the somatic nerve, it is best to make contact with the upper portion of the lateral aspect of the lamina. **B:** A 5- or 8-cm, 22-gauge, short-beveled needle is inserted through the skin wheal perpendicular to the skin. **C:** The needle is advanced until the lateral edge of the lamina is contacted (1). The needle is then withdrawn until its point is in the subcutaneous tissue, the skin is moved laterally about 0.5 cm, and the needle is readvanced until its point slips just lateral to the upper part of the lateral edge of the lamina and its point engages the uppermost part of the superior costotransverse ligament just below the proximal portion of the transverse process (2). Once the point of the needle is in the ligament, a 2-mL glass syringe filled with saline solution is attached to the needle and an attempt is made to inject the saline. It is important to test the syringe before its adaption to the needle to ensure that its plunger slides easily. As long as the tip of the needle is within the ligament, some resistance to the injection can be felt. By exerting constant pressure on the plunger of the syringe with the right hand and advancing the needle *slowly* with the left hand, a lack of resistance is felt as soon as the bevel of the needle passes through the upper part of the superior costotransverse ligament and is in the paravertebral region in the immediate vicinity of the nerve. If paresthesia is not elicited, a nerve stimulator is used to ascertain that the bevel of the needle is on the nerve **(C)**. The needle is directed in a true sagittal plane rather than at an angle, as is the case with the classical approach (see text). **D:** Lateral view showing the penetration of the superior part of the superior costotransverse ligament and the advancement of the needle until it comes in contact with the nerve.

To circumvent these problems, Bonica (2) developed the paralaminar technique described in Figure 102-22. For diagnostic purposes, 3 mL of 1% lidocaine or 0.25% bupivacaine is used. For treatment of severe acute pain, 5 mL of 0.375% to 0.500% bupivacaine with epinephrine is appropriate. With larger volumes of injectate (10 to 20 mL) the drug will pass up and down the paravertebral areas and result in a multilevel block. A continuous block technique can be achieved by placing a catheter in the paravertebral space (80).

Complications. Possible complications include accidental subarachnoid or epidural injection, intravascular injection, and pneumothorax, and, with large volumes of injectate, hypotension due to a sympathectomy.

Intercostal Nerve Block

Indications. Intercostal nerve block is a useful diagnostic procedure for defining nociceptive pathways of segmental chest and abdominal wall pain, but it must be used and interpreted with caution when differentiating somatic from visceral pain. Visceral afferent nerve fibers leave the nerve root at the intervertebral foramen, proximal to where intercostal nerve blocks are usually performed. However, the LA from intercostal nerve blocks may spread proximally from the site of injection to the intervertebral foramen and thus block both somatic and visceral fibers. The more distal the block is performed and the smaller the volume of injectate, the lesser the likelihood of spread of the LA to the paravertebral area. If there is doubt about the pain etiology (i.e., somatic versus visceral), it is best to perform a cervicothoracic sympathetic block for thoracic visceral pain or a splanchnic or celiac plexus block for abdominal visceral pain.

For therapeutic purposes, intercostal nerve block is a useful procedure for the relief of severe acute posttraumatic, postoperative, or postinfection pain in the thoracic or abdominal wall (1,81,82,83,84,85,86,87,88 and 89). Unilateral intercostal block is effective for chest pain after thoracotomy (81,84), subcostal (Kocher's) incisions (88,89), and after renal surgery through flank incisions (90,91). Bilateral intercostal blocks are necessary for sternotomy and midline upper abdominal incisions. To obtain satisfactory pain relief, it is necessary to block the nerves supplying the segments through which the incision passes, plus the segments above and below, and in the case of thoracic surgery, the segments through which chest drains pass.

The analgesia produced by intercostal nerve block may be superior to that produced by conventional narcotic analgesia. Postthoracotomy patients managed with

intercostal nerve blocks (Table 102-3) show less impairment of effort-dependent measures of respiratory function (forced vital capacity and peak expiratory flow) (26,88,91,92,93,94,95 and 96) and of arterial oxygenation (26,88) than patients receiving narcotic analgesia. Following abdominal operations, patients receiving intercostal blocks may have a better and earlier global recovery, an earlier discharge from hospital (81), better results on tests of respiratory function (e.g., forced vital capacity, peak expiratory flow), less impairment of arterial oxygenation, and a reduced incidence of respiratory complications (82) (Table 102-4). Detailed studies (82,89) imply that single unilateral posterior intercostal blocks in patients with subcostal incisions produce appreciable respiratory benefits, whereas bilateral blocks in patients with midline incisions may produce less benefit.

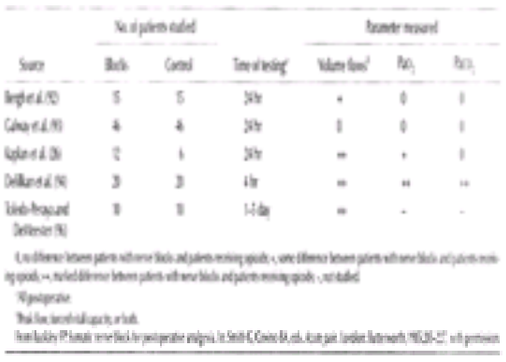

TABLE 102-3. Respiratory outcome in postthoracotomy patients given singledose intercostal blocks with bupivacaine

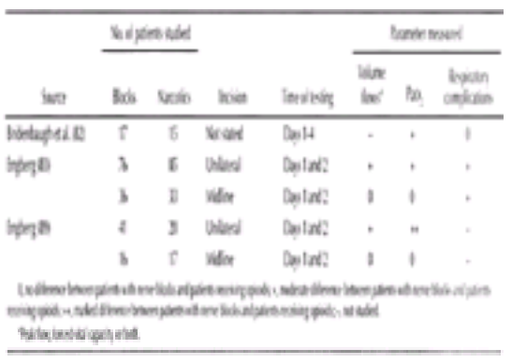

TABLE 102-4. Respiratory outcome in post–abdominal surgery patients: narcotics versus intercostal blocks

Studies of the influence of intercostal blocks on postoperative respiratory morbidity have been performed, predominantly in fit patients who have a relatively low incidence of postoperative respiratory morbidity. There is little information on the efficacy of these blocks in patients who would be expected to have a higher incidence of respiratory morbidity (i.e., those with preexisting respiratory disease), who might be expected to achieve greater benefits from intercostal nerve blocks. Anecdotal reports (97,98) suggest that bilateral posterior intercostal blocks in patients with respiratory compromise could precipitate respiratory failure, possibly as a consequence of changes in abdominal and chest wall mechanics and in functional residual capacity (99) produced by the blocks (99,100 and 101). In patients with respiratory compromise, it is probably advisable to perform intercostal blocks as far distally as possible along the course of the intercostal nerve to achieve maximal sparing of chest wall and abdominal muscle power. Patients receiving intercostal blocks that produce analgesia limited to the thoracic or abdominal wall usually require supplemental analgesia with modest doses of narcotics to relieve pain arising from the viscera and from drains or nasogastric tubes.

The use of intercostal blocks for postoperative or posttraumatic chest and abdominal pain has largely been supplanted by the use of continuous segmental epidural analgesic techniques with LA with or without opioids (see Chapter 103). Intercostal nerve blocks may have a limited niche role when epidural techniques are impossible or contraindicated. Intercostal nerve blocks with bupivacaine produce analgesia for 8 to 12 hours (102), permitting analgesia to be obtained with blocks two to three times a day. Disadvantages of the use of intercostal block compared with epidural block include the need to make multiple injections and the risk of pneumothorax.

Technique. The anatomy, course, and distribution of the intercostal nerves are discussed in Chapter 60 and shown in Figure 102-23 and Figure 102-24. Although the intercostal nerves can be blocked at any point along their course, they are usually blocked at the four sites depicted in Figure 102-23.

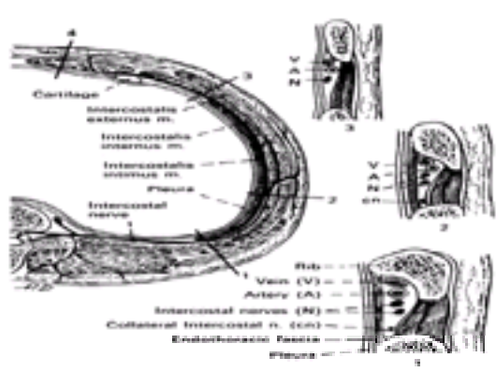

Figure 102-23. Typical intercostal nerve and the optimal sites for intercostal block. The cross section on the left shows the course of the nerve. Cross sections on the right show the relationship of the intercostal nerves to the vessels and the muscles. Angle of rib where the intercostal space is a triangular structure that contains the vein, artery, principal nerve and its lateral cutaneous branch, and collateral branch (*1*). The space is bound medially by the pleura and the endothoracic fascia and the beginning of the intercostalis intimus muscle and laterally by the intercostal groove and the internal and external intercostal muscles. Cross section along the posterior axillary line (*2*). Note the difference in shape of the space and of the cross section of the rib. Cross section at the anterior axillary line (*3*). Cross section at costochondral junction (*4*).

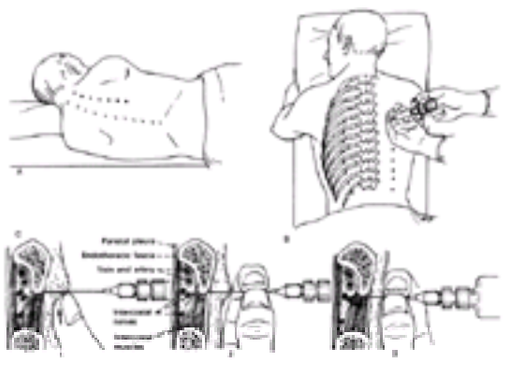

Figure 102-24. Posterior intercostal block. The injections are done at the angles of the ribs. **A:** The patient lies on the side comfortable for a unilateral block. **B:** The patient is in a prone position to facilitate bilateral block. The dots indicate the sites of injection. **C:** Details of injection. After identifying the space and sterilizing the skin over it, an intracutaneous wheal is made just below the lower edge of the rib **(B)**. A 3-cm, 25-gauge, short-beveled needle is inserted through the wheal, after which the second finger of the left hand is placed over the intercostal space and the skin is pushed slightly cephalad so that the lower edge of the rib above can be palpated at the same time the skin over lower edge of the rib is immobilized (1). This finger also protects the intercostal space, thus decreasing the risk of passing the needle too far into the lung. The needle is advanced until the lowermost part of the lateral aspect of the rib is contacted. After the rib is impinged on, the needle is grasped between the thumb and index finger of the left hand, 3 to 5 mm from the skin (2). The skin is moved caudad with the left index finger to allow the needle to slip just below the lower border of the rib. The needle is advanced until the fingertips grasping the needle are flush with the skin (3). This simple maneuver minimizes the possibility of advancing the needle too deeply and entering the lung. With the needle held steady between the second and third fingers of the left hand, aspiration is attempted; if negative, 3 to 4 mL of solution is injected.

Posterior Intercostal Block

Posterior intercostal block is most easily performed at the angle of the rib where the rib is most easily palpable, the rib is thickest, and the intercostal groove is broadest and deepest. At this point, the intercostal space is triangular, has an area of approximately 0.75 cm ^{2}, and is filled with fat within which the intercostal nerve, its lateral cutaneous branch, and the collateral branch are grouped relatively close together (1,89,103). As noted in Figure 102-21 and Figure 102-23, the space is bound externally by the intercostal groove, posterior intercostal membrane, and internal and external intercostal muscles and internally by the thin intercostalis intimus muscle and the pleura. The internal and external intercostal muscles are substantial structures bound on their internal aspects by the posterior intercostal membrane and on their external aspects by the fascia and cutaneous structures.

Posterior intercostal nerve block technique is described in Figure 102-24. Injection of 3 to 4 mL of LA at the angle of the rib results in LA spreading several centimeters distally and also proximally to the paravertebral area. Spread of LA to the paravertebral area may result in block of sympathetic afferents (100), thus helping to relieve visceral as well as somatic pain. Injection of larger amounts of LA results in both paravertebral and epidural spread of the drug (104) and, if many segments are involved, arterial hypotension can develop. Injection of LA at one intercostal site may spread subpleurally to adjacent intercostal nerves (88), although this is not a consistent finding (103). Single injections of 20 mL of LA may produce analgesia that involves multiple intercostal nerves (105,106 and 107).

Lateral Intercostal Block

Lateral intercostal block is best achieved at the posterior axillary line, 3 to 4 cm posterior to the midaxillary line (Fig. 102-25), prior to where the lateral cutaneous nerve pierces the intercostal muscles and divides into the anterior and posterior branches (see Fig. 102-21). The anterior branch supplies the skin and subcutaneous tissues of the anterolateral chest and abdominal wall as far as 7 cm from the midline, while the posterior branch supplies these tissues as far as 7 to 10 cm from the spine.

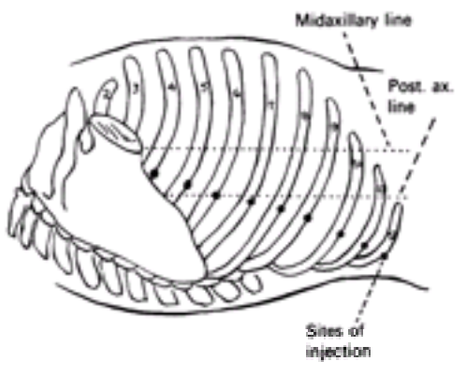

Figure 102-25. Lateral intercostal block along the posterior axillary line. The black dots indicate the sites of injection posterior to the exit of the lateral cutaneous branches. The technique for introducing the needle is similar to that shown in Figure 102-24.

When compared with posterior intercostal block, a lateral intercostal block with 3 to 4 mL of LA is less likely to spread to the paravertebral region and may be a better choice of technique when attempting to distinguish between somatic and visceral pain. For therapeutic use, however, lateral intercostal nerve block may not affect visceral pain, which may require supplemental systemic analgesics.

Continuous Intercostal Block

The practice of attempting to produce continuous intercostal nerve blocks by the insertion of catheters into intercostal spaces dates from the 1960s (108,109). More recently the placement of epidural catheters along the intercostal nerves at the end of an intrathoracic or renal operation, with the distal ends protruding through the closed incision (110), has been described.

Following the realization that the injection of a large volume of LA through a single intercostal injection produces multiple intercostal nerve blocks, techniques using this finding have been developed. An epidural catheter inserted into a single space and injected with 20 mL of 0.5% bupivacaine at intervals of 6 to 12 hours or a continuous infusion can sustain the analgesia after an initial injection has proven to be effective.

Intrapleural Block

The technique for intrapleural block (Fig. 102-26) (111) entails the insertion of an epidural Tuohy needle into the pleural space 8 to 10 cm from the posterior midline and the passage of an epidural catheter into the pleural space. The catheter is fixed in place and, after a negative aspiration, 0.5% bupivacaine with epinephrine is injected in amounts varying from 1 to 3 mg per kg body weight (i.e., 7 to 21 mL of 0.5% bupivacaine) (112). The technique produces unilateral analgesia, presumably because the LA diffuses through the pleural space in amounts sufficient to block the intercostal or paravertebral nerves. The block is maintained with repeat doses every 9 hours on average (range, 5 to 26 hours). In patients undergoing thoracotomy, the epidural catheter is introduced through a Tuohy needle one or two intercostal spaces above the incision, and the internal end of the catheter is loosely sutured next to the vertebra. In patients with thoracotomy, there is concern that intrapleural analgesia might be ineffective because LA may be removed through chest drains. This may be combated by clamping the chest drains for 10 to 15 minutes after injection of the LA (112). The technique may be used for various operations on the chest, upper abdomen, and breast and for herniorrhaphies. The technique may also be used for some more chronic pain problems, such as herpes zoster, chronic pancreatitis, and PHN, and to produce an upper extremity sympathectomy (113).

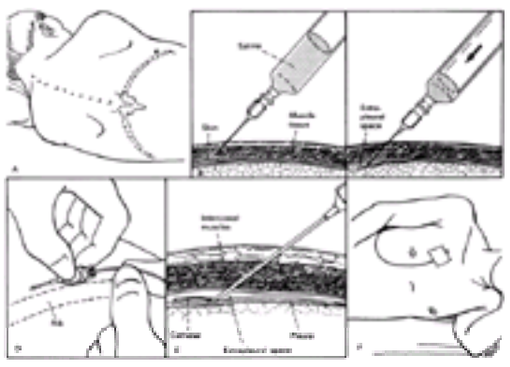

Figure 102-26. Intrapleural block. **A:** The patient lies on the unaffected side, resting comfortably on a pillow. The dot over the rib outline (*dashed lines*) shows the site of injection of a local anesthetic with a 25-gauge needle before insertion of the large Tuohy needle. **B:** A 17-gauge Tuohy needle attached to a syringe containing saline solution is introduced through the wheal with the bevel facing superficially as shown in E. The needle is directed so that its shaft makes a 60-degree angle with the skin. The needle is advanced slowly and carefully through the intercostal muscles and endothoracic fascia into the pleural space. **C:** The entrance of the bevel into the pleural space is indicated by the fact that the saline is sucked into the space by negative intrapleural pressure. **D:** Once the needle is in place, a catheter is introduced. **E:** The catheter is advanced 4 or 5 cm, the needle is removed, and the catheter is taped in place. **F:** The patient remains with the painful side uppermost, and 20 mL of 0.5% bupivacaine with epinephrine (average adult dose) is injected.

When repetitive injections of LA or infusions are used, caution must be exercised, as the resulting blood levels of LA may rise to within the toxic range (114).

Anterolateral and Anterior Intercostal Block

Anterolateral intercostal block (Fig. 102-27) is performed at the anterior axillary line proximal to the takeoff of the anterior cutaneous branches of the intercostal nerves. It is useful for poststernotomy and sternal fracture pain or pain in the abdominal distribution of the thoracoabdominal intercostal nerves (T-7 to T-10). In the latter case, the block is performed just proximal to the costochondral articulation. Figure 102-27 also depicts parasternal injection, done bilaterally to relieve sternal pain. Like lateral intercostal block, this block does not interrupt visceral nociceptive pathways. Patients with elements of visceral pain may require systemic analgesics or a combination of both.

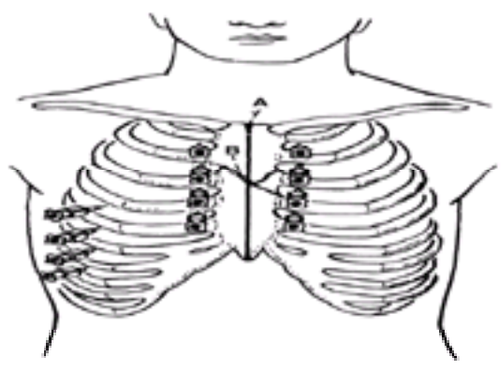

Figure 102-27. Anterolateral intercostal nerve block at the anterior axillary line (*right*). At this point the intercostal nerve and vessels lie between the internal intercostal muscle and the endothoracic fascia and pleura (see Fig. 102-24C). To relieve the pain of sternotomy (A) or fracture of the sternum (B), an anterior intercostal block is done 2 cm lateral to the lateral edge of the sternum; the block is supplemented with subcutaneous infiltration above the sternum and medial part of the clavicle to block the branches of the cervical plexus. The technique for introducing the needle is similar to that shown in Figure 102-25.

The most serious complication of percutaneous intercostal block is pneumothorax, with a quoted incidence ranging from 0.13% to 4.00% (102). Among a variety of nerve blocks, performed with a given mass of LA, intercostal nerve blocks produce among the highest peak blood levels of LA, because absorption of LA occurs at a faster rate and to a greater extent than after injection elsewhere (115,116). Hence, there is a clear potential for systemic toxic reaction, especially after injection of large therapeutic doses or repetitive blocks. Peak blood levels of LA can be reduced by adding epinephrine to the LA and by the use of an optimal concentration and reasonable volume of the drug (see Table 102-1). Inadvertent intravascular injection of drug is rare.

Although LA can spread to the paravertebral area following a percutaneous block, cardiovascular homeostasis is usually undisturbed. Following intrathoracic block (i.e., block done by the surgeon while within the thoracic cavity), hypotension or cardiovascular collapse has been reported to have been caused by SAB (117,118) or by widespread paravertebral block (119,120).

Rectus Block

Bilateral rectus block (Fig. 102-28) can be used to relieve midline abdominal incisional pain. As noted in Figure 102-21 and Figure 102-28, the anterior branch of the intercostal nerve enters the abdominal wall by passing behind the costal cartilages and entering the space between the transversus abdominis and internal oblique muscles. These anterior cutaneous nerves then pass medially within this space as far as the semilunar line, where they perforate the posterior sheath of the rectus abdominis muscle near its lateral margin. Within the sheath, they course between the posterior aspect of the muscle and the posterior sheath as far as the middle of the muscle, where they turn anteriorly and pass through the substance of the muscle and perforate its anterior sheath to become the anterior cutaneous nerves of the abdominal wall. While within the rectus sheath, they give off branches to the rectus abdominis muscles. Below the arcuate line, the rectus abdominis muscle lacks the posterior sheath and is separated from the peritoneum only by the transversalis fascia and extraperitoneal fat.

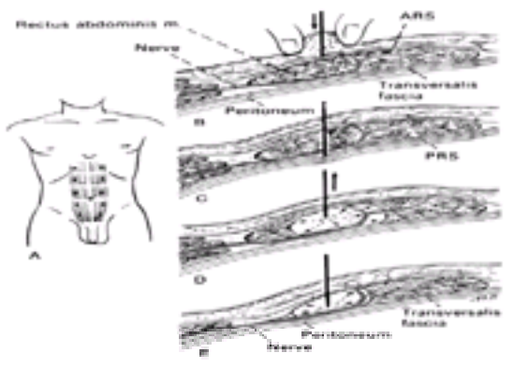

Figure 102-28. Rectus block (left side). **A:** Sites of insertion of the needle in the middle and slightly lateral part of each segment of the rectus muscle body, which can be palpated between the tendinous insertions. For an upper abdominal midline incision, the upper three sites are injected bilaterally, whereas the lower two or three sites are injected bilaterally for a lower midline incision. Skin wheals and injections of the superficial subcutaneous tissue are produced at the appropriate sites for the introduction of a 5-cm, 22- or 23-gauge, short-beveled needle attached to a Luer- Lok control syringe filled with a local anesthetic. The needle is then passed through the skin and subcutaneous tissue. **B:** Facilitating penetration of the skin by the short-beveled needle. The skin around the wheal is grasped between the thumb and second finger as the needle is passed through the skin and subcutaneous tissue and advanced until it meets the firm resistance of the anterior rectus sheath (*ARS*). The needle is advanced with steady pressure to penetrate the sheath. This is felt as a definite “snap.” **C:** The needle is advanced slowly through the softer belly of the

muscle until it meets a second site of resistance as it contacts the posterior rectus sheath (*PRS*). (The distance between the ARS and PRS should be noted to estimate the thickness of the muscle accurately.) **D:** As the needle rests on the PRS against which the nerve lies, 3 to 4 mL of local anesthetic solution is injected and the needle is withdrawn slowly. At the same time another 2 to 3 mL of solution is discharged within the belly of the muscle. **E:** Below the semicircular line of Douglas, the PRS is lacking and the nerve is against the transversalis fascia, which provides no resistance to the needle. Therefore, after penetration of the ARS, the needle is cautiously advanced for the same distance as noted for the upper levels of the muscle before injection of the anesthetic solution.

Rectus sheath block may be helpful in relieving abdominal pain following surgery, including laparoscopy (121).

Lumbar and Sacral Spinal Nerves

The lumbar and sacral nerves are considered here together because they both supply the pelvis and lower extremities and are often both involved in conditions that need analgesic block. Because these nerves, like those of the upper extremities, contain somatosensory, somatomotor, and sympathetic fibers, blockade can be used to manage the same disorders as those discussed in connection with block of the brachial plexus (see above).

Paravertebral Lumbar Somatic Nerve Block

Indications. Paravertebral block of the lumbar nerves is a useful diagnostic procedure for determining the specific nociceptive pathway(s) associated with vertebral, disk, or peripheral nerve pathology and for predicting the effects of blocking the nerves involved in spasm of leg muscles in patients with neurologic disease. For such blocks, the vertebral level of the needle placement and its closeness to the nerve must be verified radiographically and/or using a peripheral nerve stimulator. Lumbar paravertebral block may be used therapeutically for postnephrectomy pain or pain following lumbar vertebral fractures.

Technique. The anatomy of the lumbar and sacral nerves and the nerves derived from the lumbar and lumbosacral plexuses is described in Chapter 75 and illustrated in Figure 102-29. As they exit the intervertebral foramina, the lumbar nerves and plexuses are located in the psoas compartment formed by the posterior fascia of the psoas muscle anteriorly, the anterior fascia of the quadratus lumborum and the transverse processes and intertransverse ligaments posteriorly, and the bodies of the vertebrae medially. This has an important clinical application.

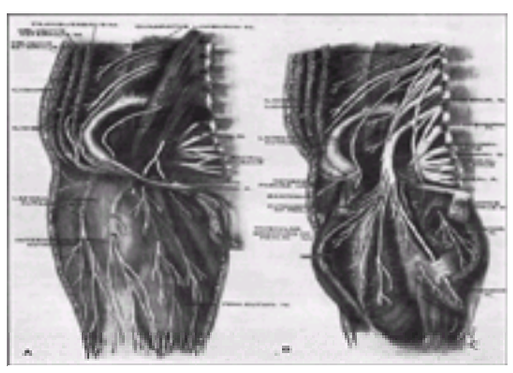

Figure 102-29. Anatomy of the lumbar and sacral nerves, lumbar and sacral plexus, and the nerves derived from these. **A:** Course of the iliohypogastric, ilioinguinal, lateral femoral cutaneous, and genitofemoral nerves. **B:** The iliopsoas, inguinal ligament, and deep fascia of the thigh have been removed to show the formation of the lumbar and sacral plexuses and the nerves derived from the lumbar plexus. The ilioinguinal and iliohypogastric nerves are derived from the anterior primary division of the L-1 nerve, while the lateral femoral cutaneous nerve is derived from the L-2 and L-3 nerves. The femoral nerve, which is derived from the L-2, L-3, and L-4 nerves, begins to divide into its muscular and cutaneous branches just behind (posterior to) the inguinal ligament and lateral to the femoral artery. The obturator nerve is formed within the substance of the psoas muscle by the union of the ventral branches of the anterior primary divisions of the L-2, L-3, and L-4 lumbar nerves. It emerges from the muscle and descends, accompanied by the obturator vessels, passes through the obturator foramen, and enters the upper thigh, where it breaks up into branches.

The technique for paravertebral block of the lumbar nerves is similar to that of blocking the thoracic paravertebral block (Fig. 102-30). For diagnostic or prognostic purposes, small volumes (e.g., 2 mL) of LA should be injected after radiographic verification of correct needle placement. For therapeutic purposes, 5 mL of LA should be used to achieve longer analgesia, but this is likely to spread, via the paravertebral area, to adjacent segments. Indeed, because the lumbar nerves and plexus are located in the psoas compartment (see Fig. 102-29), injection of 25 to 30 mL of LA solution through one needle placed at L-3 or L-4 and advanced 1 cm anterior to the transverse process to place it in the compartment will cause the solution to diffuse cephalad and caudad sufficiently to block all the sympathetic nerves, the lumbar plexus, and even the lumbosacral trunk. A special technique for “psoas compartment block” has been described (122), but it is more complicated and is associated with a higher incidence of failure to block the lumbar plexus completely than the technique described here.

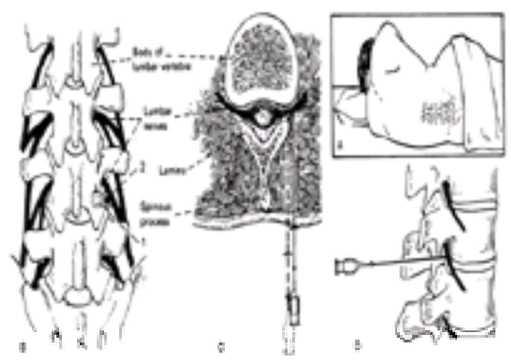

Figure 102-30. Lumbar paravertebral somatic block. **A:** Position of the patient (sterile drapes omitted for clarity). After identifying the spinous process of the appropriate vertebra (or vertebrae) and marking it with an indelible pen or marker, the skin is prepared with an antiseptic solution and a skin wheal is raised 1.5 cm lateral to the upper portion of the quadrilaterally shaped spinous process. Using a 5-cm, 25-gauge needle, the subcutaneous and deeper structures are infiltrated with 5 to 7 mL of a dilute solution of local anesthetic (e.g., 0.5% lidocaine or 0.125% bupivacaine) until contact with the lamina of the vertebra is made. This infiltration should produce a region of analgesia about 2 cm in diameter for the painless introduction and advancement of an 8-cm, 22-gauge, short-beveled needle. **B,C:** The 22-gauge needle is inserted perpendicular to the skin in a parasagittal plane and advanced until it makes contact with the upper lateral part of the ipsilateral lamina of the vertebra (*dashed line* of hub of needle; step 1). Care should be taken so that the point of the needle contacts the uppermost part of the lateral edge of the lamina, because this is at the same cross-section level as the nerve as it exits from the intervertebral foramen. Once the lamina is contacted, a rubber marker is placed on the needle shaft 1.5 cm from the skin, the needle is withdrawn until its point is subcutaneous, and the needle is then moved laterally about 0.5 cm. The needle is advanced until either the lateral edge of the lamina is contacted or the needle passes so that the marker is flush with the skin and its point makes contact with the nerve, eliciting paresthesia (step 2). It might be necessary to carry out a second or third insertion before the needle passes just lateral to the edge of the lamina. Because of the large size of the lumbar nerves, contact usually is easily made and paresthesia elicited. If difficulty is encountered, a nerve stimulator is helpful. **D:** Lateral view to show position of needle.

Complications. Complications of lumbar paravertebral block are similar, with the exception of pneumothorax, to those of thoracic paravertebral block.

Transsacral Block

Indications. Block of one or more of the sacral nerves by the transsacral technique is used for diagnostic or prognostic purposes. Block of the S-1 nerve is useful for determining specific nociceptive pathways in patients with herniated intervertebral disk of this nerve root. Block of the S-2, S-3, and S-4 nerves is also useful as a diagnostic or prognostic procedure in patients with perineal pain and can help to define specific nociceptive pathways in patients with pain in pelvic structures, such as the bladder or prostate. Because pudendal nerve block does not involve the nerves to the leg, it is preferable to transsacral block for acute pain in the perineum.

Technique. The technique for transsacral nerve blocks is illustrated in Figure 102-31. For diagnostic or prognostic purposes, a small volume of LA (e.g., 2 mL) should be used. For therapeutic purposes, a larger volume (e.g., 3 to 5 mL) can be used.

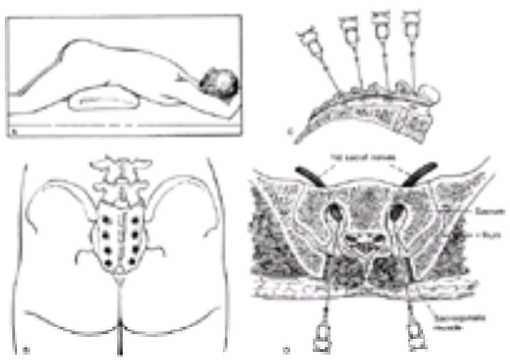

Figure 102-31. Transsacral nerve block. **A:** Position of the patient. **B:** Posterior view of the sacrum showing location of points of insertion. **C:** Sagittal view showing directions of needles. **D:** Cross section showing needles in position for block of the first sacral nerves. After identifying the posterior superior iliac spine and the sacral cornu on the ipsilateral side, a line is drawn between a point 1.5 cm medial to the spine and a point 1.5 cm lateral and cephalad to the ipsilateral cornu. For block of the S-1 nerve, a wheal is made on the drawn line, 1.5 cm cephalad to the level of the iliac spine. For block of the S-2 nerve, the wheal is made 1.5 cm below the level of the iliac spine. Because some variation exists in the location of the foramina, it is necessary to make a systematic search until the needle is felt to go through the posterior foramen to the transsacral canal. Contact with the nerve produces paresthesia.

Complications. Accidental intravenous injection is possible but, as the volume of LA is small, toxic effects are unlikely. Neuronal damage, either direct or by compression, is possible as the nerves are blocked within a bony canal of finite volume.

Femoral Nerve Block

Indications. Block of the femoral nerve just below the inguinal ligament can be used as a diagnostic procedure in patients with severe anterior thigh pain or it can be used, along with a sciatic nerve block, to produce sympathetic interruption of the lower limb. The most common use is for posttraumatic or postoperative pain in the region of the distribution of the femoral nerve, femoral fractures, and femoral and knee operations (123,124).

Technique. The anatomy of the femoral nerve is described in Chapter 75. Figure 102-32 describes the technique for femoral nerve block. The nerve usually does not branch until it emerges from beneath the inguinal ligament and, hence, the nerve trunk can easily be located by paresthesia or with a stimulator. In some individuals, however, the nerve divides into several branches above the inguinal ligament, and it is more difficult to contact these small nerves. Usually 8 to 10 mL of 1% lidocaine with epinephrine produces analgesia for 3 to 4 hours, and 8 to 10 mL of 0.25% bupivacaine with epinephrine produces analgesia for 6 to 8 hours. If longer analgesia is required, the concentration of the bupivacaine can be increased to 0.5% with epinephrine or a continuous block can be used by placing a catheter as described in Figure 102-33.

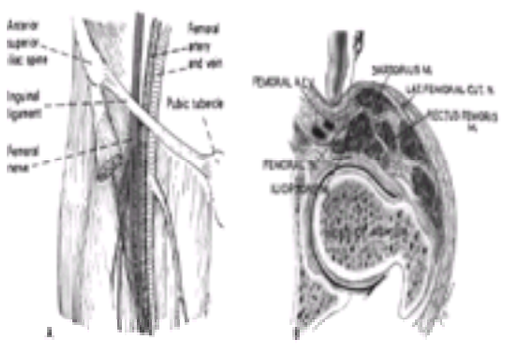

Figure 102-32. Blocking the femoral nerve. **A:** Anterior view of the region showing the relation of the femoral nerve to the artery and vein. **B:** Cross section of the femoral nerve just below the inguinal ligament. With the patient lying supine, a line is drawn joining the anterior superior iliac spine and the pubic tubercle. The midpoint of this line usually overlies the femoral artery, which is easily palpated. After preparation of the skin, a skin wheal is raised 1 cm lateral to the junction of the femoral artery and inguinal ligament. With the second finger of the left hand palpating the artery, a 5-cm, 22- or 25-gauge, short-beveled needle is introduced through the wheal perpendicular to the skin and advanced until paresthesia is elicited in the distribution of the femoral nerve. If paresthesia is not elicited, a nerve stimulator can be used. If a continuous block of this nerve is needed, a 5-cm, 20-gauge intravenous catheter can be introduced so that its shaft makes an angle of 60 degrees with the skin distal to the point of insertion, which aids in threading the catheter into the femoral sheath (see Fig. 104-35 for details of insertion).

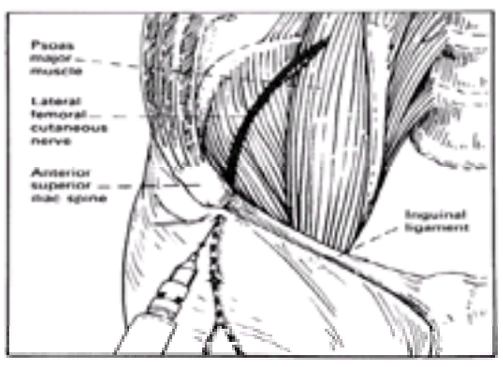

Figure 102-35. Lateral femoral cutaneous nerve block. After preparation of the skin, a wheal is produced 1.5 cm caudad to the anterior superior iliac spine just below the inguinal ligament. A 5-cm, 22- or 25-gauge, short-beveled needle is introduced through the skin wheal with its shaft at an angle of about 60 degrees with the skin. The needle is advanced until paresthesia is elicited or the bone is contacted. In the latter case, the needle should be withdrawn until its point is subcutaneous and the skin wheal moved 0.5 cm lateral and superior; the needle is then reinserted and advanced until paresthesia is elicited. The nerve is usually located by making several insertions through the same wheal in a line parallel to the inguinal ligament. A volume of 5 to 8 mL of local anesthetic is injected.

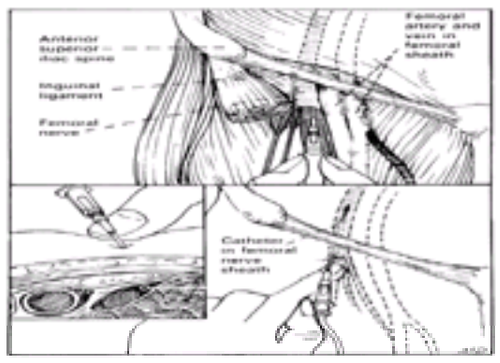

Figure 102-33. Continuous inguinal perivascular block. **A:** Following preparation of the skin with an antiseptic, an intracutaneous wheal is formed 1 cm lateral to the palpable femoral artery and 1 cm below the inguinal ligament. A 5-cm, 18-gauge, Teflon-coated intravenous catheter threaded over a 9-cm, 22-gauge spinal needle is used. It might be necessary to make a small skirt incision to facilitate introduction of the intravenous catheter through the skin. The needle is introduced through the skin wheal and advanced cephalad parallel to the artery, with its shaft making a 30-degree angle with the skin distal to it. This angle permits the catheter to be advanced within the sheath cephalad and minimizes damage to the nerve. **B:** Entrance into the tough sheath that surrounds the femoral nerve can be felt as a click or snap. The catheter is advanced about 3 cm within the sheath, the needle is removed, and the catheter is fixed in place. Once the catheter is in place, aspiration is carried out; if negative, 30 mL of solution is injected while the second finger of the left hand presses forcefully on the artery just distal to the entrance of the catheter (inset), thus forcing the fluid to flow proximally. With this volume of solution, block of the femoral, lateral femoral cutaneous, and obturator nerves is achieved.

Complications. The only possible complication of femoral nerve block involves accidental intraarterial or intravenous injection if the needle is placed medially.

Obturator Nerve Block

Obturator nerve block can be used as a diagnostic or prognostic procedure in patients with adductor muscle spasm and pain caused by neurologic injury.

Technique. The technique for obturator nerve block is described in Figure 102-34. Because the nerve is not close to bony landmarks but is located in the center of the obturator canal, it is desirable to use a peripheral nerve stimulator to ensure accurate needle placement. Usually injection of 10 to 15 mL of 1% lidocaine with epinephrine produces analgesia for 3 to 4 hours. With injection of 0.25% bupivacaine with epinephrine, the duration of analgesia is increased to 6 to 8 hours, and with 0.5% bupivacaine it can be as long as 8 to 12 hours.

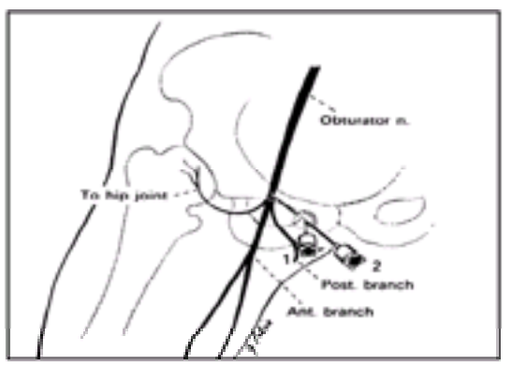

Figure 102-34. Obturator nerve block. The pubic tubercle is located and marked with the patient lying supine. After preparation of the skin, a wheal is raised 1.5 cm lateral and inferior to the tubercle. An 8-cm, 22-gauge needle is introduced through the wheal perpendicular to the skin and advanced posteriorly until contact is made with the inferior ramus of the pubis (*1*). A needle marker is placed 2.5 cm from the skin, and the needle is withdrawn until its point is in the subcutaneous tissue. The point of the needle is redirected in a lateral and slightly superior direction so that the shaft of the needle is parallel to the superior ramus of the pubis. The needle is slowly advanced while its point is kept in contact with the inferomedial surface of the superior ramus of the pubis, until the marker is flush with the skin or contact with the bone is lost (*2*). Because paresthesia is often difficult to elicit, a nerve stimulator is used to position the point of the needle on the nerve. A volume of 10 to 15 mL of local anesthetic is injected.

Complications. Accidental injection into the obturator vein is likely to produce a mild systemic reaction.

Lateral Femoral Cutaneous Nerve Block

Indications. Lateral femoral cutaneous nerve block is done primarily as a diagnostic procedure in patients with pain in the anterolateral thigh, especially those who have a presumptive diagnosis of meralgia paresthetica.

Technique. The technique for lateral femoral cutaneous nerve block is described in Figure 102-35. Injection of 5 to 8 mL of lidocaine with epinephrine produces analgesia for 3 to 4 hours. With 5 to 8 mL of 0.25% bupivacaine with epinephrine, analgesia lasts for 6 to 8 hours, and with 0.5% bupivacaine with epinephrine, it lasts for 8 to 12 hours.

Complications. Complications are rare and consist of transient neuropathy in cases of accidental damage to the nerve.

Inguinal Perivascular (Three-in-One) Block

The lumbar plexus nerves, like those of the brachial plexus, are invested in a fascial sheath that originates from the transverse processes of the vertebrae and continues distally to enclose the plexus. This sheath forms a cone whose apex is at the femoral canal. By introducing a large volume (30 mL) of LA into the femoral nerve sheath at the femoral canal and obstructing the sheath distal to the point of injection, LA flows proximally within the sheath. The LA may spread as far as the paravertebral region, bathing the lumbar nerve roots, thus producing block of the femoral, lateral femoral cutaneous, and obturator nerves in a high proportion of cases (125).

Indications. Block of these three nerves can be used for postoperative or posttraumatic pain in the area supplied by these nerves. This technique, combined with block of the sciatic nerve, produces analgesia of the entire lower limb and sympathetic block of the foot, leg, and lower two-thirds of the thigh. It can therefore be used to confirm the effects of lumbar sympathetic block when the results of the latter technique are in doubt. The technique can produce complete paralysis of the muscles of the lower limb when attempting to differentiate limitation of motion and deformity caused by reflex muscle spasm from that produced by irreversible changes in muscles and tendons, as discussed in connection with brachial plexus block (see above).

Technique. The technique for the inguinal perivascular or (three-in-one block) is similar to that described for femoral nerve block, with slight modifications (see Fig. 102-33). Injection of 30 mL of 0.25% or 0.50% bupivacaine with epinephrine produces analgesia of the three nerves for 8 to 16 hours. To produce prolonged analgesia, a catheter is inserted into the femoral sheath and LA is infused at a rate of 10 mL of 0.25% bupivacaine per hour (126).

Complications. Complications can include accidental intravenous or intraarterial injection or damage to the femoral nerve.

Sciatic Nerve Block

Indications. The sciatic nerve contains most of the sensory and sympathetic fibers of the leg. Thus sciatic nerve block can be used to control posttraumatic or postoperative pain in its distribution or to produce a sympathectomy of the leg. By combining sciatic nerve block with a three-in-one block, analgesia and sympathetic interruption of the entire lower limb can be achieved. The indications for these procedures are similar to those described for brachial plexus block for the upper limb (see above).

Technique. The anatomy of the sciatic nerve; the peripheral nerve supply to the skin, muscles, and bones of the lower limb; and the sympathetic nerve supply to the vessels of the lower limb are described in Chapter 75. The anatomy of the sciatic nerve and its major branches is shown in Figure 102-36.

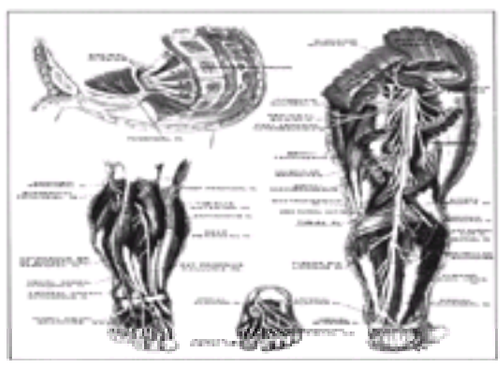

Figure 102-36. Anatomy of the sacral plexus **(A)** and of the sciatic, tibial, and peroneal nerves and their branches **(B,C). D:** Plantar surface of the foot. Block of the sciatic nerve is usually performed just below the piriformis muscle. See Chapter 70 and Chapter 75 for a detailed description of these nerves.

To block the sciatic nerve, the classic approach of Labat (127) (Fig. 102-37) or the lateral approach (Fig. 102-38) (128) is used. The lateral approach is technically challenging but useful in patients who cannot move to the lateral position required for Labat's technique.

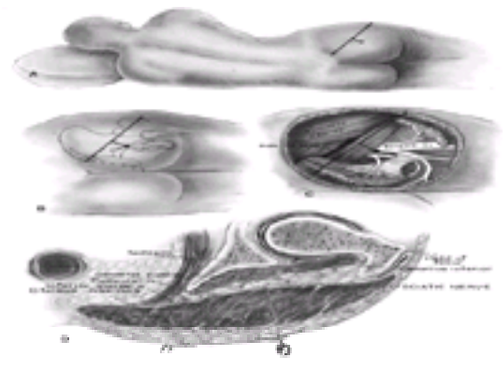

Figure 102-37. Labat's sciatic nerve block technique. **A:** The patient lies in a modified Sims position. A line is drawn between the posterior superior iliac spine and the superior border of the greater trochanter of the femur. The line is bisected at its midpoint and a perpendicular line 3 cm long passes caudad to it, with a solid dot indicating the site of the skin wheal and site of subsequent insertion of the block needle. **B:** Relation of the line to the bone and nerve. **C:** Relation of the nerve to muscles, with the lines superimposed. Following the creation of a skin wheal and infiltration of subcutaneous tissue, a 10-cm, 22-gauge security needle is introduced in a direction perpendicular to the skin and advanced until paresthesia is obtained or bone is contacted. In the latter case, the needle is withdrawn until its point is subcutaneous and is directed a little more obliquely, either cephalad or caudad. Several such explorations should be sufficient to locate the nerve. If difficulty is encountered, a nerve stimulator can be used to locate the nerve. **D:** Bevel of the needle on the nerve to elicit paresthesia, which radiates to the leg and foot. Bone depth varies from 5 cm in thin individuals to 8 cm in obese or muscular patients. If the landmark has not been determined accurately or if the needle has been improperly inserted, its point can miss the nerve and bone completely; if advanced too far, the needle can enter the pelvis.

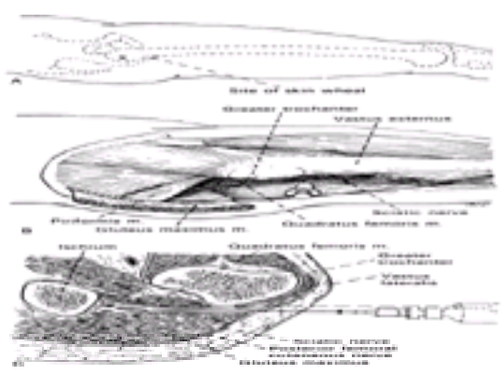

Figure 102-38. Sciatic nerve block by the lateral approach. **A:** With the patient supine the outline of the femur (*dashed lines*) is drawn. An *X* indicates the most prominent part of the greater trochanter. The skin wheal indicates the point of penetration of the skin. **B:** View of the right thigh with the skin and subcutaneous tissue removed to show the relationship of the sciatic nerve to muscles. The sciatic nerve is anterior to the gluteus maximus and posterior to the quadratus femoris, which has been cut. The syringe is positioned so that the point is on the nerve. **C:** Cross-sectional view illustrating the technique. Following preparation of the skin and creation of a skin wheal, a dilute solution of local anesthetic (e.g., 0.125% bupivacaine) is introduced through the skin wheal using a 5-cm, 25-gauge needle attached to a 10-mL Luer-Lok syringe containing the anesthetic solution. The needle is advanced slowly through the skin, subcutaneous tissue, and vastus lateralis until it contacts the posterior surface of the greater trochanter. While the needle is steadily advanced, the local anesthetic solution is injected into the subcutaneous tissue and the fascia of the muscle, with 1 or 2 mL injected into the periosteum. The depth of contact should be noted. The needle is then withdrawn until its point is in the subcutaneous tissue, the skin is moved 1 cm posteriorly and advanced in a trajectory parallel to the first injection, and dilute solutions of the local anesthetic are injected. These leave a track of anesthesia for the subsequent painless introduction of the larger needle. A 12- or 15-cm, 22-gauge needle is adapted to a 10-mL Luer-Lok control syringe containing a solution of greater strength of the local anesthetic (e.g., 0.5% bupivacaine with epinephrine) and these two steps are repeated. When the point of the larger needle contacts the periosteum or the posterior surface of the greater trochanter, the depth is noted and the needle is withdrawn until its point is in the subcutaneous tissue, and the skin is moved 1 cm posteriorly in the same fashion as earlier. The shaft of the needle should be parallel to the floor of the room. The needle is then slowly advanced. Normally, when the needle has advanced twice the distance of that in the first step, it should come in contact with the sciatic nerve and elicit paresthesia. If paresthesia is not elicited and the needle encounters bone (representing the ischial tuberosity), it is withdrawn and reinserted 2 or 3 mm anterior to its position in the second step and advanced. It might be necessary to make several penetrations before the nerve is contacted. If further difficulty is encountered in eliciting paresthesia, a nerve stimulator should be used. Special caution should be exercised in advancing the needle slowly and stopping as soon as the patient experiences paresthesia, because if the needle penetrates the nerve some axons could be damaged. It is important to inject the solution around rather than inside the nerve, because rapid expansion could also cause axonal damage. With experience and care it becomes easier to determine when the injection is extraneural because of lack of resistance. If the point of the needle is in the nerve, however, resistance can be felt and the patient experiences paresthesia during the

injection.

Efforts to achieve continuous sciatic nerve block, by introducing a catheter through a large needle and having its tip on the sciatic nerve, have historically been unsuccessful because movement of the leg can displace the tip of the catheter from the nerve. A technique for continuous sciatic nerve block has been described (129).

For single-dose techniques, injection of 10 to 15 mL of 0.25% to 0.50% bupivacaine provides analgesia for 8 to 12 hours. For the continuous technique, hourly infusions of 5 to 8 mL of 0.25% bupivacaine are used (129).

Complications. Complications include inadvertent intravascular injection and neural damage.

Nerve Block at the Knee, Ankle, and Foot

The nerves to the leg and foot can be blocked at the level of the knee to produce analgesia, sympathetic blockade, or both (Fig. 102-39). The tibial and common peroneal (lateral popliteal) nerves can be blocked in the popliteal fossa. The common peroneal nerve can also be blocked as it winds around the neck of the tibia, while the saphenous nerve can be blocked as it lies on the medial condyle of the tibia, at the cross-sectional level of the apex of the patella (Fig. 102-40).

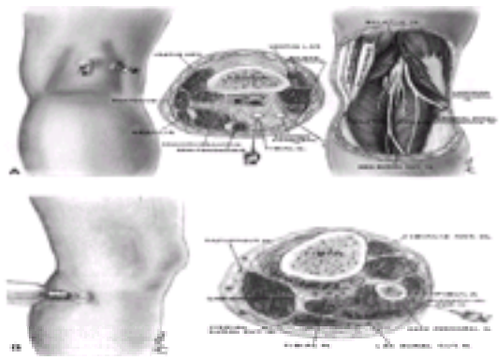

Figure 102-39. Block of the three major nerves at the level of the knee. **A:** Block of the tibial and peroneal nerves in the popliteal fossa: With the patient in the prone position, the bend of the knee is determined by having the patient flex the leg 90 degrees on the thigh and the junction of the two cutaneous surfaces is traced on the skin. After skin preparation, the popliteal artery is palpated 2 cm above the bend of the knee and a skin wheal is raised 1 cm lateral to this point. A 5-cm, 22- or 25-gauge needle is introduced through the wheal in a direction perpendicular to the skin and advanced slowly until paresthesia radiating to the back of the leg and sole of the foot is elicited, whereupon 5 mL of local anesthetic solution is injected without moving the knee. If paresthesia is not obtained, the nerve can be found by systematic exploratory fanwise insertions made in the mediolateral plane. To block the peroneal nerve, the posteromedial margin of the biceps femoris is palpated at about the same level as that for tibial block. A skin wheal is raised just medial to the edge of the biceps femoris muscle, and a 5-cm, 22- or 25-gauge needle is introduced through it. The needle is made to pass just medial to the inner margin of the biceps and is slowly advanced until paresthesia radiating to the anterolateral aspect of the leg and dorsolateral aspect of the foot is elicited, whereupon 5 mL of solution is injected. Analgesia occurs within 5 to 8 minutes. An alternate method of blocking both nerves with one needle involves injection of 10 to 15 mL of solution when the tibial nerve is blocked. Because the two nerves are located in loose areolar tissue, the drug easily diffuses to block both nerves. **B:** Block of the peroneal nerve at the neck of the fibula: With the patient in the supine or lateral position, the head of the fibula and the depression just below it, which is the neck of the fibula, are palpated. By moving the finger up and down, the cordlike common peroneal nerve can be palpated. It is not necessary to make a skin wheal if a 25-gauge, 2.5-cm needle is used. With the nerve held stationary by the index finger of the left hand, the needle, attached to a 10-mL Luer-Lok syringe, is introduced through the skin in a direction perpendicular to it and slowly advanced until the nerve is gently contacted, as indicated by paresthesia. A volume of 3 to 4 mL of solution is sufficient to block the nerve.

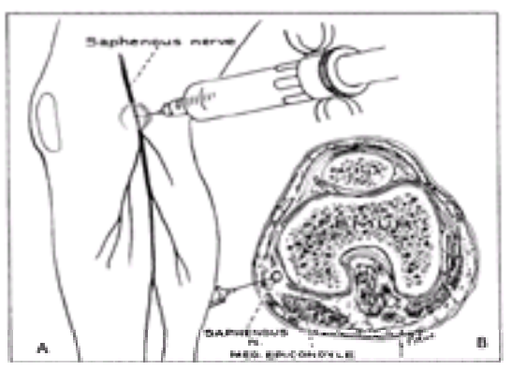

Figure 102-40. Blocking the saphenous nerve at the knee: After preparation of the skin with the patient in the supine or lateral position, a wheal is raised on the skin **(A)** over the medial surface of the medial condyle of the femur at the cross-sectional level of the apex of the patella **(B)**. A 5-cm, 25-gauge needle is inserted through the wheal in a direction perpendicular to the skin and advanced slowly until paresthesia along the saphenous nerve is elicited or until the bone is contacted. Several exploratory fanwise insertions are usually sufficient to locate the nerve, which is usually blocked with 3 to 5 mL of local anesthetic solution.

Analgesia and sympathetic blockade of the foot can be achieved by blocking the deep peroneal and tibial nerves about 2 cm above the level of the malleoli (Fig. 102-41). Block of these two nerves, plus a subcutaneous infiltration around the ankle, produces analgesia of the entire foot.

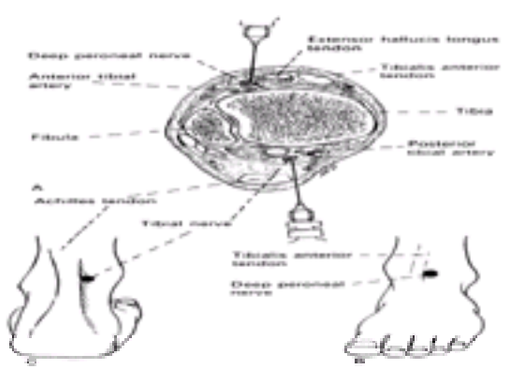

Figure 102-41. Blocking the tibial and deep peroneal nerves at the ankle. **A:** Cross section of the ankle just above the level of the malleoli. **B,C:** Anterior and posterior views showing sites of injection. The deep peroneal nerve is blocked by palpating and identifying the tendon of the extensor hallucis proprius and the anterior tibial artery. The nerve is situated between these two structures. With the patient in the supine position and the tendon and artery identified, a 5-cm, 25-gauge needle is introduced through the skin **(B)**, without making a preliminary skin wheal, and slowly advanced until paresthesia is elicited. If the nerve is not contacted before the needle point impinges on the anterior surface of the tibia, the needle is withdrawn until its level is subcutaneous and then reinserted so that its point is directed a little more laterally. The nerve is usually located with several fanwise insertions made along a transverse line across the ankle. Injection of 3 to 5 mL of local anesthetic

solution is sufficient to produce a complete block. **A,C:** The posterior tibial nerve is blocked at the level of the malleoli. **C:** A skin wheal is raised at this level just medial to the medial border of the Achilles tendon and just lateral to the palpable posterior tibial artery **(A)**. A 5-cm, 25-gauge needle is introduced in an anterior direction and advanced until paresthesia is elicited or until the posterior aspect of the tibia is contacted without paresthesia. In the latter case, the needle is withdrawn and reinserted so that its point is directed a little more medially. With several fanwise insertions in the cross-sectional plane, the nerve can usually be located. Injection of 3 to 5 mL of local anesthetic solution is sufficient to effect a complete block. Block of these two nerves, together with a subcutaneous infiltration around the ankle to block the subcutaneous sural, saphenous, and superficial peroneal nerves, produces complete anesthesia of the foot.

Block of the digital nerves is indicated for severe pain involving one or more fingers or toes, the distal portion of the metatarsal bones, or the bones of one or more toes (Fig. 102-42). LA with epinephrine should not be used for digital blocks as solution is injected close to the digital arteries. Because they are end arteries, diminution in blood flow in the digital arteries could lead to digital ischemia.

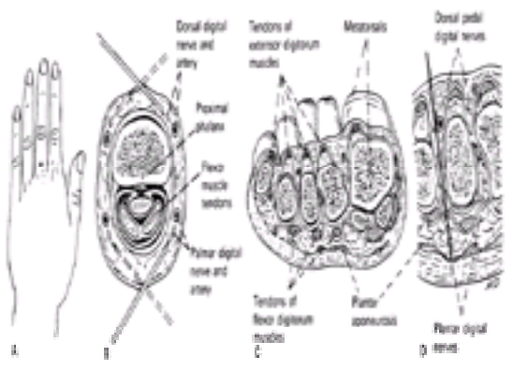

Figure 102-42. Blocking digital nerves. **A,B:** Block of the digital nerves in the fingers. **A:** An intracutaneous wheal is created on the dorsal and volar surfaces of the finger, and a 2-cm, 25-gauge needle is introduced. **B:** The needle is directed first to one side and then the other; 1.5 to 2.0 mL of 0.25% bupivacaine *without* epinephrine is injected at each site. Because the four digital nerves are in the same fascial space, the solution diffuses to produce complete anesthesia of the finger distal to the site of injection. **C:** Cross-sectional view of the foot at the metatarsal level. **D:** Relationship of the dorsal and plantar digital nerves. Skin wheals are raised on the dorsal pedal surface of the foot over each metatarsal space that bounds the toe (or toes) to be anesthetized. A 5-cm, 25-gauge needle is inserted and advanced toward the plantar surface until its point meets the resistance of the plantar aponeurosis. The needle is withdrawn 5 mm, and 2 to 3 mL of local anesthetic solution is injected to block the plantar digital nerves. The needle is then withdrawn, slowly injecting 1 or 2 mL of solution between the plantar and dorsal surfaces. When the point of the needle is at the dorsal subcutaneous space 2 to 3 mL is injected, for a total of 5 mL of anesthetic solution for each metatarsal interspace.

Pudendal Nerve Block

Indications. Block of one or both pudendal nerves is a useful diagnostic procedure in perineal pain and can be used for postoperative or posttraumatic pain in the perineum. If the pain is on one side of the perineum, a unilateral block is sufficient, but often it is necessary to carry out a bilateral pudendal nerve block.

Technique. The optimal site for injecting the pudendal nerve is just posterior to the attachment of the sacrospinous ligament to the ischial spine. In the female this can be done transvaginally, and in the male a transperineal approach can be used (Fig. 102-43). Usually 5 to 7 mL of 0.25% bupivacaine is sufficient to produce block of the nerve on one side.

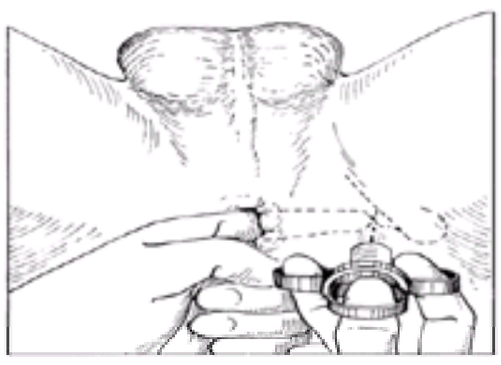

Figure 102-43. Pudendal nerve block by the transperineal approach. With the patient in the lithotomy position, the perineum is prepared and a skin wheal is made about 2.5 cm posteromedial to the tuberosity of the ischium and the subcutaneous tissue is infiltrated with a dilute solution of LA (e.g., 0.25% lidocaine). The small needle is then exchanged for a 12-cm, 22-gauge needle with a security bead, which is inserted perpendicular to the skin. The index finger of the left hand (*dashed lines*) is inserted into the rectum, first to palpate the spine of the ischium and the sacrospinous ligament and then to guide the needle just posterior to the junction of these two structures, which is the optimal site for injection of the nerve. The needle is slowly advanced through the ischiorectal fossa toward the ischial spine by having it pass behind to the urogenital diaphragm and levator ani muscle. As the needle approaches the ischial spine, it is pushed posterior to it by the guiding finger. After attempting to aspirate in two planes to ensure that the point of the needle is not in a blood vessel, 5 to 7 mL of local anesthetic solution (e.g., 0.25% bupivacaine) is injected just posterior to the tip of the spine.

Complications. Inadvertent block of the sciatic nerve and inadvertent intravascular injection are complications of pudendal nerve blocks.

Penile Nerve Block

Indications. Penile nerve block can be used as a diagnostic procedure, but its most important application is providing postoperative analgesia subsequent to penile operations, particularly circumcision in infants and children.

Technique. The anatomy of the dorsal nerve to the penis is described in Chapter 70 and depicted in Figure 70-17. The technique for blocking the dorsal nerve of the penis is described in Figure 102-44. The recommended dose of 0.25% plain bupivacaine (epinephrine strictly contraindicated) is 1 mL for infants up to 1 year of age, 3 mL for children 1 to 5 years of age, 4 to 5 mL for those 6 to 12 years of age, and 5 to 7 mL for those 13 years of age or older (130,131 and 132).

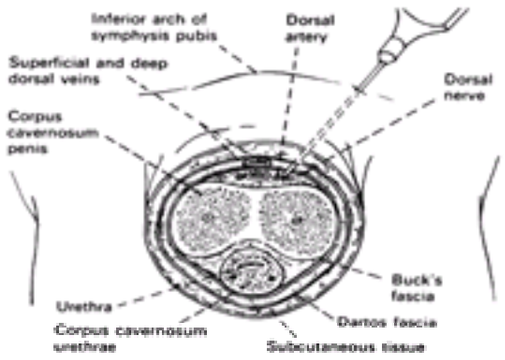

Figure 102-44. Penile nerve block: The dorsal nerves of the penis can be blocked as they pass from the pelvis to the penis. With the patient in the supine position, the skin over the symphysis pubis and the base of the penis is cleansed with antiseptic solution. The inferior border of the symphysis pubis is identified, and a mark is made at a level 1 cm from the midline. In an adult, a 3-cm, 25-gauge needle is used, but in infants a 1-cm, 30- gauge needle adapted to a Luer-Lok control syringe containing the local anesthetic solution is introduced through the mark and directed toward the midline at an angle of 30 degrees to the skin. As the needle advances, it pierces the skin, subcutaneous tissue, dartos fascia, and Buck's fascia, which can be felt as a click. Once the needle has pierced the fascia, which is 4 to 6 mm deep, an attempt at aspiration of blood is made and, if negative, 0.25% plain bupivacaine solution is injected. (The volumes to be injected, according to the age of the patient, are listed in the text.)

Complications. Complications include puncture of the corpus cavernosum or the dorsal vessels of the penis, but if a thin (27- or 30-gauge) needle is used and intravascular injection is avoided, no serious complications develop.

BLOCK OF THE SYMPATHETIC NERVOUS SYSTEM

The functional relationship between the sympathetic nervous system and many disease syndromes has long been recognized. Moreover, much experimental and clinical evidence has been accumulated to indicate that interruption, by LA or neurolytic blocks, of certain portions of the sympathetic nervous system has beneficial effects in many of these disorders (1,2 and 3). Figure 102-45 depicts the entire sympathetic chain.

Figure 102-45. Anatomy of the autonomic nervous system depicting the position of the right sympathetic trunk, its branches, and the prevertebral ganglia.

Peripheral sympathetic pathways can be interrupted at a variety of sites: (a) the subarachnoid space; (b) the epidural space; (c) the paravertebral and prevertebral regions; (d) the peripheral nerves; and (e) the endings of postganglionic axons (Fig. 102-46). Because subarachnoid, epidural, and peripheral nerve blocks are discussed elsewhere in this chapter, this section is limited to paravertebral and prevertebral sympathetic blockade. Individual segmental paravertebral injections are preferable for diagnostic and prognostic blocks because specific sympathetic pathways can be blocked by a small volume of LA. This is also true when alcohol or phenol is to be used for therapeutic block where the volume is limited to 2 to 3 mL of solution. If the use of a large a large volume of LA is acceptable, blocking individual segments is unnecessary as the anatomic configuration of the sympathetics is such that they can be interrupted at certain “key” regions: cervicothoracic, celiac, and lumbar regions (Fig. 102-47).

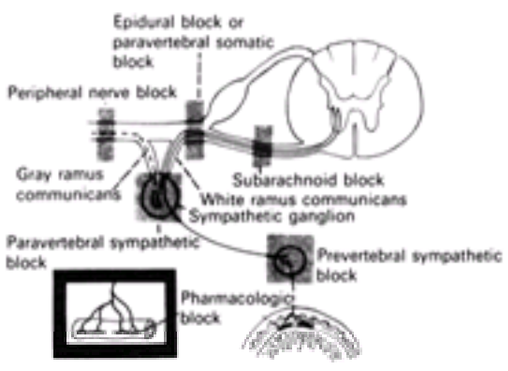

Figure 102-46. The course of preganglionic and postganglionic sympathetic fibers and techniques that can be used to interrupt them. (Modified from Bonica JJ. *Clinical applications of diagnostic and therapeutic nerve blocks.* Springfield, IL: Charles C Thomas Publisher, 1959.)

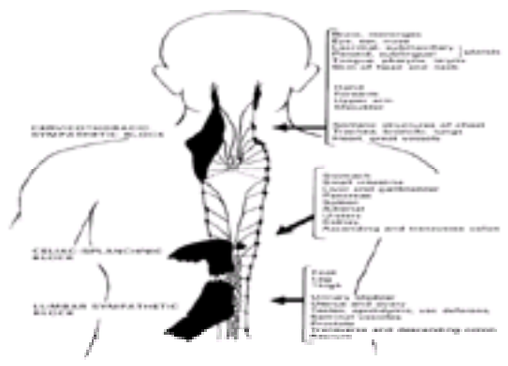

Figure 102-47. Three critical sites that can be used to interrupt the peripheral sympathetic nervous system. Left: Pattern of diffusion (*black*) of local anesthetic solutions injected in the vicinity of the cervicothoracic (stellate) ganglion, celiac plexus, and lumbar sympathetic ganglia. Injection of 15 to 20 mL of local anesthetic solution into the proper fascial plane near the stellate ganglion spreads sufficiently to involve the sympathetic chain from the lower portion of the superior cervical ganglion to the T-5 ganglion, so that all the sympathetic fibers to the head and neck, upper extremities, and the heart, and most of the fibers to the esophagus and lungs, are interrupted. Injection of 15 to 25 mL of solution bilaterally near the celiac plexus spreads sufficiently to interrupt all the sympathetic (and vagal) efferent fibers to and afferent fibers from the viscera in the upper abdomen. Injection of 15 to 20 mL of solution through a needle with its tip at the anterolateral surface of the

L-2 or L-3 vertebra interrupts all the sympathetic fibers to the ipsilateral lower extremity and pelvis. These sympathetic nerve structures are apparently contained within fascial planes that can be considered as relatively closed spaces (or even pouches) that facilitate the spread of the local anesthetic solution, so that an extensive sympathetic block is produced. Right: Names of the structures that are denervated with each block. (Modified from Bonica JJ. *Clinical applications of diagnostic and therapeutic nerve blocks.* Springfield, IL: Charles C Thomas Publisher, 1959.)

With paravertebral or prevertebral techniques, the LA (or neurolytic) solution interrupts all efferent and afferent fibers. In contrast, the more recently developed technique for blocking sympathetic function to a limb by intravenous injection of guanethidine or other adrenolytic agents by the Bier technique (see below) blocks only efferent impulses.

Indications

Complex Regional Pain Syndromes, Types I and II

Block of the sympathetic pathways to the limbs is an important mode of therapy for patients who have what was formerly termed *reflex sympathetic dystrophy* and *causalgia*, now termed *CRPS* (133) types I and II, respectively (Chapter 20). An unknown proportion of patients suffering from either disorder have a component of sympathetically influenced pain (134).

Causalgia. CRPS type II (causalgia) is a condition associated with damage to a peripheral nerve, such as a median or sciatic nerve, and is characterized by burning pain, hyperalgesia, hyperpathia, allodynia and, not infrequently, by vasomotor and sudomotor disturbances.

Studies (135,136) have shown that patients with nerve injuries can be of two types: those with sympathetically maintained pain (SMP) and those whose pain is independent of sympathetic hyperactivity, sympathetically independent pain (SIP). In these studies, SMP pain and hyperalgesia were reduced by sympathetic block, whereas in patients with SIP sympathetic blockade was ineffective and block of the somatic nerve relieved pain. Patients with mechanical hyperalgesia and SMP had increased pain with mild cooling (1.5° to 2.0°C) of the skin with acetone, or ice water, or alcohol. In contrast, only approximately one-third of SIP patients tested reported pain response to cold, implying that the response to cold stimulus can be used, in addition to sympathetic block, to differentiate patients with SMP from those with SIP.

In patients with CRPS type II with or without SMP, selective block of the regional sympathetics with an LA is a useful diagnostic procedure in demonstrating a sympathetic component. Subarachnoid, epidural, or Bier blocks with LA or guanethidine (see below) are not sympathetically selective; they all have the potential to affect somatic nerves. Specific selective sympathetic blocks require accurate placement of small quantities of LA on the sympathetic chain (fluoroscopy is advisable), demonstrating that a false-positive response is not observed (no somatic block by physical examination) and that a false-negative does not occur (a complete sympathectomy demonstrated by tests of sympathetic function; see below).

Sympathetic blocks can produce prolonged and often curative effects in CRPS type II (Chapter 20), but it is essential that a complete sympathectomy be produced. Following LA sympathectomy, patients often derive relief of many of the symptoms associated with CRPS type II. If only temporary relief is obtained from LA sympathectomy, repeated LA blocks or a neurolytic procedure should be considered. Some patients may respond to a series of six to 12 blocks; however, the role of the block is to facilitate physical therapy while pain is reduced.

For those who have not had sufficient experience with regional sympathetic blocks, intravenous injection of guanethidine by the Bier block technique is the procedure of choice. Guanethidine block lasts 24 to 72 hours (see below). In Chapter 20 it is noted that phenoxybenzamine, an a-adrenoreceptor blocker, has also proven to be effective in patients with causalgia.

Complex Regional Pain Syndrome Type I. CRPS type I is a term applied to a diverse group of seemingly unrelated disorders formerly called *reflex sympathetic dystrophy*, *minor causalgia*, *posttraumatic spreading neuralgia*, *Sudeck's atrophy*, and *shoulder-hand syndrome* (Chapter 20). This group of disorders is characterized by prolonged pain, vasomotor and sudomotor disturbances, delayed functional recovery, and the development of trophic changes, often with minimal signs of injury. CRPS type I occurs more frequently than CRPS type II and is often misdiagnosed, with a consequent delay in instituting therapy. Early treatment with repeated or continuous sympathetic block for 7 to 10 days is indicated.

Postamputation Pain Syndromes

The various pain patterns that follow amputation are described in Chapter 21. Following extremity amputation, most patients experience a phantom limb (or part); a smaller percentage develop phantom limb pain or stump pain. Pain in a limb, or phantom, usually falls in one of three categories: (a) a burning, throbbing, aching pain not unlike that of CRPS types I and II; (b) pain due to an abnormal position of the phantom limb, which is felt to be in a twisted, cramped, rigid, or flexed posture that cannot be released by the patient; or (c) a combination of these two patterns of pain. Pain in the stump is of three predominant types: (a) a constant, diffuse, burning, throbbing pain similar to that of CRPS types I and II; (b) shooting pain in a segmental or peripheral nerve distribution; or (c) a combination of these. Stump pain is usually associated with vasomotor and sudomotor disturbances.

In patients with phantom or stump pain and evidence of sympathetic disorder (vasomotor and sudomotor changes) LA sympathectomy is often helpful. If the LA block provides relief, repeated blocks should be considered with neurolytic or surgical sympathectomy considered if relief is not long-lasting.

There is some evidence that the choice of analgesic and anesthetic technique in the perioperative period may preemptively influence the incidence of postamputation phantom pain (19). Epidural analgesia with LA with or without an opioid initiated several days before an amputation, and continued for some days after amputation, may reduce the incidence of short-term and long-term phantom pain, when compared to control groups receiving systemic analgesics.

Other Neuropathic Painful Disorders

Regional sympathetic blockade and guanethidine or bretylium intravenous blocks have also been found to be effective in relieving burning pain associated with hyperesthesia, hyperpathia, allodynia, and sensitivity to cold. Patients with painful neuromata and a number of patients with pain after brain or spinal cord injury may be helped by sympathetic blockade by LA sympathectomies or RA with intravenous guanethidine (137,138 and 139) or RA with intravenous bretylium (140).

Issues with Sympathetic Blocks

In Chapter 20, several important points were made about the use of sympathetic block for sympathetic associated pain. First, the earlier the treatment, the better the prognosis for prolonged relief of the pain. Second, if patients experience even partial relief, the LA sympathectomy should be repeated on two to three occasions because occasionally subsequent blocks relieve the pain. Third, when sympathectomy is indicated, this can be done either chemically or surgically. However, it is essential to ascertain that sympathetic interruption is complete, especially in patients who derived complete relief of the burning pain with an LA sympathetic block, but who experienced only partial or no relief after sympathectomy. In such cases it is likely that, although the LA diffused widely enough to involve the sympathetic chain and anomalous sympathetic pathways (which are often present in the lower cervical and upper thoracic chain and in the lower thoracic and upper lumbar region), the operation was not extensive enough, did not include the anomalous pathways, or both. In such cases, two or three sympathetic blocks should be repeated.

Peripheral Vascular Disease

Historically sympathectomy (by LA, chemical, or surgical means) played an important role in managing the pain, ischemia, and trophic changes consequent to peripheral vascular disease. The advent of effective therapy using vascular stents, bypass grafts, and anticoagulant therapy has decreased the importance of sympathetic block in treating this group of disorders. Nevertheless, temporary or prolonged sympathetic interruption can still be a useful adjunct (Chapter 33).

Acute Vascular Disease

Some acute vascular disorders may benefit from LA sympathectomy, including posttraumatic vasospasm; vasoconstriction caused by intraarterial injection of irritating substances; acute arterial occlusion caused by thrombosis, embolism, or direct injury; acute venous thrombosis; and peripheral vascular damage from cold injuries (Chapter 33). In these conditions, it is believed that ischemia is due to direct vascular lesions; in addition, the lesion initiates reflex spasm of collateral vessels. Sympathetic block, initiated before endothelial changes that favor thrombosis in vasospastic collateral vessels have developed, may improve collateral vessel blood flow and hence reduce further ischemic damage.

Sympathetic block in these cases may help determine whether ischemia results from organic obstruction, division of the blood vessel, or vasospasm. The use of LA sympathectomy in these cases is often complicated by the fact that patients may be receiving anticoagulants or have other blood-clotting disorders. In patients with blood-clotting disorders (iatrogenic or otherwise), the use of neuraxial blocks is strongly contraindicated because of risks of bleeding producing intraspinal hematomata and neural damage. In these patients, sympathectomy outside the neuraxis carries a significant risk of bleeding, though the consequences may not be as severe as within the neuraxis. If anticoagulants are being used, sympathetic interruption may be achieved with intravenous regional sympathetic block (IRSB) with guanethidine.

Chronic Vasospastic Disorders

Chronic vasospastic disorders that may be helped by LA sympathectomy include Raynaud's disease, Raynaud's phenomenon, cold injuries, acrocyanosis, and livedo reticularis. The blocks can be used as a diagnostic and prognostic procedure in patients in whom sympathectomy is being considered, or blocks or IRSB with guanethidine (141) may be used to tide patients over difficult times (e.g., winter months). (Chapter 33 presents a detailed discussion of all aspects of these and other peripheral vascular diseases.)

Chronic Occlusive Arterial Disease

Chronic occlusive arterial disease produces decreases in tissue blood flow resulting in, progressively, claudication, rest pain, and tissue damage ranging from ulceration to gangrene. The first lines of therapy are aimed at improving blood flow by surgical means (vessel dilation, stents, bypass grafts, etc.). For patients in whom these measures do not suffice or are contraindicated, chemical sympathectomy is effective in relieving rest pain, enhancing the healing of ischemic lesions, and postponing amputation (142,143). If and when amputation becomes necessary, it can be performed at a more distal level of the limb (142) (Chapter 33). The value of chemical sympathectomy in these conditions is discussed in Chapter 104.

Visceral Pain

Block of the sympathetic nerves to thoracic or abdominal viscera relieves pain in those areas and is useful for blocking afferent and efferent arms of visceral reflexes, which may contribute to the pathophysiology. The pathophysiology may be a consequence of local sympathetic activity and/or systemic sympathetic activity (e.g., raised cardiac output, BP, heart rate). In patients with such pain, opioids in appropriate doses and by the appropriate route produce adequate pain relief but do not eliminate the abnormal reflex responses. In contrast, block of the sympathetic nociceptive pathways blocks the afferent and efferent limbs of these reflexes and thus prevents or at least minimizes the reflex responses. These comments are especially relevant to certain acute thoracic and abdominal visceral painful conditions.

Thoracic Visceral Pain

Acute Myocardial Infarction. Acute myocardial infarction produces pain and associated reflex responses that can aggravate myocardial pathophysiology. Relieving pain, anxiety, and mental stress in patients with acute myocardial infarction effectively decreases these reflex responses (Chapter 61).

Effective pain relief can be achieved with appropriate doses of intravenous opioids; however, opioids may not produce complete pain relief, may not change reflexes, and may be associated with side effects. The value of sympathectomy is suggested by a number of animal and human studies (144,145,146,147 and 148). In patients with pain that persists, despite opioids, cervicothoracic (stellate) sympathetic block may provide effective analgesia for 8 to 10 hours or more. In patients with unilateral pain, a unilateral block usually suffices. If the pain is bilateral, the block is done on the side with the most severe pain first and, after an interval of 30 minutes, is repeated on the opposite side, provided that the side effects of the stellate block (recurrent laryngeal nerve block, phrenic nerve block) are not present as contraindications.

Angina Pectoris. Modern management of angina by medical or surgical means is highly effective. However, in patients in whom angina has not been relieved, despite maximal therapy, prognostic cervicothoracic sympathetic blocks with 0.25% bupivacaine may be helpful and may predict results of subsequent chemical or surgical sympathectomy (1). The technique for neurolytic block of the upper thoracic sympathectomy is discussed in Chapter 104.

Abdominal Visceral Pain. Patients with abdominal pain from intraabdominal pathology can have their pain relieved by LA sympathectomy in the case of reversible disorders or chemical sympathectomy in the case of intractable disorders.

Acute Pancreatitis. Acute pancreatitis (Chapter 67) is often associated with severe abdominal pain and systemic disturbances. It may be managed by block of the nociceptive afferents by splanchnic nerve block, celiac plexus block (149), or continuous segmental (T- 5 to 10) epidural block (150,151). The use of regional block may decrease the severity and duration of the disease (151).

Biliary and Ureteral Colic. The pain of biliary and ureteral colic may be relieved by intravenous opioids, though these drugs may increase the smooth muscle tone in the biliary or ureteric tracts. LA sympathectomy by paravertebral block of the splanchnic nerves and of the L-1 and L-2 ganglia or a continuous segmental (T-10 to L-2) epidural block provide pain control and avoid the unwanted effects of opioids.

Adynamic Ileus. Adynamic ileus following intraabdominal surgery or following thoracic vertebra fracture has a component of sympathetic activity that can be lessened by segmental epidural block. The efficacy of this procedure in the treatment of adynamic ileus is discussed in detail in Chapter 66.

Acute Herpes Zoster and Postherpetic Neuralgia

For over 60 years LA sympathetic block has been used with variable success in the treatment of herpes zoster (152,153,154,155,156,157,158 and 159). The results of studies are summarized in Table 102-5. Sympathetic block, plus or minus somatic block, used early in the course of acute zoster eruption and pain, produces a high incidence of pain relief and probably decreases the severity of pain and eruption and may accelerate healing. The longer the interval between the start of eruption and pain, the less the quality and quantity of relief. A regimen of daily blocks for 5 to 7 days and then two to three blocks a week is advised until relief is obtained or a total of approximately ten blocks have been performed. The efficacy of such a regimen in acute zoster is supported by double-blind studies (158) but probably has little or no effect on the incidence of PHN (159).

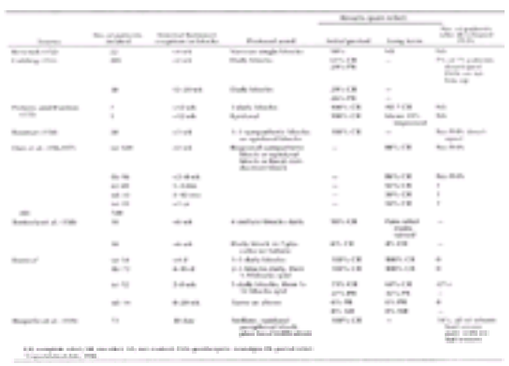

TABLE 102-5. Effects of sympathetic, somatic, or epidural blocks for acute herpes zoster

The early administration of antiviral drugs (vidarabine, acyclovir) in the acute phase of zoster reduces the spread of the zoster eruption, accelerates healing, and prevents both cutaneous dissemination and visceral complication (160). These drugs should be combined with nerve blocks to provide patients with prompt relief of pain that is not obtained with the use of antiviral agents alone.

Once PHN, usually defined as persisting pain 3 months after eruption, is established, sympathetic or other neural blockade with LA produces a low (20% to 40%) incidence of initial pain relief, which falls to 10% on long-term follow-up (153,157,161,162) (Table 102-6). It has been implied, however, that such blocks performed within 1 year of eruption produce an appreciably greater incidence of pain relief than if patients are managed only with the usual medical therapy (161,163). If RA is used for PHN, a series of blocks done every other day, for a total of seven to ten blocks, is recommended.

Source	No. of patients	Eruption to blocks	Protocol	Results: Initial success	Results: Long-term success
Colding (1953)	34	3 mo to 10 yr	3–4 blocks	48%	10%
Forrest (1963)	74	4 mo to 8 yr	3 epidural LA + steroid	Mean pain score decreased from 8/10 to	
Zhao et al. (1986)	69	1–3 mo	Various blocks	52% good	
	31	3–12 mo		39% good	
	22	>12 mo		13% good	
Milligan and Nash (1962)	34	<1 yr	Single ganglion block	38% good, 26% improved	
	1	>1 yr		25% good, 25% improved	

LA, local anesthetic; VAS, visual analog scale.

TABLE 102-6. Results of nerve blocks for pain relief in postherpetic neuralgia

Cancer Pain

Sympathetic blocks can be effective in relieving the burning, aching discomfort that is experienced by some patients with cancer of the face and head. Moreover, sympathetic blocks of the upper or lower limb are indicated in patients in whom cancer infiltration or compression of the brachial or lumbosacral plexus produces the symptoms and signs characteristic of CRPS type I (Chapter 20).

Musculoskeletal Disorders

Sympathetic blocks, used in combination with local infiltration of trigger areas or other therapeutic measures, are frequently helpful in relieving the pain, decreasing the pathophysiology, and shortening the disability in patients with myofascial pain syndromes (13).

