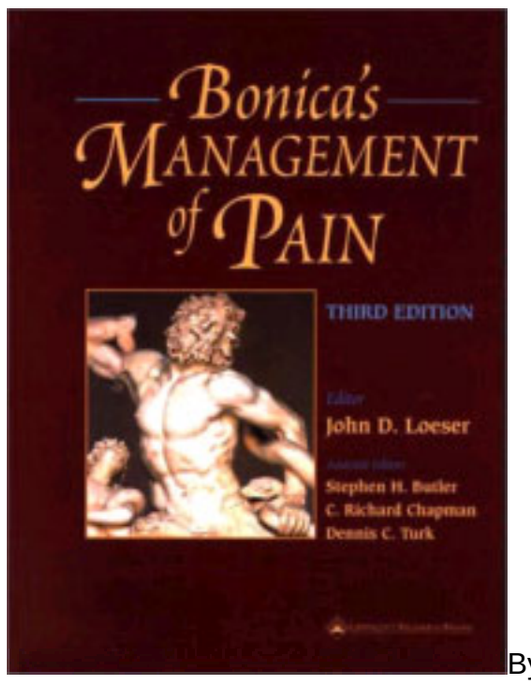
Bonica's Management of Pain 3rd edition (January 15, 2001): By John D. Loeser (Editor), Steven H. Butler (Editor), C. Richard Chapman (Editor), PhD Dennis C. Turk (Editor) By Lippincott Williams & Wilkins Publishers



By OkDoKeY

Bonica's Management of Pain

Contents

PART IV

Regional Pains

PART V

Methods for Symptomatic Control

Editor

John D. Loeser, M.D.
Professor of Neurological Surgery and Anesthesiology
Former Director, Multidisciplinary Pain Center
University of Washington School of Medicine
Seattle, Washington

Associate Editors

Stephen H. Butler, M.D.
Associate Professor of Anesthesiology
Acting Director, Multidisciplinary Pain Center
University of Washington School of Medicine
Seattle, Washington

C. Richard Chapman, Ph.D.
Professor of Anesthesiology,
Psychology, Psychiatry, and Behavioral Sciences
University of Washington School of Medicine
Member, Fred Hutchinson Cancer Research Center
Seattle, Washington

Dennis C. Turk, Ph.D.
John and Emma Bonica Professor of Anesthesiology and Pain Research
University of Washington School of Medicine
Seattle, Washington
Adjunct Professor of Psychiatry
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Illustrator

Marjorie Domenowske

132 Contributing Authors

This book is dedicated to the memory of John J. and Emma L. Bonica. John was the inspiration and guiding force behind the pain movement that began with the first edition of this book; Emma made his contributions possible. We miss them both, but the momentum they created is rapidly accelerating, and the memories of their goodness will be with all who study pain and its management.

John D. Loeser, M.D.

Contributing Authors

Roger J. Allen, Ph.D., P.T.
Multidisciplinary Pain Center
University of Washington Medical Center
Seattle, Washington
Chapter 20, Complex Regional Pain Syndromes?Type I: Reflex Sympathetic Dystrophy, and Type II: Causalgia

Edward E. Almquist, M.D.
Clinical Professor of Orthopaedics
Department of Orthopaedics
University of Washington School of Medicine
Seattle, Washington
Chapter 59, Painful Conditions of the Forearm, Wrist, and Hand

Kenneth M. Alo¢, M.D.
Pain and Health Management Center, PA
Houston, Texas
Chapter 73, Pelvic and Perineal Pain of Urologic Origin

Gunnar B. J. Andersson, M.D., Ph.D.
Professor and Department Chairman
Department of Orthopedic Surgery
Rush-Presbyterian-St. Luke's Medical Center
Chicago, Illinois
Chapter 76B, Low Back Pain: Role of Surgery in the Treatment of Low Back Pain and Sciatica

John G. Arena, Ph.D.
Professor of Psychiatry and Health Behavior
Medical College of Georgia
Director, Pain Evaluation and Intervention Program
Department of Veterans Affairs Medical Center
Augusta, Georgia
Chapter 90, Biofeedback Therapy for Chronic Pain Disorders

Michael A. Ashburn, M.D.
Professor of Anesthesiology
Director, Pain Management Center
University of Utah Health Sciences Center
Salt Lake City, Utah
Chapter 41, Postoperative Pain

Misha-Miroslav Backonja, M.D.
Associate Professor of Neurology and Anesthesiology
University of Wisconsin Center for Health Sciences
Madison, Wisconsin
Chapter 19, Painful Neuropathies

Joseph Barber, Ph.D.
Clinical Professor of Rehabilitation Medicine
University of Washington School of Medicine
Seattle, Washington
Chapter 91, Hypnosis

Alexander B. Baxter, M.D.
Department of Radiology
University of Washington School of Medicine
Seattle, Washington
Chapter 14, Imaging Pain Patients

Charles B. Berde, M.D., Ph.D.
Professor of Anaesthesia and Pediatrics
Harvard Medical School
Director, Pain Treatment Service
Senior Associate in Anesthesia
Children's Hospital, Boston
Boston, Massachusetts
Chapter 44, Pain and Its Management in Children

Stanley J. Bigos, M.D.
Professor of Orthopedic Surgery and Environmental Health
University of Washington Schools of Medicine and Public Health
Seattle, Washington
Chapter 76A, Low Back Pain: Primary Care Approach to Acute and Chronic Back Problems: Definitions and Care

Edward B. Blanchard, Ph.D.
Distinguished Professor of Psychology
State University of New York at Albany
Albany, New York
Chapter 90, Biofeedback Therapy for Chronic Pain Disorders

Andrew R. Block, Ph.D.
Department of Psychiatry
Division of Psychology
University of Texas Southwestern Medical Center at Dallas
Dallas, Texas
Director, The WellBeing Group
Plano, Texas
Chapter 76D, Low Back Pain: Psychological Screening of Spine Surgery Candidates: Risk Factors for Poor Outcome

John J. Bonica, M.D., D.Sc., D.Med.Sc. (Hon.), F.F.A.R.C.S. (Hon.) (Deceased)
Professor and Chairman Emeritus, Department of Anesthesiology
Director Emeritus, Multidisciplinary Pain Center
University of Washington School of Medicine
Seattle, Washington
Founder and Honorary President, International Association for the Study of Pain
Chapter 1, History of Pain Concepts and Therapies; Chapter 3, Peripheral Pain Mechanisms and Nociceptor Plasticity; Chapter 4, Spinal Mechanisms and Their Modulation; Chapter 5, Supraspinal Mechanisms of Pain and Nociception; Chapter 8, Applied Anatomy Relevant to Pain; Chapter 9, General Considerations of Acute Pain; Chapter 29, Myofascial Pain Syndromes; Chapter 46, General Considerations of Pain in the Head; Chapter 49, Facial and Head Pain Caused by Myofascial and Temporomandibular Disorders; Chapter 54, General Considerations of Pain in the Neck and Upper Limb; Chapter 60, General Considerations of Pain in the Chest; Chapter 65, General Considerations of Abdominal Pain; Chapter 67, Painful Diseases of the Liver, Biliary System, and Pancreas; Part V: Methods for Symptomatic Control, Section E Implanted Electrical Stimulators, Introduction

William Breitbart, M.D.
Professor of Psychiatry
Weill Medical College of Cornell University
Chief, Psychiatry Service
Department of Psychiatry and Behavioral Sciences
Attending Psychiatrist
Pain and Palliative Care Service
Department of Neurology
Memorial Sloan-Kettering Cancer Center
New York, New York
Chapter 39, Pain in Human Immunodeficiency Virus Disease

Eduardo Bruera, M.D.
Palliative Care Program
Grey Nuns Community Health Centre
Edmonton, Alberta
Chapter 40, Palliative Care

F. Peter Buckley, M.B., F.R.C.A.
Associate Professor of Anesthesiology
Department of Anesthesiology
University of Washington School of Medicine
Seattle, Washington
Chapter 102, Regional Anesthesia with Local Anesthetics

Kim J. Burchiel, M.D.
John Raaf Professor and Chairman, Department of Neurological Surgery
Oregon Health Sciences University
Portland, Oregon
Chapter 107, Surgical Treatment of Trigeminal Neuralgia

Jeffrey A. Burgess, D.D.S., M.S.D.
Clinical Associate Professor of Oral Medicine
University of Washington School of Dentistry
Seattle, Washington
Chapter 49, Facial and Head Pain Caused by Myofascial and Temporomandibular Disorders; Chapter 50, Pain of Dental and Intraoral Origin

Stephen H. Butler, M.D.
Associate Professor of Anesthesiology
Acting Director, Multidisciplinary Pain Center
University of Washington School of Medicine
Seattle, Washington
Chapter 97, Acupuncture; Chapter 104, Neurolytic Blockade and Hypophysectomy

Margaret R. Byers, Ph.D.
Research Professor, Department of Anesthesiology
University of Washington School of Medicine
Seattle, Washington
Chapter 3, Peripheral Pain Mechanisms and Nociceptor Plasticity; Chapter 50, Pain of Dental and Intraoral Origin

René Cailliet, M.D.
Professor Emeritus, Department of Physical Medicine and Rehabilitation
University of Southern California School of Medicine
Professor of Medicine
Section of Physical Medicine and Rehabilitation
University of California, Los Angeles, UCLA School of Medicine
Los Angeles, California
Chapter 54, General Considerations of Pain in the Neck and Upper Limb

James N. Campbell, M.D.
Professor of Neurosurgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
Chapter 105, Lesions of Primary Afferents and Sympathetic Efferents as Treatments for Pain

Charles Chabal, M.D.
Associate Professor of Anesthesiology
University of Washington School of Medicine
Veterans Affairs Puget Sound Healthcare System
Seattle, Washington
Chapter 98, Transcutaneous Electrical Nerve Stimulation

C. Richard Chapman, Ph.D.
Professor of Anesthesiology, Psychology, Psychiatry, and Behavioral Sciences
University of Washington School of Medicine
Member, Fred Hutchinson Cancer Research Center
Seattle, Washington
Chapter 6, Psychological Aspects of Pain; Chapter 15, Measurement of Pain; Part III: Generalized Pain Syndromes, Section B Psychological Contributions to Pain,

Introduction; Chapter 24, The Psychophysiology of Pain; Chapter 35, Cancer Pain: Assessment and Diagnosis; Part V: Methods for Symptomatic Control, Section C Psychological Techniques, Introduction; Chapter 97, Acupuncture; Chapter 110, Building the Future

J. Edmond Charlton, M.B., B.S.
Department of Anaesthesia
Pain Management Services
Royal Victoria Infirmary
Newcastle upon Tyne, United Kingdom
Chapter 104, Neurolytic Blockade and Hypophysectomy

Eric H. Chudler, Ph.D.
Research Associate Professor,
Department of Anesthesiology
University of Washington School of Medicine
Seattle, Washington
Chapter 5, Supraspinal Mechanisms of Pain and Nociception

John M. Clark, M.D., Ph.D.
Associate Professor of Orthopaedics
University of Washington School of Medicine
Seattle, Washington
Chapter 78, Pain in the Hip

David R. Clawson, M.D.
Clinical Assistant Professor of Physical Medicine and Rehabilitation
University of Washington School of Medicine
Harborview Medical Center
Seattle, Washington
Chapter 31, Treatment of Acute Musculoskeletal Pain

Barbara A. Coda, M.D.
Associate Professor of Anesthesiology
University of Washington School of Medicine
Assistant Member?Clinical Division
Fred Hutchinson Cancer Research Center
Seattle, Washington
Chapter 9, General Considerations of Acute Pain

Craig V. Comiter, M.D.
Department of Urology
University of California, Los Angeles, UCLA School of Medicine
Los Angeles, California
Chapter 68, Painful Diseases of the Kidney and Ureter

Marshall A. Corson, M.D.
Associate Professor of Medicine
University of Washington School of Medicine
Cardiology Section Chief
Harborview Medical Center
Seattle, Washington
Chapter 61, Cardiac and Aortic Pain

Joseph M. Czerniecki, M.D.
Associate Professor of Rehabilitation Medicine
University of Washington School of Medicine
Seattle, Washington
Chapter 75, General Considerations of Pain in the Low Back, Hips, and Lower Extremities

E. Patchen Dellinger, M.D.
Professor and Vice Chairman, Department of Surgery
University of Washington School of Medicine
Chief, Division of General Surgery
University of Washington Medical Center
Seattle, Washington
Chapter 69, Abdominal Pain Caused by Other Diseases

Richard A. Deyo, M.D., M.P.H.
Professor of Medicine and Health Services
University of Washington School of Medicine
Seattle, Washington
Chapter 82, Clinical Trials

Todd G. Dray, M.D.
Department of Otolaryngology, Head and Neck Surgery
Permanente Medical Group
Santa Clara, California
Chapter 52, Pain in the Ear, Midface, and Aerodigestive Tract

Samuel F. Dworkin, D.D.S., Ph.D.
Professor Emeritus, Department of Oral Medicine
University of Washington School of Dentistry
Professor Emeritus, Department of Psychiatry and Behavioral Sciences
University of Washington School of Medicine
Washington Dental Foundation Distinguished Professor of Dentistry
Seattle, Washington
Chapter 49, Facial and Head Pain Caused by Myofascial and Temporomandibular Disorders

W. Thomas Edwards, M.D., Ph.D.
Associate Professor of Anesthesiology
University of Washington School of Medicine
Director, Pain Relief Service
Harborview Medical Center

Seattle, Washington
Chapter 43, Posttrauma Pain

Mark L. Elliott, Ph.D.
Ohio State Pain Control Center
Ohio State University College of Medicine and Public Health
Columbus, Ohio
Chapter 72, Gynecologic Pain Syndromes

Joel B. Epstein, D.M.D., M.S.D., F.R.C.D.(C)
Professor and Head, Division of Hospital Dentistry
Faculty of Dentistry
University of British Columbia
Medical/Dental Staff
British Columbia Cancer Agency
Head, Department of Dentistry
Vancouver Hospital and Health Sciences Centre
Vancouver, British Columbia
Research Associate Professor, Department of Oral Medicine
University of Washington School of Dentistry
Seattle, Washington
Chapter 38, Oral Mucositis in Cancer Patients

Miklavz Erjavec, M.D., F.R.C.P.C.
Acting Assistant Professor of Anesthesiology
University of Washington School of Medicine
Seattle, Washington
Chapter 76E, Low Back Pain: Epidural Steroids for Low Back Pain

Dermot R. Fitzgibbon, M.B, B.Ch.
Assistant Professor of Anesthesiology
Adjunct Assistant Professor of Medicine
University of Washington School of Medicine
Seattle, Washington
Chapter 35, Cancer Pain: Assessment and Diagnosis; Chapter 36, Cancer Pain: Management

Wilbert E. Fordyce, Ph.D.
Professor Emeritus, Department of Rehabilitation Medicine
University of Washington School of Medicine
Seattle, Washington
Chapter 25, Learned Pain: Pain as Behavior; Chapter 88, Operant or Contingency Therapies

Bradley S. Galer, M.D.
Associate Professor of Neurology
Albert Einstein College of Medicine
Department of Pain Medicine and Palliative Care
Beth Israel Medical Center
New York, New York
Chapter 20, Complex Regional Pain Syndromes?Type I: Reflex Sympathetic Dystrophy, and Type II: Causalgia; Chapter 87, Topical Medications

Jason E. Garber, M.D.
Neurosurgical Resident
Baylor College of Medicine
Houston, Texas
Chapter 106, Neurosurgical Operations on the Spinal Cord

Gregory C. Gardner, M.D.
Associate Professor, Division of Rheumatology
Adjunct Associate Professor of Orthopaedic Surgery and Rehabilitation Medicine
University of Washington School of Medicine
Seattle, Washington
Chapter 27, Arthritis and Periarthritic Disorders

Jonathan R. Gavrin, M.D.
Associate Professor of Anesthesiology
Adjunct Associate Professor of Medicine
University of Washington School of Medicine
Harborview Medical Center
Seattle, Washington
Chapter 64, Chest Pain from Other Disorders Including Cancer

Saadi Ghatan, M.D.
Acting Instructor, Department of Neurological Surgery
University of Washington School of Medicine
Seattle, Washington
Chapter 55, Neck Pain

Bruce C. Gilliland, M.D.
Professor of Medicine and Laboratory Medicine
University of Washington School of Medicine
Seattle, Washington
Chapter 27, Arthritis and Periarthritic Disorders

Ian H. Gilron, M.D., M.Sc., F.R.C.P.(C)
Associate Medical Director, Pain Research Clinic
Pain and Neurosensory Mechanisms Branch, National Institute of Dental and Craniofacial Research
National Institutes of Health
Bethesda, Maryland
Chapter 85, Antidepressants, Muscle Relaxants, and N-*Methyl-D-Aspartate Receptor Antagonists*

Kenneth R. Goldschneider, M.D.
Department of Anesthesia

Division of Pain Management
Children's Hospital Medical Center
Cincinnati, Ohio
Chapter 44, Pain and Its Management in Children

Barry Goldstein, M.D., Ph.D.
Department of Rehabilitation Medicine
Veterans Affairs Puget Sound Health Care System
Seattle, Washington
Chapter 57, Musculoskeletal Upper Limb Pains; Chapter 75, General Considerations of Pain in the Low Back, Hips, and Lower Extremities

Robert Goodkin, M.D.
Associate Professor of Neurological Surgery
University of Washington School of Medicine
Veterans Affairs Puget Sound Health Care System
Seattle, Washington
Chapter 55, Neck Pain

D. David Graham, M.D.
Fellow, Pediatric Surgery
Children's Hospital and Medical Center
Seattle, Washington
Chapter 67, Painful Diseases of the Liver, Biliary System, and Pancreas

Daniel O. Graney, Ph.D.
Professor, Department of Biological Structure
University of Washington School of Medicine
Seattle, Washington
Chapter 60, General Considerations of Pain in the Chest; Chapter 65, General Considerations of Abdominal Pain

C. Chan Gunn, M.D.
Clinical Professor of Anesthesiology
University of Washington School of Medicine
Seattle, Washington
Chapter 28, Neuropathic Myofascial Pain Syndromes

Jan M. Gybels, M.D., Ph.D.
Professor Emeritus of Neurology and Neurosurgery
Catholic University of Leuven
Leuven, Belgium
Chapter 99, Peripheral Nerve Stimulation

Stephen W. Harkins, Ph.D.
Professor of Gerontology, Psychiatry, and Biomedical Engineering
Psychophysiology/Memory Laboratory
Virginia Commonwealth University School of Medicine
Richmond, Virginia
Chapter 45, Aging and Pain

Samuel J. Hassenbusch, M.D., Ph.D.
Associate Professor of Neurosurgery
University of Texas?Houston Medical School
M. D. Anderson Cancer Center
Houston, Texas
Chapter 106, Neurosurgical Operations on the Spinal Cord

Stanley A. Herring, M.D.
Clinical Professor, Departments of Rehabilitation Medicine and Orthopaedics
University of Washington School of Medicine
Puget Sound Sports and Spine Physicians
Seattle, Washington
Chapter 96, Basic Concepts in Biomechanics and Musculoskeletal Rehabilitation

Irene Higginson, B.Med.Sci, B.M.B.S. F.F.P.H.M., Ph.D.
Head, Department of Palliative Care and Policy
King's College School of Medicine and Dentistry
St. Christopher's Hospice
London, United Kingdom
Chapter 40, Palliative Care

Louis Jacobson, M.D.
Associate Professor of Anesthesiology
University of Washington School of Medicine
Veterans Administration Puget Sound Health Care System
Seattle, Washington
Chapter 10, General Considerations of Chronic Pain

Nora A. Janjan, M.D., F.A.C.P., F.A.C.R.
Professor of Radiation Oncology
University of Texas?Houston Medical School
M. D. Anderson Cancer Center
Houston, Texas
Chapter 37A, Radiotherapeutic Management of Symptomatic Disease

Mark P. Jensen, Ph.D.
Professor of Rehabilitation Medicine
Department of Rehabilitation Medicine
University of Washington School of Medicine
Seattle, Washington

Chapter 94, Motivating the Pain Patient for Behavioral Change

Kaj H. Johansen, M.D.
Department of Surgical Education
Providence Medical Center
Seattle, Washington
Chapter 33, Pain Due to Vascular Disease; Chapter 69, Abdominal Pain Caused by Other Diseases

Donna Kalauokalani, M.D., M.P.H.
Assistant Professor
Anesthesiology, Division of Pain Management
Internal Medicine, Division of General Medical Sciences
Washington University School of Medicine
St. Louis, Missouri
Part IV: Regional Pains, Introduction

Michael B. Kimmey, M.D.
Professor of Medicine
Department of Gastroenterology
University of Washington School of Medicine
Seattle, Washington
Chapter 66, Painful Diseases of the Gastrointestinal Tract

Joseph C. Langlois, M.D.
Clinical Associate Professor of Dermatology
University of Washington School of Medicine
Seattle, Washington
Chapter 32, Pain of Dermatologic Disorders

Roger V. Larson, M.D.
Associate Professor of Orthopaedic Surgery
University of Washington School of Medicine
Seattle, Washington
Chapter 79, Painful Disorders of the Thigh and Knee

Susan G. Leckband, B.S., R.Ph., B.C.P.P.
Psychiatric Clinical Pharmacy Specialist
Veterans Affairs San Diego Healthcare System
San Diego, California
Chapter 84, Systemic Opioid Analgesics

Linda LeResche, Sc.D.
Research Professor, Department of Oral Medicine
University of Washington School of Dentistry
Seattle, Washington
Chapter 7, Gender, Cultural, and Environmental Aspects of Pain

Bengt Linderoth, M.D., Ph.D.
Department of Neurosurgery
Karolinska Hospital
Stockholm, Sweden
Chapter 100, Spinal Cord Stimulation; Chapter 101, Brain Stimulation: Intracerebral and Motor Cortex Stimulation