Technical Considerations

Monitoring the Effects

When performed correctly, sympathetic nerve blocks produce virtually no measurable effects demonstrable by routine examination. Evaluating the effect of a sympathetic block, or its completeness, requires that specific tests of sympathetic function be used. Methods include (a) the skin conductance response, formerly known as the *sympathogalvanic reflex* (Fig. 102-48); (b) sweat tests, including the Ninhydrin, cobalt blue, and intravenous starch tests; and (c) skin plethysmography and the “ice response test.” Blood flow in the skin can be measured by change in skin temperature, a laser Doppler, healing of ulcers, or tissue Pa O_2. Blood flow in muscle can be monitored by plethysmography, radioisotope clearance tests, and electromagnetic measurements. Thermography has proven to be effective for measuring the effects of vasoconstriction and the changes in blood flow following sympathetic interruption.

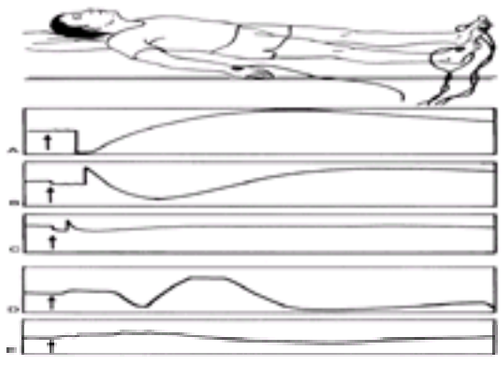

Figure 102-48. Monitoring sympathetic function by the skin conductance response: Electrodes are placed on the front and back of the hands or feet and a ground electrode is placed elsewhere on the body. **A,B:** Any unpleasant stimulus, such as a pinch or taking a deep breath, produces a typical curve. The *arrow* indicates the point where the pinch was applied. **C:** Flattening of the curve indicates absence of the reflex on the left leg after a left lumbar sympathetic block. **D:** Normal curve in the hand before the T-2 and T-3 sympathetic ganglia were blocked with 6% phenol. **E:** Tracing taken of the same hand as in **D** 2 months after the block.

Cervicothoracic Sympathetic Block

Although the cervicothoracic sympathetic block is usually colloquially referred to as *stellate ganglion block*, LA or neurolytic injected at the usual site often spreads beyond the immediate area of the stellate ganglion. Radiologic studies following the injection of contrast medium show that when the needle is correctly placed, and the agent injected into the correct fascial plane, 5 mL of injectate spreads as far as the T-2 thoracic and intermediate cervical ganglia, 10 mL of injectate spreads from the upper part of the C-5 to the T-3 or T-4 and 20 mL of injectate spreads from C-3 to the T-5. The latter will therefore likely interrupt sympathetic and visceral afferent and efferent pathways to the head and neck, upper limb, and thoracic viscera.

Anatomic Basis

The neuroanatomic basis for cervicothoracic sympathetic blocks is shown in Figure 102-49 and Figure 102-50. The sympathetic nerve supply to the head and neck is discussed in Chapter 46, that to the upper limb is described in Chapter 54, and that to the thoracic viscera is described in Chapter 60. Figure 102-49 depicts the four cervical and upper three thoracic ganglia and their relationship to the brachial plexus and thoracic spinal nerves. Precise knowledge of the anatomy of the stellate ganglion and its relationship to the upper thoracic and lower cervical ganglia is helpful when performing this block (see Fig. 102-50).

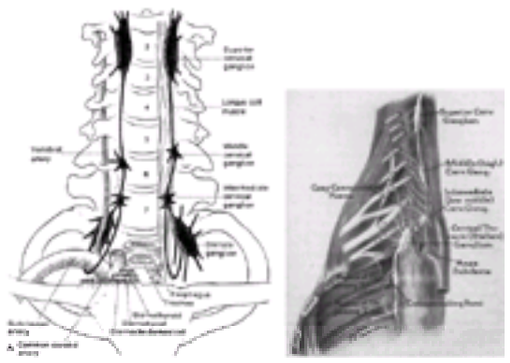

Figure 102-49. Anatomy of the cervical sympathetic chain. **A:** Anterior view of the deep region of the lower portion of the neck showing the relationship of the sympathetic ganglia to the cervical and upper thoracic vertebrae, the longus colli muscle, and the vertebral artery. (From Bonica JJ. *Blocks of the sympathetic nervous system.* Vol 2. Chicago: Frank J Corbett, 1981:64, with permission.) **B:** Relationship of the cervical and upper thoracic sympathetic chains and the gray rami communicantes, which connect the chain to the brachial plexus and other spinal nerves. Note the inconstant intrathoracic ramus from the T-2 nerve to the T-1 nerve and from the T-3 nerve to the T-2 nerve. Also note the beginning of the lower branches of the stellate ganglion, which include the ansa subclavia, the inferior cardiac nerve, and the nerve to the internal mammary artery. From the upper pole of the ganglion arises the vertebral nerve, which passes to the vertebral artery where it breaks up into the vertebral plexus (not shown). (From Moore DC. *Stellate ganglion block.* Springfield, IL: Charles C Thomas Publisher, 1954, with permission.)

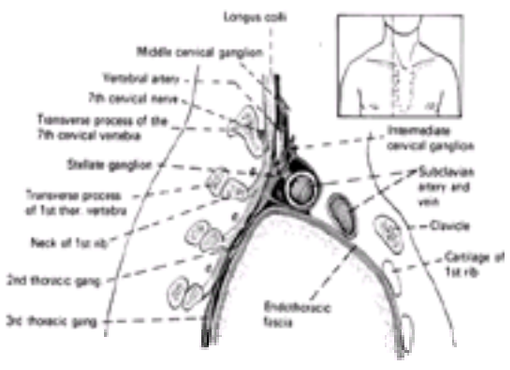

Figure 102-50. Sagittal section of the lower portion of the neck and upper part of the thorax (*inset*) showing the relationship of the stellate ganglion and other parts of the sympathetic chain to bones, blood vessels, and apex of the lung. The longus colli muscle separates the ganglia from the bones and the stellate ganglion is immediately posterior to the beginning of the vertebral artery. Injection of a local anesthetic solution within the fascial plane containing the sympathetic chain causes the solution to diffuse cephalad and caudad to block various parts of the chain (see Fig. 102-52).

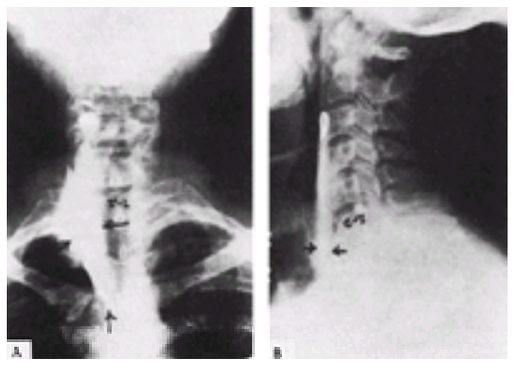

Figure 102-52. Roentgenograms showing the characteristic pattern of diffusion (*arrows*) of 10 mL of contrast medium (Diodrast) injected in the same fascial plane as the cervicothoracic sympathetic chain. **A:** Anteroposterior view showing the spread from the top of the C-5 vertebra (which includes the middle cervical ganglion) to the T-4 vertebra at the level of the T-4 or T-5 sympathetic ganglion. **B:** Lateral view. (From Moore DC. *Stellate ganglion block.* Springfield, IL: Charles C Thomas Publisher, 1954, with permission.)

The stellate ganglion is an oval mass, 2.5 cm long, 1 cm wide, and 0.5 cm thick, located just behind the subclavian artery at the point of origin of the vertebral artery and in front of the neck of the first rib near the costovertebral articulation. The ganglion lies within a concavity limited inferiorly by the posterior aspect of the pleura, medially by the portion of the vertebral column covered by the longus colli muscle, laterally by the scalenus muscle mass, anteriorly by the subclavian and vertebral arteries, and posteriorly by the neck of the first rib, the transverse process of the C-7 vertebra, and the interspace between these two structures. In most instances, the ganglion extends above the first rib so that its upper half is in front of the interspace (see Fig. 102-50). The ganglion is 5 mm anterolateral to the bony structures, separated from them by loose areolar and adipose tissue and the longus colli muscle. The loose areolar and adipose tissue facilitate diffusion of anesthetic solutions deposited near the ganglion. The branches of the stellate ganglion include the communicating, anastomotic, vascular, and muscular branches; the inferior cervical cardiac and vertebral nerves; and the ansa subclavia. The gray rami communicantes that are given to the C-7 and C-8, T-1, and sometimes the C-5 and C-6 spinal nerves constitute the major part of the sympathetic nerve supply to the upper limb (see Fig. 102-49).

The other cervical sympathetic ganglia consist of the intermediate, the middle, and the superior cervical ganglia (see Fig. 102-49). The superior ganglion is the largest, the middle is the smallest, and the intermediate ganglion is intermediate in size. These ganglia lie on the longus colli muscles and are thus in the same fascial plane as the stellate ganglion. The lower part of the stellate ganglion connects with the T-2 sympathetic ganglion, which contains the largest number of synaptic connections between the preganglionic and postganglionic sympathetic fibers that supply the upper limb.

Usually all the sympathetic nerves that supply the head and neck, and most of those that supply the upper limb, traverse the stellate ganglion. Thus, blocking this structure effects a temporary sympathetic denervation of these areas. In a significant number of individuals, however, an intrathoracic somatic branch arising from the T-2 spinal nerve joins the T-1 spinal nerve, which of course, takes part in the formation of the brachial plexus (see Fig. 102-49, and Fig. 102-50). This intrathoracic branch is almost always joined by gray rami communicantes carrying postganglionic fibers that arise from cell bodies in the T-2 sympathetic ganglion and possibly in lower ganglia. In a smaller percentage of individuals, an intrathoracic somatic branch is also present, which arises from the T-3 spinal nerve and passes to the T-2 spinal nerve. This second intrathoracic nerve, which also contains postganglionic sympathetic fibers that arise from the T-3 ganglion, joins the T-2 spinal nerve near the branch that the latter sends to the T-1 nerve. These anomalous pathways, known as *Kuntz's nerves*, bypass the stellate ganglion so that blocks limited to the stellate ganglion or a pure stellectomy do not necessarily produce complete sympathetic denervation of the upper limb. In such cases, it is also essential to block the T-2 and T-3 ganglia to denervate the limb completely. Moreover, because all the fibers to the upper limb pass through the T-2 and occasionally the T-3 ganglia, they are key relay stations that can be blocked with a small volume of neurolytic agent.

Technique

A variety of techniques have been described: anterior paratracheal, lateral, anterolateral, superior, and posterior approaches. Here only the paratracheal approach is described (Fig. 102-51). The posterior approaches to the thoracic sympathetic chain, including those that supply the upper limb, are described in Chapter 102.

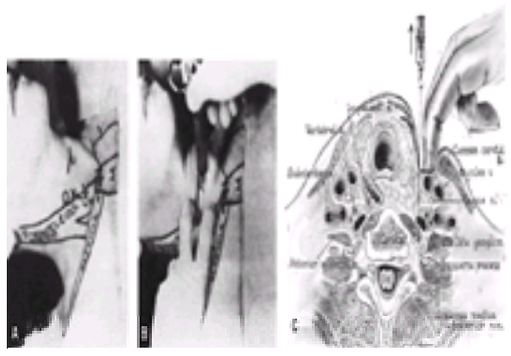

Figure 102-51. Stellate block by the anterior paratracheal approach. **A:** Outline of the clavicle and sternocleidomastoid. The level of the cricoid cartilage (c) is at the same cross-sectional level as the transverse process of the C-6 vertebra (o). *X* lies anterior to the transverse process of the C-7 vertebra and is the point on the skin where an intracutaneous wheal is formed. **B:** With the second and third fingers of the nondominant hand hooked around the medial edge of the sternocleidomastoid and the underlying carotid sheath, with its vessels and nerves retracted laterally, the needle is inserted through a wheal, directed posteriorly in the parasagittal plane, and advanced to the base of the transverse process of the C-7 vertebra. **C:** Cross section of the neck at the level of the C-7 vertebra depicting the placement of the needle for anterior paratracheal stellate ganglion block. The second and third fingers of the hand are retracting the medial aspect of the sternocleidomastoid muscle and the underlying vessels, and the needle is advanced to the base of the transverse process of the C-7 vertebra. After bone is contacted, the needle is withdrawn about 0.5 cm to place its bevel anterior to the fascia of the longus colli muscle. Injection of a local anesthetic solution anterior to the fascia permits it to diffuse cephalad, caudad, and slightly laterally to block the chain. (**A** and **B** from Moore DC. *Stellate ganglion block.* Springfield, IL: Charles C Thomas Publisher, 1954, with permission.)

When performing the paratracheal technique the tip of the needle is close to the vertebral artery and dural cuff of the C-8 nerve. Hence when LA is injected, it is important to ensure that the needle is not intravascular or subarachnoid by aspiration of the needle in two planes and the use of a test dose (1 mL of injectate) and waiting a few minutes to ensure no adverse CVS or CNS effects.

Stellate ganglion blocks for head and neck disorders can be accomplished with 3 to 5 mL of LA. If the block is intended to interrupt all sympathetic fibers to the ipsilateral upper extremity, 12 to 15 mL of solution is injected. This is sufficient to spread to and block all the sympathetic nerves that supply the upper limb, even in a patient with the anomalous Kuntz's nerves. If the block is intended to interrupt the afferents and efferents to the heart, 20 mL of solution is injected, with the patient in a semirecumbent or sitting position (Fig. 102-52).

Successful block of sympathetic fibers to the head is indicated by the appearance of Horner's syndrome (ptosis, miosis, enophthalmos, anhidrosis of the neck and face). Successful block of sympathetic fibers to the upper limb is indicated by engorgement of the veins in the back of the hand, a rise in skin temperature, absence of a skin conductance response, plethysmography, thermography, a sweat test, or a combination of these. Maximal evidence of an arm sympathectomy may take 15 to 20 minutes.

Complications

Complications of the anterior paratracheal technique include inadvertent intraarterial or intravenous injection of LA, pneumothorax; unintentional brachial plexus block, recurrent laryngeal nerve block, or accidental subarachnoid injection. These complications, their prophylaxis, and treatment have been discussed (see Basic Considerations, earlier in this chapter).

Block of the Thoracic Sympathetic Chain

Block of one, or more, of the thoracic sympathetic ganglia and the intervening interganglionic chain is indicated as a diagnostic procedure for identifying pathways or as a therapeutic measure for treating herpes zoster or other chest wall pain. Because segmental thoracic sympathetic blocks are technically difficult, many clinicians use segmental epidural block and paravertebral block for patients with chronic pain (Chapter 102).

Block of the Celiac Plexus

Block of the celiac plexus is useful for relieving pain caused by acute visceral disease and hepatic embolization. Celiac plexus block interrupts both afferent and efferent sympathetic pathways to the viscera and modifies the effects of sympathetic outflow on visceral functions. Because the celiac plexus contains vagal afferent and efferent fibers, block of this structure interrupts sensory fibers that transmit nonnociceptive information and the parasympathetic outflow to the abdominal viscera.

Celiac plexus block can be used in treating adynamic ileus. Celiac plexus block with LA should be done to predict the effects of neurolytic celiac block, which is used in patients with upper abdominal cancers. The various techniques and their use are discussed in Chapter 102 (164,165).

Splanchnic Nerve Block

The indications for splanchnic nerve block are very similar to the indications for celiac plexus block, except that this procedure does *not* produce a block of the lumbar sympathetic chain. Splanchnic nerve block requires smaller volumes of agents and probably has a lesser incidence of complications. Because splanchnic nerves are usually blocked with neurolytic agents to control chronic pain, the technique is discussed in Chapter 104.

Lumbar Sympathetic Block

Indications. Lumbar sympathetic block is a useful diagnostic, prognostic, or therapeutic procedure for pain syndromes involving the pelvis or lower limbs and for peripheral vascular disorders (see Cervicothoracic Sympathetic Block, earlier in this chapter). It has a role in predicting the effects of neurolytic blockade in patients with peripheral vascular disorders of the lower limbs.

Neuroanatomic Basis. The anatomy of the lumbar sympathetic chain is discussed in detail in Chapter 70 and Chapter 75. The lumbar sympathetic trunks consist of two ganglionated cords that extend from the L-1 to the L-5 vertebrae and are continuous above with the thoracic portion and below with the pelvic portion of the sympathetic trunk (Fig. 102-53). Each chain lies on the anterolateral surface of the vertebral column, being more medial and anterior than the thoracic chain. Both lumbar chains are situated anteriorly and slightly medially to the aponeurotic arcades giving rise to the psoas muscle and the psoas fascia, which is also attached medially by a series of arched processes to the intervertebral disks and by the prominent upper and lower margins of adjacent vertebrae. The intervals between the arched processes of the psoas muscle and fascia and the constricted part of the vertebrae transmit the lumbar arteries and veins and sympathetic nerves that connect the lumbar sympathetic chain with the somatic lumbar nerves. The relation of the sympathetic trunks to the great vessels differs on each side. On the right side, the trunk lies posterior to the lateral edge of the vena cava, which in most cases completely covers the trunk. On the left side, the chain is rarely covered by the aorta, being 4 to 10 mm lateral to the lateral edge of the vessel; on this side it is usually covered by the lumbar lymph glands and peritoneum. Inferiorly the cords pass posterior to the iliac vessels to become continuous with the sacral sympathetic trunks.

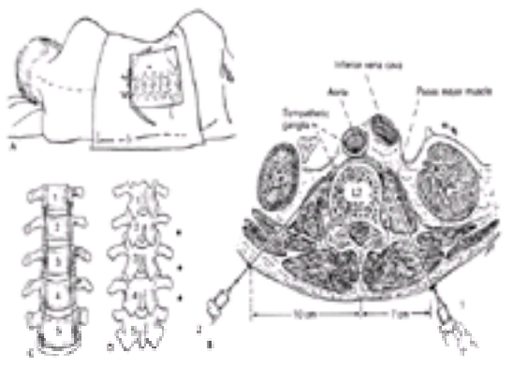

Figure 102-53. Lumbar sympathetic block. **A:** The patient lies on the side with the affected side uppermost. **B:** Cross section at L-2 to show the two techniques that can be used, a so-called classic technique (using three or four needles) or a lateral technique. For the classic technique (needle 1), a skin wheal is raised 6 to 7 cm lateral to the midline at the midpoint of the quadrilaterally spaced spinous process of the lumbar vertebrae. In many patients, 22-gauge, 8-cm security needles with rubber depth markers are used. For patients who are obese or muscular it is best to use 10- or 12-cm, 22-gauge needles. For diagnostic purposes it is best to inject through two or three needles at the levels of the L-2 and L-4 or L-2, L-3, and L-4 vertebrae. Each needle is inserted through the skin wheal and advanced anteriorly and medially. The shaft of the needle should make an angle of 75 to 80 degrees with the skin lateral to it. The needle is advanced until the lateral aspect of the lumbar vertebra is contacted, usually at a depth of 6 to 8 cm from the skin in thin or normal individuals but possibly as deep as 10 cm from the skin in obese individuals. The skin marker is placed 2 cm from the skin, and the needle is withdrawn until its point is subcutaneous and then redirected more laterally so it passes through the psoas major muscle. It might be useful to adapt a Luer-Lok control needle to a 2- or 5-mL syringe filled with air or saline solution. As the needle traverses the psoas muscle, some resistance to injection is encountered. The needle is further advanced slowly while gentle pressure is applied to the plunger of the syringe. As the point of the needle passes through the thick medial junction of the psoas fascia, significant resistance is encountered. As soon as the bevel pierces the fascia, however, a sudden lack of resistance can be felt and the air or saline can be injected easily, indicating that the needle point is in the retroperitoneal space and is near the sympathetic chain. The local anesthetic solution is injected after a negative aspiration test in four quadrants. If a diagnostic procedure is being done with three needles, 3 mL of solution injected through each of the needles is sufficient. If two needles are used, 5 mL of solution is injected at L-2 and L-4. One needle at L-2 or L-3 can be used for therapeutic purposes, and 15 to 20 mL of local anesthetic solution injected. If the needle is in the proper fascial plane (anterior to the vertebral insertion of the psoas fascia) the solution spreads cephalad and caudad to involve the entire lumbar sympathetic chain. The lateral technique (needle 2) entails the insertion of the needle through wheals made 10 cm lateral to the midline. With this technique, no attempt is made to contact the lateral aspect of the vertebra, but the needle is advanced through the psoas muscle mass for 6 or 7 cm, after which the same test volume of air or saline solution is used as for the classic technique. As soon as the needle passes through this psoas fascia, a sudden lack of resistance indicates the proper position. The rest of the technique is similar to that already described. **C:** Anterior view of lumbar vertebrae showing position of sympathetic chain. **D:** Posterior view showing sites of wheals for the lateral technique.

The anatomy of the lumbar sympathetic chains is more variable in its general form and in the number of ganglia than the rest of the sympathetic chain. The chain anatomy varies between individuals and between two sides of an individual (1). It is almost exceptional to find five ganglia—it is more usual to find only four, with a fusion of the L-1 and T-12 ganglia. The location of the ganglia is also inconstant: In some individuals they are segmentally located, while in others they are closely grouped and lie over a particular segment. The most common location is between the L-2 and the inferior border of the L-4 vertebrae. The ganglia can be situated on the body of the vertebra or anterior to the psoas aponeurotic arcades. In most people, they lie anterolaterally to an intervertebral disk with one portion of the ganglion in front of the lower part of the vertebra above and the other portion of the ganglion in front of the upper part of the vertebra below. The same degree of variability exists in regard to the size of the ganglia and the interganglionic cord and the number of branches extending from them. Ganglia range in size from 3 to 5 mm wide and 10 to 15 mm long.

The lumbar sympathetic chain contains both the preganglionic and postganglionic neurons that supply the pelvic viscera and vessels of the lower limbs and afferent (sensory) fibers, some of which transmit nociceptive information. The cell bodies of the sympathetic preganglionic neurons that supply the lower limbs are located in the T-11 and T-12, L-1, L-2, and sometimes the T-10 and L-3 spinal cord segments. Their axons pass through anterior roots of the corresponding spinal nerves and through the lower four, five, or six white rami communicantes to the sympathetic trunk (see Fig. 8-15 and Fig. 75-22). They descend to end in the lower three lumbar and upper three sacral ganglia, wherein they synapse with cell bodies of postganglionic neurons.

Some axons of postganglionic neurons pass directly to the iliac and femoral arteries, around which they form a plexus that passes as far as the junction of the upper and middle thirds of the thigh. Most of the postganglionic axons pass as the gray rami communicantes, however, which join the spinal nerves that form the lumbar plexus and the lumbosacral plexus. These sympathetic fibers pass distally as components of the femoral, sciatic, and obturator nerves and their branches and are given off segmentally to the vessels of the lower limb (see Fig. 75-23). Thus, by blocking the L-2 and L-3 ganglia, through which most of the fibers going to the lower limb pass, almost complete sympathetic denervation of the limb can be effected. In some subjects, however, some of the sympathetic pathways to the lower limb and pelvis bypass the sympathetic chain and make their synaptic connections in somatic spinal nerves. In these individuals, surgical sympathectomy limited to excision of the sympathetic chain fails to denervate the sympathetic supply to the limb completely.

Other branches given off by the lumbar sympathetic chain include the osseous branches, which supply the vertebrae; muscular branches, which supply the psoas muscles; and vascular branches, some of which accompany the lumbar arteries. They also give off four lumbar splanchnic nerves that pass anterior to the lower part of the celiac plexus to the aortic plexus and to the superior hypogastric plexuses and the plexuses that accompany the iliac vessels (Chapter 65).

Technique. Two techniques for lumbar sympathetic block are shown in Figure 102-53. The classic technique entails insertion of four needles at the L-1, L-2, L-3, and L-4 vertebral levels. This has been simplified to a two-needle technique at L-2 and L-4. A single-needle technique with needle tips placed at L-2 or L-3 has been reported to be satisfactory, even for injection of neurolytic agents (166). A two- or three-needle approach should be used for neurolytic blocks (Chapter 104). Because the sympathetic trunk crosses the lumbar arteries at the midpoint of the vertebral body, it is best to avoid placing the tip of the needle at this level. Instead, the point of the needle should be placed anterior to the attachment of the aponeurotic arcades of the psoas muscle and its fascia. This not only permits the fascia to be used for the lack of resistance test (see Fig. 102-53) but also decreases the risk of damaging the vessels and of LA solution flowing posteriorly to involve somatic nerves. To achieve the placement of the needle so that its point is in front of the aponeurotic arcades, the needle should be inserted at the level of the upper part of the spinous process of the vertebra. The insertion is made a variable distance from the midline so that the needle passes either just above the tip of the transverse process or more laterally (see Fig. 102-53B).

If block is achieved with a fairly large volume of solution (8 to 10 mL for each needle) for therapeutic purposes, radiologic visualization is not necessary. Fluoroscopic assistance is advised when using small volumes of injectate for diagnostic purposes or for neurolysis.

Complications. The complications of lumbar sympathetic block include accidental injection of the drug into the inferior vena cava (on the right) or into the aorta (on the left), damage to the lumbar vessels, unintentional contact and consequent paresthesia of somatic nerves, or diffusion of the drug to block the somatic nerves.

INTRAVENOUS REGIONAL BLOCKADE

In this section we consider the use of the Bier block technique (167), which involves the isolation of the limb from the systemic circulation by a tourniquet inflated to a pressure above systolic BP. Drugs, LA, or adrenergic blocking agents are injected into the vascularly isolated limb and left in place for a brief period after which the tourniquet is released.

Intravenous Regional Sympathetic Blockade

Systemic sympatholytic drugs, that interrupt sympathetic (efferent) function either at the pre- and postganglionic synapses or at the endings of postganglionic fibers, may be used to treat various pain disorders. The use of systemic administration of sympatholytic is simple but produces systemic sympathectomy that may be incomplete and will produce significant side effects. In 1974, Hannington-Kiff (168) proposed a technique to produce prolonged sympathetic interruption in a limb, which largely circumvents the disadvantages of systemic drugs or regional sympathetic blocks. This procedure entails the injection of the antiadrenergic agent guanethidine into the venous system of the limb after the circulation has been temporarily occluded with a tourniquet. The technique, which has become known as

intravenous regional sympathetic blockade (IRSB), has become widely used for the relief of various painful conditions in which sympathetic dysfunction is thought to be present.

Basic Considerations

Guanethidine produces a prolonged unselective sympathetic blockade. It initially displaces norepinephrine from presynaptic storage vesicles and subsequently prevents a reuptake of norepinephrine (141). Consequently, norepinephrine is rapidly depleted, resulting in the impairment and eventual loss of sympathetic adrenergic nerve function, which has the effect of sympathetic blockade. The blockade lasts for many hours, often days, and sometimes weeks because of the strong binding properties and its slow elimination.

Controlled studies have now documented the efficacy of IRSB with guanethidine in increasing blood flow (169,170,171 and 172) and skin temperature (169,171) while decreasing the vasoconstrictor ice response (170) and relieving pain in vascular disease (169,170 and 171) and CRPS type I (169,172). Sweating is not reduced because this function is mediated by cholinergic postganglionic sympathetic fibers, which are unaffected by guanethidine. The duration of effect and efficacy of guanethidine IRSB and stellate ganglion block in patients with CRPS type I is quite similar on both short- and long-term follow-up (169).

Clinical Evaluations

Advantages. The IRSB technique using guanethidine has certain advantages when compared to regional sympathetic blocks. IRSB is less invasive and more comfortable for patients, it is technically simple and may be used by physicians who do not posses RA skills, it may be used in patients with blood clotting abnormalities, and the potential complications of regional techniques are avoided.

Disadvantages. The IRSB technique has some disadvantages when compared to regional anesthetic techniques: The drug initially causes a transient release of noradrenaline with a consequent burning pain, especially in patients who have painful limbs, and some of the active drug is released into the systemic circulation at tourniquet release, resulting in some degree of systemic sympathetic blockade. The procedure can only be used in a limb. It cannot be used in patients with burning pain in the head and neck or trunk and is of no value in relieving visceral pain. IRSB with guanethidine is not as specific as regional sympathetic blockade in differentiating SMP from SIP in patients with neurologic disorders (134), possibly because guanethidine does not block cholinergic fibers. IRSB with bretylium is an effective alternative to IRSB guanethidine (140).

Technical Considerations

IRSB should be carried out observing all the precautions used for a regional anesthetic: patent intravenous line, monitoring, available resuscitation drugs and equipment (see Basic Considerations, earlier in this chapter). Modest premedication with midazolam, 0.5 to 2.0 mg, plus or minus a modest dose of opioid (fentanyl, 20 to 50 µg), helps diminish anxiety and tourniquet pain. Tourniquet pain may also minimized by using a double-cuff tourniquet and mixing a small dose of lidocaine (25 to 50 mg) in the injectate.

For IRSB of the arm, the injectate should be 10 to 20 mg (1 to 2 mL) of guanethidine in 25 mL of saline; for the leg, the injectate should be 15 to 20 mg guanethidine in 50 mL of saline, although the total dose may be raised to 30 mg of guanethidine (141). The dose of bretylium for IRSB is 3 to 4 mg per kg in 40 mL of saline (140).

Technique

After the patient has an intravenous line established in both affected and unaffected limbs and monitoring has begun, the limb should be wrapped in a thin layer of padding and the tourniquet secured. The limb should be exsanguinated by elevating the limb above heart level for at least a minute—preferably longer. Limb exsanguination can be more completely achieved by tightly wrapping a rubber bandage around the limb from fingers proximally. However, this is often impossible because of the patient's pain. With the arm elevated, the tourniquet should be rapidly inflated to 100 mm Hg above systolic BP. The limb is returned to the horizontal, and the solution is injected over a 2- to 3-minute period. Faster injections may raise the isolated arm's intravascular pressure to rise above tourniquet pressure and risk leakage of the drug under the tourniquet to the systemic circulation. The tourniquet should be maintained for about 20 minutes to allow the drug time to fix to tissues. Tourniquet times may be reduced in patients with limb ischemia; but, the shorter the tourniquet time, the more drug is released systemically at tourniquet release and the greater the incidence of systemic side effects. Side effects include hypotension, faintness, nasal congestion, and sedation. Following the procedure, patients should remain supine with appropriate CVS monitoring. Patients should be closely supervised when they get up to ensure that there is no systemic hypotension or syncope. Blocks might need to be repeated at 3- day intervals in severe cases; otherwise, weekly blocks are advised. The most common requirement is for two or three blocks (141).

Intravenous Regional Analgesia

Historical Background

The German surgeon, August Bier, reported the first use of intravenous RA with LA to alleviate pain (167). In the 1930s, Leriche and Fontaine (173) reported the use of intraarterial injection of procaine to afford relief in cases of painful arteritis obliterans. Later they advocated both IV and intraarterial injection of procaine for other painful conditions, including Raynaud's disease, causalgia, traumatic arthritis, painful phantom limb, and leg ulcers.

Indications

Although intravenous RA is a popular method of producing surgical anesthesia, it has only been used to a limited degree in the management of acute and chronic pain. It is a convenient method for determining whether the pain arises from a peripheral source in a limb and can be used as a temporary measure to relieve pain. Boas and Cousins (174) suggested that pain relief can be assessed only while the cuff is inflated because the LA may produce systemic analgesic effects as soon as the LA is released into the circulation.

Technique

The technique is similar to that described for IRSB with guanethidine, but LA, 30 to 40 mL of 0.5% plain lidocaine or prilocaine, is injected over 2 to 3 minutes. As the drug is injected, the skin usually becomes mottled and analgesia develops rapidly. Usually sufficient analgesia and muscle relaxation develop within 5 to 10 minutes. The tourniquet should be kept inflated for at least 20 minutes to prevent toxic doses of LA being released into the systemic circulation.

Continuous Infusion of Intravenous Local Anesthetics

Indications

Historically single doses and infusions of LA have been reported to be helpful for a variety of painful conditions (1,174). Intravenous LA infusions have more lately been shown to be effective in the treatment of a number of central pain states (13,175,176), as have orally administered LA congeners of LA such as tocainide and mexiletine (177). Tocainide and LA have been shown to selectively depress C-afferent fiber–evoked activity in the spinal cord (178).

Technique

Because intravenous LA is associated with a risk of LA toxicity, LA infusions must be performed in an environment in which such toxicity can be rapidly detected and dealt with (see Basic Considerations, earlier in this chapter). A variety of regimens have been described. A standard technique is lidocaine, 4 mg per kg over 1 hour, which achieves blood levels of lidocaine of 1.2 to 2.0 µg per mL. The period between treatments is usually 1 to 2 weeks, and four to six treatments may be required (174,179). Close scrutiny of efficacy immediately after treatments and at repeat visits is necessary with repeat treatments being performed according to need.

NEURAXIAL BLOCKADE

Subarachnoid Block

SAB, also known as *spinal anesthesia*, is achieved by introducing a small amount of LA (e.g., 50 to 100 mg procaine, 25 to 50 mg lidocaine, or 5 to 10 mg bupivacaine) into the subarachnoid space where the LA mixes with cerebrospinal fluid (CSF). Unlike other forms of RA, the LA comes into direct contact with nerve axons and does not have to traverse epineurium and perineurium. It thus produces a rapid onset of effect with a small amount of drug. SAB is one of the technically simplest RA techniques and, in experienced hands, permits a somewhat better control of the degree, extent, and duration of block than can be obtained with other regional techniques. The LA solution may be made hyperbaric (specific gravity greater than CSF) by the addition of dextrose or hypobaric (specific gravity less than CSF) with water, both of which enable the spread of block to be controlled to some degree by patient positioning.

Notwithstanding these advantages, SAB with LA has a limited place in managing patients with acute or chronic pain, except as a diagnostic "differential" block or a prognostic block before subarachnoid injection of a neurolytic agent. The prognostic technique, which entails injection of very small amounts of LA at a vertebral level at which the subarachnoid space contains the rootlets of the midportion of all the spinal segments to be blocked, is described in detail in Chapter 104. Here we limit our comments to "differential" or graduated SAB.

Indications

Differential SAB was introduced as a method for differentiating pain caused primarily by sympathetic hyperactivity from that caused by nociceptive input along somatic nerves and for differentiating peripheral nociception from central pain. This procedure was based on the long-held assumption that nerve fibers of different sizes are blocked by different concentrations of LA. It was believed that the small sympathetic preganglionic axons, being the smallest diameter fibers, were susceptible to a concentration of LA that did not block somatic nociceptive impulses, and that the A-d and fibers in somatic nerves could be blocked by concentrations of LA that would not block the large A-b and A-a fibers that carry tactile and motor functions. Differential or graduated SAB (180,181) has been used to permit differentiation of the source of pain. The technique was considered suitable for investigating patients with lower extremity, pelvic, lower abdominal, and lumbar spine pain. It was considered less suitable for investigating patients with pain from the upper abdomen, thorax, or cervical spine, because these blocks often entail an extensive autonomic block, accompanied by cardiovascular sequelae.

This classic concept of differential SAB is of dubious validity. It is not possible to obtain "pure" block of sympathetic, sensory, or motor fibers, and properties of LA, such as frequency-dependent conduction block and spinal cord long tract block (174), call the interpretation of the results of the technique into question. Moreover, preganglionic fibers in the subarachnoid space, though smaller than A-d fibers, may be more resistant to low concentrations of LA than nociceptive fibers (182). These findings make the concept of the differential neural blockade increasingly tenuous and cast considerable doubt on the interpretation of such block. A graduated SAB *can* be used to determine the segmental level from which pain is derived or transmitted by producing an ascending SAB with dose increments that produce rising segmental anesthesia (174).

Technique

Before a differential or graduated SAB the patient should be properly prepared and the sympathetic, sensory, and motor functions assessed and vital signs continuously monitored. A spinal needle is inserted at the chosen spinal interspace with different solutions at 10-minute intervals in the following sequence (Fig. 102-54):

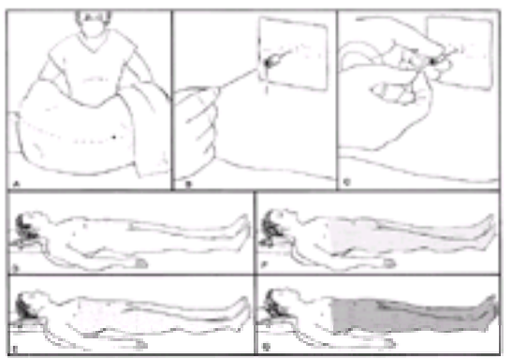

Figure 102-54. Graduated subarachnoid (spinal) block. **A:** Lumbar puncture and insertion of the catheter: lateral position for the puncture. **B:** After formation of the skin wheal, a special 25-gauge needle is advanced toward the subarachnoid space. The point of the needle is in the subarachnoid space, as shown by the emergence of cerebrospinal fluid. **C:** Introduction of the thin catheter through the needle into the subarachnoid space. **D:** The patient is supine. After injection of 8 mL of saline solution, no change is noted in sensation. **E:** Injection of 8 mL of 0.25% procaine produces a sympathetic nerve block (*light stippling*). **F:** Injection of 8 mL of 0.5% procaine produces analgesia to pinprick, pin scratch, and pinch (*heavy stippling*). **G:** Injection of 8 mL of 1% procaine produces motor block and dense anesthesia (*very heavy stippling*), as indicated by the inability of the patient to move the limbs; also, the abdominal wall is relaxed.

1. Eight to 10 mL of saline solution is injected. Because there is controversy about whether normal saline solution produces a change in sensation (183,184), the aspiration and reinjection of 8 mL of CSF may be preferable.
2. Eight to 10 mL of 0.25% procaine is injected, which should produce a sympathetic nerve block as indicated by measuring sympathetic function.
3. Eight to 10 mL of 0.5% procaine is injected, which should produce a sensory block as assessed by pinprick, pin scratch, and pinch.
4. Eight to 10 mL of 1% procaine is injected, which should produce a motor block.

After each stage of the procedure, the amount of pain the patient has, the sensory level of block, the neurophysiologic and behavioral changes in response to the block, and the analgesia produced should be assessed and noted. Interpreted simplistically, pain that responds to "placebo" is presumed to have a nonnociceptive origin and has been classified as psychogenic. Pain reliably removed by a sympathetic blockade and accompanied by objective evidence of sympathetic interruption, has been interpreted to imply a sympathetic component to the pain. Some evidence casts doubt on these assumptions (see Chapter 81) (174,185). Elimination of the pain by 0.5% or 1.0% procaine solution indicates a somatic origin of the pain. Failure of any solution or block to relieve pain implies a central pain.

The distinctions between the various causes and responses are by no means as concrete as those implied by these simplistic interpretations. It is almost impossible to produce a pure sympathetic block or a pure block of A-d fibers. Moreover, the method by which the patient is questioned and how the technique is presented can contribute to difficulties in interpretation. It is important that the technique be used according to a strict protocol that minimizes bias in both the patient's report and the observer's interpretation. The results of such a diagnostic block must be interpreted within the context of the other clinical, investigative, and behavioral information that has been obtained about the patient and the pain problem (185). Finally, the graduated procedure can be used to determine the uppermost segment of nociceptive input into the neuraxis.

Epidural Neural Blockade

Epidural neural blockade for the management of pain involves the injection of an LA into the epidural (extradural, peridural) space. The site of injection can be into the sacral canal (the so-called caudal block) or in the lumbar, thoracic, or cervical epidural space. The block can be achieved with a single injection of LA through a needle placed at the appropriate level or, more preferably, by the introduction of a catheter through a thin-walled, 18- or 17-gauge needle, advancing the tip of the catheter to the vertebral level that is considered to be the optimal site for injection.

Basic Considerations

General Indications. Continuous epidural block is one of the most versatile techniques for managing patients with acute and chronic pain. Placing the catheter at different levels of the extradural space can lead to analgesia of one or more spinal segments in almost any part of the body below the head. Continuous segmental

epidural analgesia is a most effective and practical procedure for relieving the pain of acute pancreatitis, biliary colic, renal or ureteral colic, rib fractures, and other severe posttraumatic pain and postoperative pain in the thorax, abdomen, pelvis, and lower limbs. It is also useful for providing temporary relief of severe local and segmental pain caused by herniated intervertebral disk or by fractures of the vertebrae. Continuous segmental epidural block provided through a variety of specially designed catheter systems may be extended for weeks or months for relief of pain due to cancer or nonmalignant conditions (e.g., CRPS).

Anatomic Basis. The epidural space is the interval between the periosteum that lines the vertebral canal and the various ligaments that connect the vertebrae and the pachymeninges (dura arachnoid) surrounding the spinal cord and roots in all of their extension from the foramen magnum to the conus terminalis, which in the adult extends to the S-2 vertebra (186,187 and 188). The epidural space continues inferiorly as the sacral canal, and laterally it communicates with the paravertebral tissues and spaces by the 48 intervertebral foramina through which the spinal nerves make their exit (Fig. 102-55).

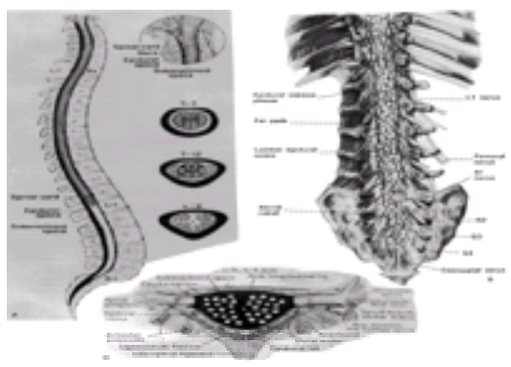

Figure 102-55. Anatomy of the epidural space. **A:** Sagittal section of the spinal column. Inset: Enlarged view of the upper cervical region indicates that the epidural space does not extend beyond the foramen magnum, where the dura attaches to the entire circumference of the foramen. Below the inset are three cross-sectional views of various levels of the vertebral column. The epidural space has a different shape in the midthoracic and midlumbar regions. (From Bonica JJ. *Principles and practice of obstetric analgesia and anesthesia.* Vol 1. Philadelphia: FA Davis, 1967:622, with permission.) **B:** Posteroanterior view of the epidural space after the spinous processes and laminae have been removed, showing that its contents consist of an internal vertebral venous plexus accompanied by loose areolar tissue and fat. **C:** Schematic cross section of the spinal canal at the level of the intervertebral disk between the L-3 and L-4 vertebrae showing the shape and size of the epidural space and its contents and the position of the rootlets that make up the cauda equina. (**B**,**C** from Bonica JJ, McDonald JS. *Principles and practice of obstetric analgesia and anesthesia,* 2nd ed. Baltimore: Williams & Wilkins, 1995:412–413, with permission.)

The width of the epidural space varies greatly, with the anterior portion being narrow and almost theoretical because of the close contact of the dura with the posterior longitudinal ligament (see Fig. 60-7). The posterolateral portion of the epidural space is found between the dura and the ligamenta flava and laminae. Because of the shape of the spinal canal, the epidural space in the posterolateral region is somewhat triangular, being widest in the midline between the dura and the junction of the two laminae. This triangular space varies in its anteroposterior diameter as follows: 1.5 to 2.0 mm at C-7, 3.0 to 4.0 mm at T-2, 3.0 to 5.0 mm in the midthoracic region, 5.0 to 6.0 mm at L-2, and only 2 mm at the lumbosacral junction (185,186).

The contents of the epidural space include solid and liquid fat and loose areolar tissue, through which run the internal vertebral venous plexus, lymphatics, and the dural projections that surround the spinal nerve roots (see Fig. 102-55). Fat is abundant in the posterolateral space, where it forms pads that intervene between the dura and the laminae and ligamenta flava. Although this tissue is loosely adherent to the vertebral canal and dura, it is easily stripped from the dura by fluids that disperse from the point of injection.

Because the spinal cord ends at the level of the lower part of the L-1 or the middle part of the L-2 vertebra in 90% of adults, the dura arachnoid below the L-2 vertebra contains only the cauda equina. This obviates the risk of injuring the conus medullaris with the epidural needle or catheter if the puncture is done below L-2. Experienced anesthesiologists, however, can safely perform epidural punctures and introduce catheters at any level, including the lower cervical, thoracic, or lumbar region, as well as the sacral canal to produce caudal analgesia.

Technical Considerations

Spinal Epidural Block. The single-injection technique for block of the epidural space in the lumbar, thoracic, or cervical region is best carried out with a 20-gauge, short-beveled spinal needle. For the continuous technique, a special 18-gauge, thin-walled needle (e.g., Tuohy) that allows passage of a catheter is used. The most important part of the procedure is to advance the point of the needle through the thick ligamentum flavum *slowly*, using the lack of resistance test, and *promptly* arresting the advance of the needle once its bevel has passed into the epidural space. Unless this step is done slowly and cautiously, with full control of the advance of the needle, the needle could be accidentally advanced too far and enter the subarachnoid space. For a single injection, the midline approach can be used (Fig. 102-56 and Fig. 102-57). To introduce a catheter, the paramedian approach, first described by Bonica (188), may be preferable (Fig. 102-58 and Fig. 102-59). Figure 102-60 illustrates the paramedian approach, which facilitates the advance of the catheter in the epidural space.

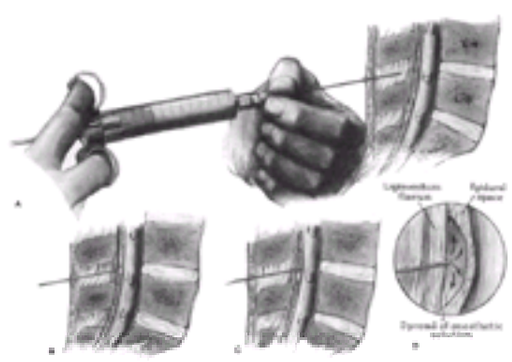

Figure 102-56. Epidural puncture into the lumbar region using the midline approach. **A:** After producing an intracutaneous wheal in the midline between the tips of adjacent spinous processes, a 20-gauge, short-beveled needle attached to a syringe filled with saline solution is introduced into the interspinous ligament. The back of the left hand is held against the patient's back, with the thumb and index finger grasping the hub of the needle; these act as a fine control of the advance of the needle while it is being pushed anteriorly with the right hand. An attempt to inject the saline solution while the point of the needle is in the interspinous ligament meets with some resistance. **B:** The point of the needle is in the ligamentum flavum, which offers marked resistance and makes it impossible to inject the solution. **C:** Entrance of the point of the needle into the epidural space is discerned by the sudden lack of resistance to the injection of the saline solution. **D:** The force of injection of 8 to 10 mL of saline solution pushes the dura-arachnoid away from the point of the needle. (From Bonica JJ, McDonald JS. *Principles and practice of obstetric analgesia and anesthesia*, 2nd ed. Baltimore: Williams & Wilkins, 1995:431, with permission.)

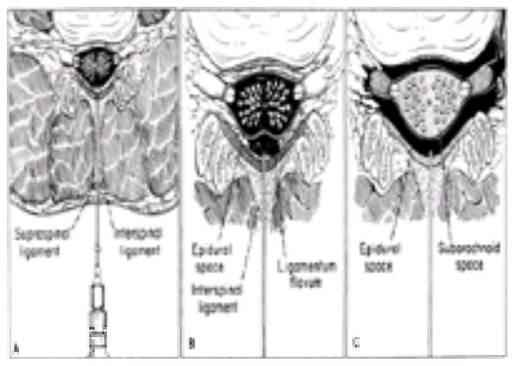

Figure 102-57. Cross section at the midlumbar region to show the technique for epidural puncture using the midline. **A:** The point of the needle is in the ligamentum flavum, which offers marked resistance to the injection of saline solution. **B:** Injection of saline pushes the dura slightly anteriorly, thus decreasing the risk of puncture of the dura by the bevel of the needle. **C:** Injection of the local anesthetic solution causes diffusion throughout the epidural space and penetrates the dura-arachnoid to involve the rootlets. (From Bonica JJ, McDonald JS. *Principles and practice of obstetric analgesia and anesthesia,* 2nd ed. Baltimore: Williams & Wilkins, 1995:432, with permission.)

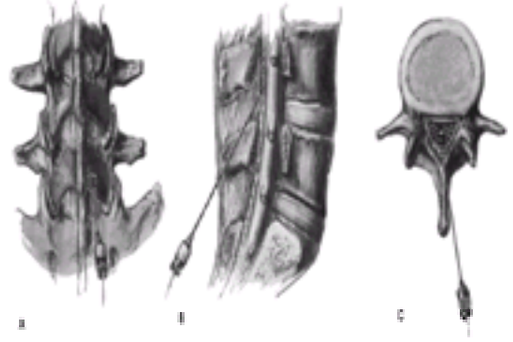

Figure 102-58. Continuous epidural block in the lumbar region using the paramedian approach. **A:** Posterior view showing the relationship of site of puncture, direction of needle, and spinous process. The anesthetic wheal is made 1.5 cm, from the midline at the same cross-sectional level as the lower tip of the spinous process. Following formation of the wheal, a 22-gauge needle is used to infiltrate the subcutaneous tissue, muscle, and upper medial part of the lamina with about 10 mL of a dilute local anesthetic solution (0.5% lidocaine). A special 18-gauge, thin-walled Tuohy needle is introduced so that its axis makes an angle of approximately 15 degrees with the midsagittal plane. **B:** Side view showing the same relationship and position of tubing in the epidural space as in A. The laminae and pedicles of the vertebrae have been removed. The needle makes a 35- degree angle with the skin inferior to the point of insertion. **C:** Superior view showing the relationship of the needle to the midsagittal plane and the position of the needle point in the epidural space, with the bevel of the needle facing cephalad. (From Bonica JJ, McDonald JS. *Principles and practice of obstetric analgesia and anesthesia,* 2nd ed. Baltimore: Williams & Wilkins, 1995:433, with permission.)

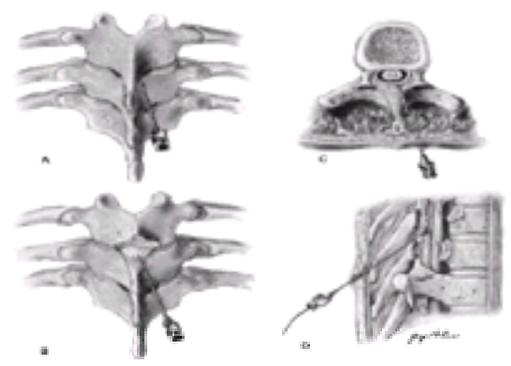

Figure 102-59. Continuous epidural block in the midthoracic region using the paramedian approach. **A:** The obliquity of the spinous processes is extreme, and bony spurs are usually on the surface of the adjacent spinous processes, making introduction of the needle through the supraspinous and intraspinous ligaments difficult, so the paramedian approach facilitates the puncture and the introduction of a catheter. The skin wheal is made 1.5 cm lateral to the tip of the spinous process of the vertebra above the interspace to be penetrated. The first step is to contact the medial upper part of the lamina. (The syringe, which is usually attached to the needle throughout its advancement, is not shown for the sake of clarity.) **B:** The bevel of the needle is in the ligamentum flavum in the midline. At this point injection of saline solution creates resistance until the ligament is traversed, after which a sudden lack of resistance can be felt. **C:** Cross-sectional depiction of the relationship of the needle to the soft tissue, spinous process, lamina, and ligaments. The bevel of the needle is near the midline of the epidural space and is facing cephalad. **D:** Sagittal section with the lamina and pedicles removed showing the relationship of the needle to the surrounding structures and to the catheter in the epidural space. (From Bonica JJ. Continuous peridural block. *Anesthesiology* 1956;17:626–630, with permission.)

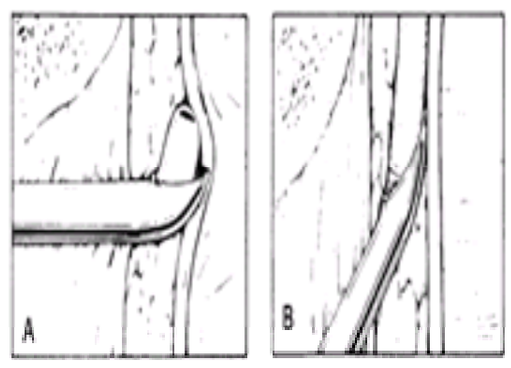

Figure 102-60. Schematic depiction of the advantage of introducing the Tuohy needle by a paramedian approach in the lumbar region at an angle that facilitates advancement of the catheter through the needle as compared to use of the midline approach. **A:** A Tuohy needle is introduced through the midline and advanced sufficiently so that its entire bevel is within the epidural space. If the space is narrow the dura might be partially punctured. Also, because of the direction of the bevel of the Tuohy needle, the tip of the catheter is directed anterosuperiorly against the dura in an attempt to make a 90-degree turn cephalad; not infrequently it is prevented from advancing by a fat pad or a vein lying on the dura. **B:** A paramedian approach with the Tuohy needle causes the catheter to be directed more cephalad, thus facilitating its advance within the epidural space. Moreover, because the point of the needle is directed cephalad, the possibility of puncturing the dura is small. (From Bonica JJ. *Obstetric analgesia and anesthesia.* Seattle: University of Washington Press, 1980:102, with permission.)

Once the bevel of the needle is actually within the epidural space, an injection can be made. Alternately, a catheter is passed through the needle and the needle is subsequently withdrawn. Using currently available catheters, only 4 to 5 cm should be inserted into the epidural space beyond the bevel of the needle. Attempts to introduce a greater length of catheter, or to thread the catheter to points remote from the site of puncture, lead to an unpredictable position of the catheter tip

(189,190). Epidural catheters can be threaded under fluoroscopic control, particularly if they have a wire stylette.

When segmental epidural analgesia is being used, the site of injection or catheter placement should be close to the center of the spinal segments that the physician wishes to block with the LA. This ensures that drug placement is accurate and that the dose of drug necessary to produce the desired effect is relatively small when compared to that of an injection at a remote site (191).

Indications and Techniques

Diagnostic Block. Segmental epidural blockade can be used as a diagnostic aid in determining the levels of nociceptive input in patients with visceral or somatic disorders. This procedure is not as useful as a selective sympathetic or somatic nerve block, because the technique invariably produces a block of both sympathetic and somatic nerves. The use of a differential epidural block may overcome some of the limitations of differential SAB; it allows better patient movement and associated testing for pain, while providing for repeated tests if some responses are equivocal. However, diagnostic differential epidural LA block carries the same limitation of interpretation as subarachnoid differential block (174). On the other hand, by using a volume of anesthetic at various intervals, the segmental level(s) of nociceptive input can be established.

A further variant of diagnostic epidural block is the “differential” epidural opioid blockade combined with epidural lidocaine as a diagnostic tool in patients with chronic pain. This procedure is based on the assumption that epidural opioids block nociceptive input at the level of the dorsal horn, leaving sensory, sympathetic, and motor functions unchanged without giving patients “cues” that blockade has occurred (192). At 20-minute intervals, patients receive epidural injections: two injections of normal saline (placebo), one injection of 1 µg per kg fentanyl, 0.4 mg intravenous naloxone, and, depending on the results obtained, 15 to 20 mL of 2% lidocaine injected through the epidural catheter. If the visual analog pain score decreased following epidural fentanyl and subsequently increased following naloxone, then a predominantly physical basis for the pain was considered to be likely. In contrast, little change in the visual analog score following the administration of fentanyl and naloxone suggested a predominantly emotional basis for the pain. The specificity of the technique has been called into question as the opioids reach both CSF and systemic circulation, providing CNS “clues,” and some types of pain are not well relieved by spinal opioids (174,193). Recommendations for a modification of the original technique are given in Table 102-7 (174).

Step	Amount and agent used	Injection type
1	10 mL of 0.9% saline without preservative	Epidural; placebo
2	10 mL of 0.9% saline without preservative	Epidural; placebo
3	10 mL solution of fentanyl, 100 µg	Epidural
4	Naloxone, 0.4 mg	I.V.
5	Lidocaine 2%, 20 mL	Epidural

Note: A visual analog scale is used to record pain relief. The pattern on response is suggested as being useful.

TABLE 102-7. Diagnostic epidural opioid blockade

Prognostic Block. Epidural blocks with LA can be used as prognostic procedures as an alternative to individual nerve blocks but suffer the same limitations as noted above in regard to diagnostic blocks. A more recent indication is the use of epidural blocks as prognostic indicators for the possible efficacy of epidural opioids in patients with cancer pain. Most physicians who use epidural opioids for pain therapy confirm catheter placement and the efficacy of the technique by injecting an LA into the epidural space and noting its analgesic spread (Chapter 103).

Prophylactic Block. The potential preemptive effect of perioperative epidural analgesia with LA and opioid on the incidence of phantom limb pain after amputation was mentioned earlier (14). This technique involves beginning the epidural preoperatively and continuing the block for several days postoperatively. A substantial reduction in the incidence of phantom limb in both short- and long-term follow-up has been reported. The possible mechanisms of this phenomenon are discussed in Chapter 9 and Chapter 41.

Therapeutic Blocks. Continuous segmental epidural or caudal analgesia with LA can be used for the relief of acute postoperative or posttraumatic pain that occurs below the clavicle (Fig. 102-61). The introduction of continuous epidural narcotics with or without added LAs for the relief of acute postoperative or posttraumatic pain has markedly decreased the indications for which LAs alone are used. This technique permits the use of smaller amounts of LA, with less risk of systemic effects, while at the same time providing the advantages of LAs as well as the relief of pain (194).

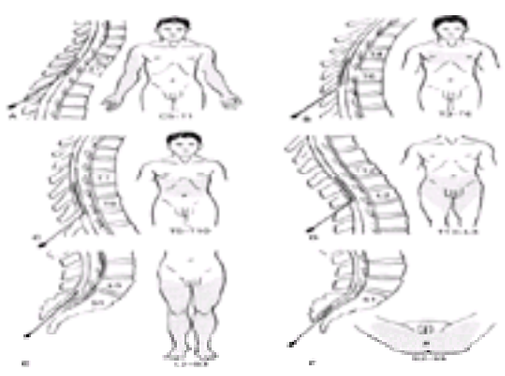

Figure 102-61. Patterns of segmental epidural analgesia, achieved with injection of a local anesthetic for the relief of pain in various regions of the body. On the left of each part of the figure is a sagittal section showing the site or level of the epidural puncture for placement of the Tuohy needle and subsequent insertion of the catheter (*black*), which is advanced 4 to 5 cm in the epidural space so that its tip is in the center of the band of analgesia desired. The right part depicts the region of the body in which pain is relieved (*stippled area*). **A:** Analgesia for pain in the upper limbs bilaterally. **B:** Analgesia to control pain in the upper part of the chest. **C:** Analgesia to control pain following upper abdominal surgery. **D:** Segmental analgesia following lower abdominal surgery to control pain and to produce continuous lumbar epidural block. **E:** Analgesia to relieve pain in the deep pelvis and the lower limbs. **F:** Continuous low caudal analgesia (S2-5) to relieve pain after hemorrhoidectomy or after other operations involving the perineum.

Epidural Blockade for Acute Pain

Chest Injuries. Patients with chest injuries present a spectrum of severity of trauma (Fig. 102-62). At the worst end of the spectrum are patients with chest wall instability and pulmonary contusion leading to pulmonary failure. At the other end of the spectrum are patients with chest wall injury with or without instability, little or no pulmonary contusion, and little or no evidence of respiratory failure. Patients with pulmonary failure require tracheal intubation and ventilation. Patients with chest wall instability and no pulmonary failure, once hemothoraces and pneumothoraces have been drained, can be managed with supplemental oxygen and respiratory therapy maneuvers (195,196), especially when effective epidural analgesia is provided (197,198 and 199). Patients with similar degrees of chest and lung injuries but suitable for conservative management regimens have had lower morbidity and mortality rates and a shorter duration of intensive care unit stay (196).

Figure 102-62. Management protocol for patients with chest injury. CPAP, continuous positive airway pressure. (Modified from Dittmann M, Steenblock U, Kränzlin M, Wolff G. A rationale for epidural analgesia in the treatment of rib fractures. *Intensive Care Med* 1982;8:89–92.)

Trials of conservative regimens show their benefit (Table 102-8). Patients with severe pulmonary contusions and respiratory failure should be treated with tracheal intubation and positive pressure ventilation (see Table 102-8, group 1). Patients with major pulmonary injury, or those who might need artificial ventilation for other reasons, should initially be treated with artificial ventilation. But, as the pulmonary lesion and pulmonary status improve, they can be weaned from such support, have the endotracheal tube removed, and be managed with spontaneous ventilation and epidural analgesia (see Table 102-8, group 2). Patients with chest wall instability but little or no discernible pulmonary injury and respiratory failure, once hemothorax and pneumothorax are drained, can be managed with epidural analgesia, oxygen, and respiratory therapy (see Table 102-8, group 3). If patients are managed by the conservative protocol, as in group 3, it is important to monitor the pulmonary status closely and to treat any incipient or declared respiratory failure by positive pressure ventilation. This was necessary in five of 112 patients (200) (see Table 102-8, group 3).

	Group			Group		
Parameter	1	2	3	1	2	3
No. of patients	13	7	16	155	27	112
Mean no. of rib fractures	5.7	4.7	5.5	6.6	–	6.8
No. of patients with hemo- or pneumothorax	9	3	8	92	–	48
No. of patients with pulmonary contusion	13	2	4	38	–	1
Mean duration of hospitalization in days	27	11	18	26	–	17
Deaths	2	0	1	18	0	5

Group 1: Endotracheal intubation and positive pressure ventilation.
Group 2: Endotracheal intubation and positive pressure ventilation followed by early extubation and pain management with epidural local anesthesia.
Group 3: Epidural local anesthesia plus supportive oxygen and respiratory therapy only. See text for more detailed definitions of groups.
[a]The group, which was part of group 1 primarily ventilated, could be weaned early under thoracic epidural analgesia without additional measure.

TABLE 102-8. Results of management of chest injuries

If epidural analgesia is to be used in patients with chest injuries, it is critical that the technique not be started until the patient has been adequately resuscitated with blood or crystalloid solutions, as needed. The adequacy of resuscitation should be ascertained by the measurement of central venous pressure and other parameters. The technique should also be used with caution in patients with CNS injuries or extensive injuries elsewhere.

When epidural analgesia is used for chest injuries, the catheter should be placed close to the middle of the segment(s) in which the analgesia is desired. If it is anticipated that the catheter might have to be in place and in use for a long period, consideration should be given to tunneling the catheter subcutaneously to minimize the risks of catheter displacement and infection. The doses of LA necessary for providing epidural analgesia are 5 to 8 mL of 0.5% bupivacaine with epinephrine or an infusion of 0.25% bupivacaine at a rate of 6 to 8 mL per hour (201) or mixtures of LA plus opioid (Chapter 103). Epidural opioids alone can be used as a baseline analgesic technique (202) or supplemented with epidural injection of LAs for painful maneuvers such as coughing (203) or with opioid/LA mixtures (44).

Postoperative Pain. Historically, segmental epidural analgesia with LA alone has been used to provide pain relief after thoracic, abdominal, pelvic, and leg operations. The drug was delivered either by intermittent injections, which could result in spotty pain control and a substantial incidence of side effects, or by constant infusions of LA. Epidural analgesia with LA alone but has been superseded by epidural analgesia with opioids alone (Chapter 103) or by the use of epidural analgesia using a combination of opioids and LA. This latter technique may provide superior analgesia and be associated with a lesser incidence of unwanted effects compared to the other two techniques. Epidural opioid and LA anesthesia is usually achieved with an infusion of a dilute solution of LA (bupivacaine 0.0625% to 0.1250%, ropivacaine 0.1% to 0.2%), at a rate to provide a “thin” block of the affected segments. The opioid is either a moderate duration of action opioid injected intermittently (morphine, 2 to 4 mg 4 hourly) or included in the infused LA solution (morphine, 10 to 40 µg per mL; fentanyl, 1 to 4 µg per mL).

Irrespective of whether the segmental epidural analgesia is produced with LA alone, opioid alone, or a mixture of the two, certain practical tenets apply with respect to catheter placement (see Fig. 102-61). The catheter tip should be placed in an interspace that corresponds with the center of the spinal segment affected by the surgical trauma. If the catheter is placed at a segment distant from the center of the affected areas, larger doses of drug will be needed to produce the desired effect, analgesia may not be as effective, and doses of drug will be larger. For thoracic operations where the incision usually passes through the fifth intercostal space, the catheter tip should be placed at T-6 to T-7. For midline sternotomy operations, the catheter tip should be placed at T-4 to T-5. For upper abdominal operations where the incision passes through T-5 to T-10, the catheter tip should be placed at T-8 to T-9. For lower abdominal operations with incisions through T-10 to L-1 to L-2, the catheter tip should be placed at T-12 to L-1. For hip, pelvic, or leg operations, the catheter tip should be placed at L-3 to L-4 or L-4 to L-5. The caudal route is a feasible route for catheter placement for the latter operations but is little used because of concern of infection in the gluteal cleft.

The manner in which LA, or LA plus opioid, is delivered follows from obstetric practice of slow infusions. The infusions are titrated to produce pain control and evidence of somatic block and to avoid side effects. Typical rates of infusion are as follows: thoracic, 4 to 8 mL per hour; upper abdominal, 8 to 10 mL per hour; lower abdominal, 8 to 19 mL per hour; and pelvic and leg, 10 to 14 mL per hour. More recently, patient-controlled epidural analgesia, using patient-controlled analgesia technology, has been shown to be effective and safe (204).

Postoperative pain relief provided by systemic opioids administered by intramuscular injection has been widely criticized as being of poor quality. The quality of pain relief has been clearly improved by the introduction of techniques (e.g., opioid patient-controlled analgesia) that permit the more pharmacokinetically and pharmacodynamically rational delivery of opioids (Chapter 84). However, other postoperative sequelae (respiratory, cardiovascular, endocrine) are little changed by these techniques. Epidural techniques with LA alone, opioid alone, or mixtures of LA and opioid provide superior analgesia, and their use is associated with other postoperative benefits.

Abdominal surgery, particularly upper abdominal surgery is followed by significant changes in indices of respiratory function and arterial oxygenation and by a high incidence of chest infection (Chapter 41). When compared to patients receiving conventional narcotic analgesia, patients receiving epidural analgesia with LA tend to maintain a more normal PaO_2 (204,205,206,207 and 208) and to have a lower incidence of chest infection (205,210). Patients have a better forced vital capacity and peak expiratory flow rate (205,206) and perhaps functional residual capacity (209,210 and 211). Patients in high-risk groups (e.g., morbidly obese patients) have a decreased incidence of respiratory complications (212,213). More recent studies in high-risk patients show significantly lower incidences of respiratory failure and respiratory infection in patients receiving epidural analgesia (214).

Surgery is associated with significant perioperative cardiovascular stressors that are manifest in a significant incidence of myocardial ischemia, arrhythmias, and myocardial infarction in patients at risk. Improved pain control, and perhaps other factors, associated with the use of epidural analgesia results in significant

improvements in incidence of arrhythmias, myocardial ischemia, and perioperative myocardial infarction (215,216).

Following surgery, there is a predictable hypercoagulable response that appears to be attenuated by LA epidural (217), and patients receiving epidural analgesia have a lesser incidence of DVT (44) and graft clotting (218).

Continuous epidural block from T-5 to the sacral segments during the perioperative period after lower abdominal operations markedly reduces the postoperative metabolic and neuroendocrine response to surgery. The marked increases in levels of the catabolically acting pituitary hormones (e.g., growth hormones, prolactin, adrenocorticotropin, antidiuretic hormone), adrenal hormones (e.g., cortisol, aldosterone, catecholamines), and serum glucose normally seen in patients given general anesthesia during surgery and managed with postoperative narcotics are minimized (219,220). Patients receiving epidural analgesia show fewer changes in hepatic enzymes (221). The significance of the reduction of these metabolic and neuroendocrine responses to trauma is not certain. Segmental epidural anesthesia for upper abdominal surgery and epidural analgesia during the postoperative period has fewer effects on these responses to tissue damage than are seen after lower abdominal and leg operations (220), probably because the vagus and the phrenic nerves are not blocked.

Acute Visceral Pain. Although celiac plexus block or splanchnic nerve block relieves the pain arising from the viscera, segmental continuous epidural block has the following advantages: (a) The block is technically easier; (b) it is more effective in relieving pain, not only that coming from the viscera but also that caused by irritation of the peritoneum (which is supplied by somatic nerves); and (c) it is much easier to produce sustained analgesia for a number of days than with other techniques.

For acute pancreatitis, the catheter is best placed with its tip at the T-7 or T-8 spinal cord segmental level. Dosage regimens should be as for upper abdominal surgery. The use of epidural analgesia to manage acute pancreatitis has been reported to reduce the incidence of early surgery and halve the mortality rate (151).

For the relief of biliary colic, a segmental analgesia of the same type is used, whereas for the relief of ureteral colic, the segments to be blocked are lower and depend on the site of the impacted stone. For pain caused by obstruction in the pelvis of the kidney or ureter, block of T-10 to L-2 provides pain relief.

CHAPTER 103

Regional Analgesia with Intraspinal Opioids

L. Brian Ready

BASIC CONSIDERATIONS

History

Opiate receptors were first identified in the central nervous system in 1973 (1); subsequently large populations of these receptors were localized in the dorsal horn of the spinal cord (2). These observations, coupled with the discovery of endogenous opioids (3), led to animal studies that demonstrated the ability of intrathecal opioids to produce analgesia (4).

In 1979, Wang et al. reported pain relief using intrathecal morphine in cancer patients (5), and in the same year, Behar et al. achieved the same result injecting the drug into the epidural space (6). Subsequent studies have confirmed that selective, long- duration analgesia is possible using these techniques in a variety of clinical settings. As experience increased, it became clear that a number of side effects might be expected, ranging from annoying (sedation, pruritus, nausea, vomiting, or urinary retention) to life-threatening (respiratory depression). It is now apparent that with attention to patient selection, appropriate choice of drugs, dosage, route of administration, and adequate patient monitoring, the benefits of intraspinal opioid analgesia can be obtained with a high degree of safety (7).

This chapter contains a discussion of the basis and clinical application of intraspinal opioids for the management of pain. The term *intraspinal* is used to include both intrathecal (subarachnoid) and epidural routes when considering them together. This chapter is devoted primarily to the use of intraspinal opioids. However, the evolution of clinical practice has led to combinations of intraspinal opioids and local anesthetics; these are also included. Brief mention is also made of a number of other drugs that produce intraspinal analgesia. These include clonidine, ketamine, neostigmine, and amitriptyline.

Theoretical Bases

Anatomy

Nerve impulses resulting from noxious stimuli and transmitted predominantly by slowly conducting A-d and C fibers are modulated in the spinal cord before ascending to higher nerve centers in the brain. This modulation occurs through interactions at sensitive interneurons and associated receptors found in high concentration in the substantia gelatinosa of the dorsal horn (2). It is mediated by endorphins—naturally occurring peptides that selectively impair the transmission of nociceptive impulses and consequently the perception of pain without affecting somatic, autonomic, or motor functions.

Since the initial discovery of central nervous system opioid receptors, five types have been demonstrated: mu, kappa, delta, sigma, and epsilon (8). Opioids administered by the intrathecal or epidural route can, like endorphins, act on these receptors to produce profound selective analgesia. It is likely that the specificity, affinity, and intrinsic activity of each agent reaching the various receptors will determine its pharmacologic effects. The mu receptor is the dominant site in mediating analgesia, although delta and kappa receptors are also believed to play a role. The receptors most important in mediating somatic pain may differ from those mediating visceral pain (9). This could explain the clinical observation that although intraspinal opioids may completely relieve incisional pain after surgery, bowel distension accompanying ileus is often not affected.

Mechanisms of Action

Intrathecal. With the injection of an opioid into the cerebrospinal fluid (CSF), a reservoir of drug is created that passively diffuses into the dorsal horn of the spinal cord. There it binds to opioid receptors, where it is presumed to inhibit the release of substance P, a neurotransmitter believed responsible for relaying nociceptive information across synapses. This inhibition is reversible with opioid antagonists such as naloxone.

Epidural. An opioid injected into the epidural space produces analgesia by two mechanisms. First, a portion of the drug crosses the dura mater to enter the CSF. From there, it penetrates into the dorsal horn of the spinal cord as after direct intrathecal injection (10). Second, systemic absorption of the extradural bolus produces a plasma profile similar to that after intramuscular injection (11). The systemic levels of opioids make a contribution to analgesia, as the drug is distributed to both the brain and spinal cord. That contribution varies with the opioid's lipophilicity and may be substantial.

Comparison of Intrathecal and Extradural Injection

When an opioid is injected into the CSF directly, only small doses are required because there are no anatomic barriers to be crossed and removal by vascular absorption is slow. Administration by this route creates a reservoir of concentrated drug close to its site of action, where its effects are limited primarily to the spinal cord. If the epidural route is chosen, the opioid dose must be higher than with the intrathecal route to produce comparable analgesia. In the case of morphine, a tenfold increase is needed (11). The CSF uptake of morphine administered into the epidural space is only approximately 2%, but morphine concentrations achieved in CSF are more than 100 times higher than those found after intramuscular injection. The highly vascular epidural space clears opioids more rapidly than the relatively avascular subarachnoid space. Even so, at least in the case of a hydrophilic opioid (e.g., morphine), the epidural dose is only a fraction of that required to produce analgesia by intramuscular or intravenous administration. After initial human experience with both intrathecal and epidural opioids, the epidural route has achieved much greater popularity. This is due in part to the ease with which indwelling catheters can be placed in the epidural space for extended use.

Comparison with Regional Analgesia Using Local Anesthetics

It is useful for the clinician familiar with offering pain relief with local anesthetic neuraxis blocks (spinal, epidural) to compare and contrast these with intraspinal opioids. Table 103-1 provides this information in a manner used previously by Cousins and Mather in a comprehensive review (12). A major difference from local anesthetic techniques relates to the highly specific “block” of nociceptive pathways with intraspinal opioids and the implications that this selectivity has for patient mobility and activity.

Combinations of opioids and dilute local anesthetics are now widely used. The rationale is to reduce the dose of each component of the mixture while preserving effective analgesia, reducing side effects, and preserving function. Experience with these techniques is discussed later in this chapter.

	Opioid	Local anesthetic
Anesthetic action		
Site	Opioid receptor in dorsal horn of spinal cord	Nerve roots
Inhibition	Neuronal excitation	Axonal membrane impulse conduction
Pathways blocked	Pain	Pain, sympathetic, sensory, motor, proprioception
Side effects		
Cardiovascular	None	Hypotension
Respiratory	Early depression (systemic absorption) Delayed depression (rostral spread in cerebrospinal fluid)	None
Sedation	Variable; less than with systemic opioids	None
Nausea/vomiting	Yes	Occasional
Pruritus	Yes	None
Urinary retention	Yes	Yes (if sacral nerve roots blocked)
Convulsions	Associated with very high doses and meperidine	With high systemic drug levels

TABLE 103-1. Comparison of intraspinal opioid and local anesthetic block

Pharmacokinetics and Pharmacology

Uptake and Distribution of Intraspinal Opioids. The efficacy of intraspinal opioids is dependent on their passage from their site of injection to the spinal cord receptors in the dorsal horn. After intrathecal injection, the rate at which a drug penetrates the tissue of the spinal cord is closely related to its lipid solubility. More rapid uptake and more rapid onset of action are seen with highly lipid-soluble drugs such a fentanyl and meperidine than with a less lipid-soluble agent such as morphine. Table 103-2 contrasts a drug of low lipid solubility (morphine) with one of high lipid solubility (fentanyl) with regard to their clinically observable analgesic effects.

	Lipid solubility of opioid	
Effect	Low (e.g., morphine)	High (e.g., fentanyl)
Spinal cord receptor uptake (onset of analgesia)	Slow	Rapid
Clearance from CSF (duration of action)	Long	Short
CSF concentration	High	Low
Rostral spread of opioid	Extensive	Limited
Systemic blood levels	Low	High

CSF, cerebrospinal fluid.

TABLE 103-2. Effects on analgesia of opioid lipid solubility

After epidural injection, an opioid must also penetrate the dura mater—a relatively thick membrane—and the arachnoid membrane. Both significantly slow its rate of diffusion. Arachnoid protrusions in the spinal root sleeves represent a possible route for passage of epidural injectates into CSF (13). The possible role of uptake and delivery to the dorsal horn by the posterior radicular arteries has also been described (12). Studies have refuted these concepts; the arachnoid itself seems to be the effective barrier to the CSF (10).

The rate of dural penetration of epidural opioids is influenced by lipid solubility (14), molecular weight (15), and their dissociation constant (pK_a). Fentanyl, meperidine, and methadone all have a relatively high pK_a. Because this favors high concentrations of freely diffusible unionized molecules, these drugs exhibit a rapid onset and limited duration of spinal analgesia. Morphine, with a lower pK_a, has a lower concentration of unionized molecules after injection. This factor contributes to its slow onset and long duration of action.

After epidural injection, vascular absorption decreases the concentration gradient across the dura, thus reducing the rate of transfer. The addition of epinephrine to epidural morphine has been reported, by reduction of systemic absorption, to increase speed of onset, quality of analgesia, duration of analgesia, and intensity of side effects (16). In another study, only an increased frequency of side effects was found (17). A majority of clinicians do not use solutions that contain epinephrine for epidural administration.

Some portion of an opioid injected into the epidural space diffuses into fat and thus does not cross the dura. Uptake by blood vessels in the epidural space results in serum levels that contribute an element of supraspinal analgesia. The more lipophilic drugs show the fastest and greatest uptake by fat and thus the highest serum levels. These agents, exemplified by fentanyl and meperidine, also move rapidly from CSF into the lipid-rich tissues of the spinal cord. With such agents, onset of spinally mediated analgesia is rapid and the effect is relatively segmental near the injection site. Low lipid solubility, as in the case of morphine, leads to prolonged high CSF drug concentration, low tissue fixation, and the possibility of rostral spread in CSF. The sustained exposure of spinal cord opioid receptors results in a long duration of action.

Metabolism and Clearance of Intraspinal Opioids. It is not yet established what role metabolism plays in the termination of the spinal action of opioids after intrathecal or epidural injection, but considering the high concentrations of drug present, it is unlikely that it is a major factor. Loss of analgesia after intraspinal injection primarily results from drug clearance from the site of action. Strong receptor binding seen with polar agents such as morphine retards clearance compared with more lipophilic agents.

Intrathecal opioids are eliminated by two routes: diffusion along the neuraxis and vascular absorption. Rostral spread of CSF from the spinal subarachnoid space to the supraspinal cisternae has been demonstrated (18), making clearance through intracranial arachnoid granulations one likely mechanism. Vascular absorption of intraspinally administered opioids may occur as a result of movement into spinal cord blood vessels or, after epidural injection, into the venous plexus found in the epidural space. High lipid solubility favors passage of drug into blood vessels at either site.

Tolerance to Intraspinal Opioids. Tolerance, the decrease in effect over time of a given dose of drug, has been demonstrated in animals with both intrathecal and epidural opioids (19), as has cross-tolerance between intrathecal and systemically administered morphine (20). In humans, conflicting information is found. Rapid development of tolerance similar to that seen in animals has been reported in cancer patients who received 1 mg of intrathecal morphine per day (21). In contrast, cancer patients receiving epidural morphine in divided doses by intermittent injection showed little or no need for increased dose for as long as 280 days (22).

The mechanism leading to the development of tolerance is not known, although there is growing evidence in support of a role of the glutamate receptor of the *N*-methyl-d-aspartate type (23,24 and 25). A number of clinical observations may be of practical importance. First, consumption of parenteral opioids before commencing epidural treatment may increase the required dose (26). Second, the rate of onset of tolerance seems proportional to the concentration of the opioid at the receptor—that is, the degree of receptor activation. Therefore, it is speculated that the rate of development of tolerance might be minimized by (a) selection of the lowest effective opioid dose, (b) precise placement of opioid for optimal segmental effect, (c) small divided doses rather than large single daily doses, and (d) the use of low-dose continuous infusion systems when there is a need for extended periods of analgesia.

Toxicology of Intraspinal Opioids

The toxicology of intraspinal opioids has been examined in a number of animal and clinical situations. Repeated intrathecal and extradural injections of analgesic doses of opioids lead to no neurologic symptoms or observable adverse effects on spinal cord cells or fibers. No turbidity is seen when morphine, meperidine, or methadone is added to CSF, but it is present after the addition of heroin, suggesting precipitation of CSF protein.

A vast worldwide human experience with intraspinal opioids, sometimes administered in high doses for long periods, has not led to signs of neural injury. A number of opioids are supplied by their manufacturer in solutions containing no additives. Others contain preservatives, antioxidants, and buffering agents. It is not known whether any of these additives can be damaging after intraspinal or epidural injection. Sodium bisulfite, an antioxidant present in some local anesthetic solutions and some opioid solutions, does appear to be a dose-related neurotoxin (27). Preservative-free preparations of morphine (Duramorph, Astramorph) are marketed specifically for intraspinal use. These are considerably more expensive than preservative-containing morphine preparations—a significant consideration in cancer patients who may require large doses for extended periods of time.

Advantages and Disadvantages

Intraspinal opioids have dramatically improved the management of many painful conditions, and as a result, hundreds of thousands of patients worldwide have experienced pain relief. In general, opioids acting on spinal cord receptors provide distinct advantages over the same agents acting through supraspinal mechanisms. Under most circumstances, the quality of analgesia is greater, sedation is less, function is preserved, and a variety of outcomes are improved.

Side effects are common using intraspinal opioids but they are probably no more frequent or severe compared with the doses of systemic opioids required to produce equivalent analgesia. The administration of intrathecal opioids requires additional knowledge, skills, and institutional organization to achieve optimal efficacy and safety. Practice guidelines have been developed and should be considered by practitioners interested in using intraspinal opioids for their patients (28).

CLINICAL INFORMATION

Applications

Acute Pain

Postoperative Pain. Intraspinal opioids have been reported to control pain effectively after a wide variety of surgical procedures. Intrathecal opioids have the appeal of ease of administration, either at the time of spinal local anesthetic injection for surgical anesthesia or as a separate technique when general anesthesia is administered. Because most clinicians give a single injection, this technique is most appropriate when surgical pain is expected to be of relatively short duration. Many patients remain comfortable for 24 hours or more after a single injection of intrathecal morphine. Some of these will require no additional pain relief during their postoperative course or will find their remaining pain easily managed by oral analgesics.

The epidural route has been used much more extensively than the spinal route for postoperative pain control. Reasons include popularity of the technique alone or in combination with light general anesthesia during surgery, ability to leave an epidural catheter in place for extended periods to maintain analgesia, familiarity with postoperative analgesia using local anesthetics, and freedom from the risk of post–lumbar puncture headache. Epidural opioids have been effective in patients of all ages, including children (29,30,31,32,33 and 34).

A number of reports regarding the use of epidural opioids for postoperative pain are of special interest. Stenseth et al. reported a prospective study of the efficacy and side effects of epidural morphine in 1,085 patients after thoracic, abdominal, urologic, or orthopedic surgery (35). This large experience from a single institution provides a wealth of observations that are instructive to the clinician contemplating the use of epidural opioids.

Rawal et al. (36), in a randomized double-blinded study of 30 obese patients undergoing gastroplasty for weight reduction, compared the effects of intramuscular and epidural morphine with respect to analgesia, time to ambulation, gastrointestinal motility, early and late pulmonary function, duration of hospitalization, and occurrence of deep vein thrombosis in the postoperative period. The protocol allowed morphine to be given by the assigned route until pain was adequately controlled. The salient findings are detailed in Table 103-3.

	Intramuscular morphine	Epidural morphine
Mean morphine use over 36 hr (mg)	66	9
Patients with adequate pain relief (%)	93	100
Patients ambulating at 24 hr (%)	13	93
Mean time to passage of flatus (hr)	75	57
Patients with pulmonary complications (5)	40	13
Evidence of deep vein thrombosis (5)	20	0
Mean postoperative hospitalization (days)	9	7.1

Data from Rawal N, Sjostrand U, Christoffersson E, et al. Comparison of intramuscular and epidural morphine for postoperative analgesia in the grossly obese: influence on postoperative ambulation and pulmonary function. Anesth Analg 1984;63:583–592.

TABLE 103-3. Effects of epidural opioids on grossly obese surgical patients

Yeager et al. (37) compared outcome of high-risk surgical patients randomized to receive either general anesthesia and conventional postoperative analgesia or epidural anesthesia and epidural morphine analgesia. The epidural group had significantly lower mortality and lower incidence of major complications, shorter intensive care unit and hospital stays, and lower hospital and physician costs.

The use of intraspinal opioids for control of pain after cesarean section is widely practiced. This is offered when spinal or epidural anesthesia is provided for surgery (38), although most reports focus on the latter application. Pain after a large episiotomy repair or perineal repair may also be managed by intraspinal opioids.

It is now apparent that epidural analgesia after surgery, in addition to providing patient comfort, can facilitate accelerated recovery—an approach labeled *postoperative rehabilitation* by Kehlet (39). With this approach postsurgical patients receive not only effective pain relief but also immediate postoperative intake of oral nutrition, reduction in perioperative stress responses and organ dysfunction, early mobilization, avoidance of fatigue, and early hospital discharge.

Posttraumatic Pain. A small dose of epidural morphine (2 mg) was reported to be effective in controlling the pain that accompanies rib fractures (40). Its advantages over epidural bupivacaine for the same purpose were longer duration of action and absence of hypotension. Pain resulting from lower extremity fractures has also been relieved by epidural morphine (41).