John D. Loeser, M.D.
Professor of Neurological Surgery and Anesthesiology
Former Director, Multidisciplinary Pain Center
University of Washington School of Medicine
Seattle, Washington
Part I: Basic Considerations of Pain, Introduction; Chapter 1, History of Pain Concepts and Therapies; Chapter 8, Applied Anatomy Relevant to Pain; Chapter 11, Multidisciplinary Pain Programs; Part II: Evaluation of the Pain Patient, Introduction; Chapter 12, Medical Evaluation of the Patient with Pain; Chapter 18, Multidisciplinary Pain Assessment; Part III: Generalized Pain Syndromes, Section A Neuropathic Pains, Introduction; Chapter 21, Pain after Amputation: Phantom Limb and Stump Pain; Chapter 22, Herpes Zoster and Postherpetic Neuralgia; Part III: Generalized Pain Syndromes, Section C Vascular, Cutaneous, and Musculoskeletal Pains, Introduction; Chapter 34, Pain in Spinal Cord Injury Patients; Part III: Generalized Pain Syndromes, Section D Pain in Malignant Diseases, Introduction; Part III: Generalized Pain Syndromes, Section E Acute Pains, Introduction; Part IV: Regional Pains, Introduction; Chapter 46, General Considerations of Pain in the Head; Chapter 47, Cranial Neuralgias; Chapter 54, General Considerations of Pain in the Neck and Upper Limb; Chapter 56, Cervicobrachial Neuralgia; Chapter 69, Abdominal Pain Caused by Other Diseases; Chapter 74, Pelvic and Perineal Pain Caused by Other Disorders; Chapter 76, Low Back Pain, Introduction; Chapter 77, Pain of Neurologic Origin in the Hips and Lower Extremities; Part V: Methods for Symptomatic Control, Section A General Considerations, Introduction; Part V: Methods for Symptomatic Control, Section B Pharmacologic Therapies, Introduction; Part V: Methods for Symptomatic Control, Section D Physical Therapeutic Modalities, Introduction; Part V: Methods for Symptomatic Control, Section E Implanted Electrical Stimulators, Introduction; Part V: Methods for Symptomatic Control,
Section F Regional Anesthesia/Analgesia, Introduction; Part V: Methods for Symptomatic Control, Section G Ablative Neurosurgical Operations, Introduction; Part V: Methods for Symptomatic Control, Section H Multidisciplinary Multimodal Pain Management Programs, Introduction; Chapter 109, Multidisciplinary Pain Management; Chapter 110, Building the Future

Deon F. Louw, M.B.Ch.B., F.R.C.S.(C)
Consultant Neurosurgeon
Department of Clinical Neurosciences
University of Calgary Faculty of Medicine
Foothills Hospital
Calgary, Alberta
Chapter 107, Surgical Treatment of Trigeminal Neuralgia

Thomas J. Mancuso, M.D.
Instructor in Anaesthesia
Harvard Medical School
Associate Director, Acute Pain Treatment Service
Director, Sedation Service
Associate in Anesthesia
Children’s Hospital, Boston
Boston, Massachusetts
Chapter 44, Pain and Its Management in Children

Kenneth R. Maravilla, M.D.
Professor of Radiology and Neurological Surgery
University of Washington School of Medicine
Seattle, Washington
Chapter 14, Imaging Pain Patients

Anthony J. Mariano, Ph.D.
Clinical Assistant Professor of Psychiatry and Behavioral Sciences
Codirector, Pain Clinic
University of Washington School of Medicine
Veterans Administration Puget Sound Health Care System
Seattle, Washington
Chapter 10, General Considerations of Chronic Pain

Frederick A. Matsen III, M.D.
Professor and Chair, Department of Orthopaedics
University of Washington School of Medicine
Seattle, Washington
Chapter 58, Shoulder, Arm, and Elbow Pain; Chapter 95, Orthopedic Management of Pain

Mitchell B. Max, M.D.
Senior Investigator
Pain and Neurosensory Mechanisms Branch, National Institute of Dental and Craniofacial Research
National Institutes of Health
Bethesda, Maryland
Chapter 85, Antidepressants, Muscle Relaxants, and N-*Methyl-D-Aspartate Receptor Antagonists*

John S. McDonald, M.D.
Professor and Chairman of Anesthesiology
Professor of Obstetrics and Gynecology
Harbor-University of California, Los Angeles Medical Center
Torrance, California
Chapter 70, General Considerations; Chapter 71, Pain of Childbirth; Chapter 72, Gynecologic Pain Syndromes; Chapter 73, Pelvic and Perineal Pain of Urologic Origin; Chapter 74, Pelvic and Perineal Pain Caused by Other Disorders

Harold Merskey, D.M., F.R.C.P.
London Psychiatric Hospital
London, Ontario
Chapter 93, Psychotherapy in the Management of Chronic Pain

Michael H. Metcalf, M.D.
Department of Orthopaedics
University of Washington School of Medicine
Seattle, Washington
Chapter 79, Painful Disorders of the Thigh and Knee

Björn A. Meyerson, M.D., Ph.D.
Department of Neurosurgery
Karolinska Hospital
Stockholm, Sweden
Chapter 100, Spinal Cord Stimulation; Chapter 101, Brain Stimulation: Intracerebral and Motor Cortex Stimulation

H. Richard Miyoshi, B.S., R.Ph.
Clinical Associate Professor
University of Washington School of Pharmacy
Department of Psychiatry and Behavioral Sciences
Harborview Medical Center
Seattle, Washington
Chapter 83, Systemic Nonopioid Analgesics; Chapter 84, Systemic Opioid Analgesics

Michael J. Moskal, M.D.
Clinical Instructor of Orthopaedic Surgery
University of Washington School of Medicine
Seattle, Washington
Chapter 58, Shoulder, Arm, and Elbow Pain; Chapter 95, Orthopedic Management of Pain

J. Cameron Muir, M.D.
Assistant Professor of Medicine
Section of Palliative Medicine
Division of Hematology/Oncology
Northwestern University Medical School
Medical Director, Palliative Care and Home Hospice Program
Northwestern Memorial Hospital
Chicago, Illinois
Chapter 37B, Chemotherapeutic Management of Symptomatic Disease

Gerd Müller, M.D.
Department of Orthopaedics
Allgemeines Krankenhaus Barmbek
Hamburg, Germany
Chapter 76A, Low Back Pain: Primary Care Approach to Acute and Chronic Back Problems: Definitions and Care

Catherine M. Neumann, M.Sc.
Division of Palliative Care Medicine
University of Alberta
Grey Nuns Community Health Centre
Edmonton, Alberta
Chapter 40, Palliative Care

Richard B. North, M.D.

Professor of Neurosurgery, Anesthesiology, and Critical Care Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland
Chapter 76C, Low Back Pain: Failed Back Surgery Syndrome

Bart J. Nuttin, M.D., Ph.D.
Assistant Professor of Neurosurgery
Catholic University of Leuven
Leuven, Belgium
Chapter 99, Peripheral Nerve Stimulation

Anne Louise Oaklander, M.D., Ph.D.
Assistant Professor of Anesthesiology and Neurology
Harvard Medical School
Assistant in Anesthesiology and Neurology
Massachusetts General Hospital
Boston, Massachusetts
Chapter 76C, Low Back Pain: Failed Back Surgery Syndrome

Akiko Okifuji, Ph.D.
Assistant Professor of Anesthesiology
University of Washington School of Medicine
Seattle, Washington
Chapter 2, Pain Terms and Taxonomies of Pain

John E. Olerud, M.D.
George F. Odland Professor of Medicine
University of Washington School of Medicine
Head, Division of Dermatology
University of Washington Medical Center
Seattle, Washington
Chapter 32, Pain of Dermatologic Disorders

James C. Orcutt, M.D., Ph.D.
Professor of Ophthalmology
Adjunct Professor of Otolaryngology, Head and Neck Surgery
University of Washington School of Medicine
Seattle, Washington
Chapter 51, Ocular and Periocular Pain

Parag G. Patil
Department of Neurosurgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
Chapter 105, Lesions of Primary Afferents and Sympathetic Efferents as Treatments for Pain

David R. Patterson, Ph.D., A.B.P.P., A.B.P.H.
Professor of Rehabilitation Medicine, Surgery, and Psychology
University of Washington School of Medicine
Harborview Medical Center
Seattle, Washington
Chapter 42, Burn Pain

Karin L. Petersen, M.D.
Postdoctoral Fellow
Pain Clinical Research Center
Department of Neurology
University of California, San Francisco School of Medicine
San Francisco, California
Chapter 86, Anticonvulsants and Local Anesthetic Drugs

Robert R. Phillips, M.D.
Division of Cardiology
University of New Mexico Health Sciences Center
Albuquerque, New Mexico
Chapter 61, Cardiac and Aortic Pain

Charles E. Pope, Jr., M.D.
Professor Emeritus
Department of Medicine
University of Washington School of Medicine
Seattle, Washington
Chapter 63, Chest Pain of Esophageal Origin

Joel M. Press, M.D., F.A.C.S.M.
Medical Director, Center for Spine, Sports and Occupational Rehabilitation
Rehabilitation Institute of Chicago
Chicago, Illinois
Chapter 96, Basic Concepts in Biomechanics and Musculoskeletal Rehabilitation

David D. Ralph, M.D.
Associate Professor of Medicine
Department of Pulmonary/Critical Care Medicine
University of Washington School of Medicine
Seattle, Washington
Chapter 62, Painful Disorders of the Respiratory System

Andrea J. Rapkin, M.D.
Professor of Obstetrics and Gynecology
University of California, Los Angeles, UCLA School of Medicine
Los Angeles, California

Chapter 70, General Considerations

Shlomo Raz, M.D.
Professor of Urology
University of California, Los Angeles, UCLA School of Medicine
Los Angeles, California
Chapter 68, Painful Diseases of the Kidney and Ureter

L. Brian Ready, M.D.
Professor of Anesthesiology
University of Washington School of Medicine
Director, University of Washington Medical Center Pain Service
Seattle, Washington
Chapter 41, Postoperative Pain; Chapter 103, Regional Analgesia with Intraspinal Opioids

James P. Robinson, M.D., Ph.D.
Clinical Assistant Professor of Rehabilitation Medicine
University of Washington School of Medicine
Seattle, Washington
Chapter 17, Evaluation of Function and Disability

Joan M. Romano, Ph.D.
Associate Professor of Psychiatry and Behavioral Sciences
University of Washington School of Medicine
Seattle, Washington
Chapter 16, Psychological and Psychosocial Evaluation; Chapter 89, Cognitive-Behavioral Therapy for Chronic Pain

Michael C. Rowbotham, M.D.
Associate Professor of Neurology and Anesthesia
University of California, San Francisco School of Medicine
University of California, San Francisco Pain Clinical Research Center
San Francisco, California
Chapter 86, Anticonvulsants and Local Anesthetic Drugs

I. J. Russell, M.D., Ph.D.
Associate Professor of Medicine
University of Texas Health Science Center at San Antonio
San Antonio, Texas
Chapter 30, Fibromyalgia Syndrome

Bruce J. Sangeorzan, B.S., M.D.
Professor of Orthopaedics
University of Washington School of Medicine
Harborview Medical Center
Seattle, Washington
Chapter 80, Pain in the Leg, Ankle, and Foot

Mark M. Schubert, D.D.S., M.S.D.
Associate Professor of Dentistry
Department of Oral Medicine
University of Washington School of Dentistry
Seattle, Washington
Chapter 38, Oral Mucositis in Cancer Patients

Lauren Schwartz, Ph.D.
Clinical Assistant Professor of Rehabilitation Medicine
University of Washington School of Medicine
Seattle, Washington
Chapter 20, Complex Regional Pain Syndromes?Type I: Reflex Sympathetic Dystrophy, and Type II: Causalgia

Sam R. Sharar, M.D.
Associate Professor of Anesthesiology
University of Washington School of Medicine
Harborview Medical Center
Seattle, Washington
Chapter 42, Burn Pain

Anders E. Sola, M.D.
Clinical Assistant Professor of Anesthesiology
University of Washington School of Medicine
Seattle, Washington
Chapter 29, Myofascial Pain Syndromes

Walter C. Stolov, M.D.
Professor and Chair Emeritus, Department of Rehabilitation Medicine
University of Washington School of Medicine
Seattle, Washington
Chapter 13, Electrodiagnostic Evaluation of Acute and Chronic Pain Syndromes

Mark D. Sullivan, M.D., Ph.D.
Associate Professor of Psychiatry
Department of Psychiatry and Behavioral Sciences
University of Washington School of Medicine
Seattle, Washington
Chapter 26, Psychiatric Illness, Depression, and Psychogenic Pain

Karen L. Syrjala, Ph.D.
Associate Professor of Psychiatry and Behavioral Sciences
University of Washington School of Medicine
Director and Associate Member

Department of Biobehavioral Sciences
Fred Hutchinson Cancer Research Center
Seattle, Washington
Chapter 15, Measurement of Pain; Chapter 92, Relaxation and Imagery Techniques

Ronald R. Tasker, M.D.
Professor Emeritus of Neurosurgery
University of Toronto Faculty of Medicine
The Toronto Western Hospital
Toronto, Ontario
Chapter 23, Central Pain States

Gregory W. Terman, M.D., Ph.D.
Associate Professor, Department of Anesthesiology and the Graduate Program in Neurobiology and Behavior
University of Washington School of Medicine
Seattle, Washington
Chapter 4, Spinal Mechanisms and Their Modulation

Richard W. Tobin, M.D.
Clinical Assistant Professor of Medicine
Departments of Internal Medicine and Gastroenterology
University of Washington School of Medicine
Seattle, Washington
Chapter 66, Painful Diseases of the Gastrointestinal Tract

Chapter 80, Pain in the Leg, Ankle, and Foot

Preface

This textbook presents a comprehensive and systematic approach to the sciences basic to the practice of pain management and to all aspects of the diagnosis and treatment of acute and chronic pain. In this respect it resembles the first edition of this book, published in 1953, and the second edition, published in 1990, both under the personal direction of John J. Bonica. My colleagues and I have attempted to meet the standards that Dr. Bonica established in the previous editions and have maintained the same organization and completeness that he developed. The reader will find that we have added new chapters, deleted some of the old topics, and updated every chapter. We have reprinted the Preface from the first edition, as it is one of the key documents in the history of the pain movement in the last half of the twentieth century.

The past 45 years have witnessed an explosion of published materials relevant to the study of pain and the practice of pain management. John J. Bonica was the driving force behind this major change in the way biomedicine approached the problem of pain. Numerous books have been published, at least 25 journals have been established, and educational materials of all types have been developed. No one person can be the author of a contemporary, comprehensive textbook on pain; this is why the second edition of this book had multiple contributors. Few authors or editors have attempted to provide the type of broad yet deep coverage of basic science, acute and chronic pain, cancer pain, and problems related to the young and the old and those with all types of illness.

This book is designed to be a source of information for both pain specialists and those who are seeking information about a specific pain topic. The organization of the chapters reflects our concepts of how the reader can best use these materials. The nature of a book is to fragment information into segments; this does not imply a deviation from the fundamental fact that patients are not a collection of body parts; optimal management of pain patients requires a holistic approach to health care. We do not expect anyone to read it from cover to cover.

The book has five general sections. Part I contains eleven chapters with information basic to an understanding of pain. It begins with the history of pain concepts and theories and definitions and taxonomies of pain. Next are chapters on anatomy and physiology and pharmacology of the peripheral nerves, spinal cord, and brain. The behavioral and social sciences are next, followed by the roles of culture, gender, and social interactions. Applied anatomy and general considerations of acute and chronic pain are then presented. The final chapter in this section addresses the development and characteristics of multidisciplinary pain treatment. Those who wish to develop an overview of all of the issues that provide a cornerstone for pain management should begin with this section.

Part II addresses the evaluation of the patient with pain. The seven chapters cover all phases of the medical and psychological assessment process, including the role and interpretation of imaging studies. Of particular import is the chapter on the evaluation of pain and disability, for this is a major medical, political, and economic problem in all the developed countries. Accurate diagnosis is the cornerstone of optimal treatment. The final chapter describes assessment in a multidisciplinary pain clinic.

Part III consists of 27 chapters focusing on generalized pain syndromes that can cause patients to present with complaints referable to any region of the body. It also contains chapters on pain in the young and the old, for these age groups merit special considerations. Pains related to cancer and to acquired immunodeficiency syndrome are discussed in Part III, as are the issues surrounding acute pain management. Organizing the book in this fashion permits the reader to obtain information about generalized or multifocal pain syndromes in a coherent fashion, without resorting to reading about the pain in every regional chapter to obtain a complete picture of the pains related to this disease.

Part IV addresses pain syndromes on a regional basis, beginning with the head and ending with the foot. Each chapter begins with an overview of the anatomy and physiology of that region and the principles of diagnosis and differential diagnosis in that part of the body. Principles of the management of pain in each area are stressed. Obviously, the discussion of disease processes in each area cannot be as detailed as in texts devoted exclusively to a single system or part of the body. Appropriate references are included to direct the reader to more detailed presentations.

Part V provides an overview of all aspects of the treatment of pain that are currently in use by medical and psychological practitioners. It begins with two new chapters, one on non-specific treatment effects and the other on the construction and evaluation of clinical trials. Both of these subjects are essential for the pain practitioner or clinical research scientist. The principles of pain management, rather than treatment of the underlying disease, are contained in this section. Presumably, any physician would first attempt to eradicate pain by eliminating the disease leading to the pain; in this volume we address the problem of managing pain when the antecedent disease processes cannot be eliminated. Each chapter attempts to place its subject in historical perspective and to indicate the current usage of this type of treatment. Although one could implement the less complex strategies for pain management that are described in each chapter just on the basis of what is written here, none of the chapters describing complex invasive procedures is designed to serve as a “how to do it” for those who are not adequately trained in this form of treatment. For example, the chapters on regional anesthesia and neurologic surgery are intended to provide adequate information for those who are not anesthesiologists or neurosurgeons so that they may understand the rationale and indications for, techniques of, and expected results of these procedures. Those who make management decisions about patients with pain should become aware of all of the treatment options; this is the purpose of Part V of this book.

We have attempted to avoid duplication of data and repetitive discussion of similar issues in multiple places as much as possible. We have also established a consistent style and depth of presentation so that the weighting of each topic is in proportion to its importance in contemporary pain research and management. The references are selected from extensive bibliographies in each area so that the reader can locate key articles or comprehensive texts that will provide in-depth information beyond that which can be offered in this text. We have worked hard to produce a balanced and thorough approach to the world of pain. Inevitably, some will be offended by the amount of space allocated to their favorite topic; we are certain that the subsequent editions of this text will add some new topics and delete old, just as we have done. Tremendous strides in our understanding of the sciences basic to pain have taken place; we hope that Chapters 3 through 7 will capture the excitement of what was accomplished in basic pain research in the 1990s. We expect that the outcomes-based movement that is gaining momentum in Western medicine will lead to superior information about the effects of pain treatments and that this will shape subsequent versions of the treatment sections of the book.

We have selected each of the authors because of his or her expertise and ability to convey information with clarity. To maintain similar format and style, we have edited each chapter. We have spent many hours resolving philosophical and content issues that are common in multiauthored texts such as this. We hope that the third edition of *Bonica’s Management of Pain* will be as valuable to its readers as the first and second editions have proved to be. It is an honor to carry on the tradition started by John J. Bonica.

Preface to the First Edition (1953)

The purpose of this book is to present within one volume a concise but complete discussion of the fundamental aspects of pain, the various diseases and disorders in which pain constitutes a major problem, and the methods employed in its management, with special emphasis on the use of analgesic block as an aid in the diagnosis, prognosis, and therapy. Although several books dealing with certain phases of this problem are available, none is complete from the standpoint of the practitioner; for it is necessary for him to consult several texts in order to obtain information regarding the cause, characteristics, mechanisms, effects, diagnosis, and therapy of pain and management of its intractable variety with analgesic block and certain adjuvant methods. The present volume is the product of the author's desire to facilitate the task of the busy practitioner and to supply him easily accessible information with the conviction that this will induce more clinicians to employ these methods of diagnosis and therapy.

One need not elaborate on the reasons for writing on the management of pain, for reflection emphasized that this age-old problem is still one of the most difficult and often vexing phases of medical practice?a fact well appreciated by most physicians. This fact, as well as other reasons, are presented in the introduction and are emphasized throughout the book, particularly in Chapter 5.

I have been motivated to write this volume by a deep feeling for those who are afflicted with intractable pain, and by an intense desire to contribute something toward the alleviation of their suffering. The plan for its writing was germinated almost a decade ago during the Second World War, while I was Chief of the Anesthesia Section of a large Army hospital, where I was afforded the opportunity to observe and manage an unusually large number of patients with severe intractable pain. The gratifying results obtained with analgesic block in some instances impressed me with the efficacy of this method in selected cases. In addition, the fact that these procedures effected relief which frequently was not only dramatic, but outlasted by hours and days the transient physiochemical interruption of nerve impulses, fascinated me and aroused my interest. Perusal of the literature revealed a paucity of material on this subject?a situation which has not changed much since then and which clearly indicated an obvious need for a practical source of information about this perplexing phenomenon and the application of analgesic block to its management.

This book is composed of three parts. *The first part* includes a discussion of the fundamental aspects of pain. While some of the material, on superficial thought, might be considered too detailed or entirely unnecessary, it has been included because of my conviction that in order to manage pain properly its anatomical, physiological and psychological bases must be understood. As is true in all fields of endeavor, a thorough knowledge of fundamental principles is an essential prerequisite without which optimal results are precluded. In order to diagnose and treat it properly, the physician must know the course of pain from its place of origin to the apperception centers in the brain and must be well versed in all the essentials and components of which pain consists; he must know its causes, mechanisms, characteristics, varieties, its localizations and significance, and the mental and physical effects it produces.

The second part deals with methods and technics of managing pain. It was originally planned to include only the method which is the central theme of the book?analgesic block. However, it was soon realized that while this important phase is, to be sure, here treated in a comprehensive manner, it does not present the complete story of the management of pain; because frequently other adjuvant methods are employed in conjunction with nerve blocking. To illustrate the point, trigeminal neuralgia is frequently treated with neurolytic blocks, but sometimes this does not afford sufficiently long relief, and neurotomy is resorted to. The pain associated with malignancy is managed with alcohol nerve block, but roentgen therapy is frequently employed as an adjuvant. Moreover physical and/or psychiatric therapy constitute integral phases of the management of pain without which optimal results cannot be hoped for. After careful consideration, it was decided to include another section in Part II in which are presented methods that are frequently employed in conjunction with analgesic block. It is hoped that such inclusion will give the book a wider scope and greater usefulness.

In the third part are presented various diseases or disorders with painful syndromes which have been and can be managed with analgesic block with or without the aid of other methods. The arrangement of this part is explained in detail on page 671. It is suggested that the reader refer to that page before proceeding further to read any on the pain syndromes. Though the material in this part mainly represents my observations, clinical impressions, and opinions, obtained or developed from experience with, and statistical analysis of, many thousands of cases, it also includes unpublished data of several outstanding authorities who have kindly placed them at my disposal. Moreover, it includes the published views and clinical experiences of others, with credit given where it is due.

In writing this comprehensive treatise, which has involved no small amount of time and effort, the one principle which has always been kept in mind and adhered to has been to present the fundamental considerations and principles of the problem before the practical aspects are discussed.