Morphine by both the spinal and epidural route has been used to treat pain after multiple trauma in patients on mechanical ventilator support in an intensive care setting (42). Because communication was difficult or impossible in this group, adequacy of analgesia was documented by noting the marked reduction in doses of parenteral opioids and sedatives needed to eliminate objective signs of pain (restlessness, sweating, tachycardia, lacrimation, pupil dilatation, hypertension). Another group of intensive care patients who could communicate clearly after multiple trauma also experienced good analgesia with epidural opioids (43).

Other Acute Painful Conditions. The pain of acute myocardial infarction has been treated effectively with 0.5 mg of intrathecal morphine (44). The comfort it produced was more rapid in onset, more intense, and of longer duration during the first 24 hours than that obtained in a control group with total doses of parenteral morphine 40 times larger. In another report, 1.2 to 3.6 mg of epidural morphine was effective in relieving postmyocardial infarction pain in six patients after conventional intravenous analgesic agents had failed (45).

Patients with a variety of other acute painful conditions have experienced relief with intraspinal opioids. These conditions include acute lumbar disk prolapse, thrombophlebitis, acute herpes zoster, nephrolithiasis, and ischemic pain (41,42 and 43). Patients in an intensive care unit suffering severe pain as a result of pancreatitis were improved with either spinal or epidural opioids (42). Although the results of these reports are promising, the numbers of patients receiving treatment were small. Spinal opioids can reduce muscle spasm and associated pain in patients with spinal cord lesions. Implanted infusion devices have been used in some of

these patients, permitting treatment to continue for extended periods. More recently, intrathecal baclofen infusions have largely replaced morphine for this purpose.

Labor Pain. Intrathecal or epidural opioids and opioid–local anesthetic mixtures are widely used to provide pain relief for women in labor. A combination of the two techniques is also used (46). Because it is beyond the scope of this chapter to discuss obstetric analgesia in detail, the interested reader is referred to Chapter 71.

Cancer Pain

Many published reports have demonstrated effective pain relief in patients with cancer using either spinal or epidural opioids (see Chapter 36). The fact that effective doses and the need for supplemental analgesics differ among reports likely reflects differences in the magnitude of the pain problems in the populations studied. Patients with the most severe pain typically receive large systemic opioid doses before intraspinal opioids are used. Effective intraspinal doses in these groups are higher than those needed in opioid-naive patients. With advancing disease and increasing pain, intraspinal opioids combined with local anesthetics, other intraspinal drugs (e.g., clonidine), or supplemental agents by another route may be required for satisfactory analgesia.

Intraspinal Opioids. Both the spinal and epidural routes are effective. Intermittent injections through conventional catheters, catheters tunneled subcutaneously, implanted reservoirs, and infusion pumps all have their advocates. Compared with systemic opioids, the benefits of intraspinal opioids to control cancer pain relate in large part to the reduced dosage required. As a result, patients remain more alert. This in turn facilitates ambulation and social activities. Increased appetite and weight gain are also frequently noted. All these advantages facilitate patient care at home, leading to a higher quality of life and substantial economic savings compared with institutional care. Unlike local anesthetic or lytic blocks, sympathetic tone, motor power, and sphincter function are preserved. Compared with neurosurgical procedures, no irreversible changes are produced, but therapy must continue as long as the patient survives. Patients must also have access to health care providers trained in the techniques of refilling and programming pumps.

Reports of opioid tolerance with the need for escalating doses and frequency of injection vary among investigators. Tolerance appears to be an uncommon problem during the first several weeks or even months of therapy but it becomes progressively more likely the longer therapy is continued. Tolerance can be difficult to distinguish from rapid malignant tumor progression. A sudden increase in pain should prompt thorough reevaluation for new disease (e.g., tumor extension into the neuraxis). It is well known that nonorganic factors such as anxiety or depression may also lead to reporting of increased pain. Appropriate treatment of these conditions should not be overlooked.

Certain technical problems with spinal or epidural catheters are common in patients with cancer pain. These include obstruction, leaking, and dislodgment. Such problems result in failure of the injected opioid to reach its site of spinal action, with an accompanying increase in previously well-controlled pain. Periodic catheter replacement may be necessary in some patients. Infection can also occur and requires prompt diagnosis and treatment (47).

Radicular pain in some patients during epidural catheter injection has been noted. Caputi et al. (48) have stated that this symptom is due to the opioid fluid bolus causing distension of the dural sleeve of a spinal nerve root near the tip of the catheter. They found it could be resolved by the injection of triamcinolone through the catheter several times at intervals of 3 or 4 days. Others have found that catheter replacement solves the problem.

Serious respiratory depression is rare in cancer patients treated with intraspinal opioids, even when very high doses have been administered. It is believed that exposure to opioids by other routes before starting intraspinal injections confers tolerance to the respiratory depressant effects sometimes seen in other populations of patients. Myoclonus with high doses of intrathecal opioids in cancer patients is a well-recognized complication (49). It is discussed later in this chapter.

Intraventricular Opioids. An alternative approach to providing analgesia for patients with cancer is the injection of morphine into the lateral ventricle of the brain. Leavens et al. in 1982 described early clinical experience with a technique of ventricular catheter insertion and attachment to a subcutaneously implanted Ommaya reservoir (50). Lobato et al. also reported experience with the technique and have analyzed the results of seven other authors (51). The review showed that among 197 patients treated, 95% obtained excellent pain relief with initial morphine doses of 0.25 to 4.00 mg. With continued use, dose requirements increased to as high as 36 mg. Obbens et al. found that patients who had previously used large doses of oral and parenteral opioids required higher intraventricular doses (52). With the development of tolerance, as much as 15 mg of morphine every 6 hours was needed by some patients. Complications of intraventricular morphine administration include reservoir malfunction and contamination resulting in meningitis. The most common side effects were nausea and somnolence.

Nonmalignant Chronic Pain

There has been considerable experience with intraspinal opioids in patients with a number of chronic nonmalignant pain syndromes. Cohn (53) alleged that a single epidural administration of morphine with methylprednisolone acetate produced pain relief lasting from 6 to 12 months in 100% of patients with chronic postlaminectomy low back pain. Other investigators have been unable to duplicate this result. Magora et al. (41) found that over an observation period of a few days, approximately half of their patients with chronic low back pain reported good relief. Coombs et al. (54) found that compared with cancer patients with similar levels of reported pain, chronic low back pain patients showed no sustained improvement. Some subsequent reports found higher efficacy (55,56) and cost savings (57).

Magora et al. (41) used epidural opioids in small numbers of patients with a variety of other chronic pain syndromes. These included ischemic pain due to peripheral vascular disease, causalgia, cervical spine syndrome, and an old vertebral fracture. Results of epidural opioids in this group were comparable to other more standard methods of treatment (physical therapy, extradural block, and nerve block with local anesthetics and steroids). Bach et al. (58) reported dramatic reduction in postoperative lower extremity phantom limb pain by pretreating patients with epidural analgesia before amputation.

Early experience with intraspinal opioids for chronic nonmalignant pain involved single-dose injections or a series of injections through percutaneous epidural or subarachnoid catheters. More recently, implanted reservoir/pump systems have gained widespread popularity. Becker et al. (59) treated two patients with intractable reflex sympathetic dystrophy with intrathecal morphine. Hassenbusch et al. (60) treated 18 patients with a variety of intractable chronic pain syndromes. An overall 39% reduction in pain scores was reported. The complication rate was high. Winkelmüller and Winkelmüller (61) treated a group of chronic pain patients for an average of 3.4 years. Average pain was reduced by 58%, with an average decrease in visual analog scale scores from 9.4 to 3.9. However, 31 of 120 patients were deemed treatment failures for a variety of reasons, including inadequate pain relief, intolerable side effects, development of tolerance, or surgical/technical complications.

The published literature on intraspinal opioid infusion for the relief of chronic pain has been reviewed by Stangl and Loeser (62). These reviewers found a lack of properly conducted clinical trials. Problems included failure to mention pretreatment trials of spinal opioids; lack of data on pretreatment psychological or functional assessment; no standardized methods of assessing pain, pain relief, or functional performance; and lack of control groups or randomization. Because of these flaws, the only possible conclusions from the review were superficial generalizations. Approximately one-third of patients apparently get good long-term pain relief without complications or side effects. Many patients require the addition of local anesthetics, and some never get effective relief.

Contraindications

Under some circumstances, intraspinal opioid analgesia should probably be avoided. These include (a) inexperience in performing lumbar puncture or epidural block, particularly in the cervical or thoracic regions; (b) inadequate nursing education or monitoring capabilities; (c) patient rejection; (d) known opioid allergies; and (e) systemic or local infection at the site of needle insertion. It is not certain whether these techniques can be used safely in patients with coagulopathies or while receiving anticoagulant therapy. Decisions should be made case by case after consideration of the relative risks and benefits for individual patients as well as the risks and benefits of alternative therapy.

Techniques

Patient Selection

Patients suffering from painful medical conditions, cancer, or trauma or undergoing a variety of surgical procedures may benefit from the superior analgesia possible with intraspinal opioids. This is particularly true in situations in which uncontrolled pain may compromise pulmonary function, leading to atelectasis and pneumonia. Examples include patients with rib fractures or pain resulting from upper abdominal or thoracic incisions. In patients receiving regional anesthesia for surgery, it is easy to offer intraspinal opioids for postoperative pain. For example, a single dose of morphine may be added to the local anesthetic solution chosen for subarachnoid injection before transurethral prostatectomy. Alternatively, an opioid may be injected repeatedly or infused continuously into a catheter that was placed in the epidural

space to provide anesthesia for patients undergoing a wide variety of surgical procedures (e.g., gastrectomy, hip surgery, thoracotomy). If general anesthesia was used for surgery, an epidural catheter may be placed any time in the postoperative period should pain control by conventional methods prove inadequate. It appears to be easier to establish good pain control immediately after surgery with these methods than to treat severe pain once it is established (63).

Intraspinal opioids should be considered in patients with cancer pain when oral or parenteral analgesics (including opioids) are ineffective or when they cause distressing side effects that cannot be adequately controlled. With the introduction of intraspinal opioids, elimination or marked reduction in the dose of systemic opioids may be possible. Reductions should be made gradually to avoid symptoms of opioid withdrawal.

Needle and Catheter Placement

Subarachnoid. Lumbar puncture is usually performed at the second or third lumbar interspace using techniques described in Chapter 102, but it can be done at other levels by those experienced with the techniques. For a single injection of opioid, a small needle (25- or 26-gauge) will minimize the risk of post–lumbar puncture headache. When it is necessary to provide analgesia for extended periods, an epidural catheter may be threaded into the subarachnoid space through an epidural needle. The catheter is then secured to the skin at its exit site and is used for bolus injections or continuous infusion of opioid. Alternately, it may be tunneled subcutaneously to exit ventrally, where it is less likely to become dislodged and where it is more accessible to the patient. There it may be injected intermittently or attached subcutaneously to a reservoir or infusion device that can be refilled as necessary with transdermal injections.

Epidural. Opioids may be introduced into the epidural space through the sacral hiatus (caudal approach) or in the lumbar, thoracic, or cervical regions using techniques described in Chapter 102. When the site of injection is close to the desired site of action, it may be possible to produce satisfactory analgesia with lower doses of opioid. If a mixture containing a local anesthetic is used, the site of catheter placement is critically important. The local anesthetic must be delivered in proximity to the spinal nerves that conduct the nociceptive impulses. For example, to effectively block chest wall pain with an epidural local anesthetic after a thoracotomy, the catheter should be placed in the thoracic region with its tip near the center of the involved dermatomes.

As with intrathecal opioids, a single injection may be used through a needle placed in the epidural space. For use expected to last a few days (e.g., after surgery), an epidural catheter is advanced through the needle and secured to the skin at its point of exit. For extended use over several weeks or months, an epidural or special Silastic catheter may be tunneled subcutaneously to a convenient location on the anterior abdominal wall. There, as with spinal catheters, it may be injected intermittently or attached subcutaneously to a reservoir or infusion pump that is refilled through the skin using a syringe and small-gauge needle.

In the cervical, thoracic, or high lumbar regions, the spinal cord is near the tip of a correctly placed spinal or epidural needle. To minimize the risk of spinal cord injury, needle and catheter placement in these areas are most safely accomplished in patients who are awake and able to report paresthesias or severe pain indicative of impending spinal cord damage. Epidural needle or catheter placement in the thoracic or cervical regions should be performed only by experts in regional anesthetic techniques.

Micropore filters are used on intrathecal and epidural catheters by some practitioners. These filters may reduce the risk of contamination by pathogenic organisms and prevent injection of foreign material such as glass particles. Even when filters were not used in surgical patients, infections have not proved to be a frequent problem. Aspiration of epidural catheters to check for intravenous or subarachnoid migration is made more difficult with some models of filters in place. Needles with filters in their hubs can be used to remove particulate matter (e.g., glass) while drawing up opioid solutions for injection or infusion. Patients receiving intraspinal opioids in a hospital setting require intravenous access to facilitate immediate treatment of side effects or complications. The use of double filters may help to reduce infection rates.

Patient-Controlled Epidural Analgesia

There is currently considerable interest in combining the potent analgesic effects of drugs delivered into the epidural space with the advantages of patient participation associated with the patient-controlled analgesia (PCA) concept (64,65,66,67,68,69,70 and 71). These studies compared the effectiveness of several epidural opioids administered on demand. It was found that the self-administered dose of morphine required to provide analgesia was significantly less than amounts required by continuous epidural infusion or by intravenous PCA. Sjöström et al. (72) reported the use of morphine via patient-controlled epidural analgesia (PCEA) (bolus: 1 mg; lockout: 30 minutes) averaged 0.5 mg per hour. Walmsley et al. (73) reported effective and safe PCEA morphine in more than 4,000 postoperative patients using a 2- to 3-mg loading dose, bolus dose of 0.2 mg, lockout of 10 to 15 minutes, and continuous infusion of 0.4 mg per hour. The maximum hourly dose was limited to 1.2 mg. PCEA fentanyl has been widely used (69,71,74,75 and 76). PCEA sufentanil (74,77,78 and 79) and alfentanil (80) have also been reported. Hydromorphone is a popular PCEA opioid with some therapists (81,82 and 83). PCEA hydromorphone requirements after cesarean section were four- to fivefold less than in patients receiving intravenous PCA hydromorphone (81). Additional observations included more rapid return of bowel function and shorter hospital stay.

Although PCEA appears to have great future potential, there has been little systematic comparison of different drugs and dosing regimens. There appear to be almost as many formulae as there are publications on the subject, and many of the clinical reports to date relate to use of the technique in obstetric patients. Considerable further research will be needed to establish criteria for patient selection, optimal drugs or drug mixtures, and PCA pump settings. Table 103-4 includes a few of the many recommended protocols. Dose schedules are generally those recommended for use through lumbar epidural catheters. They should be reduced when a thoracic epidural catheter is used.

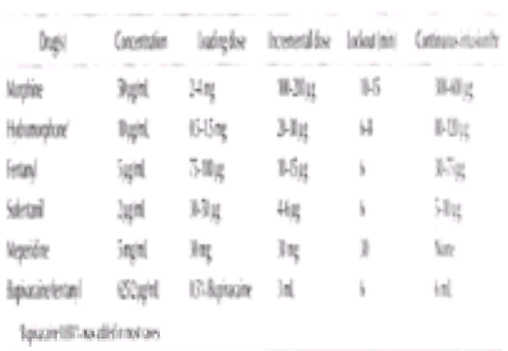

TABLE 103-4. Sample protocols for using patient-controlled epidural analgesia

Choice of Opioids

Table 103-5 lists a number of intraspinal opioids, suggested dose ranges, expected latency, and duration of analgesia. Doses necessary to produce analgesia and their duration of effect will vary considerably from one patient to another depending on age, medical condition, site of injection, type of pain, and other factors. The recommended doses are therefore only guidelines. Frequent assessment of adequacy of pain relief for each patient with changes in dose or frequency of injection as necessary is therefore the logical approach. The interested reader will find much more information is available on the subject of choosing epidural opioids (84).

Bioactic drug	Single dose (mg)[a]	Onset (min)	Duration of single dose (hr)[a]	Infusion rate (mg/hr)[a]
Epidural				
Morphine	1–6	30	6–24	0.1–1.0
Meperidine	20–50	5	4–8	5–10
Methadone	5–10	10	6–10	0.5–1.5
Hydromorphone	1–2	15	6–16	0.1–0.2
Diamorphine	2–6	5	12	–
Fentanyl	0.025–0.100	5	1–4	0.025–0.150
Sufentanil	0.01–0.05	5	1–4	0.006–0.01
Alfentanil	0.5–1	15	1–2	0.2
Subarachnoid				
Morphine	0.1–0.3	15	8–24+	–
Meperidine	10–20	–	15–24+	–
Diamorphine	1–2	–	20	–
Fentanyl	0.005–0.025	5	3–6	–

[a] Some doses may be effective in older patients or when injected in the thoracic or cervical regions.
[b] Duration of analgesia is often relatively longer than dose-to-recover duration.
[c] Use for the opioid alone or in combination with a local anesthetic.

TABLE 103-5. Suggested dose ranges, latency, and duration of analgesia with intraspinal opioids

Elderly patients in particular may require remarkably small intraspinal opioid doses. In reviewing experience treating women after abdominal hysterectomy, a significant negative correlation was found between age and effective 24-hour dose of epidural morphine (85). The relationship can be expressed by the following equation: Effective 24-hour epidural morphine dose (mg) = 18 – (age in years × 0.15). Based on this and similar additional observations, a list of suggested initial doses of epidural morphine for incisional pain in a variety of clinical situations is provided (Table 103-6).

Patient age (yr)	Nonthoracic surgery (lumbar or caudal catheter)	Thoracic surgery	
		Thoracic catheter	Lumbar catheter
15–44	4	4	5
45–65	3	3	4
66–75	2	2	3
76+	1	1	2

[a] These doses should be considered only as guidelines. Safe and effective doses for individual patients may vary considerably. Patients with opioid tolerance may require higher doses. These doses are based on the use of undiluted 0.1% preservative-free morphine.

TABLE 103-6. Initial dose (mg) of epidural morphine for acute pain [a]

Morphine is the most widely used opioid for both spinal and epidural injection. It is available in some countries specifically for intraspinal analgesia as a preservative-free isobaric solution in single-use ampoules. Standard commercial preparations have been used in a wide range of concentrations with no apparent difference in efficacy or safety. Although most early experience with morphine involved intermittent injection, it has also been used with success as a continuous infusion with a variety of external pumps or implanted devices.

A lipophilic agent such as fentanyl is useful when rapid onset of epidural analgesia is important. Its short duration, a drawback for most applications, can be offset by the use of a 50- to 100-µg epidural bolus followed by a continuous infusion (25 to 150 µg per hour) with an infusion pump. Although epidural fentanyl is widely used, questions remain regarding the primary mechanism by which analgesia is provided. There are now a number of convincing studies that show that equivalent analgesia is obtained with either epidural or intravenous fentanyl infusions (86,87,88,89 and 90). Furthermore, plasma fentanyl levels by either route are the same. Such findings are not surprising. Because fentanyl is lipid soluble, it passes rapidly and in large quantities from the epidural space into the epidural venous plexus. As with other opioids, opioid-related side effects, including respiratory depression, can occur with fentanyl.

Many other opioids have be used to produce intraspinal analgesia. These include meperidine (68,91,92 and 93), methadone (94), sufentanil (95,96,97 and 98), alfentanil (98,99 and 100), buprenorphine (101,102 and 103), and tramadol (104,105 and 106).

Regional Analgesia with Opioid/Local Anesthetic Mixtures

Although continuous infusions of local anesthetics in the usual commercial concentrations produce effective analgesia, they also produce undesirable, effects including hypotension, sensory and motor block, nausea, and urinary retention. To a lesser degree, these problems persist with combinations of dilute local anesthetics and opioids infused continuously (Table 103-7). Nociceptive pathways are interrupted at different sites with the two drugs—namely, at the level of the nerve axon with the local anesthetic and at the spinal opioid receptor with the opioid. Bupivacaine has been well suited to this application because it produces less motor block than other local anesthetics. Even so, motor function in many patients is impaired (Fig. 103-1). Early experience suggests that ropivacaine, a new local anesthetic, may spare motor nerves even more, thus preserving function better. It remains unclear whether the combination of epidural opioids and local anesthetics is superior to opioids alone.

Function blocked	Possible problem
Sympathetic	Hypotension (thoracic > lumbar)
Proprioception	Difficulty ambulating
Sensory	Pressure injury
	Mask a complication
Motor	Loss of function (cough, ambulation)

TABLE 103-7. Possible problems with epidural local anesthetic techniques

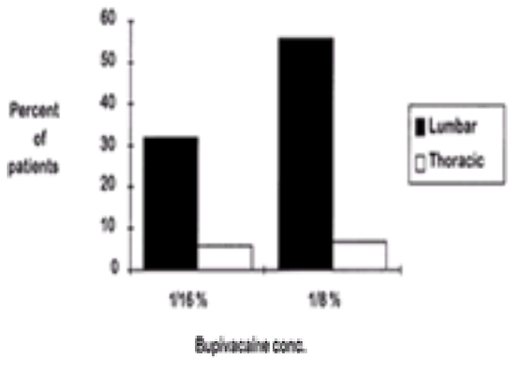

Figure 103-1. Motor block impairment of ambulation with epidural local anesthetic infusions. (conc., concentration.)

In addition to the monitoring used for patients receiving only epidural opioids, frequent measurement of blood pressure as well as sensory and motor examination is recommended. Dilute concentrations of local anesthetics produce considerable sensory and motor blockade in some patients. A 0.125% bupivacaine infusion through a lumbar catheter will render approximately 60% of patients unable to ambulate. The number drops to approximately 30% of patients if 0.0625% is used. This problem occurs in only 6% to 7% of patients if a thoracic catheter is used with either bupivacaine concentration (see Fig. 103-1).

Other Agents with Intraspinal Analgesic Properties

A number of other agents have been administered via the intrathecal or epidural route to produce pain relief. Clonidine is the only one of these currently approved for clinical use.

a_2-Adrenergic Agonists. Epidural clonidine, an a_2-adrenergic agonist, given alone or in combination with a local anesthetic, has pain-relieving properties (97,107,108 and 109). Its strongest indication to date has been in the treatment of neuropathic pain unresponsive to other measures, especially in patients with cancer (109). Side effects include sedation (110), hemodynamic instability (111), and rebound hypertension and acute withdrawal when therapy is abruptly interrupted (112). Future generations of a_2-adrenergic agonists with more selective actions may prove more useful than clonidine.

Ketamine. Epidural ketamine has been reported by a number of authors for treatment of postoperative pain (113,114,115,116 and 117). It has been used to provide labor analgesia (118) and has been found to benefit patients with reflex sympathetic dystrophy (119). Dysphoria associated with its use has been noted, and caution has been recommended until its safety (especially a lack of neurotoxic effects in humans) is established (117).

Neostigmine. In a report by Hood et al. (120), it was noted that intrathecal neostigmine produces dose-dependent analgesia, nausea, weakness, and diminished deep tendon reflexes in healthy volunteers, all of which resolve in 6 to 12 hours.

Intrathecal neostigmine provided analgesia after cesarean section (121,122) and was further evaluated after perineal surgery in women (123). In that study, 50 to 100 µg of intrathecal neostigmine produced analgesia for vaginoplasty surgery similar in duration to 50 to 100 µg of intrathecal morphine. It was noted that the combination of intrathecal morphine and neostigmine may allow reduction in the dose of each component. Lauretti et al. (124) found maximal analgesia after surgery may occur at doses of less than 25 µg intrathecally. After abdominal surgery an intrathecal dose of 100 µg caused severe nausea and vomiting (125). Antiemetics were not effective.

Amitriptyline. In sheep, a 5-mg intrathecal dose of amitriptyline produced antinociception. There was no behavioral evidence of neurotoxicity. Heart rate, blood pressure, cardiac output, spinal cord blood flow, and CSF catecholamines remained normal (126). Whether or not there is a clinical future for intrathecal amitriptyline remains to be determined.

Monitoring of Patients Receiving Intraspinal Opioids

Monitoring the Effects of Opioids. Until it is possible to identify and eliminate the factors that occasionally lead to severe respiratory depression in patients receiving intraspinal opioid analgesia, it must be assumed that all patients offered these techniques are at risk. Table 103-8 lists factors believed to be associated with increased risk of respiratory depression.

1. Age older than 50
2. American Society of Anesthesiology physical status III, IV, or V
3. Surgical site (thorax or upper abdomen)
4. Duration of surgery of more than 4 hr
5. Anesthetic (opioids or other long-acting central nervous system depressants used before or during surgery)
6. Epidural morphine dose (6 mg or more)
Subarachnoid morphine dose (0.5 mg or more)
[a]These are only suspected risk factors. Others may apply to individual patients.

TABLE 103-8. Predictors of patients at risk for intraspinal opioid- induced respiratory depression [a]

To prevent serious injury or death, there is no substitute for a high level of vigilance. This may be provided by nurses who check rate and depth of respiration, level of consciousness, and the general status of patients at regular intervals. Respiratory monitors that sound an alarm if ventilation is not detected may augment this process, but these devices are not necessary in most circumstances and should not be viewed as substitutes for alert, well-trained human observers.

Intensive care facilities are well suited to the monitoring needs of higher-risk patients (e.g., advanced age, serious underlying medical conditions, extensive surgery). However, the expense and limited availability of these facilities render them impractical for routine use. Some practitioners advocate “step-down units,” intermediate between intensive care and a regular ward with regard to the level of monitoring and nursing care available. It has been shown that with appropriate nursing education, appropriate patient selection, regular evaluation of ventilation, protocols for immediate treatment of complications, and immediate availability of medical personnel, intraspinal analgesia can safely be offered on conventional hospital wards (7). A set of preprinted “standard orders” used throughout an institution can facilitate maintaining a high standard of care. A sample of such a set of orders is found in Table 103-9. Such documents must be individualized to meet the unique needs of each institution. Delegation of all responsibility for pain control to one group of physicians within an institution can minimize errors of conflicting or duplicated orders or inadvertent administration of parenteral opioids to patients receiving intraspinal opioids.

TABLE 103-9. Sample of intraspinal opioid (and local anesthetic) preprinted orders

Monitoring the Effects of Local Anesthetics. Intraspinal local anesthetics, alone or in combination with opioids, may produce undesirable effects. When local anesthetics are administered, analgesia occurs as a result of their effects on the axonal membranes of nerves carrying nociceptive impulses. Further details on the actions of local anesthetics are provided in Chapter 102. No currently available local anesthetic at any single concentration is selective enough to block only nerves conducting nociceptive impulses. Other nerve fibers (sympathetic, sensory, proprioceptive, and motor) may also be affected. Table 103-7 summarizes the clinical consequences of blockade of these nerve fibers. Local anesthetic systemic toxicity is also possible.

Monitoring for the possible undesirable effects of local anesthetic is essential. This begins with appropriate education, especially including of bedside nurses. With a clear understanding of the actions and side effects of local anesthetics, appropriate nursing protocols and procedures can be developed. These include measures for anticipation, early recognition, and treatment of hypotension, sensory block, and motor block. In the case of patients receiving a mixture of a local anesthetic and opioid, monitoring protocols for both components of the mixture must be used.

Results

Throughout this chapter, repeated reference has been made to the results associated with using intraspinal analgesic techniques. In this section, selected additional information on the subject is provided. Studying outcomes is a complex task. This is true in part because results are a function not only of the therapy provided but also of the knowledge, expertise, and dedication of the therapists. Furthermore, when a group of reports on a subject is examined, it is not unusual to find that the study designs were inconsistent, and not surprisingly, findings were commonly contradictory. The body of literature on the subject of intraspinal analgesia outcomes is huge, and many excellent individual studies have been conducted. Some of these individually have changed our understanding. In general, the most meaningful outcome information is obtained through a systematic process of examination of the published literature (e.g., metaanalysis). As a part of the task of developing clinical practice guidelines, several such extensive works have been undertaken (28,127,128 and 129). In the case of perioperative pain, Kehlet has provided an outstanding review of current outcome data (39). Table 103-10 summarizes the most salient clinical results. It should be noted that the benefits seen may relate to intraspinal opioid, local anesthetic, or both in combination.

Parameter	Result of intraspinal analgesia
Mortality	Limited reduction after acute surgery for hip fracture
Blood loss	Reduced approximately 30% during operations in the lower part of the body
Thromboembolic complications	Favorable effects on pathogenic mechanisms and clinically important reduction in these complications
Pulmonary infective complications	Insufficient data to allow conclusions
Cardiac complications	Positive effects on hemodynamics; insufficient data to allow conclusions regarding cardiac outcome parameters
Cerebral complications	No favorable influences
Gastrointestinal function	Epidural opioids: little or no benefit Epidural local anesthetics: improve intestinal motility
Convalescence, fatigue, and hospital stay	Intraspinal analgesia alone does not alter these parameters Based on preliminary data, when combined with stress reduction, early oral nutrition, and early mobilization, improvements are likely to be seen

*Based on a review of controlled studies by Kehlet H. Modification of responses to surgery by neural blockade: clinical implications. In: Cousins MJ, Bridenbaugh PO, eds. Neural Blockade. Philadelphia: Lippincott-Raven, 1998:1291–1304.

TABLE 103-10. Effects of intraspinal anesthesia/analgesia on the perioperative morbidity [a]

It is reasonable to expect that improved outcomes resulting from use of intraspinal analgesia should result in a reduction in health care consumption and less cost. In the case of perioperative pain, many studies conclude this is true (39,130,131,132,133,134,135,136,137 and 138). But unless improved relief of pain is combined with a more comprehensive approach to accelerated recovery (39), these gains are not likely to be impressive.

Complications

Respiratory Depression

The real incidence of respiratory depression is not known. It is dependent on a number of factors, including the population studied, monitoring practices, and the definition of respiratory depression used by investigators. In a large, multiinstitutional Swedish questionnaire survey, the incidence of “depression requiring naloxone” was 0.25% to 0.40% (139). In one prospective postoperative study of 1,085 postoperative patients in a single institution, the incidence of respiratory depression based on respiratory rate was 0.9% (35). In another prospective study of 1,100 postoperative patients from a single institution, the incidence was 0.2% based on the administration of naloxone (7).

Early respiratory depression occurring in the first 2 hours after opioid injection is a feature only of epidural opioid administration and is a result of vascular uptake and redistribution (i.e., the same mechanism that follows intramuscular injection). Delayed respiratory depression is likely the consequence of rostral spread of opioid in CSF. The target site is thought to be the respiratory center, located superficially in the floor of the fourth ventricle. The risk of severe delayed respiratory depression after intraspinal morphine appears to be greatest 6 to 12 hours after beginning therapy. Risk factors appear to include large intraspinal opioid doses, advanced age, concomitant use of systemic opioids or other central nervous system depressants, high-risk surgical patients, and extensive surgery (see Table 103-8). A history of obstructive sleep apnea also may be associated with increased risk (140).

It is not known whether the risk of severe respiratory depression is greater after intraspinal opioids than after opioid administration by more conventional routes. It has been reported that in 860 hospitalized patients receiving conservative doses of morphine orally or systemically, 0.9% developed “life-threatening respiratory depression” (141).

Respiratory rate alone is not an adequate indicator of ventilatory status in volunteers (142) or in postoperative patients (7,143) receiving epidural opioids. A more global assessment is necessary, particularly during the first 24 hours of treatment. This should include assessment of level of consciousness, because increasing sedation (presumably due to carbon dioxide narcosis) has commonly been noted with advanced respiratory depression (38,144). Healthy volunteers breathing carbon dioxide mixtures have been noted to lose consciousness at arterial carbon dioxide tension levels of approximately 80 mm Hg (145). Table 103-11 illustrates a bedside sedation scale that can be used by nurses to recognize deterioration in level of consciousness in patients receiving intraspinal opioids. Every patient receiving intraspinal opioids whose level of consciousness deteriorates unexpectedly should be assumed to have respiratory depression until disproved by arterial blood gas analysis.

Sedation level	Description
0 None	Patient alert
1 Mild	Occasionally drowsy; easily aroused
2 Moderate	Frequently drowsy; easily aroused
3 Severe	Somnolent: difficult to arouse
5 None	Normal sleep; easily aroused

TABLE 103-11. Bedside sedation scale for evaluation of respiratory depression

The immediate treatment of severe respiratory depression is support of ventilation. Equipment to deliver oxygen with positive pressure must be readily available and personnel in the area must be familiar with its use. Naloxone titrated in small doses (0.1 mg) intravenously will usually restore adequate spontaneous ventilation, but repeated doses are sometimes necessary. Stimulating the patient to breathe by verbal and mechanical means will help prevent apnea until the naloxone can be administered.

Pruritus

Pruritus is common and sometimes distressing to patients. The itching may be generalized or localized, with the face being the most common site. Pruritus is seen both with opioids containing preservatives and preservative-free preparations. Although probably not due to histamine release, antihistamines often provide symptomatic relief. Diphenhydramine, 12.5 to 25.0 mg, is a common prescription for this purpose. Nalbuphine in doses of 2.5 to 5.0 mg intravenously is also effective and does not cause the sedation commonly seen with an antihistamine. Naloxone is also often effective but it may need to be administered frequently or given as a continuous infusion, thus adding complexity and cost to therapy. The mechanism of action by which pruritus occurs is not known with certainty.

Urinary Retention

The incidence of urinary retention has been higher in volunteers than in patients and higher in males than females. Naloxone may help prevent or reverse urinary retention, but doses approaching those that antagonize analgesia may be needed. Some patients will require bladder catheterization. In many patients receiving intraspinal opioids, urinary retention is not an issue because bladder catheters are maintained postoperatively for unrelated reasons.

Nausea and Vomiting

These distressing symptoms are believed to be the result of rostral spread of opioid in CSF to the vomiting center and the chemoreceptor trigger zone, located superficially in the floor of the fourth ventricle. The symptoms usually subside with continuation of therapy, so they are rarely a problem in cancer patients receiving long-term therapy. Relief is frequently possible with antiemetics, but these agents may produce unwanted sedation and even contribute to the risk of respiratory depression (146). Transdermal scopolamine patches applied to the mastoid area and designed to deliver 0.5 mg per day are remarkably effective in reducing the incidence and severity of nausea and vomiting in patients receiving epidural morphine (147,148).

Sedation

When a patient receiving intraspinal opioids appears excessively sedated, hypercarbia should be suspected and, if present, treated. The possible contributing role of other drugs that depress the central nervous system, such as anxiolytics, sedatives, and antiemetics, should also be considered.

Sedation produced by intraspinal opioids may be the result of spread of the drug in CSF to receptors in the thalamus, limbic system, or cortex. Pharmacologic treatment is seldom indicated but physostigmine, 1 mg intravenously, may be effective (149). Delirium after surgery is common, especially among older patients (150). This condition can occur for many reasons, yet it is very commonly attributed to analgesic techniques, including intraspinal opioids. It is possible that postoperative pain itself is a contributing etiologic factor (151).

Myoclonus

Occasional patients receiving high doses of intraspinal opioids develop myoclonus. Such dose requirements are usually seen in patients with cancer pain who have developed tolerance. The interested reader is referred to a review of myoclonus (49).

Neurologic Changes

Temporary. As discussed earlier in this chapter, administration of intraspinal local anesthetic solutions can produce unwanted changes involving blockade of sympathetic, sensory, proprioceptive, or motor nerves. Table 103-7 summarizes the clinical implications of these events. An issue of special concern is the possibility of dense sensory blockade masking or delaying diagnosis and treatment of a serious postsurgical complication. An example of such a complication is postoperative compartment syndrome in the lower extremity. The task of the pain therapist is to use an analgesic technique that achieves goals for comfort and function while preserving the ability to identify this complication. The best available information suggests that this can be done (152,153). Other complications that are typically recognized as a result of the pain they produce include deep vein thrombosis, pulmonary embolus, bowel obstruction, peritonitis, and myocardial infarction.

Irreversible. Serious and irreversible neurologic complications are rare events, but when they occur, they can be devastating both to patients and to their therapists. Of greatest concern in this regard is the development of neuraxial hematomas (154,155), abscesses (156,157 and 158), or direct injury to the spinal cord or nerve roots from needle or catheter placement (13). A discussion of these topics is beyond the scope of this chapter.

Technical Problems

A variety of technical problems commonly occur when large numbers of patients are treated with intraspinal analgesics. Examples include nonfunctioning epidural catheters, premature catheter dislodgment, one-sided analgesia, catheter-connector separation, technical problems with infusion pumps, and migration of epidural catheters to intravenous or subarachnoid locations. Each institution should systematically examine the frequency of such problems. With a continuous quality improvement program, the incidence of these and many other problems can be reduced.

CONCLUSIONS

Intraspinal opioids represent a powerful tool for controlling pain. The selective manner in which nociception is blocked provides unique advantages over other methods of producing analgesia. Because the potential exists for serious complications, a high level of vigilance must accompany their use. Although it is not known whether the risks accompanying the use of intraspinal opioids exceed those associated with more traditional methods of controlling severe pain, concern about possible complications has been the major factor limiting widespread acceptance of intraspinal opioid analgesia into clinical practice. Well-organized institutional approaches to the use of these techniques can facilitate effective and safe therapy.

CHAPTER 104

Neurolytic Blockade and Hypophysectomy

Stephen H. Butler and J. Edmond Charlton

This chapter consists of two sections that have been revised from the previous edition: an updated review of neurolytic blockade and a truncated review of hypophysectomy, which is waning in popularity as a first-line treatment for cancer pain. The same is also true of neurolytic blockade, which in the past was a primary treatment for many types of cancer pain. It was also used somewhat indiscriminately for many chronic pain problems of nonmalignant origin. More sophisticated use of continuous spinal drug infusions, better application of systemic drugs, and more effective anticancer therapies have altered the role of neurolysis in the approach to treating cancer pain. For chronic noncancer pain, more sophisticated approaches and the appreciation of the potential side effects as well as limited duration of relief of pain have relegated neurolysis to a very minor position in the treatment paradigm. At the University of Washington, it is little used in our patient population for chronic pain of noncancerous origin.

Neurolysis implies the destruction of neurons by placing a needle close to the nerve(s) and either injecting neurodestructive chemicals or producing neural damage with cold (cryotherapy) or heat (radiofrequency coagulation). The injected chemicals are usually ethyl alcohol, phenol, or glycerol, although in the past ammonium salts and chlorocresol were also common. New studies have looked at high concentrations of local anesthetics, primarily lidocaine (1) and butamben, as kinder and gentler therapies that may prove to have wider application for chronic, noncancer pain.

Since specific nerve block techniques are discussed in detail in Chapter 102, comment on technique is restricted to modifications necessary to produce optimum results with the specific agents.

BASIC INFORMATION

History

Neurolytic blockade was widely used during the first six decades of the twentieth century (2). The specificity theory of pain was popular, and it indicated that destruction of peripheral nerves or pain pathways would lead to lasting relief of intractable pain of any origin. Other than pharmacologic therapy, which was not very sophisticated, the only option besides neurolytic blockade, especially for cancer patients, was neuroablative surgery. Many patients were not considered fit enough to tolerate the combined stress of anesthesia and surgery. Opioid use was limited because of concerns for side effects, tolerance, and addiction, which were considered even a greater deterrent to appropriate use then than they are now.

There appears to be a renewed interest in neurolytic techniques, judging by the number of texts released lately (3,4), as the more recent technical approaches to pain relief are seen more realistically now than through the rose-colored glasses so common with any new therapy. Perhaps we are also somewhat more critical of our results as outcome studies show we have not always done as well with cancer pain as many believed. The newer neurolytic agents may also broaden the indications for neurolysis as the initial studies hint that side effects are more benign. Certainly, in regions where neurosurgical skills are not widespread, where the health care system cannot afford newer expensive technologies, or where medications are not available to utilize the World Health Organization ladder, neurolytic procedures have much greater importance and should be used, especially in patients with pain due to cancer. Neuroablation, by any means, should be thought of as only part of the pain therapy, not as a curative modality, since most studies show that it is rare for patients not to need pharmacologic or other support after a neurolytic procedure for pain.

Theoretical Bases

Alcohol

Ethyl alcohol is the classic neurolytic agent and has been used extensively in concentrations from 33% to 100% (2). It was first described by Schlosser (5) in the early 1900s, and he studied and wrote on its effects on peripheral nerves. Attempts have been made to limit the effects to the sensory system by using lesser concentrations of ethanol. There have been reports of a differential block with good pain relief using 33% ethanol that spares motor nerves.

The effects of ethanol on various parts of the nervous system have been described, but there are no pathologic studies on the differential effects on axons. The cellular and subcellular changes accounting for alcohol's nervous system effects are in general those secondary to high concentrations of ethanol.

Ethanol has a neurodestructive effect on somatic nerves, leading to wallerian degeneration, which usually spares the basal lamina around the Schwann cell tube. This permits regeneration that accounts for the return of function and pain some weeks to months after a block. The mechanism of degeneration is through the extraction of cholesterol, phospholipids, and cerebrosides and precipitation of lipoproteins and mucoproteins. Topical ethanol on peripheral nerves therefore damages both the axons and Schwann cells with disruption of the myelin sheath. There is destruction and absorption of all components of the nerve except the neurolemma. *In vivo* electrophysiologic studies in cats following alcohol deposit on peripheral nerves showed depression of compound action potentials at 8 weeks. This effect was slightly more marked using 100% alcohol than with 50% (6,7 and 8).

Clinical studies by Labat and Greene in the 1930s (9) looking at varying concentrations of ethanol concluded that 33% was the minimal concentration to produce pain relief and was accompanied by little motor effect. Long-term follow-up was not recorded, so we do not know whether duration of effect or side effects vary with concentration.

The effects on the sympathic nervous system are somewhat different. If the ganglia are affected, changes are permanent, since the cell bodies are destroyed and regeneration is not possible. However, ganglia cells are somewhat more resistant than nerve fibers and total destruction does not always occur, accounting for the gradual return of function (and pain) over time after neurolytic ganglion block. The rami communicantes suffer the same fate as somatic nerves, however, producing a temporary block. Regeneration is present at 90 days and is complete at 170 days. Retrograde changes in the cell bodies can occur as well, so with this block, recovery is variable. Blockade of preganglionic and postganglionic fibers does not affect the ganglia, and these fibers react to alcohol as do somatic nerves (10). With subarachnoid injection, effects are seen in the roots, rootlets, Lissauer's tract, and posterior columns. Wallerian degeneration can involve not only the roots and rootlets, but also the dorsal horn. There may also be local inflammatory change of the meninges (11). Alcohol is removed rapidly from the subarachnoid space, with only 10% present at 10 minutes (12).

Phenol

Phenol for neurolytic blockade has a shorter history than ethanol (13). Phenol's neurolytic properties were first described by Doppler in 1925; he and others subsequently used phenol for sympathetic neurolysis around vascular and visceral structures (14). It was not used specifically for pain until the 1950s, when it was proposed for subarachnoid use in pain and spasticity (1). The early 1960s saw its use expanded to peripheral nerve blocks, and it has been used extensively since. As with alcohol, attempts have been made to limit the neurolytic effects to C, A-d, and A-g fibers for optimum effects on pain and spasticity (15). Concentrations below 1% produce local anesthesia without toxicity; concentrations from 1% to 7% cause indiscriminate damage to afferent and efferent nerve fibers.

On peripheral nerves, phenol has an axonotmetic effect that is maximal with a concentration of 12% (16). Evaluation by light and electron microscopy shows variable degeneration in all nerve fibers from extraneural or intraneural application. There is protein coagulation and necrosis with axonal and wallerian degeneration. Electrophysiologic studies show a concentration-related depression of compound action potentials at 2 weeks. At 4 weeks, regeneration has begun but, unlike alcohol, phenol damages the neural tube and thus the regeneration is nonspecific since there is no predetermined path for the regenerating axon to follow (17).

Animal studies on the effects on the sympathetic nervous system again show differences from ethanol. There is complete necrosis of the sympathetic ganglia at 24 hours, with degeneration complete at 45 days and evidence of regeneration at 75 days, a much more rapid recovery than with alcohol. This is compatible with the clinical observations.

The most complete clinical information on phenol is on its action in the subarachnoid space, since this was the major clinical use initially (18). The data on neural effects *in vivo* and/or *in vitro* are limited. It was originally thought to have a differential effect on various nerve fibers, but animal work showed this not to be the case, other than a trend with low concentrations below 3%, not a clinically useful solution. The primary subarachnoid effect seems to be on the nerve rootlets and perivascular nerves. The effects are seen on both anterior and posterior roots with accompanying arachnoiditis, vascular thrombosis, and even spinal cord infarct (19).

Finally, there are a few pathophysiologic findings to bear in mind when weighing different agents for clinical use. Information has been available for some time showing the vascular effects of phenol. It can denature the protein in vascular structures as well as nervous structures, which may explain some of the catastrophic complications seen with spinal cord infarction in many applications. Phenol has little effect on Gore-Tex artificial vessels, but it does destroy Dacron grafts (20). Alcohol, more than phenol, causes vascular spasm, another potential cause of spinal cord infarction (21). As a final note, intravascular phenol can cause arrhythmias and cardiac arrest by an unknown mechanism (22). Seizures after intravascular injection have also been reported. These effects must be considered when deciding on the use of specific agents near the neuraxis or in large doses.

Glycerol

Håkanson's report (23) of the efficacy of glycerol injected into the trigeminal ganglion for the treatment of trigeminal neuralgia without producing significant sensory deficits led to its widespread use in the treatment of this condition (24,25) and to further histologic and electrophysiologic studies. Topical application of 50% glycerol solution on the nerve produces localized subperineurial damage but, following intraneural injection, glycerol is more damaging than topical application (26). Histologic changes include the presence of numerous inflammatory cells, extensive myelin swelling, and axonolysis (27).

Myelin disintegration occurs weeks after the injection, along with concomitant axonolysis during periods of myelin restitution, indicating an ongoing nerve fiber injury possibly caused by secondary events such as compression of transperineurial vessels and ischemia. Electron microscopic studies have revealed evidence of wallerian degeneration and, with intraneural injection, almost all nerve fibers are destroyed (27). Lipid droplets are seen in Schwann and phagocytic cells, and mast cell degranulation occurs. Burchiel and Russell (28) carried out studies on rat saphenous nerve and found differential effects of glycerol on the electrophysiologic function of the nerve. At this time, however, histologic data to support these observations are lacking.

Ammonium Compounds

In 1931, Judovich prepared an aqueous solution derived from a pitcher plant distillate (*Sarracenia purpurea*) and found that it relieved the pain of neuralgia without producing changes in skin sensation and deleterious effects on motor nerves (29). This selective action on the pain was of much longer duration than with procaine. Subsequent laboratory investigations revealed that the ammonium ion, in the form of ammonium chloride or ammonium hydroxide (depending on the pH of the distillate), was the active component. Using the unsophisticated technology available at that time, Judovich and Bates found that ammonium salts eliminated C fiber potential, with only a small effect on A fibers. In 1942, Bates and Judovich (30) reported 5,000 administrations of ammonium salts (in a 6% concentration) by paravertebral injection or local infiltration, with highly favorable results. Bonica (2) reported on extensive clinical trials that yielded disappointing results: The drug was found to lack uniformity of action, and it produced pain relief in a small percentage of cases and in an unpredictable manner. Similar results were reported by F. A. D. Alexander (*personal communication,* 1951), one of Bonica's peers and an authority on neural blockade. We have not used these compounds at the University of Washington Pain Center. A study of intrafascicular injection of ammonium sulfate in rats showed no pathologic effects (31), which may account for Bonica's impressions.

Cryotherapy

It has long been known that cooling causes a reversible conduction block in nerves. In 1945, Denny-Brown and colleagues (32) reported on the pathology of nerves subjected to cold and noted the sensitivity of A-d and C fibers to damage. Subsequent studies have revealed that a prolonged axonal potential results when nerve fibers are cooled to 5°C (27). Early cytopathologic studies revealed abnormalities of Schwann cells and endoneurial capillaries that were attributed to accelerated enzyme production, which affected Schwann cell metabolism (27). More recent studies have shown that freezing results in the formation of ice crystals and causes necrosis of all tissue elements, including nerves (33). Freezing produces a longer-lasting clinical deficit and has become a method of neurolysis of intercostal nerves following thoracotomy for relief of postthoracotomy pain.

The technique is based on the freezing of a small nerve segment with a 2-mm-diameter cryoprobe cooled to approximately –60°C by the rapid expansion of pressurized nitrous oxide from its tip. When the cryoprobe is left in contact with the nerve for 60 seconds, a 2- to 4-mm-diameter ice ball forms, freezes the nerve, and completely damages the nerve fibers (34). This initially produces severe vascular injury and edema, with diapedesis of polymorphonuclear cells through vessel walls (27). The endoneurial fluid pressure (EFP) is elevated within 90 minutes of the lesion and rises to a level of approximately 20 cm H_2O, or twice that observed in edematous neuropathies developing more slowly. In the ensuing 24 hours, the EFP is reduced, presumably due to changes in the elastic characteristics of the perineurium (27). The EFP then increases again to reach a plateau at 6 days that is associated with wallerian degeneration of the distal fibers, a prominent pathologic feature that affects the entire nerve. Although freezing causes complete damage to the nerve, the basal lamina is fortunately spared and provides a conduit for nerve fiber regeneration. Thus, freezing causes an acute and severe injury to all nerve fibers that persists for about 1 month, after which regeneration occurs; this is aided by the presence of Schwann cell basal lamina, which makes the complete and appropriate reinnervation of distal structures possible (27).

Laser and Radiofrequency Lesions

Heating of peripheral nerves with ultrasonic energy produces three levels of nerve conduction effects: enhancement, reversible depression, and irreversible depression, with the latter characterized by a functional deficit that lasts longer than 18 hours (35). With such lesions the axis cylinder is fragmented but the perineurium is unaffected. Lasers have been used to heat peripheral nerves more precisely: The energy produced by the laser heats the nerve directly without affecting the surrounding tissue, and the output of the laser can be controlled in regard to both magnitude and duration. Laser irradiation of peripheral nerves produces localized lesions characterized histologically by a concentric zone of coagulation necrosis surrounded by persistent nerve edema (36). The perineurium is not damaged, but the resulting edema increases the EFP. Sections of laser-injured nerves show discrete endoneurial lesions characterized by greatly swollen axons packed with organelles; these changes are characteristic of the axonal dystrophy that occurs during acute wallerian degeneration (27). Because laser injury produces wallerian degeneration and can be finely controlled and focused, it should prove to be useful as a neurolytic technique, provided direct visual access to the nerve is possible. Radiofrequency lesions also produce coagulation of the nerve (see Part V, Section G).

Conclusions

Neurolytic agents in the form of alcohol, phenol, and glycerol injected around or into a nerve produce pathophysiologic changes of varying degree, depending on the concentration of the agent that comes in direct contact with the nerve tissue. These agents, applied to the surface of the nerve or nerve rootlets (in the subarachnoid space), alter perineurial permeability with damage to axons or occasionally to nerve cells. Intraneural injection of these agents produces severe nerve damage,

consisting of significant axonal abnormality and wallerian degeneration. Techniques that physically damage the nerve with cold (via the cryoprobe) or with heat (via a laser or radiofrequency) produce similar results. It has been shown that a differential block of only A-d and C fibers, without affecting larger fibers and with good pain relief still being obtained, is usually not possible. Although variations in concentration produce different clinical findings, suggesting a dose-related response, the nerve needs to be damaged sufficiently to produce wallerian degeneration to achieve desirable long-lasting pain relief. The persistence of basal lamina around the Schwann cell tube allows the successful and appropriate regeneration of nerve fibers, thus eliminating the formation of painful neuroma. This is in contrast to surgical section of a nerve, which invariably results in neuroma formation. Complete and permanent transection of a nerve can only be accomplished with surgical resection; however, a painful neuroma may result.

CLINICAL INFORMATION

Block of Cranial Nerves

Indications

From 1900 to 1960, block of the gasserian ganglion or of branches of the trigeminal nerve with alcohol or other neurolytic agents was widely used for the treatment of trigeminal neuralgia, severe intractable cancer pain, and a few other chronic pain syndromes. Block of the facial nerve with a local anesthetic or alcohol has been used for the treatment of facial spasm. Block of the glossopharyngeal and vagus nerve with a local anesthetic has been used as a diagnostic or prognostic procedure in patients with neuralgia or cancer pain in the distribution of these nerves. Even block of the spinal accessory nerve has been used to treat spasm of the trapezius muscle.

The advent of the use of anticonvulsant drugs, of the highly successful microvascular decompression operation, and of controlled thermogangliolysis has superseded the use of neurolytic blocks for the relief of the pain of trigeminal neuralgia. The use of thermogangliolysis and other more sophisticated neurosurgical procedures has also reduced the use of neurolytic block in the treatment of cancer pain.

Nevertheless, neurolytic block of the gasserian ganglion or of one of the major branches of the trigeminal nerve is a potential treatment for severe intractable facial pain caused by cancer or neuralgia and other types of severe chronic pain when sophisticated neurosurgical techniques are unavailable.

Although block of branches of the trigeminal nerve or of the glossopharyngeal and vagus nerves with local anesthetic is not used widely, these procedures can be effective in patients who have severe acute postoperative or posttraumatic pain or pain caused by other self-limiting conditions. As mentioned below, block of the nerve as well as of the gasserian ganglion with local anesthetic should be done prior to the injection of a neurolytic agent or destruction of the nerve.

Optimal results with these procedures require adherence to the requirements and preliminary considerations discussed in Chapter 102. One of the most important is a thorough knowledge of the anatomy of the target nerve, of adjacent structures with which the solution might come in contact, and of structures traversed by the needle. The anatomy of the cranial nerves is discussed in detail in Chapter 46, Chapter 47, Chapter 48, Chapter 49, Chapter 50, Chapter 51, Chapter 52 and Chapter 53.

The physician must also follow the principles of the technique noted in Chapter 102 and should be aware of contraindications. When carrying out these procedures, it is essential to have fluoroscopic control of needle placement and to determine the pattern of diffusion of the contrast medium injected prior to or with injection of the neurolytic agent.

Based on his extensive experience in carrying out these procedures, Bonica believed it essential to carry out two or three diagnostic or prognostic blocks with a long-lasting local anesthetic to determine whether the neurolytic blockade can provide complete pain relief. Moreover, a local anesthetic block provides the patient with an opportunity to evaluate the degree of pain relief as well as to experience the sensory anesthesia that follows alcohol or phenol injection.

Because neurolytic agents diffuse to a much lesser extent than local anesthetics, prognostic blocks require that the volume of local anesthetic be the same as or less than the volume of neurolytic agent to be used. For example, neurolytic block of the gasserian ganglion with 1 mL of alcohol should be preceded by two prognostic blocks with 0.75 to 1.00 mL of bupivacaine, done at intervals of 1 day or longer between the blocks and before the neurolytic block.

The face and head have special meaning for most people. Because having a needle inserted into these structures invariably causes a great degree of anxiety, and because the procedures do produce moderate discomfort, it is best to administer an anxiolytic drug and/or a short-acting opioid just before the procedure.

Techniques

Gasserian Ganglion Block. The anatomy of the trigeminal nerve is depicted in Figure. 104-1, and that of the gasserian ganglion is shown in Figure. 104-2. Figure. 104-3 depicts the common sites of blocking the trigeminal nerve and its branches. Block of the gasserian ganglion is achieved by various intraoral, oral, or extraoral routes, but the best and most commonly used technique is that originally described by Härtel (37,38) (Fig. 104-4).

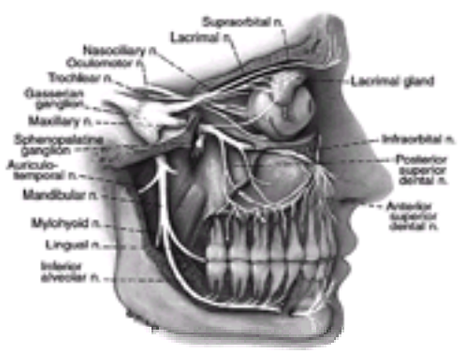

Figure 104-1. Anatomy of the trigeminal nerve. The root of the trigeminal is short, extending from the ventrolateral surface of the pons to the apex of the petrous portion of the temporal bone, where it expands into the gasserian ganglion. The crescent-shaped gasserian ganglion lies lateral to the internal carotid artery and cavernous sinus and occupies Meckel's cave, located just posteromedial to the foramen ovale. The ophthalmic nerve passes through the superior orbital fissure to reach the orbit. The maxillary nerve passes through the foramen rotundum and leaves the cranial cavity to reach the pterygopalatine fossa, where this nerve can be blocked. The mandibular nerve is formed by the union of a large sensory root and a smaller motor root that arises from the pons and passes beneath the gasserian ganglion to reach the foramen ovale, through which, together with the sensory root, it leaves the cranial cavity.

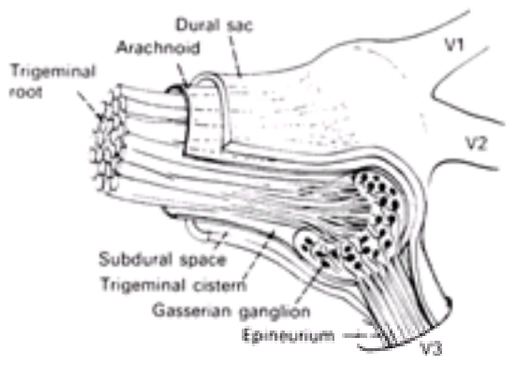

Figure 104-2. Gasserian ganglion, which contains cell bodies that have pseudounipolar axons. These break up into central branches that constitute the sensory root

of the trigeminal nerve and into peripheral branches that comprise the three major nerves. The ganglion is canoe shaped, with the three peripheral branches of the nerve attached to its anterior convex aspect. The roots emerge from the concave side of the ganglion to compose the triangular portion of the root. A variable number of anastomoses exist between the group bundle in this triangular portion, which is just behind the ganglion. The dural-arachnoidal envelope surrounding the ganglion is an evagination of the dura from the posterior cranial fossa to a position under the dura mater of the middle fossa. The dural-arachnoidal pouch behind the ganglion constitutes the trigeminal cistern, which normally contains cerebrospinal fluid that communicates with the infratentorial bases of the cisterns through the trigeminal porus. The anterior convex surface of the ganglion is adherent to the dural-arachnoidal covering and, as the latter passes distally, it becomes the epineurium of the mandibular, maxillary, and ophthalmic nerves. Also note the relationship of the subdural and arachnoid spaces. (Modified from Ferner H. The anatomy of the trigeminal root and the gasserian ganglion and their relations to the cerebral meninges. In: Hassler R, Walker AE, eds. *Trigeminal neuralgia.* Stuttgart, Germany: Georg Thieme Verlag, 1970.)

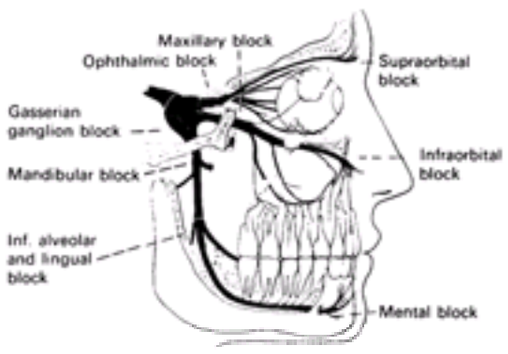

Figure 104-3. Various sites (*stippled areas*) at which the gasserian ganglion, the three major nerves, and their most important branches can be blocked.

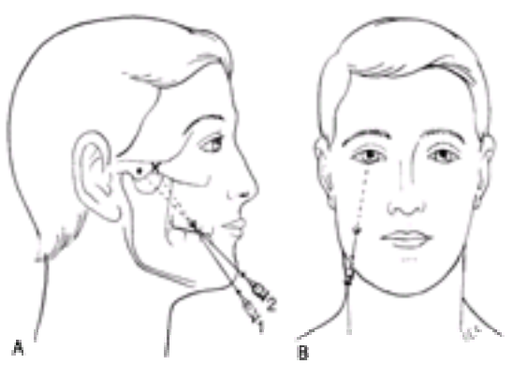

Figure 104-4. Technique of injection of the gasserian ganglion or of the mandibular nerve by the anterolateral (Härtel) approach. **A:** A skin wheal is made 3 cm lateral to the angle of the mouth at the level of the upper second molar. A 10-cm, 22-gauge needle (1) threaded with a depth marker is introduced through the wheal and advanced posteromedially and superiorly so that, when viewed from the side, its axis points to the midpoint of the zygomatic arch (*X*). **B:** When viewed from the front, the axis of the needle points to the pupil. A guiding finger of the other hand is placed in the oral cavity to ensure that the needle does not enter the mouth, which could introduce contaminating bacteria into deeper structures. As the needle advances, it passes through the buccinator muscle, beneath the mucous membrane between the mandibular ramus and tuberosity of the maxilla, and finally through the external pterygoid muscle before it contacts the infratemporal plate lateral to the base of the pterygoid process and just anterior to the foramen ovale, at a depth of 6.0 to 7.5 cm. The depth marker is placed 1.25 cm from the skin surface, and the needle is withdrawn until its point is subcutaneous. The needle is then reinserted (2) so that the axis of the needle, when viewed from the side, points to the articular tubercle (•) and, when viewed from the front, it still points to the pupil. When the needle has been advanced to a depth just 1 cm short of the rubber marker, its point usually contacts the mandibular nerve, causing paresthesia along its course. The needle is further advanced until the marker is flush with the skin.

The following anatomic points are useful in introducing the needle from the point of insertion in the skin to the foramen ovale:

- The foramen is an elliptic canal 5 mm long, with an axis that has an inferior and slightly anterolateral direction. Its greater diameter averages 8 mm, and its smaller diameter is 4 mm.
- It is situated immediately posterior to the smooth hard infratemporal surface of the greater wing of the sphenoid bone. The center of this plate, which serves as an important landmark, is approximately 4 cm medial to the midpoint of the zygomatic arch in the same frontal plane.
- The foramen is approximately 4 cm medial to the articular tubercle of the zygomatic arch in exactly the same frontal plane.

It is best to insert the needle with the patient in the supine position to avoid any orthostatic hypotension that might occur as a result of apprehension by the patient. For the injection of alcohol, the patient can remain in this position but, during the injection of phenol or glycerol, the patient should be in the sitting position to keep the agent in Meckel's cave. Usually a 10-cm, 22-gauge needle threaded with a depth marker is used for this procedure. Aspiration should be attempted with a 2-mL Luer-Lok syringe to ensure that the needle point is not in a blood vessel or the subarachnoid space. It is best to guide the placement of the needle by radiographic control (Fig. 104-5). Aliquots of 0.1 mL of alcohol, 5% phenol, or glycerol should be injected. After each injection, detailed sensory testing is done and the patient is questioned about the extent of analgesia and numbness to determine the effects of each aliquot. A total of 0.50 to 0.75 mL is injected, depending on the needs and responses of the patient.

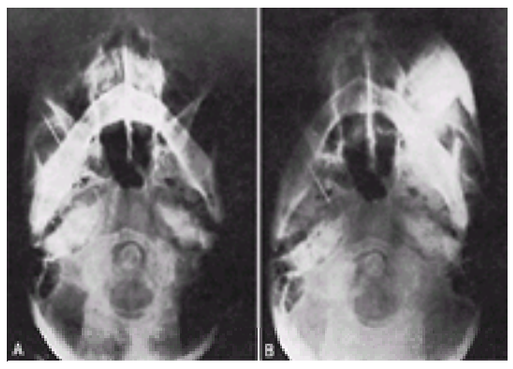

Figure 104-5. Radiographic visualization of gasserian ganglion block. **A:** The point of the needle is entering the foramen ovale. **B:** The needle has passed through the foramen and rests over the trigeminal depression of the petrous portion of the temporal bone. After B was taken, absolute alcohol, in 0.1-mL aliquots, for a total of 0.5 mL, produced analgesia of the second and third divisions.

Modifications. During the 1960s and 1970s, several refinements of blocking the gasserian ganglion or the sensory root were done to decrease the risk of serious complications. These included modifications of blocking with alcohol and the introduction of phenol in glycerin and of glycerol for gasserian ganglion block. The most

important of these are briefly described.

ALCOHOL. Ecker and Perl (39) developed a technique using radiographic control to position the needle. The patient is supine with the head extended so that the needle is inserted in a direction perpendicular to the floor. The needle is advanced through the center of the foramen ovale so that its tip lies on the target, exactly 4 mm beyond the posteromedial border of the foramen ovale and 2 mm above the base of the skull, at the petrosphenoid junction. The injected alcohol enters the ganglionic sinus where the juxtaganglionic rootlets are arrayed as in the peripheral division and where they are thinnest, most widely spread, and least intertwined. With the patient in this position, the mandibular fibers are the highest so that the alcohol, injected in tiny increments, rises to affect them and usually spares corneal sensation. Ecker and Perl (39) injected the alcohol in 0.05-mL aliquots and then tested sensation in the painful area. Additional aliquots were injected until the desired effects were obtained, usually with 0.2 to 0.3 mL of absolute alcohol. Delfino (40) modified Ecker's technique using an image intensifier to locate the exact center of the foramen ovale: 0.2 mL of 2% lidocaine solution as a prognostic block 30 minutes before injecting the ethyl alcohol in 0.05-mL aliquots, up to a total of no more than 0.2 mL.

PHENOL. Putnam and Hampton in 1936 (41) were the first to report on the use of the injection of phenol into the gasserian ganglion under roentgenographic control for the treatment of trigeminal neuralgia, but they published no follow-up of their preliminary report. In 1963, Jefferson (42) reported on the use of 5% phenol in glycerin for the treatment of trigeminal neuralgia and for postherpetic pain and cancer pain. The technique entailed inserting the needle into the foramen ovale under radiographic control, getting spinal fluid about half the time, and sitting the patient up with the head flexed forward on the chest so that the needle points vertically upward. Jefferson (42) then injected increments of 0.05 to 0.10 mL of phenol in glycerin until the desired results were achieved and then kept the patient upright for 20 to 30 minutes.

GLYCEROL. The technique for injecting glycerol into the trigeminal cistern, as advocated by Håkanson (43), is similar to that shown in Figure 104-4 and Figure 104-5. The notable difference is that the needle is inserted while the patient is in the sitting position and the dura-arachnoid is intentionally penetrated so that there is spontaneous flow of cerebrospinal fluid (CSF). Håkanson (42) has emphasized that, if spontaneous CSF drainage through the needle does not occur, the needle is not in the proper position and it is necessary to reposition it or to use the first needle as a guide and insert a second needle into its proper place. Once the needle is considered to be in the correct place and the CSF fluid has drained, 1 mL of contrast is injected slowly in 0.2-mL increments using a 1-mL tuberculin syringe and its diffusion is visualized by fluoroscopy. To fill the cistern completely, 2 mL of contrast is injected with the patient's chin against the chest. If the point of the needle is in the proper position, the contrast medium is seen to fill the cistern and to escape into the posterior fossa through the trigeminal porus.

Lateral and anteroposterior radiographs are then taken to show the pattern of diffusion of the contrast medium and to define the outline of the cistern. After the correct position of the needle tip has been verified, the contrast is evacuated from the trigeminal cistern by removing the syringe from the needle and placing the patient in a recumbent position for approximately 5 minutes. A total of 0.2 to 0.4 mL of pure sterile glycerol is then injected slowly. Because the size and shape of the trigeminal cistern are highly variable, it is necessary to vary the total volume of glycerol injected. To affect all three divisions, one must fill the cistern entirely, using 0.3 to 0.4 mL of glycerol with the patient's head in a ventrally flexed position (Fig. 104-6). For relief of neuralgia in the third division or in the second and third divisions, 0.20 to 0.35 mL of glycerol is injected. Because the specific gravity of glycerol is 1.242 (compared to that of CSF, which is 1.0065 to 1.007), with the patient's head in the flexed position, the glycerol remains in the inferolateral portion of the trigeminal cistern, which contains the rootlets of the mandibular and maxillary nerves (see Fig. 104-6A). Because the specific gravity of some contrast is even heavier than that of glycerol (1.329 versus 1.242), leaving a small amount of contrast in the bottom of the cistern protects the rootlets of the third branch in patients who have trigeminal neuralgia in the first and second divisions (see Fig. 104-6B).

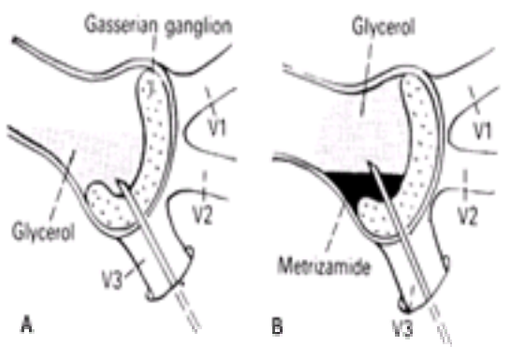

Figure 104-6. Håkanson's technique of injecting the sensory root of the trigeminal nerve with glycerol. **A:** After drainage of the cerebrospinal fluid and subsequent injection of metrizamide (see text), pure sterile glycerol is injected in 0.1-mL aliquots for a total of 0.4 mL if all three divisions are to be affected. By adjusting the volume of injected glycerol, it is possible to affect the different trigeminal divisions selectively. Because of the density of glycerol, it remains in the bottom of the cistern and a smaller volume (0.2 mL) therefore affects only the third division, while a larger volume also involves the second division. **B:** For the treatment of first- and second-division neuralgia, the rootlets of the third division can be spared by leaving a small amount of metrizamide, which is heavier than glycerol, in the bottom of the cistern. The amount of metrizamide left in the cistern is controlled before the glycerol is injected. (Modified from Häkanson S. Trigeminal neuralgia treated by the injection of glycerol into the trigeminal cistern. *Neurosurgery* 1981;9:638–646.)

Results: Neuralgia

Ethyl Alcohol. In one of the largest series on the use of ethyl alcohol for trigeminal neuralgia, Harris (44) treated a total of 1,433 patients. Of 457 patients followed for 3 years or longer, 360 (78%) had no recurrence of pain; unfortunately, the incidence of keratitis or of anesthesia dolorosa was not reported. The results obtained by others using ethyl alcohol, phenol, and glycerol are shown in Table 104-1 Most of these reports, however, lack specific data on the incidence of complications.

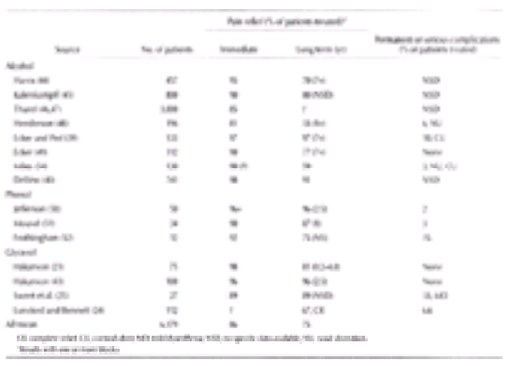

TABLE 104-1. Results of therapy with neurolytic gasserian ganglion block for the pain of trigeminal neuralgia

Bonica (2) has described the use of the Härtel technique of gasserian alcohol block with ethyl alcohol in 28 patients. He described a technique of blocking only the second and third divisions within the ganglion in four other patients who had had injections of the nerves outside the skull and had recurrence of pain. The 32 patients received 39 injections. Of those in this group, 28 patients (88%) had good relief following the injection, but the pain recurred in 17 patients (53%) during the follow-up period, which ranged from 14 months to 8 years or until the death of the patient. Of the 28 patients who had complete trigeminal analgesia, four (14%) developed keratitis (despite meticulous ophthalmologic care), one developed anesthesia dolorosa, and one sustained paresis of other cranial nerves from an accidental subarachnoid injection of the alcohol. This was the most serious complication he encountered during his extensive experience with neurolytic blocks. These complications and the advent of more refined and specific neurosurgical operations caused Bonica to discontinue the use of gasserian ganglion block with alcohol for

the treatment of trigeminal neuralgia in the 1950s.

Modern radiologic technology using the image intensifier, the advent of newer and safer contrast media, and the use of glycerol, together with skillful administration, make gasserian ganglion block easier and safer than it was two decades ago (Table 104-2; see Table 104-1). Notwithstanding the better results obtained with neurolytic blocks, patients with the pain of trigeminal neuralgia not relieved by drug therapy today should be managed with microvascular decompression or gangliolysis as discussed in Chapter 107.

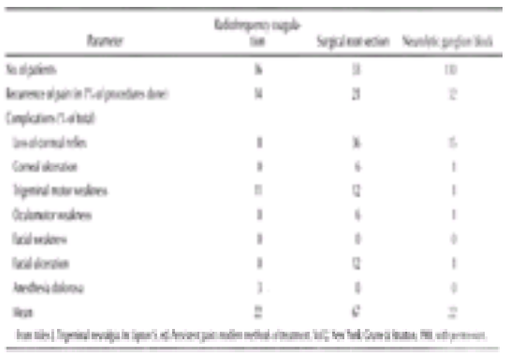

TABLE 104-2. Comparison of results of treatment of the pain of trigeminal neuralgia

Results: Cancer Pain

In contrast to its use in a trigeminal neuralgia patient with a long life expectancy, alcohol block remains a useful procedure for those with severe intractable pain in the anterior two-thirds of the face caused by advanced or terminal cancer. Radiofrequency gangliolysis is also useful for such patients. Prior to selection of the optimal method, it is essential to determine the type of cancer, the predicted rate and direction of spread, the condition of the patient, and the availability of a physician skilled in block techniques. If the neoplasm is slow growing and involves structures in the second or third division, or in both, block of the nerves is preferable to avoid keratitis. If the neoplasm could spread to affect the first division, or if it is difficult to block the second division because the tumor occupies the pterygopalatine fossa, it is better to carry out gasserian ganglion block at the outset. This should produce a widespread field of analgesia into which the cancer can spread without producing subsequent pain. Although this technique carries the risk of corneal anesthesia and possibly keratitis, the problem is different than when dealing with a patient with trigeminal neuralgia in whom life expectancy is long and in whom corneal ulcer would be a serious complication. In a patient with advanced or terminal cancer, effective relief of excruciating pain is considered to be worth the risk of these complications.

Obtaining radiographs prior to block is useful and necessary to ascertain that the foramen ovale has not been invaded, which could make proper positioning of the needle difficult. In patients with carcinoma of the nasopharynx and floor of the mouth, the tumor can destroy bone structures of the base of the skull and make it impossible to identify the foramen ovale. In such cases a different approach for the block must be adopted or a different procedure must be used. Because alcohol diffuses poorly in tissues, the point of the needle must be in the precise position. Another important step is to carry out block with a local anesthetic to predict the efficacy of the neurolytic agent before it is injected.

Between 1945 and 1977, Bonica used gasserian ganglion block with absolute alcohol in 107 patients (2). Of these, 79 patients (74%) obtained effective pain relief and, together with small or moderate doses of sedatives, codeine, or adjuvant drugs, they were made comfortable until their death, 2 weeks to 7 months later. Another 16 patients (15%) obtained only partial relief with the first injection and required either a second injection of the ganglion (nine patients) or a supplementary injection of one of the major nerves (nine patients), together with modest doses of drugs. The procedure produced little or no relief in the remaining 12 patients, and they were managed with opioids. Similar results were reported by Madrid at the First International Symposium on Cancer Pain in 1979 (53).

Complications. Most of the complications that occur with neurolytic block of the gasserian ganglion block have been mentioned. Some complications and unwanted side effects are avoidable, and some are not. Unavoidable side effects that are usually transient and not serious include Horner's syndrome from block of the paratrigeminal sympathetic fibers, and involvement of the motor root, with transient weakness of the muscles of mastication. If the entire ganglion is affected by the neurolytic agent, several problems can occur. Corneal anesthesia, with consequent loss of corneal reflex and possibly paralytic keratitis, loss of sensation on the ipsilateral side of the face and half of the tongue, paresthesia, herpetic eruptions, trophic ulcerations, and anesthesia dolorosa can and do develop. The incidence, degree, and duration of these complications from neurolytic blockade vary depending on the completeness of the destruction of nerve cells.

With injection of a larger amount (more than 1 mL) of neurolytic substance, these complications are likely to occur more frequently and to last longer. Miles (54) confirmed this when comparing the effects of neurolytic ganglion injection with those of surgical root section and radiofrequency coagulation in one center where each procedure was carried out by highly skilled personnel (see Table 104-2). The data suggest that the use of neurolytic ganglion block results in fewer complications than surgical root section, but they also show that the incidence of the recurrence of the neuralgia is greater with neurolytic ganglion block (32% versus 21%). Techniques of gasserian ganglion block that spare the cell bodies or rootlets of the first division, such as those used by Håkanson (43), Ecker and Perl (39), and Jefferson (42), are not followed by corneal ulceration or anesthesia dolorosa. Accidental subarachnoid injection of alcohol is likely to involve other cranial nerves and is probably the most serious complication of this technique. Its incidence can be minimized by repeated attempts at aspiration prior to injection of each aliquot.

Block of the Ophthalmic, Maxillary, and Mandibular Nerves Indications. Block of the maxillary or mandibular nerve, or both, remains useful for the relief of severe tic douloureux or of cancer-related pain affecting one or both of these nerves if neuroablative procedures cannot be carried out. For patients with trigeminal neuralgia, it is essential to use prognostic blocks with local anesthetics to determine which branch needs to be blocked, especially in those who have trigger areas in one branch and pain distribution in another branch. If touching the upper lip causes pain in the lower jaw, for example, it is likely that the second division needs to be blocked instead of the third division. Occasionally, however, both nerves need to be blocked.

NEURALGIA. In their classic textbook (55), White and Sweet listed six uses for injection of the major branches of the trigeminal nerve in patients with trigeminal neuralgia

- To provide prompt pain relief so that patients weakened by poor fluid intake might be strengthened preparatory to an operation for permanent relief.
- To enable those likely to die soon to live out their lives pain-free and without major surgery.
- To aid in the differential diagnosis of patients whose pain has characteristics transitional between those of trigeminal neuralgia and other forms of facial neuralgia.
- To relieve pain on the second side of the face when bilateral neuralgia has developed so as to avoid complete, lasting anesthesia on both sides of the face.
- To relieve pain by the use of alcohol block in the distribution of branches of the first division without involving the eye, to avoid the corneal anesthesia produced by rhizotomy of the ophthalmic nerve.
- To help patients adjust to the dysesthesia that might follow posterior rhizotomy.

The advent of anticonvulsant drugs has virtually eliminated the first two indications. Block with a local anesthetic remains useful to help in the diagnosis of patients with neuralgia with confusing symptoms and to obviate the need for bilateral rhizotomy in patients with bilateral neuralgia. White and Sweet (55) stated that neurolytic block should be used prior to trigeminal rhizotomy to give a clear and sustained (but reversible) indication of the sensory changes that accompany denervation to help patients decide whether they prefer temporizing drugs or surgery to produce lasting anesthesia and consequent permanent relief.

CANCER PAIN. Block of the maxillary or mandibular nerve, or both, with neurolytic agents remains useful in managing patients with severe and intractable cancer-related pain, especially if experienced neurosurgeons are not available and if life expectancy is shorter than 3 months. Cancer of the nasal cavity and paranasal structures is predominantly adenocarcinoma, which is highly malignant and all too often is inoperable when first seen. Eventually this cancer produces severe symptoms, including nasal obstruction, nasal discharge, epistaxis, and intractable pain, which is usually diffuse, dull, and aching and is frequently referred to the face. The pain can be relieved satisfactorily by blocking the maxillary nerve with alcohol. If the pterygopalatine fossa is invaded and block of the second division is

impossible, gasserian ganglion block must be carried out.

Cancer of the lower jaw, particularly Ewing's sarcoma and osteogenic sarcoma, often produces severe intractable pain. The ulcerating type of carcinoma of the lower gingiva and floor of the mouth that has resulted in extensive invasion of the mandible or overlying skin, or both, also produces intense pain. In many of these cases the pain becomes progressively more intense and is often accompanied by trismus and otalgia, all of which prevent patients from eating and sleeping, thus enhancing cachexia. Because many of these patients are in poor physical condition, alcohol block of the mandibular nerve alone or in combination with block of C-2 and C-3 is indicated. Alcohol block of the lingual nerve should be considered in those with severe pain caused by cancer of the tongue, especially if the pain involves both sides, thus obviating bilateral masticatory paralysis, which usually follows bilateral mandibular nerve block. Inferior alveolar nerve block should also be considered for patients with severe pain caused by cancer of the mandible.

In 1951, Bonica (56) analyzed the results of neurolytic blocks. These were included in the first edition of this book (2). A total of 76 patients were studied; they had undergone 102 neurolytic blocks of the maxillary or mandibular nerve or a combination of these of one of their branches. Of these, 53 patients (69%) had complete or almost complete relief of pain, 14 (19%) had partial relief of pain, and the remaining nine (12%) had no relief; there were no deaths in this group. Progressively fewer of these procedures have been done at the University of Washington Pain Center, for three major reasons: (a) Many of these patients are managed by former trainees of the Pain Fellowship Program and by other anesthesiologists practicing in other hospitals; (b) the Pain Center has become involved predominantly in the management of patients with complex, nonmalignant, chronic pain problems; and (c) more aggressive management by otolaryngology is being used. These techniques remain important tools, however, especially in those hospitals in which sophisticated neurosurgical techniques are not available and in medical centers in developing countries. Properly done, they provide much-needed relief to patients with cancer pain.

OTHER INDICATIONS. Block of the mandibular or maxillary nerve, or of both, with long-lasting local anesthetic (e.g., 0.5% bupivacaine) can be used in patients who experience excruciating pain postoperatively or postinjury. The block usually lasts 8 to 12 hours and can be repeated one, two, or even three times to tide patients over. Obviously, patients with posttraumatic pain can have distortion of the bones of the face, making the classic lateral extraoral route difficult or impossible. In such cases, the orbital (Matas) route is used.

Retrobulbar Block. Retrobulbar block, with varying concentrations of alcohol for the relief of severe persistent eye pain, has been used in the first half of the twentieth century. In 1918, Grüter (57) reported the injection of 3 mL of 80% to 90% ethyl alcohol as an alternative to the enucleation of blind painful eyes. In 1930, Weekers (58) first described the use of a dilute solution of alcohol in those with “seeing eyes” (i.e., patients who had vision) to relieve severe persistent eye pain consequent to corneal ulcers, keratitis, uveitis, and glaucoma. Since then many ophthalmologists have used alcohol block for the relief of pain in both types of patients, as well as for the control of photophobia and blepharospasm following corneal surgery and penetrating keratoplasty. The duration of pain relief varies but usually is 3 to 6 months and even longer, although pain can return sooner if the underlying pathologic process remains uncontrolled.

In 1949, Maumenee (59) published a report summarizing this technique, the results obtained by Grüter from the time he first described the technique to 1943, and those of others up to 1949. Maumenee also described the technique of injection of 95% alcohol in 41 eyes with less than 10/200 vision (“blind eyes”) and in 15 patients whose visual acuity ranged from 10/200 to 20/20 (“seeing eyes”). Of the patients with “blind eyes,” 68% had glaucoma and the remainder (32%) had corneal ulcers, keratitis, uveitis, and keratoplasty. Those with “seeing eyes” had various forms of infectious keratitis, including herpes zoster, uveitis, glaucoma secondary to uveitis, and epidemic keratoconjunctivitis. No patients in the latter group had reduction of visual acuity after the injection of alcohol and, in all of these patients, vision improved with therapy of the underlying condition. Histologic studies of the optic nerves of 15 eyes that had been removed after alcohol injection showed no evidence of damage to the nerve from the alcohol. It was concluded that the optic nerve is apparently protected from the effects of alcohol by the thick sheath that surrounds it (59). Newer ophthalmologic treatments have reduced the indications for this procedure.

Techniques. The anatomy of the ophthalmic, maxillary, and mandibular nerves is described in detail in Chapter 47, Chapter 48, Chapter 49, Chapter 50, Chapter 51, Chapter 52 and Chapter 53. Figure. 104-7 illustrates various techniques of blocking the branches of the ophthalmic nerve, and Figure. 104-8 shows the technique of retrobulbar alcohol block. Figure. 104-9 depicts procedures for blocking the maxillary nerve by the lateral and anterolateral extraoral routes. Figure. 104-10 shows the technique of maxillary nerve block by the orbital (Matas) route, which is used if the lateral technique cannot be carried out because of a tumor in the path of the needle. Figure. 104-11 shows mandibular nerve block by the lateral extraoral route, which is the most frequently used technique for injection of this nerve.

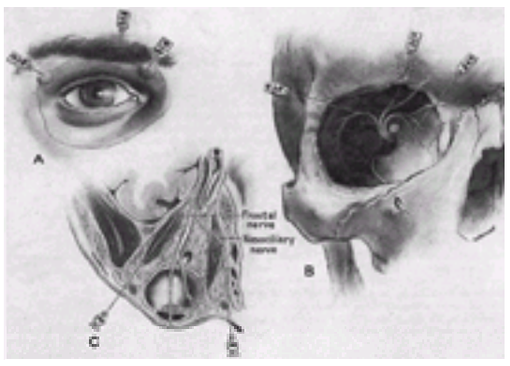

Figure 104-7. Block of the branches of the ophthalmic nerve. **A,B:** Anterior views showing, from left to right, lateral orbital block, supraorbital block, and medial orbital block. **C:** Schematic cross section of the orbit with the nerves left intact to show the techniques of lateral and medial orbital block. To block all the branches within the orbit, the lateral superior route is used. A 5-cm, 25-gauge needle is introduced through a wheal made just above the lateral canthus and advanced posterolaterally until contact is made with the bone of the lateral wall of the orbit. With its bevel flush with the bone, the needle is then advanced posteromedially toward the apex of the orbit, keeping constant contact with the bone. At a depth of 3.5 cm, the point of the needle usually loses contact with the bone, being situated at the lateral portion of the superior orbital fissure. It is then advanced another 3 to 5 mm, aspiration is attempted, and if no blood or cerebrospinal fluid is obtained, 2 to 3 mL of local anesthetic is slowly injected. To block the supraorbital nerve as it curves around the supraorbital ridge, a 1.5-cm, 30-gauge needle adapted to a 2-mL syringe, which contains a local anesthetic, or to a 1-mL tuberculin syringe, which contains alcohol, is held like a dart and thrust through the skin of the upper lid in a direction perpendicular to it. The supraorbital foramen, or notch through which the nerve passes, is easily palpable through the skin of the upper lid by retracting the eyebrow upward at a point 2.5 cm from the midline. The needle is advanced slowly until paresthesia is elicited or bone is contacted. For neurolytic block, it is essential to contact the nerve, and several reinsertions may be necessary to locate it so that the neurolytic agent can be deposited intraneurally. To block the nasociliary nerve or its branches, a 5-cm, 25-gauge needle is inserted through a wheal 1 cm above the inner canthus and directed posterolaterally, always keeping contact with bone. At a depth of 2 cm, the point of the needle should be at the anterior ethmoidal foramen, and 1.5 to 2.0 mL of local anesthetic solution is then injected. This blocks the anterior ethmoidal nerve, which eventually becomes the internal and external nasal branches. The needle is then advanced 1 cm further to reach the posterior ethmoidal foramen, where 1.5 to 2.0 mL of solution is injected to block the posterior ethmoidal nerve that supplies the ethmoidal cells and the sphenoid cavity. These two injections are also likely to block the infratrochlear nerve, which supplies the conjunctiva, lacrimal sac, inner canthus, and root of the nose.

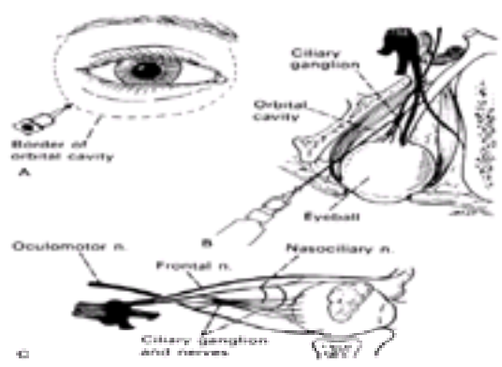

Figure 104-8. Technique of retrobulbar alcohol block. **A:** Following appropriate preparation of the field, the needle, adapted to a 5-mL syringe containing 1% or 2% lidocaine, is inserted into the lateral third of the lower eyelid just above the rim of the orbit. **B,C:** The needle is advanced and passed through Tenon's capsule (the thin membrane that envelops the eyeball), between the lateral rectus and inferior rectus muscles, into the muscle cone. The needle should be advanced until its tip is

just behind the globe. Aspiration is attempted to ensure that the bevel of the needle is not in a blood vessel; if negative, 2 mL of lidocaine is injected. The syringe is then removed, leaving the needle in place. After 15 to 20 minutes, a 2-mL Luer-Lok syringe containing either 50% alcohol (for patients with vision) or absolute alcohol (for patients with no vision) is adapted. An attempt at aspiration is again made to ensure that the needle has not entered a blood vessel, and the alcohol is injected slowly.

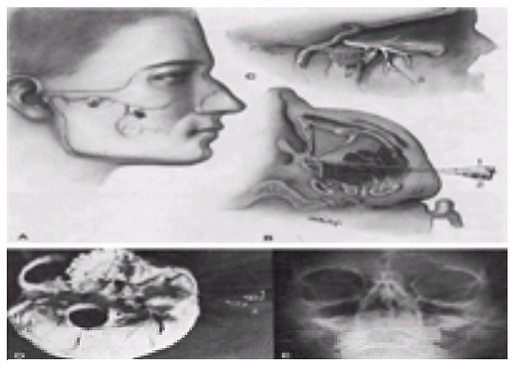

Figure 104-9. Technique of maxillary nerve block. **A:** Needles in place for the lateral and anterolateral routes. For the lateral route, a wheal is raised below the sigmoid notch of the zygomatic arch, and an 8-cm, 22-gauge needle threaded with a depth marker is introduced through it perpendicular to the skin and slowly advanced until the point strikes the lateral pterygoid plate at a depth of about 4 cm (**B:** 1). The marker is then set 1 cm from the skin, the needle is withdrawn until its point is subcutaneous, and it is readvanced in a slightly anterior and superior direction so that its point is 1 cm anterior and 1 cm superior to the point of bone contact made on the first insertion. The needle is carefully advanced in this direction until the marker is flush with the skin and the point of the needle is within the pterygopalatine fossa (**B,C:** 2). For local anesthesia, 2 mL of a local anesthetic may be injected slowly. If a neurolytic block is required, it is essential that the bevel of the needle be on or in the nerve. The nerve is located by eliciting paresthesia or by using a nerve stimulator. If the point of the needle is on the nerve, 1 mL of alcohol is injected, but, if the needle bevel is within the nerve, 0.4 mL is sufficient to destroy the nerve. **D:** Inferior view of the skull showing needle 1 with its bevel against the lateral pterygoid plate and needle 2 with its distal centimeter in the pterygopalatine fossa and its bevel in front of the foramen rotundum. **E:** Radiograph showing the needle in place and its bevel in front of the foramen rotundum. For the anterolateral route, a skin wheal is raised at the angle formed by the coronoid process of the mandible and the inferior border of the zygomatic arch, and an 8-cm, 22-gauge needle is introduced and advanced medially, superiorly, and slightly posteriorly **(A,C)**. At a depth of 4 cm, the upper part of the posterior surface of the maxilla is contacted and the needle is advanced further with its bevel facing the bone to a depth of 4 to 5 cm, where contact with the bone is lost and paresthesia in the upper jaw is elicited. If difficulties are encountered, a nerve stimulator and radiographic control can be used. Once contact is made, the same volumes of local anesthetic or neurolytic agent, as mentioned for the lateral route, are injected.

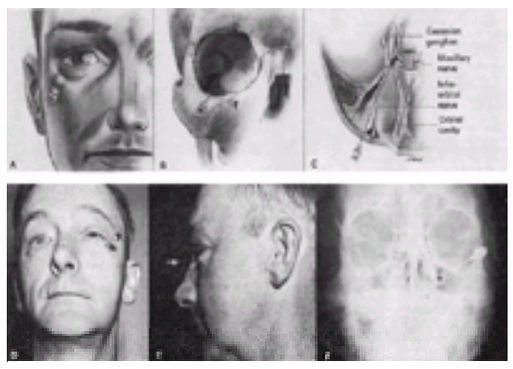

Figure 104-10. Maxillary nerve block by the orbital (Matas) route. **A:** An 8-cm, 22-gauge needle is introduced through a wheal made just above the inferior orbital margin, 1 cm medial to the inferior lateral angle of the orbital rim. Contact with the floor of the orbit is made, and the needle is advanced posteriorly and slightly medially, keeping constant contact with the bone. **B:** At a depth of about 3.5 cm, the point of the needle enters the inferior orbital fissure and loses its contact with bone. **C:** The needle is then slowly advanced so that its point passes through the pterygopalatine fossa, and it finally enters the foramen rotundum at a depth of about 5 cm. Paresthesia can be elicited while the needle is advancing through the pterygopalatine fossa and should always be elicited when the needle enters the foramen rotundum containing the nerve. **D,E:** Patient with the needle in place. **F:** Radiograph showing the bevel of the needle within the foramen rotundum. Injection of 0.5 mL of alcohol is sufficient to destroy the nerve.

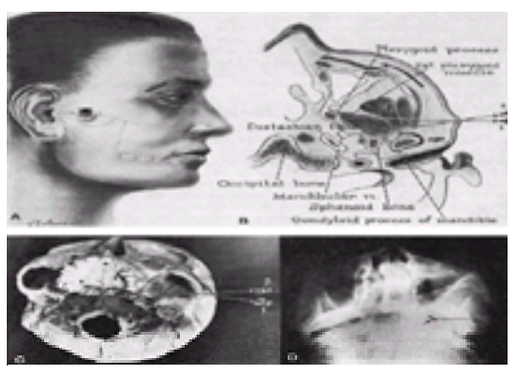

Figure 104-11. Mandibular nerve block by the lateral extraoral route. **A:** A skin wheal is raised just below the midpoint of the zygomatic arch, and an 8- cm, 22-gauge needle threaded with a rubber marker is inserted through it perpendicular to the skin. **B:** The needle is advanced until its point strikes the lateral pterygoid plate at a depth of about 4 cm from the skin (1). The marker is set 5 mm from the skin surface, and the needle is withdrawn until its point is subcutaneous and reinserted so that its point is 1 cm posterior to its previous position (2). The needle is gently advanced until the marker is flush with the skin, at which depth the bevel of the needle usually contacts the nerve just inferior to the foramen ovale and elicits paresthesia. For a diagnostic block, 2 to 3 mL of local anesthetic can be injected on the nerve but, for a neurolytic block, it is best to inject 1 mL of alcohol intraneurally. Because intraneural injection of alcohol is painful, it is essential to either give the patient a short-acting opioid, such as fentanyl, before injecting the alcohol or inject 0.5 mL of 2% lidocaine, wait about 30 minutes, and then inject the alcohol. **C:** Inferior part of the skull showing two needles in place. Needle *1* has its bevel against the lateral pterygoid plate, while needle *2* has its bevel in the center of the foramen ovale. **D:** Radiograph showing the needle (*arrow*) below the foramen ovale.

A neurolytic block should be preceded always by a block with a long-lasting local anesthetic, such as bupivacaine. As noted, the volume of local anesthetic should be the same or smaller than the volume of neurolytic agent to be used. Bonica preferred alcohol injected intraneurally to obtain a longer-lasting neural blockade. This is best done with the mandibular nerve because of its size and position below the foramen ovale. The maxillary nerve in the pterygopalatine fossa is smaller, and it is more difficult to place the point of the needle in the nerve. In any case, good results require that the point of the needle be in or very near the nerve as indicated by eliciting paresthesia. If difficulty is encountered, a nerve stimulator could be used.

With absolute alcohol, the average duration of blockade, as reported by many workers, has been 12 to 14 months for the maxillary nerve and 16 to 18 months for the mandibular nerve (55,60). In Bonica's series, maxillary nerve block afforded relief for an average of 14.6 months, with a range of 8 to 27 months, and mandibular

nerve block provided relief for an average of 18.4 months, with a range of 7 to 29 months (2).

The technique of injecting alcohol to relieve persistent eye pain (see Fig. 104-8) is somewhat different from that described for ophthalmic nerve block. Most ophthalmologists use a 3.5-cm, 22-gauge needle, but a 25-gauge needle produces less tissue damage. As part of the psychological preparation, patients should be reassured about the procedure and instructed to alert the physician promptly if a flash of bright light is experienced, which indicates that the needle has penetrated the optic nerve. In some patients, the injection is done during the course of surgery with general anesthesia.

Complications

RETROBULBAR BLOCK. Following retrobulbar alcohol injection, patients have routinely developed some degree of ptosis, proptosis, chemosis, and extraocular muscle palsy within hours of injection, but all these resolve in 2 days to several weeks (59). Temporary muscle paralysis is commonly seen if injection is done too far posteriorly in the muscle cone, instead of using the technique described above. Properly done, little or no risk of optic nerve damage is involved, because the nerve is protected by the thick sheath that surrounds it. Moreover, no permanent muscle palsy or other serious complications have been noted. Several cases of optic nerve damage have been reported following accidental injection of alcohol into the optic nerve.

MAXILLARY NERVE BLOCK. Because of the highly vascular nature of the contents of the pterygopalatine fossa, bleeding often occurs with maxillary nerve block but is usually not serious. Injection of neurolytic agents in excess of 1 mL increases the risk of having the drug pass through the inferior orbital fissure into the orbit and of damage to the oculomotor and abducens nerves, producing visual difficulties; for reasons noted above, this does not damage the optic nerve. Moore (61) reported a case of necrosis of the mucosa and cartilage of the palate, with a consequent large defect in half of the roof of the mouth on the ipsilateral side following alcohol injection of the maxillary nerve. In view of the numerous patients who have received maxillary nerve blocks with alcohol, these are rare complications that can be minimized and even eliminated by using a small volume of alcohol and precise technique.

MANDIBULAR NERVE BLOCK. Minor complications of mandibular nerve block are postinjection pain and hemorrhage into the cheek, which occur during and following mandibular block by the anterolateral extraorbital route. Both have transient effects. The most frequent, more serious complication is involvement of the motor root with consequent weakness or paralysis of the muscles of mastication of the affected side, which causes the mandible to deviate from the midline. If more than 1 mL of alcohol is injected into the mandibular nerve, it is likely that some of the solution can diffuse cephalad and affect the lower part of the gasserian ganglion.

Block of Branches of the Maxillary and Mandibular Nerves. Figure. 104-12 depicts the technique of blocking the infraorbital nerve, Figure. 104-13 shows the technique of blocking the lingual and inferior alveolar nerves, and Figure. 104-14 illustrates the technique of blocking the mental nerve by the intraoral and extraoral routes. Injection of these branches with a long-acting local anesthetic (e.g., bupivacaine) can be used to relieve severe acute postoperative or posttraumatic pain and to control the severe pain of herpes zoster in the distribution of each of these branches. Because of their simplicity, injections can be repeated twice daily until the pain subsides.

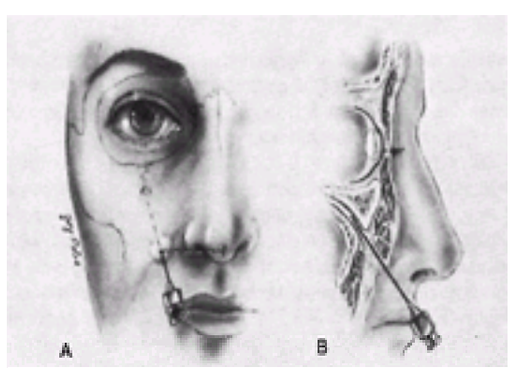

Figure 104-12. Technique of infraorbital nerve block. **A:** A 5-cm, 25-gauge needle attached to a 2-mL Luer-Lok syringe and containing a local anesthetic, or to a 1-mL tuberculin syringe containing alcohol, is introduced through a skin wheal made 1 cm lateral to the middle part of the ala nasi, or 2.5 cm from the midline, and advanced superiorly, posteriorly, and slightly laterally. The bone just inferior to the foramen is contacted at a depth of 1.0 to 1.5 cm, and paresthesia is elicited, usually radiating to the upper lip. To block the branch that supplies the lip, the injection is made at this point, but, to block the nerve supply to the front teeth, it is necessary to pass the needle into the canal 7 to 10 mm **(B)**. Paresthesia is usually elicited during the advance. After negative aspiration tests, 1 mL of local anesthetic or 0.3 to 0.5 mL of alcohol is sufficient to destroy the nerve.

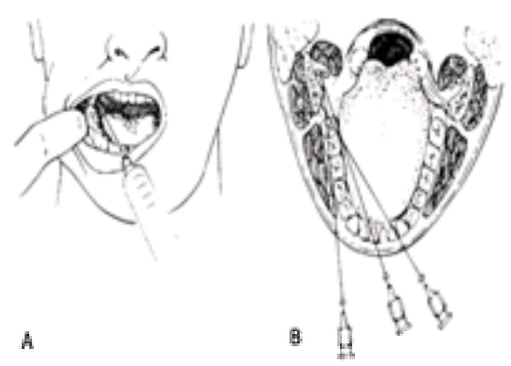

Figure 104-13. Technique of blocking the inferior alveolar and lingual nerves by the oral route. **A:** After the mucous membrane of the retromolar trigone is topically anesthetized and prepared with an antiseptic solution, a 10-cm, 22-gauge needle attached to a 5-mL syringe containing local anesthetic, or to a 1- mL tuberculin syringe containing alcohol, is introduced 1 cm above the triturating surface of the last molar tooth. **B:** The angle is such that the shaft of the needle rests 1 cm above the dental arch between the canine and first premolar tooth of the opposite side (1). After contact is made with the trigone at its medial side, the needle is swung horizontally so that its shaft rests parallel to the teeth of the same side and it is gently and slowly advanced so that its point slips to the medial border of the trigone (2). The needle is swung back so that its shaft finally rests above the first incisor of the same side, and it is advanced about 1.5 cm to bring the point midway between the anterior and posterior margins of the ascending ramus (3). At this juncture, the bevel of the needle is just medial to the mandibular foramen, where 2 to 3 mL of local anesthetic solution (or 1 mL of alcohol) is injected. For neurolytic block, it is essential to contact the inferior alveolar and lingual nerves separately and to elicit paresthesia before injecting alcohol.

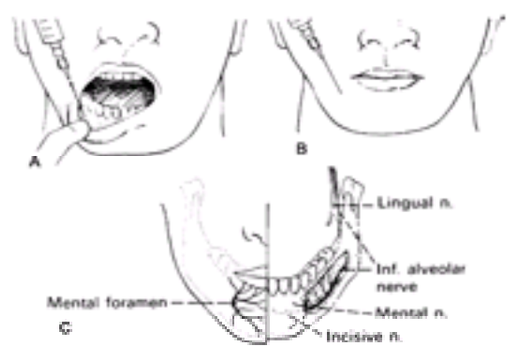

Figure 104-14. Technique of mental nerve block by the oral and extraoral routes. **A:** Oral route. A 5-cm, 25-gauge needle is introduced through the gingivobuccal reflection on a line drawn between the premolar teeth. After contacting the upper margin of the mandible, the needle is advanced inferiorly on the same line to a point

midway between the upper and lower margins, where the nerve is usually contacted and paresthesia is elicited. **B:** Extraoral route. A 5-cm, 25-gauge needle is introduced through a wheal raised on the skin of the lower lip inferior and anterior to the root of the second premolar tooth. On making contact with the bone, the needle is advanced anteriorly, inferiorly, and medially until it passes into the foramen, which faces posteriorly, superiorly, and laterally, and paresthesia is elicited. Usually, 2 mL of local anesthetic is used for prognostic block, but, for neurolytic block, 0.3 mL of absolute alcohol is injected intraneurally or into the mental canal. **C:** View of the mandible to show the emergence of the mental nerve through the mental foramen (left) and dissection of the inferior alveolar canal to show the distribution of the inferior alveolar nerve to the teeth.

Alcohol block of these nerves is used as a prognostic and therapeutic procedure in patients with tic douloureux, postherpetic neuralgia, and severe cancer pain limited to their distribution. For optimal results, it is best to inject the drug intraneurally to destroy these nerves, thus producing a prolonged effect. Some patients develop postinjection neuropathy with neuralgia, with degeneration of the nerve. Local ulceration and necrosis have been reported.

Block of the Glossopharyngeal and Vagus Nerves

Indications. Block of the glossopharyngeal or vagus nerve, or both, is indicated for patients with severe intractable pain caused by ticlike neuralgia or with cancer-related pain in the distribution of these nerves. Block of these nerves with a long-lasting local anesthetic is used to help in the differential diagnosis of ticlike pain in the angle of the jaw, which can be caused either by glossopharyngeal or mandibular neuralgia. Glossopharyngeal block is used in differentiating glossopharyngeal neuralgia from the geniculate ganglion neuralgia that causes pain deep in the ear and has some of the features of glossopharyngeal neuralgia. Because geniculate neuralgia involves the sensory root of the facial nerve (nervus intermedius), glossopharyngeal nerve block at the jugular foramen or below the styloid process does not relieve it. In such cases, the initial step involves provoking glossopharyngeal neuralgia by applying a cotton applicator to the tonsils, posterior pharynx, or back of the tongue and then applying a topical anesthetic such as 4% cocaine or 0.5% bupivacaine to produce analgesia of the trigger points within 10 to 15 minutes.

A small percentage of patients develop a variant of glossopharyngeal neuralgia, in which the vagus nerve is also involved. Robson and Bonica (62) reported a method of aiding the diagnosis of this type of neuralgia. In two patients who presented with typical clinical pictures of glossopharyngeal neuralgia, complete topical anesthetization of the entire pharynx, which completely relieves the pain of neuralgia limited to the glossopharyngeal nerve, failed to do so. Block of the glossopharyngeal and vagus nerves below the jugular foramen, however, afforded complete relief. In these patients, resection of the sensory root of the glossopharyngeal nerve, as well as of the anterior half of the sensory root of the vagus nerve, produced permanent and complete relief of the neuralgia.

Block of the vagus nerve with a local anesthetic is also useful as a diagnostic or prognostic procedure in those with cancer pain in the tracheobronchial tree. This type of pain is effectively treated with section of the vagus nerve below the recurrent laryngeal nerve. Because block of each of these two nerves is best done at the base of the skull, motor nerves are also interrupted, and therefore neurolytic blocks are contraindicated because they produce prolonged paralysis of the pharyngeal and laryngeal muscles and consequent loss of the ability to swallow and phonate.

In earlier years, Bonica advocated the cautious use of unilateral glossopharyngeal block with neurolytic agents for the relief of severe cancer pain in patients who could not tolerate intracranial rhizotomy. The development and clinical application of percutaneous thermocoagulation of the glossopharyngeal nerve, described by Broggi and Siegfried (63) and used by other workers for the treatment of glossopharyngeal neuralgia and cancer pain, have decreased the need for unilateral neurolytic blockade of this nerve. Using the thermocoagulation procedure (see Fig. 104-5), several workers have reported good pain relief in about half of patients with glossopharyngeal neuralgia and in about two-thirds of patients with cancer pain. The procedure produces transient vagal dysfunction and occasionally causes dysarthria and dysphagia. This procedure is done only in a few medical centers worldwide, however, and is not available to most patients with severe cancer pain in the throat. If patients can tolerate it, intracranial section of the sensory root of the glossopharyngeal nerve should be done, but if patients are in poor physical condition and the pain cannot be controlled with opioids, a unilateral neurolytic block should be considered.

Block of the internal laryngeal branch of the superior laryngeal nerve with local anesthetic and subsequently with alcohol or phenol can be used to control severe neuralgia, cancer pain, or other chronic painful conditions in the larynx. In patients who have cancer pain involving branches of the glossopharyngeal or mandibular nerves, block of the internal laryngeal nerve must be supplemented with block of these nerves.

Techniques. The anatomy of the glossopharyngeal and vagus nerves is described in detail in Chapter 46 and Chapter 47. The technique of blocking the glossopharyngeal nerve is depicted in Figure. 104-15, and block of the vagus nerve is shown in Figure 104-16 Because of the proximity of both nerves just below the jugular foramen, selective block of the glossopharyngeal nerve is difficult. Inserting the needle just posterior to the angle of the mandible, which is approximately 5 cm below the level of the jugular foramen, the glossopharyngeal nerve is 1.5 to 2.0 cm anterior to the vagus nerve (see Fig. 104-15C). Using a nerve stimulator and an insulated needle, the nerve is contacted 2 or 3 cm below and anterior to the tip of the styloid process. Once the nerve has been contacted, 1.0 to 1.5 mL of 0.5% bupivacaine with epinephrine is injected. If the block produces analgesia limited to the distribution of the glossopharyngeal nerve, one can consider following it up with the injection of 5% aqueous phenol to obtain a block of several months. Figure. 104-17 shows the technique of blocking the internal branch of the superior laryngeal nerve.

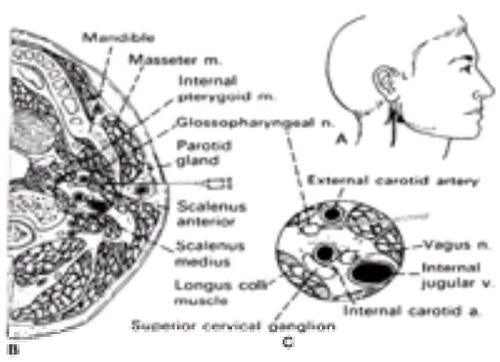

Figure 104-15. Technique of glossopharyngeal nerve block. **A:** A skin wheal is made just posterior to the angle of the mandible, and a 5-cm, 22-gauge Teflon-coated needle attached to a stimulator is passed through the wheal. At this level, the glossopharyngeal nerve is 1.5 to 2.0 cm anterior to the vagus nerve and can be blocked exclusively with small volumes of solutions without involving the vagus nerve. **B:** The needle is advanced medially and just posterior to the mandible until its bevel is 4 cm deep, and the stimulator is used to help locate the nerve. Once the nerve has been found, 2.0 to 2.5 mL of the local anesthetic or 1.5 to 2.0 mL of alcohol is injected. **C:** Enlargement of the circled area in **B** to show the point of the needle on the nerve. Because the section is below the tip of the styloid process, this is not seen as it is in Figure. 104-16C. If the nerve cannot be located with the stimulator at this level, the classic approach is used. This involves the passage of the needle through a wheal raised at the point of bisection of a line drawn between the mastoid process and the angle of the mandible. The needle is advanced perpendicular to the skin until the styloid process is contacted, the rubber marker is placed 5 mm from the skin, and the needle is withdrawn and reintroduced to pass anterior to the styloid process and advanced until the marker is flush with the skin, at which point paresthesia should be elicited.

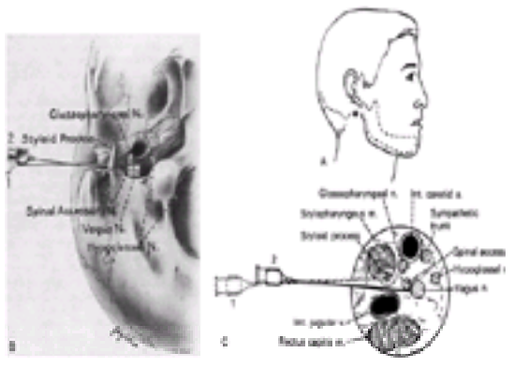

Figure 104-16. Technique of vagus nerve block. **A:** A skin wheal is raised just anterior to the mastoid process and immediately below the external auditory meatus. **B:** The relations of the styloid process and cranial nerves IX, X, XI, and XII. **C:** Cross-sectional enlargement of the area just below the jugular foramen. Note the close proximity of the various nerves, vessels, and the styloid process. A 5-cm, 25-gauge needle is introduced through the wheal and advanced until the styloid process is contacted (**B,C:** 1), whereupon the needle marker is placed 1 cm from the skin. The needle is withdrawn until its bevel is subcutaneous and reintroduced so that it passes posterior to the styloid process until it is flush with the skin (**C:** 2). A volume of 2 to 4 mL of local anesthetic solution is injected, which is likely to block not only the vagus but also the ninth, eleventh, and twelfth cranial nerves because of their close proximity. Neurolytic block of the vagus nerve is not done at this level.

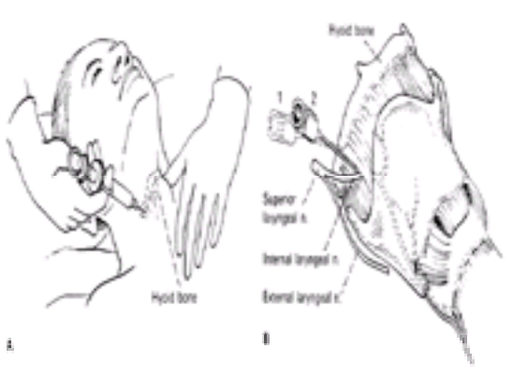

Figure 104-17. Technique of blocking the internal branch of the superior laryngeal nerve. **A:** After identifying the great cornu of the hyoid bone on the side to be blocked (facilitated by exerting pressure on the opposite side of the bone to render the great cornu more prominent), a wheal is raised in the skin overlying the tip of the cornu. A 5-cm, 25-gauge needle is inserted through the wheal and advanced perpendicularly (1) to the skin until the hyoid bone is contacted. **B:** The needle is withdrawn (2) and redirected inferiorly and slightly medially until its bevel lies midway between the inferior border of the hyoid bone and the superior border of the thyroid cartilage, about 1 cm anterior to the lateral thyrohyoid ligament, where the nerve is usually contacted. Injection of 2 mL of local anesthetic produces analgesia of the laryngeal inlet down to the level of the vocal cords. Injection of a neurolytic agent (e.g., 0.5 mL alcohol) should be done only when the nerve is contacted.

Complications. Glossopharyngeal block causes dysphagia from paralysis of the pharyngeal muscle, whereas block of the vagus causes paralysis of the ipsilateral vocal cord with impairment of phonation, and block of vagal fibers to the heart produces tachycardia. If the block is done below the jugular foramen, it is likely to involve the spinal accessory and hypoglossal nerves. In this case, the patient develops paralysis of the trapezius muscles and of half of the tongue on the same side as the block. Furthermore, use of excessive amounts of neurolytic solution can cause sloughing and fibrosis in surrounding tissues, particularly the carotid artery and internal jugular vein, but this is usually a result of improper technique.

Neuraxial Neurolytic Blocks

Injection of a neurolytic agent into the subarachnoid, extradural, or subdural space is one of the most effective methods of relieving severe intractable pain caused by advanced or terminal cancer. The use of these techniques for chronic nonmalignant pain is to be discouraged except in special circumstances that are considered in this section.

Agents that have been used for this purpose include ethyl alcohol, phenol in glycerin, chlorocresol in glycerin, aqueous phenol, hypertonic saline solution, and ammonium compounds. Most of this section discusses basic considerations, including indications, techniques, results, and complications of the use of subarachnoid alcohol and subarachnoid phenol in glycerin. Extradural neural blockade and subdural neural blockade are also considered briefly.

Subarachnoid Neurolytic Block

Basis for Application. The bases for the injection of a neurolytic agent into the subarachnoid space to relieve severe pain include the following

- Most nociceptive impulses from the skin, subcutaneous tissue, deep somatic structures, and viscera pass to the spinal cord through the posterior roots and their rootlets.
- By proper positioning of the patient, hypobaric ethanol or hyperbaric phenol in glycerin can be made to diffuse predominantly to the posterior rootlets involved in the transmission of nociceptive information.
- On contact with the rootlets, neurolytic agents destroy axons (wallerian degeneration) of the rootlets, extending from the dorsal root ganglion to their attachments to the spinal cord. With alcohol, the dorsal root ganglion and dorsal root entry zone may also be involved.
- By using appropriate technique, the solution can be made to block as many segments as are involved in the transmission of pain information. Thus, with this method, it is possible to produce a predominantly posterior chemical rhizotomy to relieve pain for weeks, months, and even for a year or more.
- Because cell bodies may not be affected, regeneration can occur over varying periods, depending on the degree of destruction caused by the neurolytic agent.

Indications and Advantages. In properly selected patients, subarachnoid rhizotomy is an effective method for controlling severe intractable pain located below the head. Dogliotti (64), when first describing the technique, advocated the use of subarachnoid alcohol not only for the relief of cancer pain but also for severe nonmalignant pain caused by other pathologic processes. The procedure has been used mostly for the management of cancer pain in the trunk. The technique has also been used for the relief of pain in the neck, upper limbs, pelvis, and lower limbs, but in such patients it is associated with varying degrees of complications (see below). Subarachnoid neurolysis has been used also for managing patients with spasticity.

Intrathecal neurolysis is relatively simple to carry out. It is not associated with much pain and causes few serious complications. It can be carried out in patients in poor physical condition and in the elderly. Because it involves only a brief stay in the hospital, it can be made available to a relatively large number of patients and requires no special, costly, or highly sophisticated equipment or facilities. Subarachnoid neurolytic injection can be repeated or extended if the pain spreads or persists. In those with terminal cancer, the duration of pain relief is usually sufficient to afford a relatively comfortable end.

In individuals who are in fairly good physical condition and who have an anticipated survival of longer than 4 to 6 months, an open or percutaneous cordotomy can provide a longer and more certain period of pain relief. In patients with a shorter life expectancy and in those who are unable, unfit, or unwilling to undergo surgery, however, intrathecal neurolytic injection offers a good prospect of worthwhile pain relief so that patients can remain ambulatory and on minimal oral analgesic medication. Subarachnoid neurolytic blockade is also valuable for patients with extensive bilateral cancer pain, in whom the risk of performing bilateral cordotomy is significant. The risk can be minimized by performing cordotomy on the side with the most intense and extensive pain, and the subarachnoid neurolytic block can be done on the other side.

Some authorities (65) have stated that, in those with bilateral pain, subarachnoid neurolysis should be used with great caution, if at all. Derrick (66) has advocated

treating bilateral pain by placing patients prone, but to obtain effective relief, it is necessary to use a large volume of neurolytic agent, which consequently increases the risk of complications. It is extremely important to avoid increasing disability through motor weakness, sphincter incompetence, and loss of positional sense, unless it can be justified by the degree of pain relief achieved. Usually ambulatory patients choose not to lose control of bladder function, even if pain relief with the use of an alternative method is inferior. However, in a patient whose bladder is already involved with a tumor and/or has a bladder catheter in place, bladder paresis is not a problem.

Disadvantages and Contraindications. The major disadvantages of intrathecal neurolysis (or of any other neurolytic procedure) are inadequate pain relief and complications. Inadequate pain relief results either from failure of the original injection to interrupt all the nociceptive pathways completely or from spread of the pain beyond the anesthetized region.

The block might initially interrupt the nerves to the painful region and afford complete relief of pain but, in days to months, the neoplasm can spread beyond the confines of the analgesia and cause additional pain. Fortunately, the block can be repeated several times with relatively little inconvenience to the patient, so not all these disadvantages are as significant as they might seem.

A more important disadvantage includes complications that can occur during or following the procedure. Muscle weakness in the limbs and involvement of the rectal and bladder sphincters are the most serious. Relative contraindications to the use of subarachnoid neurolysis include the following:

- Pain that is extensive and poorly localized.
- Intraspinal tumor infiltration, with involvement of the cord or the spinal column at the level of injection.
- Two diagnostic or prognostic procedures with a local anesthetic provide no relief of pain.

Principles of Application. Subarachnoid neurolytic block should be used as part of a comprehensive program, which should include opiates as well as sedatives, antidepressants, and anxiolytic drugs and, most importantly, psychological care for the patient's anxiety, depression, and other serious emotional reactions (Chapter 24, Chapter 25 and Chapter 26). Bonica (2) has stressed that optimal results require adherence to the following steps and principles

- If subarachnoid neurolytic blockade is considered as the method of choice for controlling severe pain, it should be carried out at the earliest possible time.
- Patients should be admitted to the hospital 1 or 2 days before the procedure to allow proper preinjection assessment and management, including one or more diagnostic or prognostic blocks at intervals of 8 to 10 hours between each injection.
- Even with a detailed history and a comprehensive physical and neurologic examination from the previous outpatient consultation, it is necessary to reassess the patient. This includes recording the site, quality, intensity, and other characteristics of the pain using the visual analog scale, descriptors, or other measures discussed in Chapter 12, Chapter 15, and Chapter 16. It is also important to repeat a neurologic examination even if one has been done because it is important to determine whether any changes have occurred during the interval between the preceding and the present examinations.
- The patient, family, and referring physician should be thoroughly informed about the incidence and degree of pain relief expected and about any complications associated with the procedure. It is important to inform patients that the procedure might not relieve all the pain and that it is frequently necessary to repeat the injection once or twice to achieve optimal pain relief. Patients must also be told that the procedure is intended to relieve the pain and not to cure the disease, so that they do not develop a false hope of cure when the pain is eliminated.
- Diagnostic blocks should be carried out at least 12 hours prior to the intrathecal neurolysis. If alcohol is to be used for the neurolysis, hypobaric local anesthetic is used, whereas if phenol in glycerin is to be used, hyperbaric drugs are used. The slow injection of 0.2 mL of local anesthetic using a tuberculin syringe for precise measurement usually blocks the rootlets of one or two segments.
- Generally, premedication should be avoided, because the full cooperation of patients is necessary to decide on immediate localization of the neurolytic solution after it is injected. If patients are unduly apprehensive, an anxiolytic, sedative, or combination should be given in moderate doses that do not impair mentation. Swerdlow (67) has suggested that no opioid analgesic be given for 4 hours before the block to assess the degree of pain and pain relief with the procedure properly. However, circumstances do exist in which the position required for the injection is so painful that modest doses of short-acting opioids should be given intravenously. This not only helps patients but also permits dural puncture during the peak effects of the analgesic and thus decreases any associated discomfort.

Although some difference has been noted between the use of hypobaric alcohol or hyperbaric phenol in glycerin in regard to the degree and extent of nerve damage, the incidence of pain relief and complications is similar with both techniques. Different results occur primarily because of the knowledge, skill, and experience of the anesthesiologist with a particular agent and the technique used. On the other hand, the comparison between the two agents given below does suggest differences in the hands of some who have had extensive experience with both techniques.

Techniques

Subarachnoid Alcohol. The technique of subarachnoid alcohol block is based on the fact that ethyl alcohol is a neurolytic agent that is hypobaric, with a specific gravity of 0.789. Therefore, when it is slowly injected into the CSF, which has a specific gravity of 1.0065 to 1.007, the alcohol diffuses upward and forms a layer on top of the spinal fluid (Fig. 104-18). To achieve the best results it is therefore necessary to have the patient placed on an operating table that can be moved to various positions (Fig. 104-19, Fig. 104-20, Fig. 104-21 and Fig. 104-22). Once the patient is in position and the area has been properly prepared, puncture is carried out with an 8- or 10-cm, 22- or 25-gauge, short-beveled needle using the technique depicted in Figure. 104-23.

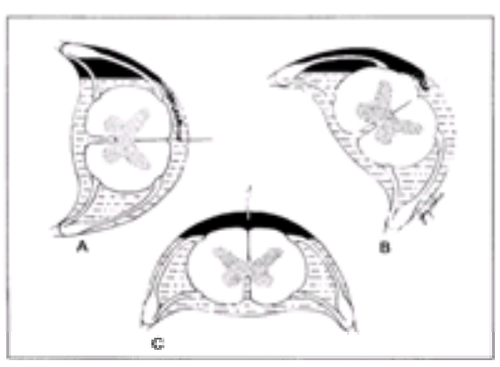

Figure 104-18. Diffusion of alcohol into the subarachnoid space. **A:** With the patient in the lateral position, both the anterior and posterior roots are affected. **B:** The patient is in the lateral-prone position, with the posterior rootlets uppermost. The bevel of the needle is just anterior to the dura- arachnoid. The alcohol, which is hypobaric, is injected in small aliquots so that it diffuses along the surface of the arachnoid membrane and comes in contact predominantly with the posterior rootlets. **C:** With the patient in the prone position, small amounts of alcohol are insufficient to affect the posterior rootlets. The use of larger volumes increases the risk of damaging the posterior columns of the spinal cord and of other complications.

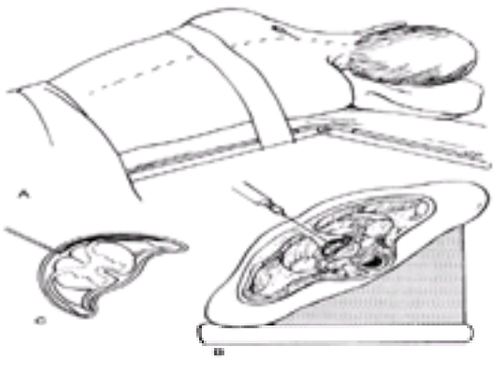

Figure 104-19. Subarachnoid alcohol block for pain in the lower cervical and upper thoracic regions. **A:** Position of the patient, showing the angle of the body with the surface of the table. **B:** Cross-sectional representation of the body showing the angle it makes with the table. **C:** Enlargement of the intrathecal structure showing diffusion of the alcohol to bathe the posterior rootlets and root.

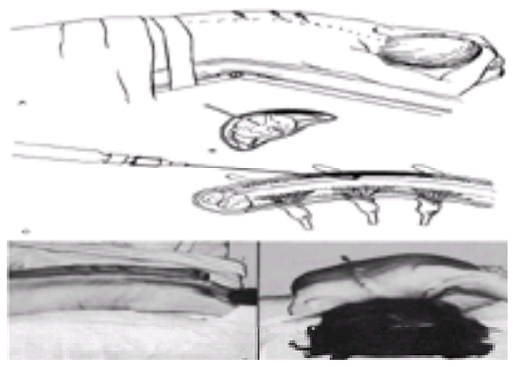

Figure 104-20. Position of a patient for subarachnoid alcohol block in the thoracic region. **A:** One or two pillows are placed under the region to be blocked, and the table is flexed to produce a scoliosis of the spine, with a maximum curve corresponding to that of the nerve rootlets conveying the nociceptive impulses. This places the posterior (sensory) nerve rootlets and roots uppermost, with the head and extremities lower than the point of injection. **B:** Cross section of the thoracic subarachnoid space, showing diffusion of the alcohol uppermost to involve the posterior rootlets. **C:** Schematic of the spinal cord (posterolateral view). The alcohol diffuses to affect the rootlets of two segments by injection of 0.1-mL aliquots over 90 seconds, repeated at 3-minute intervals until 0.4 to 0.5 mL of alcohol has been injected through each needle. **D,E:** Patient in position for block of the left side to relieve chest pain caused by metastasis to and multiple fractures of the ribs. These conditions produced pain during normal respiration and severe pain during deep respiration, causing the patient to hypoventilate markedly. Three needles were used to permit injection of small volumes of solution and thus minimize complications. The first injection on the left side produced good relief from pain, extending from T-4 to T- 10. The procedure was repeated 10 days later on the right side, and the patient derived sufficient pain relief to permit adequate ventilation for 4 weeks. A second series of blocks produced relief until death, 7 weeks after the second series of subarachnoid alcohol therapy, for a total of 11 weeks of pain relief.

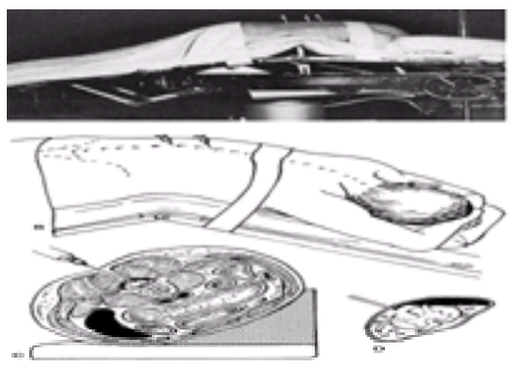

Figure 104-21. **A,B:** Position of the patient for subarachnoid alcohol block of the lower thoracic vertebral levels for the relief of cancer pain in the pelvis and thigh. The gallbladder lift and the pillow over it are used to obviate lumbar lordosis. The table was then moved so that the upper part of the body was lower than the lower trunk. Three needles are in place for the injection of 0.05-mL aliquots of alcohol. **C:** Cross-sectional representation of the body showing the angle it makes with the table. **D:** Diffusion of the alcohol to bathe the posterior rootlets and roots.

Figure 104-22. **A:** Patient in steep Kraske's position for injection of alcohol to destroy the rootlets of S-4, S-5, and the coccygeal nerve to relieve severe perineal pain. The needle puncture is made at the L-5 to S-1 interspace, with the bevel of the needle just anterior to the dura-arachnoid. **B:** Injection of hypobaric alcohol drop by drop causes the alcohol to rise to above the cerebrospinal fluid level and eventually to settle in the lowest part of the sac. **C:** Diffusion of the alcohol is limited to S-4, S-5, and the coccygeal nerves. Properly done, this produces analgesia in the perianal region and posterior part of the perineum. The procedure is especially indicated for patients with severe pain after abdominoperineal resection and subsequent metastasis to the region.

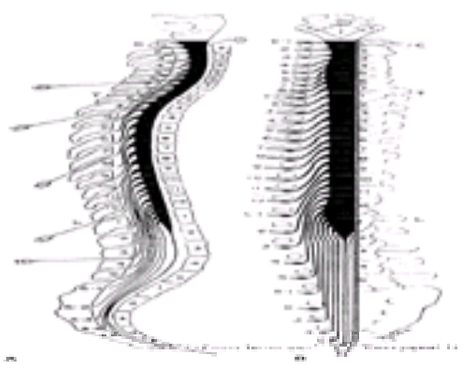

Figure 104-23. Schematic of relationships of the spinal column, spinal cord, spinal nerves, and sites of attachment of their rootlets. **A:** Lateral view showing the angles of the shafts of needles inserted for dural puncture at different vertebral levels. **B:** Posterior view showing relationships of the vertebrae to the spinal cord segments and to the rootlets of various spinal nerves.

The patient is placed in the lateral position on the side opposite the one to be blocked, with one or two pillows under the region to produce a scoliosis with a maximum curve corresponding to that of the nerve rootlets conveying the nociceptive impulses (see Fig. 104-19, Fig. 104-20). The convexity of the curve, which is upward, can

be accentuated by “breaking” the table or by using the kidney lifts (see Fig. 104-21, Fig. 104-22). This places the involved posterior nerve rootlets uppermost, with the head and lower part of the body below the puncture site. In addition, the patient is turned forward 45 degrees so that the posterior rootlets of the nerves of the upper side are horizontal (see Fig. 104-18) and they become bathed with the injected solution, while the anterior roots are (theoretically) less affected. The patient is made as comfortable as possible and is loosely strapped in place to prevent movement from the desired position.

The site of puncture also depends on the segments involved. It is best to deposit the alcohol at the level where the involved rootlets originate from the spinal cord and not at the point of exit of the roots through the intervertebral foramen, as suggested by some. Where the roots attach to the cord are eight to 12 fila radicularia, which provide a greater surface area and are thus much more susceptible to the action of the neurolytic agent than the root or the dorsal root ganglion. To place the bevel of the needle precisely at the desired segment(s), it is necessary to recall that below the third cervical spinal segment the spinal cord levels from which the rootlets of a spinal nerve originate are not at the same levels of the corresponding vertebrae (see Fig. 104-23). This is particularly true for the thoracic, lumbar, and sacral segments. Although a patient might not have the exact correlation between spinal cord segments and vertebrae as that shown, it is sufficiently accurate that it can be followed with a certain degree of assurance. Once the interspaces are decided on, the spinous processes of the vertebrae must be counted carefully, beginning with C-7 downward, and the findings confirmed by counting from the L-5 interspace upward. Confirmation by x-ray is helpful.

Puncture in the lumbar region is usually simple because the interspaces are wide and almost perpendicular to the skin and the subarachnoid space contains the cauda equina, but puncture is much more difficult above the T-11 or T-12 interspace. Between the T-2 and T-8 or T-9 vertebrae, the laminae and spinous processes of the vertebrae are imbricated, making the interspaces narrow. Also, elderly people can have bony spurs on the tips of the adjacent spinous processes and, in some cases, the supraspinous ligament is ossified, making a midline approach impossible. Also, the subarachnoid space in this region is much narrower. Thus, the greatest of care must be exercised in placing the short bevel of the needle in the posterior part of the subarachnoid space just anterior to the dura-arachnoid. Equally important, the injection must be made in the most posterior part of the subarachnoid space so that the alcohol rises along the curvature of the arachnoid to the top of the CSF as a layer and thus bathes only the desired posterior rootlets. Using the technique illustrated in Figure. 104-24, it is possible to puncture the dura-arachnoid safely and obtain CSF and to inject the neurolytic agent without difficulty.

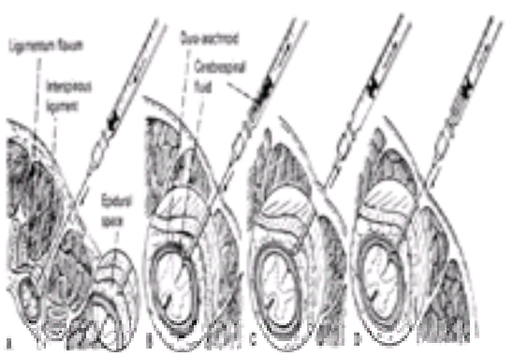

Figure 104-24. Technique of puncture of the dura-arachnoid for subarachnoid injection of neurolytic agents. It is essential to have the bevel of the needle just anterior to the anterior surface of the arachnoid membrane to limit diffusion of the neurolytic agent to the posteromedial part of the subarachnoid space. **A:** The needle is inserted in the usual manner except that, when the needle is felt to pass through the tough ligamentum flavum and into the epidural, the needle is attached to the 2-mL Luer-Lok syringe and advanced 3 to 4 mm within the lumbar epidural space or 2 to 3 mm in the thoracic epidural space and 1 to 2 mm in the cervical epidural space. To detect penetration of the dura-arachnoid promptly, the plunger of the syringe is withdrawn while aspirating to cause a negative pressure at the bevel of the needle. **B:** The needle is advanced slowly until its passage through the dura-arachnoid and its entrance into the arachnoid space are indicated by the usual snap and the almost simultaneous appearance of cerebrospinal fluid (CSF) in the syringe. **C:** The proper position of the bevel of the needle is further ascertained by first reinjecting the CSF into the subarachnoid space and then attempting to aspirate fluid with the empty syringe while the needle is slowly withdrawn, until the free flow of fluid stops. If the needle point has been properly placed, it need only be withdrawn 1 or 2 mm before its point leaves the subarachnoid space. **D:** The needle is advanced again until CSF can be aspirated once more. Because aspiration of fluid is frequently impeded by a veil of arachnoid and in the lumbar region by nerve rootlets, the injection of 0.3 to 0.5 mL of air or saline solution causes the obstructing structure to move away from the bevel. Once the bevel of the needle is just anterior to the anterior surface of the arachnoid, the neurolytic agent can be slowly injected. (Insets represent an enlargement of the region to show details of the structures.)

Once the bevel of the needle is in the subarachnoid space, the alcohol is slowly injected in 0.1-mL aliquots with 60 to 90 seconds between each injection. Before and during injection, the patient should be told to expect a feeling of warmth, burning pain, and tingling that lasts a few seconds and then fades. In addition, the skin of the segments involved manifests hyperemia. After injection of each aliquot, the effect of alcohol in producing hypalgesia should be assessed by the pin scratch technique.

Bonica believed that if more than two segments of the spinal cord are involved in transmitting nociceptive impulses, it is preferable to insert multiple needles and inject small amounts through each needle rather than to inject a large amount of alcohol through one needle to obtain a widespread effect. If, for example, the pain involves the T-5 to T-10 segments, a needle is placed in the T-3, T-5, and T-7 interspaces and 0.2 mL of alcohol is injected through each needle in 0.1-mL aliquots. This drop-by-drop injection technique prevents widespread diffusion of the alcohol and thus increases its concentration to the target rootlets and decreases the risk of complications. This is especially important in blocks to provide relief of pain in the upper limb, where it is essential to minimize the diffusion of the alcohol to the anterior roots.

During and following the injection, the vital signs are noted and recorded. The patient should remain in the same position for 25 to 30 minutes to ensure that the alcohol is completely “fixed” to the nerve tissue and that none is left in the CSF to diffuse to undesired rootlets. Precautions to prevent postdural puncture headache may be followed but the use of small-gauge needles usually is sufficient.

Subarachnoid Phenol. The technique of injecting phenol in glycerin is different from that for subarachnoid alcohol for several reasons. The first is that because the solution is hyperbaric, the patient needs to be placed on the table with the affected rootlets lowermost. The second is that because the solution is viscid, a 20-gauge, short-beveled needle is required, and the injection with the tuberculin syringe requires considerable force. Finally, the onset of definitive blockade can be evaluated with a day of the injection, whereas it requires a longer period with alcohol. The procedure is carried out with the affected side down and the back turned, so that its surface makes a 45-degree angle with the surface of the table (Fig. 104-25 and Fig. 104-26). Swerdlow (67) has used a total dose of phenol in glycerin ranging from 0.5 to 1.0 mL, depending chiefly on the number of segments being blocked, the length of the spine, and the part of the spine being injected. Thus, a smaller volume is injected in the sacral segments and a larger one in the thoracic region.

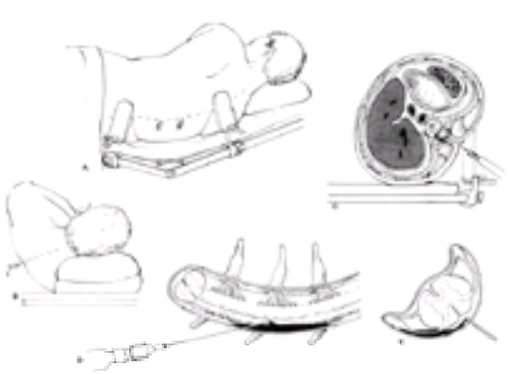

Figure 104-25. Technique of subarachnoid injection of hyperbaric phenol in glycerin. **A:** The dura-arachnoid puncture is made with the patient on the side, with the affected side underneath. **B:** Once cerebrospinal fluid emerges from the hub of the needle, the upper part of the body is displaced posteriorly so that the posterior surface of the back makes an angle of 45 degrees with the superior surface of the table. **C:** Cross-sectional representation of the body in the same position as **B**. This position is maintained with kidney rests or with wide adhesive tape across the patient's body attached to the lateral edges of the table. Schematic longitudinal section

(D) and cross section **(E)** show diffusion of hyperbaric phenol to the posterior (sensory) rootlets that transmit nociceptive information, which are lowermost.

Figure 104-26. Technique of injecting hyperbaric phenol in glycerin to block the rootlets of the lower sacral and coccygeal nerves. **A:** Position of the patient for puncture at the L-5 to S-1 interspace. **B:** Position of the patient for injection of phenol to achieve bilateral block. **C:** Position of the patient for unilateral block of the lower lumbar and sacral roots. **D:** Diffusion of phenol along the left side of the subarachnoid space to contact the rootlets of the S-4, S-5, and coccygeal nerves.

Evaluation of Results and Reinjection. When the block is effective and is localized to the involved segments, the relief of pain is remarkable. Such relief can occur within a few hours or a day after injection of phenol, or it might not be complete until several days after injection of alcohol. Following injection, zones of hypalgesia, analgesia, and hypesthesia occur, frequently with diminution or complete loss of pinprick and temperature sensation. The stretch afferents usually are blocked and certain reflexes are diminished or absent. Sometimes a zone of hyperesthesia extends beyond the zone of analgesia, possibly also with fibrillary muscle twitching and muscle jerking; all of these effects disappear within a few days. Because the maximum effect of alcohol block might not be obvious for several days, assessment must be postponed until 3 to 5 days after injection. If the patient is still having pain after this period, it is advisable to reinject the various segments that remain painful. It has been our experience that the initial injection provides adequate relief in approximately 60% of patients, so that approximately 40% require a second injection and 50% of these require a third injection.

If a patient has been on a strong opioid for over 2 weeks and derives good pain relief with one or more subarachnoid neurolytic injections, tapering of the opioid should be done rather than discontinuing it suddenly to prevent withdrawal symptoms from developing. Such symptoms might cause patients to complain and confuse the issue of whether the subarachnoid neurolytic blockade is completely effective. Often it is necessary to continue to give patients small or moderate doses of opioids to relieve “other pain” that might be present outside of the area of the neurolytic blockade. There has been some concern in the literature that sudden pain relief with neural blockade in those on high-dose opioids can produce respiratory depression and possibly arrest. This has not been the case in our experience with these procedures.

In individuals who have bilateral pain, it is preferable not to attempt to block both sides with one injection, because this would require a large volume of solution and consequently increase the risk of complications. Usually the side that has the most intense pain is blocked and the injection is repeated until good relief is achieved. After an interval of several days, blocks are carried out for the other side.

It has been claimed that subarachnoid alcohol or phenol does not produce the same beneficial effect in the upper thoracic and cervical segments (67,68). Several factors are involved. The dural sheath in which the neurolytic agent “settles” in the cervical segments is relatively short, and the cervical nerve roots and rootlets have a short intrathecal course and therefore have less exposure to the neurolytic agent. Also, the spinal canal is narrow, with a stronger current of CSF that tends to carry the neurolytic agent away from the target nerve rootlets. Bonica obtained good results, however, by inserting a needle through each of the interspinous spaces involved and injecting 0.2 mL of absolute alcohol in 0.05-mL aliquots through each of two or three needles (see Fig. 104-20). Others have used extradural or subdural injection of phenol for this purpose.

Results. Various reports on the results of therapy using subarachnoid neurolytic blockade are difficult to compare because of differences in the assessment of pain and of pain relief, the types and sites of tumor for which the procedure was done, and the sites and doses of alcohol injection. Moreover, many of the reports lack specific data on the incidence, severity, and duration of side effects and complications.

Table 104-3 summarizes some of the most important reports of results with subarachnoid alcohol, and Table 104-4 summarizes some reports of results obtained with phenol in glycerin. *Good* pain relief means the patient obtained complete or almost complete relief of pain for which the procedure(s) was done until the patient's death; *fair* relief means complete relief of pain for less than 1 month or pain relief of 50% or more until the patient's death; and *poor* relief means that the patient experienced partial relief for a few days or no relief at all. In many cases, more than one block was done to achieve the reported results. Based on personal experience, Bonica believed that in those reports in which the incidence of combined good and fair relief was lower than 60%, an improper technique was used. For example, the neurolytic agent was injected into the lumbar region and then change in posture was used in an attempt to direct the neurolytic agent to the affected segments in the mid- or high thoracic area. As Bonica (2) emphasized, this practice not only produces inadequate pain relief but also results in an unacceptably high complication rate.

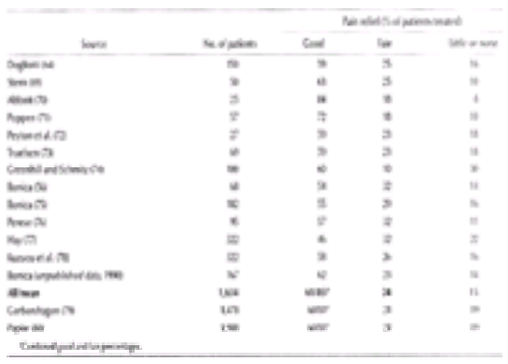

TABLE 104-3. Comparison of results with subarachnoid alcohol block for the relief of cancer pain

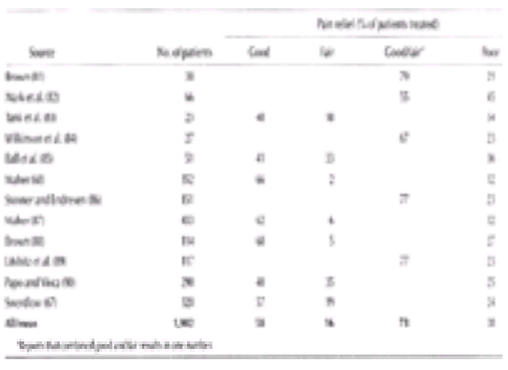

TABLE 104-4. Comparison of results with intrathecal phenol in glycerin or iophendylate for cancer pain

In 1951, Bonica (56) presented the first report analyzing the results obtained in 194 patients with cancer pain who were treated with various neurolytic techniques, including 68 patients who received 107 subarachnoid blocks with alcohol. As noted in Table 104-3, 37 patients (54%) obtained complete or almost complete relief of pain, which permitted the gradual reduction in dosage of strong opioids in those who had received them. Another 22 patients (32%) had partial relief and were made comfortable with moderate doses of opioids and adjuvants (usually less than half the amount they had been receiving at the time of the block). Despite one or even two reinjections, nine patients (14%) derived only transient relief of pain and required strong opioids.

Seven years later, in 1958, Bonica published a summary (75) of the results obtained in an additional 114 patients, which was added to the results of the first group and shown as a second series in Table 104-3. Although the results regarding pain relief were similar, those in the second group experienced a lower incidence of complications (Table 104-5), because the earlier experience (when one needle was used to inject 1.0 to 1.5 mL of alcohol to block several segments) prompted him to adopt the multiple-needle technique and to inject small volumes of alcohol as explained above. In the ensuing 19 years, Bonica carried out subarachnoid block with alcohol in an additional 167 patients, who received a total of 228 blocks (see Table 104-3) (*unpublished data*). As noted in Table 104-3 and Table 104-5, the analgesia improved slightly, with a further decrease in complications, reflecting a more conservative attitude and a more careful selection of patients.

TABLE 104-5. Complications with the use of subarachnoid neurolytic block for cancer pain

It is generally acknowledged that, in the hands of those who have experience extensive enough with one or the other agent to be considered an “expert,” the results of therapy with subarachnoid alcohol are similar to those obtained with phenol in glycerin. Pain relief appears to be better and to last longer with alcohol, however, than with phenol. On the other hand, Maher (68) stated that phenol is easier to handle, spares “non–pain-conducting fibers,” and yields better results than alcohol. The latter two advantages are disputed by the histologic evidence previously cited in Basic Information, earlier in this chapter, and also by the clinical experience of those who have used both agents. Brown (91) stated that “alcohol has proved to be easier to control and to achieve better results than when phenol solutions are employed.”

Important causes of failure with the use of subarachnoid neurolytic agents include intraspinal tumor infiltration, which prevents the neurolytic agent from coming into contact with the rootlets. Therefore, prior to carrying out the procedure, it is essential to rule out this possibility by appropriate radiographic tests, such as computed tomography (CT) or magnetic resonance imaging, especially in patients who have tumors that are likely to spread or metastasize to the intraspinal canal. If such screening has not been done and the first injection effect, one should consider this possibility. Prior radiation therapy to the spinal canal can also interfere. It is also important to consider assessing patients for other sites or causes of pain, such as physical disabilities. A frequent cause of “failure” is the extension of the lesion, with consequent pain beyond the area in which block for the previous pain remains effective. In such a case it would be necessary either to carry out an additional subarachnoid block or another neurolytic technique. Consideration should also be given to cordotomy in such a patient (Chapter 106).

Complications. Complications can occur even when a flawless technique is used, but the incidence of serious complications can be minimized by proper selection, preparation, and positioning of patients and by the use of precise technique. Some complications are transient; others occur rarely and only with a break in aseptic technique, whereas still others can occur as a result of diffusion of the neurolytic agent to the anterior roots in the lower cervical and T-1 regions or to the lumbosacral region. Headache can occur following the block, but this is transitory and responds well to conservative therapy. Aseptic meningitis, caused by irritation by the neurolytic agent, occurs but is rare. Septic meningitis can also occur, but only a few cases have been reported (60).

Paresis or paralysis of muscles occurs if the anterior rootlets are sufficiently involved in the pathophysiologic process to interrupt motor function. Involvement of the anterior roots by the neurolytic agent in the three middle sacral segments interrupts the parasympathetic fibers to the bladder, the rectum, and lower colon, which could cause loss of sphincteric function, urinary retention, and bowel incontinence. Annoying and sometimes distressing side effects of block of the posterior rootlets include loss of proprioception and touch and dysesthesias. Complication rates reported by various authors are presented in Table 104-5. Fortunately, most of these complications are transient. A case of fatal meningitis was believed to have been caused by meningeal irritation by silver nitrate incorporated into the phenol solution (60). A few patients with postblock paraplegia were subsequently found to have vertebral metastasis (71).

Muscle weakness in the upper or lower limbs occurs as a result of involvement of the anterior roots, the risk being much higher in the lower limbs because of the proximity of the anterior and posterior roots in the lumbosacral enlargement of the cord (at the T-10 and L-1 vertebral levels). Below the L-1 level, injection is made into the cauda equina, where the anterior and posterior rootlets are not as well separated as above these levels. Except in patients who have severe respiratory , paresis of the intercostal muscles, of segments of the abdominal muscles on one side, or even of a few segments bilaterally, do not significantly affect ventilation.

Bladder dysfunction occurs most frequently with injection below the T-10 interspace. Although some have reported that injection to relieve perineal pain at the L-5 interspace is associated with an incidence of bladder paresis ranging from 25% to 60% (92), use of the technique shown in Figure. 104-22 is associated with an incidence lower than this.

Gerbershagen (79) reviewed reports that provided data on the duration of 303 complications (Table 104-6) and obtained the following results: 28% disappeared within 3 days, 23% disappeared within 1 week, 21% disappeared within 1 month, 9% disappeared within 4 months, and 18% lasted longer than 4 months. Table 104-7 presents an analysis by Swerdlow (67) of the incidence of complications in 300 patients managed with 5% or 7% phenol in glycerin, 2% or 2.5% chlorocresol in glycerin, or a combination of these.

Complication	No. of patients with complications (%)		
	Transient	Permanent	Total

TABLE 104-7. Complications lasting longer than 7 days

Epidural Neurolytic Blockade

The theoretical advantages of the use of epidural injection over intrathecal neurolysis include less risk of meningeal irritation, less spread of the solution to cranial nerves, and supposedly less risk of bladder and rectal involvement. Swerdlow (67) used epidural neurolytics in noncancer intractable pain, and a fair degree of success was achieved with the injection of phenol in glycerin. Madrid (93) used 7.5% phenol in glycerin and noted good pain relief in a high percentage of patients. Others have used aqueous phenol injected through an epidural catheter. Raftery (94) reported using an epidural catheter and used intermittent doses of 0.5 to 1.0 mL of 6% aqueous phenol, which produced good pain relief in 65% of 27 patients. While staff members of the Clinical Pain Service at the University of Washington, Colpitts and associates (95) used epidural phenol on patients with cancer-related pain and obtained prolonged pain relief in slightly more than 80% of patients. Racz and coworkers (96) have used phenol in saline for the same purpose. More recently, Korevaar (97) reported favorable results using transcatheter thoracic epidural neurolysis achieved with ethyl alcohol.

Most authors use phenol in glycerin, but some use an aqueous solution of phenol. The technique of epidural puncture is described in detail in Chapter 102. A 22-gauge needle can be used for a single injection of aqueous phenol, but it is necessary to use a 20-gauge spinal needle for injection of phenol in glycerin. Once the bevel of the needle is in the epidural space, the patient is tilted backward into a 45-degree angle (as for subarachnoid phenol injection) and a test dose of 0.2 mL of phenol is injected. After ascertaining that the solution has not been deposited into the subarachnoid space, approximately 2 mL of 7% phenol in glycerin or of 8% to 10% aqueous phenol is injected for each nerve root to be blocked. Swerdlow (67) has recommended that in the cervical region the dose should be 1.5 mL per dermatome. After injection the patient remains in the tilted position for approximately 40 minutes. With successful blocks, pain disappears in 10 to 15 minutes.

Swerdlow (67) reported relief of pain for as long as 9 months, but Madrid (93), using 7.5% phenol in glycerin for pain in the neck, noted that pain relief lasted only a few days. Some clinicians have used an epidural catheter to allow repeated injections of phenol in glycerin into the cervical region. The epidural puncture is made at the C-7 to T-1 interspace and the catheter is advanced 4 to 5 cm.

Placement of the catheter can be checked by injection of a small amount of contrast medium, which should produce a rather diffuse outline immediately anterior to the posterior wall of the pierced canal. Catheter placement can also be checked by injection of small doses of a local anesthetic, such as 2 mL of 1% lidocaine at 15- to 20-minute intervals, and this should produce a narrow band of segmental sensory loss. If a local anesthetic is used for this purpose, it is essential to allow the anesthetic to dissipate and to wait 2 hours more after its disappearance before the neurolytic agent is injected.

In a series of 18 patients with cancer pain treated with this technique (98), six of 11 patients (54%) with metastatic cancer and six of seven patients (86%) with primary cancer derived good relief. In patients with primary cancer, pain relief lasted less than a month in one patient (17%), 1 to 3 months in three patients (50%), 3 to 6 months in one patient (17%), and longer than 6 months in one patient (17%). In those with metastatic cancer, the figures were 3 months (50%), 2 months (33%), 0 (0%), and 1 month (17%). Among those patients whose pain returned within 1 month, a second series of injections increased the duration of relief by 1 to 3 months.

In treating patients with cancer-related pain, Colpitts and associates (95) first stabilized them on a narcotic-containing “pain cocktail” (Chapter 84). Once patients were stabilized, the amount of opioid was gradually reduced until patients began to experience moderate pain. The epidural catheter was inserted and placed with its tip in the center of the band of pain and 3 to 4 mL of 1% to 2% lidocaine was injected to ascertain the proper position of the catheter and the volume of phenol required to relieve the pain. They then injected the same volume of phenol, and patients were observed for 24 hours. Patients were followed in a Veterans Administration hospital, where they were either inpatients or outpatients who returned for follow-up every 2 weeks. Pain relief lasted until all the patients who had initial relief died, which varied from 3 weeks to 4.5 months.

Korevaar (97) has recently reported on the use of a technique similar to that reported by Raftery (94) for phenol. He used “transcatheter” thoracic epidural neurolysis with alcohol in 36 consecutive inpatients with intractable somatic or visceral pain of malignant and nonmalignant origin that was referable to the cervical or thoracic nerve roots. These included 14 patients with cancer of the pancreas, 13 with metastatic cancer in the abdominal or thoracic region, four with chronic pancreatitis, two with postherpetic neuralgia (in the T-4 and T-5 regions), and three with diffuse abdominal pain of unknown origin.

The epidural catheter was introduced so that its tip was in the center of the dermatomal pain distribution (97). Five to 7 mL of 0.25% bupivacaine was injected in 2-mL increments to determine correct catheter placement. Patients were in a 30-degree, head-up supine position for bilateral visceral or somatic pain or were positioned with the affected side up in a lateral position for unilateral somatic pain. Once the efficacy of the local anesthetic block had been ascertained, Korevaar (97) injected increments of 0.2 mL of absolute alcohol until 3 to 5 mL of neurolytic agent had been injected over a 20- to 30-minute period.

After completion of the alcohol injections, the catheter was flushed with 0.25 mL of the 0.25% bupivacaine solution and capped (97). Patients were returned to their hospital rooms 30 minutes after completion of the injections and followed for pain relief. The second and third alcohol injections were done on a daily basis unless patients experienced 100% pain relief that persisted over a 24-hour period and decreased their opioid use by at least 25%. On the second and third days, 3 to 5 mL of ethyl alcohol was slowly injected 10 minutes after the catheter was tested using 2 mL of 0.5% bupivacaine.

Patients were monitored closely; 89% of patients reported 70% pain relief or greater, supported by a decrease in opioid dose of 25% or more; this was defined as successful treatment (97). All 27 patients who had pancreatic and metastatic cancer had immediate pain relief that continued for the first week, as compared to pain relief in 55% of patients with nonmalignant chronic pain. The overall duration of pain relief for patients who had been successfully treated ranged from 2 weeks to 7 months (mean, 3.3 months), reflecting the large number of patients who died of their underlying illness during the period of study. Twelve patients with cancer died within 4 months after treatment. Twenty patients who died during the study reported continued relief of pain until death, and 12 patients survived long enough to have recurrence of pain. The duration of pain relief in these patients extended from 3 weeks to 7.25 months (mean, 4.4 months). Although a few complications such as hypotension, vomiting, pain on injection, and pain at the site of the catheter during the first 3 days were noted, no long-term serious complications occurred. Korevaar's results (97) are impressive and suggest that the technique should be given a more extensive trial.

Subdural Neurolysis

In 1960, Maher (68) introduced the use of the subdural injection of phenol in glycerin for the cervical and upper thoracic regions as an alternative to subarachnoid neurolysis. Since then, the technique has been used by only a few others and the results have not been impressive.

Neurolytic Sympathetic Blockade

Chapter 102 reviews indications for sympathetic blocks with local anesthetics for various painful conditions in the upper limb, visceral pain, severe pain caused by disease of the thoracic or abdominal viscera, and other painful conditions in the lower limbs. This section describes the injection of neurolytic agents to cause destruction and consequent prolonged interruption of sympathetic pathways in various parts of the body, including indications, techniques, results, and complications of neurolytic block of the thoracic chain, celiac plexus, splanchnic nerves, and lumbar sympathetic chain.

To obtain optimal results with these procedures it is essential to adhere to the basic principles of application, including preliminary preparation and various other considerations (Chapter 102). Because the use of neurolytic agents can be associated with serious and unwanted side effects and complications, neurolytic blocks of this part of the nervous system must be preceded by two or more diagnostic or prognostic blocks using local anesthetics with different durations of action. These give information on the diagnosis and pathophysiologic mechanism(s) underlying the condition and help to ascertain whether prolonged interruption is going to be beneficial.

Block of Thoracic Sympathetic Chain

Indications

Block of Sympathetics to the Upper Limb. Block of the sympathetics to the upper limb achieved by the neurolytic blockade of T-2 and T-3 and the interganglionic part of the chain is indicated in the management of complex regional pain syndromes (CRPS) types I and II, postamputation pain syndromes, and other painful neuropathic conditions discussed in detail elsewhere in this book. Block of the same structures is indicated for certain chronic occlusive vascular diseases affecting the upper limb in individuals in whom preliminary blocks with local anesthetic have indicated that prolonged interruption would prove beneficial.

There are anatomic and physiologic bases for limiting neurolytic block to the T-2 and T-3 ganglia and the interganglionic chain to produce prolonged interruption of the sympathetics of the upper limb. The peripheral portion of the sympathetic supply to the upper limb is composed of preganglionic neurons whose cell bodies are in the intermediolateral horn of the spinal cord at the T-2 to T-8 or T-9 levels, while their axons pass along the anterior root of the spinal nerves, the white rami communicantes, and pass to the lateral sympathetic chain. Here they ascend cephalad and synapse with the postganglionic fibers, primarily in T-2 but also in T- 3 and in the stellate and middle cervical ganglia. By blocking T-2 and T-3, which are considered to be “key” synaptic stations, all the sympathetic nerves destined for the upper limb can be interrupted.

Sympathetic block of the upper limb is usually achieved by anterior paratracheal block of the cervicothoracic sympathetic chain (see Chapter 102 and Fig. 102-51). With this technique, however, injection of a neurolytic agent carries a high risk of producing a prolonged Horner's syndrome, prolonged block of the recurrent laryngeal nerve with impairment of phonation, unintentional block of the brachial plexus, or accidental injection of the neurolytic agent into the vertebral artery. Moreover, a small number of patients apparently have fascial barriers that prevent the caudad diffusion of the neurolytic agent to involve the T-3 and sometimes even the T-2 ganglia. In the latter case, this would result in an incomplete sympathetic denervation of the upper limb in those patients who have the anomalous sympathetic pathway known as *Kuntz's nerve*, which bypasses the stellate ganglion. The posterior approach to the T-2 and T-3 sympathetic ganglia and the interganglionic chain obviates this problem and is less likely to produce the other complications of paratracheal block.

Block of Sympathetics to the Chest. Neurolytic block of the sympathetic chain at the levels of the T-1 to T-5 ganglia is used for the relief of pain in the rare patient with severe intractable cardiac pain that is not relieved by medical therapy and is not amenable to aortocoronary bypass surgery or to percutaneous intramural angioplasty. Neurolytic block of the sympathetic chain from T-2 to T-8 using multiple needles can be used in those with severe intractable pain caused by carcinoma of the esophagus or by some other chronic pathologic process of the upper two-thirds of the esophagus. If the lesion is in the lower part of the esophagus, it is necessary to block the splanchnic nerves, which contribute an important sensory nerve supply to the lower third of the intrathoracic part and to the abdominal portion of the esophagus.

In all these cases, neurolytic block is intended to destroy the sensory fibers that convey nociceptive impulses from the thoracic viscera. Interruption of sympathetic efferent fibers can also help to relieve pain by eliminating any arterial vasospasm. Finally, neurolytic block of the sympathetic chain extending from T-2 to T-6 is indicated in patients who have chronic intractable pain caused by aortic aneurysm and who are not suitable for neuroablative surgery. White and Sweet (55) used this technique in a number of patients with large and intensely painful aneurysms of the aortic arch after a preliminary block with procaine produced complete pain relief.

Block of Sympathetics to the Abdominal Viscera. Neurolytic block of the lower two-thirds of the thoracic sympathetic chain is indicated in patients with severe intractable pain produced by cancer of one or more of the viscera. It may be considered cautiously in chronic pancreatitis or in some other chronic disease of one or more of the abdominal viscera that is not amenable to other therapy. Block of individual segments that supply each of the various viscera with a local anesthetic can be used as a diagnostic procedure. However, in most patients with severe intractable persistent pain, it is preferable to carry out a neurolytic block of the celiac plexus or of the three thoracic splanchnic nerves (see below).

Technical Considerations. The anatomy of the thoracic sympathetic trunk is discussed in detail in Chapter 102 and depicted in Figure 102-27 as well as in Figure 104-27 and Figure 104-28 in this chapter.

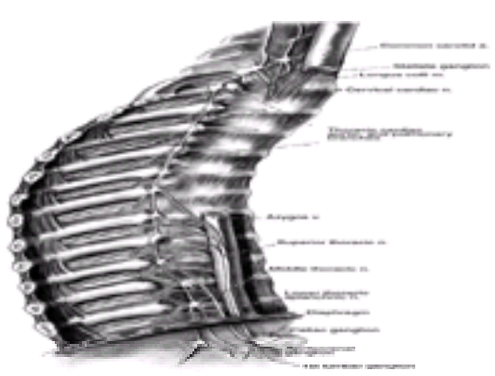

Figure 104-27. Anatomy of the right thoracic sympathetic chain showing the precise relation of the ganglia to the vertebrae and ribs at various levels, as well as the major branches given off by the chain. The T-2 sympathetic ganglion is located anterior to the medial portion of the neck of the rib, the T-3 to T-6 ganglia are located in front of the head of the corresponding ribs, the T-7 to T-10 ganglia are located anterior to the radiate ligaments of the costovertebral joints, and the T-11 to T-12 ganglia are more anteriorly placed than the rest and are on the lateral surface of the vertebral bodies. In the upper three or four segments, the lower half of each ganglion is located in front of the upper portion of the neck or head of the rib. In the lower thoracic segments, the ganglia are located in front of the head of the ribs, extending their total length. This is clinically significant because the point of the needle cannot be placed in contact with the lower ganglia. In the upper three segments, the intercostal vessels are immediately posterior to part of the ganglia, whereas in the lower segments, where the ganglia rest wholly on the periosteum of the neck or head of the ribs, these vessels are superior to the ganglia. The somatic spinal nerves pass posterior and cephalad to the interganglionic chain. Moreover, the pleura is immediately in front of and closely related to the ganglia, being separated from the ganglia by the thin endothoracic fascia.

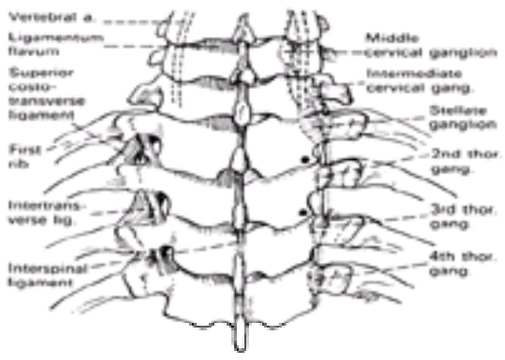

Figure 104-28. Posterior view of the lower cervical and upper thoracic vertebrae showing the relationships of the sympathetic chain to the vertebra and vertebral artery. The supraspinous ligament has been removed to more easily identify the posterior tips of the spinal processes. The sympathetic ganglia (on the right, depicted by *stippled areas* surrounded by *dashed lines*) are lying in front of the necks of the ribs. The black solid circles indicate the site of contacting the lower and lateral part of the lamina with the bevel of needles inserted by the paralaminar technique (see Fig. 104-29). Injection at the level of the T-2 and T-3 ganglia causes block of this portion of the chain and consequently completes interruption of the sympathetic supply to the upper limbs, while block of T-1 to T-5 denervates the heart. (Modified from Bonica JJ. *Sympathetic nerve blocks for pain diagnosis and therapy.* New York: Breon Laboratories, 1981.)

To obviate the problem of pneumothorax, commonly seen with the classical approach, Bonica developed the paralaminar technique (Fig. 104-29). For injection of the neurolytic solution, an 8- or 10-cm, 22-gauge, short-beveled needle is used with a 2-mL glass syringe that has been tested to ensure that its wet plunger fits properly so that it can be advanced and withdrawn without any resistance. This is crucial to the second step of determining passage of the bevel of the needle through the superior costotransverse ligament. For verification of the level of the injection, it is highly desirable to use an image intensifier and to know the relationship between the posterior lower end (tip) of the spinous process of one vertebra and the lamina to be contacted at the cross-sectional plane (Fig. 104-30).

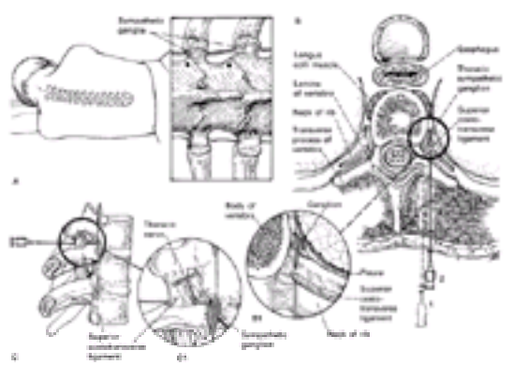

Figure 104-29. Paralaminar technique of blocking the thoracic sympathetic ganglia and interganglionic part of the chain. **A:** Position of the patient on the side, with the spine flexed. Inset: Close-up of the T-5 and T-6 vertebrae shows the relation of the sympathetic ganglia anterior to the necks of the ribs and the sites of contact of the bevel of the needles with the laminae of the vertebrae. At this level, the site of puncture is at the same cross-sectional plane as the posterior end of the spinous processes of one vertebra above (T-4 and T-5). Skin wheals are made 2 cm lateral to the midline of the back with a 5-cm, 25-gauge needle, which is then inserted and directed anteriorly. The dilute local anesthetic solution is liberally injected into the subcutaneous tissue and muscle and onto the periosteum of the ipsilateral laminae to produce a tract of analgesia. **B:** Cross-sectional view at the level of the T- 5 vertebra showing the two steps in placing the point of the needle. After a few minutes, an 8- or 10-cm, 22-gauge, short-beveled needle adapted to a 2- mL glass syringe with a Luer-Lok and containing saline is inserted and advanced until the lamina is again identified (needle 1). At this point, a depth marker is placed 1.5 cm from the skin, the needle is withdrawn until its point is in the subcutaneous tissue, and the skin is moved 0.5 cm laterally. The needle is then advanced in the same sagittal plane parallel to the first insertion (needle 2). When advanced to the same depth as the lamina, its point contacts either the lateral edge of the lamina or the superior costotransverse ligament, which is lateral to the lateral edge of the lamina and just above the transverse process of the vertebra below. Here the needle encounters a structure that is much less resistant than bone but more resistant than muscle—the superior costotransverse ligament—as shown in **C**, which is a schematic lateromedial view of the vertebrae, the proximal parts of the ribs, and the superior costotransverse ligament. Once the point of the needle has engaged the ligament, the needle is advanced slowly (2 mm at a time) while exerting continuous unremitting pressure on the plunger of the syringe. A sudden loss of resistance indicates that the bevel of the needle has traversed the ligament and is wholly anterior to the anterior surface of the ligament. The needle is then advanced another 7 to 10 mm so that its bevel is in the same coronal plane as the anterior surface of the neck or head of the rib, as shown in position 2 **(B)** and in inset **B1**, which is an enlargement of the circled area in B and shows the point of the needle in contact with the upper pole of the sympathetic ganglion. **C1:** Enlargement of the circled area in C showing the needle through the ligament. Its point is in contact with the upper pole of the ganglion. Once the needle is considered to be in a proper position, 1 mL of saline solution is injected to dislodge any tissue in the needle. Aspiration is then attempted in two planes to ensure that the point of the needle is not in a vessel or within a prolonged dura-arachnoid cuff. After a negative aspiration, a test dose of 1 mL of 0.5% bupivacaine anesthetic solution is injected. If no sign of subarachnoid block or other complications is evident, 2 to 3 mL of 0.25% bupivacaine or 2 to 3 mL of a neurolytic agent is injected. This volume is usually sufficient to block one segment (a ganglion and its upper interganglionic fibers). The procedure is repeated at subsequent lower levels.