I have endeavored to make this book as complete as possible, and to this end have thoroughly searched the literature, both English and foreign, and have taken from it all that I thought might be valuable to the reader. In order to comply with the aim of completeness and still keep the book concise and within reasonable size, the material has been selected with care and discretion. In a field so vast and complex as pain, it is unavoidable that what might be thought sufficiently important to deserve detailed discussion is presented in an abbreviated manner or entirely omitted. In other instances, mere mention or omission represents a reluctant compliance with the requirements dictated by the size of the volume. Nonetheless, I believe thoroughness and important detail have not been sacrificed. The bibliography represents the most important references, and many excellent articles on each subject were also reluctantly omitted for that reason.

The book is intended for practitioners of every field of medicine, because pain is universal and provides the main reason why patients seek the aid of the doctor. It is hoped that it will prove useful, not only to the anesthesiologist, neurologist, neurosurgeon, orthopedist, and physiatrist to whom especially is relegated the task of caring for patients with intractable pain, but also to the general practitioner, surgeon, internist, psychiatrist, and any other physician who may be confronted with this problem. It is especially intended for general practitioners, particularly those practicing in smaller communities where the services of a specialist in analgesic blocking are not available. With this aim in mind the technics of analgesic block are presented in such a manner that most of them may be effectively accomplished by any physician, even though he may be a novice with regional analgesia. In order to facilitate the task of the busy reader, less relevant facts?material which has been included because of its academic importance, for the sake of completeness, or for consumption by students and those who wish to delve deeper into the problem?are presented in small type. These can be omitted without losing continuity of thought. In this manner, while completeness, detail, and thoroughness are not sacrificed, emphasis is laid on the practical aspects of the problem at hand.

The unusually large number of illustrations, many of which are original and composed from dissected material or clinical cases, have been included with the conviction that these frequently tell the story much better than words.

A book of this nature is made possible only by the contribution of many individuals. The information set forth in the first part of the volume represents the fruition of the joint effort of anatomists, physiologists, pharmacologists, neurologists, neurosurgeons, anesthesiologists, psychiatrists, and many other laboratory and clinical investigators who have spent untold time, labor, and effort to discover the mystery of pain. I am grateful for their elucidating knowledge. To clinicians who have reported their experiences, and to others who have placed at my disposal unpublished data, observations, and opinions, my sincere thanks. I am particularly obliged to General Maxwell Keeler, and Col. Clinton S. Lyter, of Madigan Army Hospital for their continuous cooperation in obtaining much of the clinical data embraced in this volume. I want to express my gratitude to Mr. Harold Woodworth for his friendship, sympathetic understanding and devotion to the cause of medicine. I also want to thank the other members of the Board of Trustees of Tacoma General Hospital, but particularly Mr. Alex Babbit, and Mr. Walter Heath and John Dobyns, Directors of the hospital. Their continuous cooperation has facilitated the activities of the Department of Anesthesia, Nerve Block Clinic, and Pain Clinic.

I am very grateful to Dr. Robert Johnson, Associate Professor of Anatomy of the University of Washington School of Medicine, for his encouragement and criticism of some parts of the manuscript; to Doctor Frederick Haugen for his assistance, criticism and suggestion.

My collaborators, Professor Robert Ripley, Doctors Wendell Peterson, Frank Rigos, John T. Robson, Col. Clark Williams, M.C., and Lieut. Col. Walter Lumpkin, M.D., have my heartfelt thanks for their contributions and cooperation.

My appreciation is extended to Miss Joy Polis, Miss Virginia Coleman, and other artists for the illustrations and to Mr. Kenneth Ollar for the photography; to Mrs. Louise Cameron for her cooperation in obtaining the roentgenograms; to Mrs. Katherine Rogers Miller, Miss Eleanor Ekberg and the late Mrs. Blanch DeWitt of Tacoma, Miss Bertha Hallam, Portland, and Mr. Alderson Fry, Seattle?all librarians whose cooperation has facilitated a difficult task, and to Mr. John Morrison for editorial work.

This preface would be incomplete if I did not acknowledge my indebtedness to my secretaries, Miss Katherine Stryker and Mrs. Dorothy Richmond, for the inestimable

aid they have given me in the preparation of the manuscript.

My appreciation is extended to my publishers for their courtesy, cooperation, and considerateness throughout the preparation of this volume.

John J. Bonica
Tacoma, Washington

Acknowledgments

This book reflects the contributions of many scientists and clinicians. Some have authored the chapters; others have made the research discoveries and clinical observations that have been summarized in our text. We are, of course, deeply indebted to those who contributed their valuable time to write the chapters contained in this volume. We are particularly grateful to John J. Bonica, who wrote so many of the chapters in the second edition. We have updated many of these chapters, particularly those based upon anatomy of each region, and used them as the foundation for the similar chapters in this edition. We have also created many new chapters on topics that were not covered in the second edition.

Marjorie Domenowske has again prepared all of the new illustrations for this edition. Because she did the illustrations for the second edition, we have been able to continue her elegant style for all of our original figures. Her efforts to prepare informative and easily grasped visual images have again been a great contribution to our text.

We thank the John C. Liebeskind History of Pain Collection of the University of California, Los Angeles Biomedical History Library for the loan of illustrations from the second edition of Bonica's *Management of Pain*.

Donna Rowe was the glue that held our work together and made certain that it was always perfect. She acted as executive secretary for this, the third edition, just as she did for the second edition. Without her attention to detail, patience, and desire to make this edition every bit as complete and perfect as the prior one, we could never have succeeded. It is to her that we owe the greatest debt. Finally, Tanya Lazar at Lippincott Williams & Wilkins has been patient and thorough in the preparation and printing of this book.

Part I Basic Considerations of Pain - Introduction

John D. Loeser

The chapters in Part I contain basic scientific and clinical information essential to an understanding of the fields of pain research and management as they have evolved since the late 1940s. Chapter 1 contains a historical review of pain concepts and treatment dating back to the earliest recorded time. Chapter 2 presents the definitions and taxonomy of pain as developed and then refined by the International Association for the Study of Pain under the direction of Professor Harold Merskey. We also discuss some of the issues surrounding the development of a taxonomy and the attempts to validate different means of classifying pain syndromes. The syndrome codes created by International Association for the Study of Pain appear in various chapters of Parts III and IV of this book, because they help to standardize nomenclature and facilitate scholarly and clinical interchange.

Chapter 3, Chapter 4 and Chapter 5 present an overview of our current understanding of the anatomy, physiology, biochemistry, and pharmacology of the peripheral nerves, spinal cord, and brain. This section is significantly reorganized from that of the second edition of this text, because we wish to present the information in a more contemporary style. Chapter 6, Psychological Aspects of Pain, and Chapter 7, describing the influences of gender, social, cultural, and environmental factors relevant to pain, deal with all aspects of acute and chronic pain. More detailed information on these topics is found in Chapter 9 and Chapter 10 and in various chapters in Part III.

The next four chapters in this part address the basic issues in clinical pain diagnosis and management. Chapter 8 focuses on applied anatomy; Chapter 9 addresses acute pain; and Chapter 10, chronic pain. Both of the latter chapters provide an overview but do not deal with specific syndromes or treatment strategies. The presence of this type of material at the start of the text obviates the need for such general considerations in Parts III and IV.

The final chapter of Part I begins the discussion of multidisciplinary pain diagnosis and treatment as developed since 1960 by Dr. John J. Bonica and his successors at the University of Washington. Multidisciplinary pain centers and clinics are a direct legacy of Bonica's pioneering efforts throughout the world to bring about improvements in the alleviation of pain and suffering. Their evolution, as typified by the Multidisciplinary Pain Center at the University of Washington, is one of the essential developments of the pain treatment movement since the 1950s. Various aspects of the types of therapies used in such treatment facilities are discussed in Chapter 88, Chapter 89, Chapter 90, Chapter 91, Chapter 92, Chapter 93 and Chapter 94 as well as in highly focused sections of the chapters in Part III. For information about outcomes of this type of treatment, consult Chapter 109.

The editors' concepts of pain underlie the selection of topics considered essential for an understanding of pain management and pain research. We believe that knowledge of the history of ideas about pain and methods of classifying it is an important foundation. Along with the traditional biomedical sciences, such as anatomy, physiology, and biochemistry, the sciences of human psychology and behavior are also essential for an adequate understanding of patients with pain. Sociocultural factors also must be given attention, as these influence patients' presentation, understanding, acceptance, and response to treatments. Health care professionals' responses to patients also are influenced by a wide range of sociocultural and economic factors. Finally, the fundamental differences in the phenomena of acute and chronic pain and their management strategies make them appropriate topics for the introductory section of this text.

Part II Evaluation of the Pain Patient - Introduction

John D. Loeser

Chapter References

The seven chapters in this part discuss the components of the evaluation of the patient whose complaint of pain does not readily correspond to a specific pathologic change in some part of the body. In most patients with acute pain, the region of tissue damage is obvious and the patient's complaints clearly stem from the injured region. In patients with pain associated with cancer, the search for an etiology of the patient's pain usually reveals disease, such as metastasis to bone or tissue damage from the attempts to cure the malignancy, such as radiation-induced fibrosis or chemotherapy-induced neuropathy. In patients with chronic pain associated with nonneoplastic diseases, the linkage between specific pathology and the patient's pain behaviors is quite loose, and the search for an explanation of the symptoms requires a comprehensive assessment that is often beyond the skills of any one health care provider. A multidisciplinary team of health professionals who have special knowledge and experience in the evaluation of pain patients can best accomplish this. The interactions between those who perform the assessment are often essential in formulating a meaningful diagnosis and treatment plan.

Bonica stated in the first edition of this text, published in 1953, that all complex patients required multidisciplinary evaluation, but his viewpoint did not gain wide acceptance for at least two decades. He wrote and spoke extensively on this topic, but few physicians understood the complexities of chronic pain patients and most were tied to their own disciplinary approaches to diagnosis and treatment. A second factor was the widespread belief that graduation from medical school qualified one to deal with all aspects of pain diagnosis and treatment. Another problem was the increasing specialization of medical practice and the relative isolation of information into narrow disciplinary areas. A fourth issue was the failure to recognize that chronic pain was not just a by-product of a disease process but was a form of illness that required direct assessment and treatment.

The complex, multidimensional nature of pain was unrecognized—a shortcoming nurtured by the continued widespread teaching and acceptance of the Cartesian concepts of the separation of mind and body and the clockwork mechanisms of body function, by the preeminence of the specificity theory of pain, and by the rapid growth of scientific medicine and the consequent practice of reductionism. Any problem could be understood by analyzing the body in ever smaller units, until the causative diseased part became evident. Human beings, however, are more than the sum of their individual parts.

One of the great triumphs of Bonica's career was that he lived long enough to see his concepts of the multidimensional nature of pain validated and disseminated throughout the world. Advances in our understanding of the complaint of pain have led to much greater appreciation of the complexities associated with the report of pain and the critical roles not only of tissue damage, but also of changes in the nervous system in response to noxious input, and of cognitive, affective, and environmental factors in the genesis, exacerbation, and perpetuation of the complaint of pain. Multidisciplinary assessment of chronic pain patients is now a standard approach. Changes in clinical practice stem from the tremendous increases in our understanding of central nervous system mechanisms that influence the recognition of and response to noxious stimulation. We now recognize the complexities of what was once thought to be a simple, line-labeled information system. Concepts about pain drive the strategies for the evaluation and subsequent treatment of the patient with pain, and it is the conceptual change that Bonica initiated that is his greatest legacy.

Cartesian dualism is dually deficient as a conceptual model for pain. In the first place, one cannot separate mind and body in a living human being. The mind is an emergent property of the human brain. All responses of the organism involve mind and body. More important, what Descartes left out was just as essential as the two factors he included. Mind and body alone do not suffice to predict behavior; the environment is just as potent a force. Human beings are social organisms from the moment of birth. All too often, those who provide health care are oblivious to the major role that environmental factors play in the genesis and perpetuation of chronic pain. Newer conceptual models for pain incorporate the role of learning, cognitive, and affective factors in the genesis of chronic pain. These models overtly state that nociception derived from tissue damage is not the sole determinant of pain and its behavioral expression, and that the nervous system can modulate nociceptive stimuli by physiologic as well as psychological mechanisms.

A conceptual model was published by Loeser (1) in 1982. It has proven to be a useful adjunct in the understanding of the components of pain. According to this model, the phenomenon of human pain can be separated into four nested components: nociception, pain, suffering, and pain behaviors. The model (Fig. II-1) emphasizes that nociception, pain, and suffering are personal, private, internal events that one cannot measure directly in another human being. Their existence can only be inferred by the assessment of pain behaviors. *Nociception* is the detection of tissue damage by transducers in the skin and other tissues and the propagation of this information to the central nervous system by A-d and C fibers in the peripheral nerves. Inflammation or injury is now known to be capable of biasing the nociceptive transducers and lowering their threshold for activation (see Chapter 9). *Pain* is the perception of the nociceptive signaling by neural mechanisms in the spinal cord and brain. Pain can arise from lesions in the peripheral or central nervous system that send impulses to the spinal cord or brainstem and higher centers. When impulses that imply tissue damage reach the nervous system, the brain cannot discriminate a peripheral tissue damage origin from electrical activity generated in the axon, cell body, or central connections of the peripheral nerve.

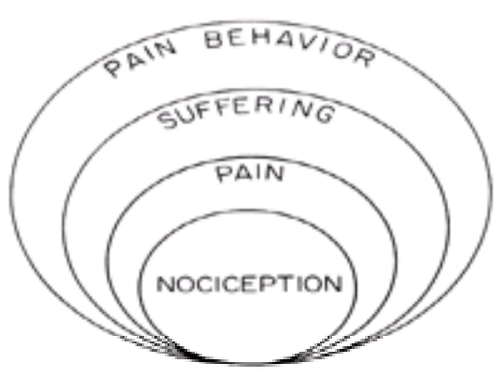

Figure II-1. Loeser's conceptualization of the phenomenon of pain. See text for explication. (From Loeser JD. Concepts of pain. In: Stanton-Hicks M, Boas R, eds. *Chronic low back pain*. New York: Raven, 1982:146, with permission.)

Suffering is a negative affective response generated in the forebrain by pain or by a wide variety of emotional states such as isolation, depression, fear, and anxiety. Suffering reflects a threat to the physical or psychological integrity of the individual, as eloquently presented by Cassell (2). It is true that many physicians and patients use the language of pain to describe suffering of any etiology. Patients who manifest suffering are therefore evaluated as if the only possible etiology was tissue damage. This can lead to unnecessary and inappropriate diagnostic tests and potentially harmful surgical procedures.

Pain behaviors are the actions or inactions of a person that imply the presence of tissue damage, such as saying “ouch,” grimacing, taking pills, lying down, refusing to work, and seeking health care. All pain behaviors are real, for they can all be observed. The proper questions are not about the reality of the patient's symptoms, but instead are the following: What are the roles of nociception, pain, suffering, and pain behaviors in the genesis and perpetuation of the patient's pain complaint? What are the stimuli that lead to the generation of pain behaviors? The originating cause of the pain—for example, trauma—may not be the predominant factor in the perpetuation of the pain behaviors. The diagnostician must be aware of this possibility. Changes in the nervous system in response to massive sensory input or from cognitive and affective factors can lead to alterations in the way sensory information, including nociception, is processed. All pain behaviors can be quantified and used as measures of pre- and posttreatment status to evaluate outcomes. Pain behaviors also follow the general rules of behavior: They are real and they are exquisitely sensitive to environmental consequences, either anticipated or actual (see Chapter 16).

The complex nature of pain makes multidisciplinary assessment a necessity. A physician *pain management specialist* usually takes the lead in the assessment of the

pain patient. Not many people today like the terms coined by Bonica of *dolorologist* or *algologist*. Complex problems may benefit from the knowledge and skills of different types of medical specialists, in addition to the obvious need for psychological and vocational assessment to supplement the medical information. The medical diagnostic workup is described in detail in Chapter 12. Chapter 13 discusses the role of electrodiagnostic testing, and Chapter 14 reviews contemporary imaging studies. The next chapter addresses the critical topic of pain measurement; this has clinical and research implications. Chapter 16 details the psychologist's assessment of the patient and the patient's environment. Multidisciplinary evaluation is also discussed in Chapter 11 of Part I. Chapter 17 considers problems in the evaluation of pain and disability. This topic is included because of the widespread use of physicians as arbiters of whether or not a claimant is able to perform in the workplace. This type of assessment goes far beyond the medical diagnosis of a painful state and is not well grounded on evidence about the validity of this administrative decision-making process. Indeed, there are reasons to question the morality of the physician's role in disability evaluation as well as the accuracy and reliability of such determinations (3). The final chapter describes multidisciplinary pain assessment using the University of Washington model.

This part of our text contains essential information about the conduct of a clinical evaluation of the patient who presents with chronic pain. This material should be mastered by anyone who is going to evaluate chronic pain patients. Even when dealing with acute pain, such as that after burns, trauma, or surgery, the assessment methods described in this part of the text will be of great value to the clinician.

Section A. Neuropathic Pains - Introduction

John D. Loeser

The 27 chapters in Part III contain comprehensive yet concise discussions of acutely painful conditions and chronic pain syndromes that can occur in different regions of the body. We provide this information here to avoid discussion of these pain syndromes in every region of the body in which they can occur. We hope that this minimizes the discussions of etiology, mechanisms, pathophysiology, symptoms and signs, and therapy for these syndromes in every body region included in Part IV. Chapter 19, Chapter 20, Chapter 21, Chapter 22 and Chapter 23 focus on pains of neuropathic origin. They build upon the basic science information presented in Chapter 3, Chapter 4 and Chapter 5. Chapter 24, Chapter 25 and Chapter 26 discuss pain of psychological origin and supplement the information in Chapter 6, Chapter 7, and Chapter 10. These three chapters provide background for the discussions of the various types of pain that are presented in Part IV.

We devote Chapter 27, Chapter 28, Chapter 29, Chapter 30, Chapter 31, Chapter 32 and Chapter 33 to pains of musculoskeletal, vascular, and cutaneous origin, with particular emphasis on arthritis and myofascial pain syndromes, which are common and poorly understood. Chapter 34 addresses pain after spinal cord injury, a particularly difficult aspect of pain management. The organization of this part generally follows that of group I in the *IASP Taxonomy*.

Chapter 35, Chapter 36, Chapter 37, Chapter 38, Chapter 39 and Chapter 40 address pain related to cancer and acquired immunodeficiency syndrome and the treatments that patients receive in the attempt to eradicate their diseases. We believe that it is necessary to expand the coverage of these topics in this edition. These chapters include a discussion of palliative care, which is becoming an ever-important issue as the population ages. Better treatments for heretofore rapidly lethal diseases have prolonged the lives of those who are likely to suffer from painful afflictions. Chapter 41, Chapter 42 and Chapter 43 consider the acute pain syndromes that follow surgery, burns, and trauma. These, of course, are often the focus of anesthesiologists, but other health care providers need to understand the issues and management principles.

Chapter 44 and Chapter 45 focus on pain in children and pain in the aged. These topics are also relatively new in the pain movement and deserve special attention because of the unique issues related to age and problems associated with the ability to communicate verbally.

Part III contains diagnostic and therapeutic information about specific generalized pain syndromes. More detailed information about treatment technologies for generalized and regional pain syndromes appears in Part V. The reader should consult that portion of the book to learn more about the treatment strategies and their risks, benefits, and outcomes. Although it is convenient to discuss generalized pain syndromes with regard to the organs or tissues that are involved in disease processes, one must remember that the patient is the focal point in the delivery of health care. We address disease processes for ease of presentation; those who treat patients with pain must address all of the issues that interfere with normal health and well-being.

Section B. Psychological Contributions to Pain - Introduction

C. Richard Chapman

Every experienced clinician knows that psychological factors play a central role in chronic pain problems. This is hardly surprising, because pain is a psychological phenomenon: It depends on consciousness, it is a somatic perception with emotional as well as sensory features, and it exists solely in the personal reality of the sufferer. We know of another's pain only when the person in pain speaks of it or emits behaviors consistent with injury or personal discomfort. Moreover, the effect of chronic pain on the patient manifests as a cascade of psychological problems. Pain prevents adequate restorative sleep, causes fatigue, impairs attention to and concentration on the events and demands of daily life, and fosters inactivity. Poor sleep and inactivity, in turn, contribute to a general myalgia and malaise, somatic preoccupation, and negative affect. Most people experiencing chronic pain have difficulty meeting the physical, emotional, and cognitive demands of daily life, and many become partly or wholly disabled. Months or years of chronic pain force habit patterns and adjustments in lifestyle and self-image that lead the person to redefine him- or herself.

Pain management would be straightforward if most chronic pain cases had identifiable and treatable causes. However, many chronic pains by definition defy conventional explanation. More important, even when a patient presents with a detectable and treatable cause, the physician cannot assume that the patient is *self-righting*. Removing the cause of the pain does not necessarily result in the patient's recovery and return to productive living. The secondary myalgia, poor sleep, fatigue, discouragement, and social problems, may remain as a self-perpetuating cycle of misery and disability long after the original injury has healed or responded physiologically to treatment. The real challenge in many chronic pain cases, therefore, is not simply pain relief, but rather rehabilitation. This generally requires a fully integrated team approach that combines psychology and rehabilitation medicine.

The complicating influence of psychological factors sometimes extends beyond the evaluation and rehabilitation of otherwise normal patients with chronic pain. Some patients who develop chronic pain have preexisting psychiatric conditions that greatly befuddle evaluation and impair rehabilitation. Sometimes, these conditions contribute to abnormal illness behavior and excessive health care use. Other patients are predisposed to specific psychiatric problems, such as depression, and these problems manifest only because of the constellation of personal and social stressors that chronic pain creates. Patients with coexisting medical and psychiatric conditions need parallel intervention and treatment for such conditions if rehabilitation for chronic pain is to succeed.

The chapters in this section provide a knowledge base for understanding some of the fundamental psychological factors that determine the experience of pain and that influence and perpetuate chronic pain. The concepts in this section provide the conceptual foundation for the psychological interventions that appear in Part V, Section C. These chapters show that antiquated distinctions between mind and body are of little help in explaining chronic pain, and they offer contemporary explanatory frameworks. The reader seeking further information on the role of psychological factors in pain should consult Chapter 6 and Chapter 81.

Chapter 24 addresses the central mechanisms of the negative emotion that accompanies nociception. Drawing support from brain imaging studies of persons experiencing pain, they show that negative affect and somatic hypervigilance are an intrinsic part of pain. Moreover, during emotional arousal, the brain alters bodily states via autonomic mechanisms, and these in turn influence somatic perception and sense of well-being.

Chapter 25 offers a learning theory explanation for the development of chronicity in patients with pain. Although one would normally consider pain a subjective and private experience, it is equally plausible to consider it a set of behaviors. It is through behavior, after all, that one person perceives that another is experiencing pain. Viewing pain as a behavior opens a powerful explanatory framework and an avenue for intervention. Behavioral patterns, including sick-role behaviors and expressions of distress, develop as a function of contingencies (rewards for specific actions) in the individual's environment, and such patterns change in response to changes in those contingencies. Some chronic pain behavior, therefore, may be learned. Learned pain behaviors stem from environmental contingencies rather than perseverating nociception.