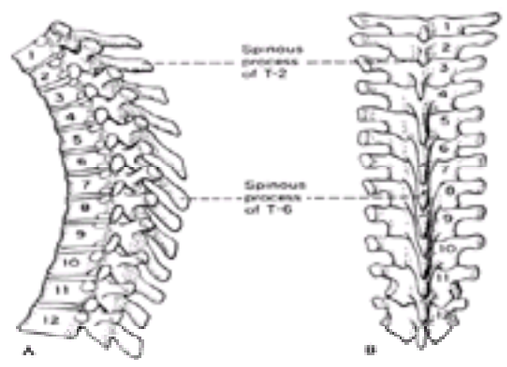

Figure 104-30. Posterior view **(A)** and lateral view **(B)** to show relationship at the cross-sectional level of the lower tip of the spinous processes and laminae. The lower tip of the spinous process of the T-1 vertebra is at the same cross-sectional level as the lamina of the T-2 vertebra. Because of the greater imbrication of the spinous processes in the middle thoracic region, the spinous process of the T-6 vertebra is at the same cross-sectional level as the upper portion of the lamina of T-8 (i.e., two segments below). In the lower portion of the thoracic vertebra, much less imbrication is present and, consequently, the spinous process of T-11 is at the same cross-sectional level as the lamina of T-12 and the spinous process of T-12 is at the same cross-sectional level as the middle of the lamina of L-1.

The needle is inserted only 2 cm lateral to the spinous process, and its contact is made in the lower portion of the lateral part of the lamina. The second insertion places the bevel of the needle just above the upper surface of the rib below and at some distance below and anterior to the thoracic somatic nerve (see Fig. 104-29C, Fig. 104-29C1). This placement decreases the risk of involving the somatic nerve with the neurolytic agent. Compare Figure. 104-30 with Figure 102-22, which shows the technique of blocking the thoracic somatic nerve. For somatic nerve block, the needle is inserted more cephalad to contact the upper portion of the lateral part of the lamina and then is made to pass through the upper portion of the superior costotransverse ligament below the transverse process of the vertebra above.

If the technique is carried out by someone who has a thorough knowledge of the anatomy, is skilled in regional analgesia, and proceeds slowly and cautiously, the

risk of contacting the somatic spinal nerve and puncturing the dura is lower than with the use of the classic posterior approach. Even the approach described here, however, requires patience and skill to avoid advancing the needle too far anteriorly, which could pierce the lung.

Complications. Possible complications of the paralaminar technique for blocking the thoracic sympathetic chain include puncture of the lung from placing the needle too far anteriorly, producing pneumothorax; puncture of the intercostal vein or artery; or contact with the thoracic somatic nerve if the bevel of the needle is placed higher than recommended. If aspiration is not carried out in two planes, the neurolytic agent might be injected into the vessel, with consequent necrosis, or into the subarachnoid space of a prolonged dural cuff, with consequent diffusion to the subarachnoid space, prolonged block of the somatic nerve, or both. All of these complications can be prevented with proper technique.

Neurolytic Block of the Celiac Plexus

Indications. Neurolytic block of the celiac plexus is useful in relieving severe intractable pain caused by cancer or chronic visceral disease. In addition to blocking all the nociceptive (pain) pathways that supply the viscera in the upper abdomen, the procedure relieves visceral vasospasm and other pathophysiologic processes caused by abnormal reflexes consequent to persistent noxious stimulation by the disease process. Because the celiac plexus contains vagal afferents and efferents, block of this structure interrupts the sensory fibers that transmit nonnociceptive information and the parasympathetic outflow to the abdominal viscera. Prior to neurolytic block of the celiac plexus, it is essential to carry out at least one and preferably two diagnostic or prognostic blocks with a local anesthetic. Doing so enables prediction of the effects of the neurolytic blockade. The neurolytic agent diffuses to a lesser extent than the local anesthetic, so it is essential to carry out the preliminary block with a volume of local anesthetic that is about two-thirds the volume of neurolytic agent to be injected.

Anatomic Basis The neuroanatomic basis for block of the celiac plexus is summarized and illustrated in Figure. 104-31. More than 60 years ago, Hovelacque (99) emphasized that, contrary to the classic textbook description, the celiac ganglia vary in number, size, and location; more recently, Ward and associates (100) "rediscovered" this fact. The number of ganglia varies from one to five, and the size of each ranges from 0.5 to nearly 5.0 cm in diameter. Moreover, they are located at a variable distance in the anteroposterior plane from the anterior surface of the L-1 vertebra, which is used as a landmark in blocking the plexus. In addition to understanding the anatomy of the celiac plexus itself, it is also essential to understand the anatomy of the surrounding structures, which might be subjected to trauma by needles, drugs, or both. On the right side, and anterior to the plexus, is the inferior vena cava, and on the left side is the aorta, with the kidneys posterolateral to these vessels. Anteriorly, the plexus is near the posterior surface of the pancreas.

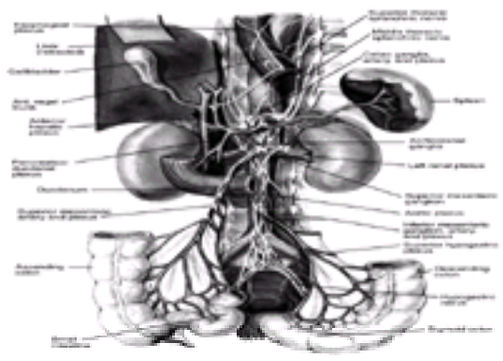

Figure 104-31. Anatomy of the celiac plexus and subsidiary plexuses. The celiac plexus occupies an area 3 cm long and 4 cm wide between the two adrenal glands. It is located in the epigastrium just anterior to the crura of the diaphragm around and below the celiac axis and on either side of the midline. It is often subdivided into right and left portions and consists of a number of prevertebral ganglia and a dense network of autonomic fibers that unite and enmesh these ganglia. The autonomic fibers include sympathetic preganglionic fibers contributed by the thoracic splanchnic nerves, sympathetic postganglionic fibers provided by the lumbar splanchnic nerves (contributed by the lumbar sympathetic chain), and parasympathetic preganglionic fibers contributed by both vagus nerves. Sensory fibers are contributed by the phrenic nerves, the vagus nerves, and the splanchnic nerves, which provide sympathetic afferents. Only the phrenic and sympathetic afferents transmit nociceptive information from the upper abdominal viscera. Although the celiac ganglia are usually depicted as two large masses, semilunar in shape and located on each side of the origin of the celiac axis, their shapes and sizes are actually variable. Note the location of the superior and inferior mesenteric ganglia and plexuses.

Technique The technique of neurolytic celiac plexus block (NCPB) is illustrated in Figure. 104-32. Preparation of patients should include discontinuing antihypertensive agents, which could enhance the hypotensive effect of the block, and anticoagulants, which could produce excessive bleeding. No sedatives or narcotics should be given for the prognostic block, which, if done correctly, should be rather painless. Because the injection of alcohol causes severe pain, sedatives and opioid analgesics can be given parenterally 15 minutes before the block and should not interfere with the results. All patients should have supplemental intravenous fluids in doses of 10 to 15 mL per kg as a bolus at the time of the alcohol block.

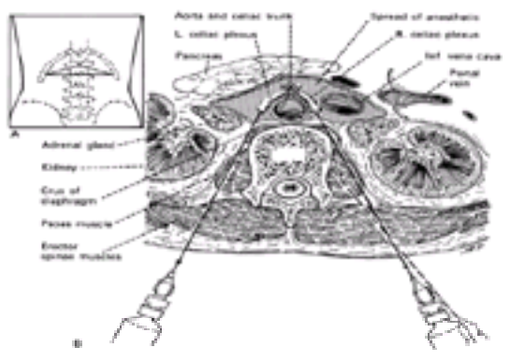

Figure 104-32. Technique of blocking the celiac plexus. The patient is placed prone with a pillow under the abdomen after an intravenous infusion has been started. **A:** The spinous processes of T-12 and L-1 are marked, as are the lower borders of both twelfth ribs, and these are connected to make a flattened isosceles triangle. Skin wheals are raised 6 to 7 cm lateral to the inferior part of the quadrilaterally shaped spinous processes of L-1. **B:** Using a 25- gauge disposable spinal needle, the subcutaneous fascia and muscles are infiltrated with a dilute solution of local anesthetic. Security needles of proper length are selected for injection of the local anesthetic or of a neurolytic agent. Each needle, with a depth marker attached, is inserted through the skin wheal with its bevel facing medially and directed so that its shaft makes an angle of 40 degrees with the midsagittal plane. The first needle should be inserted on the left so that contact with the lateral aspect of the aorta can be ascertained by feeling the transmitted pulsation up the shaft of the needle, which is held firmly. This provides an approximation of how far the right needle needs to be advanced. The needle is then advanced slowly until contact with the lateral surface of L-1 is made, usually at a depth of 8 to 9 cm. If bony contact is made more superficially, it is likely that the needle has contacted the transverse process; if this occurs, the needle must be withdrawn and redirected to advance below the transverse process. Once the needle impinges on the lateral side of the body of the L-1 vertebra, the rubber marker is placed 4 cm from the skin. The needle is withdrawn until its point is in the subcutaneous tissue, the angle is decreased by 30 degrees on the left side, and it is readvanced slowly until the marker is flush with the skin. At this point, the pulsation of the aorta should be felt, indicating that the needle is lateral to the vessel. If bone is encountered before the marker is flush with the skin, the needle is withdrawn and readvanced so that its shaft makes an angle of 25 degrees with the sagittal plane. This permits passage of the needle without further bony contact; it is then advanced until the marker is flush with the skin. The depth is noted, and the right needle is similarly inserted and advanced, except that, on the second insertion, the needle is directed so that its shaft makes an angle of 35 degrees. If bone is contacted, the needle is withdrawn and the angle is decreased to 30 degrees because the aorta is to the left of the midline. Once the needles have been positioned, aspiration is attempted in four quadrants to rule out accidental intravascular or subarachnoid injection. For diagnostic purposes with local anesthetics, 15 mL of 0.5% bupivacaine with epinephrine is injected through each needle. This is usually sufficient to spread and involve the celiac and subsidiary plexuses laterally as far as the adrenal glands. The injection of solution should offer no resistance because it is made into the loose areolar tissue of the retroperitoneal space. An effective block generally relieves abdominal pain within 15 minutes, and the patient manifests orthostatic hypotension. If difficulty is encountered, it is advisable to use an image intensifier or computed tomographic scanning to place the bevels of the needles correctly. A volume of 15 to 20 mL of 50% alcohol is injected through each needle for a neurolytic block.

It is important to use a needle that is of sufficient length—10 cm for thin individuals, 12 cm for average patients, and 15 cm for obese or muscular persons. There is some discussion in the literature: Thompson and Moore (101) preferred a 20-gauge needle, Brown et al. (102) had no preference, and Bonica preferred a 22-gauge needle to a 20 gauge since it was less traumatic.

The neurolytic solution consists of equal parts of absolute alcohol and saline solution or, preferably, 0.75% bupivacaine or 2% lidocaine to lessen the severe alcohol-induced pain. If radiographic control of the spread of the solution is to be done, a mixture containing 25 mL absolute alcohol, 18 mL local anesthetic, and 7 mL of contrast medium should be used.

The needle should pass through the crura of the diaphragm and have its bevel lateral to both sides of the aorta, just below the level of the celiac plexus (see Fig. 104-32). Although the plexus is presumably in loose areolar tissue behind the pancreas, which enhances the diffusion of local anesthetic drugs, Moore (103) verified needle placement and spread of injected solution by conventional radiography and by CT scan and showed that spread of the solution tends to be confined to the side of the injection. Therefore, it is essential to do a bilateral block to obtain maximum pain relief.

Several modifications of the classic technique have been described. Some authors insist that radiographic control is absolutely essential for proper placement of the needle and visualization of the neurolytic agent. In a critical analysis of results in 136 patients who underwent NCPB for the relief of pancreatic cancer pain, Brown and associates (102) found that radiographic verification of needle position does not influence the quality of the block. Nevertheless, radiographic control can be helpful, especially to those who have not had extensive experience with celiac plexus block. It should be used if the initial block fails to produce complete pain relief (Fig. 104-33).

Ischia and colleagues (104) have developed a technique that uses a combination of fluoroscopy and fingertip feel to penetrate the aorta with a 20-gauge needle intentionally. The needle is advanced until its bevel penetrates the anterior wall and no blood can be withdrawn. Theoretically, this places the bevel of the needle directly in the middle of the preaortic network of the celiac plexus and should guarantee correct placement, but it confers the risk of producing postblock hemorrhage: In this series, six patients developed retroperitoneal hematoma, as shown by CT scan.

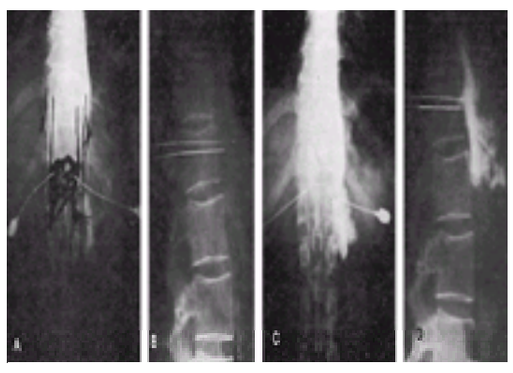

Figure 104-33. Radiographs showing needles in place for injection of the celiac plexus. **A:** Anteroposterior view with drawing of the plexus superimposed in front of the body of the L-1 vertebra in the upper part of the L-2 vertebra. **B:** Lateral view with both needles in place. The distal 3 cm of the needle are anterior to the anterolateral surface of the vertebral body. **C,D:** Diffusion of 10 mL of 35% Diodrast injected through the right needle, with most of the spread being anterior to the anterior surface of the L-1 and upper part of the L-2 vertebrae.

A series of modifications to celiac plexus block have been described. The anterior approach is being used by many radiologists (105,106), possibly because it is a more comfortable position for patients with pancreatic disease. The radiologists at the University of Washington, who do many procedures for pain relief of liver metastases, report that it is less successful in their hands, 75% versus 95% (Feeney, *personal communication*, 1990). The use of ultrasound to guide needle placement is also popular (106,107 and 108).

Results The results obtained by some who used the classic technique and by others using modifications of the technique are shown in Table 104-8. With the classic technique, between 70% and 85% of patients with severe upper abdominal cancer pain obtained pain relief lasting from 1 month up to 1 year. Best results were obtained in those with severe pain caused by cancer of the pancreas.

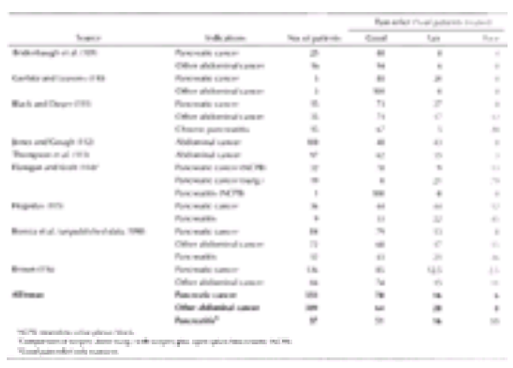

TABLE 104-8. Comparison of results with neurolytic celiac plexus block

Brown and colleagues (102) analyzed 166 patients with cancer of the pancreas and found that 141 patients (85%) obtained good pain relief, which lasted until death in 75% and for longer than 50% of the survival time in an additional 12.5%. Analysis of patient variables revealed that the quality of the block was not affected by age or sex; by whether they had metastasis; or by anticancer therapy such as surgery, chemotherapy, radiation therapy, or a combination of these. When block was repeated for recurrence of pain after a successful first block, 81% of patients again obtained beneficial pain relief. Moreover, repetition of the block did not increase the incidence of complications, which were limited to pneumothorax in two patients. In patients in whom an initial poor result was obtained, a second NCPB was performed with CT scanning to verify the spread of injected solution. In a subsequent report by Brown (116) on another 66 patients who had other types of abdominal cancer pain and who underwent 75 NCPBs, 48 patients (73%) had good pain relief until their deaths. Four reports from the Virginia Mason Medical Center in Seattle (102,109,113,114) indicated that those in the group led by Moore carried out a total of 370 NCPBs over a 25-year period, with an impressive success rate. Many of these were done without radiographic control. An important factor in their high success rate is Moore and associates' routine use of celiac plexus block combined with intercostal nerve block for most patients undergoing upper abdominal surgery.

The value of NCPB for the management of severe pain caused by unresectable cancer of the pancreas has been impressively demonstrated by Flanigan and Kraft (114). They compared pain relief from palliative surgery alone, including biliary and duodenal bypasses, to pain relief obtained from surgery plus injection of the celiac plexus and splanchnic nerves with 15 to 20 mL of 6% phenol at the time of operation. All patients had severe preoperative pain. Of the 19 patients who had conventional operations alone, only four patients (21%) experienced partial relief of pain postoperatively, whereas, of the 32 patients who had the operation and NCPB, 28 patients (88%) experienced excellent pain relief postoperatively for a mean duration of 4.3 months. The mean postoperative survival time was 5 months, and 84% of patients experienced no recurrence of their pain prior to death. In view of these and other results, it is surprising that most surgeons do not use neurolysis of the celiac plexus and splanchnic nerves during the course of surgery.

In the treatment of chronic pancreatitis and other nonmalignant chronic pain syndromes, the initial results were almost as good as those in patients with cancer pain, but the pain recurs with time, so that long-term results can be considered to be only fair. In most patients, the technique should be viewed as a temporary measure to aid in the management of these patients. The same comment could apply to other nonmalignant abdominal chronic pain syndromes. Intrathecal opioids may have value in the management of patients with pancreatic pain (Chapter 103).

Complications A frequent adverse side effect of celiac plexus block with a local anesthetic is extensive vasomotor block because the drug diffuses to involve not only the plexus but also the upper part of the lumbar sympathetic chain, and subsequently hypotension develops. The degree of hypotension in normovolemic patients in the supine position is mild, but elderly patients, or those who are hypovolemic, are likely to develop moderate to severe orthostatic hypotension, especially if they attempt to assume the upright position too quickly. The treatment of hypotension is discussed under Basic Information, earlier in this chapter.

Possible complications include accidental injection of the entire volume of local anesthetic into the inferior vena cava causing a systemic toxic reaction. Accidental injection of the drug into the aorta is less likely to cause a reaction because it is diluted as it passes with the blood to the lower part of the body before being returned to the heart. Accidental intravascular injection of alcohol or phenol can produce necrosis of the vessels. In patients with coagulation defects, puncture of the inferior vena cava with a large needle can result in retroperitoneal hematoma. Pneumothorax can develop if the pleura extends below its normal caudad border of the twelfth rib.

Other more serious complications of NCPB reported include postinjection neuropathy with neuralgia, paraplegia consequent to thrombosis of a major feeder artery to the spinal cord, accidental neurolytic injection into the kidney with consequent necrosis or hemorrhage, and failure of ejaculation (presumably because of involvement of the hypogastric plexus) (71). Paraplegia is arguably the most devastating complication, and its genesis is discussed by Brown and Rorie (117). Cardiac arrest has also been reported but is likely due to intravascular phenol (22).

Neurolytic Block of Splanchnic Nerves

Indications for neurolytic block of the splanchnic nerves are similar to those for celiac plexus block except that the procedure is less likely to involve the lumbar sympathetic chain. The technique is therefore more discrete, requires a smaller volume of neurolytic agent, and offers a lower risk of complications. Boas (118,119) has indicated a preference for block of thoracic splanchnic nerves rather than celiac plexus block because it has the advantage of being a true compartmental block, and thus is safer for the patient.

Technique The anatomy of the thoracic splanchnic nerves is discussed in detail in Chapter 65 and depicted in Figure 104-34 and Figure 104-35 where the technique is outlined. Other approaches using CT guidance have also been described (120,121).

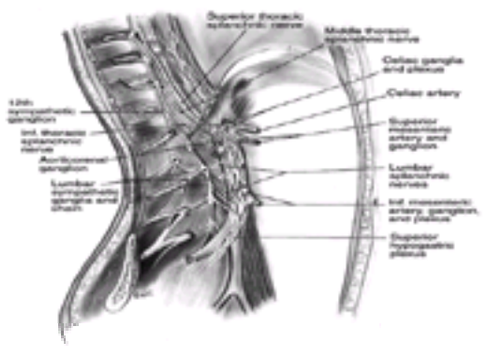

Figure 104-34. Relationship of the lower thoracic and lumbar sympathetic chains, splanchnic nerves, celiac ganglia and plexuses, and their branches (lateral view). These relationships serve as a basis for block of the splanchnic nerves and block of the lumbar sympathetic chain.

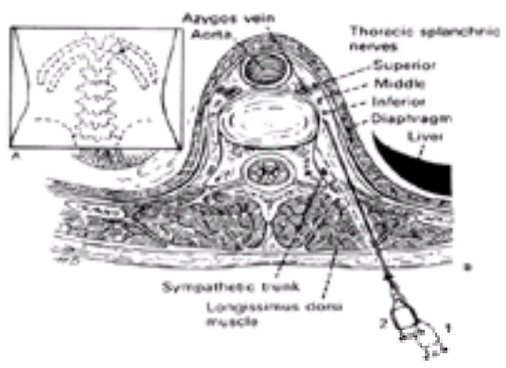

Figure 104-35. Technique of blocking the thoracic splanchnic nerves. **A:** Following identification and marking of the lower tip of the spinous process of the T-11 vertebra, the area is prepared and an intracutaneous wheal is produced 6 to 7 cm lateral to the lower tip of the spinous process of the T-11 vertebra (*black dot*). This is at the same cross-sectional level as the upper part of the body of the T-12 vertebra. A 10- or 12-cm, 22-gauge needle is adequate for the thin or average individual, whereas a 15-cm, 22-gauge needle is necessary for an obese or muscular person. **B:** The needle is introduced through the skin wheal and directed anteriorly and medially so that its shaft makes an angle of 45 degrees with the midsagittal plane. The needle is advanced until the posterolateral surface of the upper part of the body of the T-12 vertebra is contacted (1). A marker is then placed approximately 2 cm from the skin. The needle is withdrawn until its point is in the subcutaneous tissue and reinserted in a slightly more lateral direction, which places the bevel of the needle just lateral to the anterolateral surface of the body of the vertebra where the three thoracic splanchnic nerves are located near each other (2). To avoid damage to the pleura, it is essential that the bevel of the needle be maintained in contact with the vertebra during its anterior advance. Injection of 10 mL of 0.25% to 0.50% bupivacaine with epinephrine solution diffuses throughout the region to involve all three nerves on one side. A bilateral block is often essential for the relief of upper abdominal pain.

Complications Hypotension consequent to vasomotor block is seen less often with splanchnic block than with celiac plexus block because the lumbar sympathetics are usually not interrupted. Pneumothorax occurs if the needle is not kept in contact with the lateral surface of the vertebra. Accidental injection of the neurolytic agent into the azygos vein on the right side or into the hemiazygos vein on the left side can result in necrosis of these vessels. The thoracic duct might be damaged, leading to a chylothorax, or it might become obstructed, leading to lymphedema. All of these complications can and must be prevented by correct technique.

Neurolytic Lumbar Sympathetic Block

Chapter 102 presents the indications for lumbar sympathetic block with a local anesthetic. The neuroanatomy and technique are also described in Chapter 102. Here, the indications for neurolytic blockade of the lumbar sympathetic chain are discussed.

Indications Neurolytic block is indicated for the relief of various chronic painful conditions in the lower limbs in individuals who achieve good but transient results from local anesthetic block but are elderly and not suitable for surgical sympathectomy. These conditions include CRPS types I and II, phantom limb and other postamputation pain, other neuropathic conditions that are temporarily relieved with local anesthetics, various chronic peripheral vascular disorders, pain caused by cancer of the pelvic viscera, and severe persistent tenesmus. Duthie and Ingham (122) reported on patients with persistent lower abdominal pain that was not relieved by surgical excision of various organs but was completely relieved by several lumbar sympathetic blocks with local anesthetic. These results prompted them to carry out lumbar sympathectomy with 7.5% aqueous phenol. All nociceptive pathways from the uterus and cervix pass through the lumbar sympathetic chain (Chapter 70);

patients with persistent pain caused by cancer limited to the uterus or nonmalignant chronic painful conditions not amenable to other forms of treatment should be given several bilateral diagnostic or prognostic lumbar sympathetic blocks with local anesthetic. If good relief is obtained, bilateral sympathectomy can be considered. These procedures are ineffective once cancer begins to infiltrate the lumbosacral plexus.

The largest experience to date with neurolytic lumbar sympathetic block is in the treatment of occlusive vascular disease of the lower limbs. Based on Bonica's experience, as well as that of Löfstrom and Zetterquist (123), Reid and colleagues (124), Boas and associates (125), Löfstrom and Cousins (126), and Cousins and coworkers (127), it is clear that chemical sympathectomy is highly effective in relieving rest pain and in helping to heal ischemic lesion. It can even relieve the pain of intermittent claudication in a smaller percentage of patients. The procedure is indicated in patients for whom bypass graft surgery cannot be used because the obliterating disorder is too extensive.

Better surgical procedures and improved medical therapy have decreased the demand for neurolytic lumbar sympathetic block in peripheral vascular disease. In Europe, spinal cord stimulation has supplanted the procedure (Chapter 100).

Technique The neuroanatomic basis for block of the lumbar sympathetic chain is described in Chapter 102.

The lumbar sympathetic chain is the most variable portion of the sympathetic system, particularly in regard to the number of ganglia and the general form of the two chains. These differ greatly, not only among patients but also on either side of the same patient. In most individuals, they lie anterolateral to the intervertebral disk, with one portion of the ganglion in front of the lower part of the vertebra above and the other portion of the ganglia in front of the upper part of the vertebra below. In addition, the size of the ganglia and the interganglionic cord and the number of branches extending from them exhibit great variation. The lumbar sympathetic chain contains both preganglionic and postganglionic neurons that supply the pelvic viscera and vessels of the lower limbs and have afferent (sensory) fibers, some of which transmit nociceptive information.

Boas (118) has effectively used a single needle placed at L-2 or L-3 and has found it to be satisfactory for injection of the neurolytic agent. It is best, however, to use two needles at L-2 and L-4 or even three needles at L-2, L-3, and L-4, placed in the center of the vertebral body. Insertion of the needle is the same as that illustrated in Figure 102-53. For placement of the block needle, it is essential not only to anesthetize the skin but also the subcutaneous tissue and fascia of muscles, using the lack of resistance test to determine passage of the point of the needle through the psoas fascia.

Although some clinicians have the patient in the prone position during the procedure, the lateral position is preferable because it facilitates monitoring of diffusion of the solution in the lateral view, probably diminishes its retroperitoneal spread, and enhances its cephalad-caudad spread. Once the needles are in place, the positions of the bevels are checked with fluoroscopy. The lateral view should show the bevel of the needle near the anterior of the bodies of the vertebrae. The anterolateral view should show the bevels of the needles to be 1 cm medial to the lateral edges of the vertebral body, and the anteroposterior view should show the needles close to the lateral aspects of the vertebral bodies. When this placement has been accomplished, a 2-mL syringe containing a contrast solution is attached and aspiration is attempted in two planes to ensure that the bevel is not in a blood vessel or in a dural cuff. If the aspiration is negative, 0.5 mL of contrast solution is injected under image intensifier monitoring using the lateral view. If each needle is in the correct position, the contrast medium spreads in a thin linear fashion that conforms to the anterior edge of the vertebra (Fig. 104-36). The appearance of a “blob” or fuzzy patch of the contrast medium indicates that the injection was made into the psoas muscle or fascia, both of which offer resistance to injection. Occasionally, a small vessel is entered without backflow of blood during aspiration, but on injection of the contrast medium it is promptly whisked away along the path of the vessel. In either case, the needle should be readjusted and the preliminary injection of contrast medium should be repeated.

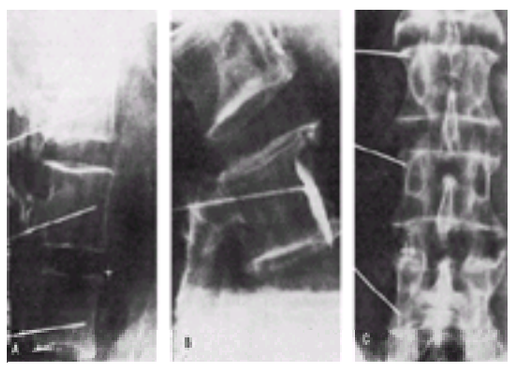

Figure 104-36. **A:** Radiographs showing lateral views of lumbar vertebrae with needles in place to carry out lumbar chemical sympathectomy. **B:** Injection of 1 mL of 10% phenol in Conray-420 at each level causes spread of the solution from L-2 to L-4. **C:** Posteroanterior view. (From Cousins MJ, Reeve TS, Glynn CJ, et al. Neurolytic lumbar sympathetic blockade: duration of denervation and relief of rest pain. *Anaesth Intensive Care* 1979;7:121–135, with permission.)

Once it has been confirmed that the bevels of all the needles are correctly positioned, 3 to 4 mL of 10% phenol in contrast medium is injected through the needles at L-2 and L-4. If three needles are used, 2 mL of solution is injected at L-2 and L-3 and 3 mL of the solution is injected at L-4. With one needle at L-2 or L-3, 10 mL of phenol–contrast medium is injected. The image intensifier is used to monitor the spread of the solution. Using these volumes, the phenol-containing solution spreads in the same linear fashion as above, extending from the upper level of L-2 or the lower level of L-1 to the level of L-5. With such a spread, the phenol can destroy the entire sympathetic nerve supply to the limb below the knee. A 0.5-mL bolus of air or saline is then injected through each needle before it is removed—to prevent spilling of the small amount of neurolytic agent in the needle onto a somatic nerve during needle withdrawal, thus minimizing the risk of postinjection neuralgia.

Patients are kept on their side for 10 to 15 minutes to prevent spread of the solution laterally toward the genitofemoral nerve or posteriorly through the aponeurotic arcades or spaces in the origin of the psoas muscle and its fascia along the fibrous tunnel occupied by the rami communicantes, which connect the sympathetic chain with the lumbar spinal (somatic) nerves.

Because this entire procedure requires the patient to stay in the same position for 90 to 120 minutes, frequent reassurance throughout the procedure is essential. Moreover, if the patient manifests apprehension or anxiety or complains of discomfort, it might be necessary to give an additional dose of a sedative, opioid, or both, especially if the discomfort develops early in the procedure and is likely to persist.

After the 10-minute waiting period, the patient is turned supine but is instructed not to raise the head for 1 hour, during which time observations of skin temperature, blood pressure, and pulse are made at frequent intervals. If blood pressure remains stable after this period, the patient is allowed to sit for 45 minutes and resume oral intake. Patients with unstable cardiovascular disease should be observed and their vital signs monitored for at least 24 hours after the block.

In patients in whom the chemical sympathectomy is being done for relief of CRPS type I or II, or following an above-the-knee amputation, more extensive blocks may be indicated. It might be necessary to block the lowermost thoracic portions of the sympathetic chain to eliminate all sympathetic function to the entire limb and provide complete relief of pain. Because such extensive sympathectomy in men can produce sexual impotence, especially if done bilaterally, it should be considered only when severe pain is present and patients are informed about the complications and agree to proceed.

Results Three sets of results of the use of lumbar chemical sympathectomy are summarized in Table 104-9.

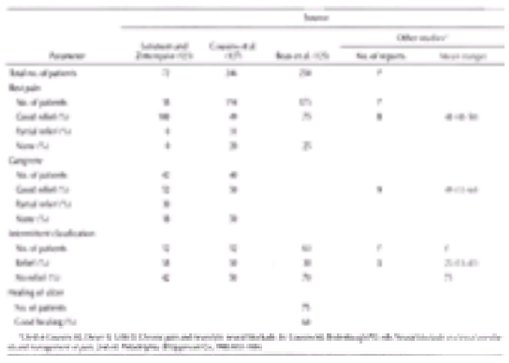

TABLE 104-9. Comparison of results of lumbar chemical sympathectomy for pain due to occlusive peripheral vascular disease

Löfstrom and Zetterquist (123) and Löfstrom and Cousins (126) treated patients with occlusive peripheral arterial disease by continuous lumbar sympathetic block with a local anesthetic. They then proceeded to carry out a block with phenol in those who were only temporarily relieved of their symptoms. The local anesthetic block produced prolonged pain relief in 28 of 55 patients (51%) with arteriosclerotic gangrene, 14 of 28 patients (50%) with pain caused by diabetes, five of 23 patients (22%) with severe rest pain, and one of 16 patients (6%) with intermittent claudication.

In a series of 250 percutaneous chemical sympathectomies done by Boas (125), 70% of patients had rest pain; 30% had trophic changes with ulcerations, gangrenous changes, or both; and 25% had intermittent claudication. Long-term results included relief of rest pain in 75% of patients (better than that achieved with surgical sympathectomy), healing of the ischemic lesions in 60%, but improvement of claudication in only 30% of patients with this complaint. Subsequently, Boas (119) mentioned that his group had obtained similar results with phenol block on more than 500 patients with arteriosclerotic symptoms and signs.

In the series reported by Cousins and associates (127), relief from rest pain was complete in 49% of patients and partial in 31%. In those without preexisting gangrenous changes, 84% of patients derived partial or complete relief as compared to 56% of those with a gangrenous lesion. The onset of pain relief coincided with the onset of sympathetic block and with increases in skin blood flow and temperature. The mean duration of pain relief was 5.9 + 0.6 months, which was similar to the mean duration of sweat modification (6.0 + 0 months). Two years after the blockade, 35% of patients were alive and the skin was intact, without evidence of ulcer or gangrene; 15% had undergone reconstructive surgery; and 25% required either local debridement or major amputation within an average of 10 months after the block. Only 10% of patients required a repeat block on the same side within a period of 3 to 12 months. Pain relief after the second block was always at least equal to that obtained with the first block. Cousins and colleagues (127) also noted that another, often neglected, benefit of sympathectomy is that it shortens the time to a clear demarcation area of the amputation level and improves the vascular supply to the stump. Moreover, because early sympathectomy is beneficial in treating some types of phantom limb pains, sympathectomy for pain relief performed 1 month before amputation can prevent postamputation pain, as suggested by the fact that none of their patients who underwent amputation developed severe phantom limb pain.

Cousins et al. (127) used prognostic blocks of the lumbar sympathetic chain with 0.5% bupivacaine in most of their patients. They believed that unless this is carried out, some patients who manifest the steal phenomenon because of the response of healthy vessels and the lack of response of diseased vessels might not be identified. Moreover, Cousins and coworkers (127), as well as Boas and associates (125), excluded patients whose primary complaint was intermittent claudication on the premise that such patients are best treated with reconstructive surgery. In a review of 14 studies, Löfstrom and Cousins (126) cited the percentage of patients with occlusive vascular disease who responded to lumbar sympathetic block in regard to such parameters as rest pain, skin lesion, and intermittent claudication: Rest pain was relieved in a mean of 48% of patients (range, 48% to 80%).

Complications In addition to the complications mentioned in Chapter 102 associated with the use of lumbar sympathetic block with local anesthetics, the most serious complication with chemical sympathectomy is genitofemoral neuralgia, which occurs in 5% to 7% of patients. It is presumably caused by the diffusion of the alcohol to the genitofemoral nerve as it lies on the anterior surface of the psoas major muscle, not too far from the lumbar sympathetic chain. This same complication follows surgical sympathectomy, suggesting that the nerve is damaged during the course of the operation. The condition is characterized by the usual burning and aching pain; allodynia may be present. It sometimes can be relieved by transcutaneous electrical nerve stimulation. In many patients, this condition is transient. Although some authors have claimed that the incidence of this complication is much higher with alcohol, this was not Bonica's experience in the more than 50 patients in whom chemical sympathectomy was done with 50% alcohol.

Neurolytic Block of Somatic Spinal Nerves

Based on his early experience with neurolytic block of somatic spinal nerves, Bonica continued to insist that, except in patients with severe terminal cancer pain not amenable to any other procedure, neurolytic block of somatic nerves should not be used. The primary rationale for this approach is that, during nerve regeneration, patients experience severe neuralgia in the nerves supplying the limb or trunk. Although some authorities (3) have suggested that the neuralgia is related to the fact that the nerve damage is caused by imprecise needle placement and incomplete neurolysis, this condition occurs in patients in whom the neurolytic agent was injected intraneurally, with complete destruction of the nerve.

Transsacral nerve block with a neurolytic agent is useful in individuals with severe unremitting perineal pain caused by inoperable cancer of the rectum or after abdominoperineal resection when that pain is not relieved by subarachnoid neurolysis. Because the S-4 segment provides predominant sensory innervation to the perineum, transsacral block of this segment with 2 mL of 6% aqueous phenol has been used to provide prolonged pain relief. Robertson (128) reported the use of this technique in nine patients with cancer of the rectum. Eight had undergone abdominoperineal resection, and one had an inoperable lesion and a defunctioning colostomy. The pain was asymmetric in all nine patients, more pronounced on one side of the perineum than the other, and was of such severity to be considered an indication for intrathecal neurolysis. All patients received a prognostic block with 2.5 mL of 0.5% bupivacaine, and an equal volume of 6% aqueous phenol was injected 24 hours later. The first injection provided pain relief of less than 1 week's duration in six patients, of 10 days' duration in one patient, of 202 days' duration in one patient, and of 414 days' duration each in one patient. A second injection produced pain relief lasting from 18 to 122 days, and three patients received a third block. Treatment was carried out on an outpatient basis, with no disturbances of bladder or motor function and with sensory changes limited to the perineum.

Neurolytic Somatic Block for the Relief of Chronic Nonmalignant Pain

Brief mention is made here of several indications for the use of neurolytic block in patients with nonmalignant chronic pain, including transsacral block for severe bladder pain and spasticity, abdominal nerve entrapment syndrome, coccyodynia, and the injection of small neuromas consequent to surgery.

Cystitis Simon and associates (129) reported on a prospective study to evaluate the results of the injection of 2 mL of 6% aqueous phenol at S-3 in 15 patients with severe pain caused by interstitial or hemorrhagic cystitis and in one patient who had a neurogenic spastic bladder. Following a diagnostic block with 0.5% bupivacaine, 2 mL of 6% aqueous phenol was injected through the right S-3 foramen. Of these patients, ten who received bupivacaine subsequently received phenol and, of these, seven reported significant long-lasting pain relief, one had pain relief for 1 week, and two received no benefit. The average follow-up period was 24 months, and the duration of response in those with persistent pain was at least as long. No patients suffered urinary or rectal incontinence.

Abdominal Nerve Entrapment Syndrome The abdominal nerve entrapment syndrome is a source of significant discomfort that can be disabling. It presents as intermittent pain in the region of the rectus abdominis muscle or a segmental neuralgia. It is provoked by increased intraabdominal pressure and twisting the trunk. It is relieved by focal injections of local anesthetic. The condition is usually treated with repeated injections of a long-lasting local anesthetic. McGrady and Marks (130) reported on a series of 76 patients treated with 1 mL of 6% aqueous phenol using a nerve stimulator to locate the optimal point of injection. Of those in the group of 44 patients whose diagnosis had been definitively made, 95% derived complete or partial relief of symptoms at follow-up lasting from 6 months to 4 years. In a group of 32 patients who had other symptoms that made the diagnosis less certain, 48% gained partial relief and 8% obtained complete relief.

Cryoanalgesia

The term *cryoanalgesia* was coined by Lloyd and colleagues (131) to describe the destruction of peripheral nerves by extreme cold to achieve pain relief. The

histologic effects of cryoanalgesia on nerves are summarized under Basic Information, earlier in this chapter. The procedure produces a small ice crystal that causes a second-degree nerve injury consisting of wallerian degeneration with axonal disintegration and breakup of the myelin sheath but with minimal disruption of the endoneurium and the basal lamina. Cryolesions are claimed to produce less fibrous tissue reaction than other forms of destruction (132). Since its introduction in 1976, this method has had limited clinical application, and the number of published reports is small (133,134,135 and 136).

Indications Cryoanalgesia has been used for local destruction of brain tissue and to block cranial and spinal nerves to relieve such problems as intractable facial pain, postthoracotomy pain, posttraumatic chest pain, and cancer pain. Because the duration of pain relief averages 2 weeks (range, 2 days to 7 months), the most fruitful uses are relief of postoperative and posttraumatic chest pain and relief of medium duration in patients with various chronic pain syndromes.

Technique Cryoanalgesia is done with a 15-gauge cryoneedle. Blockade is based on the principle of the Joule-Thompson effect, with nitrous oxide being used as the refrigerant gas (137). The Joule-Thompson effect occurs when gas at approximately 700 psi is injected through a nozzle; as it expands, it cools to approximately –75°C. The cooled gas impinges on the inner surface of the needle tip and absorbs heat from the surrounding tissue, and the warm gas is exhausted back up the needle and vented through the scavenger system. The Spembley-Lloyd cryoneedle uses a thermocouple to confirm the temperature achieved at the tip, and an electrical connection at the tip of the probe is connected to a peripheral nerve stimulator for precise location of the nerve. The probe is connected by a 6-foot piece of flexible tubing (Fig. 104-37) to a console that has a gas pressure regulator switch, a nerve stimulator socket, and dials for displaying gas pressure and probe tip temperature.

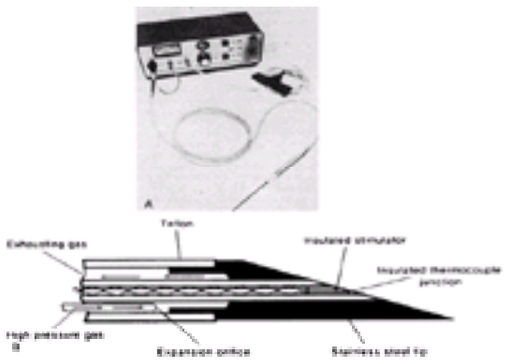

Figure 104-37. **A:** Spembley-Lloyd cryoanalgesia apparatus. The unit incorporates a cryosurgical system coupled to a nerve stimulator for accurate positioning of the probe. The probe is connected by 6 feet of flexible tubing to a console that has a gas pressure regulator switch, a nerve stimulator socket, and dials to display gas pressure and probe tip temperature. **B:** Details of the cryoprobe tip. A chrome-constantan thermocouple is fitted to the tip of the probe to monitor the temperature. The probe is 10 cm long and is constructed from a 15-gauge stainless steel hypodermic tube with an 18-degree, short-beveled point. An electrical connection is made to the tip of the probe from the nerve stimulator, and all parts of the probe are insulated from the patient and operator by a Teflon coating. (**B** from Lloyd JW, Barnard JD, Glynn CJ. Cryoanalgesia: a new approach to pain relief. *Lancet* 1976;2:932–934, with permission.)

Results Lloyd and colleagues (131) reported on the use of cryoanalgesia in 64 patients, of whom 52 obtained good relief of pain that lasted for a median period of 11 days, up to 7 months. Best results were obtained in providing pain relief to 15 of 17 patients (88%) with intercostal nerve pain, to all of six patients with facial neuralgia who underwent infraorbital or mental nerve block, and to eight of nine patients (89%) who had cancer (four of these had intercostal blocks, and five had the cryoprobe introduced through the sacral hiatus to produce caudal analgesia). Subsequently, the same group (133) reported on 29 patients who received intercostal block with cryoprobe under direct vision prior to closure of the thoracotomy. They compared postoperative opioid requirements with those of a control group of 29 patients who were matched for sex, age, and diagnosis and managed with intramuscular opioids (133). Those patients in the cryoanalgesia group derived more effective relief and required significantly fewer opioid injections for less time as compared to those in the control group. Barnard and colleagues (134) used cryoanalgesia in the management of chronic facial pain in 43 patients who received 85 cryogenic blocks of branches of the trigeminal nerve for the relief of the pain of tic douloureux, postoperative neuralgia, postherpetic neuralgia, and other types of facial pains. In 67% of patients with nonherpetic neuralgia, the pain relief persisted for a median of 93 days. Of 26 patients with postherpetic neuralgia, only 11 (42%) derived relief, which lasted 6 weeks. None of those in the three groups of patients treated by Lloyd et al. (131), Glynn et al. (133), and Barnard et al. (134) developed neuralgia subsequent to treatment, and no other serious complications have been reported.

Katz and associates (135) reported good relief of postthoracotomy pain following intercostal cryoanalgesia carried out under direct vision. Katz also stated (*personal communication,* 1988) that he and coworkers have used cryoanalgesia in nearly 150 patients, with good pain relief achieved in over 85% of patients. Jones and Murrin (136) reported results with the use of percutaneous cryotherapy of intercostal nerves in patients with various chronic chest pain syndromes who had had pain for 6 months to 2 years. Of 32 patients with postthoracotomy scar pain, 13 (40%) derived good relief, 10 (30%) had partial relief, and nine (30%) had little or no relief. Among 15 patients with postherpetic neuralgia, 11 (74%) derived good relief, two (13%) had partial relief, and two (13%) had little or no relief. The duration of pain relief for those in the latter group was less than 7 days in 79% of patients, whereas for those in the former group relief lasted considerably longer (136).

Neuroadenolysis of the Pituitary

Neuroadenolysis of the pituitary involves transnasal placement of a trochar tapped through intervening structures with a metal mallet to reach the pituitary fossa. Following verification of position, 0.5 to 6.0 mL of absolute alcohol was injected to destroy the pituitary gland. Complex hormonal and neurochemical responses were invoked to explain the sometimes dramatic pain relief that followed this procedure. There have not been further reports of its use or efficacy since the 1980s; its use appears to have languished with the advent of other advancements in the treatment of cancer pain. It was felt to be appropriate in severe pain from advanced cancer such as of the breast or prostate with widespread metastases. Several authors [Moricca (138), Lipton (139), Katz (141), Waldman (140), Levin (142)] reported on the procedure undertaken with the aid of fluoroscopy or stereotactic equipment in lightly anesthetized patients. Table 104-10 shows pain relief varying between 27% and 87% in over 1,500 patients. More details on the technique and outcomes are in the references. It has never been performed in our institution, and therefore we cannot comment directly on the procedure; from the absence of recent reports, it appears to be waning in popularity.

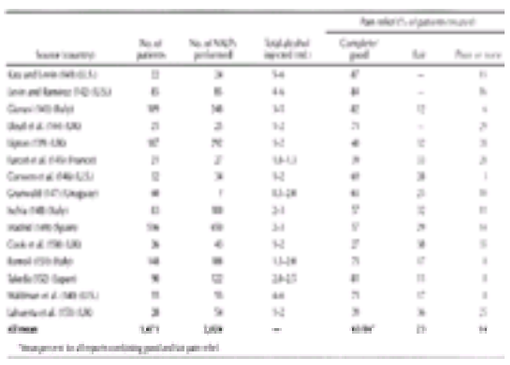

TABLE 104-10. Comparison of results with neuroadenolysis of the pituitary (NALP) for cancer pain

Neurolytic Blocks for Control of Spasticity

Indications

Although neurolytic nerve blocks are usually used for the control of chronic pain, they are also important for the treatment of spasticity consequent to injuries to the

central nervous system (e.g., stroke, cerebral palsy, and spinal cord damage secondary to trauma or disease, such as multiple sclerosis). Such patients often develop spasticity that is uncontrolled and often produce sporadic spontaneous and uncontrolled flexor or extensor movements that can severely compromise the patients' ability to sit in a wheelchair. Sometimes such spasms can be so violent that patients are catapulted out of their wheelchairs. Many patients with spinal cord injury develop spasms of the adductor muscles of the thigh, which in addition to the painful spasm affect the ability to perform perineal toilet and to carry out other aspects of nursing care.

Reduction of such profound skeletal muscle spasm by neurolytic block has been helpful in these patients (154,155,156,157,158,159,160 and 161). Less commonly, such blocks can be used to treat muscle spasms in the trunk or in the upper extremity associated with quadriplegia (154).

Some special indications for producing reversible spasms in such individuals also exist. Many patients use the muscle spasms as an integral part of their support for sitting and functioning both during recreation and at work. It is sometimes necessary, however, to reduce such spasms temporarily. For example, a patient might need to be nursed in the prone position for some length of time (e.g., during and after placement of a skin graft for a gluteal bed sore). Therefore, prolonged and complete elimination of flexion spasms would not be indicated because such spasms are useful to the individual during normal activities. In such cases, prolonged reversible therapy for the spasms is needed.

With the introduction of baclofen and the use of implantable intrathecal catheter and pump systems (162,163 and 164), the control of spastic problems has been revolutionized, and in our clinic population, there is very little call for neurolytic blockade. In the past, the majority of neurolytic procedures done in the clinic were for spasticity, but comparing the results with those from the use of baclofen pumps, it is apparent that the new method is far more user-friendly. Adjustment of dose to titrate to effect was not possible previously but is a routine part of the new technology.

Neurolytic procedures are still useful for the small minority of individuals who do not respond to intrathecal or oral baclofen.

CHAPTER 105

Lesions of Primary Afferents and Sympathetic Efferents as Treatments for Pain

Parag G. Patil and James N. Campbell

In this chapter, we consider ablative operations of the peripheral nervous system for pain. Ablative procedures interrupt signal flow between pain generators in the periphery and the brain, or they remove neural structures that contribute to pain generation. As an example of the former, transection of a peripheral nerve prevents the transmission of pain-encoding signals from a painful region to the spinal cord. As an example of the latter, ablation of paraspinal sympathetic ganglia can eliminate the distal release of norepinephrine, which triggers nociceptor activity in the periphery.

Two fundamental approaches exist to address the problem of intractable pain: attempts to palliate and attempts to eliminate pain definitively. Ablative procedures have the capacity to eliminate pain and, therefore, have great appeal. However, ablative procedures are notorious for achieving only short-term benefits, a reputation that undermines their appeal. In support of such skepticism, animal research suggests that axotomy alone may be sufficient to induce pain (1). However, regardless of the perception that inappropriate patient selection may lead to considerable morbidity, the experience of some clinicians remains that ablative procedures have the capacity to relieve pain enduringly and that ablative procedures are useful therapeutic ventures in properly selected patients.

This chapter is divided according to the three major categories of ablative operations involving the peripheral nervous system: peripheral neurectomy, dorsal rhizotomy and ganglionectomy, and sympathectomy. The surgical treatment of trigeminal neuralgia, which is one of the most common of the diseases that are successfully treated by ablative procedures, is presented in Chapter 107. Ablative procedures aimed at the spinal cord, such as the DREZ operation for treatment of avulsion injury of the brachial plexus or cordotomy, used in pain due to malignant disease are presented in Chapter 106.

PERIPHERAL NEURECTOMY

Basic Considerations

There are two reasons a nerve may be cut to eliminate pain. One purpose is to denervate a pain-producing structure. For example, facet rhizotomy denervates the facet joints of the spine as a treatment of axial spine pain. A second purpose of nerve ablation is the interruption of pain signals from an injured nerve. Yet, there is some irony in this use of neurectomy. In mice, rats, and monkeys, transection of a somatic nerve may cause pain. To understand then how ablation may relieve pain, we must consider some aspects of the pathophysiology of neuropathic pain.

Pathophysiology of Neuropathic Pain

When sensory nerve fibers are severed, the proximal axons, which are still in continuity with cell bodies in the dorsal root ganglion, sprout and seek Schwann-cell guides. If the perineurium of the injured nerve has remained intact, such as in cases of crush or certain thermal injuries, the sprouts successfully reinnervate the target tissue. Successful regeneration may also occur when the transected ends of the nerve are surgically reapproximated (neurorrhaphy). However, when continuity with Schwann-cell guides is not present, the axon sprouts fail to reach the target tissue and randomly double-back on themselves, ultimately forming a densely packed cluster of nerve sprouts known as a *neuroma*.

Removal of a neuroma as a treatment of nerve injury pain is conceptually flawed. Cutting the nerve at a location that is proximal to the site of nerve injury, to remove the neuroma, results in the formation of a new neuroma. Surgery in which neuromas are removed should therefore be labeled *neuroma relocation surgery.* Relocating a neuroma in a non–pressure-sensitive area may alleviate pain in some patients.

Though nontraumatic neuropathies may induce pain in a variety of ways, pain from a single nerve lesion offers perhaps the clearest model for considering the mechanisms of neuropathic pain. Weir Mitchell brought attention to the problem of painful nerve injury after caring for injured soldiers during the American Civil War. A century later, Denny-Brown and Kirk (2) presented one of the first studies demonstrating that axotomy may induce behavioral signs of pain in an animal model. More recent studies have corroborated the observation that axotomy of a major nerve, by itself, may induce hyperalgesia in animals (see Chapter 3).

An important generator of neuropathic pain must be located at the site of nerve injury. This is demonstrated by the common finding that placement of local anesthetic at the site of the injury can dramatically relieve pain. Clearly, neural activity that arises from the nerve lesion site somehow produces pain. Four pathophysiologic mechanisms seem likely to play a role:

- *Ectopic generation of action potentials.* Though normally silent, nociceptive afferents may become spontaneously active following nerve injury, producing action-potential activity in the absence of any stimulus (3). This activity without a stimulus could be experienced as spontaneous pain.
- *Ectopic excitability.* Uninjured nerve trunks are minimally sensitive to stimuli. Following injury, these fibers may respond to normally nonpainful stimuli at ectopic, normally insensitive sites. For example, application of a mechanical stimulus may result in neural activity in an injured fiber, while having no effect on an uninjured fiber. Such ectopic mechanical excitability gives rise to Tinel's sign, an electrical sensation in the nerve's original target distribution, elicited by mechanical stimulation at the location of regenerating axons. As a second example, injured nociceptive axons may become abnormally sensitive to catecholamines, leading to pain when norepinephrine is released from local sympathetic terminals. This condition is termed *sympathetically maintained pain* (SMP) (4).
- *Nervi nervorum.* Nerves themselves appear to be innervated by nociceptive fibers. These nervi nervorum fibers may become sensitized to mechanical stimuli following nerve injury. Such a mechanism may explain, for example, the local tenderness and mechanical hyperalgesia of the ulnar nerve when it is entrapped at the elbow. Similarly, activation of the nervi nervorum may explain the local tenderness of nerves that are entrapped by scar tissue.
- *Ephaptic conduction.* Under normal physiologic conditions, signals in adjacent afferent fibers are insulated from each other. Activity in an injured nerve fiber may evoke activity in a nearby fiber, through a direct electrical connection between the two. During such ephaptic transmission, or *cross talk*, nonnoxious sensory stimuli may evoke activity in nociceptive fibers and may thereby cause pain.

Some of the mechanisms of ectopic generation of action potentials and ectopic excitability are now understood. Sodium ion channels that are sensitive to natural stimuli (mechanical, thermal, and chemical stimuli) are normally present in the membranes of sensory terminals. When an axon is severed, axonal transport of these channels from the cell body to the sensory terminal is interrupted. As a result, the channels are expressed ectopically in the neuroma formed at the injury site. Nociceptive fibers in the neuroma thereby become sensitive to natural, normally nonpainful stimuli, producing pain when these stimuli are present (5,6). The mechanisms of spontaneous activity in a neuroma are not as well understood, but both potassium and sodium channels may play a role.

In addition to neural activity arising at the site of injury, there are other mechanisms of neuropathic pain. Evidence supports what may be termed the *wallerian*

degeneration hypothesis. According to this hypothesis, uninjured nociceptors that are adjacent to nerves undergoing wallerian degeneration may become spontaneously active and may develop sensitivity to catecholamines, resulting in spontaneous pain and SMP. For example, injury to the L-6 nerve root in monkeys induces these changes in the nociceptive afferents of adjacent roots serving the same region of skin (7). To the extent that neuropathic pain results from this mechanism, peripheral neurectomy might be expected to worsen pain, since the nerve undergoes wallerian degeneration distal to the site of neurectomy. By contrast, such pain may be improved by topical application of capsaicin or by sympathectomy, since these therapies do not involve degeneration of the distal axon.

Rationale for Neuroma Relocation Surgery

Neuromas arise from nerve fibers, proximal to a region of transection or severe injury, which remain in continuity with their cell bodies in the dorsal root ganglia. Hence, the idea of *removing* a neuroma is conceptually flawed, since a new neuroma always will form at the freshly severed end of the nerve. Moreover, not all neuromas are painful. The use of peripheral neurectomy as a treatment for painful neuromas is therefore predicated on the hope that *relocation* of the neuroma may convert it from a painful to a painless one.

Why should neuroma relocation surgery ever work? Here, the basic sciences take their cues from the clinic. Clinical experience demonstrates that neuroma relocation surgery does work in some situations. The tissue milieu surrounding the nerve may determine whether a neuroma becomes painful or remains painless. Ectopic excitability and sensitivity of injured nociceptive fibers and of the nervi nervorum may provide a dominant mechanism of pain production. Furthermore, neuromas tend to be painful in locations where the severed nerves are subjected to excessive mechanical forces. Relocation of the neuroma may move it into a milieu that is shielded from mechanical stimuli. However, to the extent that there is location-independent, ectopic generation of action potentials in the neuroma, relocation surgery will fail.

Some investigators have argued that central mechanisms may account for pain in many situations of nerve injury and that neuroma relocation surgery may fail because of this. For cases in which anesthetic blockade of the injured nerve fails to relieve pain, an important trigger for pain may reside central to the neuroma. However, our observations as well as those of other experienced clinicians suggest that, in the great majority of patients with nerve injury pain, anesthetic block of the injured nerve strikingly relieves pain. In these latter cases, discharge in the peripheral nerve is required for the pain to be experienced. Thus, efforts to relieve pain by addressing the neural impulses that arise from the region of injury have some theoretical support. Central nervous system changes after peripheral nerve injury may also contribute to chronic pain.

Clinical Considerations

Preoperative Evaluation

Neurectomy is used in a variety of clinical scenarios that can be broadly divided into two groups: neuropathic pain resulting from nerve injury and nociceptive pain from a diseased tissue other than nerve. To decide that pain comes from nerve injury, the clinician needs to establish first that there has been an injury. The history is helpful. Something should have happened to the patient that would cause nerve injury. A patient with pain in the stump of an amputated limb probably has nerve injury pain. In fact, nerve injury pain frequently arises as a complication of previous surgery. In addition, the character of the pain may be helpful. For example, burning pain connotes neuropathic pain. On examination, the clinician should search for appropriate sensory/motor deficits. Often, a neuroma sign will be prominent at the site of nerve injury; if the nerve is undergoing regeneration, there may be both Tinel's sign at the advancing region of axon regeneration and a neuroma sign at the injury site where some axons have been irreversibly transected.

A prerequisite for the diagnosis of nerve injury pain is an anesthetic block. If blockade of the putative, pain-generating neuroma fails to relieve the pain nearly in its entirety, the rationale for neuroma relocation surgery is precarious. In addition, findings associated with complex regional pain syndrome, such as edema, hyperalgesia, and trophic changes, suggest that neurectomy will not help the patient. In such cases, however, there typically is no clear relief of pain following peripheral nerve blockade. Patients should be assessed for hyperalgesia to cooling stimuli. This finding is suggestive of SMP, discussed under Sympathetically Maintained Pain, later in this chapter. Finally, local tenderness in combination with a neuroma sign suggests entrapment-induced nerve injury. In this instance, nerve decompression would be indicated rather than neurectomy. It is important to note that even subtle entrapments without significant motor or sensory loss may induce severe pain.

After one has identified a specific nerve as a pain generator, the second step is to decide what to do with the nerve. Neuroma relocation is not the only option. If the injury is relatively recent and the nerve is relatively unimportant, a wait-and-see recommendation may be most appropriate. In some cases, there may be only a partial nerve injury. If this is the case, neurectomy may sacrifice function without assurance that the new neuroma will be less painful than the old one. Thus, nerve repair should be considered before performing a neurectomy.

Nerve repair has the potential to eliminate the neuroma with the bonus of restoring neurologic function. The clinician sometimes faces the ironic situation that, to repair an injured nerve, a normal nerve (e.g., sural nerve) may need to be sacrificed to provide donor grafts. Thus nerve repair is, in a sense, a neuroma relocation operation: The neuroma is relocated to the donor nerve. For conceptual reasons, repair of an injured nerve, when feasible, is preferable to permanent transection.

Other options may be considered for the treatment of neuropathic pain, including implantation of peripheral nerve stimulators, spinal cord stimulation, and medical therapy (opiates, anticonvulsants, membrane stabilizers, and tricyclic antidepressants). Prudent decision making is based on an analysis of risk versus benefit. Of note, if a nerve has already been completely severed, the risk of relocating that neuroma to a new location is low. Thus, in a case of a well-defined neuroma, when an anesthetic block relieves pain, surgical neurectomy may be the preferred *first* line of therapy when medications have failed.

Careful analysis may lead to rewarding outcomes. The following case presents the history, preoperative evaluation, and treatment of a patient with neuropathic pain:

> A 44-year-old woman presented with a chief complaint of right vaginal pain. This problem had been present for 3 years and originated with an excisional biopsy of a right-sided vaginal ulcer near the introitus. The pain was always present but especially disturbing were lightning attacks of pain that occurred unpredictably several times a day. Examination disclosed a subtle sensory loss in the right vulvar area. Medication trials were minimally helpful. An anesthetic block of the right pudendal nerve led to 50% pain relief. A combined ilioinguinal and genitofemoral nerve block also led to 50% pain relief. A local anesthetic block of all three nerves together led to 100% pain relief. As treatment, the right pudendal nerve was severed near the ischium through a perivulvar approach, and the patient, predictably, had 50% pain relief. At a separate setting, the right ilioinguinal and genitofemoral nerves were severed through a retroperitoneal approach. At 3-year follow-up, the patient had complete relief. There were no adverse sequelae.

In this case, both lumbosacral neural segments provided innervation to the painful neuromas. Failure to appreciate this would have led to a less than satisfactory result. This case underscores the need for complete blockade of pain during the application of local anesthetic to ensure that all involved nerves are identified.

Evaluation of patients with nociceptive pain in diseased tissue follows a similar strategy. The anatomy of sensory nerves in the damaged region must be defined. Once candidate nerves are identified, direct local anesthetic blocks indicate the level of benefit that could be obtained following nerve ablation. A successfully applied block should induce complete anesthesia in the distribution of each target nerve, but not beyond, to avoid issues of deficient test specificity and sensitivity. Remote blocks with different agents may enhance specificity by identifying problems due to nonspecific responses. As stated in Chapter 102, a surgical decision should never be made on the response to a single nerve block.

Operative Technique

Given that abatement of neuroma pain is the object of treatment, the primary surgical issue is where to relocate the neuroma. Troublesome neuromas typically are in areas near joints, scars, and structures with wide excursion. The implied mechanism is that mechanically tethered neuromas produce pain when subjected to mechanical stress. The idea of surgery is to relocate the neuroma to a location where this does not happen (8). Nerves may be cut back to locations such that the ends can be placed in healthy, well-vascularized muscle. Some have advocated that neuromas be placed in holes in bone. Placement of the nerve in these environments does not change the fact that the cut ends of the nerve will sprout and that a neuroma will form. However, with placement of the nerve into muscle or bone, the chances are reduced that the nerve will be subject to tension and shearing forces likely to play a role in pain generation.

Alternatives to neuroma relocation exist. The nerves may be cauterized, frozen, burned, or injected with toxic chemicals. These options have been reported to be successful, but their advantage over surgical neurectomy has never been demonstrated. However, a surgical procedure where the neurectomy is done sharply, with limited damage to the surrounding environment of the nerve, is the gold standard. Damage to the surrounding tissues, such as necrosis due to phenol injection, may

set up a new focus for pain generation (9).

Treatment of Neuropathic Pain

Indications. Division of major nerves can cause significant motor deficits, sensory deficits, or pain. Ablation of such nerves as a treatment of pain should ordinarily be considered only if the nerve is already divided. Nerve graft repair must always be considered prior to repeat transection. Neurectomy of minor nerves is more commonly performed than neurectomy of major nerves due to the relative loss of function. The following conditions may respond to neurectomy for pain treatment. In many of these conditions, the origin of the problem is entrapment of the nerve. In these instances, it is better to preserve the nerve when it can be decompressed. Neurectomy should be reserved for those situations in which decompression is unlikely to provide a satisfactory result and nerve repair is not possible.

Amputation Stump Pain. Amputation of a limb is necessarily associated with considerable nerve injury. Some amputations are associated with enduring pain for reasons that are not at all clear (10). In particular, amputees with neuromas in weight-bearing regions or regions of scar are more likely to experience stump pain. Surgical relocation of neuromas to more proximal or protected locations may provide benefit.

Intercostal and Intercostobrachial Pain. Chest trauma or thoracotomy may damage intercostal nerves. Shoulder trauma and axillary node dissection may damage the intercostobrachial nerve. Motor deficits associated with intercostal and intercostobrachial neurectomy are clinically insignificant; neurectomy is usually without significant drawbacks.

Perineal and Inguinal Pain. Injuries to the pudendal, ilioinguinal, iliohypogastric, and genitofemoral nerves occasionally result in severe pain. These injuries are often due to abdominal and pelvic surgery, episiotomy, hernia repair, entrapment, or blunt trauma. Stulz and Pfeiffer (11) reported relief of pain with neurectomy in 70% (16 of 23) of patients with ilioinguinal and iliohypogastric neuralgia as a complication of prior surgery. Starling and Harms (12) reported similar rates of success: 89% (17 of 19) for ilioinguinal neuralgia and 71% (12 of 17) for genitofemoral neuralgia. Others have not found such uniformly high success rates, and pain clinics often are referred patients who have failed to respond to multiple neurectomies.

Meralgia Paresthetica. Entrapment or injury of the lateral femoral cutaneous nerve may result in pain and dysesthesia in the anterolateral thigh, called *meralgia paresthetica*. Section of the nerve usually relieves pain (13). However, nerve decompression procedures may achieve the same benefit with the added advantage of restoring sensation. Nonsurgical treatments should always be undertaken prior to referral for surgery.

Saphenous Neuralgia. Spontaneous entrapment of the saphenous nerve in the subsartorial canal (14) or damage to the saphenous nerve during surgery (15) may lead to pain along the anterior and medial leg and the dorsum of the foot. Luerssen et al. (14) reported 50% (three of six patients) success following nerve decompression and 100% (three of three patients) success following saphenous neurotomy in patients with spontaneous saphenous neuralgia.

Morton's Neuroma. Formation of neuromas along an interdigital plantar nerve produces sharp, burning pain along the plantar surface of the foot with radiation into the toes (see Chapter 80). Such neuromas are associated with thickening of the epineurium and perineurium of the nerve, suggestive of chronic trauma. Johnson et al. (16) reported relief of pain in 67% (22 of 33) of patients, with 6 years' average follow-up, following excision of the plantar interdigital neuroma.

Results. What are the predicted results of neurectomy for nerve injury pain? The question is difficult to answer because the patients subjected to this treatment are heterogeneous. In addition, measurement of patient outcome varies greatly among studies with regard to methodologic rigor and technique. As suggested by the studies cited above, success rates vary from modest to high.

Burchiel and colleagues (17) have taken a systematic approach to the treatment of nerve injury pain, moving the field toward a definition of the indications for neuroma surgery. Forty-two patients with nerve injury pain were divided into four treatment groups:

1. Patients with distal sensory neuromas treated by excision of the neuroma and implantation of the proximal nerve into muscle or bone marrow.
2. Patients with *suspected* distal sensory neuromas in which the involved nerve was sectioned proximal to the injury site and implanted.
3. Patients with proximal neuromas-in-continuity of major sensorimotor nerves treated by external neurolysis. (*Neurolysis* is a term is a term used by surgeons to mean freeing a nerve from adjacent tissue; anesthesiologists sometimes use the term to mean destruction of the nerve; the former meaning applies here.)
4. Patients with nerve injuries at points of anatomic entrapment treated by external neurolysis and transposition.

Surgical success (rated as a greater than 50% subjective improvement in pain levels, subjectively rated pain relief as “good” or “excellent,” and no postoperative narcotic usage) varied between the groups. In the 40 patients who received postoperative follow- up care over 2 to 32 months (average, 11 months), 16 (40%) met these criteria. By group, successful pain relief was accomplished in 44% (eight of 18) of group 1, 40% (four of ten) of group 2, 0% (zero of five) of group 3, and 57% (four of seven) of group 4.

After obtaining these results, Burchiel and colleagues (17) attempted to determine retrospectively the extent to which indicators of nerve injury predicted surgical success. Such indicators included Tinel's sign, hyperalgesia, a “discrete nerve syndrome,” litigation, and prior procedures. Some predictors showed promise. For example, a *discrete nerve syndrome*, defined as a condition in which a single nerve could account for all the neurologic findings and pain distribution, tended to predict success. However, none of the relationships between preoperative diagnostic variables and treatment success achieved statistical significance.

One can only speculate as to why the results of this series differ substantially from those of other series. Perhaps patient selection accounts for differences, yet Burchiel et al. (17) appeared to discriminate the patients at high risk of failure. Surgical technique could play a role, but there is no evidence on which to base such a statement. In some cases, neuromas are innervated by more than one nerve. For example, proximal resection of the superficial radial nerve to treat dorsoradial wrist neuromas often relieves pain only temporarily. Further inspection reveals that the lateral antebrachial cutaneous nerve also innervates these neuromas, and thus success may require section of this nerve as well (18).

Another reason for failure in neuroma relocation surgery may relate to the discovery that the *distal* side of a severed nerve may also form a neuroma at the site of injury. Plexus formation distal to the neurectomy may allow intact nerve fibers from other nerves to sprout in retrograde fashion to innervate this distal site. This retrograde sprouting may create a potentially painful neuroma on the “wrong” side (19). Neuroma relocation surgery should perhaps therefore attend to neuroma formation on both sides of a severed nerve.

Indications and Results for the Treatment of Nociceptive Pain

Neurectomy may be performed to interrupt the flow of pain signals from a diseased tissue to the spinal cord. In these cases, a balance is sought between elimination of input from the pain-generating tissue and the potential formation of painful neuromas. Following neurectomy, regrowth of the transected nerve and invasion of the diseased tissue by surrounding nerves may result in a return of pain. In addition, progression of the disease process may enlarge the injured region, producing pain beyond the region of surgery. In the following disease processes, neurectomy may be an effective treatment of nociceptive pain:

Axial Spine Pain. The medial branches of dorsal rami innervate the paraspinal muscles, the interspinous ligament, and the zygapophyseal (facet) joints. Pain associated with movement of the lower back, which is relieved by rest and is not attributable to other spine pathology, may be relieved through bilateral, percutaneous radiofrequency or chemical ablation of these branches in the lumbar spine (20,21). In addition, neck pain associated with whiplash injury may benefit from a similar procedure in the cervical spine (22). The mechanism of pain relief is thought to relate to denervation of the facet joint. Since the dorsal ramus innervates several structures, other mechanisms are possible. Diagnostic anesthetic blocks of the facets should precede any denervation procedure. Only patients whose axial pain is not associated with radicular symptoms and who get dramatic pain relief from nerve blocks should be considered candidates for this denervation procedure. Most often, the procedure is performed percutaneously with radiofrequency heat lesions. The advantages of this procedure are that it can be done on an outpatient basis and morbidity is low. The disadvantage is that the procedure often confers only temporary relief or often no relief at all, regardless of the temporary effects of the diagnostic facet blocks. In patients with no prior spine surgery, these procedures have been reported to provide initial relief for 60% to 70% of patients (22,23 and 24). Rates are reported to be considerably lower, 20% to 50%, for patients with prior spine surgery (23,25,26). Our view is that this is a low-morbidity procedure that helps a modest number of patients with axial spine pain. Properly conducted clinical trials have not been reported.

Extremity Joint Pain. Denervation procedures aim to eliminate pain arising from degenerative processes in the joint, while preserving functions that may be lost after other forms of joint surgery. Buck-Gramcko (27) reported retention of wrist mobility with substantial reduction of pain in 69% of patients (135 of 195) following wrist

denervation surgery. Wilhelm reported success in 90% of patients with tennis elbow treated by denervation (28). Dellon et al. reported satisfaction in 86% (60 of 70) of patients following partial denervation surgery for persistent, postoperative knee pain (29).

Pelvic Pain. Neurectomy of the superior hypogastric (presacral) plexus has been advocated as a treatment for medically refractory pelvic pain. In 1948, Ingersoll and Meigs (30) reported complete relief of primary dysmenorrhea in 81% (72 of 89) of women treated with neurectomy. More recently, with the development of more effective analgesics, ablative approaches to pelvic pain have been largely limited to patients with secondary dysmenorrhea associated with endometriosis. Nezhat et al. (31) reported at least 50% relief from pain in 70% to 85% of patients with various stages of endometriosis, with 1-year follow-up, following presacral neurectomy combined with excision and vaporization of endometriotic lesions. The debate over the proper role of presacral neurectomy has been ongoing for well over 50 years; the introduction of the biopsychosocial model of chronic pain has spared many women unnecessary surgery (see Chapter 72).

Pain of Neoplastic Origin. Peripheral neurectomy is infrequently used in the treatment of pain due to cancer. This is due to the availability of alternative strategies with low morbidity and higher success rates, such as spinal opiates. Transecting a peripheral nerve may fail to relieve pain because of overlapping receptive fields of adjacent nerves or central plasticity. Sectioning most peripheral nerves results in not only numbness but also unacceptable motor loss. Peripheral neurectomies are rarely indicated in the extremities. However, localized chest or abdominal wall pain can successfully be treated with intercostal neurectomies; alcohol injection, cryoprobe, or radiofrequency lesions may be just as successful as an open surgical procedure and have less morbidity.

DORSAL RHIZOTOMY AND GANGLIONECTOMY

Rationale for Dorsal Root Surgery

The law of Bell and Magendie states that the dorsal root comprises solely primary afferent fibers while the ventral root comprises efferent fibers. Based on this, dorsal rhizotomy has immediate appeal as a way to block the inflow of nociceptive signals to the spinal cord. Injury to motor fibers in the ventral root is avoided (Fig. 105-1). No neuroma forms at the cut ends of the rootlets, as nerve fibers that enter the spinal cord are deprived of their cell body and hence degenerate (32).

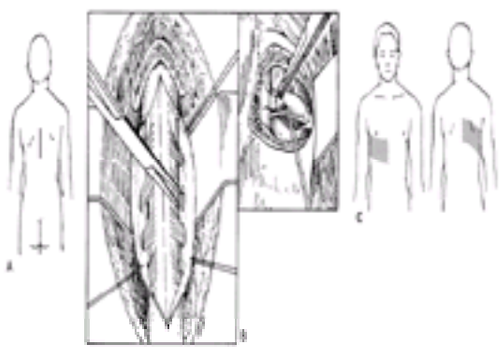

Figure 105-1. Dorsal rhizotomy. **A:** Location of midline dorsal incision for T-4 to T-7 dorsal rhizotomy. **B:** Intradural dorsal rhizotomy with application of metal clip on the rootlets of a root already transected above and being applied to the rootlets of a root below just prior to sectioning them. Inset on the right depicts extradural dorsal rhizotomy showing division of the dorsal root central to the ganglion prior to extirpation of the ganglion by a lesion that will be made just distal to the ganglion. **C:** Expected area of sensory loss following right T-4 to T-7 dorsal rhizotomy.

Traditionally an appealing treatment option for pain, rhizotomy in practice often fails to confer the lasting benefit that one might expect. Early surgeons performed dorsal rhizotomy for a broad range of conditions including stump pain, intercostal neuralgia, angina, visceral pain, and spastic hemiplegia. After comparing operative results for pain with those for spasticity in 1911, Groves (33) remarked, “Strangely enough, the division of the posterior spinal roots has given the least satisfactory results in those very cases where we should have expected it to be the most efficient … the relief of pain.”

An important problem with rhizotomy is that the sensory afferents that arise from a region of the body may provide contributions to multiple spinal nerves. Conversely, fibers from a single spinal nerve may innervate multiple segments of the spinal cord. As a result, sensory dermatomes overlap considerably, so that ablation of a single dorsal root produces little sensory deficit (34). The earliest studies (35,36) of the dermatomes appreciated this complexity, and early surgeons performed rhizotomy at multiple levels to achieve pain control (33). More recently, extensive remodeling of sensory dermatomes, attributed to intraspinal sprouting of dorsal root axons (37), functional reorganization of existing sensory pathways (38), and other mechanisms, has been described. Thus, the finding that patients often fail to derive sustained benefit from dorsal rhizotomy is no longer surprising.

A second problem involves the presence of afferent fibers in the ventral roots. In 1894, Sherrington (39) noted degeneration of fibers on the cord side of a transected ventral root (40). He suggested that these fibers, which he presumed would double back and reenter the cord through the dorsal root, might provide a physiologic basis for the observation that stimulation of the ventral root results in pain. Microscopy has demonstrated that some fibers do in fact enter the cord through ventral roots, cross the ventral horn, and synapse within the dorsal horn or enter the dorsal columns (41). Thus, dorsal rhizotomy may fail ultimately because of the presence of afferents that reach the spinal cord via the ventral root.

To obviate this problem, consideration may be given to performance of a sensory ganglionectomy. The cell body for all primary afferents is believed to reside in the dorsal root ganglion regardless of whether the fibers reach the spinal cord via the dorsal or ventral roots. One report cites a patient with recurrent pain following dorsal rhizotomy that experienced enduring pain relief following removal of the dorsal root ganglia at the same level, providing further evidence that afferents concerned with pain may enter the spinal cord through ventral roots (42). However, including ganglionectomy in a dorsal rhizotomy has not been demonstrated to yield better long-term results.

Clinical Considerations

Preoperative Evaluation

Identification of spinal levels appropriate for ablative lesions of nerve roots is accomplished through paravertebral local anesthetic nerve blocks. To predict most accurately the expected improvement with rhizotomy or ganglionectomy, local anesthetic blocks should be performed with placebo controls and at multiple levels.

Although rhizotomies are now done infrequently for pain, some patients in fact have enduring pain relief from rhizotomy or ganglionectomy, with acceptable morbidity. The challenge clinically is to pick the patients. Feasibility dictates selection of procedures to some extent. If the clinical problem is limited to one root, ganglionectomy has appeal in order to avoid the problem of ventral root afferents. Unfortunately, surgical ganglionectomy involves destruction of a substantial portion of the facet and therefore may not be practical if two or more roots are involved. Rhizotomy may be considered in this instance. However, the problem of pain recurrence may be higher. No clinical studies really compare rhizotomy and ganglionectomy. Thus, differences in outcome between the two procedures are not well understood.

Dorsal rhizotomy and sensory ganglionectomy spare motor efferents and do not lead to the formation of neuromas. However, careful attention must be given to the potential complications of dorsal root surgery. Ablations of the dorsal roots attenuate not only pain but also vibratory, temperature, and proprioceptive inputs. Loss of these sensory functions may be troublesome, particularly in the extremities. In addition, with the ablation of the highly vascularized dorsal roots, the blood supply to the spinal cord can be jeopardized. Ablation of more than six dorsal roots increases this risk considerably (34). Finally, dorsal rhizotomy and ganglionectomy, if unsuccessful, preclude the use of dorsal column stimulation as a means of pain treatment, because the primary afferents, on which the stimulator acts, undergo wallerian degeneration.

The following case presents the evaluation and treatment of a patient with neuropathic pain, in an ideal setting for performance of a ganglionectomy:

> A 42-year-old woman underwent an anterior cervical diskectomy and fusion with harvesting of a bone graft from the left iliac crest. An anterior abdominal

wall hernia developed at the site at which the bone was harvested. This defect was repaired with mesh, and the patient developed severe pain at the repair site. Eventually the repair site was explored, and injury to the subcostal nerve (T-12) was noted. The neuroma was resected back and relocated to a healthy muscular bed away from scar. Pain was relieved for several weeks and then returned. An additional attempt at neuroma relocation surgery met with the same fate. Opioid treatments as well as other pharmacologic approaches failed to provide satisfactory relief. Nerve root blocks of T- 12 but not of T-11 or L-1 led to complete pain relief. A ganglionectomy was performed at T-12, and the patient had sustained pain relief.

In this case, pain was limited to a single, clearly defined spinal level. The return of pain following neurectomy demonstrated the high likelihood of reformation of a painful neuroma. A single ganglionectomy both eliminated the pain and precluded the reformation of a painful neuroma.

Indications and Results for Rhizotomy in Cancer Pain

Indications for dorsal rhizotomy may be broadly divided into procedures for cancer and noncancer pain (43). Barrash and Leavens (44) reported success in 70% (50 of 71) of patients with cancer, with 10.5-month average follow-up. By contrast, Onofrio and Campa (45) reported an overall success rate of 41% (46 of 112) in patients with localized idiopathic pain. The differences in success rate between cancer and noncancer pain may result from earlier mortality among patients with cancer-related pain. Average results as derived from the literature are contained in Table 105-1.

Disease	Approximate no. of reported cases	Approximate long-term relief (% of total cases)
Occipital neuralgia	60	50
Cervicothoracic lumbar neuralgias	120	60
Postherpetic neuralgia	20	25
Failed lumbar disk	200	33[a]
Coccygodynia	70	60
Cancer	600	50

[a]Range: 10% to 86%.

TABLE 105-1. Average results reported with dorsal rhizotomy

Cranial and Cervical Pain. Rhizotomy of C-1 to C-4 in combination with cranial nerves V, IX, and X may provide effective pain relief from extensive head and neck cancers (46). In considering such a procedure, one would have to consider the morbidity of such an extensive operation in terms of sensory loss. In some cancer victims, however, sensory loss is already extensive. Dorsal cervical rhizotomy may also be combined with trigeminal tractotomy. Cancers of the lung or breast with brachial plexus involvement, with loss of function in the upper limb, may also benefit from cervical rhizotomy.

Thoracic Pain. Pain associated with cancers of the lung and breast with extension into the chest wall may benefit from dorsal rhizotomy. Arbit et al. (47) reported complete pain relief in 64% (nine of 14) and 50% to 100% pain relief in an additional 29% (four of 14) of patients with cancer pain, with 22-month median follow-up, following thoracic dorsal and ventral rhizotomy.

Sacral Pain. Cancers of the colon, rectum, urinary tract, cervix, and prostate may result in pain attributable to sacral roots. Ablation of the second and third sacral roots may affect bladder, sphincter, and sexual function. Saris et al. (48) reported success in 47% (7 of 15) of patients with colorectal cancer presenting with perianal pain, with 1-year median follow-up, following bilateral S-3 to S-5 rhizotomy. Felsoory and Crue (49) reported satisfactory results in 69% (20 of 29) of patients with colorectal (17), cervical (five), anal (three), and other (three) cancers, with unstated follow-up duration, following transection of the cauda equina at L-5/S-1. Sacral root division in cases where patients have already lost bladder and bowel function is a simple procedure that may confer striking benefit. The surgical anatomy is depicted in Figure 105-2.

Figure 105-2. Technique of extradural sacral rhizotomy. An S-1 laminectomy is performed, and thecal sac is dissected out circumferentially between S-2 and S-3, doubly ligated, and divided. (From Burchiel KJ. Neurosurgical procedures of the peripheral nerves. In: North RB, Levy RM, eds. *Neurosurgical management of pain.* New York: Springer-Verlag, 1997:148, with permission.)

Indications and Results for Rhizotomy in Noncancer Pain

Occipital Neuralgia. The greater occipital nerve, formed by the posterior primary ramus of C-2, and the lesser occipital nerve, formed by the C-2 and C-3 roots in the cervical plexus, jointly innervate the occipital region of the scalp. Occipital neuralgia is headache, characterized by severe paroxysmal lancinating or continuous pain, localized to this innervated region (50). Occipital neuralgia may be due to migraine, compression of the C-2 root, entrapment of the greater occipital nerve at the superior nuchal line, or nerve injury (51). Onofrio and Campa (45) reported relief from occipital neuralgia in 64% (nine of 14) immediately and 50% (seven of 14) after months to years following ablation of one to three cervical roots. Dubuisson (52) reported success in 71% (ten of 14) of patients, with 33-month average follow-up, following partial posterior rhizotomy at C-1 to C-3.

Extremity Pain. There are few indications for use of rhizotomy and/or ganglionectomy for the treatment of extremity pain, except possibly for monoradiculopathies as noted below. The fact that multiple roots may be involved, the morbidity of sensory loss, and the problem of frequent pain recurrence mean that these procedures are infrequently used for extremity pain. The choice of rhizotomy or ganglionectomy for the treatment of extremity pain requires a balance between (a) compromise of function due to elimination of sensation and (b) the elimination of pain. For the upper extremity, White and Kjellberg (34) reported successful treatment of diffuse upper extremity pain in 50% (seven of 14) of patients, with 3-year median follow-up, following rhizotomy at various levels. Following the procedure, none of the patients complained of unpleasant numbness or clumsiness of the hand, perhaps reflecting the seriousness of the preoperative condition. In the lower extremity, White and Kjellberg (34) reported successful treatment of lateral femoral cutaneous neuralgia in 67% (four of six) of patients, with 3-year median follow-up, following L-2 to L-3 rhizotomy.

Postsurgical Truncal Pain. Persistent pain following thoracotomy or laparotomy may be responsive to dorsal rhizotomy. White and Kjellberg (34) reported successful treatment of intercostal neuralgia in 75% (three of four) of patients, with 8-month median follow-up, following thoracic rhizotomy. Loeser (43) reported success in 33% (one of three) of patients at more than 3 months. By contrast, Onofrio and Campa (45) reported on 18 patients with postthoracotomy pain and five patients with postlaparotomy pain, none of whom obtained benefit. White and Kjellberg (34) also reported successful treatment of postherniorrhaphy neuralgia in 75% (three of

four) of patients, with 2-year median follow-up, following thoracolumbar rhizotomy. There is no large series of patients on which to base a useful discussion.

Visceral Pain. Though rarely used today, due to the advent of other techniques, dorsal rhizotomy has been reported to be highly effective in controlling visceral pain. White and Kjellberg (34) reported successful treatment of medically intractable angina in 75% (three of four) of patients, with 14-month median follow-up, following T-1 to T-4 rhizotomy. Success was 50% (three of six) for treatment of other forms of visceral pain (34).

Low Back Pain. Local and radicular pain due to lumbar spine disease is largely unresponsive, in the longer term, to dorsal rhizotomy. Loeser (43) reported success in 75% (12 of 16) at up to 3 months but only 14% (two of 14) at more than 3 months for patients with disk disease. Onofrio and Campa (45) reported improvement in 17% (11 of 64) of patients with lumbosacral pain following rhizotomy, with unstated follow-up. Wetzel et al. (53) reported success in 55% (28 of 51) at up to 6 months and 19% (seven of 37) at 2 years for patients with lumbar radiculopathy after lumbar surgery.

Postherpetic Neuralgia. Dermatomal pain following herpetic infection responds poorly to dorsal rhizotomy. Loeser (43) reported failure in two of two patients. Onofrio and Campa (45) reported success in only 20% (one of five) of patients, with 5-year follow up, following unilateral rhizotomy. The treatment of postherpetic neuralgia is discussed in Chapter 22.

Indications and Results for Ganglionectomy

Several series consider the efficacy of ganglionectomy and are worth noting. Stechison and Mullin (54) reported success in 100% (four of four) of patients with idiopathic greater occipital neuralgia, with 2-year average follow-up. Lozano et al. (55) reported that patients with occipital neuropathic pain due to trauma are more likely to experience significant pain reduction, following C-2 ganglionectomy, than other patient groups with occipital pain. Smith (56) reported success in 100% (ten of ten) of patients with intercostal pain due to thoracotomy (seven), herpes zoster (two), and cancer (one), following thoracic ganglionectomy. North et al. (57) reported greater than 50% relief from failed back surgery syndrome in none of the 13 patients they studied, with 5.5-year average follow-up. By contrast, Taub et al. (58) reported success in 59% (36 of 61) of patients with intractable monoradicular sciatica following dorsal root ganglionectomy, with 5 to 9 years' median follow-up. This unusually high rate of success likely reflects very careful patient selection.

Conclusions

There is little evidence in favor of ganglionectomy over dorsal rhizotomy and a wide variation in reported outcomes with either procedure for any diagnosis. Some patients do obtain long-term benefits, but prediction of outcome has been perilous.

SYMPATHECTOMY

Basic Considerations

Sympathetic efferents reach their target structures in two steps (see Chapter 8). Preganglionic sympathetic efferents arise in the intermediolateral cell column of the spinal cord at T-1 to L-3. Thinly myelinated fibers emerge in the ventral roots and transit briefly through the spinal nerve before exiting to form the white rami communicantes, leading to the paravertebral sympathetic ganglia. Some preganglionic fibers form synapses in the sympathetic chain with postganglionic neurons, from which unmyelinated fibers return to the spinal nerves, forming the gray rami communicantes. These postganglionic efferents provide sympathetic innervation to blood vessels, sweat glands, and other structures. Other preganglionic fibers pass through the paravertebral sympathetic chain without forming synapses and continue to the prevertebral ganglia. In the prevertebral ganglia, these efferents synapse with postganglionic effector neurons. From the prevertebral ganglia, unmyelinated fibers innervate the abdominal and pelvic viscera. Sympathectomy has been used in the treatment of pain from the limbs, the heart, and abdominal viscera. Presacral neurectomy and thoracic sympathectomy for cardiac pain are discussed earlier in this chapter and are not further addressed here.

There are three distinct mechanisms through which ablation of sympathetic nerves or ganglia may lead to pain relief:

- The sympathetic efferents in T-1 to L-3 that pass through the paravertebral sympathetic ganglia to the abdominal and pelvic viscera do not travel alone. They are accompanied by afferents, with cell bodies in the dorsal root ganglia of T-1 to L-3, which convey sensory information about distension and inflammation of visceral organs to the central nervous system. As a result of this colocalization, ablation of the prevertebral ganglia (or the nerves originating from them) interrupts the flow of nociceptive signals from visceral structures to the brain, thereby producing pain relief. Hence, as a treatment of visceral pain, sympathectomy is a form of sensory neurectomy.
- Sympathectomy may improve pain associated with ischemia. Sympathetic efferents maintain arterial tone. In vasospastic and vasoocclusive conditions, the vasodilation consequent to sympathectomy may ameliorate ischemia, thereby decreasing pain (59).
- Finally, sympathectomy may eliminate norepinephrine-mediated activation of nociceptors and thereby relieve SMP. In this section, we concentrate on this latter mechanism and extremity pain related to complex regional pain syndromes in which a component of pain has been demonstrated to be sympathetically maintained.

Sympathetically Maintained Pain

In some patients with chronic pain syndromes, the pain depends on the activity of sympathetic efferents in the painful area. This pain, termed *sympathetically maintained pain* (SMP), is defined as that aspect of pain that is relieved by blockade of sympathetic efferents (60). Pain that is unaffected by the activity of sympathetic efferents is termed *sympathetically independent pain*. The diagnosis of SMP is empiric. In any pain syndrome, a portion may be sympathetically maintained, while another part is sympathetically independent. Most notably, complex regional pain syndrome (Chapter 20) and other neuropathic conditions may or may not be associated with SMP.

SMP cannot be diagnosed purely from the history and the physical examination of the patient (61). However, a number of clinical features are helpful: (a) In general, SMP does not occur in places other than the extremities or the face. As a rule, the likelihood of developing SMP parallels the density of sympathetic innervation of the skin. Hence, truncal pain is far less likely to be due to SMP than is extremity pain. (b) Signs that may be inferred to represent increased sympathetic activity in the painful area do not denote the presence of SMP (62). For example, limbs associated with SMP may be warmer, cooler, or the same temperature as unaffected limbs. Similarly, differences in sweating, nail growth, and muscle tone do not contribute to the diagnosis of SMP (3). We have found that among patients with traumatic nerve or soft tissue injury with touch-evoked pain, all patients with SMP and 50% of patients with sympathetically independent pain have striking sensitivity to mild cooling stimuli (63,64).

In recent years, understanding of the pathophysiologic mechanisms underlying SMP has advanced significantly. By definition, SMP is eliminated by blockade of sympathetic efferent innervation of the painful area. Thus, an anesthetic block of the relevant sympathetic ganglia relieves pain in patients with SMP. Walker and Nulson (65) and White and Sweet (10) observed that stimulation of the sympathetic chain evokes pain in patients with SMP but not in those without SMP. Moreover, Walker and Nulson (65) noted that stimulation of the severed distal end of the sympathetic chain evokes pain in those diagnosed with SMP but not in other patients. Thus, the central connections of sympathetic efferent fibers are not required for stimulation of the sympathetic system to evoke pain. These observations establish that efferent sympathetic fibers, rather than afferent sensory fibers that may travel with the sympathetic fibers, account for SMP.

Three independent lines of evidence suggest that norepinephrine released from sympathetic fibers is critical in SMP. First, the regional infusion of guanethidine relieves pain in patients with SMP (66). Guanethidine is thought to act by depleting norepinephrine from sympathetic terminals. Second, in patients whose pain had been relieved by either sympathetic block or sympathectomy, an intracutaneous injection of norepinephrine into the previously painful area rekindles the pain and hyperalgesia. However, norepinephrine injected intracutaneously into normal subjects induces less pain and less hyperalgesia (67,68). Finally, administration of sympathetic a-adrenergic antagonists, such as prazosin (69), phenoxybenzamine (70), or phentolamine (71,72), relieves SMP.

Following nerve injury, the neuromas that form may acquire sensitivity to norepinephrine. As evidence in support of this hypothesis, injection of pH-balanced norepinephrine solution into normal subcutaneous tissues causes little pain. However, injection of norepinephrine onto painful neuromas does induce pain (73). Thus, nerve injury may be associated with SMP.

These observations suggest that an abnormal increase in the amount of norepinephrine released from sympathetic terminals is not likely the mechanism of SMP. Rather, it is the response to norepinephrine that appears to be critical in SMP. Whether this change is due to an upregulation of a-adrenergic receptors or increased

receptor sensitivity is unknown.

Clinical Considerations

Preoperative Evaluation

The most likely cause of poor pain relief after surgical sympathectomy is inadequate patient selection. Thus, preoperative evaluation is of great importance.

Quantitative Sensory Testing. Patients with SMP have hyperalgesia to a mild cooling stimulus, such as a drop of acetone placed on the skin. Our group and others have found that essentially all patients with SMP have cooling hyperalgesia (61,63,64). In fact, patients with SMP often spontaneously volunteer that the one stimulus that they most dread is cooling of the painful area. Cooling hyperalgesia occurs less frequently in patients with sympathetically independent pain. This suggests that cooling hyperalgesia is a highly sensitive, though not specific, indicator of SMP.

Local Anesthetic Sympathetic Ganglion Blocks. The traditional procedure to diagnose SMP is percutaneous injection of local anesthetic onto the sympathetic ganglia serving the painful region. In local anesthetic sympathetic ganglion blocks (LASB), ganglia are localized through anatomic landmarks, ideally under fluoroscopic guidance, and local anesthetic is injected into the region. The presence of local anesthetic at the ganglia prevents norepinephrine from being released into the peripheral tissues. Though frequently used to diagnose SMP, LASB results must be interpreted with care: (1) Incomplete block of individual ganglia may falsely underestimate the contribution of SMP to a painful condition. The extent of sympathetic block must be evaluated by assaying for the effects of sympathetic block, such as changes in skin temperature. (2) Spread of local anesthetic onto somatic afferents in the nerve roots, or blockade of sensory afferents that accompany sympathetic efferents, may induce pain relief by way of somatic block rather than sympathetic block. A careful sensory examination must be performed to ensure that somatic afferents are not affected by the injection of local anesthetic. (3) LASB may evoke a placebo response, causing overestimation of pain relief. In addition to these interpretive issues, LASB has some risk. Complications that have been reported with LASB include pneumothorax, phrenic and laryngeal nerve block, cardiac arrhythmia, kidney injury, hemorrhage, and inadvertent intravascular or epidural injections (see Chapter 102).

Systemic Phentolamine Infusion. An alternative strategy to assess the potential efficacy of sympathectomy involves the intravenous infusion of phentolamine, a short-acting antagonist of a-adrenergic receptors (71,72). There is good correlation between pain relief with LASB and that with systemic phentolamine infusion (SPI) (61,71). As a systemic infusion, phentolamine does not provide any information about anatomic localization, as is available with LASB. However, SPI has a number of advantages over LASB: (1) The test is painless in that the phentolamine is delivered systemically and does not require fluoroscopy or needles to be placed in the paravertebral space. (2) With SPI, a significant observation period can be used prior to the administration of the drug, and the patient can be blinded to the time of drug administration, allowing a placebo-control period in every trial. (3) SPI appears to be safer than LASB, with only nasal stuffiness and peripheral vasodilation reported as side effects (61,74). Furthermore, because the activity of nearby sensory afferents is preserved, SPI appears to be a more specific diagnostic test for SMP (61,71).

Intravenous Regional Block (IRB). A third method to detect SMP involves regional intravenous infusion of an agent that impedes peripheral release of norepinephrine (66). Such agents include bretylium, reserpine, and guanethidine (64). To avoid systemic circulation of the sympatholytic agent, a tourniquet is applied to the limb during the test. The central advantage of intravenous regional block (IRB) is localization of sympathetic block to the limb of interest. However, there are shortcomings: (1) Certain patients poorly tolerate the required tourniquet application. (2) The dramatic release of sympathetic neurotransmitter accompanying infusion of guanethidine in SMP patients may be severely painful. (3) The blocking agent may leak beyond the tourniquet, in some instances, with significant hemodynamic effects. (4) The need for a tourniquet makes IRB difficult to perform either in the trunk or in the lower extremity. (5) It is difficult to evaluate placebo responses with IRB. Though frequently mentioned as a means to diagnose and treat SMP, we believe that IRB has few advantages. The same degree of a-receptor blockade can be achieved with systemic phentolamine.

Medical Treatment of Sympathetically Maintained Pain

Once the diagnosis of SMP is made, the mainstay of treatment is operative or medical sympatholysis. A remarkable feature of SMP is that extended sympathetic blockade may lead to long-term or permanent relief from the disorder. When the goal of blockade is diagnosis, the diagnostic technique should be specific to the sympathetic nervous system. By contrast, when the goal is treatment, there need not be specificity. There are several medical and interventional means by which to achieve sympatholysis. The choice of technique should be based on considerations of safety, comfort, and efficacy. Multiple sympathetic ganglion blocks with local anesthetics have, in the past, served as the gold standard treatment. However, local anesthetic treatment of peripheral nerves may work as well, by inducing similar blockade of the distal sympathetic fibers. For example, SMP in the upper extremity could be treated either by LASB of the thoracic sympathetic ganglia or by local anesthetic application to the appropriate nerves. Alternatively, while epidural administration of anesthetic may lack specificity as a means to diagnose SMP, it may provide an effective treatment regimen. SPI has been used successfully to treat SMP in a patient with pain in all extremities due to Sjogren's associated polyneuropathy (75). When episodic treatments fail to provide adequate relief, chronic treatment with oral sympatholytics may reduce SMP. Both phenoxybenzamine and prazosin have been used in this regard (69,70). However, the systemic hypotension that frequently accompanies the use of these agents may preclude adequate sympathetic blockade. Finally, topical clonidine, which is likely to inhibit local norepinephrine release, may be a low-morbidity treatment of SMP in some patients (67). If well tolerated, this and other medical techniques could substantially reduce the need for surgical sympathectomy.

Operative Techniques

To achieve sympathectomy of the upper extremity it is necessary to resect the T-2 and the T-3 and T-4 sympathetic ganglia. Removal of less than all three ganglia risks inadequate sympathectomy for pain. One of our patients required extension of the sympathectomy to T-5. This is best achieved through a thoracoendoscopic technique, although all of the data on this operation have been acquired through open supraclavicular transaxillary or posterior costotransversectomy approaches. By contrast, the lumbar sympathetic chain is generally accessed through an anterolateral retroperitoneal surgical approach. Percutaneous approaches have been suggested, but these procedures often do not achieve enduring results. In addition, the addition of scarring by these approaches makes later surgical treatment more difficult.

Many clinicians have reported limited success in the treatment of pain with surgical sympathectomy (76,77). Failures of sympathectomy may reflect inadequacies either of the preoperative evaluation, as discussed above, or of the extent of the sympathectomy. For example, sympathetic outflow to the arm derives predominantly from the T-2 and T-3 ganglia and not from the stellate ganglion. Failure to remove the T-2 ganglion, at a minimum, will result in continued sympathetic innervation of the hand. An important feature in the lower extremity is that sympathetic innervation is often bilateral. Bilateral lumbar sympathectomy of L-2 to L-4 is typically necessary (Fig. 105-3). A typical history is that a patient will have impressive relief of pain that will last several weeks, following an ipsilateral lumbar sympathectomy. The pain then returns, and now this pain is relieved by a contralateral block of the lumbar sympathetic ganglia. Patients will typically have enduring relief of pain following contralateral lumbar sympathectomy (78,79). As in the upper extremity, complete sympathectomy is required for pain relief; the partial denervation that is successful for vascular diseases is not adequate as a treatment for pain.

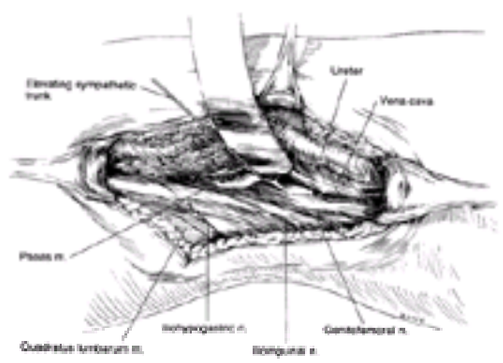

Figure 105-3. Open lumbar sympathectomy is done through retroperitoneal exposure of the sympathetic chain. (From Wilkinson HA. Neurosurgical procedures of the sympathetic nervous system. In: North RB, Levy RM, eds. *Neurosurgical management of pain.* New York: Springer-Verlag, 1997:170, with permission.)

Results of Sympathectomy for the Treatment of Pain

Ulmer and Mayfield (80) reported successful treatment of 96% (67 of 70) of soldiers with burning pain due to nerve injury by surgical sympathectomy of appropriate ganglia. In studies of a civilian population, Manart et al. (81) reported a “good” response to thoracic sympathectomy in 59% (13 of 22) of patients with burning posttraumatic pain, even when diagnostic blockades were not typically performed. For patients selected for preoperative diagnostic sympathetic block, Mockus et al. (82) reported improvement in 94% (29 of 31) of patients, with 3.4 years' average follow-up. Thompson (83) reported successful surgical treatment in 46% (55 of 120) of patients with SMP following minor trauma who were unresponsive to medical therapy.

As noted, results of sympathectomy largely depend on how carefully patients are selected (70). Our experience has been that patients do exceedingly well if the pain responds dramatically to sympathetic ganglion block and systemic infusion of phentolamine and there is provocation of pain with injection of norepinephrine when the patient is under the influence of an LASB. Though our conclusions are preliminary, it appears that if one or more of these elements is missing, the patient does less well. The modest response rates to sympathectomy in other series may reflect improper patient selection and inadequate sympathectomy (e.g., bilateral sympathectomy required for lower extremity pain) or more extensive unilateral ganglionectomy for total denervation of an extremity.

Postoperative Complications

Surgical sympathectomy may be associated occasionally with idiosyncratic complications. The most frequent complication, affecting 20% to 50% of patients, is postsympathectomy pain (or postsympathectomy neuralgia) (82,84,85). This condition is characterized by the sudden onset, a few weeks after the procedure, of superficial burning pain, deep aching pain, and cutaneous hyperalgesia (86). The pain arises in the *proximal* regions of limbs and the trunk, despite surgical ablation of sympathetic innervation to the *distal* limbs. Fortunately for most patients, postsympathectomy pain resolves spontaneously in several weeks to a few months and no further surgical intervention is warranted (84).

Ablation of sympathetic input to a region of skin results in sudomotor paralysis. In the upper extremity, the resultant dryness can be uncomfortable. In the lower extremity, dryness is better tolerated. Postural hypotension also can be a transient problem. However, even in patients with sympathectomy of all four extremities, this problem is usually not enduring.

Two additional complications of sympathectomy include paradoxical vasoconstriction and ileus. Sympathetic fibers arising from the celiac and mesenteric ganglia modulate gastrointestinal motility. Both complications are generally transient.

CONCLUSIONS

Ablative surgical procedures have a significant role in the treatment of a variety of painful conditions. Like many surgical procedures, enthusiasm for these techniques must be tempered by a keen appreciation of the potential complications. Nerve transection may induce pain, for example, and may dramatically relieve pain. This leaves to the clinician the sometimes daunting task of deciding if, when, and how to perform neurectomy. Each patient must be carefully evaluated. In the case of minor nerves previously transected, the clinician should not labor over the decision to relocate the neuroma to a protected, unscarred site. In this instance there is little to lose. Dorsal rhizotomy is seldom used in modern practice, but a survey of the existing literature reveals that patients certainly exist in whom rhizotomy conferred long-term benefit. Today's pain clinician does well to keep this option in mind in properly selected cases. Ganglionectomy has certain theoretical advantages over rhizotomy and neurectomy and is still another technique that should be considered in certain cases. Sympathectomy is helpful in patients with persistent SMP who are refractory to medical management. The key to success with this procedure, as with most surgery, is meticulous patient selection and proper execution of the operation.

CHAPTER 106

Neurosurgical Operations on the Spinal Cord

Jason E. Garber and Samuel J. Hassenbusch

This chapter discusses various neurosurgical operations carried out on the spinal cord for the relief of chronic pain. Three major procedures are presented: anterolateral cordotomy, myelotomy, and dorsal root entry zone (DREZ) lesions. These ablative spinal procedures, as expected, occupy roles that are intermediates between the intracranial brainstem ablations and peripheral nerve lesions. The risks of the spinal procedures for pain are generally lower than with intracranial procedures, but they have a more restricted pattern of anatomic coverage. Peripheral denervations are technically easier to perform but often affect only a very limited anatomic area and have a higher chance of pain recurrence. Each procedure is discussed in terms of indications and contraindications, but the actual selection of an operation for a specific patient should be based on the type of pain (e.g., nociceptive, neuropathic, or visceral), the location of the pain, and the cause of the pain (e.g., cancer vs. noncancer).

The role of these intraspinal procedures is at the bottom of a long treatment continuum that includes (a) systemic treatments, such as various medications or physical therapy; (b) direct operations, such as spinal stabilization or surgical decompression; (c) thorough psychological evaluation and treatment as appropriate; (d) chemotherapy and/or radiotherapy (for cancer patients); and (e) regional anesthetics and opioids.

ANTEROLATERAL CORDOTOMY

Anterolateral cordotomy is an operative procedure in which the spinal anterolateral ascending system for the transmission of nociception, known as the *spinothalamic tract*, is interrupted for the relief of pain. Both percutaneous and open surgical techniques are available; the anatomic goal is the same, and results differ only with respect to the risks of each approach and to long-term results. Cordotomy is an example of an older procedure that has found increased use because of the development of a percutaneous technique. Computed tomographic (CT) guidance has led to even greater safety and efficacy.

The concept of relieving pain by section of the pain-conducting pathways in the anterolateral quadrant of the spinal cord was first proposed by Schuller (1) in 1910 based on observed deficits from spinal cord lesions in the anterolateral quadrant. It was not until 2 years later, however, that Martin (2), at the urging of Spiller, performed the initial thoracic cordotomy in a patient with pain from a tuberculoma. Stookey (3) was the first to report successful high cervical unilateral and bilateral cordotomy for severe pain. Foerster and Gagel (4) reported similar unilateral procedures a year later.

To avoid or minimize the risks of open surgery, a percutaneous stereotaxic procedure was advanced by Mullan and associates (5,6). This percutaneous method could be accomplished under local anesthesia simply, easily, and with a low morbidity rate in patients who otherwise might not be suitable for a major open operation.

The initial method for percutaneous cordotomy used a radiostrontium-tipped needle that was inserted into the spine at the C-1 to C-2 interspace laterally and came to lie anterolaterally in the subarachnoid space adjacent to the ventral quadrant of the spinal cord. The next approach introduced a wire electrode into the parenchyma of the spinal cord so that anodal current could be used to create the lesion in the ventral quadrant. In 1965, Rosomoff and associates (7) proposed a technique using a radiofrequency (RF) current to produce the lesion, which allowed rapid and solid lesion-making. Electrophysiologic monitoring of electrode position by electrical impedance and electrical stimulation were described by Gildenberg and associates (8) and by Hitchcock and Tsukamoto (9) and Tasker and Organ (10), respectively. The technique has become standard with the use of myelography to confirm spinal cord and dentate ligament position (11). CT guidance has added another level of accuracy to this procedure (12) (Table 106-1). Two other approaches (low anterior cervical “through-the-disk” and occipital to C-1 dorsal cervical) have also been described but have never been widely used (13,17). After discussing the percutaneous technique, including CT-guided electrode placement, the open operation is briefly considered.

Source	Technique	Comments or modifications
Mullan et al. (5)	Isotope needle; lateral cervical	Unpredictable, radiation risk, complex to prepare
Mullan et al. (6)	Unipolar electrode; lateral cervical	Erratic lesion, prolonged current time, unpredictable
Rosomoff et al. (7)	Radiofrequency current; bilateral or unilateral cervical	Rapid, solid lesion, portable, predictable
Crue et al. (13)	Radiofrequency; high cervical	Posterior approach, traverses spinal cord, higher levels (?)
Fox (14)	Radiofrequency	Current related to lesion size
Gildenberg et al. (15,16); Lin et al. (17)	Radiofrequency; low cervical, transdiskal	Anterior approach, decrease respiratory complications (?), more difficult technically, impedance measurements, increased safety
Hitchcock (18)	Radiofrequency; high cervical	Posterior approach, traverses spinal cord, higher levels (?)
Tasker et al. (19); Tasker and Organ (20)	Radiofrequency; lateral cervical	Physiologic identification of target site
Todd et al. (21)	Radiofrequency; high cervical, medulla	Posterior approach, useful for somatic and facial pain
Mullan (22)	Radiofrequency; lateral cervical	Electrical stimulation to identify tract, increased safety
Kanpolat et al. (23)	Radiofrequency; lateral cervical	Computed tomographic guidance for trajectory, min trials

TABLE 106-1. Developments in percutaneous cordotomy

Basic Considerations

The anatomy and physiology of the spinothalamic and other important ascending tracts in the anterolateral quadrant of the spinal cord that transmit nociceptive information are discussed in detail in Chapter 4. Important additional insights into the mechanism of action for this procedure have suggested that it interrupts more than just C fibers since pain relief correlates best with lessened sensation of cutaneous pinching and skin cooling (24). A diminished blood flow in the contralateral thalamus but not in cerebral cortex has also been demonstrated after cordotomy by positron emission tomography (25).

Indications

The optimal candidate for this operation should have unilateral severe pain, not adequately treated by other less invasive methods. As for neuropathic pain, cordotomy appears to be more effective in the treatment of intermittent shooting pain and evoked pain (i.e., allodynia and hyperpathia) rather than distressing dysesthesias, such as steady, burning, prickling, aching, or crawling (26). The former is mediated by the lateral spinothalamic tract, and ventrolateral cordotomy alleviates pain in more than 85% of patients. The latter is not transmitted entirely through the ventral quadrant, and these discomforts are relieved imperfectly or not at

all. Tabetic or pseudotabetic pain, although it has a dysesthetic quality, seems to respond well to cordotomy.

Anatomically, the procedure is indicated for pain in C-5 or lower dermatomes, preferably unilateral. It is almost entirely used for patients with pain from cancer, including those who previously could not be subjected to the major operation of laminectomy and spinothalamic section because of debilitation or a preterminal state. It is increasingly rare to use cordotomy to treat painful conditions that are intractable and nonmalignant in nature, although some argument can be made for use in the treatment of nociceptive pain, albeit of noncancer origin (27). When bilateral cordotomy is required, the contralateral procedure can be performed as a second stage no less than 1 week after the first.

Contraindications

Severe pulmonary dysfunction is the major contraindication to either percutaneous or open surgical cordotomy. The absence of a lung, *per se*, does not interdict the procedure, provided remaining pulmonary function is satisfactory. The site of concern is the reticulospinal tract, located near the spinothalamic tract and critical for automatic or unconscious breathing. Prior loss or significant decrease in this automatic breathing on the opposite side (e.g., from prior contralateral cordotomy or Pancoast syndrome) can lead to a total loss of unconscious respiration (Ondine's curse).

Recently incurred neurologic deficits, such as paresis or rectal or bladder disturbance, can be aggravated or recovery delayed by the superimposition of cordotomy; if this is the case, the effect is usually temporary. Midline pain is a relative contraindication, even with bilateral cordotomy. General medical contraindications such as a severe bleeding diathesis, unstable cardiac function, and untreated severe systemic infection should also be observed.

Clinical Considerations

Technique

The patient is placed in the supine position with the upper cervical spine horizontal (Fig. 106-1). The patient is given light intravenous sedation during the time of the needle placement prior to physiologic testing for the actual electrode placement. Using local infiltration anesthesia between the first and second cervical vertebrae, a lumbar puncture-cordotomy combination needle is introduced in the side of the neck on the contralateral side to the pain. An image intensifier is used to define the point of dural puncture, just anterior to the point halfway between the posterior and anterior bony margins of the spinal canal.

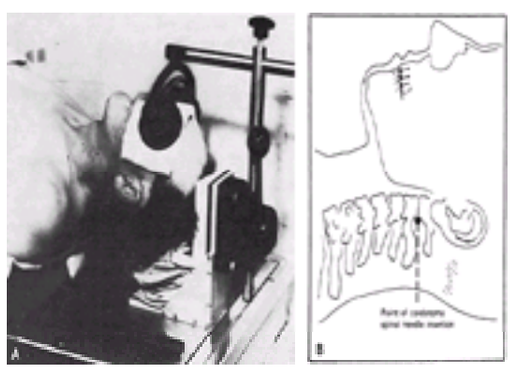

Figure 106-1. **A:** Position of patient for percutaneous C-1 to C-2 cordotomy. **B:** Site of insertion of needle for percutaneous C-1 to C-2 cordotomy.

Once the needle has been introduced into the subarachnoid space of the spinal canal, hyperbaric (heavier than water) contrast medium is injected to visualize the dentate ligament. A special insulated electrode (2-mm exposed metal tip) is inserted through the needle. Using physiologic monitoring (impedance readings), the electrode is directed so that the bare metal tip enters the parenchyma of the spinal cord (Fig. 106-2).

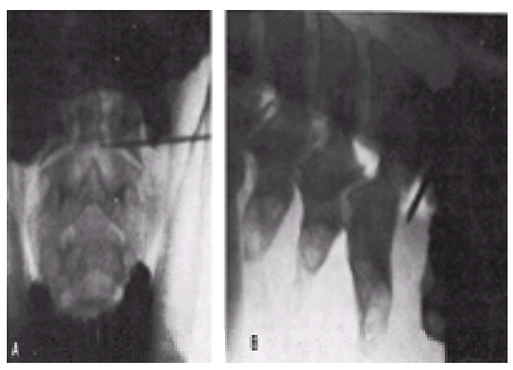

Figure 106-2. Position of needle electrode for percutaneous C-1 to C-2 cordotomy as seen on anteroposterior **(A)** and lateral **(B)** radiographs.

The cable of an RF generator is attached to the electrode, and the electrode tip is stimulated with 2-Hz and 100-Hz current. The patient is closely questioned about sensory changes and motor twitching during each stimulation. Ideally, at 2-Hz, there will be contractions in the ipsilateral neck or upper limb and, at 100-Hz, a sensory experience of contralateral warmth or occasionally cold or paresthesias in the target dermatomes. Spinothalamic evoked potentials have been used to aid in electrode localization (28). In this testing, stimulation is applied to the spinothalamic tract via the cordotomy electrode and recordings are made in the scalp area. Although the recordings correlate with the extent of the lesion, their clinical usefulness remains unclear.

A thermocouple-monitored temperature lesion is made, starting at 50°C and increasing by 5°C to 10°C increments (Fig. 106-3). The patient is tested carefully after each increment, both for the level of analgesia and for the possibility of complications—in particular, ipsilateral hemiparesis. Disturbances in temperature sensation are usually seen as a result of the cordotomy lesions. The location of the loss of temperature sensation, however, can vary significantly from that of the analgesia (29). It is even possible to perform a successful cordotomy without any alteration in temperature sensation.

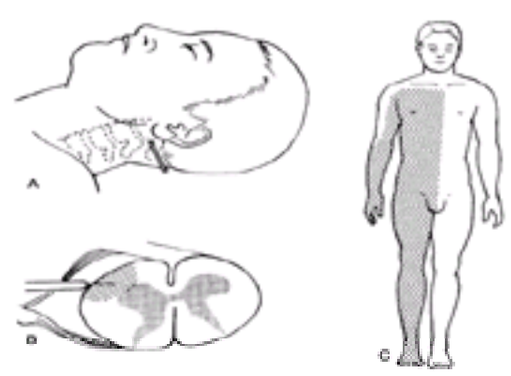

Figure 106-3. **A:** Site of percutaneous C-1 to C-2 cordotomy. **B:** Lesion produced by percutaneous C-1 to C-2 cordotomy. **C:** Extent of analgesia produced by left C-1

to C-2 percutaneous cordotomy.

Postoperative care consists of observation for ipsilateral leg weakness, bladder control changes, significantly lower analgesic requirements, and possible respiratory depression. Because of the degree and rapidity of pain relief, patients should be watched for possible narcotic withdrawal if systemic analgesics are lowered too quickly.

The CT-guided cordotomy technique is similar to the traditional percutaneous method except that the cordotomy electrode needle is inserted with the patient in a CT machine (23). CT images (512 × 512 matrix) with 2-mm slice thickness are used. A special electrode system (KCTE Kit, Radionics Inc., Burlington, MA) is also used to diminish the metallic artifact interference in the CT image (30).

An anterior approach for percutaneous cordotomy has also been described (31). An uninsulated 18-gauge spinal needle is inserted medial to the carotid sheath and lateral to the tracheoesophageal complex until it enters the disk. Using CT axial plane guidance, the needle is directed to the contralateral anterolateral spinal cord quadrant. Once the needle enters the spinal canal, water- soluble contrast dye is injected to delineate the spinal cord. An insulated RF electrode is inserted through the spinal needle and advanced into the spinal cord. The remainder of the procedure is similar to that described above.

Results

In most series, almost all cordotomies have been performed for pain from cancer, often lung or gastrointestinal cancer. Rarely, the procedure has been used in the treatment of lumbar radiculopathy or peripheral neuropathy (32). The target sites are the lower body as opposed to upper body in about two-thirds of patients.

In the hands of experienced surgeons, the spinothalamic tract can be located in 95% to 99% of patients, although the surgeon should not be hesitant to perform an early reoperation if appropriate analgesic levels are not obtained for technical reasons in the first cordotomy (27). “Adequate” levels of pain relief are found in as high as 95% of patients on discharge from the hospital. At last follow-up, however, the success rate can drop to 84% (Table 106-2) (27). Review of other published series suggests long-term success rates of 50% to 75% (Table 106-3). Rosomoff and colleagues (32) have reported that the satisfactory analgesia rates gradually drop over time since the operation: 84% at 3 months, 43% at 1 to 5 years, and then 37% at 5 to 10 years (see Table 106-2). It should be noted, however, that this refers to absolute pain relief. It is estimated that more than 50% of these patients felt they had received major help, could return to routine activities, and did not have problems of drug usage or distress severe enough to undergo repeat cordotomy.

Duration of follow-up	No. of operations	Results (successful)	
		No.	%
3 mo	599	495	84
3 mo to 1 yr	304	185	61
1-5 yr	299	127	43
5–10 yr	86	32	37

TABLE 106-2. Results of percutaneous cordotomy

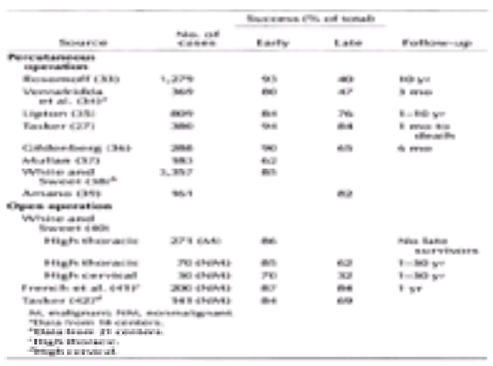

TABLE 106-3. Comparison of results of percutaneous and open cordotomy

Repeat cordotomies can be necessary in 10% to 20% of patients and, despite the prior cordotomy, can usually achieve levels of analgesia to acute testing pain. It appears that true pain relief, however, is captured in only about one-half of these patients undergoing a repeat cordotomy (27,32).

Four major groups account for the vast majority of patients with persistent pain after cordotomy (27). As many as 40% represent untreated neuropathic pain, either unmasked by the operation or as a component of a preoperative mixed nociceptive-neuropathic syndrome. This emphasizes proper patient selection and recognition that the procedure is more effective, in general, for nociceptive rather than neuropathic pain. Where there is apparent failure of pain relief for nociceptive pain, almost one-half are unexplained, but the rest represent inadequate levels of analgesia and early reoperation should be considered. The third group is a very small group (1% to 2%) with new nociceptive pain above the level of analgesia and might represent progression of disease. The last group is a relatively large group (40%) with development of “mirror pain.” This apparently new-onset pain is located ipsilateral to the side of the lesion and has classically been thought to be an “unmasking” of preoperative pain that was eclipsed by the more severe pain on the opposite side. There is other evidence, however, suggesting that ongoing stimuli in the area of the treated, contralateral pain might now trigger pain on the opposite side via some form of new synaptic sprouting in the spinal cord (43). In either event, this mirror pain is generally mild and controlled with significantly lower amounts of analgesics than those used prior to the cordotomy (44).

In the series of Rosomoff and associates (32), almost one-third of patients underwent bilateral cordotomies for pain relief. These were staged operations, at least 1 week apart. Of all patients with malignant disease, 35% required bilateral intervention. Only 30% of those with benign disease required bilateral intervention. The success of the second side appears to be similar to the first side—the major issue here is the complications that are specific to bilateral cordotomies.

Complications

A comprehensive summary of complications from unilateral cordotomy indicates that, in general, the complication rate is low (27) (Table 106-4). The mortality rate can vary between 0.6% and 6.0%, almost always related to respiratory problems. Bowel incontinence and mild worsening of micturition can be seen in up to 2% to 10% of patients—both should be transient. Significant, permanent worsening of bladder function, however, can be seen in 2% to 10% of patients. Although information relative to sexual function is difficult to obtain, it appears that about 4% of men note decreased sensation about the genitals on the analgesic side; true impotence appears to be very rare, even with bilateral cordotomies.

Type of complaint	Temporary		Permanent	
	No.	%	No.	%
Paresis	63	5	34	3
Ataxia	252	20	44	3
Urinary	123	10	29	2
Sexual			54	4
Postcordotomy dysesthetic syndrome			10	1
Respiratory				
Minor	36	3		
Major	23	2	12	1*
Dysesthesias			199	16

*Includes one death.

TABLE 106-4. Complications of 1,279 percutaneous cordotomies

Although a postoperative Horner's syndrome is frequently seen (as often as 75% of patients), it is essentially unavoidable but transient. Many patients complain of transient neck pain, often described as burning or dysesthetic, from the area of the needle puncture. Transient hypotension can also be seen (2% to 8%).

Of more concern is significant permanent weakness or ataxia, usually ipsilateral to the side of the cordotomy (2% to 10%). Ipsilateral weakness/ataxia, which is described as mild or transient, is reported in 3% to as many as 70% of patients. Contralateral limb weakness, presumably from lesioning too deep into the spinal cord, can also occur (1% to 6%).

Respiratory problems after unilateral cordotomy are rare and mild or transient (1% to 5% of patients). Severe respiratory failure can occur in 0.5% to 1.0% of patients but is more often seen as sleep-induced apnea (Ondine's curse) after bilateral cordotomies. The mechanism is related to an ascending system that contributes to the control of ventilation and is mediated through the upper cervical spinal cord (45). It may be delayed in onset, but its presence can be predicted by testing the patient's response to breathing carbon dioxide (46). Ablation of the response, which is normally a two- to threefold increase in minute volume, predicts the appearance of the syndrome, but not all patients go on to apnea. The process is usually self-limiting, lasting a few days to 3 weeks.

Postcordotomy dysesthetic syndromes—that is, burning distress throughout the entire area that was made analgesic—can occur in 1% to 10% of patients. Its pathophysiologic mechanism is unknown. Dysesthesias, in 16%, are noted separately. These sensations (e.g., tingling, burning, prickling in the area of pathologic implication) are not complications *per se*. They are uncomfortable feelings that were usually present preoperatively but were not conspicuous because of overriding pain. Once the pain has been eliminated by the cordotomy, the dysesthesias become discernible and prominent, although they usually take time to develop.

Open Surgical Cordotomy

Since the last edition of this text, the open surgical technique has become mainly of historical interest. The open technique might still be used in some rare circumstances such as in facilities in which percutaneous cordotomy equipment is not available or the surgeon performs it so infrequently as to lose skill in the procedure. However, thoracic cordotomy can be performed for lumbar and sacral pains without jeopardizing upper extremity or respiratory function; thus, it may have more utility than open upper cervical cordotomy. When the patient is unable to tolerate any procedure while awake, a percutaneous cordotomy can be performed under general anesthesia in a manner similar to above except that, of course, sensory testing with 100-Hz stimulation cannot be performed. The indications for the open technique are the same as the percutaneous counterpart.

Technique

Open surgical cordotomy is almost always performed under local anesthesia. High cervical cordotomy is done if levels of analgesia above C-8 are required. It is carried out with the patient in either the sitting or prone position. A lower-level cervical cordotomy can be carried out through an anterior approach with the patient in the supine position.

Thoracic cordotomy and a posterior cordotomy are carried out with the patient in the prone or lateral position (Fig. 106-4). After a midline incision is made, a laminectomy is carried out, which is extended to the facet on the side of the spinal cord to be incised. The dura and the arachnoid are opened, and the dentate ligament is identified. The anterolateral surface of the spinal cord is viewed, and an avascular area is found for the incision. A down-cutting cordotomy knife tip, projecting 6 mm in the cervical area and 4 to 5 mm in the thoracic area, is inserted just ventral to the dentate ligament, pulling the spinal cord onto the knife blade so as to penetrate cleanly. The blade cuts ventrally to transect the ventral quadrant down through the exit of the motor rootlets but spares the medial funiculus. In the thoracic area, if a bilateral cordotomy is required, the second side is sectioned one or two segments below the first cut at the same sitting.

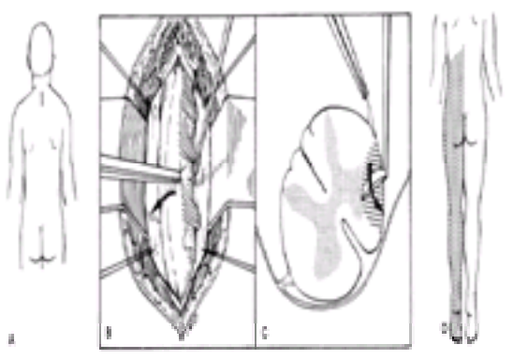

Figure 106-4. **A:** Site of open thoracic cordotomy. **B, C:** Method of performing open thoracic cordotomy. **B:** After T-1 to T-2 laminectomy, the dura is opened and the dentate ligaments sectioned. The linea alba is grasped in a hemostat and the spinal cord is rotated 45 degrees. **C:** A special cordotomy knife is used to section the anterolateral quadrant. **D:** Extent of analgesia on dorsal surface produced by right T-1 to T-2 open cordotomy.

Results and Complications

After open cordotomy, immediate relief was reported in 70% to 90% of patients who had undergone unilateral procedures and in 40% to 78% of those with bilateral procedures. A comparison of results from a sample of the larger series is presented in Table 106-3.

Mortality rates for open cordotomy ranged from 3% for the unilateral procedure to 20% for bilateral procedures. Paresis and urinary complications were high (10% to 20%), especially after bilateral procedures. Respiratory complications were the most common cause of death, but the exact numbers were not listed. Postcordotomy dysesthetic syndromes can occur in 11% of patients. Open surgical cordotomy seems to be less effective and certainly has a higher risk of complication than the percutaneous techniques.

Conclusions

Percutaneous cordotomy is simpler and better tolerated than open surgical techniques. Because the anatomic and physiologic bases for pain relief are the same for all cordotomies, true differences in long-term results might not be discernible. However, such advantages as the ease of performance, significant reduction of risk, and

the literally infinite repeatability make percutaneous cordotomy the procedure of choice.

Percutaneous cordotomy is a valuable procedure for the treatment of severe pain syndromes, especially if they are located in one limb and are nociceptive in quality. With the addition of CT guidance, the technique has become more facile. The risks of the procedure are significant but acceptable for this group of patients, especially those with limited expected survival times from cancer. The benefits, in terms of almost immediate pain relief and limited need for outpatient follow-up, are both cost-effective and gratifying.

MYELOTOMY

Commissural myelotomy at the thoracolumbar level for the treatment of pain was first described by Armour in 1927 (47) for a patient with tabetic abdominal pain. Putnam (48) was apparently unaware of this report when he claimed to have performed the first myelotomy in 1934. Since then, the popularity of this operation has waxed and waned. It seems quite logical that neurosurgeons would aim at producing bilateral pain relief with a single low-risk procedure that has little risk of damage to the important spinal axonal systems. Unfortunately, this apparently attractive operation has not been as effective as predicted on theoretical grounds. After the initial attempts on a few patients, commissural myelotomy was applied on a relatively large scale by French and German neurosurgeons in the 1940s and 1950s (49,50 and 51), subsequently becoming relatively obsolete for several years. At the end of the 1960s, Sourek (52,53 and 54) published encouraging results and once more aroused the interest of neurosurgeons in this technique. In the last 15 years, the topic has recurred sporadically in the neurosurgical literature, with various results reported (55,56,57,58,59,60,61,62,63,64,65,66,67,68 and 69). Approximately 425 myelotomies have been reported in the neurosurgical literature.

Basic Considerations

The original aim of commissural myelotomy was the interruption of all the decussating second-order spinothalamic fibers subserving pain perception on both sides of the body as they travel in the anterior commissure of the spinal cord. Theoretically, bilateral symmetric analgesia should have been achieved, with pain relief restricted to the segments where sensation had been altered. The length of the myelotomy incision should have been proportional to the extent of pain. What was seen, however, even after extensive longitudinal splitting of the spinal cord over several centimeters, was that a girdle of analgesia was present in the expected area but that pain relief extended caudally into regions that had no demonstrable sensory changes. Hence, the role of the spinothalamic fibers in pain relief after myelotomy is not clear.

Various hypotheses have been proposed to explain this antalgic but not analgesic effect of myelotomy. Sourek (52,53 and 54) theorized that the spinal commissurotomy interrupts two systems that conduct pain information: the slow-conducting anterolateral system and the fast-conducting mediodorsal system. The latter was believed to have a somatotopic arrangement and is contained in the medial portion of the posterior columns.

Sunder-Plassmann and Grunert (55) have reported their experiences with 56 midline myelotomies and described only bilateral segmental analgesia appropriate to the level of the myelotomy. In contrast, Hitchcock (56,57) and Schvarcz (58,69) carried out cervical stereotaxic myelotomies and reported extensive areas of pain relief without sensory changes. They thought that their procedure specifically interrupted an extralemniscal centrospinal multisynaptic pathway, with Schvarcz referring to “extralemniscal tractotomy (58).”

From an anatomic standpoint, Kerr and Lippman (70) have reported that the projections to the periaqueductal gray matter seen in cordotomy are topographically different from those seen in myelotomy. The gray matter around the central canal has been shown to have anatomic connections to brainstem areas involved in nociception (71). In patients who have had an open myelotomy, disorders attributable to damage to the posterior columns are frequently observed for several weeks after surgery.

A midline afferent pathway has been hypothesized that is a multisynaptic chain of short tracts (72). This operation would not only affect the crossing spinothalamic fibers but also the spinoreticular tracts (73). Finally, there is evidence for a tract in the anterior part of the medial borders of the posterior columns mediating visceral pain, both for pelvic pain and for more proximal epigastric visceral pain (74,75,76 and 77). This pathway synapses in the nucleus gracilis and activates neurons in the ventral posterior lateral nucleus of the thalamus.

Clinical Considerations

Technique

The two basic strategies for midline myelotomy are (a) open, requiring a laminectomy, opening of the dura, and making a lesion under direct vision, and (b) closed, making a lesion through a needle that has been passed through the skin, between adjacent laminae, and into the spinal cord.

The open operation requires a midline dorsal incision that is usually performed in the low thoracic and upper lumbar area. The upper end of the myelotomy is placed at least three cord segments above the highest level of the patient's pain. A laminectomy is performed, and the dura is opened widely. Retention sutures are used to hold the dura open, and the spinal cord is visualized. The arachnoid is incised, and the dorsal midline of the spinal cord is identified. The incision in the spinal cord is made in the exact midline between the two gracilis tracts and carried down ventrally until the ventral pia has been divided. The spinal cord is therefore totally transected so that the right and left sides no longer communicate. The central gray matter is destroyed, as are the decussating fibers that go on to form the spinothalamic tract (Fig. 106-5).

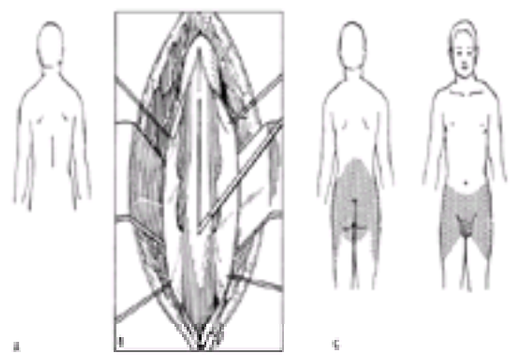

Figure 106-5. **A:** Site of thoracolumbar midline myelotomy. **B:** Method of performing midline myelotomy in thoracolumbar region. After a laminectomy of T-9 to L-1, the dura is opened and the dorsal midline of the spinal cord identified. A microknife is used to make a midline incision to the ventral pial surface. **C:** Extent of analgesia produced by thoracolumbar midline myelotomy.

Different techniques have been described over several decades. It is obvious that spinal commissurotomy or midline myelotomy is by no means a standardized procedure. Similar results have been obtained with quite different operations: The level, length, and depth of the spinal lesions vary extensively. For example, some neurosurgeons have reported limited myelotomies or even single stereotaxic RF lesions; others have used complete longitudinal splitting of the spinal cord over multiple segments from 100 to 110 mm long. It appears that no reliable or widely accepted criteria exist as to how long or how deep the incision should be to interrupt all fibers subserving a given painful area. Complete division of the anterior and posterior commissures appears to be the most effective method. Second, postoperative sensory changes are too variable to allow any physiologic appraisal of the effect of myelotomy; consequently, correlations between lesion size and site and outcome are impossible. Finally, the mechanism of pain relief after myelotomy is not understood.

Open myelotomy is a major surgical procedure that should be considered with caution. Patients in poor condition who have a short life expectancy are not often suitable. On the other hand, even the most extensive myelotomies have not guaranteed long- lasting pain relief. A CT-guided technique has also been described in the creation of lesions in the same area (78).

Percutaneous myelotomy has been described by only four surgeons; the procedure has probably been performed in about 150 patients, although pain relief in large regions of the body has been reported in as many as 79% of patients with cancer. Hitchcock (56,57) Schvarcz (58), and Gildenberg and Hirshberg (59) have described making a lesion at C-1, and Sourek (52,53 and 54) made lesions both at C-1 and at T-8 to T-10. Coagulation of the high spinal central gray matter produces dramatic changes in sensation and pain relief over variable but widespread regions of the trunk and extremities. In this technique, only a single lesion is made in the center of the spinal cord, at a segment just above the highest level of the painful areas. A single lesion is made at the thoracolumbar junction of the spinal cord (so-called punctate midline myelotomy) for the most common use of this procedure—pelvic visceral pain from rectal or uterine cancer (79). Follow-up times and areas of sensory loss have been variable, and the duration of pain relief is not clear.

Results

Despite the well-documented shortcomings, rewarding clinical results, mostly in cancer patients with pain in the pelvis, perineum, and/ or both lower extremities, have been reported in the literature (Table 106-5). Good pain relief without significant analgesia is also occasionally seen (80). In combined series, total relief of pain or total cessation of analgesics was initially reported in 92% of patients (161 of 175), most of whom had cancer pain. This rate, however, dropped to 59% (103 of 175) at last follow-up or death in the cancer pain patients. There has been great variance in these results, however, between different series, possibly because of differences in technique, especially the depth of the sectioning.

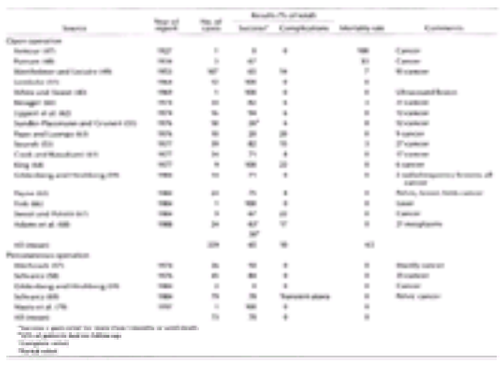

TABLE 106-5. Results of commissural myelotomy

Wertheimer and Lecuire (49), who applied myelotomy on a large scale more than 40 years ago, initially stated that myelotomy provided satisfactory pain relief in most patients with bilateral pain in the lower half of the body. The same clinical material was subsequently reanalyzed by Dargent and colleagues (50), who concluded that myelotomy was effective only for the management of vaginal and visceral pain, whereas rectal and lower limb pain were not significantly influenced. Later, Sourek (52,53 and 54) and Broager (60) reported good results for the relief of lower limb pain, whereas Cook and Kawakami (61) and Lippert and associates (62) did not succeed in relieving lower limb or spinal pain. As for the pain located in the upper part of the body, Lembcke (51) and Cook and Kawakami (61) reported satisfactory results, whereas Sourek's (52,53 and 54) experience was disappointing.

With stereotaxic cervical procedures, Hitchcock (56,57) and Schvarcz (58) succeeded in most patients irrespective of the location of pain. Between these two series, 100 patients were treated. Follow-up until death or for up to 5 years indicated that approximately 70% of patients had satisfactory pain relief. Papo and Luongo (63), however, obtained only short-lasting relief with a cervical procedure (superficial splitting and deep coagulation) regardless of the type and location of pain, which always recurred in patients who survived more than 2 to 3 months.

Sunder-Plassmann and Grunert (55) claimed that 91% of their patients were pain-free after midline myelotomy; 26% remained pain-free until their deaths or for the duration of follow-up, which lasted up to 4 years. Others feel that late pain recurrence as a result of a falling sensory level is rare (81). Myelotomy is a procedure confined to selected patients (82). All the published series have contained small numbers of patients.

Complications have been reported in 5% to 10% of the reported cases. Most surgeons agree that the typical open longitudinal midline myelotomy produces only a temporary loss of pain and temperature sensation in a girdle area that corresponds to the region of the cord incision. How long this unexplained sensory loss persists is unclear. Postoperative mortality has been low (up to 3%) in most recent series. Rarely, a dysesthetic or radicular pain of mild severity might occur at the top end of the area of pain relief (81). Other side effects include hyperesthesia, diminished proprioception, paresis, incoordination of gait, and motor and sphincter disturbances (80).

Conclusions

Although myelotomy remains a useful procedure, caution should be exercised when recommending myelotomy as the initial procedure for the relief of cancer pain. This procedure can be useful for the relief of bilateral pelvic and perineal pain because the other surgical alternative is bilateral cordotomy, which carries increased risk of bladder dysfunction. Epidural and intrathecal narcotics have unquestionably greatly reduced the numbers of patients who need ablative surgery for cancer pain. For the management of noncancer pain, open myelotomy is difficult to accept. So few surgeons have reported on C-1 RF myelotomy that it is impossible to adequately evaluate this variant, which can have a different anatomic substrate from the low thoracic myelotomy. Using the present understanding of the anatomy and physiology of mesial spinal cord systems, myelotomy techniques can be chosen but should be coupled with objective assessments of side effects and effects on different aspects of the pain (83). Present data strongly suggest that this is an effective procedure, albeit for a limited subset of cancer patients with intractable pain that is either bilateral or midline, especially located in the pelvis.

DORSAL ROOT ENTRY ZONE LESIONS

The DREZ operation entails making a series of lesions aimed at the substantia gelatinosa Rolandi and the surrounding fiber tracts. This operation was conceived and first used by Nashold and coworkers (84) in 1976 in a patient with severe pain secondary to brachial plexus avulsion. That patient has been reported to be free of pain ever since. By 1989, the Nashold group had done a total of 550 operations for various conditions (*personal communication* to Bonica, 1989). Almost 500 additional operations have been reported by other authors. Although Nashold and associates have the most extensive experience with this operation, many other neurosurgeons are performing this ablative procedure. The data published to date permit us to make reasonable inferences regarding its efficacy.

Basic Considerations

The DREZ operation involves the destruction of dorsal horn neurons and perhaps of the axons traveling in juxtaposition to the gray matter, particularly those segments that correspond to the patient's reported area of pain. The detailed anatomy of the human dorsal horn is discussed in Chapter 3 and Chapter 4; this chapter contains only a brief anatomic review relevant to this operation. The dorsal horn can be segmented on a cytoarchitectonic basis into six laminae (Rexed laminae). The five most superficial are clearly involved in the transmission of nociceptive information from the periphery and can play an essential role in some deafferentation or central pain states.

Not only are the synaptic connections from peripheral nociceptors localized in laminae I through V, but studies have demonstrated major concentrations of opiate receptors, substance P, and other biologically active peptides in these regions (85). Indeed, many believe that the “gate,” as described by Wall and Melzack (85), resides in this region of the spinal cord. The combination of classic neurophysiology and modern pharmacology points to this region as being critical in the processing of sensory information. In 1967, Loeser and Ward (86) reported that neurons in the dorsal horn became hyperactive when deafferentated. Nashold and coworkers (84) subsequently designed an operation to destroy the dorsal horn in patients with deafferentating lesions and severe pain. Initial successes have led to increasing use of this procedure; it has been almost exclusively used for pain states characterized by an injury to the nervous system referred to in this book as *deafferentation pain* and thought to have a peripheral-central pain mechanism; others have used the term *central pain*.

Few, if any, traditional surgical procedures have a significant chance of alleviating the pain that follows deafferentation (87). Certainly, rhizotomy, cordotomy, myelotomy, or sympathectomy is unlikely to produce long-term pain relief. DREZ lesions appear to be remarkably effective in brachial plexus avulsion and are reasonably effective for the relief of some types of postparaplegic pain, postamputation pain, postherpetic neuralgia, and for a small number of miscellaneous neuropathies and myelopathies.

The following chronic pain states are diagnoses that have been considered most appropriate for treatment by DREZ lesions: brachial plexus avulsion, other brachial plexus destructive lesions, sacral root avulsion, and postparaplegic pain. The procedure has also been used, although with a lower success rate, in the treatment of phantom limb pain, stump pain, postthoracotomy pain, postherpetic neuralgia, peripheral mononeuropathy, spinal cord tumor, multiple sclerosis, causalgia, and postrhizotomy pain. Specific predictive factors to indicate a favorable outcome are being developed.

Indications

The indications for DREZ lesions for the treatment of chronic pain include an established diagnosis and failure of medical-pharmacologic management. In addition, it is important that the patient have an understanding of alternative strategies, risks, and potential benefits. As previously mentioned, the diagnoses listed above are those that have thus far been considered to be appropriate for DREZ lesions. The number of patients treated, however, is currently limited in some of these diagnostic groups.

Contraindications

Contraindications relate to the patient's general health and ability to withstand a major surgical procedure, including such factors as infection, resistance to wound healing, blood and coagulation problems, and poor cardiopulmonary status. Patients who have a significant emotional component to their pain are rarely good surgical candidates, although the ravages of chronic pain can alter patients' judgment and emotions.

Clinical Considerations

Technique

DREZ lesions are performed under general anesthesia and require a laminectomy over each segment to be lesioned. For brachial plexus avulsion involving C-5 to T-1 dorsal roots, it is necessary to do a C-4 through T-1 laminectomy (Fig. 106-6). In the sacral segments, the anatomy of the conus permits extensive lesioning with a more limited laminectomy. The dura is opened, and the spinal cord is visualized. The dorsolateral sulcus is identified; the operating microscope is an important adjunct. Some neurosurgeons section the dentate ligaments so that the spinal cord can be rotated to orient the dorsal horn vertically. When the dorsal roots have been avulsed, the dorsolateral sulcus has a series of microcysts and gliosis. It is essential to see the intact dorsal roots rostral and caudal to the avulsion to identify the dorsolateral sulcus positively. Injury to nerves in the periphery or herpes zoster often leads to atrophic dorsal roots.

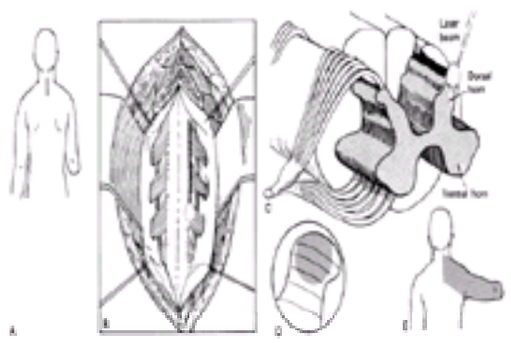

Figure 106-6. **A:** Site of C-5 to T-1 dorsal root entry zone (DREZ) lesions. **B,C:** Production of DREZ lesion using CO_2 laser. **B:** After a laminectomy of C-5 to T-1, the dura is opened and the dorsolateral sulcus is identified. The pial vessels are coagulated and a continuous lesion made in the dorsolateral sulcus to destroy the DREZ. **C:** After the laser is used, a microprobe is inserted into the dorsal horn to verify its destruction. **D:** Extent of lesion in dorsal horn. **E:** Analgesia produced by right C-5 to T-1 DREZ lesions.

Nashold and coworkers' (84,88) careful studies of this operative procedure should be required reading for any surgeon who wants to use DREZ lesions. His original RF electrode made too large a lesion and was apparently responsible for the high incidence of postoperative dorsal column and pyramidal tract dysfunction. The neurologic complication rate has fallen dramatically since Nashold shifted to a smaller thermistor-controlled electrode, which is 0.25 mm in diameter and 2 mm long for DREZ lesions in the spinal cord (88). Each lesion is made at 75°C for 15 seconds, and a series of lesions is done at 1-mm intervals; the longest series in one patient extending over a 5-cm length of the spinal cord. Using these parameters, each lesion in the spinal cord will measure 2.0 × 1.5 mm, which is adequate to destroy laminae I through V of the dorsal horn (88).

Sweet and Poletti (89) have described the deliberate use of a larger lesion in a small number of cases, and others have used variations of lesion making. The advent of the laser as a surgical tool has led to the use of both C_2 and argon lasers to lesion the DREZ (90,91). In research on cats regarding DREZ procedure (92), the lesions in dorsal horn produced by the RF probe were compared with those produced by CO_2 laser. Histologic examination revealed that depths of the laser and RF lesions were similar but the RF lesions showed more lateral spread. Laser lesions comprised 4.4% ± 1.6% of the cross-sectional area of the spinal cord, whereas the RF lesions occupied 22.8% ± 4%, demonstrating that the CO_2 laser produces smaller lesions than the RF electrode. Although the laser technique seems to be less traumatic to the spinal cord, it has not gained widespread use. This lower use might be a result of the possibility that the smaller lesions might not be as effective and/or the use of laser equipment is more cumbersome as compared to RF equipment. Another surgical technique is to coagulate the pia and vessels over the dorsolateral sulcus and to use a sickle knife to incise into the dorsal horn, followed by a ball dissection to destroy the dorsal horn under microscopic control. The dura is then closed in a watertight fashion, and the muscular and soft tissues are closed in the standard manner.

The postoperative course is usually benign; many patients have transient dorsal column or pyramidal tract dysfunction, but few have permanent deficits. It is presently unclear which method of destroying the dorsal horn is safest and most effective.

It is also unclear why lesions in the dorsal horn stop deafferentation pain states. Two or three autopsy reports published showed that DREZ lesions made at 450 mA for 5 to 15 seconds destroyed laminae I through IV of the dorsal horn and some of the white matter medial and lateral to the dorsal horn (89,93). In the third patient, who died on the twenty-eighth postoperative day and in whom the DREZ lesions were done according to the parameters mentioned above, the lesions involving the dorsal horn extended halfway into lamina VI, but there was minimal impingement on the white matter (94). These findings suggest that the technique described above accomplishes the objective and that additional neurologic deficits in either the posterior column or pyramidal tract functions are not required for effective pain relief.

A major concern with regard to the placement of DREZ lesions is proper localization for placement of these lesions. The dorsolateral sulcus is varyingly discernible; when the dorsal roots have been avulsed, the dorsolateral region can be densely adherent to the arachnoid or to the dura. The dorsal horn is obliquely oriented and the electrode, knife, or laser beam must be angled or the spinal cord rotated to create the desired lesion and avoid damage to the pyramidal tract or the dorsal column. When roots have been avulsed or the spinal cord damaged, it is helpful to expose the levels rostral and, when feasible, caudal to the proposed operative area so that normal dorsal roots can be visualized and the dorsolateral sulcus can be identified. Evoked potentials can also be used to localize the superficial tracts in the spinal cord and assist in the placement of lesions (94).

Results

Brachial Plexus Avulsion. The most common and most successful application of DREZ lesions is for the relief of the pain of brachial plexus avulsion. This traumatic disaster is most common in young men who ride motorcycles. Nashold's first patient suffered from this injury. An overall 83% success rate has been reported with many follow-ups of longer than 5 years (84,90,95,96,97,98,99,100,101,102,103,104 and 105). A few patients with sacral root avulsions have been included in these series. No other diagnosis has as high a likelihood of success, and no other operation is as likely to relieve this type of deafferentation pain. Table 106-6 summarizes the results obtained to date.

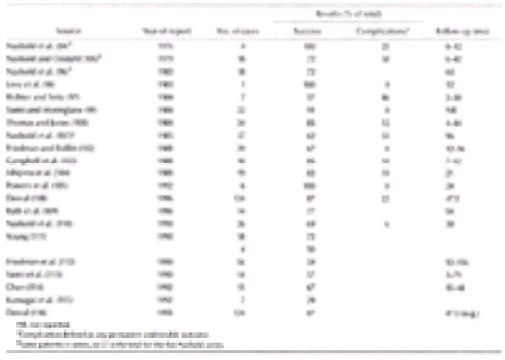

TABLE 106-6. Results of dorsal root entry zone operation for brachial plexus avulsion

Postparaplegic or Postquadriplegic Pain. Postparaplegic or postquadriplegic pain has also been relieved by DREZ lesions, particularly pain occurring at the transition between normal and anesthetic skin (90,91,96,97,99,105,117). The long-term success rate is 54%, but the duration of follow-up has been variable (Table 106-7). Some of the reported patients had drainage of posttraumatic syringomyelia at the same time; it is unclear whether DREZ lesions alone are responsible for their pain relief. It is puzzling that distal spinal cordectomy does not often relieve this type of pain but that DREZ lesions are sometimes effective. It should be recognized that this is not radicular pain, nor is it the pain associated with osseous instability that can occur with traumatic injury to the vertebral column. Although cordotomy is sometimes effective for this type of pain, the long-term results do not approach those obtained with DREZ lesions.

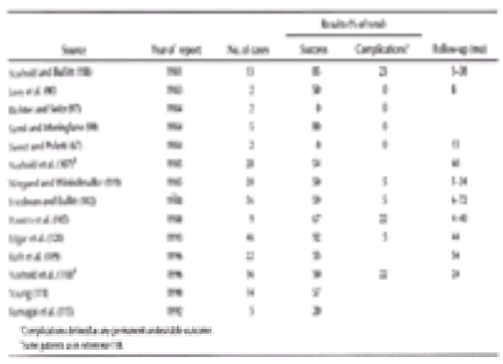

TABLE 106-7. Results of dorsal root entry zone operation for paraplegic pain

Postamputation Pain. Another type of central pain that has responded to DREZ lesions is postamputation pain (96,99,100,104,105,107,121) (Table 106-8). Hidden in this category are two different types of pain syndromes: stump pain and phantom limb pain (121,122). The overall results for postamputation pain are 39% success (11 patients) in a group of 28 patients. In Saris and associates' series (121), phantom limb pain is highly likely to respond (six of nine patients), whereas stump pain was never relieved (none of six patients). When phantom limb pain and stump pain were both present, good results were noted in two of seven patients, but only the phantom pain responded regularly. None of the other reports clearly discriminated between phantom limb pain and stump pain. Because of the aforementioned failures, DREZ lesion is not highly recommended for stump pain.

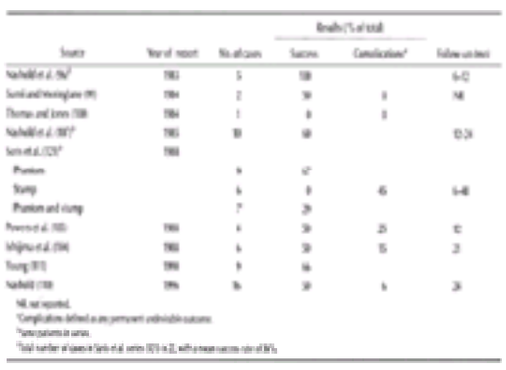

TABLE 106-8. Results of dorsal root entry zone operation for postamputation pain

Postherpetic Neuralgia and Other Disorders. In the earlier reports on the use of the DREZ lesion for postherpetic neuralgia, Nashold and associates (107) and Friedman and Nashold (117,123) reported that ten of 17 patients (59%) had good pain relief accompanied by a complication rate of 35%. In patients who had postherpetic pain for 6 months to 11 years and were followed 6 months to 6 years postoperatively, 29 of 32 (91%) had immediate relief. At 6 months, however, the figure dropped to 17 (53%), and at 18 months and thereafter only eight (25%) had persistent relief of postherpetic neuralgia involving the spinal nerves (Table 106-9) (102). Thirty-one patients with various myelopathies and neuropathies have also been treated with DREZ lesions (87,88,94,124). Approximately two-thirds had good results, with follow-ups of 6 to 19 months and a complication rate of 10% to 20%. The results are summarized in Table 106-10.

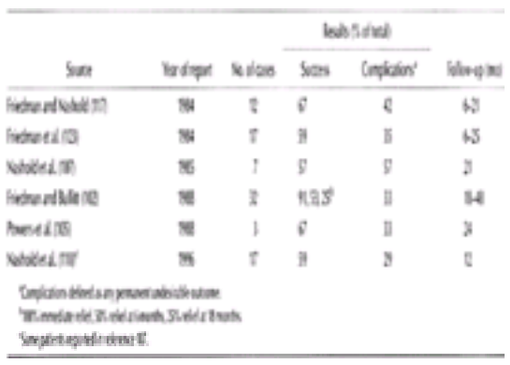

TABLE 106-9. Results of dorsal root entry zone operation for postherpetic neuralgia

Source	Year of report	No. of cases	Results (% of total)

TABLE 106-10. Results of dorsal root entry zone operation for other neuropathies and myelopathies

Subnucleus Caudalis Dorsal Root Entry Zone Lesions. Nashold and Brophy (125) and Bernard and associates (126) reported on the use of DREZ lesions on the subnucleus caudalis for the treatment of severe postherpetic neuralgia and other severe intractable facial pain. Following laminectomy of the C-1 to C-3 vertebrae and a small suboccipital craniectomy, the lesion is made to extend from the upper dorsal rootlet of C-2 to the tuberculum cinereum, slightly rostral to the level of the obex and the fourth ventricle. Production of DREZ lesions in the subnucleus caudalis also entails destruction of the descending trigeminal tract; the anatomic correlate of pain relief is unclear (121,125).

Since 1989, there have been at least 46 reported operations for facial pain using a two-electrode technique for subnucleus caudalis DREZ lesions. The overall pain relief was noted as “excellent” in 34% of patients and good in another 40%. The best results were obtained in patients with postherpetic pain involving one or more divisions of the trigeminal nerve (127). Pain resulting from facial trauma or dental surgery was not improved. In general, deafferentation pain responds to lesioning, but pain of a peripheral origin does not.

Comments and Conclusions

As more reports continue to be published regarding DREZ lesions, clear indications become more apparent for DREZ lesions in the management of chronic pain. The DREZ lesion is the only operation that was specifically designed to treat central and deafferentation pain. It is widely recognized that all standard ablative neurosurgical procedures are much more effective against pain associated with nociception (especially cancer pain) than they are against peripheral-central pain states. It remains unclear whether DREZ lesions are useful in patients with cancer pain; dorsal rhizotomy seems to be a less formidable operation for denervation of the painful area. The results of rhizotomy are variable, however, and it remains unclear whether the addition of ganglionectomy can improve them. Perhaps DREZ lesions will be effective in this type of pain.

More than any other ablative procedure, use of DREZ lesions can achieve variable results because of differences in lesion placement. It is not known how many segments above or below the level of injury the lesions should be made. Patients who have failed to obtain good pain relief might continue to suffer because the lesions did not extend far enough rostrally or caudally, yet the failure to relieve pain is ascribed to a deficiency of the operation itself. The poor results that sometimes follow DREZ lesions could be caused by failure of the surgeon to destroy the necessary amount of tissue, or could be a result of inherent shortcomings in the operation as a concept (95).

CHAPTER 107

Surgical Treatment of Trigeminal Neuralgia

Deon F. Louw and Kim J. Burchiel

HISTORY

The trigeminal nerve was initially described in the sixteenth century by Fallopius (1). The eponymous designations of the Gasserian ganglion and Meckel's cave are derived from Gasser and, of course, Meckel more than a century later. In 1829, Charles Bell determined that the nerve had both a motor and a sensory root and that severance of the infraorbital nerve provoked loss of sensation without paralysis (2). He differentiated between the sensory function of the fifth nerve and the motor function of the seventh nerve, thus sparing patients misdirected surgical interventions. Trigeminal neuralgia is discussed in detail in Chapter 47. Stookey and Ransohoff have beautifully presented the history of the treatment of this disease (3).

The indication for surgery in the treatment of trigeminal neuralgia (tic douloureux) is the failure of medical management. This occurs either because of the lack of a response or the inability to tolerate medication side effects. No patient should be offered a surgical procedure in the absence of an adequate trial of medication management. On the other hand, surgery should not be withheld from the patient who suffers from this terrible affliction. The choice of surgical procedure is governed by the patient's age, medical condition, and preferences as well as the surgeon's available resources. The history of attempts to control the pain of tic douloureux with surgery is long, dating back to the sixteenth century. With the advent of anesthesia in the end of the nineteenth century, the development of new surgical techniques rapidly progressed (Table 107-1).

Neurectomy	Maréchal (1756)
Gasserian ganglion resection	Krause (1892)
Retrogasserian rhizotomy	Horsley et al. (1891)
	Spiller and Frazier (1901)
Report of 298 consecutive Gasserian ganglionectomies without mortality	Cushing (1920)
Partial section of V roots at the pons	Dandy (1929)
Electrocoagulation of Gasserian ganglion	Kirschner (1931)
Decompression of the trigeminal root	Taarnhøj (1952)
Compression of the trigeminal root	Shelden et al. (1955)
Vascular decompression	Gardner and Miklos (1959)
Temperature-controlled coagulation of Gasserian ganglion and rootlets	Sweet (1968)
Stereotactic radiosurgery of V root	Leksell (1971)
Microvascular decompression	Jannetta (1976)
Retrogasserian glycerol injection	Håkanson (1981)
Percutaneous compression of Gasserian ganglion	Mullan and Lichtor (1983)

TABLE 107-1. The history of surgical treatments for tic douloureux

NEURECTOMY

History

Maréchal, surgeon to Louis XIV, performed peripheral sectioning of the trigeminal nerve branches (3). These procedures were attempts at sectioning the infraorbital

nerve by making a generous intraoral incision. Andre's report of 1756 claimed superior results by destroying the same nerve with caustics (3). In the nineteenth century, Wood, Fowler, and Wagner published on the efficacy of neurectomy (3,4 and 5). As more direct attacks on the ganglion and root became feasible, neurectomy has been relegated to a secondary or palliative procedure.

Advantages

The procedures are readily and rapidly accomplished, with very low risk of complication. They can be performed under local or general anesthesia. Neurectomy results in complete anesthesia in the nerve distribution, and functional regeneration usually does not occur with wide separation of the two nerve ends (6).

Disadvantages

Relief, although very likely, is temporary. Most patients have a recurrence within 2 years. Substantial loss of sensation is initially evident in the territory of the sectioned nerve, and this may be followed by denervation hypersensitivity (anesthesia dolorosa) (6). Furthermore, neuromas occur at the site of transection and may be exquisitely sensitive.

Indications

Neurectomy is useful as a palliative procedure, particularly in debilitated patients. Loeser et al. suggest that appropriate candidates are those individuals who have failed gangliolysis and cannot withstand open intracranial procedures (6). The mandibular, infraorbital, and supraorbital nerves may be sectioned in patients with refractory trigeminal neuralgia, and attention may be directed either at the zone of referred pain or the trigger locus. It is important to avoid neurectomy in patients with atypical facial pain (see Chapter 47).

Technique

The skin incision for the supraorbital nerve is made within the unshaven eyebrow. The nerve is isolated distal to its foramen or notch. A hemostat is used to wind the nerve from its proximal portion, whereupon a second, more proximal hemostat is applied and rotated. This twisting action allows the nerve to be torn as close as possible to the ganglion (3). Stookey and Ransohoff maintained that the duration of relief is directly related to the extent of ganglion cell injury. The nerve is then also sectioned as distal as is feasible.

The infraorbital nerve is exposed through a sublabial incision. The mucosa is incised approximately 1.5 cm above the alveolar border (3) and the periosteum elevated. The infraorbital foramen and nerve are identified in the plane of the upper canine, and the nerve is resected as above.

The lateral approach to the mandibular nerve is the preferred route for neurosurgeons, whereas oral surgeons favor transoral exposure (7). A 3-cm curvilinear incision is based on the angle of the mandible, allowing the masseter fibers to be splayed concentrically. A burr hole is performed over the angle of the ramus, exposing the nerve. The nerve is transected in the usual manner and hemostasis ensured.

Results

Grantham and Segerberg reported an average relief of 33.2 months, ranging from 5 months to 8 years (8). Stookey and Ransohoff noted maximal duration of pain relief as 6 years for supraorbital nerve avulsion, and 2 years for the infraorbital (3). Rasmussen obtained good initial, but only modest 2-year, success rates (9).

PERCUTANEOUS RADIOFREQUENCY TRIGEMINAL GANGLIOLYSIS

History

Wright is credited with the first chemical Gasserian gangliolysis, injecting osmic acid after operative exposure of the ganglion (10). Harris was able to perform percutaneous alcohol injections into the ganglion in 1910, obtaining significant relief for his patients (11). In 1914 Härtel reported his still currently used extraoral technique for cannulating the foramen ovale and delivering alcohol into the ganglion (12). Other investigators tried boiling water and phenol, all with varying degrees of success.

Kirschner introduced electrocoagulation of the ganglion in 1932, using x-ray and stereotactic guidance (13). Progress in technique was reported by Sweet and Wepsic in 1974, who developed the use of radiofrequency current for gangliolysis (14). They also introduced electrical stimulation for localization and temperature monitoring to enhance modulation of lesion size. Many variations in technique have subsequently been reported.

Anatomy

Soeira et al.'s measurements of the Gasserian ganglion determined a mean length of 17 mm and a thickness of 4 mm (15). During ontogenesis, dura and arachnoid evaginate from the posterior fossa to cover the ganglion. The trigeminal cistern is the retroganglionic (retrogasserian) pocket of dura and arachnoid. It contains cerebrospinal fluid (CSF) and communicates with the basal cisterns through the trigeminal porus. The ganglion and cistern occupy Meckel's cave. The cell bodies are somatotopically oriented: ophthalmic anteromedial, mandibular posterolateral, and maxillary interposed (Fig. 107-1).

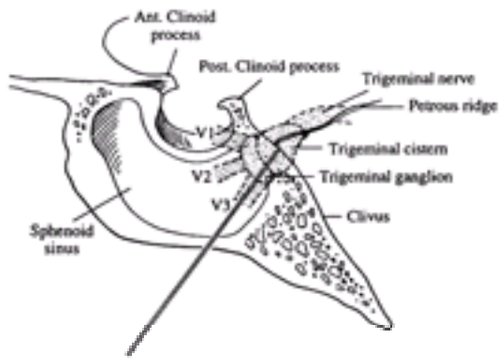

Figure 107-1. Lateral view of the region of the trigeminal ganglion. For trigeminal gangliolysis/rhizolysis, a needle (radiofrequency electrode, or spinal needle) is directed through the foramen ovale, through the third division (mandibular nerve), through the ganglion and into the trigeminal cistern. Note that the cistern is in communication with the posterior fossa and that agents injected into the cistern (i.e., radiocontrast agents or glycerol) will run directly into the posterior fossa unless the patient is sitting up with the head horizontal (see Fig. 107-4). (Ant., anterior; Post., posterior.)

Figure 107-4. Patient in a sitting position undergoing injection of glycerol into the cistern of Meckel's cave (the trigeminal cistern). The initial injection is of radiocontrast, which confirms location in the cistern. The contrast is then allowed to run back out of the needle, and the anhydrous glycerol (typically 0.3 mL) is injected. The patient remains in the sitting position for 2 hours to prevent loss of the glycerol into the posterior fossa and to maximize the neurolytic effect.

Advantages

Percutaneous radiofrequency trigeminal gangliolysis (PRTG) is rapid and well tolerated by the elderly or the debilitated. It is an outpatient procedure and carries very few major complications in experienced hands. Through awake stimulation the lesion can be accurately localized to encompass the pain or trigger zone. The technique can be safely repeated on multiple occasions should the pain return.

Disadvantages

PRTG is clearly not curative, and in many cases the neuralgia recurs. The average time to pain recurrence is approximately 3 years (16). Another disadvantage is that a minimum degree of sensory loss must accompany each gangliolysis. It is difficult to predict how disagreeable this may be to the individual patient, and, of course, anesthesia or analgesia dolorosa may occur in 5% to 10% of cases.

Indications

Strict clinical criteria (as outlined above) for typical trigeminal neuralgia constitute the best predictor of outcome. Patients offered surgery have developed either tolerance to or side effects from anticonvulsants. Many patients have experienced recurrent attacks of increasing severity, commonly complaining of severe suffering for a decade or more. Patients who are either unsuitable for or unwilling to undergo microvascular decompression (MVD) should be offered radiofrequency gangliolysis. Advanced age is not a contraindication, but coagulopathy or tenuous pulmonary or cardiovascular status may be.

Technique

We perform percutaneous radiofrequency gangliolysis in the operating room, although excellent results may be obtained (in experienced hands) in the fluoroscopy suite. The administration of glycopyrrolate will block a vagal response when the ganglion is cannulated. The face is prepped and an entry point chosen 2.5 cm lateral to the angle of the mouth and 1 cm inferior to the occlusal plane, if the V-3 fibers are targeted. A steeper trajectory, and hence an even lower and more lateral entry point, facilitates penetration of V-1 fibers. The patient's neck is placed in extension, and submental vertex fluoroscopy is used to identify foramen ovale. This orientation provides bilateral visualization of foramen ovale and foramen spinosum and is particularly useful in the older, osteoporotic patient. The anesthesiologist administers sufficient propofol (Diprivan) to rapidly achieve a surgical plane of anesthesia. The contralateral nare is cannulated with a nasal airway, through which the patient may be ventilated should respiratory arrest occur. The evanescent half-life of this agent has proven to be of great benefit in this procedure. Once the eye-blink reflex is lost, a stab incision is made in the skin and the 20-gauge cannula and stylet advanced toward the foramen ovale under continuous fluoroscopic control (Fig. 107-2). This trajectory is initially based on Hartel's points and subsequently on fluoroscopy. For third-division pain, the geometric center of the foramen ovale is perforated. For second- or first-division pain, the needle is directed into the more medial parts of the foramen. Foraminal entry is accompanied by a jaw jerk, at which point fluoroscopy is moved to the lateral plane. The cannula is then carefully advanced in relation to the petroclival angle, ensuring that overpenetration does not occur. Advancement more than 7 mm beyond the clival plane may result in abducens nerve injury (17). V-3 fibers are most likely encountered 5 mm proximal to the clival profile. The needle is advanced in 5-mm increments to impale V-2 and V-1 fibers, respectively (17). The stylet is removed and CSF frequently encountered. A straight or curved electrode is inserted. The patient is allowed to wake up, and 50 Hz of stimulation at fractions of a volt are used to confirm electrode positioning. Patients identify the division in which the needle is positioned by confirming the distribution of paresthesias produced by threshold stimulation, usually less than 0.2 to 0.3 V (1-millisecond pulse width). The patient is reanesthetized and thermal lesions created for 90 seconds, commencing at 75°C in previously untreated patients. The patient is reawakened and tested for sensory loss. The patient should not be able to discriminate sharp (pinprick) sensation from dull contact but should have preserved touch sensation. If further lesions are necessary to achieve adequate sensory loss, the patient is reanesthetized, and lesions are created in graduated fashion at 5° increments up to 95°C, with the patient reawakened and retested for sensory loss at each step. Reoperated cases are commenced at higher temperatures. The patients are observed in the recovery room and discharged the same day if stable.

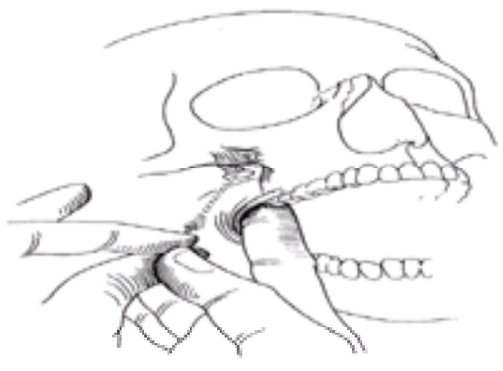

Figure 107-2. Hartel's technique of passing a needle through the foramen ovale via lateral puncture of the cheek. The needle is directed through the foramen under fluoroscopic control and does not pass intraorally.