Chapter 26 provides a review of psychiatric disorders that may complicate the evaluation of a chronic pain patient, accentuate abnormal illness behavior, or confound efforts to rehabilitate the patient. The review follows *Diagnostic and Statistical Manual*, Fourth Edition, criteria, discussing psychiatric disorders that appear most commonly in pain clinics. The chapter illustrates how one might view these disorders and their effect on pain and sick-role behavior from different perspectives. Several explanatory models exist for these disorders and how they may affect illness behavior. Chapter 26 briefly describes them.

Section C. Vascular, Cutaneous, and Musculoskeletal Pains - Introduction

John D. Loeser

Chapter Reference

This section is devoted to consideration of the disorders of the musculoskeletal system that produce acute or chronic pain. In the United States and most other industrialized nations, disorders of muscles, tendons, fasciae, bones, joints, and ligaments are the most frequent cause of pain, disability, limitation of activity, and impairment. Issues related to impairment and disability are discussed in Chapter 17. The part of the musculoskeletal system most frequently affected is the back or spine, followed by the lower extremities and hips and then upper extremities and shoulders.

In Chapter 8 it was emphasized that pain caused by disorders of deep somatic structures that make up the musculoskeletal system are associated with localized and referred pain, together with skeletal muscle spasm and tenderness, either locally if the structure is superficial or in the region of the referred pain if the lesion involves deep structures. The tenderness is usually not severe, and, like the pain, is not evenly distributed; one or more areas of maximal tenderness are found over the structures normally more sensitive to pressure. These tender spots in the area of reference should not be confused with the deep tender areas or trigger points that are found in myofascial pain syndromes. Referred tender spots usually correspond to the points of maximal spontaneous pain, whereas trigger points are also located outside the distribution of the pain. Not infrequently, there are also autonomic disturbances, the type depending on the causative lesion.

The chapters in this section are presented in order of clinical importance (incidence, prevalence, and difficulty in diagnosis and treatment) of the disorders. The arthritides are considered first because they afflict approximately 15% of the American population and cause sufficient pain, suffering, and disability to prompt over 25 million Americans to seek medical attention each year.[1] The next chapters are devoted to myofascial pain syndromes, which, although not recognized by many physicians, are a common cause of pain and disability among the general population. Fibromyalgia is, of course an enigmatic musculoskeletal disorder that affects women primarily and often leads to profound disability. The chapter on trauma includes discussion of major and minor trauma and a special discussion of athletic injuries. The next two chapters discuss dermatologic and vascular pain syndromes that are often difficult for the pain physician to diagnose and treat. The final chapter on pain after spinal cord injury is a new addition to this text, as it was not covered in detail in the prior editions. We have tried to include some data on prevalence for each of these conditions, but epidemiologic studies are often scarce.

CHAPTER REFERENCE

Section D. Pain in Malignant Diseases - Introduction

John D. Loeser

We have greatly expanded the discussion of cancer pain in this edition to reflect the dramatic increase in knowledge and concern about the optimal management of patients with pain due to cancer. All of the material in this section is completely new; it is one of the few sections of our text that has virtually no carryover from prior editions.

Chapter 35 and Chapter 36 address general issues in the diagnosis and treatment of cancer pain. Chapter 37 presents information on the use of radiation and chemotherapy for the treatment of pain associated with cancer. Oral mucositis, a common problem in patients receiving bone marrow transplants and in those receiving orofacial radiation therapy, is discussed in Chapter 38.

Pain in acquired immunodeficiency syndrome is the subject of Chapter 39; this protean disease is usually characterized by multiple sites and causes of acute and chronic pain. Finally, palliative care, a new specialty of medical practice that includes much pain management, concludes this section.

Section E. Acute Pains - Introduction

John D. Loeser

Chapter 41, Chapter 42 and Chapter 43 present information on the management of postoperative pain, burn pain, and posttrauma pain as developed at the University of Washington. The mechanisms underlying these acute pain states are probably similar, but the strategies utilized by pain management physicians must be designed for the specific situation. The treatment of postoperative pain begins with the preanesthetic visit and the surgeon's operative and postoperative intentions. Burn and trauma pain do not permit individualized preplanning, but must be dealt with as the patient presents to the treatment facility and during his or her hospitalization and recovery periods. The standards published by the Joint Commission on Accreditation of Healthcare Organizations in 1999 will force American hospitals to focus more on the adequacy of their acute pain management. Bonica would have been thrilled with this development in the war on pain.

Chapter 44 (Pain and Its Management in Children) and Chapter 45 (Aging and Pain) address the special diagnostic and therapeutic needs of people at the beginning and end of life. These chapters include both acute and chronic pain management issues. Unique technical and ethical issues need to be considered when dealing with these groups of patients.

Part IV Regional Pains - Introduction

John D. Loeser and Donna Kalauokalani

Part IV consists of six sections, each of which is devoted to a region of the body. There is also a discussion of epidemiology, included in this introductory section. Each regional section commences with a chapter that provides an overview of the anatomy and physiology, with particular emphasis on the nerve supply of that region. A comprehensive table summarizing the etiology and differential diagnosis of regional pains concludes the first chapter in each section and precedes the individual chapters on painful conditions involving different organ systems in that region. Such a tabular listing of diseases and differential diagnoses was a feature of the first edition of this book and proved to be a valuable feature; we have therefore continued it. The reader can use the table to make a tentative diagnosis based on key features of the pain syndrome and then move to the relevant chapter in each section. The arbitrary system of classifying pain syndromes by region and systems was also a feature of the first edition of this book and proved to be one of Bonica's major contributions to the diagnosis and management of pain. The International Association for the Study of Pain Subcommittee on Taxonomy adopted this scheme in the development of its taxonomy of pain as axes 1 and 2. We continue to use this strategy of classification because it seems to be of heuristic value and to be consistent with the International Association for the Study of Pain taxonomy (see Chapter 2).

Many chapters in Part IV present painful disorders not discussed in Part III, whereas other chapters overlap the discussions of generalized diseases covered in that part. We intend to minimize the redundant material; consequently, the reader should refer to the relevant chapter in Part III to obtain complete information on a regional pain syndrome that could also occur in another part of the body. For example, herpes zoster can occur in the lower extremity and sacral dermatomes, but it is only mentioned in Chapter 77; the reader should consult the discussion of the disease in Chapter 22, in Part III. Similarly, treatment methods may appear in the chapters in Part IV, but detailed discussion of the potential risks and benefits of each form of treatment can be found in Part V. For example, tic douloureux is discussed in Chapter 47, but a detailed description of the surgical management of tic appears in Chapter 107.

Although we have divided the human body into six regions for ease of presentation, no one should assume that we believe that this is an appropriate way to provide comprehensive pain management diagnostic or treatment services. All pain symptoms are the product of electrochemical events within the brain, and that organ responds not only to messages from specific sites within the body, but also to past experiences, the present environment, and anticipated consequences. The physician must address the patient as a person and not as a set of symptoms.

EPIDEMIOLOGY AND PAIN MANAGEMENT

Epidemiology is the study of variance in the occurrence of disease and the reasons for that variation. It is a science of structured observation and appraisal of the nature and strength of inferences drawn from those observations (1). This definition incorporates both descriptions of the contents of the discipline and the purpose for which epidemiologic investigations are carried out. Epidemiology focuses on various measures of disease occurrence and risk used to measure the distribution, determinants, and natural history of disease in a population. Application of epidemiologic principles to the judgments and intuitions that comprise the practice of pain management is important to better understand the distribution and natural history of pain conditions, as well as to improve diagnosis, prognosis, and treatment.

Although this section focuses on epidemiologic concepts, many biostatistical concepts and methods are applied in epidemiologic research. Biostatistical methods are used to measure and explain overall variation (some of which is due to errors); distinguish between random versus meaningful and reproducible variation; and facilitate interpretations of data used for diagnosis, prognosis, and treatment. Three important considerations of data collection and analysis are (a) accuracy and precision, (b) random error and bias, and (c) intra- and interobserver and patient variability. These are discussed briefly as they relate to the discussion of epidemiologic concepts.

For the clinician who treats chronic pain, this section discusses basic epidemiologic concepts and measurements, the study of causation in epidemiologic research, an overview of common research designs, assessment of risk and treatment efficacy, biostatistical methods, and policy implications.

Disease States and Events

Typically, disease is regarded as an adverse health state that characterizes an individual over a period of time. Onset of the disease state is an event that occurs at a particular point in time. This is depicted in Figure IV-1. Some conditions are more naturally regarded as events that occur at a certain point in time with negligible duration—for example, fracture of a femur or rupture of the Achilles tendon. States and events may occasionally be defined in terms of each other—that is, the onset of a disease state is an event that occurs at a particular point in time (e.g., onset of shingles marks a bout of acute herpes zoster) or prior occurrence of a certain event may be required for some conditions (e.g., amputation and phantom limb pain).

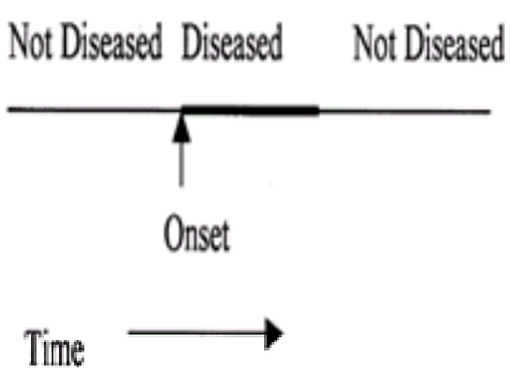

Figure IV-1. Health-related states and events. A disease can be regarded as an adverse health state that characterizes an individual over a certain period of time.

An operational definition is used in deciding whether a given person has the condition. Whether the definition of the condition is simple, complex, or study-specific, the basic approach to quantifying disease frequency remains unchanged. Defining a population requires similar criteria specification for membership. Criteria may involve geographic boundaries, membership in a predefined group, or specification of a time or time interval. In populations monitored over time, it is important to know whether membership in a population can change. If no changes occur, this is called a “fixed cohort.” If membership changes during the observation period, this is called a “dynamic population.” Epidemiologic research on chronic pain aims to investigate pain in populations as a dynamic process characterized by interactions

between the patient, causative agents, and the environment. Von Korff (2) has described a dynamic population model such that, at any given point in time, persons may be pain free or experiencing acute, recurrent, or persistent pains, with or without dysfunction.

Epidemiologic Measures: Frequency and Severity

Frequency

Characteristics of a pain condition to consider in determining its importance are frequency and severity. The frequency of a pain condition is usually measured by its incidence rate and prevalence. *Prevalence* refers to the proportion of a population with a condition at a given point in time. Prevalent cases are persons who have the condition at a specified point in time. Prevalence is a proportion that has no units; people in the numerator are also in the denominator. Hence, the proportion accounts for population size, permitting valid comparisons among populations of different sizes.

The “point in time” used for determining prevalence may refer to any of several scales. For example, one could refer to calendar time to determine the prevalence of low back pain in Seattle on July 1, 1998. This is known as “point prevalence.” Alternatively, age is often used as a time scale, for example, to determine the prevalence of postherpetic neuralgia among 65-year-olds, regardless of when they achieved age 65 in calendar time. Another method is to use the time since an event occurred, for example, to determine prevalence of phantom limb pain among amputees 6 months after amputation. The proportion of persons affected by the condition during a defined period of time is sometimes referred to as “period prevalence,” or if the period of interest is a lifetime, “lifetime prevalence.”

Incidence is the measure of the frequency at which new cases of a disease are occurring in a population over time (3). For different pain states, it is the *onset* of that state whose frequency is measured over time. Incidence is expressed as the ratio of the number of new cases of a condition during the given time period and the population at risk for developing the target condition during the given time period. Thus, it represents the probability, or rate of onset, of a condition among people with no prior history. The denominator does not refer to any specific high-risk group, but includes all members of the population of interest whose probability of becoming a new case is greater than zero. For example, if one is studying the annual incidence of neuropathy among U.S. adults with diabetes mellitus, then the population at risk for developing the target condition is all adult diabetics residing in the United States with the exception of those who already have diabetic neuropathy before the beginning of the study time period.

Severity

Severity is expressed by a variety of measures that are used to estimate severity of the condition and the impact of pain management interventions. Traditional measures of severity include mortality, morbidity, and survival. More recently, outcome measures have been developed that incorporate quality-of-life domains that attempt to capture functional status and preference (4,5). Such measures are important to determine the significance of pain conditions and the impact of interventions. When these measures are combined with an understanding of the prevalence in a defined population, one can quantify the burden of the condition of interest in the population—for example, to help determine the level of health care resources required to meet current needs of people with the condition (6).

Natural History of Disease: Expressing Prognosis

Another objective of epidemiology is to define the natural history of a disease in quantitative terms. Natural history quantifies different aspects of clinical course, such as the interval between exposure to a risk factor and onset of the condition, episode duration, the likelihood of recovery or relapse, the likelihood of death (mortality rates and survival rates), and the likelihood of becoming disabled.

Patients seen in tertiary pain centers represent a small proportion of patients in the general population who experience pain. Therefore, inferences generated about this select group may help in identifying the specific factors or characteristics that place them at high risk and in modifying those factors. In contrast, study of individuals with pain both in and outside of the treatment setting would allow for investigation into the etiology, natural history, and risk factors for pain as distinct from factors associated with seeking treatment.

As new modes of intervention are developed, we can compare results of using such new modalities to the baseline data to see whether the new approaches are truly effective. The new measures of intervention subjected to evaluation may be preventive measures, therapeutic measures, or new modes of health care delivery. Conditions with higher frequencies in specific populations, conditions of greater severity, or those with high cost to society may merit greater attention in terms of preventive efforts, resources, and research (7).

Study of Causation in Epidemiologic Research

Epidemiologic research often seeks to identify causes of disease in the environment, nutrition, lifestyle, or genes of individuals and populations. When such causes are removed or modified, a reduction in disease burden follows. Three fundamental types of causations in order of decreasing causal strength include a sufficient cause, a necessary cause, and a risk factor. A sufficient cause precedes a disease, and if present, the disease will occur. A necessary cause also precedes a disease, and if absent, the disease will not occur. A risk factor is a characteristic that, if present, increases the probability of a particular disease in a group of persons who have the factor compared with an otherwise similar group who do not. A risk factor is neither a sufficient nor a necessary cause of the disease.

Three types of associations between a possible cause (risk factor) and an effect (disease) include a directly causal association, an indirectly causal association, and a noncausal association. If an association is causal, the pathway may be direct or indirect depending on whether there are intermediary factors between the cause and effect. In contrast, the association between a factor and a condition may be statistically strong and yet not be causal. Research to determine causation is complicated, particularly because of the need to rely on observational methods that usually do not have experimental control. Consequently, among the most common challenges encountered in causal research is to deduce differential and nondifferential (random) errors.

Several possible sources of error may obscure true causal relationships. *Bias* is an introduction of error in the measurement or interpretation of data that systematically favors one result. *Random error* produces findings that are too high and too low in approximately equal amounts, owing to random factors. Random error can, but usually does not, introduce bias into the results of an analysis. *Confounding* is confusion of two supposedly causal variables so that part or all of the purported effect of one variable is actually due to the other. *Effect modification* occurs when the strength or direction of the influence of a causal factor on outcome is altered by a third variable, the effect modifier.

Although it is important to appreciate the types of challenges described above, it is also necessary to understand two other concepts related to causation. First, one causal factor may increase the risk for several diseases. For example, diabetes mellitus may be a risk for several pain conditions, including carpal tunnel syndrome and peripheral neuropathy. Second, one disease may have several different risk factors. Although diabetes is a risk factor for carpal tunnel syndrome, it is only one of several contributing factors. Other factors may include occupation and recreational activities that involve repetitive movements. Assessing the relative amount that each factor contributes to a disease, also known as *attributable risk*, is discussed below. Identifying causal factors for diseases and reducing or eliminating exposure to those factors can serve as a basis for prevention programs. Two important epidemiologic study designs used to define factors that are associated with pain conditions are the case control and cohort study designs.

Common Research Designs Used in Epidemiology

Case Control Study

In clinical settings, we often observe patterns across patients and hypothesize about the relationship between exposures or characteristics and the development of a particular condition (Fig. IV-2). In a case control design, both cases and controls are chosen based on a condition or disease rather than on exposures or risk factors. A clinician doing independent medical examinations for patients presenting with upper extremity disorders observes a number of patients with carpal tunnel syndrome. He or she also notes that virtually all patients seen with carpal tunnel syndrome are obese and suggests that there is an association between obesity and the development of carpal tunnel syndrome. Although such observations are interesting, they are difficult to interpret without a comparison group of patients without carpal tunnel syndrome. It is possible, for example, that those patients with and without carpal tunnel syndrome have the same rate of obesity. The question, therefore, is whether the prevalence of obesity is greater in persons with carpal tunnel syndrome (cases) than in persons without carpal tunnel syndrome (controls). To determine the significance of such observation in a group of cases, a comparison or control group is needed. Without such a comparison, these clinical observations would only constitute a case series without a possible conclusion based on comparative observations. The case control study design exemplifies the

comparison component of epidemiologic investigation. It is particularly useful when disease occurrence is rare and generally requires a small study group. This feature makes these studies relatively inexpensive to carry out. This design is often a first step in identifying an association between exposure and a disease or condition. If, in the example above, the apparent association is true, one still cannot be certain whether carpal tunnel syndrome predisposes to obesity, or vice versa, because the temporal sequence of exposure and outcome in a case control study is uncertain. To reach further conclusions regarding the association would require further study. Schlesselman (8) provides an in-depth discussion of this study design.

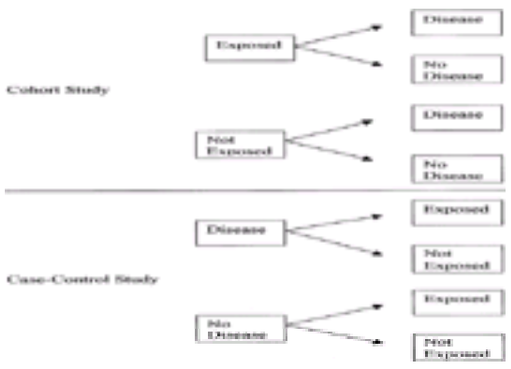

Figure IV-2. Design of cohort and case control studies.

Cohort Study

A cohort study forms groups based on exposure status at the beginning of the study period. Relative sizes of exposed and nonexposed groups may not necessarily reflect true prevalence of exposure in the source population. In contrast to randomized trials, there is no random assignment of subjects to exposure groups, only classification of exposure status. This design allows direct measurement of disease incidence in both groups, permitting comparison in terms of ratios or differences. Thus, cohort studies allow for determining both absolute and relative measures of risk.

The cohort design is most desirable when the exposure of interest is rare. On the other hand, it is impractical for studying rare diseases. Prospective cohort studies have the advantage of demonstrating a better temporal relationship between exposure and outcome and have less potential for recall bias. Among the limitations of the cohort design, however, is that they generally require large sample sizes and therefore tend to be expensive to carry out. Retrospective cohort studies depend on data from the past, often require less time, and are generally less expensive. Among disadvantages for the retrospective cohort design are that the temporal relationship between exposure and disease is often more difficult to establish and enhanced susceptibility to bias both in assessing exposure and outcome (9).

Nested Case Control Study

The nested case control design is a hybrid design in which a case control study is nested in a cohort study. By combining elements of both designs, it offers a number of advantages. Recall bias is eliminated because exposure data are obtained before the disease develops. Exposure data are likely to represent the preillness state, with little assessment bias. Finally, costs are reduced, because data acquisition is needed only for the subjects later chosen as cases or controls (10).

Cross-Sectional Studies

Cross-sectional studies are characterized by the simultaneous collection of exposure and disease outcome data. Comparison is made between the prevalence of the disease in exposed subjects and nonexposed subjects or between the prevalence of exposed subjects with disease and exposed subjects without disease. This design is limited in its ability to determine the temporal relationship between exposure and disease. Although there is limited ability to derive causal inferences, it can provide direction for further research by using one of the aforementioned designs.

Assessment of Disease Risk

Measures of risk compare differences of incidence or prevalence among people differing in a risk factor. Risk factors for developing, enhancing, or detecting a pain condition may be distinct from one another, yet differentiation between these various types of risk factors may be difficult.

Characteristics to consider in determining the importance of a risk factor are its frequency and *magnitude of risk*. A person is at risk for a condition if it is possible for him or her to develop it during a time period of interest. Reasons for a person not being at risk for a condition include the circumstance in which the person already has the condition, was never biologically capable of developing the disease, or has acquired immunity. Analogous to its use for conditions, the frequency of a risk factor or “exposure” is measured by prevalence and incidence.

Distinguishing between those who have a risk factor being studied from those who do not and between those who have a disease from those who do not is seldom simple and is subject to both random error and biases. In addition, the need to analyze several independent variables at the same time (including how they interact) and the need to measure different degrees of strength of exposure, duration of exposure, or both can complicate understanding. Depending on the risk factor, it may be difficult to determine the time of onset of exposure to it. Another problem is the need to measure different levels of disease severity. Despite the complexities, much epidemiologic research relies on the fundamental dichotomies that are commonly presented in the form of the 2 × 2 table, as shown in Table IV-1.

		Disease status		
		Present	Absent	Total
Risk Factor	Present	a	b	a + b
	Absent	c	d	c + d
Status	Total	a + c	b + d	a + b + c + d

Interpretation of the cells:
a, subjects with both the risk factor and the disease; b, subjects with the risk factor but not the disease; c, subjects with the disease but not the risk factor; d, subjects with neither the risk factor nor the disease; a + b, all subjects with the risk factor; c + d, all subjects without the risk factor; a + c, all subjects with the disease; b + d, all subjects without the disease; a + b + c + d, all study subjects.

TABLE IV-1. Standard 2 × 2 table for demonstrating the association between a risk factor and a disease

The magnitude of risk associated with a factor is defined in absolute terms or in relative terms. The method used will depend on the type of the study performed. Whenever possible, it is important to examine both the absolute and relative risks because they provide different information. Absolute risk is the rate of occurrence of the condition in a particular group. Relative and attributable risks are two measures of the association between exposure to a particular factor and a particular outcome. A risk factor can predict the outcome but it may not necessarily “cause” the condition or predict benefit from an intervention.

Relative risk is the incidence of disease among persons with the risk factor compared to the incidence among those without the risk factor. A relative risk of 5 suggests that persons with the risk factor are five times as likely to develop the condition as persons without the risk factor. Relative risk does not measure the

probability that any given person with the risk factor will develop the condition.