Results

Initial relief is rated at 83% in Burchiel et al.'s series and as high as 99% in the report by Tew et al. (16,18). Long-term (more than 4 years) studies report recurrence rates as low as 14% and as high as 80% (14,16,17,18,19,20,21,22,23 and 24). The reported incidence of uncomfortable paresthesias ranged from 2% to 93%. Anesthesia dolorosa has been reported in 0.8% to 13.0% of patients.

Complications

Sweet has assiduously recorded data on surgical complications for percutaneous radiofrequency rhizotomies (25). Postoperative deaths were reported in 27 patients, largely from intracranial hemorrhage. Myocardial infarction, intracranial abscess, intracranial hemorrhage, and meningitis have also occurred (26,27 and 28).

Sweet reports 10 cases of major bradycardia, including two that progressed to asystole (29). These events are particularly common in balloon compression (see later). Dysesthesia is a distressing and common complication in radiofrequency gangliolysis. It occurs most often in fully anesthetic areas but may be experienced in

analgesic and even hypalgesic zones. We recommend avoiding profound analgesia in the trigger zones, and Sweet suggests scrupulous testing of the awake patient's tolerance of new numbness. This can be accomplished more readily by performing the final lesions with the patient alert. Corneal anesthesia, a common accompaniment to V-1 lesions, is readily managed with lateral eye shields, artificial tears, and frequent eye inspections. Neuroparalytic keratitis is distinctly uncommon with PRTG involving the first division, even after elimination of the corneal reflex. Acute visual loss has occurred for various reasons. Subhyaloid hemorrhage has been reported, as has central retinal artery occlusion. Complete blindness, along with total ophthalmoplegia, has also resulted, likely a consequence of electrode penetration of the inferior orbital fissure. The relatively minor (but frequent) complication of motor root weakness may become severely disabling if bilateral. Sweet recommends identification of the motor fibers by 2-Hz stimulation, followed by rotation of the Tew curved electrode to a sensory-specific site before lesioning (25). Using this technique, Tobler et al. reports an incidence of masticator paralysis of 1 in 150 cases (30). Although many complications have been anecdotally reported, the rate of complications in large series is less than 1%.

PERCUTANEOUS TRIGEMINAL GANGLION COMPRESSION

History

Mullan introduced percutaneous trigeminal ganglion compression (PTGC) in 1978 and initially published his results in 1983 (31). He recognized the need for developing a simple percutaneous compressive technique after studying the procedures of Täarnhøj and Sheldon. Sheldon initially performed an open decompression of the trigeminal peripheral branches, eventually realizing that the pain relief was a result of ganglial manipulation. He then proceeded to deliberately compress the posterior root fibers with a blunt dissector and obtained greater duration of pain relief compared with decompression alone (32).

Technique

Indications for PTGC are as for other percutaneous procedures. However, it carries a very low risk for corneal anesthesia and thus is particularly suitable for V-1 distribution pain. Patients are administered a general anesthetic. Using the same principles as in PRTG, a 14-gauge needle-cannula is inserted into the foramen ovale (see Fig. 107-1). The cannula has been modified by Gerber, who developed a blunt tip to prevent balloon laceration (33). A No. 4 French Fogarty embolectomy catheter is advanced 15 to 20 mm into the needle and inflated with 0.5 to 2.0 mL of water-soluble nonionic contrast medium. Initial inflation times were up to 10 minutes, but Mullan has now reduced this to 1 minute. This allows continued good results but with a significantly lowered dysesthesia rate. Fluoroscopy is used to confirm contouring of the balloon to a pear shape (Fig. 107-3). Continuous pulse and pressure monitoring is performed, as severe bradycardia and hypotension may occur. Intravenous atropine or glycopyrrolate and external pacing should be available.

Figure 107-3. Percutaneous trigeminal ganglion compression using the Hartel technique. The balloon is inflated with radiocontrast in the trigeminal cistern to produce a pear shape on fluoroscopic imaging.

Results

Immediate pain relief is reported from 89.9% to 100% (34). The longest recorded follow-up is that of 10 years for Mullan and Lichtor (35), who reported an 80% successful outcome at 5 years and 70% at 10 years. Average recurrence times have also been documented from 42 to 65 months by Meglio et al. (36,37). Rates of recurrence have been variously reported as 30%, 55%, and 77.4% (34). These relapses may respond to carbamazepine, even if the patient was refractory to the agent preoperatively. Most recurrences occur within 4 years but have been noted to occur up to 9 years after surgery (35). The 5-year reoperation rate (13%) is superior to PRTG (21% to 28%) and MVD (17% to 26%). However, 15% of patients surviving 10 years or longer undergo further, more invasive intracranial surgery.

PERCUTANEOUS RETROGASSERIAN GLYCEROL RHIZOLYSIS

History

Håkanson fortuitously discovered that intracisternal instillation of glycerol produced lasting pain relief with modest sensory loss (38). The mechanism of glycerol neurolysis is likely a nonspecific conduction blockade of small and large fibers (39). Spontaneous firing in large, damaged axons is also exquisitely sensitive to the application of glycerol. It has been postulated that these injured myelinated axons may rate the pain in trigeminal neuralgia (40).

Technique

The procedure is outpatient, and the set-up and monitoring as for PRTG. Under propofol anesthesia, the foramen ovale is penetrated with a 20-gauge, 3.5-inch spinal needle, as previously described. The foramen is penetrated slightly anterior to its midpoint, ensuring cisternal placement of the needle. After ensuring free flow of CSF, the patient is awakened and placed in the sitting position (Fig. 107-4). Isovue, 300 mg per L, is injected under fluoroscopic control, usually outlining the cistern with 0.15 mL and filling it with 0.35 mL (see Fig. 107-1). The contrast is allowed to drain from the needle, and approximately 0.3 mL of anhydrous glycerol instilled. Preferential neurolysis of the ophthalmic and maxillary divisions may be attempted by altering head tilt. It is mandatory for the patient to remain seated in a slightly flexed position for approximately 2 hours after surgery.

Results

Pain relief is rarely immediate, although approximately 50% are pain free within 24 hours. Resolution of pain occurs over the ensuing days to weeks in the remainder. Complete relief of pain has been reported to occur in 72% to 99% of those treated (41). Rates of recurrence range from 18.5% to 72% for both short- and long-term follow-up. Burchiel noted a higher recidivism rate for multiple sclerosis patients and those with technically unsatisfactory injections (41). Importantly, he detected an 80% recurrence of pain in the short term if the procedure failed to produce some sensory loss. Generic complications for needle trauma may accompany percutaneous retrogasserian glycerol rhizolysis. Glycerol may also provoke anesthesia dolorosa, dysesthesia, corneal anesthesia, oculomotor palsy, and aseptic meningeal reaction (42). In summary, the three methods of performing gangliolysis have similar success and complication rates. Balloon and glycerol techniques do not require patient communication and are better suited for those patients with whom the surgeon cannot communicate effectively due to language barriers or the patient's inability to cooperate. These procedures are quite safe, are relatively low cost, and do not require hospitalization but probably average about an 80% 1-year and 60% 5-year success rate.

RADIOSURGERY FOR TRIGEMINAL NEURALGIA

Bloodless brain surgery is inherently appealing under any circumstances but perhaps even more so in the chronic pain patient. Although there has been a recent flurry of interest in radiosurgery for trigeminal neuralgia, it in fact was first performed by Lars Leksell in 1951 (43). The target he chose was the trigeminal ganglion, and he reported excellent results on two patients in 1971 (44). Subsequently, Lindquist reported on the same procedure in 46 patients but with disappointing long-term results (45). Rand et al., noting a lack of response in some patients, suggested that the Gasserian ganglion was a suboptimal target (46). Kondziolka et al.'s

multicenter study hence reported on stereotactic radiosurgery targeting the proximal nerve and root entry zone (47). They postulated that inclusion of radiation-sensitive oligodendrocytes would enhance the radiobiological effect of the gamma knife (47). Additionally, the proximal nerve is more easily identifiable on magnetic resonance imaging than the ganglion, facilitating accurate target placement. Using doses varying from 60 to 90 Gy, they were able to report absence of pain in 58%, good control (50% to 90% relief) in 36%, and failure in 6%. Median follow-up was 18 months, during which time an additional 6% of cases recurred. The median time to pain reduction was 1 month, and there was a tendency to a better outcome in patients who had not had prior surgery. More recently, Young et al. noted pain relief in 95.5% of patients with classic tic symptoms who had not undergone prior surgery, with a recidivism rate of 3.3% in the follow- up period (mean 19.8 months) (48). Stereotactic radiosurgery appears to be low risk, and there are no reported cases of anesthesia dolorosa. A small number of patients have developed facial paresthesia or hypesthesia, but the overwhelming majority have intact sensation. Unfortunately, the delayed onset of pain relief may not appeal to the more desperate tic patients. It is also not feasible to tailor a target to the anatomic divisions of the trigeminal nerve. Larger cohorts and longer follow-ups should provide critically important information on what is potentially a useful addition to the surgical treatment of tic douloureux.

MICROVASCULAR DECOMPRESSION

History

Dandy's seminal surgical investigation of trigeminal neuralgia led him to write in 1945 that “in many instances the nerve is grooved or bent by the artery. This I believe is the cause of tic douloureux.” He also believed that on occasion tumors in the cerebellopontine angle could cause tic douloureux (49). Dandy, however, championed the suboccipital approach for trigeminal rhizotomy and did not advocate MVD. Gardner and Miklos recognized similar anatomic relationships and reported mobilization of an offending vessel from the nerve root (50). Jannetta's large series of decompressions brought general acceptance of the procedure to the neurosurgical community (51,52). He and Rand introduced the microscope to the procedure, initially favoring the transtentorial, subtemporal route (53). They later preferred the retromastoid approach, which has become standard throughout the world.

Anatomy

Jannetta et al. suggested that a looped superior cerebellar artery was the cause of 80% of trigeminal neuralgia (V-3) cases (54), noting a correlation of vascular compression (VC) site and pain distribution. V-2 pain was believed to be a consequence of lateral compression, the offending vessel usually an aberrant trigeminal vein communicating with the dura mater around Meckel's cave. V-1 pain was thought to result from caudal compression usually by the anterior inferior cerebellar artery. The incidence of trigeminal neuralgia increases with age, and this may result from associated brain “sag” and vascular tortuosity. Chronic nerve compression [particularly at the root entry zone (REZ)] could conceivably cause demyelination and provoke ectopic impulse generation or ephaptic conduction, leading to pain. Surgical displacement of the offending vessel should thus be “curative.”

Adams, however, contested this hypothesis. He contended that the episodic and usually unilateral characteristics of tic douloureux are incompatible with the Dandy model (55). In addition, asymptomatic nerve compression has been noted to occur in cadavers (56). Pagura et al. stated that VC is unlikely to explain trigeminal neuralgia in young patients without atherosclerosis and wondered about the mechanism of venous compression (57). Most neurosurgeons accept the VC hypothesis at this time.

Indications

Candidates for MVD are those with typical or atypical trigeminal neuralgia refractory to or intolerant of medical therapy. MVD is probably the procedure of choice in young patients, as it generally avoids sensory loss. It is therefore particularly appealing for V-1 distribution trigeminal neuralgia, avoiding the risk of corneal anesthesia. With modern neuroanesthetic techniques, advanced age has become less of a contraindication, but medically unstable patients should most likely be offered percutaneous procedures. It is unlikely that MVD would benefit anesthesia dolorosa or MS patients.

Technique

Patients undergo routine preoperative testing as well as baseline brainstem auditory-evoked responses (BAERs). General endotracheal anesthesia is administered and the patient positioned supine with an ipsilateral shoulder roll. The head is secured with pins, flexed, and contraversively rotated. The lateral decubitus and park bench position are also popular, as is the sitting position. The latter carries a higher risk of air embolism and sciatic stretch injury.

A vertical 4- to 6-cm incision is placed within 1 cm of the asterion. A “quarter-sized” craniectomy is performed and the dura mater incised parallel to the transverse and sigmoid sinuses. CSF is aspirated, and, using the operative microscope, the trigeminal nerve exposed in the cerebellopontine angle. Gentle cerebellar retraction may be needed, and ongoing BAER monitoring reduces the risk of acoustic nerve injury. Under microscopic control, compressive arterial loops are mobilized from the REZ and restrained with shredded Teflon felt. Large compressing veins may be similarly dealt with, or more likely, require coagulation and division. The dura is closed in watertight fashion and titanium mesh secured to the cranium for cosmetic purposes and to prevent muscle adherence to the dura.

Results

Reported outcomes vary, some studies having longer follow-ups than others. The patient pool is also heterogeneous in terms of gender, age, and prior treatments. Nevertheless, many groups report excellent short-term results, ranging from 69% to 94% (16,19,58,59,60,61,62 and 63). Jannetta et al. stated that 82% to 85% of patients experienced complete relief of pain, without numbness, and that an additional 10% have modest pain that is readily controlled on oral medication (54). Piatt and Wilkins' study noted 78% satisfactory and 22% poor results in patients with arterial VC, as opposed to 54% satisfactory outcomes in those without (64). The subgroup of patients with VC in the pontine-REZ angle did particularly well. Hamlyn and King detected a recurrence rate of 17% for arterial VC and 75% for venous VC, and 60% if they coexisted (65). Patients with typical, exclusively episodic pain respond far better than those with relentless, superimposed background pain (66). Bederson and Wilson reported better results for males, presumably a consequence of their greater incidence of root distortion (67). Barba and Alksne determined that a prior destructive procedure resulted in a recurrence rate of 50%, in contrast with 7% undergoing primary MVD (68). The outcomes reported above do not represent cures, average recurrence time (12% of cases) approximating 2 years (67,69). There is an annual recurrence rate of 2% following this: The 50% success rate occurs at 15 years postoperatively.

Complications

Mortality, although rare, may occur. Jannetta has reported four deaths and Apfelbaum three (70,71). Infarction and hemorrhage are the mainstay of mortality. Sweet noted that published data present a mortality of less than 1% and permanent disability of approximately 1%, which he believed to be considerably lower than the results of his private poll of 200 neurosurgeons (72). Morbidity can include brainstem or cerebellar stroke. CSF leaks may occur with or without meningitis. Cranial nerve palsies have been reported at a 4% to 10% incidence, the facial and auditory nerves being most susceptible (64,66,73). Intraoperative BAERs have helped reduce the incidence of these injuries, however. More rarely, abducens or trochlear paresis may result.

In summary, retromastoid craniectomy with MVD offers an 80% 5-year success rate, a 50% 15-year success rate with a complication rate of 5%, and a mortality rate of 0.5% based on our own experience and a review of the published literature.

TRIGEMINAL RHIZOTOMY

History

The first published account of trigeminal rhizotomy was that of Horsley et al. in 1891 (74). His candid account of this subtemporal intradural approach referred to the death of this patient. Macewen performed a similar procedure at a similar time, but this remained unpublished. Hartley and Krause followed in short order with an extradural subtemporal technique, and the procedure was designated the Hartley-Krause method by Horsley (75,76). Hartley resected V-2 and V-3 at their foramina as well as beyond the ganglion (75). Cushing recommended complete ganglion excision as well as motor root section (77). Frazier is credited with refining the procedure, recognizing that selective division of “symptomatic” portions of the root reduced morbidity (78). He also advocated sparing the motor root. “Frazier's operation” became the standard open procedure for decades, despite Dandy's assertion of the advantages of his retromastoid rhizotomy. With the benefits of the

microscope and modern anesthesia, Dandy's approach today affords the option of rhizotomy in the setting of a negative exploration for microvascular compression.

Indications

Trigeminal rhizotomy is less frequently used as a primary procedure for trigeminal neuralgia today, although it is still recommended by Adams (79). It is most commonly performed as a “palliative” alternative to MVD should the surgeon fail to detect convincing VC. It continues to be used for orofacial cancer pain, as it can completely denervate the face. A retromastoid exposure allows concomitant interruption of the glossopharyngeal nerve or nervus intermedius, if required.

As with all open cranial procedures, rhizotomy should be avoided in the aged or medically infirm and in those with hemorrhagic diatheses. It also can produce the spectrum of sensory side effects from paresthesias to anesthesia dolorosa. The risk of the latter, although small, is increased if a total rhizotomy is performed.

Technique

The retromastoid approach for rhizotomy is as described for MVD. The REZ is exposed in identical manner and fibers subtending the topography of pain targeted. It is generally assumed that somatotopy dictates a caudal location for mandibular fibers, and rostral for ophthalmic. However, variable rotation of the REZ may occur and a more reliable indicator is that the ophthalmic fibers are those most closely applied to the portio minor, irrespective of its pontine entry angle.

The traditional Frazier procedure is conducted under general anesthesia in the sitting position. The scalp is vertically incised for 8 cm from the zygomatic root and a 4- to 6-cm craniectomy performed in the temporal squamosa and lateral sphenoid wing. Extradural dissection is performed, and the middle meningeal artery coagulated and divided. The foramen ovale and mandibular division are identified, followed by mobilization of the dura propria from the temporal lobe dura. The maxillary division, the ganglion, and the root are located without placing undue traction on the greater superficial petrosal nerve, as this may cause facial palsy. The dura propria is incised, and the lateral two-thirds of the retrogasserian rootlets are sectioned (Fig. 107-5). The motor root is of course spared. The dura, fascia, and scalp are closed in the usual fashion.

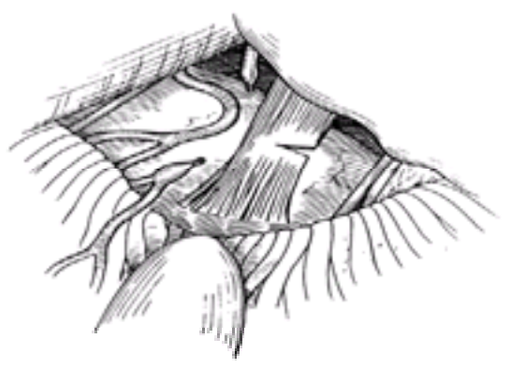

Figure 107-5. Depiction of a microscopic view of the right trigeminal nerve via a right retromastoid craniotomy. In this view, the petrous bone and the tentorium are located on the right and left sides of the upper part of the drawing, respectively. The fourth cranial nerve can be seen next to the tentorium, and the seventh and eighth cranial nerves are located to the right of the trigeminal nerve. The petrosal vein complex has been divided, and the cerebellum retracted in the lower part of the figure, exposing the trigeminal nerve. A lateral one-half rhizotomy of the main portion of the nerve (portio major) has been performed, sparing the more medial motor rootlets (portio minor).

Results

Recent statistics on the efficacy of rhizotomy are often combined with those on MVD. Nevertheless, extensive historical data exist, noting an initial success rate from 85% to 98% (80,81,82,83,84,85,86 and 87). Klun suggests that this diminishes to 50% at 5 years (87). The majority of recurrences occur in the first postoperative year and are related to the degree of sensory loss (88,89 and 90).

Complications

Mortality is reported to occur in 0.4% to 1.6% of cases (81,85), analogous to the incidence for MVD. General complications ranged from 5% to 25% (81,86). Specifically, paresthesias were noted in up to 55% of patients (81), whereas anesthesia dolorosa varied from 3.1% to 26.0% (85,87). Corneal anesthesia was detected in 0% to 4.6% of procedures (67,88). Cranial nerve injury may be seen in up to 10% of cases, although the majority are transient (64).

TRIGEMINAL TRACTOTOMY

History

In 1938 Olof Sjöqvist reported sectioning the descending tract of the fifth nerve at the inferior olivary level (91). He hypothesized that interrupting the tract before entering the nucleus caudalis might selectively section the pain fibers. White and Sweet noted hypalgesia in the distribution of the seventh, ninth, and tenth cranial nerves after trigeminal tractotomy (92). In 1965 Kunc reported selective tractotomy 12 mm above the second cervical root to alleviate glossopharyngeal neuralgia (93). Crue et al. and Hitchcock independently performed the first stereotactic percutaneous trigeminal tractotomies in 1967 and 1968 (94,95). Schvarcz targeted the nucleus caudalis oral pole, emphasizing the benefit of lesioning second-order neurons (96). He coined the term *trigeminal nucleotomy* for this procedure. In 1989 Kanpolat et al. pioneered computed tomography guidance for percutaneous trigeminal tractotomy-nucleotomy (97).

Anatomy

Pain and temperature fibers of the trigeminal nerve travel in the descending tract to the medulla and upper cervical cord, where they terminate in the spinal trigeminal nucleus. Pain fibers from the seventh, ninth, and tenth cranial nerves enter the medial aspect of the descending tract, which is then collectively called the *descending cranial nociceptive tract*. The spinal nucleus is divided rostrocaudally into the subnuclei oralis, interpolaris, and caudalis. The nucleus caudalis straddles the spinomedullary junction and represents the rostral extension of the substantia gelatinosa. It is a convergence zone for afferents from cranial nerves V, VII, IX, and X, as well as high cervical branches. The caudalis neurons are also prone to spontaneous activity if deafferented. This intersection of anatomy and pathophysiology provides a useful target in the surgical management of facial pain.

Technique

Percutaneous Tractotomy

Orofacial cancer pain and anesthesia dolorosa are the most common indications for percutaneous tractotomy. The patient is administered 8 to 10 mL of iohexol (240 mg per L) intrathecally and placed in Trendelenburg, approximately 15 minutes before the procedure (97). One-millimeter computed tomography slices are performed to confirm diffuse spread of contrast at the cervicomedullary junction. The still-awake patient is positioned prone on the computed tomography table, with the neck slightly flexed in the head support. Kanpolat's kit (Radionics) has 20- to 22-gauge needles and 2-mm thermocouple electrodes of 0.3 and 0.4 mm in diameter. Local anesthetic is administered 8 mm from the midline at the occiput–C-1 level. A 22-gauge needle (20-gauge for thick necks) is aimed toward the occipitocervical space on the lateral scanogram and on axial cuts. An ideal trajectory aims the electrode tip at the lateral third of the equator of the hemicord. A typical penetration is 3 mm deep and 6 mm lateral to the midline, at the level of the first cervical segment. Cord penetration is confirmed by an increase of impedance from 400 Ohm in CSF to usually greater than 1,000 Ohm in the spinal cord. Low- and high-frequency stimulation is used to confirm target acquisition. Initial lesions are performed for 20

seconds at 60°C and incrementally increased to 60 seconds at 70°C to 80°C while monitoring neurologic function.

Open Tractotomy

Patients are administered a general anesthetic and needle electrodes are applied to the ipsilateral supraorbital, infraorbital, and mental nerves at their foramina (34). A bipolar electrode is also applied over the median nerve. The patient is placed prone and the skull secured in a Mayfield clamp. A midline suboccipital incision and craniectomy is performed, as well as a C-1 laminectomy. Durotomy displays the cervicomedullary junction, which is then mapped with evoked potential responses to 500 milliseconds, 5 to 7 V, and 2- to 3-Hz pulses applied to the trigeminal and median nerve electrodes. Loss of median nerve–evoked potentials delineates the lateral boundary of the fasciculus cuneatus. Similarly, the vertical and horizontal borders of the descending tract are demarcated by trigeminal peripheral branch stimulation. The trigeminal divisions subtending the patient's pain are then ablated by a 3-mm deep radiofrequency electrode lesion (Fig. 107-6). Lesions are repeated until the appropriate evoked potentials are eradicated.

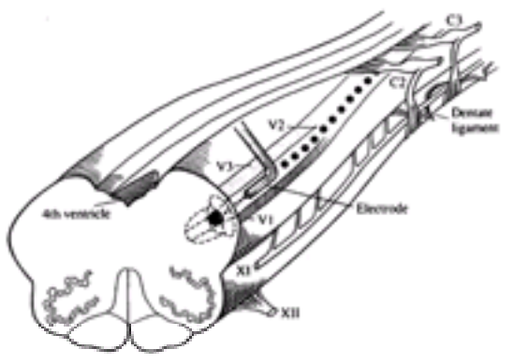

Figure 107-6. The caudalis dorsal root entry zone (tractotomy/nucleotomy) procedure. A suboccipital craniotomy is performed with C-1 laminectomy. The dura is opened, and the upper spinal cord and medulla just beyond the level of the obex of the fourth ventricle are exposed. A series of radiofrequency thermal lesions are then made in the nucleus caudalis and descending tract of the trigeminal system using a special radiofrequency needle electrode, insulated so as to spare the overlying dorsal spinocerebellar tract from thermal injury. Radiofrequency lesions are made from the obex to C-2.

Results

Kanpolat et al. reported a mean follow-up of 62 months on 30 cases of percutaneous tractotomy-nucleotomy, with complete or partial pain relief in 80%. He notes successful outcomes for all patients with glossopharyngeal and geniculate neuralgia, with good results for malignancy, atypical facial pain, and trigeminal neuralgia. The single case of anesthesia dolorosa did not respond (97).

Schvarcz reported on 100 cases, with a 57% good outcome for anesthesia dolorosa and 83.8% for cancer pain (98). Plangger et al. documented that 58% of open tractotomy procedures for trigeminal neuralgia accomplish complete, and 42% partial, pain relief (99). King reported a success rate of 75% to 85% for malignant pain (100). Clearly, long-term follow-up is more difficult in cancer patients. In addition, extensive malignancies may require sectioning of C-2 to C-4 dorsal roots to more completely denervate the skull base and upper neck.

Complications

The procedure has been aborted on two occasions by Kanpolat when electrode insertion/stimulation provoked unbearable pain (97). Ipsilateral limb ataxia can occur in at least 10% of patients, as the dorsal spinocerebellar tract and the external arcuate fibers overlie the descending trigeminal tract (101). Contralateral sensory loss is reported in 14% of cases as a result of injury to the spinothalamic tract. Hemiparesis, facial or masticatory paresis, and anesthesia dolorosa occur rarely (99). Complication incidence is related to lesion volume and can be minimized by physiologic mapping techniques.

CONCLUSIONS

Trigeminal neuralgia is unique among chronic pain conditions in that it reliably responds to both medical and surgical treatment. When patients become medically intractable, as discussed in Chapter 47, a large number of surgical procedures can be brought to bear on the problem. We believe younger patients in this group should have MVD of the nerve. For patients not wishing this degree of invasiveness and risk or in older patients who represent significant risk for a major neurosurgical procedure, including the risk of anesthesia, percutaneous rhizolysis is the best option. This can be performed by radiofrequency, glycerol, or balloon compression techniques, depending on the clinical situation and the experience of the neurosurgeon. Open rhizotomy is usually reserved for intractable cases or in patients in whom exploration for MVD proves negative for neurovascular compression. The role of tractotomy-nucleotomy, whether performed by open or percutaneous route, is still being defined; it is certainly not a primary procedure now, but should be reserved for the most difficult cases of refractory trigeminal neuralgia pain.

There is a loud debate in neurosurgical circles about the most appropriate neurosurgical operation for patients with tic douloureux. We have tabulated the published results of the common surgical treatments of tic douloureux (Table 107-2). Gybels and Sweet have written, “We conclude from available results that performance of a conservative percutaneous lesion represents the best tactic as the first invasive procedure” (102). Apfelbaum has advocated suboccipital craniectomy with MVD for patients younger than age 65 but gangliolysis for the elderly or medically infirm (or those with multiple sclerosis) (103). Jannetta et al. believe that suboccipital craniectomy with MVD “is indicated as a primary operative treatment” (54). Many other experienced neurosurgeons have published their viewpoints and the results on which they have based their conclusions. The introduction of stereotactic radiosurgery as yet another method of traumatizing the trigeminal nerve will certainly offer a third, less invasive strategy to provide pain relief to those who have failed medical management.

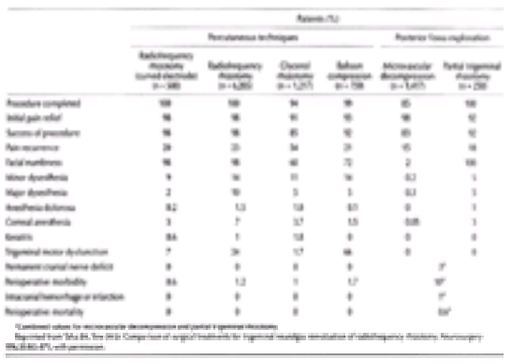

TABLE 107-2. Results of percutaneous techniques and posterior fossa exploration for patients treated for trigeminal neuralgia

Fortunately, most patients with trigeminal neuralgia can anticipate a good outcome from surgical management of the condition. The patient's choice of procedures should be based on a thorough discussion of the options, rationale, and risks with a neurosurgeon experienced in the management of trigeminal neuralgia.

CHAPTER 108

Ablative Brain Operations for Chronic Pain

Ronald F. Young

The Melzack and Wall gate hypothesis of pain gave rise to a variety of electrical stimulation methods (e.g., peripheral nerve, spinal cord, deep brain) to treat pain; as a result, a decrease in the use of central ablative procedures ensued (1). Although the stimulation procedures are certainly useful, they produce satisfactory long-term relief of pain in a maximum of 50% of patients, and at least in the United States, neither deep brain stimulation nor trigeminal nerve stimulation is available due to lack of approval by the U.S. Food and Drug Administration (2,3,4,5 and 6). The increasing use of chronic intraspinal or intraventricular administration of analgesic agents also reduced interest in the use of central ablative neurosurgical operations to treat intractable pain. However, the long-term effectiveness of chronic intraspinal or intraventricular administration remains unproven and at best appears to be successful, even in the short-term, in no more than 50% of patients (7). Consequently, there has been a renewed interest in central ablative procedures as an important component of the surgical armamentarium available to treat chronic pain. This chapter reviews the author's approach to the use of central ablative procedures and their suitability for treatment of chronic pain, with emphasis on those procedures currently commonly in use. A few other procedures rarely used today are also discussed, mainly for the sake of history and completeness.

MEDULLARY AND PONTINEC SPINOTHALAMIC TRACTOTOMY

Those procedures that involve section of the lateral spinothalamic tract at either the medullary or pontine level were first executed in 1941 by Schwartz and O'Leary and by White (8,9). Their purported advantage over high cervical cordotomy is the ability to obtain a more rostral level of analgesia with medullary or pontine lesions, which may be useful in the treatment of pain in the shoulder or neck.

Basic Considerations

Anatomy

The lateral spinothalamic tract originates in nociceptors in the periphery that enter the spinal cord via A-d and C fibers that make synaptic connections in the spinal dorsal horn, cross to the contralateral side, and ascend in the spinal cord in the anterolateral quadrant (10,11,12 and 13). In addition, Jones and colleagues have demonstrated in cat and primate the existence of a dorsal spinothalamic tract, composed exclusively of fibers that originate in C nociceptors (14). This latter pathway travels in the dorsolateral funiculus of the spinal cord and projects widely to the medial and lateral thalamus as well as the suprageniculate areas and the pulvinar (15). Classically, the spinothalamic tract has been divided into two primary components: (a) the neospinothalamic tract, which conveys information concerning the spatial and temporal qualities of painful stimuli, and (b) the paleospinothalamic tract, which conveys information about the affective and motivational components of pain (see Chapter 4). In the ventral quadrant of the spinal cord, these two components are more or less homogeneously mixed, but at the medullary level, the paleospinothalamic component begins to diverge centrally and give off collaterals to the reticular formation (Fig. 108-1). This component then ascends in a multisynaptic reticulothalamic pathway to the medial nuclei of the thalamus and then to the limbic lobe. The neospinothalamic component, at the mesencephalic level, is composed of as few as 1,500 fibers, whereas the spinal component of the spinothalamic tract contains approximately 15,000 fibers (16). Unfortunately, a great deal of what we know about the spinothalamic tract was derived from experiments that used brief, acute, noxious stimuli, which are more easily studied electrophysiologically and behaviorally. More recent experiments, some of which have used chronic noxious stimuli, have elucidated many other components of the nervous system involved in pain perception. For instance, direct spinothalamic tract projections have been identified to the hypothalamus, to other limbic structures such as the amygdaloid nucleus, to the preoptic and septal areas, as well as to the basal ganglia (12,13). The presence of nociceptive afferents in the dorsal columns with projections to the gracile nuclei and to the thalamus has been demonstrated (12,13). Visceral pain afferents, particularly, may travel in the medial portion of the fasciculus gracilis bilaterally and also project via the gracile nuclei to the neutral posterolateral thalamic nuclei (12,13). Thus, it is not surprising that although section of the spinothalamic tract at the medullary or pontine levels may produce a more rostral level of “analgesia”—that is, loss of cutaneous pinprick and temperature sensation—effective, long-term relief of pathologic pain with these procedures is not common. This feature, combined with the complexity of the surgical operation required to perform the procedure, has led to its rarely being used today.

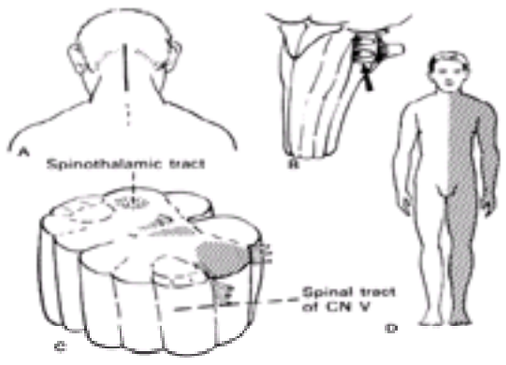

Figure 108-1. Medullary spinothalamic tractotomy. **A:** Site of skin incision. **B:** Dorsolateral view of medulla indicating site of incision in brainstem. **C:** Cross section of medulla indicating depth of incision into dorsolateral medulla. **D:** Extent of analgesia after right medullary spinothalamic tractotomy.

Indications

Ablative procedures that interrupt components of the neospinothalamic tract are generally used for the treatment of cancer pain because effective pain relief beyond 6 to 12 months is unusual, because the resulting sensory loss increases the risk of tissue injury (e.g., burns) of which the patient is unaware, and because a small but definite proportion of patients develop painful dysesthesias that are often more distressing than the original pain. These may be even more difficult to treat.

Most commonly, medullary or pontine spinothalamic tractotomy is considered for treatment of cancer-related pain in the shoulder or neck, such as lung cancers that produce Pancoast's syndrome or squamous cell cancers of the head and neck (17,18). Although purportedly more successful than high cervical cordotomy for relief of shoulder or neck pain, medullary tractotomy carries a similar risk of paralysis of the automatic phase of respiration, with resulting sleep apnea, and the same risk of death as with high cervical cordotomy. Interference with the automatic phase of respiration, although not fatal when a unilateral procedure is performed, may be fatal if the opposite hemidiaphragm is paralyzed due to a lung cancer (19). Finally, in spite of a high level of analgesia produced by medullary or pontine spinothalamic tractotomy, the deep aching, burning, and distressing pain that usually accompanies malignancies is frequently not relieved by these procedures. This is thought to occur because a significant proportion of the paleospinothalamic tract has already left the ventrolateral quadrant at the level of the surgical section. Alternatively, such sensations may be transmitted via the dorsal spinothalamic tract previously referred to (14,15). Patients who suffer from shoulder, neck, and arm pain due to involvement of the brachial plexus with cancer and who have lost functional use of the extremity may be effectively relieved of their pain by dorsal root entry zone (DREZ) lesions (20). If such patients continue to have use of the painful extremity, I prefer a medial thalamotomy, which, although perhaps slightly less effective than pontine or medullary tractotomy, carries a minimal risk of loss of extremity function (21). The loss of proprioception that accompanies DREZ lesions, in my experience, leads to a functionless extremity. I have not been able to produce the differential sparing of proprioception that Sindou describes with his micro- DREZotomy technique (22).

Results

Although success rates of 80% to 90% for relief of cancer pain were reported in the past, the virtual absence of any recent data casts doubt, in my opinion, on these figures (23,24,25 and 26). Furthermore, most of the reported patients survived for less than 6 months postoperatively. When one considers the current availability of multiple oral and parenteral opiates, the use of intraspinal opiates, and the availability of modern stereotactic techniques, it appears unlikely that patients with an expected survival of 6 months or less will be subjected to a major operation that requires a posterior fossa craniotomy to perform a medullary or pontine spinothalamic tractotomy. The reported 50% success rate and 14% complication rate for medullary or pontine tractotomy in the treatment of non-cancer pain also, in my opinion, makes this operation a poor choice *vis-à-vis* the other options (e.g., deep brain stimulation, medial thalamotomy). Although a stereotactic technique for pontine spinothalamic tractotomy has been described, only a handful of patients who have had the procedure performed have ever been reported. I am unaware of other surgeons who currently perform this procedure (27,28,29 and 30).

Clinical Considerations

Open medullary or pontine tractotomy is usually performed under general anesthesia, although combinations of regional or local anesthetic blockade combined with varying levels of intravenous sedation may also be used (23,24,25 and 26). I prefer the prone position for such operations, although the lateral decubitus position may be used as well. I do not recommend the sitting position because of the risk of air emboli. A small posterior fossa craniotomy and upper cervical laminectomy give adequate exposure. The use of an operating microscope is highly recommended. Although some authors recommend making the incision into the spinothalamic tract 2 to 10 mm below the level of the obex, lesions performed at these low levels are little more than high cervical cordotomies and could be more safely and easily performed using percutaneous techniques. Lesions performed well above the obex may damage the restiform body (inferior cerebellar peduncle) and lead to ipsilateral ataxia or lateropulsion or they may damage the ventrally located corticospinal tract, which, at this level (decussation of the pyramids), could lead to either contralateral or ipsilateral, or even bilateral, motor deficits.

Summary

Medullary or pontine tractotomy, although initially an appealing operation from the anatomic standpoint for the treatment of upper arm, shoulder, or neck pain, is, in reality, rarely used today. Its increased risk and marginal advantage over percutaneous high cervical cordotomy, as well as the frequent failure to relieve the deep, distressing pain of malignancies, generally make it a poor choice.

MEDULLARY TRIGEMINAL TRACTOTOMY

Rationale and History

Trigeminal tractotomy was first described by Sjöqvist and was based on the anatomic idea that all pain input from the orofacial structures is conducted via the descending trigeminal tract into the so-called nucleus caudalis, the most caudal of the three subdivisions of the spinal trigeminal nucleus (31) (Fig. 108-2). The nucleus caudalis is anatomically identical to the dorsal horn of the spinal cord, but the “trigeminal tract” is not a tract at all in the usual sense of that term. The term *tract* is usually applied to postsynaptic pathways within the spinal cord or brain (e.g., the spinothalamic tract) but the trigeminal tract is in reality a direct continuation of the primary afferent fibers in the trigeminal sensory root. The operation of medullary trigeminal tractotomy is, in reality, a partial rhizotomy of the trigeminal sensory root and nothing more. Its purported efficacy is based on the concept that all nociceptive trigeminal input in the trigeminal sensory root courses via the descending trigeminal tract into the nucleus caudalis and that nonnociceptive input enters the rostral portions of the spinal trigeminal nucleus (i.e., nucleus interpolaris and nucleus oralis) or into the principal sensory nucleus (31) (Fig. 108-3). Unfortunately, this is not the case. Studies have identified nociceptive input into more rostral components of the spinal trigeminal nucleus (i.e., the nucleus interpolaris and nucleus oralis). It is, in fact, input from the central portion of the face and intraoral structures that preferentially relays rostral to the nucleus caudalis (32,33 and 34). Nociceptive input in the seventh, ninth, and tenth cranial nerves also relays via the nucleus caudalis but does not travel via the descending trigeminal tract *per se*, but occupies a position on its medial edge (35). Our previously published experience confirms that trigeminal tractotomy at the level of the obex results in analgesia confined to the peripheral portion of the face, sparing virtually all intraoral structures (36) (Fig. 108-4). We suggested that the lesion at the medullary level be extended into the trigeminal nucleus to sever the intranuclear connections between the nucleus caudalis and the more rostral trigeminal subnuclei, which are also important in orofacial nociception (36). Certainly trigeminal tractotomy represents an advantage over complete section of the trigeminal sensory root; tractotomy spares many afferents responsible for tactile and proprioceptive sensation in the orofacial region. The corneal reflex is usually preserved after tractotomy and abolished after complete rhizotomy.

Clinical Considerations

Indications

Medullary trigeminal tractotomy may be helpful for treatment of cancer-related pains of the face. This operation was, in the past, often combined with upper cervical rhizotomies for treatment of pain due to extensive head and neck cancers. It has also been described as effective for refractory cases of trigeminal neuralgia, but as previously described, medullary trigeminal tractotomy is anatomically little different from a partial rhizotomy of the trigeminal sensory root and is particularly ineffective if the pain originates, as it usually does, from central facial structures (e.g., lips) or intraoral structures (e.g., teeth) (37,38,39,40,41,42,43 and 44). Neuropathic orofacial pain (e.g., anesthesia dolorosa) is virtually never effectively treated by medullary trigeminal tractotomy because such pain is probably generated by spontaneously hyperactive neurons within the trigeminal nuclei, which are already disconnected from peripheral input (42). Neuropathic facial pain may be treated by trigeminal DREZ lesions, but my experience has been that trigeminal DREZ lesions are also often ineffective and the rate of complications is high (43) (see later discussion in this chapter). I prefer medial thalamotomy or deep brain stimulation for treatment of neuropathic facial pain (44,45,46 and 47).

Technique

Open trigeminal tractotomy is usually performed under general anesthesia with the patient in the prone position. A small posterior fossa craniotomy and upper cervical laminectomy are required for exposure. After dural opening, the operating microscope is used to identify the obex, the dorsolateral sulcus, and the emerging fibers of the accessory nerve, which mark the ventral extent of the incision into the tract. I prefer a deeper incision (at least 5 mm) than the 3-mm incision usually recommended because, as described earlier, I intend to section not only the trigeminal tract, but also the subjacent connections between the nucleus caudalis and the more rostral nuclei (36). I also prefer to make the incision as far rostral to the obex as possible in order to interrupt as much input from the central face and oral structures as possible. Unfortunately, the more rostral the incision is, the greater the likelihood of injury to the restiform body with ipsilateral arm ataxia and lateral pulsion (Fig. 108-5). If the lesion is extended dorsally and medially, there may be injury to the dorsal column nuclei with ipsilateral proprioceptive loss, and if the incision is too ventral, the spinothalamic tract may be injured with a contralateral loss of pain and temperature sensation in the extremities and trunk. Intraoperative electrophysiologic identification of the trigeminal tract and nucleus increases the efficacy and reduces the complications of the procedure (48).

Medullary tractotomy for pain relief. In: Wilkins R, Rengachary S, eds. *Neurosurgery*. New York: McGraw-Hill, 1983;2452–2454, with

permission.)

Stereotactic Trigeminal Tractotomy

The descending trigeminal tract in the medulla can be interrupted by a stereotactic technique (49,50,51,52,53,54 and 55). The procedure is done under local anesthesia with the patient in the prone or sitting position, depending on the type of stereotactic apparatus. One reason this procedure has not gained popularity is the difficulty in obtaining a satisfactory suboccipital approach with most types of stereotactic apparatus, but the Hitchcock apparatus is particularly suited for this approach (49,53). The electrode is angulated 30 degrees craniad and introduced 6 mm from the midline, where the trigeminal fibers lie 4 mm below the surface. A fine sharpened electrode is used because the pia is quite firm in this area. Verification of the electrode position can be obtained by electric stimulation at 50 Hz. With proper placement of the electrode, sensation is projected to the face at a low voltage. If the electrode is too deep or lateral in the spinothalamic tract, sensation can be projected elsewhere in the body. Stereotactic trigeminal tractotomy has been used both in cancer pain and as a secondary procedure for various noncancer chronic pains (49,50,51,52,53,54 and 55).

Hitchcock (49) reported pain relief in four out of five patients with head and neck pain caused by malignancy, in one out of two with neuralgialike facial pain, and in two out of three with postherpetic pain. Schvarcz (50) reported 25 patients, with a 94% success rate for various forms of neuralgia and a 100% success rate for relief of pain from various neoplasms (Table 108-1).

Source	Year of report	No. of cases	Indications	Results (% of total cases)

TABLE 108-1. Results of percutaneous trigeminal tractotomy

Medullary trigeminal tractotomy can be helpful in selected patients with pain secondary to malignancy of the head and neck. Its role in the relief of other pain states has not been well established. A small number of neurosurgeons have used percutaneous trigeminal tractotomy for other pain states; results have been encouraging (49,50,51,52,53,54 and 55).

TRIGEMINAL DORSAL ROOT ENTRY ZONE LESIONS

Rationale and History

In the late 1970s and early 1980s, Sindou and Nashold described mechanical and radiofrequency (RF) techniques to ablate the so- called DREZ of the spinal cord (20,22). This method was based on the idea that many types of chronic pain are related to spontaneous neuronal hyperactivity in the DREZ and that ablation of these neurons may lead to pain relief (42). Later, Nashold and colleagues described an RF technique for ablation of the descending trigeminal tract and subjacent trigeminal nucleus caudalis, the trigeminal homologue of the spinal DREZ (56). The nucleus caudalis extends from about the level of the obex caudally to at least the second cervical spinal segment.

Clinical Considerations

Indications

Trigeminal DREZ lesions have been proposed for treatment of a wide variety of facial pain conditions, including postherpetic neuralgia, anesthesia dolorosa, poststroke facial pain, central facial pain in multiple sclerosis, posttraumatic facial pain, atypical facial pain, and migraine/cluster headache (57,58). Because the trigeminal DREZ operation is a major neurosurgical operation, it should be considered only after other less invasive methods have failed.

Technique

The procedure is usually performed under general anesthesia with the patient in either the prone or lateral decubitus position. A small posterior fossa craniotomy and upper cervical laminectomy are used to expose the medulla and upper cervical spinal cord as low as the second cervical nerve root (56,57 and 58). Using the operating microscope (see Fig. 108-2), the bulge that represents the trigeminal tract is identified just lateral to the fasciculus cuneatus of the dorsal columns. Tactile stimulation of the face or electrical stimulation of peripheral branches of the trigeminal nerve may be combined with microelectrode recording at the operational site to localize the trigeminal tract and underlying nucleus caudalis electrophysiologically. Nashold and colleagues have designed two special RF electrodes for the performance of trigeminal DREZ lesions (59) (Fig. 108-6). The electrodes are inserted sequentially into the trigeminal tract/nucleus from the obex to the C-2 nerve root, and a series of adjacent RF lesions is made over the entire extent of the nucleus caudalis.

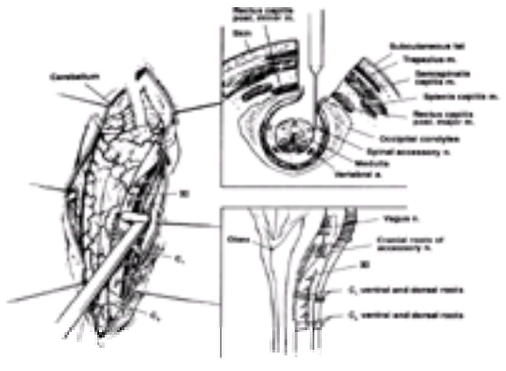

Figure 108-6. Techniques of trigeminal dorsal root entry zone procedure as described by Nashold using the electrode designed specifically for the trigeminal dorsal root entry zone procedure. (a, artery; m, muscle; n, nerve.) (Reprinted from Nashold BS, Abdul-Hak M, Ovelmen-Levitt J, et al. A new design of radiofrequency lesion electrodes for use in the caudalis nucleus DREZ operation. Technical note. *J Neurosurg* 1994;80:1116–1120, with permission.)

Results and Complications

In 1995, Gorecki et al. and Rawlings et al. reported on 101 trigeminal DREZ procedures performed at Duke University (57,58). Forty-six of these patients had the procedure performed with the newest electrodes. Overall, excellent pain relief was described in 34% and good pain relief in 40%. In postherpetic neuralgia, 71% obtained excellent or good pain relief. Eighteen patients (38%) described an improved quality of life. Complications in the form of ataxia were described in 54% of patients. My own experience and that of others with the trigeminal DREZ operation have been less rewarding (51). Only 30% to 40% of my patients have achieved satisfactory relief of pain. Other complications—for example, contralateral sensory loss due to injury to the spinothalamic tract and severe ataxia due to dorsal column injury—have led me to recommend trigeminal DREZ lesions only in desperate circumstances in which other procedures (e.g., trigeminal nerve stimulation, deep brain stimulation, thalamotomy, cingulotomy) have failed.

MESENCEPHALOTOMY

At the level of the mesencephalon, the spinothalamic tract is just below the pial surface and the so-called quintothalamic tract, which carries pain fibers from the face, is immediately subjacent. It was Walker who first suggested open surgical section at this level, but a high rate of complications led to the development of a stereotactic technique for mesencephalotomy (60).

Basic Considerations

The mesencephalon is an inviting target for a pain-relieving operation (61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77 and 78). The vast majority of pain input from the entire body and head are collected in three immediately adjacent pathways: the most superficial, the spinothalamic tract, the deeper, the quintothalamic tract, and the deepest, the spinoreticular tract (78). Not only do these pathways encompass the entire topography of the contralateral body, they also encompass the spatial and temporal qualities of pain, as well as the affective and motivational components. Theoretically, one would think that a correctly placed lesion in the mesencephalon could eliminate virtually any kind of pain. There are, however, some problems with this concept. First, with regard to neuropathic pain due to lesions of the nervous system, there is evidence that spontaneous neuronal hyperactivity at thalamic levels may be an independent generator of neuropathic pain (79). As thalamic pain generators are central to the level of a mesencephalic tractotomy, the later lesion would not be effective in relieving such pain. Also, because of the concentration of structures at the mesencephalic level, it is very difficult to make a lesion large enough to completely ablate the necessary pathways to relieve intractable pain without damaging important adjacent structures. The pathways for regulation of eye movements, particularly the medial longitudinal fasciculus and the oculomotor nucleus, are immediately adjacent to the pain pathways. Thus, disorders of ocular motility, such as diplopia and skew deviation, are very common if adequate-sized mesencephalic lesions are made (80).

Clinical Considerations

Indications

The major indication for stereotactic mesencephalic tractotomy is cancer pain in the head and neck, and/or the shoulder and arm. The procedure may be useful when unilateral diaphragm paralysis related to lung cancer would make high cervical cordotomy hazardous because of the risk of sleep-induced apnea, which does not occur with mesencephalic tractotomy. Neuropathic facial pains, such as anesthesia dolorosa or postherpetic neuralgia, may also respond to mesencephalic tractotomy. Neuropathic pains of the body, such as postcordotomy dysesthesias, phantom limb pain, brachial plexus, or lumbosacral plexus avulsion pain, may also respond to mesencephalotomy (61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77 and 78,80) (Table 108-2).

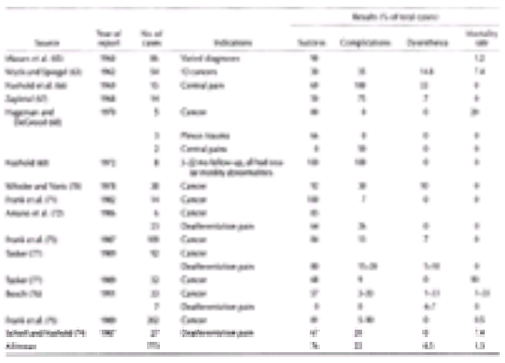

TABLE 108-2. Results of stereotactic mesencephalotomy

For nociceptive pain, relief can be expected in perhaps 60% to 70% of patients, whereas for neuropathic pain, long-term success may be anticipated in perhaps 40% to 50% (see Table 108-2).

Technique

The procedure is performed stereotactically using local anesthesia with minimal intravenous sedation. Stereotactic magnetic resonance imaging (MRI) may be used anatomically to localize the target but intraoperative electrophysiologic localization has been described as essential for final target localization. This information, however, derives from a time when ventriculography was used for anatomic localization. With the advent of stereotactic MRI localization very accurate lesion localization can be obtained, and whether this newer method will reduce or eliminate the need for physiological localization for the performance of mesencephalotomy is unclear.

The intended or best target for mesencephalotomy is also debatable. Lesions at the level of the superior colliculus are said to result in successful pain relief in up to 75% of patients but to result in defects in ocular motility in 87%. Lesions at the level of the inferior colliculus result in pain relief in less than 60% of patients, but the incidence of defects in ocular motility is reduced to approximately 17% (78,80).

Lesions are usually generated with an RF electrode, and emphasis has been placed on making small lesions using low temperatures and gradually enlarging the lesions while continuously assessing the patient's neurologic status, particularly extraocular movements and the strength and sensation of the face and extremities. It is well to emphasize that the size of the RF electrode and temperature are the primary controllable parameters that determine the size of RF lesions (81). The time of lesioning is a poor parameter for controlling the size of an RF lesion because the lesion gradually enlarges once the local temperature is above 48°C until it reaches its final size at approximately 30 seconds. The slope of the curve, which describes lesion enlargement, is relatively linear between 0 and 30 seconds, but even a few seconds' difference can significantly affect lesion size. To produce lesions of a consistent size that will yield reproducible results, only changes in electrode size and temperature should be used to alter the size of RF lesions, and the duration should be greater than 30 seconds.

The primary problem with stereotactic mesencephalotomy is its complications (78,80). The high rate of abnormalities of ocular motility has already been discussed. In addition, postmesencephalotomy dysesthesias, sensory loss due to injury to the lateral lemniscus, and motor complications due to injury to the extrapyramidal motor pathways in the ventral tegmentum make mesencephalotomy a high-risk procedure. These complications may be reduced by careful electrophysiologic localization, but the small size of the target and the multiple adjacent tightly packed structures to be avoided will continue to make mesencephalotomy a high-risk procedure.

THALAMOTOMY

Rationale and History

Virtually all pain-related information was thought to relay through one of several thalamic nuclei, and thus the thalamus was one of the early targets for stereotactic operations to relieve pain (82). As mentioned previously, however, direct relays from nociceptive neurons via the spinothalamic tract have been traced to several

limbic structures, and these targets are not ablated by thalamotomy (12,13). In general, thalamotomy has a high early success rate in pain relief, but in the past, frequent recurrences reduced the long-term effectiveness to perhaps 30% (83,84,85,86,87,88,89,90 and 91). Advances in understanding the role of the thalamus in chronic pain as well as advances in imaging and lesion making have, in my opinion, made thalamotomy a reasonable operation for dealing with particularly difficult patients with intractable pain (44,45).

Basic Considerations

Both the neospinothalamic and paleospinothalamic tracts, as well as the quintothalamic trigeminal tract, relay through the thalamus (82). The neospinothalamic tract terminates in the ventral posterolateral (VPL) thalamic nucleus, and the homologous fibers from the trigeminal system relay in the ventral posteromedial thalamic nucleus (Fig. 108-7). Likewise, the dorsal spinothalamic tract (at least in nonhuman primates) relays through these thalamic nuclei (15). Lesions placed in the VPL and ventral posteromedial nuclei are reasonably successful in relieving pain, but they are associated with loss of pain and temperature sensation contralateral to the lesion and are associated with a risk of producing a secondary pain syndrome akin to the so-called thalamic syndrome of Dejerine-Roussy. In addition to this role in the transmission of information concerning painful stimuli, studies have shown that neurons in the VPL thalamic nucleus may become independently or spontaneously hyperactive and potentially be independent generators of chronic pain (85,86). If this situation is truly the case, then the emphasis on pain transmission pathways as sites for lesioning, especially with neuropathic pain, may be misguided. Tasker and colleagues described groups of neurons in VPL that exhibited three different patterns of spontaneous bursting discharges (85,86). These neuronal discharge patterns were identified via microelectrode recordings in awake patients with neuropathic pain who were undergoing stereotactic operations. The neurons studied did not discharge in response to peripheral stimuli, and the firing patterns suggested cellular pathology similar to that seen in neurons injured by calcium influx after ischemia. It was postulated that such abnormal discharges may represent either a form of postsynaptic degeneration after injury or loss of presynaptic input.

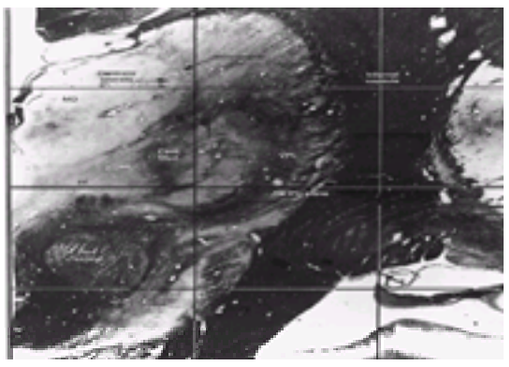

Figure 108-7. Coronal section of the brain 10 mm posterior to the mid-commissural point. See text for explanation. Med., centré median nucleus; MD, medial dorsal nucleus; PF, parafascicular nucleus; VPL, ventral posterolateral nucleus; VPM, ventral posteromedial nucleus.] (Reprinted from Young RF. Stereotactic surgical ablation for pain relief. In: Rengachary SS, Wilkins RH, eds. *Neurosurgical operative atlas*. Baltimore: Williams & Wilkins, 1992;177–188, with permission.)

Our own microelectrode studies have identified neurons with similar discharge patterns in the medial thalamic nuclei of patients with both neuropathic and nociceptive pain (79) (Fig. 108-8). The medial thalamic nuclei—the intralaminar nuclei, the lateral portion of the medial dorsal nucleus, the parafascicular and center median nuclei—are the relay points for the paleospinothalamic tract and the dorsal spinothalamic tract and project widely to the association cortex of the cerebral hemispheres and to many of the nuclei of the basal ganglia (see Fig. 108-7). Lesions in the medial thalamus may result in relief of pain without detectable sensory loss and without the risk of producing a secondary neuropathic pain syndrome (44,45,87,89). Other projections from the multisynaptic spinoreticular system project to the dorsomedial and anterior thalamic nuclei and relay to the frontal cerebral cortex and to the limbic system. Lesions in these nuclei are thought to affect the suffering associated with chronic pain and may blunt the patient's overall response to stimuli in general, but not to the degree described with extensive prefrontal lobotomies.

(Reprinted from Young RF. Stereotactic surgical ablation for pain relief. In: Rengachary SS, Wilkins RH, eds. *Neurosurgical operative atlas*. Baltimore: Williams & Wilkins, 1992;177–188, with permission.)

Indications

In the past, cancer-related pain was the most frequent indication for thalamotomy (87,88). In the past 15 years, most cancer pain is treated by oral, parenteral, or intraspinal opiates, and few patients are now referred for thalamotomy to treat cancer pain. Thalamotomy, however, may be particularly useful for pain related to carcinomas of the head and neck or to shoulder and arm pain related to the Pancoast syndrome, neither of which responds well to opiates (86,87,88,89,90 and 91). Our own primary experience with medial thalamotomy has been in the treatment of non–cancer-related pain (44,45). As with most ablative procedures for the treatment of pain, nociceptive pain responds much better to thalamotomy than does neuropathic pain.

Results

For pain due to chronic spinal disorders (e.g., the failed laminectomy syndrome) or other types of nociceptive pain, approximately 70% of patients can be expected to report at least a 50% decrease in pain intensity, cessation of narcotic analgesics, and improvements in ability to function in daily living. For neuropathic pain (e.g., thalamic syndrome, anesthesia dolorosa, postherpetic neuralgia, phantom pain after amputations, and spinal cord injury pain) similar results are reported for approximately 50% of the patients in our experience. Many have reported an initial high success rate with thalamotomy but a marked decrease in efficacy within 6 to 12 months of the procedure. This observation has led to the recommendation that thalamotomy be performed only for patients with cancer-related pain with limited life expectancy. Our own experience has been that with lesions of proper size and location the results of thalamotomy are long lasting. It is for this reason that we continue to use the procedure for the treatment of other forms of noncancer pain where life expectancy is not limited. Several reviews of thalamotomy for treatment of chronic pain have been published as well (87,88,89,90 and 91).

Clinical Considerations

Thalamotomy is performed using stereotactic techniques and local anesthesia (44,45,87,88,89,90 and 91). Thus, the procedure is suitable for nearly all patients, and considerations that might contraindicate more extensive neurosurgical procedures performed under general anesthesia are not of concern when considering thalamotomy. The patient's head is held in a rigid fixation device, which serves both to immobilize the head and also to act as a stereotactic reference system to

identify the intended thalamic target radiographically. Classically, ventriculography was used to identify the anatomy of the third ventricle and certain reference points in the brain (e.g., the anterior and posterior commissures), from which the stereotactic coordinates of the intended target could be determined by reference to standard brain atlases. With the advent of first computed tomography and more recently MRI scanning, ventriculography is not required. Thus, the overall morbidity of thalamotomy has been reduced because seizures, hemorrhages, and infection, among other possible complications of ventriculography, are eliminated. Stereotactic MRI scanning provides more information than ventriculography, but in a noninvasive manner. Earlier concerns about the accuracy of MRI-guided stereotactic procedures have been overcome by recent advances in stereotactic MRI procedures (92,93). MRI also provides important details about thalamic size and location of important adjacent structures to be avoided (e.g., internal capsule) but currently MRI scanning is not sufficiently detailed to allow identification of individual thalamic nuclear groups. Thus, some dependence on stereotactic atlases is still required but advances in technique allow standard atlases to be adjusted using computer techniques to conform to the anatomy of individual patients' brains.

Intraoperative electrophysiologic recording has usually been used to provide detailed localization of thalamic nuclear targets and, in addition, to elucidate the somatotopic arrangement within certain thalamic nuclei (91). Within the medial thalamic nuclei, which is the primary target of thalamotomy to treat pain, there is no somatotopic arrangement and the area in which beneficial lesions may be placed for pain treatment is fairly large, so that the need for electrophysiologic target identification has been questioned. Our medial thalamotomy lesions performed with RF lesioning and with electrophysiologic guidance, based on identification of the neurons previously described with abnormal bursting and firing patterns, have been carefully studied as to their anatomic locations (79) (Fig. 108-9 and Fig. 108-10). The most effective lesions encompassed the lateral portion of the dorsomedial nucleus, the intralaminar zone, and the center median and parafascicular nuclei. Based on these observations, we have been able to target the same region based on stereotactic MRI scanning alone and create radiosurgical lesions in the same target area using the Leksell gamma knife radiosurgical system (94,95,96,97 and 98) (Fig. 108-11). This noninvasive technique allows thalamotomy lesions to be created in an identical location to those performed with RF lesioning but without the necessity to insert a lesioning probe through the brain, thus eliminating any risk of intracranial hemorrhage or infection. The RF and radiosurgical thalamotomy lesions are, in our experience, approximately equally successful with effective relief of nociceptive pain in nearly 70% of patients and relief of neuropathic pain in approximately 50%. One difference between RF and radiosurgical thalamotomies is the time course of onset of the effect. RF lesions are created virtually immediately, and the pain-relieving effect is also immediate. Radiosurgical lesions, however, develop over 2 to 3 months and reach maximal size approximately 6 months after the procedure. Pain relief with radiosurgical thalamotomy follows a similar time course, with gradual onset approximately 2 to 3 months after the procedure and a stable effect by 4 to 6 months. Thus, for patients with cancer pain, the RF method is probably more suitable, whereas with noncancer pain, the radiosurgical method may have some advantage in terms of safety when speed of onset of the pain-relieving effect is not as necessary. Leksell and colleagues first reported their experience with radiosurgical or so-called gamma thalamotomy in the 1970s for treatment of cancer-related pain (99,100). Our experience with radiosurgical thalamotomy has been almost exclusively in the treatment of noncancer pain, both nociceptive and neuropathic.

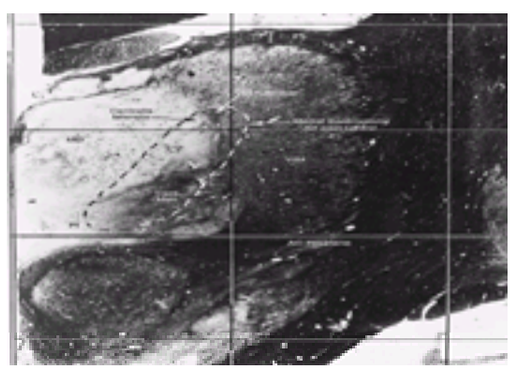

Figure 108-9. Coronal section of the brain 7 mm posterior to the mid-commissural point. The ideal location of a medial thalamic lesion to treat chronic pain is outlined by the dashed line. Figure 108-10. **A:** Coronal magnetic resonance imaging scan immediately after a right radiofrequency medial thalamotomy that resulted in complete relief of intractable shoulder and arm pain caused by lung cancer with brachial plexus invasion. The patient remains alive and free of pain 1.5 years after the procedure. **B:** Autopsy specimen demonstrating a right radiofrequency thalamotomy lesion that resulted in complete and lasting relief of postherpetic neuralgia that had failed to respond to deep brain stimulation. The patient died 1 year after the procedure of unrelated causes.

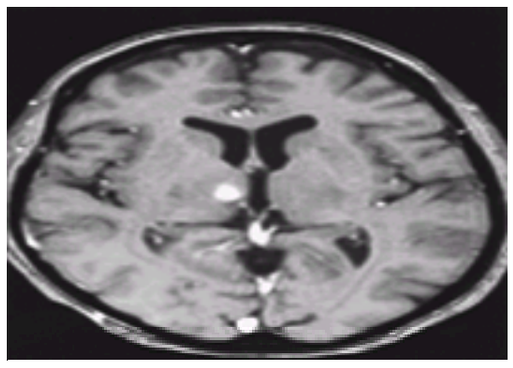

Figure 108-11. Axial magnetic resonance imaging scan that demonstrates a medial thalamotomy lesion made with the Leksell gamma knife that relieved intractable back and leg pain related to the failed lumbar laminectomy syndrome. The pain, which had not responded to either spinal cord stimulation or to intraspinal opiates, has been completely relieved for more than 3.5 years.

Other Thalamic Targets

Lesions have also been performed in other thalamic nuclei for treatment of intractable pain. These include the anterior nuclei and the pulvinar (101,102,103,104 and 105). The anterior nuclei have primary connections with the frontal lobes, and anterior nucleus thalamotomy is thought to alter mainly the affective and motivational components of chronic pain. Anterior thalamotomy is rarely performed today. The possible mechanism of pain relief by lesions in the pulvinar is unclear. Animal studies have shown involvement of the pulvinar as an indirect route for afferent stimuli with projections to the temporal lobe and thence to the sensory cortex of the

brain (77,78 and 79). Some relation of the pulvinar to pain perception has also been suggested (105,106). The exact target sites within the pulvinar are unclear and there is no electrophysiologic guide to targeting for pulvinotomy, which is currently usually based on MRI anatomic guidance alone. Both medial and lateral lesions in the pulvinar have been suggested and bilateral lesions appear more successful than unilateral lesions. Pulvinotomy has been used to treat both cancer-related and non–cancer-related pains (101,102,103,104 and 105). No sensory loss accompanies pulvinotomy and pain relief extending beyond 1 year after the procedure has been reported in approximately 25% of the patients.

Summary

Thalamotomy is a useful procedure for treatment of intractable pain, both cancer-related and non–cancer-related. Lesions in the medial thalamus, anterior thalamus, and pulvinar may relieve pain without altering normal sensory function and are the most desirable target areas. Technical advances, particularly stereotactic MRI target localization and noninvasive lesioning techniques using radiosurgery, have made thalamotomy safer and more accurate. The procedure is probably underused in the management of chronic pain even given the difficulty in interpreting the published results of thalamotomy due to differences in reporting methods and the limited length of follow-up periods in many reports.

HYPOTHALAMOTOMY

The procedure of making small stereotactic lesions in the posterior hypothalamus was introduced by Sano (107) in 1962 for the treatment of violent aggressive behavior, especially in those with epilepsy and mental retardation. Because of the theoretical consideration that painful stimulation always causes signs of sympathetic discharges, Sano and associates began to perform posteromedial hypothalamotomy for intractable pain (108,109). It was also reported by Fairman (110) at approximately the same time but has not become widely used.

Basic Considerations

Anatomy and Physiology

The anatomy of the area of the hypothalamus in which a lesion is made for pain relief does not correspond to a specific nucleus as defined by anatomic studies. It corresponds, however, to the area in which microelectrode recording demonstrates evoked activity at a latency of more than 100 milliseconds on stimulation of the contralateral superficial radial nerve, which has been shown to be a result of C-fiber stimulation transmitted along a multisynaptic pathway (108,111).

This area of the posteromedial hypothalamus has connections with the parafascicular nucleus and probably with the primary and secondary somatosensory cortex, as well as with the ipsilateral ventrocaudalis parvocellularis but not the dorsomedial nucleus (108,111,112). The physiologic basis of hypothalamotomy has been described as the normalization of ergotropic and trophotropic balance coordinated by that area (108), but the meaning of this concept is unclear.

Indications

Stereotactic posteromedial hypothalamotomy is used infrequently and is generally reserved for the patient with cancer pain, particularly if it involves the face and especially if the patient manifests a great deal of suffering, anxiety, or depression in addition to the pain (113). It has been used with mixed success for pain of postherpetic neuralgia involving the face (108,110). Hunter (112), Hassenbusch (103), and Gildenberg et al. (26) have reviewed this interesting procedure.

Results

Patients who obtain pain relief after hypothalamotomy behave differently from patients who obtain relief after frontal lobotomy. After lobotomy, cingulumotomy, or dorsomedial thalamotomy, patients might be relieved of suffering and no longer require pain medications but might indicate, when asked, that the pain is still perceived. After hypothalamotomy, the response is much more like that seen after an intralaminar thalamotomy: Patients report that they no longer perceive the pain. Satisfactory pain relief was obtained with hypothalamotomy for cancer pain in 70% of patients in one series (113) and in five of six patients in another series (108), but it must be recognized that this group of patients does not ordinarily require long-term follow-up. Partial relief has been reported in the use of hypothalamotomy for herpes zoster, causalgia, and thalamic pain (110). Two-thirds of patients with somatic pain, particularly after cancer, had relief from hypothalamotomy, but in general those patients with dysesthetic pain did poorly.

Clinical Considerations

Anesthesia

Hypothalamotomy is always done under local anesthesia because of the desirability of identifying electrode localization by stimulation or recording. Sedation must be carefully selected so as not to interfere with those activities (114).

Lesion Site

An electrode is introduced stereotaxically to a target 2 mm below the midpoint of the intercommissural line and 2 mm lateral to the lateral wall of the third ventricle. The operation can be done bilaterally in cases of widespread pain, but success can result from a unilateral lesion placed contralateral to the location of pain.

Electrode Localization by Stimulation

Recording of evoked activity on painful electrical stimulation of the contralateral radial or medial nerve can verify proper position of the electrode. In addition, application of pinpricks to the skin over wide areas of the body can produce evoked responses, with latencies of 300 to 2,000 milliseconds (108). Electrical stimulation causes signs of sympathetic discharge such as rise in blood pressure, tachycardia, pupillary dilation, or occasionally neck movement or ocular movement. Patients report a sensation of fear or horror during stimulation, but no sensation of pain.

Summary

More logical and potentially more successful procedures than hypothalamotomy currently exist for the treatment of pain. Few reports have been presented in the literature, and few neurosurgeons have found the procedure to be particularly helpful.

Hypothalamotomy is a surgical procedure that does not have a rational foundation in our understanding of the anatomy and physiology of the brain. Other stereotactic procedures have a clearer anatomic substrate and appear to have a higher likelihood of success. The indications for hypothalamotomy are not clear, nor is it clear that it offers any advantages over more commonly performed thalamotomies.

PRECENTRAL AND POSTCENTRAL GYRECTOMY

Excision of portions of the sensory cortex was first proposed by Leriche (115) and apparently was first performed by De Gutiérrez-Mahoney (116,117). Although the initial short-term results of excision of the postcentral gyrus were encouraging, the vast majority of patients who had this procedure have described recurrence of their pain.

Basic Considerations

Anatomy and Physiology

The postcentral gyrus, which includes Brodmann's areas 1 to 3 and part of area 5, is the principal cortical region for the integration and interpretation of sensory information. The precentral gyrus plays a similar role for motor activities; the precise localization of function varies from patient to patient. It has been known since the

turn of the century that lesions involving the human postcentral gyrus could dramatically alter sensation and could alter chronic pain states. Precise localization could be determined only by autopsy studies, and these were infrequent. The role of the cerebral cortex in the perception and response to pain is not clear and major disagreements remain as to the rational basis of cortical resection for relief of pain (see Chapter 5).

Indications

Certainly, gyrectomy is not a primary procedure for relief of pain. The development of stereotactic surgery and implanted electrodes for stimulation has probably played a role in the infrequent use of this surgical procedure. The lack of data makes it difficult to determine the possible advantages of gyrectomy.

Clinical Considerations

Technique

With the technology currently available, this operation is best performed under local anesthesia so that cortical mapping can be undertaken and the resection can be based on both physiologic and anatomic data. A large craniotomy is required to expose the central and precentral regions, similar to that used for cortical resection of an epileptic focus.

Results

In 1969 White and Sweet (118) summarized their review of 21 publications, which included data on 38 patients (Table 108-3). Of the 18 initial successes, only four were said to be relieved of their pain when assessed one or more years later. Even the much more extensive lesion used by Pool and Bridges (119), which undercut the parietal lobe for 7.5 cm posterior to the central sulcus, provided pain relief for only a little more than a year. Lende and coworkers (120) removed both the precentral and postcentral gyri of the face projection area to the upper border of the insula. This resection included both the primary and secondary sensory areas for the face as well as all of the precentral motor sensory cortex. Only mild contralateral facial weakness was noted, probably because of the bilateral cortical representation for the face. Data were reported on two patients. One had continuous unilateral burning facial pain secondary to a pontine stroke and was rendered pain-free until he died 20 months later from heart disease. The other had continuous facial pain after a retrogasserian rhizotomy for trigeminal neuralgia and was pain free for at least 17 years.

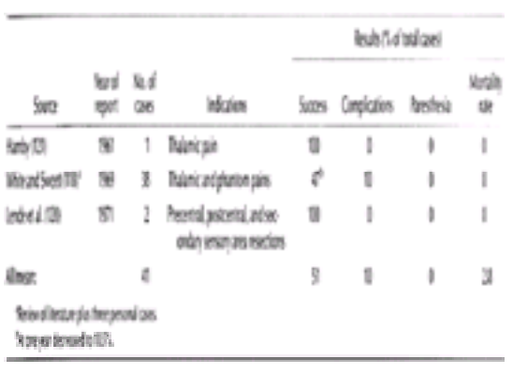

TABLE 108-3. Results of postcentral gyrectomy

It is possible that removal of the entire primary and secondary sensory areas along with the corresponding motor area can succeed where less extensive operations have failed (121). I am not aware of any reports of such operative procedures.

Complications

Cortical excisions do involve some risk of focal epilepsy, especially in the region of the central sulcus. Extensive cortical lesions can also result in contralateral sensory and motor loss.

FRONTAL LOBE OPERATIONS FOR PAIN

Prefrontal Leukotomy

Contemporary frontal lobe operations for pain evolved from prefrontal leukotomy, an operation originally devised for the treatment of severe intractable psychiatric disorders (122). No other class of surgical procedures has been subjected to the political and scientific scrutiny that has accompanied “psycho-surgery.” The abusive use of prefrontal leukotomy in the first 25 years of its widespread acceptance led to a rebound that, at least in the United States, makes it difficult to perform any psychosurgical procedure. Although prefrontal leukotomy probably has no contemporary application, its descendant, cingulumotomy, can be effective for the relief of pain in properly selected patients.

Basic Considerations

Anatomy and Physiology. The prefrontal leukotomy procedure was based on experimental observations in animals of calming effects after bilateral division of white matter fibers immediately anterior to the frontal horns of the lateral ventricles (123). These fibers project from the cingulate gyrus and dorsomedial thalamus to areas 9 through 14 of the frontal cortex. They are the rostral projection of the reticular-activating system and diffuse thalamic projection pathways. Subsequent reports indicated that some patients with complaints of pain as part of their mental illness lost their pain after prefrontal leukotomy (124,125). These reports stimulated the use of bilateral prefrontal lobotomy for the treatment of various chronic pain states (126,127,128,129,130 and 131). The operation, whether primarily for psychiatric disorders or chronic pain, was then refined, at first by restricting the bilateral leukotomy to medial frontal white matter (132).

Clinical Considerations

Techniques. Although prefrontal lobotomy is popularly regarded as a surgical procedure done by inserting an icepick through the orbital roof and blindly traumatizing the frontal lobes, most neurosurgeons have used a trephine hole placed anterior to the coronal suture, either laterally or superiorly. The dura is opened in a cruciate fashion and blood vessels on the cortical surface are coagulated. A ventricular needle is passed in the plane of the proposed leukotomy to ensure that it is anterior to the frontal horn of the lateral ventricles. A leukotome is then inserted to transect the bulk of the white matter. The operation is usually performed under local anesthesia.

Variations in the surgical technique include suction-coagulation under direct vision, injection of sclerosing solutions, and use of RF current to make lesions. Limited leukotomies have been performed by manually directing the lesion to the area of interest.

Results. The effectiveness and limitations of these procedures in the treatment of various pain states were well described by Elithorn and colleagues (133). They evaluated 25 patients managed with standard bilateral prefrontal leukotomy or with the more restricted bilateral section of only the medial frontal white matter. Evaluation, at a minimum of 6 months after operation (mean 24 months), was based on patients' and relatives' opinions and on a social functioning rating scale. All patients but one had chronic pain; the largest groups were five with postherpetic neuralgia, four with atypical facial pain, and three with painful torticollis.

These operations did not change the perception of acute pain or responses to it except for a suggestion of a more intense but briefer response to noxious stimulus. Two-thirds of the patients were considered to be improved, however, with six of 25 much improved based on the social function rating scale, although only one-third of

the patients or relatives thought there had been improvement. Patients with the most extensive operations had the best outcomes based on the evaluation by the patients and relatives, but not on the social function rating scale. Those with the most severe pain did least well by any measure. Older patients had better outcomes. Patients with large “standard” leukotomies all showed some personality change, which was considered severe in one-third. Eight of 13 patients with more limited medial frontal leukotomies demonstrated personality changes; these were severe in two.

Benefit in patients with severe organic pain usually required some personality change. Elithorn and associates (133) concluded that the major beneficial effect of these operations was to reduce depression and anxiety, with a more variable effect on obsessive behavior. In pain patients the typical postleukotomy picture was one in which patients still complained of severe pain but at the same time showed an inappropriately cheerful affect and the inability to sustain an attitude or mood. Unfortunately, only 13 of 25 patients returned to their preoperative level of intellectual and physical activities. Generally similar results were reported by others (134).

Unilateral Prefrontal Leukotomy

The value of unilateral prefrontal leukotomy in chronic pain of diverse causes were evaluated by Scarff (135,136) in 33 patients. He found that two-thirds of patients were improved without major personality changes. White and Sweet (137) disagreed with this conclusion, however, and stated that mental changes were always present when suffering had been alleviated, although unilateral prefrontal leukotomy was less likely to lead to the severe personality changes seen after bilateral lesions. White and Sweet (137) also indicated that suffering returned if patients survived more than 6 months after a unilateral prefrontal lobotomy. When psychological functioning returned to normal, patients were likely to suffer again.

Summary

In these reports, the major features of frontal lobe procedures for pain were evident: major effects on depression and anxiety, little or no effect on pain perception or on the patient's report of pain, but an apparent reduction in the impact of the pain on the patient's affect and functioning. These same features also apply to modern, more limited, frontal operations for pain, although these newer operations have no measurable effect on personality or intellectual performance. Prefrontal leukotomy is no longer considered to be a reasonable operation for pain relief because of its devastating effect on social activities and intellectual performance.

CINGULUMOTOMY

Basic Considerations

Cingulotomy or cingulumotomy is one of a number of operations that involve lesioning a part of the frontal lobes (Fig. 108-12). Early operations, such as extensive prefrontal lobotomies and resection of various portions of the frontal cortex, did not dissociate effects on reducing suffering from intractable pain and effects on more general aspects of emotional responses to nonpainful stimuli and intellectual function. Resection of the anterior cingulate gyrus (cingulectomy) was reported to relieve suffering without producing major effects on personality and intellect (138). With the advent of stereotactic methods, the idea of placing an RF lesion in the outflow path of the cingulate gyrus, the cingulum, was proposed, thus the term *cingulotomy* or *cingulumotomy*. Foltz and White described an experimental study in which morphine withdrawal was nearly abolished by cingulumotomy and then they reported pain relief in humans after stereotactic cingulumotomy guided by ventriculography (139,140). Other investigators reported that addiction to narcotics or alcohol could also be cured by cingulumotomy. Neuropsychological studies showed that these positive effects of cingulumotomy were not accompanied by adverse effects on personality or intellectual function (141,142). More recently, positron emission tomography scan studies have demonstrated increased metabolic activity in the cingulate gyrus elicited by the application of noxious stimuli, thus solidifying a role for this region in pain appreciation (143,144).

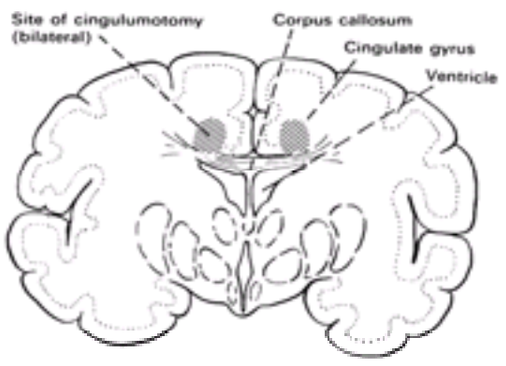

Figure 108-12. Coronal section of brain indicating sites of lesions for cingulumotomy.

Clinical Considerations

Indications

Cingulumotomy is indicated for intractable pain that has failed to respond to other less invasive forms of therapy. Both pain due to cancer and non–cancer-related pain may be alleviated with this procedure (145,146,147 and 148) (Table 108-4 and Table 108-5). Nociceptive and neuropathic pain may respond to cingulumotomy. There is no somatotopic representation within the cingulate region, and therefore cingulumotomy may be used for treatment of pain in any location within the body. It is important to know that cingulotomy is performed bilaterally; unilateral cingulotomy is of no demonstrated benefit for treatment of chronic pain. It has also been suggested that cingulotomy may be particularly indicated if anxiety or “suffering” and/or narcotics addiction are compounding problems because of the beneficial effect of cingulotomy on these two problems. Where cingulotomy should fit *vis-à-vis* other central ablative pain-relieving procedures such as thalamotomy has not been clarified.

TABLE 108-5. Results of cingulumotomy for nonmalignant chronic pain

Technique

Cingulotomy is usually performed under local anesthesia but may be performed under general anesthesia as well because intraoperative electrophysiologic localization does not help in target location. Initially, cingulotomy was performed using ventriculography but more recently, a technique using MRI localization has been proposed that is superior to ventriculography and presumably safer (146,147). The target is located approximately 25 mm posterior to the tips of the frontal horns of the lateral ventricles as identified on axial, coronal, or sagittal MRI scans. The center of the proposed lesion is located in the center of each cingulate gyrus. We make the cingulotomy lesions using a 2-mm-diameter RF lesioning probe with 10-mm exposed tip and with a thermistor in order to measure the temperature (Fig. 108-13). The probe is introduced via a 6- to 8-mm scalp incision located just anterior to the coronal suture and 15 to 20 mm lateral to the midline. The stereotactic coordinates of the planned target are determined and set on the Leksell stereotactic frame. The twist drill opening is then made by passing the drill through the stereotactic guides, which ensures that the opening is oriented in the correct trajectory for introduction of the lesioning probe directly to the target. Using this technique, the procedure is minimally invasive and avoids some of the problems that may be associated with larger cranial openings such as dural bleeding and especially loss of cerebrospinal fluid, which may result in brain shifts that could move the intended target significantly from its preoperative location. Because electrophysiologic localization is not helpful, we do not recommend either electrical recordings or stimulation before lesioning. An early attempt by us to use electrical stimulation resulted in a grand mal seizure, presumably due to cortical spread of the stimulating current. The lesioning probe is introduced to the target and an RF lesion is created at 85°C for 60 seconds. The probe is removed and the procedure is repeated on the contralateral side. The entire procedure can be easily accomplished in 30 to 45 minutes. Some authors have recommended enlarging the lesions either superficially and/or deeper, but we have not usually done this (147,148). Also, some authors have recommended placing a second set of lesions just posterior to the first ones, but we have usually not done this either (147,148). We have performed an immediate postoperative MRI with contrast while the patient remains in the stereotactic frame in order to confirm the accuracy of lesion placement and to assess for possible postoperative hematoma. So far we have not identified intracranial hemorrhage after cingulotomy, but it is a risk of any stereotactic operation in which a probe is introduced into the brain.

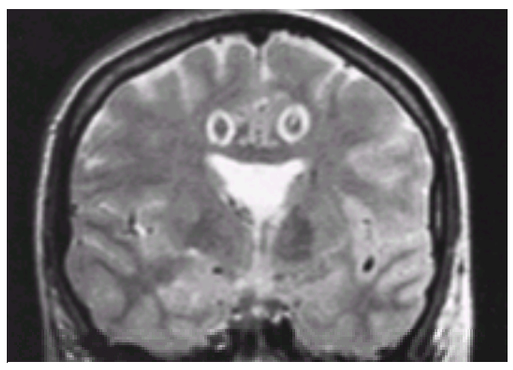

Figure 108-13. Coronal magnetic resonance imaging scan immediately after bilateral radiofrequency cingulotomy for treatment of facial anesthesia dolorosa. The pain had failed to respond to prior trigeminal dorsal root entry zone lesions and to medial thalamotomy but has been relieved for more than 1.5 years after the cingulotomy.

Results

The reported results of cingulotomy are encouraging, with approximately 50% of patients reporting significant decreases in pain. There were only minor differences in the success rates for cancer-related or non–cancer-related pains. Reported success rates do appear to decrease if follow-up time is extended so that overall the procedure may be slightly more effective for cancer pain. As is usual with most pain-relieving surgical procedures, neuropathic pain appears to respond less well to cingulotomy than nociceptive pain.

Complications of cingulotomy are few and primarily due to rare cases of intracranial hemorrhage. Otherwise, neurologic deficits do not occur and effects on neurocognitive behavior, even with large lesions, are minimal or nonexistent.

We have found cingulotomy to be useful in combination with medial thalamotomy where one or the other lesion was not successful alone. In most of our combined lesion patients, we have begun with a medial thalamotomy if the pain is unilateral and then proceeded to cingulotomy if the pain relief was unsatisfactory from thalamotomy alone. For more widespread or midline pain, we have begun with cingulotomy and then added unilateral or in some cases bilateral medial thalamotomy (usually in staged procedures 2 to 3 months apart) if cingulotomy alone is unsuccessful.

CHAPTER 109

Multidisciplinary Pain Management

John D. Loeser and Dennis C. Turk

The differentiation of chronic pain from acute pain was a seminal development in both clinical medicine and basic research. It has led to new research strategies focusing on the changes that occur in tissues and the nervous system in response to injury. Another important change in the traditional approach to pain patients was the subdivision of chronic pain patients into those with cancer, those with injury to the nervous system, those with chronic diseases, and those whose complaints of pains could not be understood on the basis of observable pathology (see Chapter 2). Every patient's complaints are likely to be influenced by his or her attitudes, beliefs, expectancies, and current mood. Individuals express their pain verbally and nonverbally (i.e., by overt expressions of pain and distress), and these behaviors are largely under the influence of environmental parameters including responses from significant others (see Chapter 10). In this chapter, we focus on patients who have failed to respond to traditional medical treatment and for whom cognitive, affective, and environmental factors are particularly important in the maintenance of the pain and disability. This distinct subset of patients warrants identification by appropriate diagnostic evaluation and referral to and treatment at a multidisciplinary pain center (MPC) (see Chapter 18).

This is the last part of a three-chapter segment (see Chapter 11 and Chapter 18) addressing the conceptual basis and implementation of multidisciplinary pain management. The assessment of patients who are candidates for multidisciplinary pain management is presented in Chapter 18. Here, we discuss the design and implementation of multidisciplinary pain treatment and its reported outcomes. Multidisciplinary pain management originated in the 1950s because of Bonica's (1,2) emphasis on pain patients and gained momentum with the work of Fordyce in the 1960s and 1970s (3). Many other psychologists and physicians also have contributed to this rapidly developing field (4,5). For patients who do not respond to traditional medical and surgical strategies, it has become a common treatment strategy. Since this type of treatment of chronic pain patients engages the skills of many providers, much of the content of this textbook is relevant to multidisciplinary pain management. Many other chapters contain specific information on the building blocks of this treatment, especially Chapter 10, Chapter 12, Chapter 16, Chapter 24, Chapter 25, Chapter 26, Chapter 88, Chapter 89, Chapter 90, Chapter 91, Chapter 92, Chapter 93 and Chapter 94.

The epidemic of chronic pain complaints and the disability associated with them has afflicted all of the industrialized countries to some degree. As health care costs for those who suffer from chronic pain have grown, it has become apparent that the traditional biomedical model provides an inadequate foundation for the delivery of effective health care. Multidisciplinary pain management evolved because it has proven to be more effective and less costly than the traditional methods of addressing chronic pain (6,7). It employs a biopsychosocial model and relies heavily on the cognitive-behavioral approach (see Chapter 89).

For many chronic pain patients, the forces that have led the patient to report persistent pain remain obscure. Traditional diagnostic processes have failed to identify a remediable cause of pain. These patients require treatment because of the disruption of their life that they ascribe to pain. Indeed, their health care providers must feel comfortable abandoning the search for cure and, instead, accept palliation as a viable outcome. The goal, then, is to improve the patient's ability to function, not to cure the disease that has led to pain. Hence, the diagnostic process must identify the areas of functional impairment and disability, and treatment must address all of the factors that contribute to disability. In contrast to traditional medical therapy, patients cannot be passive recipients of the ministrations of providers. Such patients must accept responsibility and work to achieve the benefits of treatment.

A useful conceptualization of the problem of chronic pain without identifiable and treatable pathology is that “the patient is hurting more than he or she needs to.” Secondary effects of the pain, such as depression, physical deconditioning, social isolation, inappropriate medications, vocational dysfunction, and superstitious beliefs about the body may be the primary determinants of the patient's overall condition. It is the treatment of these and related issues that are the focal point of multidisciplinary pain management.

Vast numbers of people will, if asked, report that they have chronic pain problems of more than trivial severity (8). They may even take occasional medications or consult a physician or other health care provider. Infrequent sickness days may occur. However, these people remain functional and do not suffer from their pain or become disabled to any significant degree. They are not appropriate candidates for multidisciplinary pain management. Many other people have chronic pain and seek health care. They may have a diagnosable disease and receive appropriate therapy from their primary physician or a single specialist. As long as function returns and their pain complaints diminish, they have no need of multidisciplinary pain management.

Several epidemiologic studies (9,10) have compared the characteristics of people who have chronic pain in the community with those of patients treated at MPCs. The patients treated at the specialized pain centers are more likely to demonstrate higher levels of emotional distress, work-related injuries, use of the health care system, constant pain, use of opioid medication, prior surgeries, and functional impairments. Moreover, they have lower levels of education and were more likely to have negative attitudes about the future. Flor et al. (11) reported that patients treated at MPCs had a mean duration of pain of more than 7 years. Obviously, those referred to MPCs have long histories of severe pain intensity, are high health care users, and suffer from significant emotional distress. They are a particularly recalcitrant set of pain patients. As discussed in Chapter 18, only those patients who meet the criteria for multidisciplinary pain management should be enrolled in such a treatment program.

It has been our observation, however, that many patients are treated as if they had a clear-cut diagnosis and as if they were showing a good response to therapy, when, in fact, the diagnosis merely reflects what the provider does to earn a living and the patient has not benefited from the treatment. Interminable therapy often adds to the patient's disability and is not acceptable. Some patients are sent from one biomedically fixated physician to another, like billiard balls caroming across a table from cushion to cushion. Each provider does his or her thing and sends the patient on to another ineffective series of treatments. Timely referral to an MPC, not a parade of specialists, is required.

DESCRIPTION OF MULTIDISCIPLINARY PAIN PROGRAMS

Although there is no single format for multidisciplinary pain management, almost every treatment facility of this type has a generic concept and plan (Table 109-1). These treatment programs also share general features (Table 109-2). This is probably because of the pioneering and preeminent role of the University of Washington Multidisciplinary Pain Center and its faculty in training pain management specialists, lecturing throughout the world, and publishing scientific articles and numerous book chapters (12). The concept underlying this form of treatment is the biopsychosocial model, in contrast to the biomedical model that characterizes most of medicine. Figure 109-1 depicts the components of this concept and emphasizes that health care providers can only observe pain behaviors, not pain itself (13).

Reconceptualization of the patient's pain and associated problems from uncontrollable to manageable.
Overt or covert efforts are made to foster optimism and combat demoralization.
Flexibility is the norm with attempts to individualize some aspects of treatment to patient needs and unique physical and psychological characteristics.
Emphasize active patient participation and responsibility.
Provide education and training in the use of specific skills such as exercise, relaxation, and problem solving.
Encourage patient feelings of success, self-control, and self-efficacy.
Encourage patients to attribute success to their own role.

TABLE 109-1. Concepts of treatment at multidisciplinary pain clinics

Share a common conceptualization of chronic pain patients.
Synthesize the diverse sets of information based on their own evaluations, as well as those of outside consultants, into a differential diagnosis and treatment plan customized to meet the specific need of each patient.
Work together to formulate and implement a comprehensive rehabilitation plan based on available data.
Share a common philosophy of disability management.
Act as a functional unit whose members are willing to learn from each other and modify, when appropriate, their own opinions based on the combined observations and expertise of the entire group.

TABLE 109-2. General features of multidisciplinary pain treatment teams

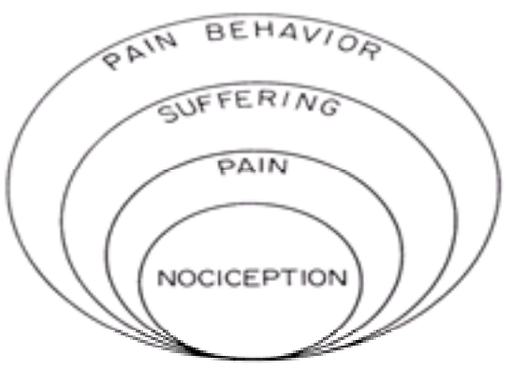

Figure 109-1. Loeser's model of the four components of pain. (From Loeser JD. Concepts of pain. In: Stanton-Hicks M, Boas R, eds. *Chronic low back pain.* New York: Raven Press, 1982:146, with permission.)

Nociception, pain, and suffering are personal, private, internal events whose existence can only be inferred by observing a patient's behavior. In the clinical setting it is impossible to measure any of these internal events; external observers can only quantify pain behaviors. The biopsychosocial model assumes that all human behavior, including the complaint of pain, reflects a combination of the events occurring within the patient's body, the recognition of these events, the appraisal of these events, the affective responses to these events, and the influence of the environment. The model calls for addressing all of these components at once and in a coordinated fashion, to present the patient with a single treatment program that encompasses all of the treatable issues.

In multidisciplinary pain treatment and rehabilitation programs, patients are usually treated in groups of five to 15. Patients work on at least four generic issues simultaneously: physical, pharmacologic, psychological, and vocational. Programs usually emphasize physical conditioning, medication management, acquisition of coping and vocational skills, and gaining knowledge about pain and how the body functions. Individual and group counseling addresses patient needs. In contrast to traditional Western health care, the emphasis is on what the patient accomplishes, not on what the providers accomplish. The providers see themselves as teachers, coaches, and sources of information and support.

Multidisciplinary pain management requires the collaborative efforts of many health care providers, including, but not limited to, physicians, nurses, psychologists, physical therapists, occupational therapists, vocational counselors, social workers, and support staff (Table 109-3). The health care providers must act as a team, with extensive interactions among the team members. In the current managed care environment in the United States, with occult rationing (managing costs, not care, is the true agenda), it is often difficult to arrange for funding of this type of health care, even though this model offers more outcome data than any other type of treatment of chronic pain. This is particularly true for low back pain. We review some of these results later in this chapter, but see also Turk and Okifuji (6,7).

Facilities

The facilities for a multidisciplinary pain treatment program can exist within a large hospital or medical center or they can be completely free-standing. The evaluation of new patients and the follow-up of those who have graduated from the treatment program require dedicated space. Along with individual examination rooms there must be a conference room for group meetings with patients and their significant others. Other larger rooms must accommodate patient education groups, group psychotherapy sessions, relaxation sessions, and physical therapy activities. High-tech physical therapy equipment may impress patients and payers, but it is certainly not an essential aspect of this type of pain management. Adequate space to permit the simulation of aspects of occupational activities is highly desirable.

Support staff and space for their activities are essential.

Patient Treatment Strategies

Table 109-4 itemizes the goals of multidisciplinary pain management. Every patient has a different mixture of functional limitations, pain behaviors, affective disturbance, physical disability, and vocational dysfunction. Successful treatment addresses each of these general areas.

Identify and treat unresolved medical issues.
Eliminate inappropriate medications.
Institute desirable medications.
Improve aerobic conditioning, endurance, strength, and flexibility.
Eliminate excessive guarding behaviors that interfere with normal activities.
Improve coping skills and psychological well-being.
Alleviate depression.
Assess patient resources and identify vocational and recreational opportunities.
Educate the patient about pain, anatomy, physiology, psychology, and discriminating hurt from harm.
Educate the patient about prudent health care consumption.
Assist the patient in establishing realistic goals and maintaining treatment gains.

TABLE 109-4. Goals of multidisciplinary pain management

The original multidisciplinary pain management programs were all inpatient-based. It is now apparent that outpatient programs can be equally successful if they have adequate intensity and duration (14). There are no controlled studies to determine the optimal duration of treatment and hours per day; nor does the literature reveal which aspects of the various components are most important for a treatment program. It is clear that the effects of a multidisciplinary pain treatment program are greater than the sum of its parts, however. Common features of all programs include physical therapy, medication management, education about how the body functions, psychological treatments (e.g., coping skills learning, problem solving, communication skills training), vocational assessment, and therapies aimed at improving function and the likelihood of return to work. Programs usually have a standard daily and weekly format that providers can tailor to an individual patient's needs. The overall length of a program depends in part on unique patient requirements.

Typical programs operate 8 hours per day, 5 days per week, and last 3 to 4 weeks, although some programs meet less frequently and last for longer periods. The daily schedule used at the University of Washington Multidisciplinary Pain Center is shown in Table 109-5. All good programs include a prolonged follow-up period with options for brief interactions to help patients maintain their gains.

Monday through Friday	
8:00–8:25	Movement, stretch, body mechanics
8:35–10:35	Physical and occupational therapy, individual and group sessions
10:45–11:15	Skill building group (nursing)
11:15–11:45	Relaxation group/muscle reeducation (nursing)
12:00–12:30	Lunch
12:15–12:55	Rounds with treatment team
12:30–12:55	Individual sessions/muscle reeducation
1:00–1:50	MD didactic group
2:00–2:55	Physical and occupational therapy, individual and group sessions
3:00–3:50	Psychology didactic group
4:00–4:55	Physical therapy individual sessions
Saturday	
8:30–9:30	Physical therapy (group)
9:30–10:30	Occupational therapy (group)
10:30–11:00	Stretch class (group)

TABLE 109-5. Structured program patient schedule at University of Washington Pain Center

Each of the treatment team members makes a specific contribution to the overall program. The most difficult aspect of multidisciplinary pain management is identifying health care providers who can function as members of a treatment team.

Role of the Physician

The physician is responsible for the initial history and physical examination, review of outside records, and determination of the need for any further diagnostic tests. Detailed assessment of the patient's medication history is also a key physician contribution. The implementation of medication management, including drug tapering by means of a pain cocktail technique (see Chapter 88), is also the physician's responsibility. Another important task for the physician is to review the medical issues and the findings in diagnostic tests and imaging studies with the patient. The physician also plays an essential role in the education of the patient and in legitimizing all of the other components of the treatment program.

Role of the Psychologist

The psychologist conducts the initial psychological evaluation, monitors and implements the cognitive and behavioral treatment strategies, teaches the patient coping skills, and educates patients about the relationships among thoughts, feelings, behavior, and physiology. It is important to recognize that working with chronic pain patients requires appropriate education and training for the psychologist, just as it does for the physician. The psychologist leads both individual and group educational and counseling sessions for the patients. In addition, the psychologist plays a critical role in helping other members of the treatment team use sound behavioral principles in designing patient treatment activities (see Chapter 88).

Role of the Nurse

The nurse is a key part of the treatment program, playing a major role in patient education regarding such topics as medication, diet, sleep, hygiene, and sexual activity. Another nursing function is assisting patients in the practice of newly learned skills, assessing medication responses, and acting as the focal point of the communications that keep such a program operational. The roles of nurses vary with their skills and the interactions with other providers. Since the nurses tend to be with patients throughout their entire treatment course, they are a focal point for continuity in the treatment program.

Role of Physical and Occupational Therapists

Physical and occupational therapists provide assessment and active physical therapies for patients to improve their strength, endurance, and flexibility. They do not provide passive modalities of treatment. They assist the patient in developing proper body mechanics and strategies for coping with the physical demands of a job and everyday life. They function mainly as teachers and coaches.

The occupational therapists review the patient's work history, disabilities, and factors that may play a role in determining who goes back to work and who does not. They help in the establishment of work-hardening and training activities. Some programs heavily emphasize ergonomic issues and use high-tech in physical therapies; however, the need for this type of treatment is unclear.

Role of the Vocational Counselor

The vocational counselor plays a critical role in the treatment of an individual for whom return to work is a treatment goal. Initial assessment occurs as part of the screening process (see Chapter 18), but in-depth evaluation of interests, education, aptitude, physical capacities, learning capabilities, work experience, transferable skills, and vocational goals occurs on entry into the treatment program. The goals are to identify vocational opportunities and barriers to effective return to work. In addition to occupational counseling, counselors provide job-seeking skills training, placement counseling, job hardening, information about educational options, and liaison services. Information obtained by the vocational counselor is critical for other team members to establish realistic goals for the patient. In some organizations, rehabilitation nurses provide this service.

TREATMENT PRINCIPLES

The goals of multidisciplinary pain management are normally specific, definable, operationalizable, and realistic. Table 109-6 lists a set of goals commonly targeted in MPCs. As they have evolved, MPC treatments have become performance-based, goal- directed, and outcome driven. Integration of medical evidence related to patients' pain and physical impairment with information concerning what patients are doing or failing to do because of their pain, how these behaviors influence patients' physical capacity, how others respond to the patient, the influence of psychosocial factors that contribute directly and indirectly to patients' physical and emotional status, and the potential for rehabilitation (i.e., disability) is essential. The treatment team must build an alliance with patients to instill a willingness to accept the need for self-management.

Identification and treatment of unresolved medical problems
Elimination of inappropriate medication
Symptomatic improvement
Restoration of physical functioning
Restoration of social and occupational functioning—social reintegration, return to productive employment
Reduction in use of health care system
Improvement in coping and psychological functioning—foster independence

Adapted from Turk D, Stacey B. Multidisciplinary pain centers in the treatment of chronic pain. In: Frymoyer J, Ducker T, Hadler N, eds. *The adult spine: principles and practice*. New York: Raven, 1997:253–274.

TABLE 109-6. General goals of multidimensional pain centers

Physical therapy uses behavioral medicine principles (15) and engages few, if any, passive modalities. Biofeedback can be a useful adjunct because it teaches the patient that he or she can gain control over various bodily functions (see Chapter 90). The emphasis is on improving strength, endurance, and flexibility through the patient's physical activities. The therapists provide instruction, guidance, safety, and encouragement. Accomplishments, rather than pain behaviors, receive rewards. Patients maintain graphs of their daily activity and track their progress. As patients progress, they engage in more complex activities that simulate the workplace requirements.

Medications are given on a time-contingent basis, to uncouple the reinforcement of pain behaviors by medications. In general, patients in an MPC program do not derive adequate pain relief from analgesic medications, and thus, they are usually tapered by means of the pain cocktail technique. This technique is simply a method of converting all opioids to an equivalent dose of methadone and delivered with a masking vehicle. The dose is then tapered over the period of treatment, always with the full knowledge of the patient. Most medications are discontinued; the common exceptions are antidepressants, which often help chronic pain patients. Pain clinics discourage long-term use of other medications both because of their potential side effects and because their use undermines the philosophical concept that the patient must learn to control his or her pain and not depend on health care providers or their prescriptions.

Psychological strategies generally aim to alter behavior rather than change the patient's personality. Patients learn coping skills because this is frequently a deficiency that has led to the patient's many difficulties (Table 109-7). Couples therapy is sometimes appropriate. Issues that patients bring up receive attention in either the group format or in individual therapy, as needed. As depression is so often a component of the chronic pain problem, it warrants psychological as well as pharmacologic interventions. Psychologists provide relaxation and consolidation sessions that allow patients to work on newly acquired skills and explore educational topics and new psychological skills (Table 109-8).

Maintenance of gains	Program orientation
Making and using a coping plan	Purposes of group sessions
Relaxation training	Program goals
Physiology of stress	Goal setting
Quieting response	Focused breathing
Evaluation of use of coping plan	Hurt vs. harm
Preparing for new patients	Identifying gains
Time planning	Review of patient education materials

TABLE 109-8. Patient education topics

Another important aspect of multidisciplinary pain management is education. This is an activity that is shared by physicians, psychologists, and nurses. Topics cover a wide array of the problems facing those who suffer from chronic pain. Subject selection and content is, to some degree, are functions of the needs of each group of

patients, but content always includes a core set of issues (Table 109-9).

Stress management	Assertiveness training
Relaxation training	Cognitive strategies
Coping skills	Communication skills
Anger management	Dealing with depression
Pain behaviors	Crisis management
Sleep disorders	Costs/meanings of pain
Physiology of stress	

From Loeser JD, Egan KJ. Inpatient pain treatment program. In: Loeser JD, Egan KJ, eds. *Managing the chronic pain patient: theory and practice at the University of Washington Multidisciplinary Pain Center*. New York: Raven Press, 1989:41, with permission.

TABLE 109-9. Topics for skills training

Team meetings occur daily to review any patient problems. Formal review of all patients takes place on a weekly basis. Communications with the patient's primary care providers, financial sponsors, compensation systems, and so forth are a major issue for such treatment programs and occupy a significant amount of professional time and effort. Numerous papers describe different treatment programs and their individual treatment strategies (12,16). The International Association for the Study of Pain, many national societies, and several medical specialties (17) have offered guidelines for multidisciplinary pain management facilities. These are all very general and do not specify any details of the components of a treatment program.

Variations around the themes described above continue to evolve, based on availability of resources, policies of major payers, theoretical constructs, and the preferences and biases of those who establish such treatment facilities. Our experiences at the University of Washington Multidisciplinary Pain Center and the University of Pittsburgh and observations made during our travels throughout the world suggest a set of broad principles, outlined in Table 109-10.

The single most important ingredient is the existence of health care providers who are willing to work together as a team. "The magic is in the interactions" has been an oft-repeated answer when I was asked to explain how we could successfully carry out such a treatment program.
The health care providers must care about chronic illness and not be totally locked into acute disease, as is fostered by the biomedical model.
The commitment of the provider to the patient is essential.
Patients must want to change their lives and must be willing to give the program a try.
They must recognize that in this type of treatment program, the patients do the therapeutic work.
The treatment is the start of a journey to reclaim one's life from the pain problem; long-term support is required to keep the patient on the road to recovery.
The attempt to treat the untreatable leads to demoralization of the treatment team. Patients must be properly selected.

TABLE 109-10. Principles of multidisciplinary pain management

An important issue is the maintenance of gains that have occurred during the treatment program. Surrounded by a team of supportive health care providers and other patients, most patients see some gains by the end of treatment. However, many are unable to maintain their gains when they return to their normal family and occupational activities. In the closing days of a treatment program, each patient must learn strategies for maintaining his or her gains in a less supportive environment. Most programs have established brief follow-up interactions to try to assist patients in keeping up their physical and psychological skills and preventing relapses.

Every year since the mid-1980s the University of Washington Multidisciplinary Pain Center and the University of Pittsburgh Pain Evaluation and Treatment Institute have received visits from health care professionals who wish to learn the “magic” of our treatment programs. They are certain that our providers know some tricks and have original techniques to cure pain patients. The “magic” that such programs possess, of course, is simply the interactions between providers and patients. All of the providers are of equal standing and earned respect for their activities in the pain treatment program. The team presents a unified front to each patient. Effective leadership, consistency of treatment philosophy and implementation, dedicated providers, and the realization that the whole is greater than the sum of its parts all contribute to our success (12,18).

OUTCOMES

Given constraints on health care resources, there is a growing interest in accountability and evidence-based treatment outcome data. All components of health care delivery are under scrutiny to determine whether they are not only clinically effective but also cost-effective. The effectiveness of pain treatment facilities and, in particular, multidisciplinary pain rehabilitation treatment has been debated and singled out by some third-party payers for special criticism (19). Often the debates have centered around anecdotal information and hearsay. Surprisingly, the dialogue largely ignores the growing body of outcomes research published over the past quarter century. Referring physicians and third-party payers tend to rely on salient cases, usually failures, treating them as representative and relying on them as the basis for criticizing pain centers. Conversely, pain centers often respond based on their clinical experience and the recall of particular successes that are viewed as representative of the outcomes from their facility, rather than systematically collected empirical data. The battles are taking place on the wrong fields.

To many third-party payers, the term *multidisciplinary pain center* is often synonymous with *expensive*. It is true that treatment at an MPC can be expensive. Involvement of multiple disciplines is labor intensive and costly, because each of the clinicians involved in treatment receives payment for the services provided. Based on a survey of pain treatment facilities conducted in 1995, Marketdata Enterprises (20) concluded that the average cost of treatment at an MPC was $8,100. Estimates tally over 3,300 pain treatment facilities and solo pain-treatment practitioners in the United States (20). The American Pain Society (21) has compiled detailed information on 352 MPCs. Based on the Marketdata survey, it appears that approximately 2.9 million Americans (0.11% of the population) are treated for chronic pain each year with only about 176,850 (6%) of these treated at MPCs. Over 60% of these treated patients had their backs as the primary location of their pain. Research indicates that an average back pain patient treated at an MPC has had 1.7 surgeries prior to treatment (11). Extrapolating from these numbers, 106,111 back pain patients (60% of the total) with 1.7 prior surgeries are treated at MPCs each year.

Several epidemiologic studies have examined the characteristics of patients treated at MPCs as compared to patients with chronic pain not treated at these facilities (9,10,22). The patients treated at MPCs had reports of constant pain, high levels of emotional distress, work- related injuries, significantly lower levels of education, high levels of health care utilization, and high levels of opioids, high levels of functional impairment, and negative attitudes about the future. Furthermore, the average duration of pain for patients treated at MPCs is over 7 years (11). Weir et al. (23) concluded that the “picture that emerges is one of a pain clinic patient who is isolated from meaningful relationships, whose pain interferes with all aspects of his life, who has lost his energy and determination, is unemployed, is in constant pain and experiences the threat, loss and harm of his pain problem” (p. 1413). Furthermore, these patients are refractory to other types of treatment regimens, including surgery. Given these characteristics, it seems reasonable to assume that chronic pain patients for whom MPCs provide services have the most recalcitrant problems and are resistant to improve. As we examine the question of the effectiveness of MPCs, it is important to keep these patient characteristics in mind.

Using the Marketdata Enterprises survey data (20), we can estimate that the cost of treating chronic pain patients at MPCs is over $1.5 billion per year (average cost of treatment $8,100 × 176,850 patients treated). This figure confirms that treatment at an MPC can be expensive. To put these costs in perspective, consider that the annual costs for treatment of chronic pain in general is very high. Frymoyer and Durett (24) estimated that back pain cost $33.6 billion for medical payments, $11 to $43 billion for disability compensation, $4.6 billion for lost productivity, and $5 billion in legal services. In one study, the average cost of nonsurgical health care in the

year prior to treatment of patients at MPCs was over $13,284 (25). We can again apply this average cost to the estimated 176,850 patients treated at MPCs (20) and estimate that the nonsurgical expenditures in health care for these patients would exceed $3 billion. Thus, total expenses for surgical and nonsurgical health care costs for a cohort of patients prior to their treatment at MPCs would be in excess of $4.5 billion. This figure omits inflationary increases in health care in the United States in the past 5 years.

Returning to the data cited regarding the primary location of pain (60% with back) and the number of surgeries (1.7), we suggest that patients treated at MPCs each year have had 106,111 operations on their backs. Assuming $15,000 per surgery (24), the cost of back operations for one cohort of patients treated at MPCs would be in excess of $1.6 billion. Consider that, when evaluating the effectiveness of treatment at MPCs, a substantial proportion of the patients are surgical failures.

The cost of multidisciplinary treatment compared with the alternatives merits attention. Approximately 250,000 lumbar surgeries are performed for pain each year at an estimated cost of $15,000 per operation. Using these figures, the cost of lumbar surgery for back pain alone is over $3.5 billion each year. Although there is no question that the cost of treatment for chronic pain is high, the cost of treatment at an MPC is comparatively low.

Asking whether MPCs are effective, however, may be an unsuitable way to phrase the question of whether they are worthwhile. It might be more appropriate to broaden the question to ask how effective are pain treatment facilities *compared to alternative treatments* and *on what outcome criteria*. That is, in the example of back pain, one might ask how effective are pain treatment facilities compared to alternatives such as surgery on measures such as reduction in pain, reduction in medication and health care utilization, increased physical activity, closure of disability claims, and return to work.

Numerous reviews and several metaanalyses on treatment outcome studies have evaluated the clinical and cost-effectiveness of MPCs (11,26,27). There is an array of outcomes reports for multidisciplinary pain treatment programs (28,29,30,31 and 32). Not all clinics have the same patient mix, and not all treatment programs are as potent as others. There are far too many publications about MPCs to review each one independently and to comment on its strengths and weaknesses. Despite the recalcitrance of the pain problems of the patients treated, they generally support the efficacy of MPCs on multiple outcome criteria (11,26,27,33).

Criteria of Treatment Success

Chronic pain conditions present not a single but multiple problem areas. Thus, the evaluation of treatment effectiveness must target several criteria. Among the most important criteria are (a) pain reduction, (b) iatrogenic complications, (c) reduction or elimination of inappropriate opioid medication, (d) health care utilization, (e) increase in activity, (f) return to work, and (g) closure of disability claims.

The importance of these criteria varies depending on who asks the question. For example, whether a patient resumes gainful employment may be the most significant outcome criterion for a workers' compensation carrier, and pain reduction may be of only limited consequence. A managed care organization may view use of the health care system as the most important outcome, caring less about patients' employment status. Referring physicians, in contrast to some patients, may be most concerned about reduction in opioid medication (34).

Pain Reduction

Pain reduction is perhaps the most common criterion measure of outcome in various treatment approaches for pain problems. Pain reduction following treatment at MPCs ranges from 20% to 40% (11). Studies investigating the long-term maintenance of pain reduction for MPCs have generally reported that pain reductions observed at discharge tend to be maintained at follow-up of up to 2 years (16).

On the other hand, pain reduction following conventional medical and surgical treatments is discouraging. For example, Dvorak and colleagues (35) studied 575 patients who were operated on for lumber disk herniation and concluded that 70% continued to complain of back pain 4 to 17 years after surgery. Lehmann et al. (36) showed similar results with follow-up of patients who had undergone spinal fusions for back pain, with 57% continuing to have back pain during the previous year. In another study, North et al. (37) noted that 66% of the patients who underwent repeated surgeries for back pain continued to experience pain symptoms 5 years after the surgeries.

Spinal surgery is not the only set of operative procedures that have been proven to be less than optimal in alleviating pain. Seres (38) noted that deep brain stimulation achieved some pain relief for only around 30% of chronic pain patients. In a direct comparison, Gallon (39) showed that only 17% of the surgical patients viewed themselves as improved compared to 38% of nonsurgically treated patients. Thus, the results for different surgical procedures seem at best comparable and at times not as good as the results for MPCs in reducing pain (11). However, when it comes to pain reduction, *per se*, the effectiveness of both surgery and treatment at an MPC is rather modest. Complete elimination of pain seems the exception rather than the rule for most treatments.

Iatrogenic Complications

In evaluating any treatment, the prevalence of iatrogenic complications is important because these can greatly increase costs as well as contribute to disability. Dzioba and Doxey (40) examined the outcome of 116 occupationally injured lumbar back surgery patients and found that over 43% had poor results. Surgical procedures themselves sometimes cause additional problems that may require repeat surgery. In a series of 78 surgical patients, Long et al. (41) observed that 11.6% developed serious complications from the procedure. Furthermore, of all the operations performed, 56% were necessary to correct a complication from a previous surgery. Gallon (39) reported that a significantly higher proportion of chronic low back pain patients who had surgery (58%) described themselves as worse on a measure of disability when compared to conventionally treated patients (30%). Repeated surgery, however, may not resolve the problem. The Workers' Compensation Board of Ontario, Canada, estimated that after a second back operation, 20% worsen, 60% stay the same, 20% improve, but no one is cured (42). In contrast to surgery, MPCs rarely report any significant iatrogenic problems following treatment.

Elimination or Reduction of Opioid Medication

A national survey of opioid prescribing practice suggests that the long-term use of opioid medications for chronic noncancer pain is relatively common (43). However, the appropriateness of such practice is embroiled in debate because adverse side effects, such as physical and psychological dependency, have been observed in up to 66% of chronic noncancer pain patients (migraine patients) treated with opioids (44). For a review of these studies, see reference 45. One trial of long-term opioids for geriatric pain patients was terminated early because of the significant side effects reported by patients (46).

Flor et al. (11) found that over 50% of patients treated at MPCs were taking opioid medication on admission. Yet despite taking opioids, these patients were referred for treatment at MPCs for their intractable pain. Because of potentially detrimental effects of opioids and attempts to encourage self-initiated pain management, elimination or reduction of opioid intake is an important part of most multidisciplinary treatment programs.

In general, MPCs appear to be effective in eliminating or greatly reducing opioid intake in chronic pain patients. Studies report that up to 100% of patients decrease opioid use by the time of treatment termination at MPCs (11). Maintaining opioid-free status after multidisciplinary treatment also seems promising: Over 65% of treated patients remain opioid-free at 1-year follow-up (32,38).

The figures on reduction of opioids are particularly impressive because they are concurrent with a statistically significant reduction of pain. In contrast, the prevalence of opioid intake seems to remain approximately at the same level when patients received conventional pain treatment (11). In one surgical study, Lehmann et al. (36) noted that 53% of patients who had spinal fusions to eliminate back pain continued to take analgesic medication after the procedure.

Utilization of the Health Care System

Utilization of the health care system is of particular interest because it demonstrates one of the major areas of economic impact of chronic pain problems. MPCs effectively reduce utilization of the health care system following treatment. In these studies (32,38), 62% to 90% of patients did not seek any additional treatment for their pain during a 3- to 12-month posttreatment period. Caudill et al. (28) reported that of 109 patients who were treated at an MPC conducted within the context of a health maintenance organization reduced their pain-related clinic visits by 36% during the first year after MPC treatment. Compared to conventionally treated patients (i.e., medication and/or surgery), MPCs consistently show superior rates of reduced health care utilization (6,7). Several studies directly compared the outcomes for MPCs and conventional treatments on the number of additional surgeries and hospitalizations (47,48,49 and 50). The findings seem consistently to demonstrate that

MPC treatment reduces subsequent health care utilization significantly more than conventional treatment for chronic pain (Fig. 109-2).

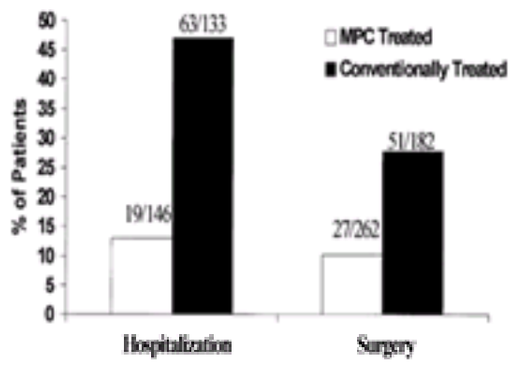

Figure 109-2. Frequency of patients receiving additional surgery and hospitalization following treatment: comparisons between multidisciplinary pain center (MPC) and conventional treatments.

On the other hand, invasive medical procedures may result in undesirable complications, thereby increasing the subsequent use of the health care system. Lehmann et al. (36) reported that 15% of patients who had undergone spinal fusion for back pain required repeated surgery. Earlier, we noted the Long et al. (41) observation that 56% of the surgeries performed were conducted to remedy complications from a previous surgery. Thus, in addition to the surgeries performed, over 50% of operated-on patients are likely to require yet another surgery.

Increase in Activity

Increase in activity and functional restoration are central goals of multidisciplinary pain treatment. According to the quantitative review of outcome studies (11), substantially greater increases in activity level occurred in patients treated at MPCs (65%) compared to conventionally treated patients (35%).

When studies have examined the effects of surgical treatment on patients' activity levels, the results are far from satisfactory. In general, most studies report no change in patients' ability to engage in functional activities such as ability to walk, go up stairs, sleep, or drive following surgery (37).

Return to Work

Although return to work is an important outcome as it has significant socioeconomic implications, several factors impede patients' return to work, aside from their pain. Return to gainful employment for chronic pain patients depends on factors such as local economy, job availability, and the aggressiveness of case managers. Most chronic pain patients have been off work for a substantial period. As noted, the average time off from work is over 7 years (11). Skills that were useful prior to the pain onset may be outdated, making patients less marketable. Some employers may be unwilling to hire someone with a history of back pain, especially if a job requires a significant amount of physical exertion and there is no way to make reasonable accommodations for the physical demands of the job. Denial of continuing disability may lead some patients to return to work even when they are significantly impaired.

Despite these constraints, multidisciplinary pain treatment returns a significant percentage of patients to gainful employment, as numerous studies show. The results of 11 studies with 259 conventionally treated and 435 MPC-treated patients indicate that the rate of returning to work among treated patients is substantially higher (67%) when compared to the rate among the untreated patients (24%) (16). Reviewing the literature, Flor et al. (11) and Cutler et al. (26) arrived at similar figures, suggesting that heterogeneous groups of patients treated at MPCs were twice as likely to return to work as conventionally treated patients.

Most of the published studies on return to work following treatment at MPCs have included patients with diverse pain syndromes. Chronic back pain is a particularly difficult problem to treat, with the odds of returning to work following a conventionally treated back injury of at least 3 months quite poor (51). In light of this statistic, such patients should be less likely to benefit from treatment at MPCs. Feuerstein et al. (52) specifically looked at return to work for chronic back pain patients treated at MPCs and, based on 11 published studies, reported that 71% of MPC-treated patients returned to work, compared to 44% of conventionally treated patients. Thus, even for the difficult problem of chronic back pain, MPCs appear to do remarkably well in returning people to work.

It is useful to compare the return-to-work rates for back pain patients between multidisciplinary and surgically treated patients. In an early study, Beals and Hickman (53) reported that only 36% of industrially injured patients receiving surgery for back pain returned to productive labor following surgery. Wiesel et al. (54) noted that approximately 50% of surgically treated patients returned to gainful employment following surgery. More recently, North et al. (37) reported that only 25% of patients who had spinal cord stimulators surgically implanted returned to work. Even more abysmal outcomes were reported in a study conducted in Belgium, in which only seven of 145 (5%) pain patients implanted with spinal cord stimulators had returned to work 1 year following the surgery (55).

The results of studies of back pain patients treated at MPCs suggest that these facilities return anywhere from 50% to 150% more patients to work than does surgery. These results are even more impressive when we note that the typical patient treated at an MPC has already undergone surgery (11); thus, patients treated at MPCs are often surgical nonresponders.

A word of caution is in order concerning the use of return to work as an outcome criterion. The figures presented do not account for recurrences in symptoms or disability after an initial return to work. Recurrence is a commonly observed phenomenon for those with musculoskeletal injuries. Bergquist-Ullman and Larsson (56) and Biering-Sorenson (57) reported 1-year recurrence rates of over 60% for back pain patients. More recently, Crook and Moldofsky (58) observed a 43% recurrence for a sample of workers' compensation patients with musculoskeletal injuries.

Closure of Disability Claims

Chronic pain is costly to society due to loss of productivity and disability payments to patients. A handful of studies examined the success in closure of disability claims. For example, Seres and Newman (31) reported that within 3 months after discharge, closure of the claims was recommended for 75% of the cases. Painter et al. (59) followed patients for a longer period and reported that the proportion of the patients receiving compensation declined from 70% at admission to 45% at 2-year follow-up. Focusing specifically on workers' compensation patients, Fey et al. (60) observed that at 2- to 3-year follow-up, 89% of the cases were closed. In one study of litigation status, it was reported that 86% of the litigation cases were resolved within 1 year after discharge (61).

Cost-Effectiveness of Multidisciplinary Pain Centers

Although the results reported for MPCs suggest that these facilities are clinically effective, one must also ask whether they are cost-effective. We can examine cost-effectiveness by considering data on savings in health care utilization and closure of disability claims and subtracting the cost of treatment at the pain facility.

Savings in Health Care Utilization

The impressive reductions in health care utilization reviewed above translate readily into monetary figures. Simmons et al. (25) reported a 62% reduction of medical costs as a result of treatment in an MPC. They noted that the costs for medical treatment of their patients in the year prior to treatment averaged $13,284 ($34,794 corrected for inflation) and in the year after MPC treatment averaged $5,596 ($15,303 corrected for inflation), resulting in a total savings of $123,000 ($299,485 corrected for inflation) in medical costs for 16 patients (savings of $18,718 per patient corrected for inflation). If we extrapolate the savings reported by Simmons et al. to the 2,318 patients successfully treated in MPCs reported in the Flor and associates' (11) metaanalysis, a savings of over $43 million in medical expenses accrue in the first year following treatment. If we further assume that the average cost of pain clinic treatment is $8,100, then treating the entire set of pain patients cited in Flor et al. (3,089) would cost approximately $25 million (correcting for inflation). This would result in a net saving in medical expenses alone during the first year of $18 million. These figures are only for the first year's medical expenses and do not consider savings in reduced disability payments, gains in productivity, and gains in

revenue from taxes paid by successfully treated patients.

Based on Simmons and associates' (25) data, we estimated a first year savings of $18,718 in medical expenditures. Subtracting the cost of the multidisciplinary treatment, $8,100, yields an average savings in medical expenditures of $10,618 per patient for the first year. Using the figure of 176,000 patients treated at MPCs (11), we estimate that the medical cost savings during the first year following treatment at an MPC of over $1.87 billion. The savings are likely to continue in subsequent years. Bell et al. (62) estimate the annual medical costs for failed back syndrome patients to be $12,900 (including hospitalization, physician visits, medications, alternative therapies, diagnostic procedures, rehabilitation, and other therapies). Note that this is only about one-half (inflation corrected) of that reported by Simmons et al. (25). Using the figure of 68% reduction in health care costs in the year following treatment at an MPC reported by Simmons et al., we estimate that the cost savings for health care expenditures in years subsequent to the first year following treatment at $8,772 per treated patient per year. Again using Marketdata Enterprises' (20) estimate of the number of treated patients at MPCs of 176,850, the annual savings in health care expenditures would be over $1.5 billion. The average age of patients treated at MPCs is 45 (11), and assuming a mean life expectancy of 75 we estimate $45 billion in savings in health care expenditures (without correcting for inflation rates during those 30 years).

Stieg and Turk (63) pointed out the impressive figure of $250,000 (over $350,000 in 1998 dollars) as the cost for each compensation-covered worker with a back injury on the job lost to permanent disability. In their metaanalysis, Flor et al. (11) reported that, of the 50% of patients treated at MPCs who were receiving financial compensation at admission, an average of 43% returned to work following treatment. Thus, a substantial percentage of patients with long-standing disability can return to work following treatment at an MPC.

Savings in Disability Compensation

We can extrapolate from the 3,089 patients included in the Flor et al. (11) metaanalysis. From this sample, 1,544 were off work and receiving disability compensation. Following treatment, 664 (43%) returned to work. If $350,000 was saved in disability for each of these patients, the net savings in disability would exceed $2 billion. Of course we could carry this extrapolation forward to the approximately 176,850 patients treated in rehabilitation programs at MPCs each year in the United States. In this example, the savings would amount to over *$13 trillion* (176,000/2 × 0.43 × $350,000) for a 1-year cohort of treated patients!

In the past, patients who have been referred to MPCs consisted of those who did not respond to conservative treatment measures and surgical interventions. Thus, the “easiest” problems had already been solved. This selection process results in the bias that those who are referred to MPCs have the most refractory problems. In addition to the pain syndrome, these patients have concomitant medication dependency problems, emotional disturbance, and general life disruptions. Moreover, the mean duration of pain in pain clinics is over 7 years. The cost-saving potential of MPCs, therefore, is quite telling.

Systematic comparisons of the cost-effectiveness across different modalities need a common index. The index of cost-effectiveness can be defined as:

$$\text{Cost-Effectiveness Index} = \frac{\text{Improvement}}{\text{Cost of Treatment}} \times 100$$

One can compare the cost-effectiveness of MPCs with alternative interventions when comparable outcome data are available. Turk and Stacey (16) reported that rate of return to work for MPC patients was 67% compared to 24% for conventionally treated patients. For surgically treated patients, the average of two studies is 43% (53,54). Treatment costs for MPC, conservative, and surgical treatments are estimated as $8,100 (20), $26,000 (64), and $15,000 (24), respectively. Using the return-to-work rate as the improvement score, we report the cost-effective index score for each treatment modality in Figure 109-3. The cost-effective index score of the multidisciplinary pain treatment far exceeds surgical and medical treatments. Indeed, based on the index scores, multidisciplinary treatment can be considered nine times as cost-effective as conservative treatment and 3.6 times as cost-effective as surgical treatment in helping patients return to work.

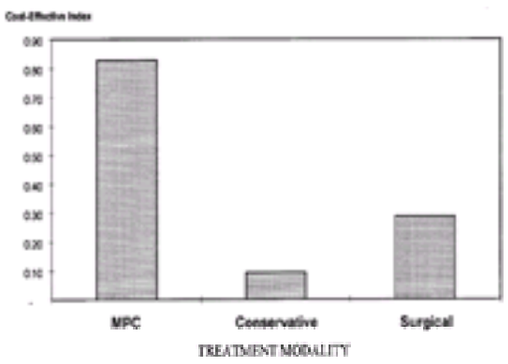

Figure 109-3. Cost-effective index by treatment modalities. (MPC, multidisciplinary pain center.) (From Turk DC, Okifuji A. Treatment of chronic pain patients: clinical outcomes, cost-effectiveness and cost-benefits of multidisciplinary pain centers. *Crit Rev Phys Med Rehabil* 1998;10:181– 208, with permission.)

Flor et al. (11) concluded that “[o]verall . . . multidisciplinary pain clinics are efficacious. Even at long-term follow-up, patients who are treated in such a setting are functioning better than 75% of a sample that is either untreated or that has been treated by conventional, unimodal treatment approaches” (p. 226). Based on calculations using published data, Turk and Okifuji (6,7) estimated that the cost of returning one patient to work following treatment at an MPC was approximately $15,000 compared to $320,000 to return one patient to work following lumbar surgery. Thus, multidisciplinary pain treatment programs are 21 times more effective than surgery in returning patients to gainful employment. Okifuji and colleagues (65) extrapolated from available data reported in the Flor et al. (11) metaanalysis of 3,089 patients and estimated a savings of $280 million from savings in medical and surgical expenditures and disability compensation for these patients. In this light, the success rate is very impressive.

CONCLUSIONS

The team approach to complex chronic pain patients as found in a multidisciplinary pain treatment facility has evolved with an underlying set of principles. These include the recognition that cartesian mind-body dualism is a curse on effective health care. Second, a biopsychosocial model is required to capture all of the relevant factors. Third, the treatment must address the pain itself and not just be a search for hidden causes and specific remedies for these causes. Fourth, the treatment must address the restoration of well- being and not just the alleviation of symptoms. Finally, the illness is not just chronic pain but is also the failure to work, often ascribed erroneously to the pain instead of the patient or the patient's circumstances.

Pain is not a monolithic entity such as a fracture or deficiency of some essential nutrient. Rather, pain is a concept used to focus and label a group of behaviors, thoughts, and emotions. Pain has many dimensions, including sensory and affective components, location, intensity, time course, and the memories, meaning, and anticipated consequences that it elicits. Since there are many facets to pain, no single outcome measure captures all of the relevant issues. Thus, outcomes assessment must look at a variety of criteria to adequately describe the effects of any treatment. Furthermore, the dissociation of specific effects of a treatment from nonspecific treatment effects or the natural history of the disease process requires prospective, randomized clinical trials (see Chapter 82). Such studies have examined patients who have chronic pain.

We suggest that simply asking whether MPCs are effective is not the appropriate question. Rather, we believe that it is important to focus on the results for a set of outcomes and to compare these results to alternative treatments. From our analysis, we believe we can answer the questions posed by stating that a substantial body of literature supports the assertion that multidisciplinary pain treatment is effective in reducing pain, the use of opioid medication, and the use of health care services; it increases activity, returns people to work, and aids in the closing of disability claims. Moreover, treatment at MPCs targets patients with the most recalcitrant problems, yet the benefits appear to exceed those for conventional treatments including surgery and, in contrast to surgery, there are no known iatrogenic complications of treatment at MPCs. Not only do MPCs appear to be clinically effective, they also appear to be cost-effective, with the potential to provide substantial savings in health care and disability payments.

Ironically, the best outcomes data in terms of clinical trials and the widest array of predictive variables occur with multidisciplinary pain management. It should become the gold standard against which all other treatments for chronic pain are measured. The treatment principles developed in MPCs should be applied much earlier in the career of chronic pain patients; prevention is always better than remediation. Even for patients who have been disabled for prolonged periods, multidisciplinary pain management can offer restoration to a normal lifestyle.

CHAPTER 110

Building the Future

C. Richard Chapman, John D. Loeser, and Dennis C. Turk

Dr. John Bonica wrote the first edition of this book in the 1950s, when anesthesiology was a young specialty and very little organized knowledge existed on the subject of pain. Defining the scope of the book largely from clinical experience, he combed the limited literature of the day for evidence, opinions, and techniques. The end product of his work was a compendium of knowledge about pain—nearly everything that medicine knew about pain to that date. Although Bonica could not have foreseen the splendid progress that medical science would make in the second half of the twentieth century, he produced a book that became a milestone for progress in medicine. It defined pain as a field of scientific inquiry and clinical care, and thus changed the lives of countless patients around the world.

In the decades that followed publication of the first edition, neuroscientists uncovered nociceptors, nociceptive-specific pathways in the spinal cord, and the processes of peripheral and central sensitization. The gate-control theory introduced the idea of descending modulatory processes. Multiple discoveries uncovered new ideas of endogenous modulation: neuropeptides, stress- produced analgesia, stimulation-produced analgesia. The discovery of opioid receptors led to an understanding of how opioids mimic endogenous peptides in the central nervous system. Work on arachidonic acid and the prostaglandin pathway solved the long-standing mystery of how aspirin relieves pain and opened the door to new advances in the control of pain related to inflammation.

In the 1990s, research on functional brain imaging during the experience of pain demonstrated that what we call *pain* involves massive, distributed processing in limbic structures as well as somatosensory pathways. This work supported one of Bonica's basic principles: Pain is not a simple signal of tissue trauma traveling along specific pathways in the nervous system, but rather a complex sensory and emotional experience. Psychologists gained a basis for arguing that pain is a subjective phenomenon constructed within the brain and embedded in the context of ongoing cognitive activity and the social environment specific to the person.

Progress in the psychological study of pain showed that the experience of pain is not simply a primitive warning signal that the mind detects and appreciates. Awareness of injury and anguish both depend heavily on what people expect or think about themselves, the meaning of the symptom, the immediate situation, the treatment, and the implications for the future. Early on, psychologists introduced the important distinction between pain as a private experience and pain behavior. This helped physicians understand that the clinical presentation of pain is not necessarily an accurate rendering of nociceptive activity in the patient's nervous system. Further development of the psychology of pain has helped elucidate the powerful role that psychological factors play in the transition from acute to chronic pain, in the response to interventions aimed at relieving pain, in the disability associated with chronic pain, and in the success of rehabilitation in patients with chronic pain.

This edition of *Management of Pain* is a resource for a new century—a century in which the rate of technological progress in medicine and related fields almost certainly will be unprecedented and exponential. Advances in genetics, molecular biology, immunology, neuroscience, and many other technologically sophisticated areas are already staggering. As scientific achievement moves forward on multiple fronts, it will open opportunities for medicine that even the best science fiction writers of our time cannot imagine. What, if anything, will technological advances in genetics and other areas mean for the field of pain? What advances will occur in the field of pain itself? What control can we exert today on the kinds and quality of developments that will define the field of pain medicine in the years to come?

The purposes of this chapter are to (a) consider pain in light of ongoing evolution in medicine and related sciences, (b) examine the conceptual bases of the field that define how we assess patients with pain, (c) choose interventions and evaluate outcomes, and (d) forecast progress in both the scientific understanding of pain and clinical practice issues. Unlike the chapters that precede it, this chapter emphasizes time. Borrowing a distinction from Greek, we concern ourselves less with time as *chronos* than with time as *kairos*. *Chronos* is time as we measure it with watches and calendars; *kairos* refers to an opportune time, the right time, the time to act on an opportunity. *Kairos* is important because the values we emphasize today, the choices we make, the interventions we introduce or favor, and our vision of treatment outcomes all have long-range consequences. The roots of the future lie in the present. We should pay close attention to the future consequences of our current choices and actions. The dramatic impact that Bonica had on medicine in the last half of the twentieth century stemmed directly from the groundwork he laid in the first edition of this book. In this chapter, we explore the opportunities that our generation of pain clinicians and scientists has for shaping the future.

EVOLUTION IN MEDICAL SCIENCE AND PRACTICE

Scientists who gather facts would like to believe that accumulation of facts is synonymous with understanding and that scientific understanding is fundamental and immutable. Clinicians, similarly, like to think of medicine as practice based on a growing body of stable evidence. Unfortunately, humans are more complex and dynamic. Medicine is a part of society, and society evolves continuously. Continual changes in ethics and values, economics, technology, knowledge, and their interactions provide an ever- changing context for what we call *facts*. The ongoing processes of self-organization that govern all of nature affect medicine as well.

Ideally, scientific evidence should govern practice. Figure 110-1, however, illustrates some of the forces that shape the practice of medicine. When the acquired immunodeficiency syndrome emerged during the 1980s, it quickly became obvious that social issues can greatly affect the allocation of resources and priorities in medicine. During the 1990s in the United States, economic forces exerted enormous influence on the practice of medicine, imposing significant change and disruption in practice patterns. As the diagram in Figure 110-1 indicates, the factors that govern change in medical practice also influence one another. Day-to-day medical practice takes place in a complex and dynamic social context.

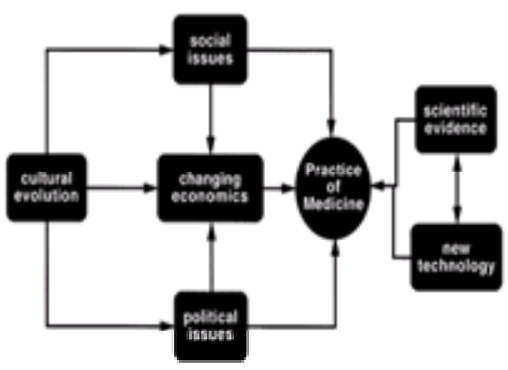

Figure 110-1. Forces that shape the practice of medicine.

The social evolution framework offers a useful perspective for considering the future of pain management in medicine. The principles of evolution apply as readily to social entities like pain management in medicine as they do to biological entities such as animals surviving in the wild. Darwinian theory indicates that the survival of an organism depends on successful adaptation, and social evolutionists find clear parallels in social and cultural entities. Dawkins (1) and others (2,3,4 and 5) have applied this reasoning to social constructions and ideas, like those that govern the practice of medicine. They have introduced the field of *memetics*: the study of ideas and concepts viewed as living organisms, capable of evolution and reproduction in the collective of social intelligence. Memetics is based on an evolutionary model of social information transmission. A *meme* (which rhymes with theme) is an information pattern, held in one person's memory, that can be copied to another person's memory. Put another way, a meme is a cognitive or behavioral pattern that one individual can transmit to another. In describing memes, Brodie (5) said

> Memes are to a human's behavior what our genes are to our bodies: internal representations of knowledge that result in outward effects upon the world. . . . Memes are hidden, internal representations of knowledge that result, again along with environmental influence, in external behavior and the production of cultural artifacts.

There are many ways to transmit a meme, including scientific publication (6), but the primary mechanism for such transmission is simple imitation, according to Blackmore (7). Her model seems to fit the memes that govern everyday medical practice. For example, the principles for when to prescribe and when to withhold opioid medication from a cancer patient constitute a meme. We strive to make this an evidence-based decision rule, but in everyday practice, it is something that young physicians generally learn by imitating older role models in day-to-day practice. The belief that surgery is the best treatment for low back pain is also a meme.

Late in the 1990s in the United States, a new meme emerged among pain physicians: off-label use of gabapentin to control neuropathic pain. Despite a paucity of scientific evidence, pain physicians began prescribing gabapentin for virtually every intractable pain on a trial-and-error basis. This pattern, which one can observe again and again in all areas of medicine, illustrates the spread of a meme by imitation. Carr and Cousins (6) recognized the potential importance of the memetics framework for pain management. Although they discussed scientific publication as a vehicle for memetic replication rather than imitation, they usefully described the replication of a new meme as occurring at an exponential rate, up to the maximum level that the environment will sustain. This produces the familiar S-shaped curve. The gabapentin fad nicely fits this pattern. Of course, rapid replication does not ensure survival of the meme, but it does affect the social climate of practice.

Memetics views ideas and practices as units of cultural information that fail or survive across generations in a Darwinian social environment. It parallels contemporary biology, which tends to view life as the propagation of genetic information: Evolution promotes the selective survival, generation after generation, of some part of that information. When an idea survives because people pass it on to other people, it qualifies as a meme. Memeticists emphasize that a meme resembles a gene rather than a message in that the transmission is a replication: The person who transmitted the meme continues to carry it. Memes are replicators: They are to society what genes are to biology. They are mechanisms of both social stability and adaptational social change.

Memetics, then, is a young theoretical and empirical approach to studying the replication, spread, and evolution of memes. It can account for the spread of ideas and practices, resistance to change, and causal influences in general. Clearly, the transmission of myths and values across generations through storytelling played an essential role in the survival and evolution of preliterate human societies. The transmission of memes is no less important today, but the ways in which we transmit memes and the strategies that memes seemingly employ to adapt and survive are much more complicated.

Just as evolutionary theorists can account for disease due to microbial organisms, memeticists can account for destructive social forces. Some writers have used memetics to introduce the concept of information disease. A meme can adapt and survive in human culture as a pathogen that threatens the survival of other memes just as microorganisms can cause biological disease (5). Misinformation, biases, and prejudices replicate and fight for survival just as effectively as ideas and beliefs based in scientific evidence. Memes that act against the good of society as a whole and the individuals who transmit them are pathogens that constitute thought contagion.

The emerging field of memetics has important implications for medicine, which, after all, is a form of social organization. We may wish to believe that ideas and practices survive in medicine because they are true (i.e., they have support in valid evidence), but the memeticist insists that memes will survive in any way that they can. Just as some organisms manage to evolve devious and seemingly ingenious ways of surviving in a hostile environment (e.g., deception, symbiosis), memes find surreptitious ways of adapting and propagating themselves within medicine. Having a body of supporting scientific evidence, as Carr and Cousins (6) describe, definitely confers an advantage on a meme for survival in medicine, but clever memes (including the pathogens) can find many other ways to survive.

Consider, for example, the belief that administering opioid drugs to cancer patients will cause addiction. Extensive evidence indicates that this is incorrect, and multiple policy statements speak against it (see Chapter 36 and Chapter 84). Yet this meme continues to thrive. One of its strategies is clever use of public media. Newspapers and television inform the public that some celebrity has become addicted to pain killers, occasionally celebrities make public statements about their addiction to pain killers, and now and again one of them dies from an overdose or an accident, again allegedly due to inadvertent addiction to pain medication. No expert ever validates such claims of addiction, and no one ever questions their validity: Such assertions are generally false or badly distorted. The impressions that such claims make on health care providers and patients alike is far more powerful than the evidence that science and sound policy accumulate. The memeticist would emphasize that the “pain medication causes addiction” pathogen will readily stoop to deceit or other tricks to ensure its survival. Its only natural enemy is evidence, and evidence lives only in the environment of science.

In this and other ways, memetics helps us to see the complexity of the challenges we face in our attempts to improve pain management. In the sections that follow, we apply memetics in an attempt to examine the present and the constraints that the past has imposed on it, and we use this framework to envision the future. We suggest that awareness and strategic use of memes may provide pain management specialists a way of exerting control in the social evolution that lies ahead.

CONCEPTUAL BASICS AND EVOLUTION IN PAIN MEDICINE

Our ability to advance the field effectively depends not only on discovery and the introduction and adaptation of new memes but also on our ability to identify and control meme pathogens, both new and old. In this section we consider three basic memes: mind-body medicine, the concept of pain, and the concept of interdisciplinary management. The notion of mind-body interactions has achieved current popularity, but it derives from Cartesian dualism and it is the Cartesian meme in thin disguise. As the contributions to this volume indicate in multiple areas, the constraints of dualism are a major threat to progress in pain management. In contrast, the concept of pain is a meme that must continually adapt to a changing base of evidence in neuroscience, behavioral science, cognitive science, and other areas. Failure to evolve the concept and to integrate it with progress elsewhere in medicine and science will retard the field's future growth and compromise its viability. Finally, the relatively new concept of interdisciplinary pain management has benefited patients and medicine alike, but whether it can survive in a harsh economic climate is far from certain. We discuss these three concerns within the memetic framework.

Mind-Body Medicine

Books and journal articles too numerous to count proclaim the importance of mind-body awareness in medical practice [see, e.g., the journal *Advances in Mind-Body Medicine* published by Harcourt Health Sciences, Chopra (8), or the nonprofit foundation, *The Center for Mind-Body Medicine*, located in Washington, D.C.]. Continuing medical education programs celebrate this theme, and the National Institutes of Health in the United States offer program grants based on the mind-body relationship. That the mind can affect the body in astonishing ways seems to be a truth that medicine regularly rediscovers. Dualism, which nearly everyone rejects on a conceptual basis, survives and thrives for many reasons. Perhaps the chief reason is that it offers a very convenient conceptual basis for describing experiences such as pain.

The distinction between mind and body originated with the ancient Greeks, but it took root in Western medicine because of Descartes' early theories (see Chapter 1). For Descartes, the body functioned as a machine, and the mind, an essentially independent entity, resided and presided in the brain. The Cartesian homunculus experienced pain as the delivery of injury signals from a mechanical and otherwise passive nervous system. As an independent entity, it decided what to make of those signals. Dennett (9) described the Descartes' mind as the “Cartesian theatre.”

Today we know that the brain is the organ of awareness and of behavior. There is no homunculus or other brain center of awareness and executive control that houses an independent mind. The so-called mind is an emergent property of the brain and its intrinsic properties of self-organization. The uniquely human sense of past and future and the sense of self stem not from soul but from the frontal lobes. What we call the *mind* is the functioning of the brain. Moreover, as Freeman (10) has usefully pointed out, human brains exist in relationship to other brains. Our brains have evolved to make adaptive, complex social relationships possible. Culture, society, human values, and other abstract constructs are products of the social human brain and not the stuff of a separate mind. As Turner (11) put it, the human

person consists of “patterns of dynamic activity in a human brain that has evolved to serve the human body of which it is a part. Culture, society, language, and the rest of human life are patterns in brains. Meaning is patterns in human brains.” And so is pain, whether or not it corresponds in the expected way to observable tissue pathology.

One of the ongoing challenges in pain medicine is the poor fit between observable tissue trauma and the anguish and disability that the patient manifests. The pain control requirements of multiple patients with identical trauma vary widely, with some suffering severe pain and others little or none. Many chronic pain patients have pathology insufficient to account for their debilitating pain and, in some cases, no pathology at all. Conversely, in about one-third of patients, imaging of body areas for reasons unrelated to a pain complaint reveals structural or other pathologies that should be causing pain and pain-related dysfunction in an apparently pain-free individual (12). Responses to interventions vary as widely as the presentations of pain themselves due to nonspecific treatment effects, as Chapter 81 explains. We do not have, as yet, good scientific explanations for the wide range of individual differences that we see.

Physicians perplexed, and sometimes frustrated, by the poor fit of patient complaint to scientific accounts of pain mechanisms have tended to invoke popular psychology for explanations and guidance. Popular psychology is a folk wisdom rooted in mentalism that has little or nothing to do with the extensive field of psychology, which is well-grounded in scientific method. Popular psychology would have us believe that a patient's back pain might be all in his mind, that a woman's inexplicable pelvic pain is psychogenic, or that a painful phantom limb is a mental phenomenon. When patients gain pain relief unexpectedly, as with a placebo, we sometimes attribute this to the power of the mind. In these and many other ways, popular psychology would separate the mental from the physical: emotions, fatigue, mood disorders, and medication seeking are all mental phenomena. Medicine is obliged to cope with these nuisances, but its business is to treat the body. The implicit dualism meme, symbiotically aligned with popular psychology, all too often acts as a barrier that keeps the physician from seeing the patient as a complete entity. It also offers a quick and dirty explanation for phenomena that should challenge further study. Slowly but surely, neuroscience is revealing that many of the seeming mysteries of pain are due not to mentalism but to the plasticity of the nervous system.

One of the challenges we face for the future, then, is that of escorting the dualism meme to the end of its natural life, at least in pain medicine. We need to introduce competitive conceptual frameworks that work better and more naturally in daily practice. Perhaps one avenue to achieving this goal will be to integrate psychological services more fully within everyday pain management practice. Except in the case of the anesthetized patient, no patient is free of psychological characteristics. Often the most important parts of the evaluation and the outcome indicators are inherently psychological measures (see Chapter 12, Chapter 13, Chapter 14, Chapter 15, Chapter 16, Chapter 17 and Chapter 18). The purposes of psychologist participation in a case are not the conducting of mental measurement and documentation of outcomes in the realm of subjective reality. Psychological services complete the description of the patient as a whole person, and they embed both the pain problem and the projected impact of an intervention in that larger framework.

Patients with chronic pain often fear and sometimes resent seeing a psychologist. This represents to them the invocation of a pathogen meme: “Let's see if it's all in his or her head.” They fear that psychological evaluation is an attempt to invalidate the pain, to relegate it to the realm of mentalism. Sadly, in some settings they are correct. Some physicians still work on the basis of old memes: “If a pain exists without an evident cause, it must be psychological (mental).” This meme plays to the extreme in some settings. In psychiatric long-term care facilities, for example, the staff often tends to invalidate pain complaints by ascribing them to hallucinogenic or reinforcement mechanisms. A clear need exists for a new meme—a model of pain that recognizes pain as a complex pattern of brain activity of variable origin that interacts with the person's ongoing social environment and experiences. Both medical practitioners and the lay public as a whole need to receive and embrace this meme.

Concept of Pain

There is no reason to assume that the fundamental experience of pain has changed much as the human race has progressed. For the cave dweller who struck his or her head on the cave roof in the dark, the feeling of anger-tinged pain was probably rather like the experience of a contemporary human who bumps his or her head in an unfamiliar building in the dark. Our concept of what pain is, however, continues to evolve. We have no idea what primitive humans thought about pain. The ancient Greeks, like Aristotle, spoke of pain as a passion of the soul. Through the early to mid-twentieth century, medicine viewed pain primarily as a primitive sensory modality. Today, we formally construe it as a subjective experience, negative in hedonic tone, that has both sensory and emotional features, and it bears cognitive associations to tissue injury.

Informally, pain means very different things to different people in the health sciences. To the sensory neurophysiologist, it is still primarily a sensory messaging system designed to accurately render injurious change in bodily tissues. The neurologist addressing neuropathic pain may think of it as pathologic or dysfunctional sensory signaling. The psychologist may see pain as a complex perceptual experience with sensory, emotional, and cognitive dimensions, constructed within the brain and constrained by immediate context and individual past history. The pain meme clearly evolves, spinning off many variations. What will tomorrow bring?

In the memetic framework, of course, the question becomes “What will survive?” The notion of pain as a primitive sensory signaling system has survived well throughout medicine and in related disciplines, albeit not in the multidisciplinary world of pain itself. It works well enough for the ophthalmologist who sees a patient with pain secondary to glaucoma or the emergency room physician who sees pain related to a minor burn. It fails, however, for the physician who encounters a complex regional pain syndrome or a painful phantom limb. It has in some chronic pain cases led to needless and ultimately harmful surgical invasion, ill- advised amputations, inappropriate prescribing of strong medications, and extensive trial-and-error invasive procedures. In many respects, the satisfyingly simple notion of pain as a primitive sensory signaling system has become a memetic pathogen.

We need to develop and introduce a concept of pain that integrates explanations of mechanisms from nociceptors and peripheral neuropathic conditions to subjective awareness of tissue damage. The emerging field of consciousness research should prove helpful. Consciousness researchers regard the emergence of phenomenal reality from the activity of a physical brain as “the hard problem” (13). This explanatory gap, between brain activity and subjective awareness, stymies pain researchers as well. As functional brain imaging and consciousness theory evolve, our ability to conceptualize the complexity and dynamic nature of pain will grow. Continuously updating our definition and understanding of pain should rank among our highest priorities.

Concept of Interdisciplinary Management

Early in his experiences with chronic pain, Dr. Bonica envisioned the advantages that multiple and varied specialists could confer for the assessment and treatment of chronic pain. In founding the University of Washington Multidisciplinary Pain Clinic, he brought clinical psychologists, pharmacists, and other nonphysician providers to the conference table with anesthesiologists, neurologists, physiatrists, neurosurgeons, orthopedic surgeons, psychiatrists, and others. This blend of perspectives kept each specialist from exercising specialty-specific tunnel vision, and in conferences a group understanding often emerged that greatly exceeded the understanding that the record would yield after a series of serial consultations. Experience of this sort, gathered in many settings, shows that complex, chronic problems have optimal, multifaceted solutions.

Unfortunately, standard practice patterns are barriers to such solutions. Current economic forces seek to optimize short-term clinical efficiency at the cost of benefits such as rehabilitation and return to work, despite the evidence of the cost-effectiveness of multidisciplinary rehabilitation (see Chapter 109). The meme Bonica introduced—that of interdisciplinary management of chronic pain— must struggle to survive. Unfortunately, the short-term cost to a health care organization for chronic pain is not the same as the long- term cost of that patient to society. Moreover, the emphasis on traditional invasive treatments to the exclusion of rehabilitation will have financial consequences for third-party payers. The cost-effectiveness of surgery has proven poor for some of the common chronic pain syndromes (see Chapter 109). Worse yet, this is not a win-win situation for the patient and the health care organization: The benefits to the organization exceed those to the patient. Economic memes are proving to be dangerous pathogens.

Because the meme of interdisciplinary management of chronic pain is of potentially lasting value, it is important that we take steps to ensure its successful adaptation to climatic change and hardship. Adaptation, survival, and reproduction (we would like to see this meme spread) would benefit from three steps: (a) economic adaptation, (b) evolution and improvement, and (c) a symbiotic relationship to public opinion and the media.

The economic adaptation of a clinical service is straightforward. It must save money, not add to costs. Fortunately, technological progress is on our side and can help in minimizing costs. Electronic technology and developments in informatics have made it increasingly easy to obtain extensive interview and testing data from patients with minimal staff time, to summarize such data and make them immediately available in electronic form to the various specialties, and to add each specialist's findings to the record in a timely fashion. List servers provide an alternative to face-to-face conferencing when necessary. Teleconferencing minimizes the inconvenience of working together across multiple sites. Thus, it should be possible for an innovative clinic to minimize the cost of interdisciplinary collaboration.

The long-range financial benefits of interdisciplinary management, compared to standard unidisciplinary management are already clear, as Chapter 109 indicates. A steady growth of evidence that unequivocally demonstrates the long-range economic benefits of interdisciplinary management should eventually carry the day, because health care organizations are maturing and improvements in their long-range planning will eventually make good use of such evidence.

Finally, the interdisciplinary management of chronic pain needs public opinion on its side. Pain specialists have not transmitted the meme of interdisciplinary management of chronic pain to the lay public. Worse yet, some obstreperous patient groups are promulgating a memetic pathogen on the World Wide Web and elsewhere. They contend that physicians can cure pain surgically, but they are evading their responsibilities by insisting on multidisciplinary evaluation and rehabilitation. “Know your enemy” is their slogan. Paradoxically, this meme draws indirect support from various physician groups who have financially vested interests in one or another invasive procedure. As Figure 110-1 indicates, public opinion is a major force that helps shape the practice of medicine. Interdisciplinary management needs to marshal public opinion to its side. This requires aggressive efforts to diffuse the meme for interdisciplinary management of chronic pain into the public arena. Millions of people suffer from conditions in which pain is a major symptom. To date, this segment of the public has exerted little or no organized influence on public policy.

SCIENCE AND PAIN

Neuroscience, behavioral science, cognitive science, and social science all contribute to pain research and treatment. Each is its own world with its own subculture and associated memes; indeed, some of these areas comprise multiple competing paradigms. The scientific aspects of pain, therefore, are complex. The challenge for the future is not simply to pursue neuroscience and thereby further explicate the basic nature of pain. It will require integration of knowledge and cooperation across these areas. For the early part of the twenty-first century, four scientific themes are likely to prove important for clinical practice: (a) role of emotion in pain mechanisms; (b) physiologic consequences of nociception; (c) assessment of people in pain; and (d) individual differences in pain and its expression.

Emotion and Pain Mechanisms

The field of emotion research is growing rapidly, with many levels of scientific inquiry advancing in parallel (14). Investigations into emotion's basic mechanisms, theory about its evolutionary origins and purposes, and study of its expression and communication all bear on pain. As Chapter 24 indicates, pain has emotional features, and for the patient an experience of pain is more like an intense negative emotion than a burden of sensory information about location, quality, and intensity.

For most of the twentieth century, pursuit of the mechanisms of pain targeted sensory pathways and the central mechanism of sensory processing. The introduction of functional brain imaging to the pain field revealed substantial distributed processing in the brain during pain with several limbic foci (see Chapter 24 for a review). In parallel, neurophysiologic studies revealed spinohypothalamic and spinoreticular pathways for nociceptive traffic in the central nervous system. The fate of the nociceptive signals in these areas is uncertain and perplexing because they appear to initiate complex limbic and arousal processes rather than lead to a succinct destination such as somatosensory cortex. Still, the unfolding evidence seems to indicate that pain, as evolution formed it, involves an integration of sensory information with adaptive negative emotional arousal. As Chapter 24 indicates, sensory processes provide basic information about tissue trauma to the brain; emotional processes represent the biological threat (meaning) that the tissue trauma has for the organism at a given moment in a given setting. Put simply, negative emotion is not a response to pain but rather a part of pain. It is an adaptive response to tissue trauma.

Because pain has diagnostic value for acute disorders such as appendicitis or herpes zoster, physicians tend to ask patients only for pain's sensory features. From the patient's perspective, however, the affliction of pain is the anguish that it brings, not its sensory qualities. Patients seek relief from the unpleasantness and negative emotional features of pain.

Future research on the mechanisms of pain will need to explicate the complementary nature of sensory and emotional processes. The mechanisms of the emotional aspect of pain have received too little attention and remain comparatively ill defined. Preceding negative emotional states such as fear and apprehension can worsen the emotional severity of a painful condition such as postoperative pain (15), and emotional preparation can minimize the severity and distress of pain (16). Although it is always better to prevent nociception from the outset, it is important to consider the emotional features of pain and to include them as targets in pain relief interventions. The knowledge base necessary for assessing and addressing the emotional dimension of pain is only now beginning to emerge.

Physiologic Consequences of Nociception

Preoccupation with pain as a subjective experience has caused researchers to place heavy emphasis on tracing sensory transmission. However, as Chapter 3 indicates, most of the neural traffic occasioned in the dorsal horn of the spinal cord by an injurious event serves purposes other than sensory signaling. There is ongoing bidirectional communication at an unconscious level between the brain and other parts of the body, and through this the central nervous system takes care of basic housekeeping tasks necessary for life. Nociceptive signaling plays an important role in pattern of communication. Postural changes, overuse of joints and muscles, the development of inflammation, exposure to temperature extremes or other dangerous environmental factors, and other adjustments go on constantly, beneath the threshold of awareness. This signaling activity is nociception, but it is not pain because it is not conscious. It represents the monitoring of tissue to detect and prevent impending trauma rather than a response to trauma.

When frank trauma occurs, the consequent nociception induces largely unconscious reflex responses at the segmental level. These are both motor and sympathetic. Motor reflex responses include reflex withdrawal, as when a person touches a hot object, and sometimes they induce skeletal muscle tension that provides bracing in the area of a wound. Severe motor reflex responses can cause muscle spasm that becomes a secondary source of nociception. Sympathetic reflexes constrain peripheral blood flow and thus protect against blood loss at the site of an injury. Prolonged changes in microcirculation can affect the chemical environment of nociceptors in and around a wound, affecting function and sometimes contributing to tissue sensitization. In persons who are not otherwise healthy at the time of injury, sympathetic reflexes can contribute to cardiovascular morbidity.

Nociceptive stimulation of the hypothalamus can produce a complex array of consequences (see Chapter 24), including excitation of the paraventricular nucleus. The paraventricular nucleus can activate the hypothalamic-pituitary-adrenocortical (HPA) axis, introducing various peptides and increasing cortisol in the systemic circulation. HPA activation mounts a stress response that readies the individual to meet an emergency. The short-term benefits of HPA axis arousal are largely positive, but the consequences of long-term arousal are deleterious, fostering sleep disturbance, circadian dysrhythmia, myalgia, and fatigue (17).

Finally, recent work is showing that the central nervous system demonstrates substantial plasticity (18). The classical Cartesian assumption of a mechanistic nervous system faithfully transmitting signals of injury to the mind is clearly erroneous. Studies of changes in brain representation related to amputation indicate that major changes begin within hours of deafferentation. Our understanding of how prolonged nociception or neuropathic signaling affects the brain and its representation of body areas is still primitive, but all indications are that prolonged nociception can create lasting changes in both function and structure.

Clearly, a need exists for more research on the physiologic consequences of nociception, with attention to the implication of special patient populations. Institutionalized patients who cannot speak or who are confused or demented may experience pain that they cannot express. Often, the only behavioral evidence is diffuse distress and social withdrawal. The consequences of untreated nociception on the overall health of the patient are never positive and may lead to further morbidity and increased costs of care (see Chapter 45).

Future research on nociception is likely to call into question the standard definition of pain. Medically, the consequences of nociception are important, and nociception is not necessarily conscious. Indeed, pain as a conscious event is but one of many products of nociceptive activity.

Measurement of Pain

Current tools for measuring pain in clinical situations are crude. More fundamentally, the assumption behind pain measurement is primitive and somewhat misguided. Health care providers often believe that they should measure the pain *per se*. That is, one should quantify the various features of pain. In fact, the challenge is to measure the person in the role of patient with regard to a particular feature that interferes with normal living. That feature is pain, and it is multidimensional in nature. Pain measurement is about measuring people; it is not an exercise in mentalism.

Normally, the clinician simply asks the patient in one way or another to report features of the pain such as its intensity and location. Moreover, conventional pain measurement tools focus predominantly, and in most settings entirely, on the sensory features of the pain. As noted above, this is of some diagnostic value to the

health care provider, but it is the affective features of the pain that distress the patient. One major problem is that such methods effectively exclude several important populations such as preverbal infants and cognitively compromised patients, including some populations that require institutional care. We also have problems in assessing therapeutic outcome following interventions for pain, particularly chronic pain, as Chapter 82 indicates. This problem area has important economic implications because, if we restrict pain measurement to subjective report, we cannot demonstrate convincingly that interdisciplinary intervention for chronic pain is efficacious and cost-effective.

Chapter 15 reviews the tools available for measuring pain and its relief. We emphasize here that measurement approaches depend on the formal definition of pain and the memes associated with it. Pain measurement does not take place in a vacuum: Major cultural and historical influences constrain how we think and our ability to proceed innovatively in pain measurement.

Our methods for clinical pain measurement rest on the assumption (yet another meme) that introspection is the only valid method. Pain is a conscious state or at least a conscious experience, and therefore the only access we have to it is through direct first- person examination of the contents of consciousness. This is a bold approach because there is little or no justification for assuming that untrained, nonobjective patients can examine themselves and report in an accurate, unbiased way what they feel. Most pain management anesthesiologists have seen chronic pain patients who, immediately after a well-executed nerve block, simply cannot say whether a pain of many years' duration has gone away.

Beneath the surface of our current measurement practices lurk several memetic pathogens. The Cartesian dualism meme is the most egregious. We assume implicitly that the patient has a separate and objective mind that can examine what is going on in the mechanical body and provide a faithful report. In fact, the same brain is simultaneously producing, experiencing, and reporting the pain. The act of reporting affects attention and thereby changes the producing and experiencing.

The “pain as a primitive sensory experience” pathogen is also at work in such measurement efforts. It seems appropriate to put a simple number on a patient's pain to gauge its intensity and then to intervene in hopes of lowering that number. Unfortunately, the sensory intensity of a pain is but one of its features, and its subjective reality depends on context. The constant intensity of a patient's aching shoulder, for example, may seem a mild annoyance during a day filled with activity and yet become a major source of distress and a barrier to restful sleep at night when the environment is quiet.

Yet another memetic pathogen is that the report of chronic pain always stems from a continuous awareness of one or more foci of marked nociceptive activation in the periphery or of neuropathy. This pathogen thrives because it is sometimes true, but the overwhelming majority of exceptions defeats the rule.

Finally, when a patient is noncompliant during pain measurement, the physician often invokes the mentalism meme—“it's all in his or her head.” As if to collude, some patients, when asked to rate pain on a scale of one to ten, report pain of 15 or 20, with a subtle or sometimes obvious disdain for the assessment process. Because of this meme, it is easy to assume that the problem is psychological because the patient exaggerates. It is hard to consider that the patient may have a need to communicate the emotional intensity of the pain experience rather than the sensory intensity and to feel that the care providers understand the anguish and intend to address it. In these and other ways, our current pain assessment practices serve us poorly.

Quantifying outcomes after chronic pain relief intervention is another vexing conundrum. Mentalism demands that we measure the conscious experience of the patient, but payers and health care institutions are loath to spend substantial sums of money for nothing more than a change on a subjective numeric rating scale. The obvious answer is that the goal of the intervention must be to improve function, and this we can quantify in many ways (e.g., range of motion, endurance, return to work). That such measures correlate poorly with subjective ratings of pain intensity seems to challenge the validity of the pain. The meme that pain as a conscious entity impairs function and ultimately causes disability exerts a heavy influence, and it, too, may be a pathogen.

Chronic pain is a complex state, and progress in pain measurement will depend in part on progress in causal modeling. We need a better understanding, not only of the causes of pain, but also of the factors that produce disability and chronicity. In cases in which patients have ongoing nociception or neuropathy, it is reasonable to predict a causal relationship between what the patient can do and what his or her nervous system is doing. In other cases, where there is little or no evidence of cause for noxious signaling in the nervous system, the very concept of having uncontrollable chronic pain and the integration of that concept with the sense of self may have a causal influence in perpetuating disability. In some cases, both of these factors causally influence ability to work or function normally. Unfortunately, a numeric rating of pain intensity measures neither of them. We need tools that measure the person comprehensively, with regard to pain, function, beliefs, and resilience. Progress in outcomes measurement may well require multivariate causal modeling grounded in theory more advanced than we can presently produce.

Broadly speaking, meaningful progress in pain measurement cannot take place until a favorable memetic climate emerges. Dualism and the mentalism that it fosters are major barriers. We need to resolve the question of whether deleterious nociceptive traffic in the nervous system that is unperceived should qualify as pain. If so, then we cannot relegate pain to the realm of mentalism. In addition, we need to further develop our understanding of the importance of the affective component in clinical pain states. Our current approaches do not quantify this in a satisfactory manner. Again, the scientific community that studies emotion would not relegate emotion to the realm of mentalism: Affect has physiologic mechanisms and physiologic manifestations. The affective aspect of pain should be no different. These considerations point to future objectification in pain measurement.

CONCLUSIONS

As clinicians and scientists we wish to believe that we make independent choices, that we see things as they are. Social evolutionists challenge this. They assert that medicine and science, like everything else produced by humans, take place in a cultural context governed by unseen forces. The memeticist approach to social evolution, an analogue of Dawkin's radical notion of the selfish gene (1), offers a provocative perspective. Dawkins argued that genes are active agents of their own replication and survival and the organisms that they express (including humans) are but tools produced to meet these ends. As genes are to biology, so are memes to culture. The memeticist contends that a meme is an idea that takes on its own life. It seeks to survive and replicate itself. Whether its survival strategy supports the good of humankind or the destruction of those who embrace it and transmit it is immaterial to the meme. Humans are mere agents of memes; they are never the masters.

Since Dawkins first introduced these ideas in 1976, humans have begun to take control of genes. The Human Genome Project is well under way, and the first experiments in cloning are behind us. Genetic engineering has become a major focus of scientific and technical development. It would seem that Dawkins must now acknowledge that humans have gained the upper hand and are not now solely the instruments of their genetic code.

In the memeticist framework, we face the parallel dilemma. We can be instruments of the memes that govern our behavior, or we can assert ourselves and take charge of them. Just as geneticists need to map the human genome, so pain medicine needs to map the memes that govern its practice. When we fully understand what makes us what we are, we are free to eradicate pathogens, shape evolution, and introduce new memes compatible with science and compassionate care.

A new century invites new visions, new beginnings. It is a moment of *kairos*. If pain management is going to survive and thrive into the future, then we must begin now to examine the beliefs and assumptions on which we base our reasoning and our action. The future is ours to define.