Absolute difference in risk is the difference between the risk in the exposed group and the risk in the unexposed group. Also known as the *attributable risk*, it is expressed as AR = [*a*/(*a* + *b*)] – [*c*/(*c* + *d*)] (see Table IV-1 for definitions of *a, b, c,* and *d*). *Relative risk* is the ratio of the risk in the exposed group to the risk in the unexposed group: RR = [*a*/(*a* + *b*)] / [*c*/(*c* + *d*)]. A large relative risk that applies to a small segment of the population may actually produce few cases of disease, whereas a small relative risk that applies to a large segment of the population may produce many cases of disease. The odds ratio (OR) is the odds of exposure in the diseased group divided by the odds of exposure in the nondiseased group: OR = (*a/c*)/(*b/d*) = *ad/bc.* When the disease or condition is rare (i.e., *a* and *c* are small relative to *b* and *d*), the odds ratio is a good estimate of the risk ratio.

Assessing Efficacy of Treatment Measures

The rational evaluation of clinical pattern recognition (symptoms, signs, laboratory tests) demands critical appraisal of how this clinical finding has behaved previously among groups of patients with the same conditions. Similarly, the rational selection of a treatment for each patient requires appraisal of how similar patients have fared with various treatments in the past. If, on average, patients experienced better clinical outcomes and fewer side effects while on one treatment compared with untreated (or differently treated) patients, we will likely prescribe that regimen (other variables and costs being equal).

When exposure cannot be assigned at random, observational studies are relied on or performed. However, randomized studies are superior to observational studies because this experimental form reduces the probability that the results obtained were due to random errors. It does not, however, necessarily prevent systematic errors or bias. Commitment to randomized trials as the standard of proof should be especially strong when the public health implications are great. Clinical trials are discussed in Chapter 82.

Data Collection and Analysis Considerations

As alluded to earlier, biostatistical methods are used to compensate for unavoidable errors in clinical data. Two distinct but related goals of data collection and analysis are to promote both accuracy and precision. *Accuracy* refers to the ability to obtain the correct measure on average, whereas *precision* refers to the ability to provide the same or very similar results with repeated measurements (10). This is also referred to as *reproducibility* or *reliability*. A high degree of precision is not proof of accuracy.

The study of accuracy is important in deciding the usefulness of a medical test as applied to a particular population. Important measures of test function are sensitivity, specificity, and predictive value. Although the definitions of these measures are straightforward, several factors influence whether a test result for a particular patient is accurate and whether the test in general is useful for a particular population. Two such factors are (a) stage of the condition or disease and (b) spectrum of disease or condition in the study population.

Sensitivity refers to the ability of a test to detect a condition when it is present. It is expressed as the proportion of persons with a condition who correctly test positive when screened: *a/a+c*. A test with poor sensitivity will miss many cases and therefore produce a large proportion of false-negative results. *Specificity* refers to the proportion of persons without the condition that correctly test negative when screened: *d/b+d*. A test with poor specificity incorrectly labels persons as having the condition. The incorrect labeling of true negative results produces false-negative cases. False-positive results can produce a whole series of untoward consequences, including psychological problems and a cascade of further tests and procedures.

Predictive values follow a different direction of analysis to answer perhaps a more clinically relevant question—that is, if the patient's test result is positive, what is the probability that the patient has the disease being tested? Positive predictive value indicates what proportion of the subjects who have positive test results have the disease or condition: *a/a+b*. Negative predictive value indicates what proportion of the subjects who have negative test results do not have the condition: *d/c+d*. Both the prevalence of the condition and the specificity of the test affect the predictive value (3).

Measuring Pain: Intervariations and Intravariations

With pain conditions, we are making observations based on a construct (see Chapter 2). There is, as yet, no laboratory test or imaging study that affirms or refutes the patient's report of pain on quantifiable terms (11). Thus, we are bound not only to measure the variation of symptoms *within* individuals—for example, how individuals' bodies may respond differently—but also the variation in patient report *between* individuals—for example, qualitative variation in how patients express their experiences. Issues dealing with the measurement of pain and specific methods used to measure this are discussed in detail in Chapter 15.

It is also important to determine the extent of observer agreement of the same phenomenon. If there is high intraobserver agreement, high interobserver agreement, or both, the data in a study are considered highly reliable and will elicit more confidence.

Evaluation and Policy

Finally, epidemiology can provide the foundation for developing public policy and regulatory decisions relating to environmental problems. For example, which occupations are associated with increased risk of injury and disability in workers? What types of regulations are required? Understanding the burden of disease in the community is crucial for planning health services and facilities and to training future health care providers.

Epidemiologists are concerned with human ecology and, in particular, the impact that health interventions have on disease patterns and on the environment. An ecological perspective suggests that changing only one element in an ecosystem is virtually impossible and that interventions send out ripples of a secondary effect. This is consistent with the biopsychosocial model for pain that is the cornerstone of this text.

By viewing disease patterns ecologically, the interaction between and among diseases may be appreciated (12). Synergy occurs when the impact of two or more diseases on an individual or population is greater than the sum of the separate effects of each individual disease. Just as malnutrition and infection often occur in the same populations and each exacerbates the other, such synergy is observed for chronic pain states and depression (13).

Even with good evidence that an intervention is *efficacious* under *ideal* or controlled conditions, it may be less *effective* in a *routine* practice setting. Potential benefits of an intervention must be weighed against potential harms, costs, and implementation considerations.

CONCLUSIONS

Epidemiologic concepts can be applied to increase understanding of pain conditions. An epidemiologic approach increases understanding through addressing a set of questions. First, what are the extent and magnitude of the problem? Does a certain group of individuals suffer more or less from a given condition compared to other groups? Does variation in sickle cell disease risk among black Americans belonging to different geographic and cultural groups exist? Are these diseases or conditions occurring more or less frequently in recent times compared with the past? Second, what is known about the etiology and pathogenesis of these conditions and are risk factors unique to certain populations? What are relative contributions of environment and genetic risk factors in accounting for the observed frequency and distribution of these diseases? Finally, what prevention and control strategies are available for these diseases and conditions, and has their effectiveness been evaluated? To what extent are described interventions applicable to different populations? In many chronic pain syndromes, social and ecological influences are of particular importance and thus appear to call for an integration of the social sciences (e.g., anthropology, sociology) and epidemiology for future research. The chapters in Part IV all contain some references to epidemiologic information. However, the field of pain management is in need of well-constructed, systematic epidemiologic studies.

Low Back Pain - Introduction

With Introduction by John D. Loeser

Chapter Reference

Low back pain is a common complaint in any developed nation. It is a major cause of health care consumption and by far the most common reason for disability in the working years (1,2). Although headache may be more common, the impact of low back pain on a society is far greater. The importance of the back in all human endeavors is often overlooked by health care providers, but Melville certainly understood this region of the body. At the height of the phrenology craze he wrote the following:

> For I believe that much of a man's character will be found betoken in the backbone. I would rather feel your spine than your skull, whoever you are. A thin joist of a spine never yet upheld a full and noble soul. I rejoice in my spine, as in the firm audacious staff of that flag which I fling half out to the world.
>
> *Moby-Dick*

This chapter is divided into five sections, each of which focuses on an aspect of the low back pain problem. In addition, the reader is referred to Chapter 17, in which disability and functional assessment are discussed. Section A, by Bigos and Müller, is aimed at the diagnosis and management of acute low back pain. Wise and Andersson, in Section B, have addressed chronic low back pain. Oaklander and North present the problem of failed back surgery syndrome and its management. Although this is primarily an American problem because of our excessive rate of surgery for low back pain, it is not an unknown phenomenon in other countries. In Section D, Block has addressed the issue of using psychological evaluation to predict surgical outcomes. Finally, in Section E, Erjavec discusses the role of epidural corticosteroids in the treatment of low back pain. Although these are five important general issues, an entire book of the size of this text could be written about all the facets of low back pain. Many books have, in fact, been written on this topic, all too often to promote totally unscientific theories and treatment strategies. There is some reason to believe that many of the treatments advocated for back pain are not only ineffective but also may increase disability and health care consumption.

The incidence, prevalence, and costs of low back pain have been the subjects of numerous reports and research projects (3,4 and 5). In addition to the customary epidemiologic issues surrounding such studies, there are inherent difficulties in the ascertainment of low back pain and its costs. First, pain is not a discrete entity that can be exactly measured. There is no tank into which one can insert a dipstick and determine the volume of contents. Second, the researcher is totally dependent on the patient's complaint or behavior. There is no gold standard to measure low back pain. Third, the validity of the patient's complaint is unprovable. There is enough literature on eyewitnesses to give one cause for concern. A patient is, of course, the epitome of an eyewitness. Fourth, low back pain is certainly a condition with heterogeneous precipitating and perpetuating factors. Finally, the legitimacy of extrapolating from one population to another is often unclear, at least in part due to the various etiologic agents that may play a role in low back pain.

The best data currently available suggest that more than three-fourths of all people will have low back pain at some time in their lives. The annual prevalence has been reported to vary from between 15% and 45%. Of course, the severity of an episode is not ascertained in most of the reported studies, and therefore the significance of low back pain remains unclear. Much depends on what a person is expected to do with his or her back, independent of what messages the back is sending to the brain. Back pain is the most common cause of activity limitation in the working years of 18 to 55 in the United States and in every developed country that has yet been studied. It is responsible for 10% to 15% of all work absences in the developed countries. Similarly, between 2% and 8% of the workforce in a developed country is disabled by back pain annually. A variety of interventions designed as primary prevention for low back pain have not been effective.

Health care consumption for low back pain is enormous. In 1990 in the United States there were 15 million office visits to physicians for low back pain, second only to the common cold as a symptomatic reason for a physician visit. This accounts for 2.8% of all office visits to physicians. The number of visits to chiropractors was probably even greater, but reliable data are not available on this topic (6). Similar or even higher rates of office visits are found in the United Kingdom and Sweden (4). Rates of hospitalization for low back pain have decreased in the United States over 20 years, while the rates for surgery have significantly increased (7,8). Indeed, there are wide regional variations within the United States for the surgical management of low back pain and even greater variations in the rate of surgery in 13 countries contrasted with the United States (9). From this type of data one could conclude that the American back was disintegrating at a rate faster than in any other country, but it seems more likely that the large number of surgeons has something to do with the rate of surgery. In fact, with the exception of Sweden, whose neurosurgeons and orthopedists seem to do half as many cases as in 11 other countries, the number of cases done in a country is 11.1 times the number of eligible surgeons and is not as directly related to the population at risk. Clearly, we do not understand the reasons for wide variations in the use of health care in the diagnosis and treatment of low back pain. This would be a fertile arena for health services research.

The natural history of back pain has been studied in many countries; this certainly is a recurrent symptom for most patients, even though each episode has a rather benign prognosis. Approximately 25% of patients have a recurrence within 1 year and 75% in their lifetime. By 6 weeks, 65% of patients have recovered from an episode of low back pain. By 12 weeks, 85% are without significant symptoms. After 12 weeks, recovery is not likely: Fewer than half of those off work for 26 weeks ever return to work and, after 104 weeks, the likelihood of returning to work is virtually nil. Being a participant in a compensation system delays return to work after an episode of low back pain, whether or not an operation was performed and whether or not the injury was work related. In fact, compensation is best thought of as a comorbidity, as it adversely affects many different outcomes measures (10). It is not known whether the failure to return to work is due to events within the patient's back or is more related to workplace and other social, cultural, and economic factors. Predictors of return to work have been shown to include age, educational level, back pain alone rather than sciatica and low back pain, and a variety of job characteristics. As is true for most chronic illnesses, psychological distress and depression are correlated with symptom persistence. We certainly need further studies on the etiologies for low back pain and their successful treatment. It is unlikely that a single strategy for dealing with all patients with low back pain will be forthcoming, as this is certainly a protean disorder that involves multiple systems both within and without the patient's body.

Section A. General Considerations - Introduction

John D. Loeser

The final part of this text consists of eight sections, each of which has chapters that describe specific therapeutic modalities for the symptomatic control of both acute and chronic pain. We use the word *symptomatic* to emphasize that these treatment strategies are not intended to eliminate the cause of the pain, but rather to reduce the pain, suffering, and pain behaviors without recourse to the underlying disease process. Methods to eliminate the cause of the pain are discussed when appropriate, in the regional pain syndrome chapters in Part IV. We have attempted in this part to present the therapeutic modalities in order of their frequency of usage by all health care professionals and not just specialists. Thus, Sections B and C present noninvasive techniques that physicians apply universally; Sections E, F, and G contain information about more invasive techniques that are not likely to be used by those who do not have specialist training. Section H describes the results of multidisciplinary pain management, which, although certainly not invasive, is a relatively infrequent strategy used in far fewer pain treatment programs than, for example, nerve blocks or surgery.

Section A (Chapter 81 and Chapter 82) contains two new and essential chapters for those who wish to evaluate treatment outcomes and ascertain the roles of nonspecific treatment effects. These chapters appear deliberately at the beginning of this part, and clinicians should start by reading them. The information in these two chapters is basic to an understanding of all types of clinical trials. Those who wish to understand the significance of statements of efficacy for treatments must begin with the methods of assessing outcomes and the ubiquitous nature of nonspecific responses to all forms of treatment.

Section B, Chapter 83, Chapter 84, Chapter 85, Chapter 86 and Chapter 87, discusses the pharmacologic agents commonly used for the management of both acute and chronic pain. We have divided the discussions for convenience into chapters on systemic nonopioid drugs, systemic opioid drugs, psychotropic drugs, anticonvulsant and membrane-stabilizing drugs, and a new chapter on topical drugs. There can be little question that drugs have been, and are likely to continue to be, the mainstay of the treatments of both acute and chronic pain states. New insights into the mechanisms of drug action will likely lead to the introduction of new agents in the immediate future, it is hoped with beneficial results for the patients.

Section C contains Chapter 88, Chapter 89, Chapter 90, Chapter 91, Chapter 92, Chapter 93 and Chapter 94, on psychological and psychosocial techniques in the management of chronic pain. These include contingency management, cognitive-behavioral therapy, biofeedback, hypnosis, relaxation therapy, and psychotherapy. A new chapter on the use of psychological strategies to enhance the patient's motivation to change his or her lifestyle and reduce the disabilities associated with chronic pain and its concomitant behaviors concludes this section.

Section D, Chapter 95, Chapter 96, Chapter 97 and Chapter 98, includes discussions of operative and nonoperative orthopaedic procedures for the management of musculoskeletal pains, physical therapy and rehabilitation medicine, acupuncture, and transcutaneous electrical stimulation. It addresses musculoskeletal pain syndromes and pains of uncertain etiology. Section E, Chapter 99, Chapter 100 and Chapter 101, describes methods of implanted electrical stimulation of nerves, spinal cord, and brain, often called “neuroaugmentative” by their proponents. Section F, which contains Chapter 102, Chapter 103 and Chapter 104, describes anesthesiologic techniques for pain management: regional anesthesia with local anesthetic agents, regional analgesia with opioids, and regional analgesia with neurolytic blocks. Section G consists of Chapter 105, Chapter 106, Chapter 107 and Chapter 108, on ablative neurosurgical procedures, with one chapter devoted to the surgical management of tic douloureux. Section H contains Chapter 109, which discusses multidisciplinary pain treatment programs and their outcomes. The final chapter (Chapter 110) presents some of our beliefs and aspirations about the future of pain research and management.

The short introduction that precedes each section puts the treatment modalities into historical perspective. We have edited the chapters to follow a consistent format, with an introduction that assesses the current status of the therapy, an overview of the contents of the chapter, and selected references. Next is a presentation of the basic considerations that describe the rationale for the treatment methodology based upon scientific information and then a discussion of indications for this type of treatment. After a description of the technique itself, the text discusses the results and complications.

When techniques are simple and suitable for use by all physicians managing pain patients, the text provides sufficient detail to allow the physician to base his or her treatment upon what is written here. The presentation of more specialized treatment strategies such as major nerve blocks or surgery provides only enough detail to allow the generalist physician to understand the principles of a procedure and its risks and benefits. With this information, one can counsel patients and reach appropriate management decisions. Those who wish to perform interventional therapies need more instruction than this book can provide before they treat patients. There is, of course, some overlap with the information in Parts III and IV, but this part is designed to contain a comprehensive overview of all of the currently used treatments for pain. It is also important to recognize that cognitive/behavioral strategies require specialized training for their optimal use.

The editors have obviously selected from the almost infinite varieties of treatment methods for both acute and chronic pain. As pain is ubiquitous, so are its treatments. We have focused upon those treatments that currently are offered by physicians and psychologists as well as those who customarily work in conjunction with these professionals. We have not included discussions of what is commonly labeled as *alternative health care*, such as chiropractic, homeopathy, naturopathy, massage therapy, or healing touch, to name just a few, because we believe that the conceptual basis for such therapies falls outside the canons of modern allopathic medical sciences. Moreover, they are rarely used by those who specialize in comprehensive pain management. The exception to this rule is acupuncture, which we include despite its utterly foreign conceptual basis for those trained in Western medicine. Thanks to former President Richard Nixon, acupuncture has swept across the United States (and elsewhere) and is in widespread use.

Those who are offended by our selection strategies would be wise to consider carefully Chapter 81 and Chapter 82 to understand some of our reason to include and exclude treatment modalities and approaches. We identify a progression in the history of pain management that follows upon the evolution of medical thinking from the reductionism of the nineteenth and early twentieth centuries, through the fusion of mind and body, as seen in psychosomatic medicine, to the current behavioral medicine perspective that links the events within a person's body to the surrounding world. Alternative health care strategies are often anachronistic and recidivist; they impede the evolution of new treatment strategies that incorporate the role of the environment in health and illness. On the other hand, the public attraction to many alternative therapies is a sign of the failure of modern medicine to acknowledge the reality of pain and to treat human beings as whole persons existing within a social framework rather than a collection of biological parts. The challenge for those who wish to espouse “alternative” health care is to develop a meaningful conceptual framework and to demonstrate specificity of treatment effects. The challenge for allopathic physicians is to provide compassionate health care that encompasses not only the search for a structural lesion, but also consideration of the patient as a human being. We believe that this part provides a comprehensive overview of the treatments employed by pain management specialists.

Chapter 110 completes this textbook by reviewing the past and present and looking into the new millennium. It provides a new way of looking at pain management concepts and opens a window into the world of ideas about pain.

Section B. Pharmacologic Therapies - Introduction

John D. Loeser

This section is devoted to the use of drugs in the management of pain. We have covered the systemic administration of nonopioids and opioids in Chapter 83 and Chapter 84, psychotropic drugs in Chapter 85, anticonvulsant and membrane-stabilizing drugs in Chapter 86, and topical medications in Chapter 87. The last chapter is a new addition to this text; this subject was not covered in the second edition of this book.

Opioids, of all drugs, probably have the longest known association with humans, for they were described by the ancient Sumerians more than 5,000 years ago. The juice of *Papaver somniferum* was known to the Greeks and the Romans as well as the pre–Christian era Hebrews. The German pharmacist, Friedrich A. W. Serturner, extracted an alkaloid from opium in 1803 that was soon known as *morphine*. Many other alkaloids have been identified and synthetic molecules constructed to mimic the naturally occurring drugs. The use of opioids has greatly expanded in the past 20 years as knowledge about receptors, endogenous opioids, and molecular biology has exploded (Chapter 84).

Nonsteroidal agents also have a long history: Salicylic acid obtained from willow bark was first recognized in Western literature by Stone in the early nineteenth century. The development of synthetic nonsteroidal agents has been prodigious; they are the most commonly used group of pharmacologic agents (Chapter 83).

Psychotropic medications also have a long history, although not exclusively for medicinal purposes. Today, antidepressant medications are frequently used in the management of chronic pain. A wide assortment of other classes of mind- and mood-altering medications is considered in Chapter 85. Anticonvulsants are also used frequently, as discussed in Chapter 86. These medications were once used exclusively for neuropathic pains with shocklike properties such as tic douloureux, but they have been found to be useful for many other types of pain.

Topical medication is a new aspect of pain management whose ultimate utility is not yet determined. Several classes of drugs have been administered this way and are discussed in Chapter 87. It is highly likely that some of the systemic drugs will be found to have useful properties when administered topically.

Pain management must include not only medications but also psychological and physical treatment strategies. Nonspecific treatment effects, discussed in Chapter 81, certainly are important aspects of the use of drugs and all other therapies. We must not overlook the fact that the giver of the pill, as well as the pill itself, is likely to have an impact on the patient. It is also essential to recognize the role of nurses in the administration of pain medications, especially in a hospital or clinic setting. Nursing education has dramatically improved in the past 2 decades in regard to pain treatment; patients have benefited from this development. Drugs are the most common method used to treat pains of all types. Optimal therapy is often denied our patients because of inadequate knowledge of pharmacology, inordinate fear of side effects, governmental policies, and patient reluctance to use effective therapies.

Section C. Psychological Techniques - Introduction

C. Richard Chapman

Pain is a psychological state. It depends on consciousness, it has perceptual and emotional features, and a person's expression of pain is a behavior that exerts a psychological impact on other persons. Chronic pain has become a socioeconomic problem, largely because it causes disability or limits productive behavior and not just because it requires costly, ongoing invasive treatment. One of the frustrating difficulties that pain specialists face in managing pain, particularly chronic pain, is that knowledge of the sensory neurophysiology of a pathologic pain rarely allows one to predict the impact of the pain on the patient's functional capability and quality of life. Moreover, much of the task of managing chronic pain and related disability is psychological rather than medical. Psychological aspects color every aspect of chronic pain management, from patient assessment to treatment adherence and rehabilitation. Given these considerations, it is surprising that well-established psychological interventions for pain play so small a role in the management of most pain patients. This section of the book is intended as a resource for physicians who need a general introduction to psychological techniques in pain management.

Many physicians in community practice continue to overlook the role of psychological factors in response and adaptation to chronic pain as well as the potential contributions of psychological interventions. There are three primary reasons for this. First, traditional medical education, including most continuing medical education, prepares physicians to practice in a monodisciplinary rather than a multidisciplinary manner. The concept of working jointly with a psychologist to address simultaneously the patient's medical and psychological needs is foreign to most practitioners. This is curious because academic medicine has forged many links between clinical health psychology and medical practice. Many departments of anesthesiology (and indeed many departments) in schools of medicine across the United States include psychologists on their faculties, and it is no accident that two of the editors of this book are psychologists. Because of their methodologic skills, psychologists contribute solidly to evidence-based medicine, and they excel in both rigorous patient assessment and measurement of treatment outcome as well as in the delivery of health care. Experience demonstrates that psychologists are invaluable in the pain field, not because they set up alternatives to medical intervention, but because they can enhance medical intervention in a variety of ways.

Second, the practice of medicine has long regarded psychological issues in patient care as marginal or irrelevant dimensions of patient evaluation and treatment. The implicit assumption persists that dysfunctional or disabled persons are self-righting: Remove the cause of the pain (or otherwise prevent the noxious signaling from reaching the brain), and the patient will recover. This assumption becomes increasingly indefensible as knowledge of neuroplasticity grows. Mounting evidence shows that persistent noxious signaling can permanently alter the nervous system in which it occurs in complex ways. Consequently, in many cases in which pain has become chronic, the patient requires rehabilitation as well as a reversal or minimizing of the pathophysiology that may underlie the pain. In cases in which practice dictates medication prescription, issues of medication adherence and outcome assessment are paramount. Psychologists are well prepared to deal with such issues. The varied psychological aspects of pain management are simply too many and too important to ignore.

Finally, many physicians fail to work with psychologists or use psychological methods simply because they know too little about the field of clinical psychology or have an incorrect image of the field. In American society as a whole, the image of folk psychology overshadows that of professional psychology. Self-help books or tapes and self-proclaimed televised experts hold forth on how to take charge of one's life, how to deal with stress, how to become productive, and even how to free oneself of pain. Physicians and patients alike confuse their offerings with those of professional psychologists. Nonetheless, folk psychology is to professional psychology as folk medicine is to professional medicine. The professional psychologist offers evidence-based assessment and practice, including outcome assessment, and many can provide valuable theoretical frameworks that help clarify knotty problems in medical pain management. The negative image of folk psychology, which trivializes the profession, is often a barrier to appropriate use of psychological services.

The chapters in this section introduce several areas of psychological practice. They present varied psychological approaches to pain control and illustrate the application of several traditions in the field of psychology to the challenge of pain management. Fordyce's chapter (Chapter 88) discusses the application of operant conditioning in the rehabilitation of chronic pain patients, an approach that had a revolutionary impact early in the development multidisciplinary patient care. Turner and Romano (Chapter 89) write from the rapidly evolving perspective of cognitive-behavioral therapy, perhaps the dominant framework in clinical psychology today. They call attention to the importance of patient beliefs and thoughts in the search for pain relief and the response to intervention. They describe how the field has evolved and articulates current thinking about pain in the contemporary behaviorist perspective. In Chapter 90, Arena and Blanchard review and describe biofeedback, a technology-based application of psychological principles that helps patients develop and accept control of their own physiologic responses to stressful events or conditions. In Chapter 91, Barber reviews the field of hypnosis and describes its applications for pain control. Syrjala (Chapter 92) addresses short-term psychological interventions that use relaxation and imagery. Because this area is so easily confused with folk psychology, she provides a strong review of the evidence supporting these approaches as well as a description of what they entail. The chapter by Tunks and Merskey (Chapter 93) discusses the classic application of psychotherapy to the care of the patient in pain. It emphasizes that the pain management physician, by virtue of his or her relationship to the patient, can and should take on the role of supportive psychotherapist. Finally, Jensen (Chapter 94) provides a cutting-edge perspective on motivational dimensions of patient management. Successful management of chronic pain entails changes in patient lifestyle, thinking, and functional capability. Some patients are ready and able to change in response to intervention, but others are not. Jensen outlines an approach by which the physician can help bring the otherwise intransigent chronic pain patient to a point where he or she will be willing and able to accept the importance of self-management in response to rehabilitation. This chapter provides an excellent example of how psychology can help improve the “take” of a medical intervention.

One of the benefits of involving psychologists in pain management is that many key psychological ideas and insights diffuse into the thinking of physicians, making them better able to assess and skillfully manage complicated patients. The fundamental goal of psychology in medicine is not to offer an alternative or complementary service to physicians, but rather to integrate progress in psychology into medical practice. In this, everyone benefits. The use of sound psychological principles in patient care can help most patients in some respect and can facilitate the process of care delivery.

The topics covered in this section are by no means an exhaustive list of the ways that psychology can contribute to pain management. In any setting in which pain requires medical management, psychology has skills to offer. Those skills often extend to bettering patient assessment, care delivery, outcome evaluation, and other key aspects of pain management.

Section D. Physical Therapeutic Modalities - Introduction

John D. Loeser

The four chapters in this section deal with subjects that have been arbitrarily labeled physical modalities. Chapter 95 covers orthopedic nonsurgical and surgical procedures for treating musculoskeletal disorders; one of the primary objectives of these procedures is the relief of pain. It contains concise descriptions of the procedures intended to relieve acute and chronic pain and the anatomic and functional bases of these procedures. It includes a short section on the use of orthopedic operations for patients with cancer-related pain.

Chapter 96 provides an overview of various modalities used in physical medicine and rehabilitation for patients with acute and chronic pain. The physiologic bases, indications, side effects, and contraindications of each of the many types of thermotherapy, cryotherapy, electrotherapy, mechanotherapy, therapeutic exercises, traction, manipulation, immobilization, and laser therapy are discussed and the rationales for their utilization as well as outcomes are presented.

Chapter 97 discusses acupuncture for the management of patients with acute and chronic pain. A comprehensive and fair critical review of the methods, indications, side effects, and complications of classical acupuncture as practiced by traditional practitioners, and modern techniques used in various parts of the world, including electroacupuncture, are presented. The scientific knowledge derived from animal studies, human laboratory studies, and clinical studies is reviewed. The efficacy of acupuncture in the management of patients with acute and chronic pain is discussed.

These chapters cover treatment modalities that often have widespread utilization but unclear data for efficacy with modern outcomes research. They often appear to provide symptomatic relief for patients with pathologic processes that are not clearly understood. There are many similarities between acupuncture and transcutaneous electrical nerve stimulation (covered in Chapter 98); the latter has even been labeled *Western acupuncture*. Vast numbers of patients have received this treatment, the efficacy of which is still debated.

Section E. Implanted Electrical Stimulators - Introduction

John D. Loeser and John J. Bonica

Chapter References

This section consists of three chapters devoted to the use of implanted electrical stimulation for the control of chronic pain. In Chapter 99, Gybels and Nuttin discuss the use of peripheral nerve stimulators. In Chapter 100 and Chapter 101, Meyerson and Linderoth describe the use of spinal cord and brain stimulation. All of these chapters are aimed at the nonneurosurgeon, with the goal of elucidating the potentials for this type of neuroaugmentative surgery. Actual surgical techniques can be found in standard texts or the manufacturers' product descriptions.

The resurgence of the use of electricity to treat pain was provoked by publication of the Melzack-Wall gate theory (1). Indeed, the first modern application of this modality, reported by Wall and Sweet (2) in 1967, provided support for the Melzack-Wall gate theory, which emphasized the important role of the dorsal horn of the spinal cord in modulating sensory transmission. The subsequent discovery and eventual detailed description of the anatomic, physiologic, and pharmacologic aspects of the periaqueductal gray and other brainstem sites and the descending inhibitory systems led to the use of deep-brain stimulation.

Although these implantation techniques have been considered an important recent advance in pain therapy, the practice of applying electricity to relieve pain is as old as recorded history (3,4 and 5). Egyptian tombs of the Fifth Dynasty (2750 b.c.) displayed the Nile (electrical) catfish (*Malopterurus electricus*), and the ancient Greeks, including Aristotle, described the numbness caused by the torpedo ray (*Torpedo marmorata*). Among the Romans, Pliny in *Natural History* and Plutarch in *Morales* referred to the numbing effect of the ray (6), and Scribonius (circa a.d. 46) advocated electrotherapy specifically for the relief of “chronic and unbearable headache,” gout, and other conditions (7). At the same time Dioscorides, a Greek army surgeon in the service of Nero, also advocated electrotherapy for a variety of painful and nonpainful disorders (8). A century later Galen, after studying live and dead electrical fish, concluded that the latter had no effect. He wrote the following about application of a live torpedo ray to a patient suffering from headache: “It could be that this remedy is anodyne and could free the patient from pain as do other remedies which numb the senses: This I found to be so” (9). These and other Roman physicians indicated that in order to be effective, the torpedo fish should be placed on the spot where the pain was felt.

The clinical application of the torpedo fish as a therapeutic modality for pain and other conditions continued throughout the Middle Ages, the Renaissance, and well into the nineteenth century. In non-Western cultures, electrical fish are still used for this purpose (6). During the eighteenth century, many improvements were made in an electrostatic apparatus constructed earlier by Von Guericke, including the development of the Leyden jar (5). Consequently, electrotherapy was applied even more widely despite the skepticism and opposition of a number of authorities.

During the nineteenth century, development of the electrical “pile” and the subsequent development of the induction apparatus provided further impetus for electromedical application (10). Voltaic (galvanic) and faradic currents were stronger and/or more easily modulated than was static electricity, and increased efforts were made to use electricity as a surgical anesthetic especially for tooth extraction and other dental therapies (5). In the years just before and after 1860, numerous reports were published on the use of electrical anesthesia for dental surgery and subsequently for surgery on the limbs. In the United States, the most widely known exponents were Francis (11) of Philadelphia, Garratt (12) of Boston, and Oliver (13) of Buffalo. These three individuals became involved in a bitter controversy as to who was the first “discoverer” of electrical anesthesia. Interestingly, this controversy occurred at about the same time as the intense controversy with regard to the discoverer of general anesthesia by demonstrating the anesthetic properties of ether and nitrous oxide.

In England, Althaus (14), a prominent electrotherapist, was the first to adopt and use the new electroanesthesia. In 1859, he applied “interrupted current” transcutaneously to peripheral nerves and eventually convinced his most prominent critic, Benjamin Richardson (who was a friend of John Snow, the patriarch of anesthesiology and epidemiology), of its efficacy to diminish sensation and produce analgesia by stepwise increase of the electrical stimulus to Dr. Richardson's ulnar nerve. Althaus applied these techniques for the relief of neuralgia and found that analgesia was more effective and more readily attained in pathologic conditions than in normal situations (14). Unfortunately, the controversy continued and prompted the appointment of a commission headed by Richardson. After studying the efficacy of electrical anesthesia in patients undergoing tooth extraction, the commission concluded that the technique produced no local anesthetic effect (15).

The use of electroanesthesia in dentistry was introduced to France in 1858, and subsequently reports also were published in Germany and Italy (3). The results obtained in these countries were variable, and toward the end of the century, this modality was virtually abandoned for surgical anesthesia, although a number of workers continued to use it for the treatment of neuralgia and other pain syndromes.

During the first six decades of this century, a number of clinicians attempted to resurrect electroanesthesia for surgical operations, but because it was much less predictable than pharmacologic anesthesia, it never became widely used. Electroanalgesia is considered a curiosity today and is not in general clinical use in the developed countries.

In 1928, Thompson et al. (16) from the University of California at Berkeley noted that “the cutaneous areas supplied by a nerve may be rendered insensible to light touch by subjecting the nerve trunk to the influence of an alternating current.” Increasing the current produced analgesia. With this technique they determined the distribution of all the cutaneous nerves in the forearm of one individual (16). Fourteen years later Paraf (17), using the same technique, reported the successful treatment of 127 patients with sciatic pain, lumbago, postherpetic neuralgia, and tic douloureux.

In 1953 Guenot (18) wrote a thesis on local electrical analgesia in which he described the work of Perrin, Bernard, LeGo, Presle, Wild, and Probst, all of whom used local and regional electroanesthesia. Probst (19) experimented with 50- to 100-Hz monophasic and diphasic waves, which caused initial excitation and paresthesia but soon caused “inhibition” and raised the sensory threshold to the current. Whether or not the effects of intense stimulation leading to nerve impulse blockade are related to the pain relief obtained with modern implanted stimulators that do not produce analgesia remains unclear.

During the 1950s and early 1960s, reports on the use of electrical stimulation of the spinothalamic tract, the thalamus, and other parts of the brainstem for the relief of pain, with varying degrees of success, were published by Mazars et al. (20) and others (see 4 for references). The most recent development is stimulation of the motor cortex for the relief of neuropathic pains. This is not yet an approved treatment in the United States, and clinical experience is limited to a few centers.

The development of safe, compact electrical generating systems and the fabrication of electrodes and lead wires using new, inert materials allowed the application of electricity to deep structures and not just the skin or mucous membranes. For these reasons, electrical therapies entered a new era in the later half of the twentieth century. The focus of electrical stimulation shifted from acute to chronic pain because of these technologic advances. However, we remain ignorant of the mechanistic relationships between skin stimulation and neural stimulation for pain relief. The ultimate place of implanted stimulators will be determined by properly conducted outcomes trials.

Section F. Regional Anesthesia/Analgesia - Introduction

John D. Loeser

This section addresses regional analgesia and anesthesia in the management of patients with all types of pain, both acute and chronic. Chapter 102 focuses on regional anesthesia with local anesthetics, Chapter 103 discusses regional analgesia with opioids, and Chapter 104 deals with neurolytic blockade. The intended audiences for these chapters are not so much anesthesiologists, who will need far more detailed anatomy and pharmacology to carry out these procedures, but instead other health care providers who need to know the indications for and techniques of regional anesthesia and analgesia as well as their potential complications.

The modern era using nerve blocks for the control of pain, began in the 1850s with the invention of the hollow needle and syringe. Koller first reported on the injection of cocaine to block nerves in 1884. Subarachnoid injection of cocaine was described by Corning in 1886. The first half of the twentieth century was the zenith of the use of nerve blocks in the management of pains of all types. Lytic substances, such as alcohol, as well as new local anesthetics were widely used for both diagnostic and therapeutic purposes. Blocks were also used in research on both anatomic pathways and physiologic states. The enthusiasm for nerve blocks was certainly one reason why anesthesiologists were in the vanguard of the development of the pain movement that Bonica launched in the aftermath of World War II.

However, better clinical trials and increased understanding of the factors that contribute to chronic pain states have combined to lessen the use of nerve blocks in the management of chronic pain. It remains the case that some patients have painful conditions that are treated successfully by local or regional anesthetic techniques. New drugs and new delivery systems may lead to a recrudescence of this approach to pain management.

The first edition of this text, published in 1953, focused on regional anesthesia and nerve block techniques in the management of pain. Indeed, it was this aspect of pain treatment that led Bonica into the new field of pain medicine. His perspective broadened as he gained experience with pain patients; this is what resulted in his desire to write a comprehensive textbook. This subject takes up less space in this, the third edition, for we know much more about the sciences basic to an understanding of pain and the clinical aspects beyond nerve blocks. We have tried to preserve Bonica's wisdom in these areas in the chapters of this section.

Section G. Ablative Neurosurgical Operations - Introduction

John D. Loeser

This section, composed of four chapters, discusses the neurosurgical procedures used for the management of chronic pain. Each chapter contains sections devoted to specific operations, which have been arbitrarily divided into three groups. Thus, Chapter 105 discusses operations on the peripheral nerves, Chapter 106 discusses operations on the spinal cord, Chapter 107 discusses operations for tic douloureux, and Chapter 108 discusses operations on the brain and brainstem. Each chapter contains sections with an up-to-date summary of the fundamental basis of the procedure, indications for its use, the clinical results obtained by the author and others who have had extensive experience with the procedure, a brief description of the operation, and a summary of the possible complications. The material is intended to provide an overview to physicians (and other health professionals) who are not neurosurgeons. As emphasized elsewhere in this book, it is essential for pain management physicians to be knowledgeable about various therapeutic procedures so that they can discuss them objectively with their patients.

This introduction commences with a brief historical perspective on surgery performed to relieve pain and then analyzes the requirements and guidelines for applications of the various operative procedures used to obtain relief of nonmalignant chronic pain and pain caused by cancer. The importance of patient selection is emphasized, and criteria for choosing a particular operation are identified. More detailed discussions of the indications, techniques, and results of neurosurgical procedures for pain relief have been superbly presented by White and Sweet (1), North and Levy (2), and Gybels and Sweet (3). The neuroanatomy, physiology, and biochemistry of the pain systems are discussed in detail in Chapter 3, Chapter 4, and Chapter 5.

HISTORICAL CONSIDERATIONS

In Chapter 1, we presented the concepts and surgical procedures used by the ancients in their attempts to understand and relieve pain. Ambroise Paré recognized in the late sixteenth century that cutting a nerve in the arm could relieve chronic pain secondary to a penetrating wound of the extremity. By the end of the seventeenth century, Maréchal, the surgeon to the court of Louis XIV, was performing peripheral neurotomies for tic douloureux. Modern neurosurgery began in the latter part of the nineteenth century after the advent of anesthesia and Lister's concepts of asepsis. Probably the first procedure to be used was peripheral neurotomy, described in a book published in 1873 by Letievant (4), in which he discussed sectioning of cranial nerves and of nerves supplying the extremities. One of the greatest neurosurgical pioneers was Horsley, who inaugurated surgery on the gasserian ganglion for tic douloureux in 1891. His work was continued by Krause and perfected by Frazier. The first spinal dorsal rhizotomies are accredited to Abbé and to Bennett in 1889. Spiller and Martin performed the first cordotomy in 1912. Förster continued the clinical studies of cordotomy and made many contributions to the surgery of pain (5).

The development of sympathectomy was mainly the work of Leriche, with major contributions by Jonnesco and Gomoiu. Many other great men of early twentieth-century neurosurgery played important roles in the development of neurosurgical procedures for pain relief: Chippault, Jaubolay, Sicard, Van Gehuchten, de Beule, Thiersch, Sjöqvist, Cushing, Dandy, and White all made significant contributions. Horsley and Clark's apparatus for producing lesions in animal brains was brilliantly adapted by Spiegel and Wycis in their pioneering work on human stereotaxis. Certainly, the major neurosurgical treatise on pain relief of the twentieth century was the text by White and Sweet (1), which introduced the modern era of surgical pain relief.

There is little doubt that developments in our understanding of the anatomy, physiology, and psychology of chronic pain will spur the advance of surgical procedures directed at new targets. Events of the past decade have already shown the inventiveness of surgeons in applying both new information and new technological methods to the problems of chronic pain.

Some of the most dramatic changes in the domain of neurologic surgery have occurred in regard to procedures designed to relieve pain. Early neurosurgical operations, in the late nineteenth and early twentieth centuries, involved section of nerves, roots, spinal cord, and then brainstem. The development of frontal lobotomy permitted a new approach—alteration of the suffering component of the patient's complaints rather than interruption of the pain pathways. Surgeons added new stereotaxic procedures for interruption of both specific and diffuse pain pathways at specific sites for the alleviation of suffering. Finally, the development of new theories of the nature of pain and of technological refinements in the electronic industry has led to the use of implanted electrical stimulators to augment rather than reduce sensory input in attempts to relieve pain (Chapter 99, Chapter 100, Chapter 101).

Another important technical development has been the use of controlled radiofrequency current or cold probes to generate a thermally destructive lesion; this has enabled surgeons to make discrete lesions through a needle rather than by a surgical incision. Patients who could not withstand the physical and psychological stress of a surgical operation can now be offered a percutaneous procedure that does not entail significant risk of infection, hemorrhage, or problems with wound healing. Technological developments of the twentieth century continue to add to the surgeon's repertoire for alleviating pain and suffering, and new operations are described regularly. Long-term results are often not included in the initial optimistic appraisal of the value of each procedure, and some caution seems warranted before new procedures are widely used.

OPTIMIZING SURGICAL RESULTS

The role played by the neurosurgeon in the treatment of chronic pain is a function of local patterns of medical care and the success of the patient's interactions with the health care delivery system. The development of multidisciplinary groups and pain clinics has altered the conceptual approach to the patient with chronic pain and has led to more sophisticated approaches for using surgical methods to deal with the patient with chronic pain. Ablative procedures, whether by knife, alcohol, or thermal coagulation, are often not the primary choice for the management of the patient with chronic pain caused by nonmalignant diseases; they are more useful for cancer pain. Unfortunately, far too many have been subjected to destructive surgical procedures that have not provided long-term relief of symptoms.

The neurosurgeon usually is well advised to avoid destructive operations for chronic pain unless the patient is known to have a life-shortening malignancy or has been thoroughly studied, and all other feasible treatments attempted. Of course, the patient with classic tic douloureux who has not responded to intensive medical therapy is an exception, because the response of this disease to various surgical procedures is likely to be favorable. Few other diseases respond well to surgery. Technical success is not always mirrored by patient improvement; reciprocally, the good results ascribed to an operation can be related to events other than the destruction of a portion of the nervous system.

Technical Skill and Experience

The results of an operation are directly related to the surgeon's knowledge and skill. Appropriate training and experience should be prerequisites for performing operative procedures of any type, especially those affecting the nervous system. Most neurosurgeons have the necessary skills, but few have had adequate experience dealing with the many facets of many chronic pain patients. Most errors in the management of these patients do not occur in the operating room but are made during the preoperative and postoperative evaluation of the patients by the surgeon. The operation is often technically adequate, but patients might have been unwisely selected for the procedure.

Experience in Managing Chronic Pain Patients

Few neurosurgery training programs currently offer adequate exposure to the multiple problems of patients with chronic pain; the overall poor therapeutic results are often not known, and short-term successes are considered adequate reasons for major surgery. For example, it is commonly stated that the “success rate” for initial lumbar diskectomy varies from 60% to 85% as a function of the patient population, but long-term follow-up in a 20-year multicenter Veterans Affairs Hospital study did not show an advantage for surgical therapy over conservative treatment (5).

Such data should make the neurosurgeon consider the indications for diskectomy carefully. Other studies have indicated that the natural history of patients with a ruptured disk is not altered by surgery when the patients are followed for 5 years (6). Furthermore, the long-term results after second or third lumbar disk operations have long been known to be dismal, yet surgeons still use this approach to chronic low back pain, often before other less hazardous avenues are explored. These issues are discussed in depth in Chapter 76 in relation to low back pain.

This situation can be ascribed to various aspects of the systems of medical care: I choose to identify inadequate long-term follow-up and feedback to the surgeon as the primary reasons for its continuation, although economics can be a factor. Careful long-term follow-up and increased participation by the neurosurgeon in the overall management of the patient with chronic pain are needed. Major neurosurgical textbooks often describe operative procedures with little or no discussion of long-term success rates. Many operations can be done to alleviate pain and suffering; the tough decision is not which one, however, but whether any destructive procedure is warranted at a specific time in the patient's course.

In contrast to the circumspect attitude that a neurosurgeon should exhibit toward destructive operative procedures for most nonmalignant diseases, certain types of patients should be promptly offered appropriate surgical relief of their pain or suffering. Two common examples of specific conditions are tic douloureux that has not responded to anticonvulsants and the pain resulting from uncontrolled cancer.

Some guidelines for the management of cancer pain are important for the surgeon. If the patient has a short life expectancy (less than 60 to 90 days), it is unwise to consider a major surgical procedure; narcotics or a percutaneous neurolytic procedure is usually more appropriate. The patient who is this close to death rarely has adequate infection resistance, wound healing, or blood coagulation and is a high surgical risk. For the patient who is going to survive more than 6 months, it is unlikely that oral narcotics or percutaneous procedures are optimal, and a surgical procedure is often indicated. Intermediate survival periods are often best managed by percutaneous procedures such as cordotomy, rhizotomy, epidural narcotics, or intrathecal injections of phenol or alcohol.

The patient with cancer is more likely to have a good result from a surgical procedure because the pain most likely is a result of nociception, which is eliminated by ablative procedures, and the patient is not likely to survive long enough for the beneficial effects of the surgical procedure to disappear. Furthermore, I suspect (but cannot prove) that those personality factors that play such a large role in the pain behavior of some patients with chronic pain secondary to a nonmalignant disease process are not usually found in the patient with a malignancy. These factors can predispose a patient with chronic pain of nonmalignant origin to operative failure. It is the younger patient with a vague pain syndrome related to a nonmalignant disease who so often fails to obtain pain relief from an operative procedure that seemed so promising.

Prediction of Long-Term Results

The major problem for the neurosurgeon is the prediction of long-term operative results for individual patients. A few studies of adequate numbers of patients followed for more than 3 months are available, but how can particular patients be related to a larger group? Are any reliable predictors of operative outcome available? For patients with low back pain, several studies now indicate that return to work 1 year after surgery is not related to the preoperative examination or the findings at surgery, but is predictable from preoperative psychological testing results (7). Few, if any, studies for such procedures as cordotomy, myelotomy, and rhizotomy have been done. The latter operation has been the subject of several reviews, which clearly show that spinal rhizotomy does not provide long-term relief for most patients (8,9).

Psychological and Psychiatric Evaluation

A patient with chronic pain not caused by a malignancy is frequently referred to a psychiatrist or psychologist for evaluation. Unfortunately, few of these patients have been evaluated before embarking on a career of chronic pain, so we do not know if the psychological evaluation describes the type of patient who suffers from chronic pain or describes the effects of chronic pain on the patient. It is clearly unwise to perform a major surgical procedure on a psychotic or severely depressed patient, not so much because of the risk of technical failure but because of the patient's inability to handle the stresses of hospitalization and surgery.

Hysterical or somatically preoccupied patients are likely to respond favorably on a short-term basis to any procedure, but little is known about a procedure's long-term efficacy in such patients versus patients with a healthier outlook on life. The indications for surgery in somatically preoccupied patients must be thoroughly scrutinized; these patients seem all too likely to receive more therapies for body ailments than are required. A significant proportion of patients with chronic pain are labeled as having psychological reasons for their pain behavior. With the exception of the malingerer or the overtly emotionally ill, this type of diagnostic evaluation does not seem to influence the therapeutic results. Therapy should be based on the identification of specific factors that indicate the need for operative intervention.

Many surgeons have relied on the Minnesota Multiphasic Personality Inventory (MMPI) as an indicator of the suitability of patients for surgical therapy. No controlled studies have been done to validate this use of the MMPI, but the test does eliminate the problem of observer bias and seems to predict the types of behavior patterns patients manifest and their responses to illness and stress. The MMPI can effectively identify people who have great readiness to convey to others that something is wrong with their body; to the extent that such tendencies are present (hypochondriasis), surgery or any other therapy is unlikely to reduce health care seeking behavior. The MMPI can be used to identify those individuals whose characteristic modes of responding to environmental stresses make it unlikely that any surgical procedure can restore them to a productive lifestyle. This issue is discussed in detail in Chapter 76.

Influence of Compensation and Litigation

Neurosurgeons have long been aware of the roles of compensation and litigation as factors in the determination of therapeutic outcome. I am not sure that these are particularly valid, because their effects have never been separated from such factors as the passage of time and intervening therapies. It is now quite obvious that environmental factors can and do influence pain behavior regardless of the cause of the pain. Compensation and litigation are only two of the many environmental influences impinging on pain patients. Family interactions can perpetuate pain behavior long after healing has occurred. Health care and insurance programs should be designed to offer rewards for recovery—not prolonged illness; some clearly have the opposite effect and lead to unnecessary surgical procedures.

The lack of motivation to “get well” can influence the search for continued medical assistance. Several studies of specific operations, however, failed to show a poorer prognosis for patients receiving compensation for their illness (9). It is too simplistic to consider only economic compensation when psychological and environmental factors can play such large roles in the genesis of pain behavior (10). Issues such as these have made it difficult to assess the results of surgical procedures.

The influences of duration of pain and prior attempts to alleviate pain have not been ascertained. Santayana's statement that “He who is ignorant of the lessons of history must be prepared to repeat them” is probably relevant to patients with chronic pain who fail to respond to many other well-chosen treatment regimens.

Prognostic Nerve Blocks

The role of nerve blocks in the selection of patients for surgical procedures must be scrutinized. The proper use of diagnostic blocks is discussed in Chapter 102 and Chapter 103 and other sections of this book; certain points need to be emphasized for the neurosurgeon. A single nerve block cannot be relied on to provide meaningful information—too many extraneous factors can influence the patient's response. A carefully planned series of blocks is often helpful but does not, as far as I can tell, predict long-term outcome of an ablative procedure except for sympathectomy for causalgia or trigeminal neurectomy for tic douloureux. Nerve blocks can identify the source of pain and the nerves or roots that must be cut to isolate that region of the body from the spinal cord or brainstem. They can also determine whether the patient's responses seem to be related to the duration of the anesthetic agents used and the nerve structure injected; these seem to be important measures of patient reliability. This issue is difficult to clarify, because no results have been reported in regard to operations performed on the patient who does not respond to nerve blocks in the region of the proposed surgery. Another indication for preoperative nerve block involves allowing the patient to experience the

expected numbness on a short-term basis. Some prefer their pain to this numbness.

Managing Narcotics in the Preoperative and Postoperative Periods

The neurosurgeon must have a strategy for dealing with patients who are taking significant amounts of narcotics and are being considered for an operative procedure. If the genesis of the pain has been clearly established as nociception, as in many patients with cancer-related pain, it is reasonable to relieve the pain with an operation and then taper the medications. Patients with an unclear cause of their pain behavior (e.g., associated with nonmalignant diseases) should be converted from short-duration narcotics to a long-acting drug such as methadone and the dosage gradually tapered (11). In many of these patients, the pain behavior diminishes as the narcotic level falls, and no operation is required. In others, a more accurate diagnosis can be made as the narcotic-induced mental impairment clears; surgical indications might then be more clear-cut (11).

Pain relief obtained with a surgical procedure is likely to reduce the patient's tolerance for narcotics dramatically, and consequently respiratory depression and even apnea can develop (Chapter 84). The dosage should be sharply curtailed in the immediate postoperative period while the patient is under close observation and, if respiratory depression becomes evident, incremental doses of naloxone are used.

Informed Consent

Another issue that must be considered concerns informed consent. The patient and family should be thoroughly informed about the therapeutic options and the risks and benefits of alternative treatment strategies. Not only the neurosurgeon but also the patient's primary care physician(s) must be knowledgeable about the likely outcomes from alternative treatments. The patient's primary physician should have a clear idea of what a proposed neurosurgical procedure entails so that this can be discussed with the patient.

The neurosurgeon who deals with patients with chronic pain must recognize that the greatest problems lie in the selection of therapeutic methods rather than in the application of the techniques themselves. Every operation and every other form of therapy has its advantages and disadvantages (10). What is appropriate at one point in time for a patient might not be optimal during any other phase of treatment. Not infrequently, surgical procedures must be performed in conjunction with other modes of therapy if the patient as a total human being is to be rehabilitated. In general, destructive procedures should not be considered until other modes of therapy have been thoroughly evaluated. When indicated, surgical intervention should not be delayed. That decision reflects the art of neurosurgery.

Section H. Multidisciplinary Multimodal Pain Management Programs - Introduction

John D. Loeser

Chapter References

In contrast to the other sections of this book, this last section has only one chapter. It describes the multidisciplinary/multimodal team approach using multiple therapeutic strategies in the management of patients with complex chronic pain problems. This chapter is the fourth and last in a series that describes chronic pain patients (Chapter 10), the principles of multidisciplinary pain diagnosis and management (Chapter 11), the strategies for diagnostic assessment (Chapter 18), and treatment in multidisciplinary programs (Chapter 109). Of course, the diagnostic and therapeutic strategies described in many other chapters of this book provide the foundations for the multidisciplinary approach. As clearly indicated in Chapter 10, Chapter 11, and Chapter 18, the focus of this series of chapters is on those chronic pain patients who do not have a directly treatable physical or psychological cause for their chronic pain. After assuring themselves that this is indeed the case, the multidisciplinary team turns its attention to improving the patient's functional status and reducing his or her pain complaints (1).

This type of treatment program was one of John Bonica's major accomplishments. He persisted in the pursuit of this new method of treating pain patients despite the intrinsic and extrinsic problems that he encountered during the 1950s and 1960s and the skepticism expressed by some national authorities who were medical traditionalists and did not like the concept of sharing patient responsibility with other health care providers. Fordyce added the behavioral medicine approach, and the multidisciplinary pain management concept rapidly spread throughout the developed world. Twenty-five years of experience have shown that comprehensive pain programs of the type described in Chapter 109 have been successful in returning roughly half of their patients to a productive life. The results reported from a number of such programs are summarized in this chapter, which uses the University of Washington Multidisciplinary Pain Center as its example. The usefulness and value of such programs has been emphasized by two important task groups, one in the United States and the other in Canada. In the United States the prestigious Institute of Medicine appointed the Committee on Pain, Disability, and Chronic Illness Behavior to consider the various aspects of chronic pain and disability (2). In Canada the Quebec Task Force on Spinal Disorders focused on pain in all parts of the spine, with emphasis on the rates of such disorders among workers in Quebec (3). In their reports, both groups encouraged physicians and other health professionals to refer patients with chronic pain who have failed to respond to the usual medical therapy to a multidisciplinary pain team.

The Quebec Task Force suggested that if management by the treating physician and a consultant specialist has not been successful and the patient still has pain after 3 to 6 months, he or she should be referred to a multidisciplinary team, which should focus primarily on psychological and psychosocial elements, on the premise that these factors are primarily responsible for the persistence of pain. Nothing is said of having the team reassess pathologic or pathophysiologic bases for the pain. Persistent pain due to pathologic lesions can cause serious psychological and psychosocial disorders and they should therefore be included in the assessment, but we wish to emphasize that the multidisciplinary team has the responsibility to evaluate the patient for physical and pathologic processes that might have been missed by prior physicians.

Dr. H. La Rocca, then editor-in-chief of the journal *Spine* (in which a summary of the report was published as a supplement), expressed concern about this issue in an editorial (4) in which he stated that “many patients with symptoms of 6 months' duration or more, can still have intractable organic disease without significant psychologic component. Every effort must be made to identify them” (see Chapter 18). Stoeckle and Boyd (5), members of the Institute of Medicine committee, also mention the unresolved problem posed by patients with chronic pain in whom a diagnosis of an underlying physical illness was missed because of inadequate diagnostic assessment or because the assessment was carried out before identification of the disease process was possible. They cite three publications reporting morbidity rates of undiagnosed physical illness presenting as psychiatric disease. As emphasized in Chapter 18, time and effort must be expended to carry out a comprehensive evaluation to diagnose structural pathology that can be eliminated. On the other hand, one should not be oblivious to the data on the low likelihood of identifying a structural disease in patients who consult their primary physicians with a wide variety of symptoms (6).

Most multidisciplinary pain programs focus on patients who manifest chronic pain behavior and disability long after the healing process should have been completed and have no treatable structural pathology. However, the same principles of multidisciplinary diagnosis and management should be applied to patients with obvious chronic pathology that cannot be removed, such as arthritis, cancer, deafferentation pain, and other chronic pain syndromes. Chronic pain that is not adequately relieved causes the patient to develop psychological, psychosocial, and behavioral problems as well as progressive physical deterioration. All patients with unresolved chronic pain are best managed by multidisciplinary teams.

The experiences of cancer and palliative care programs provides impressive evidence that an integrated approach is much more effective in improving the quality of life of patients with incurable, fatal diseases than can be achieved by traditional ways, in which the oncologist alone manages the patient with the support of nurses. In recent years, the difference between the team approach and the traditional care of cancer patients has become more and more appreciated, and most cancer programs offer both multidisciplinary diagnoses and treatments that include psychosocial issues (see Chapter 35 and Chapter 36). Therefore, what is described in Chapter 109 has usefulness beyond the typical chronic pain patient with nonmalignant disease.

We must continue to emphasize to physicians (particularly family physicians), other health care professionals, the consumers of health care, and third-party payers the critical importance of the team approach in managing patients with chronic pain. We encourage treating physicians who have been unsuccessful with the first or at most the second attempt in using surgery or medical therapies in managing complex pain problems to refer such patients to a multidisciplinary pain center that can carry out a coordinated effort to establish a diagnosis and develop an effective treatment strategy.

Although such comprehensive centers in the past have been viewed as “court of last resort” for the treatment of chronic pain, health professionals should refer patients with complex problems early in order to prevent the development of what some improperly refer to as “chronic pain syndrome” and—most important—reduce the suffering among millions of patients with chronic pain. The success rates reported by such programs suggest that increasing use of such facilities is likely to obviate the multiple, often useless, and at times mutilating operations and attendant complications. Multidisciplinary pain management also saves money, as discussed in Chapter 109.

CHAPTER 1

History of Pain Concepts and Therapies

John J. Bonica and John D. Loeser

> We must all die. But that I can save him from days of torture, that is what I feel as my great and ever new privilege. Pain is a more terrible lord of mankind than even death itself (1).

Thus did Albert Schweitzer, the great humanitarian, physician, and Nobel Laureate, elegantly describe the nature of pain and the obligation and privilege of the physician (and other health professionals) to relieve it. Dr. Schweitzer wrote these sentences in 1931, after nearly two decades' experience of medical practice in the African jungle. Today, as then, proper management of pain remains one of the most important and most pressing issues of society in general and the scientific community and the health professions in particular. This importance stems from the fact that acute and chronic pain afflicts millions upon millions of persons annually, and in many patients with chronic pain and a significant percentage of those with acute pain, it is inadequately relieved. Consequently, pain is the most frequent cause of suffering and disability that seriously impairs the quality of life for millions of people throughout the world. Although accurate statistics from national and international epidemiologic studies are not available, data from a variety of sources suggest that annually in the United States and many other industrialized nations, 15% to 20% of the population have acute pain, and between 25% and 30% have chronic pain. Additional data can be found in Chapter 9 and Chapter 10 and in those chapters dealing with specific pain and pain syndromes.

In most instances, acute painful disorders are correctly diagnosed and effectively treated. Despite improvements since 1990, evidence suggests that all too many patients with severe or very severe postoperative and post-traumatic pain, and severe visceral pain, are not effectively relieved. In addition to needless suffering, in many patients unrelieved pain and perhaps the underlying pathophysiology cause it to progress to chronic pain. Of the patients with chronic pain, one-half to two-thirds are partially or totally disabled for periods of days (e.g., those with headache), some for weeks and months (e.g., those with complex regional pain syndromes), and some permanently (e.g., those with low back pain, cancer pain, and arthritis). Because pain impairs one's ability to have a productive life, pain in general and chronic pain in particular are serious economic and social problems as well as major health issues.

This introductory chapter includes (a) a review of the concept and treatment of pain from primitive times to the middle of the twentieth century; (b) the theories that have evolved from the mid-nineteenth century to the present time; (c) past and current status of pain therapy and reasons for deficiencies; (d) recent advances in pain research and therapy; and (e) goals for improving the management of acute and chronic pain. Because of the extensive literature on these issues and because of limitation of space, only those publications considered essential and references to key review articles are cited. For a more detailed exposition of the history of pain concepts and therapies, the reader is referred to the books by Castiglioni (2), Fulop-Mueller (3), Keele (4), and Sigerist (5), and to the reviews by Bonica (6,7), Dallenbach (8), Macht (9), Procacci and Maresca (10), Tainter (11), and Rey (12).

HISTORICAL PERSPECTIVES

Pain has been a major concern of humankind since our beginnings, and it has been the object of ubiquitous efforts to understand and control it. Indeed, pain is even older, for there is reason to believe that pain is inherent in any life linked with consciousness (3). Evidence exists that humans have been afflicted with this evil since their beginning, for as the records of every race are examined, one finds testimonials to the omnipresence of pain. Prayers, exorcisms, and incantations bearing testimony to the prevalence and scourge of pain are found on Babylonian clay tablets, in papyri written in the days of the pyramid builders, in Persian leathern documents, in inscriptions from Mycenae, and on parchment scrolls from Troy. Such records continue through the ages in every civilization and in every culture.

The unearthing of prehistoric human skeletons added millions of years to human recorded history of several millennia, and with these findings our knowledge of pain has been thrust into the dark chasm of time, back into the eons. Many of these bones were indelibly stamped with signs of painful diseases, giving us evidence of how early were the beginnings of humans' *via dolorosa*. The French surgeon Daetigus wrote, “Were we to imagine ourselves suspended in timeless space over an abyss out of which the sounds of revolving earth rose to our ears, we would hear naught but an elemental roar of pain uttered as with one voice by suffering mankind” (3).

Pain has been one of the greatest factors to affect the course of human events, for scarcely any human has escaped its throes. As classical authors related the lives of heroes, as medieval chroniclers told the legends of saints, and as biographers wrote of philosophers, artists, soldiers, inventors, scientists, and reformers, invariably one chapter of these biographies was entitled “Pain” (3). The emotional and physical consequences of persistent severe pain have been emphasized repeatedly by scientists, writers, and poets. Milton (13) wrote in *Paradise Lost*: “Pain is perfect miserie, the worst/Of evils, and excessive, overturns/All patience.” It is natural that from its beginning our species should have engaged its energies to understand the nature of pain and make attempts to control it.

Primitive Concepts and Therapies

Apparently, primitive humans had little difficulty in understanding pain associated with accidental injury, but were mystified by pain caused by internal disease or inflicted by an arrow or spear. They treated pain from injury by rubbing (massaging) the part or exposing it to the cold water of streams or lakes; the heat of the sun; and, later, the heat of fire (4). Pressure also was used to numb the part and thus lessen the pain, and probably in time primitive humans learned that pressure over certain regions (nerves and arteries) had a more pronounced effect, although they did not know why (2,3).

The cause of painful disease, or pain inflicted by a foreign object, was linked with intrusion of magic fluids, evil spirits, or pain demons into the body (11). Treatment consisted of extracting the intruding object or making efforts to ward off, appease, or frighten away the pain demons with rings worn in the ears and nose, talismans, amulets, tiger claws, and similar charms. In some primitive societies, skin was tattooed with exorcistic signs to keep these evil spirits outside the body. Above all, conjurations, spells, and words of might were used by the injured person, enabling the person to put the pain demons to flight.

When primitive people could not relieve their own suffering, they called the head of the family, who, according to anthropologists, was a woman in prehistoric times, an incarnation of the Great Mother, who acted as priestess and sorceress in one, perhaps because the maternal instinct made her better qualified to protect the life she had given (3). Even in the subsequent patriarchal states, women remained preeminent as healers. The sibyls and pythonesses of the ancients and the blonde Agamede of the Greeks are classical examples of women who wielded the exclusive power of exorcising the demons of illness and pain. Gradually, however, the duties of banishing pain were taken over by the medicine man, conjurer, or shaman of the tribe, who, having no maternal instinct and having the same shape as all other men of the village, had to rely on the art of conjuring. It was therefore necessary for him to change his shape by dressing as an antidemon and to make his house a special medicine hut in which he muttered incantations and fought and wrestled with the invisible pain demons. In some primitive societies, the shaman made small wounds in the patient that allowed bad fluids, spirits, or demons to escape. In others, the shaman sucked the spirit directly from the wound, taking it into himself

and neutralizing it with magic power, a therapy that survives in some countries.

In addition, herbs were used by primitive humans, who, experimenting with various plants as foods, discovered that some of these were efficacious in assuaging pain. Their use was gradually taken over by the medicine man, who surrounded his knowledge of the mystic herbal concoctions handed down to him by sorcerers and magicians with mystery, incantations, and rituals.

Ancient Civilizations

Ancient Babylonia

In Babylonia, physicians were priests, as the Babylonian civilization was structured around religion. Sciences were part of theology; the physician's role was to placate the gods and keep them benevolent. The physician-priest observed the stars, watched a flickering flame, and observed the organs of sacrificed animals to determine the fate of the patient and the therapeutic actions to be taken. Omens were also included in the symptoms of disease. These, too, had to be observed and given meaning. This allowed rational diagnosis and treatment to be established without transgressing the religious attitudes of the culture. Treatments often used incantations, and we have many descriptions of the physician, garbed in a red cloak with a raven in one hand and a falcon in the other, pronouncing an incantation over the patient. Natural remedies were also used. Object intrusion into the body (by demons or by natural means) was the cause of pain. For example, the pain of dental caries was thought to be caused by worms' burrowing into the teeth (4,5).

Ancient Egypt

The ancient Egyptians believed painful afflictions other than wounds were caused by religious influences of their gods or spirits of the dead, which usually arrived in darkness and entered the body through the nostril or the ear. The types and numbers of demons of Egypt were myriad: spirits of dead “Asiatics,” “Negresses,” and “foreign women,” and the gods Sekhamet and Seth were considered the most active in inflicting pain. The Ebers (14) and Berlin papyri (15) mention that the routes of departure of the intruding demons could be through vomit, urine, the sneeze of the nose, or the sweat of the limbs. According to the Ebers papyrus (14), a widely distributed network of vessels called *metu* carried the breath of life and sensations to the heart. This was the beginning of the concept that the heart was the center of sensation (*sensorium commune*), an idea that lasted more than 2,000 years.

Ancient India

The earliest concepts of pain and other medical knowledge in ancient India were attributed to the god Indra, as recorded in the Vedas and Upanishads (16). Buddha, approximately 500 bc, attributed the universality of pain in life to the frustration of desires: “Birth is attended with pain, decay is painful, disease is painful, death is painful. Union with the unpleasant is painful; painful is separation from the pleasant and any craving that is unsatisfied, that too, is painful” (17). Although recognizing pain as a sensation, Buddhist and Hindu thought in general attached far more significance to the emotional level of the experience. As did the Egyptians, the ancient Hindus believed that pain was experienced in the heart, and as late as 100 ad, Charaka, the first of India's great teachers of medicine, stated that all joy and pain were experienced in the heart, which was considered the seat of consciousness (4).

Ancient China

Medical practice in ancient China was codified in the *Huang Ti Nei Ching Su Wen*, the Chinese canon of medicine, traced back to the time of the Yellow Emperor, Huang Ti, who lived approximately 2600 bc. This work, compiled between the eighth and fifth centuries bc, brings medicine from legend into the realm of history and carries it through the centuries to the practice of traditional medicine in modern China (17). According to the Chinese concept, in a normal person, the two opposing unifying forces, the *Yin* (the feminine, negative, passive force) and the *Yang* (the masculine, positive, active force), are in balance and assist the vital energy called the *chi* to circulate to all parts of the body via a network of 14 channels or meridians, each connected to an important internal organ or function to which it branches. Obstruction (deficiency) and outpouring (excess) in the circulation of the chi cause an imbalance of the two forces and thus result in disease and pain. Acupuncture therapy, at one or more of the 365 specific points located along the meridians, corrects the imbalance and thus eliminates the disease and pain (see Chapter 97).

Ancient Greece

The ancient Greeks were intensely interested in the nature of sensory data, and the sense organs of the body found a prominent place in their physiologic speculations (see reference 4 for detailed review). Pythagoras (566 to 497 bc), the first great Greek thinker, who traveled widely to Egypt, Babylon, and India, apparently stimulated his disciple Alcmaeon to carry out intensive study of the senses (4). Alcmaeon, without apparent precedent, produced the idea that the brain, not the heart, was the center for sensation and reason (18). Despite support by Anaxagoras, and subsequently by Diogenes, Democritus, and others, this view did not gain widespread acceptance in ancient Greece, caused in part by the opposition of Empedocles and, above all, Aristotle, for whom the heart constituted the *sensorium commune*. Anaxagoras (500 to 428 bc) saw sensation as a quantitative change in the subject, resulting from the contrast of opposites (4). All sensations, he held, must be associated with pain, and the more the subject and the object are unlike or contrary, the more intense the sensation of pain, which was perceived in the brain (10). In contrast, Empedocles (490 to 430 bc) believed that the capacity for all sensation, especially pain and pleasure, was located in the heart's blood (10).

It is not easy to interpret the thought of Hippocrates, because the *Corpus Hippocraticum* was written by different authors at different times (19). Of main importance was the theory of four humors: blood, phlegm, yellow bile, and black bile. Pain was felt when one of these humors was in deficit or excess (*dyscrasia*). The brain was considered a gland, the center of thought, and perhaps of sensations. Hippocrates' son-in-law Polypus emphasized this concept in his book *The Nature of Man*, when he wrote that “pain is felt when one of the humoral elements is in deficit or excess” (4). It is obvious that this conceptualization of pain was similar to that held by contemporary Chinese physicians.

Plato (427 to 347 bc) believed that sensation in humans resulted from the movement of atoms communicating through the veins to the heart and liver, which were the centers for appreciation of all sensation (20,21). He further believed that pain arose not only from peripheral stimulation, but also as an emotional experience in the soul, which resided in the heart. The function of the brain in sensory processes was not clearly described; this organ was considered mainly active in elaborating the concepts derived from the sensations. He considered pain and pleasure as affections common to the whole body. Plato observed that pleasure often derived from pain relief. In the dialogue *Phaedo*, this concept is exposed by Socrates: When the chain has been taken off his leg, Socrates observes that the disappearance of pain induced pleasure (21). Plato therefore deduced that pain and pleasure, although opposite sensations, are linked as originating from the heart as passions of the soul (21).

Aristotle (384 to 322 bc) elaborated on Plato's concepts on sensations and pain mainly in *De Anima* (on the soul) (22) and in *Nichomachean Ethics* (23). He distinguished five senses: vision, hearing, taste, smell, and touch. For Aristotle, the brain had no direct function in sensory processes; as previously mentioned, the *sensorium commune*, or center of sensory perception, was located in the heart, which he considered the center of all the fundamental life functions and the location of the soul. For Aristotle, the function of the brain was to produce cool secretions that cooled the hot air and blood arising from the heart. Pain sensation was an increased sensitivity of every sensation, but especially touch, caused by excess of vital heat. Like touch, pain arose in end organs of the flesh and was conveyed by blood to the heart. Aristotle appreciated the value of the touch-pain sense, but also emphasized that when it was excessively intense it had a deleterious and indeed destructive effect. This concept was stressed in *De Anima* (22), in which Aristotle wrote that “sensations are pleasant when their sensible extremes such as acid and sweet are brought into their proper ratio, whilst in excess they are painful and destructive.” Like his teacher Plato, Aristotle believed that pain was felt in the heart as a “quale”–a quality or passion of the soul, a state of feeling, the experience opposite to pleasure and the epitome of unpleasantness.

Soon after Aristotle's death, Theophrastus (372 to 287 bc), his direct successor, cast doubt on his master's views, and Straton, who succeeded Theophrastus, propounded the view that the center of sensation, including pain, was in the brain (4). Later, Herophilus (335 to 280 bc) and Erasistratus (310 to 250 bc) of Alexandria provided anatomic evidence that the brain was part of the nervous system and that nerves attached to the neuraxis were of two kinds: those for movement and those for feeling (4). Human dissection was used to advance anatomic knowledge.

Ancient Rome

Celsus (24) considered pain in relation to the phenomenon of inflammation, along with redness, swelling, and heat. Although he recognized the concepts of Herophilus and Erasistratus regarding pain, particularly that of internal disease, he failed to mention their concept about the brain, spinal cord, and motor and sensory

nerves. For nearly four centuries, the work of the Egyptians and Greeks was lost to the Roman world until rescued by Galen (ad 131 to 200) (25).

Galen was educated in Greece and Alexandria and then settled in Rome, where he became court physician to Marcus Aurelius. He carried out extensive studies on sensory physiology and reestablished the importance of the central and peripheral nervous system (25). He clearly established the anatomy of the cranial and spinal nerves and the sympathetic trunks. On the basis of experiments on nerves and discrete section of the spinal cord on newborn pigs, Galen elaborated a complex theory of sensation. He defined three classes of nerves: *soft* nerves, to which he attributed sensory functions; *hard* nerves, which were concerned with motor function; and a third type, related to the lowest form of sensibility, *pain sensation*. Soft nerves contained invisible tubular cavities in which a *psychic pneuma* flowed. These nerves served different senses: Every organ had a nerve supply suited to its physiologic function. The largest nerves subserved the special senses. The center of sensibility was the brain, which was softer than any nerve and received all kinds of sensations.

Despite Galen's great contribution on the function of the nervous system in sensation, the Aristotelian concept of the five senses, and of pain as a “passion of the soul” felt in the heart, prevailed for 23 centuries.

After Galen, writers of the third and fourth centuries summarized concepts expressed by the ancient Greek philosophers with somewhat different interpretations of the sense of touch. Two writers of this period are noteworthy for their concepts of pain: Nemesius first considered the cerebral ventricles as the center for sensory perception, a concept that was accepted by many authors of the Middle Ages and Renaissance (4). Caelius Aurelianus used for the first time the term *passio cardiaca propria* for pain of the heart some 14 centuries before Heberden termed pain in the heart *angina pectoris* and *dolor pectoris* (10).

Ancient Remedies

During ancient times, there was a transition from attributing the cause of pain to evil spirits to the commitment of sins, and the consequent punishment inflicted by an offended deity. As a result, the medicine man was replaced by the priest, servant of the gods. Along with the natural remedies, the priest relied on prayers, usually made at the shrines of the deities, whether these shrines were the ziggurats of the Babylonians and Assyrians, the pyramids of the Pharaohs, the pillared temples of the Greeks, or the teocallis of the Aztecs (2,3). In holy ecstasy, the priests besought deities to enlighten them of the offense committed by the sufferer smitten with a painful illness, using charms and sacrifices to propitiate the immortals. With sacrifices duly made, the gods were ready at times to listen to the supplications of the priests and perhaps to grant relief. Classical medicine was based on such belief, and even Hippocrates believed that “Divinum est opus sedare dolorem” (Divine is the work to subdue pain).

The concept of sin and punishment was also prevalent in the Judeo-Hebraic civilization, which of course believed in only one God. The same concept was adopted in the Christian ethic. The fundamental significance of the word *pain* in English is derived from the Latin word *poena*, meaning punishment, and its relief through prayer. One task of Jesus Christ and His disciples was to heal the sick and to banish pain and suffering (11,25). Consequently, Catholicism laid great stress on and devoted much attention to the alleviation of pain by its clergy through prayer. Faith in prayer could turn every action into a remedy. Its efficacy in relieving pain, probably through psychotherapeutic mechanisms, has long been respected by physicians. However, philosophical and religious concepts often denied the medical significance of pain and the necessity for medical intervention to minimize human suffering.

In addition to prayer, priests, like the medicine men of primitive people, used natural remedies consisting mostly of herbs. The origin of the medicinal use of herbs is lost in antiquity. We are told in the *Rig-Veda* of the ancient Hindus that “such herbs come to us from the most ancient times, three eras before the gods were born” (17). The use of analgesic agents derived from plant life was prominent in all ancient cultures (11). The earliest records relate legends of the pain-relieving effects of such plants as the poppy, mandragora, hemp, and henbane. Aesculapius, the Greek god of medicine, was said to have used a potion made from herbs, called *nepenthe*, to produce relief of pain (3). Perhaps the first written records on the use of analgesia are those contained in ancient Babylonian clay tablets from Nippur, which date back to 2250 bc (15,16). One of these describes the remedy for the pain of dental caries as a cement consisting of henbane seeds mixed with gum mastic, which was applied to the cavity in the tooth (4). The Ebers Papyrus, written approximately 1550 bc, includes an early Egyptian pharmacopoeia with many prescriptions for the use of opium, one of which was a remedy prescribed by Isis for Ra's headaches (14).

The use of analgesics derived from plants and herbs was also widespread in ancient Greece. Among the earlier references to the use of pain-relieving drugs are those found in the writings of Homer, who lived in approximately 800 bc. In his *Odyssey*, Ulysses and his comrades are treated by Helen of Troy, daughter of Zeus, who “cast into the wine whereof they drank, a drug to lull pain and anger and bring forgetfulness to every sorrow” (26). In the *Iliad*, Homer cites the use of an “astringent” anodyne, applied by the physician Petroclus to relieve the pain in Eurypylus, who had been wounded in battle. Hippocrates refers to a substance called *mecon*, to which he attributed a narcotic action, and some believe that this substance was opium (27). The first authentic reference to the use of opium for pain relief is found in the writing of Theophrastus in the third century bc (9).

Celsus, in his *De Medicina*, written during the first century ad, provides one of the first references to analgesic pills (24). At approximately the same time lived Pliny the Elder, Scribonius Largus, and Dioscorides, a Greek army surgeon in the service of Nero, all of whom wrote extensively on the preparation and use of mandragora, opium, henbane, hemp, and other drugs for the relief of pain (9,28). Later Galen (25) wrote enthusiastically about the analgesic efficacy of opium, mandragora, and other substances.

In addition to prayer and pain-relieving drugs, the Assyrians, Babylonians, and particularly the Egyptians used such surgical methods as trephine of the skull for headache and physical procedures such as exercise, heat, cold, and massage. Moreover, the ancient Chinese used not only acupuncture, but also moxibustion, massage, physical exercise, and dietary regimens to relieve painful conditions. In ancient Egypt, Greece, and Rome, electrotherapy in the form of shocks from the Nile electric fish and the torpedo fish was used for the treatment of neuralgia, headache, and other painful disorders (29).

Middle Ages and Renaissance

In the Middle Ages, the philosophy of Aristotle dominated, but the concept of the sensory heart was not accepted by all scientists. During this period, the center of medicine shifted to Arabia, where Avicenna (ad 980 to 1038), “the prince of physicians,” proved to be the dominant figure. Avicenna was particularly interested in pain and the means for relieving it. In his *Canon of Medicine*, in which he codified all available medical knowledge, he distinguished five “external” senses and five “internal” senses, and located the latter in the cerebral ventricles (30). He described the etiology of 15 different types of pain caused by different kinds of humoral changes and suggested such methods for their relief as exercise, heat, and massage, in addition to the use of opium and other natural drugs.

In Europe during the Middle Ages, the shift of the center of sensory perception from the heart to the brain began with the work of Albertus Magnus (3), who located the *sensorium commune* in the anterior cerebral ventricle. According to the *Anathomia* of Mondino de'Liucci (31), a work that remained the fundamental text for more than 200 years in many European medical schools, the brain was not only the site of sensation, but also had the power to cool the heart. In this book, Mondino presents an overlapping of Aristotelian and Galenic thought.

The Renaissance fostered a great scientific spirit to encourage many remarkable advances in chemistry, physics, physiology, and anatomy, especially the anatomy of the nervous system. During this period, Plato's and Aristotle's works were studied, with particular interest in the Greek originals and not in the Arabian translations, and comments were made especially by Marsilio Ficino, Pico della Mirandola, and the other members of the famous Academia Platonica founded in Florence by Lorenzo the Magnificent. The great scientist and artist of the Renaissance, Leonardo da Vinci, considered nerves as tubular structures, and pain sensibility was strictly related to touch sensibility (10). The *sensorium commune* was located in the third ventricle of the brain, and he considered the spinal cord as a conductor that transmitted sensations to the brain. During the sixteenth century other scientists, including Vesalius (32) and Varolius (4), followed Leonardo's concept on the anatomy and physiology of sensations. In their works the brain was considered the center of sensation; the nerves were generally considered as tubular structures.

During the Middle Ages and Renaissance there was virtually no advance in pain therapy. Thus, we find that Paracelsus (1490–1540) still advocated the use of opium and other natural herbs and such physical therapeutic methods as electrotherapy, massage, and exercise (11). During the latter part of the Middle Ages, the somniferant sponge, which was a sea sponge saturated with a concoction of the juices of opium, hyoscine, mandragora, and other plants, became quite popular in Europe for the relief of pain and to produce insensibility to surgical operations. The effects of the sponge were unpredictable and occasionally sleep progressed to death.

Seventeenth and Eighteenth Centuries

During the seventeenth century, additional evidence was acquired on the role of the brain in sensation, but the Aristotelian concept was still accepted by many

authorities. Thus, William Harvey, who in 1628 discovered the circulation of blood, still believed that the heart was the site at which pain was felt (10). In contrast, Descartes (1596–1650), Harvey's contemporary, adhered to Galenic physiology and considered the brain the seat of sensation and motor function. In his book *L'Homme* (Man) published in 1664 (14 years after his death), Descartes described the results of his extensive anatomic studies, including sensory physiology (33). He considered nerves as tubes that contain a large number of fine threads that form the marrow of the nerves and connect the proper substance of the brain with the nerve endings in the skin and other tissues. Sensory stimuli were transmitted to the brain by means of these threads. Figure 1-1 depicts the famous drawing that has been used for over 35 years to indicate that Descartes' concept was the precursor of the specificity theory that was introduced two centuries later.

Figure 1-1. Descartes' (1664) concept of the pain pathway. He writes: “If for example fire (*A*) comes near the foot (*B*), the minute particles of this fire, which as you know move with great velocity, have the power to set in motion the spot of the skin of the foot which they touch, and by this means pulling upon the delicate thread (*c*) which is attached to the spot of the skin, they open up at the same instant the pore (*d,e*) against which the delicate thread ends, just as by pulling at one end of a rope makes to strike at the same instant a bell which hangs at the other end.” (From Melzack R, Wall PD. Pain mechanisms: a new theory. *Science* 1965;150:971, with permission.)

The eighteenth century was ushered in with the same concepts on the nature of pain and the same methods for its control as had been advocated during the preceding centuries. Because up to the eighteenth century the main textbooks of medicine contained the works of Hippocrates and Aristotle, the idea of the heart as the *sensorium commune* remained parallel to the theory that the brain was the center of sensory perception. Thus, we note that Erasmus Darwin (34), grandfather of Charles Darwin, following the Aristotelian idea regarding pain as a phase of unpleasantness, said that pain resulted “whenever the sensorial motions are stronger than usual . . . a great excess of light . . . of pressure or distention . . . of heat . . . of cold produces pain.” He apparently anticipated the “intensive” theory of pain, which was to be a subject of great controversy 100 years later. Willis, Borelli, Baglivi, Malpighi, von Haller, and others (3) made significant progress in the knowledge of the anatomy and physiology of various parts of the central nervous system. Moreover, Winslow and others defined the anatomy and some of the physiology of the sympathetic nervous system. During the latter part of the eighteenth century, the new era of analgesia was initiated with Joseph Priestley's discovery of nitrous oxide and the subsequent observation made by Sir Humphrey Davy of the analgesic properties of this gas.

Nineteenth Century

Pain Research

In the early nineteenth century, physiology emerged as an experimental science. This development led to the scientific study of sensation in general and pain in particular. This era was initiated in part by the publications of Bell (35,36) and Magendie (37), who demonstrated with animal experiments that the function of the dorsal roots of spinal nerves is sensory and that of the ventral roots is motor. The impetus to the scientific study of pain was further enhanced by the writings of Johannes Müller, who, in 1840, proposed *The Doctrine of Specific Nerve Energies*, which stated that the brain received information about external objects and body structures only by way of sensory nerves and that the sensory nerves for each of the five senses carried a particular form of energy specific for each sensation (38). Müller recognized only the five classical senses (i.e., sight, hearing, smell, taste, and touch), the sense of touch incorporating, for him, all the qualities of experience that we derive from stimulation of the body including the sensations of itching, pain, heat, and cold. Müller's concept was that the somesthetic sensations are a function of a unitary straight-through system that conveys information from the sensory organ to the brain center responsible for sensation. The publications of Bell, Magendie, and Müller provoked much discussion and research on all aspects of sensation including pain.

Pain Therapy

During the nineteenth century, significant advances were made also in pain therapy, and these are considered in detail in Part V of this book. Among the most important was the isolation of morphine from crude opium by Serturner in 1806, which was followed by the development of techniques of getting pure crystalline drugs from previously crude and uncertain mixtures and of isolating other opium alkaloids, including codeine in 1832. In 1828, Wohler reported the synthesis of urea and Leroux reported the isolation of salin, which led, years later, to the introduction of salicylic acid, sodium salicylate, acetanalid, and acetyl salicylic acid, which came to be marketed as aspirin. A milestone in the prevention and treatment of pain was Morton's public demonstration in 1846 of the anesthetic properties of ether, which led to the development of general anesthesia. In approximately the same period Rynd developed the needle and Wood the syringe, which permitted the injection of analgesics. This development, together with the isolation and pharmacologic studies of cocaine, eventually led to Karl Koller's demonstration of its local anesthetic efficacy in 1884 and the subsequent widespread use of regional analgesia and anesthesia, not only for surgery but also for diagnosis and therapy of nonsurgical pain.

During the nineteenth century, hypnosis for surgery and for nonsurgical pain therapy became widely used and psychotherapeutic methods were developed. The advent of anesthesia and aseptic surgery and the evolution of the specificity theory led to still another method of relieving chronic intractable pain–neurosurgical operations on sensory pathways in peripheral nerves and spinal cord. Advances also were made in physical therapy, including electrotherapy, hydrotherapy, thermotherapy, and mechanotherapy. Finally, the discovery of x-rays by Roentgen ushered in an era of radiation therapy for many painful conditions.

PAIN THEORIES

During the remainder of the nineteenth century, anatomic, physiologic, and histologic studies were undertaken that prompted the explicit formulation of two physiologic theories of pain, the specificity theory and the intensive theory.

Specificity (Sensory) Theory

The specificity theory stated that pain was a specific sensation, with its own sensory apparatus, independent of touch and other senses. This theory, which, as previously mentioned, had been suggested by Galen, Avicenna, and Descartes, and in 1853 by Loetze (8), was definitively formulated by Schiff in 1858 (39) after his analgesic experiments in animals. Noting the effects of various incisions in the spinal cord, he found that pain and touch were independent: Transsection of the gray matter of the spinal cord eliminated pain but not touch, and a cut through the posterior white matter caused touch to be lost, but pain was unaffected. The results of these vivisections were promptly corroborated by clinical evidence as a number of clinicians reported pathologic cases of disease or injured spinal cords with similar sensory defects (3).

Schiff's theory was supported by later experiments by Funke in 1879 (40) and by the classical experiments by Blix (41), Goldscheider (42), and Donaldson, who discovered separate spots for warmth, cold, and touch in the skin between 1882 and 1885 (8). A decade later, von Frey (43) extended these studies to map out pain and touch spots, but he also did histologic examination of skin intended to identify specific end organs responsible for each sensation. On the basis of his findings and some imaginative deductions, von Frey expanded Müller's concept of the sense of touch to four major cutaneous modalities: touch, warmth, cold, and pain.

Intensive (Summation) Theory

The intensive theory, which was implied in Aristotle's concept that pain resulted from excessive stimulation of the sense of touch, was first suggested by Darwin and subsequently embraced by Romberg, Henle, and Volkmann (8) in the 1840s and 1850s. The theory was explicitly formulated by Erb (44) in 1874. He maintained that

every sensory stimulus was capable of producing pain if it reached sufficient intensity. This theory received subsequent support from Wundt (45) and later from Blix (46), Kulpe (47), Titchener (48), and especially Goldscheider. Blix's aforementioned studies in 1882 had led him to believe that pain was a specific sensation, but a year later he discarded this view. Goldscheider also shifted views. At first he did not believe that pain was specific, but by 1885, just as Blix was shifting in the other direction, Goldscheider (42) came to the conclusion that the evidence was in favor of specificity. He held this view until 1891, when he shifted once more (49) because of the results obtained by Naunyn 2 years earlier, which led the latter to conclude that pain was the result of summation (8).

In 1894 Goldscheider (50) fully developed the theory that stimulus intensity and central summation were the critical determinants of pain. This theory suggested that the particular patterns of nerve impulses that evoke pain are produced by the summation of the skin sensory input at the dorsal horn cells. According to this concept, pain results when the total output of cells exceeds a critical level as a result either of excessive stimulation of receptors that are normally fired by nonnoxious thermal or tactile stimuli or of pathologic conditions that enhance the summation of impulses produced by normally nonnoxious stimuli. Goldscheider assumed the long delays and persistent pain observed in pathologic pain states were caused by abnormally prolonged time periods of summation. He further proposed that the spinal "summation path" that transmitted the pain signal to the brain consisted of slowly conducting, multisynaptic fiber chains and that the large fibers that project up the dorsal column pathways carried the tactile discriminative properties of cutaneous sensation (50).

Controversies

Thus, by the end of the nineteenth century, three conflicting concepts existed on the nature of pain. The specificity theory and the intensive theory, which were in opposition to each other, were embraced by physiologists and a few psychologists. These two theories opposed the traditional Aristotelian concept that pain was an affective quality, which at this time was being supported by most philosophers and psychologists, including Lehmann in Germany; Gain, Bradley, Spender, and Ward in England; and Baldwin, Dewey, James, and especially H. R. Marshall in America (8). The latter was the most active proponent of the pleasure–pain theorists and wrote extensively on the subject (51). During the decade between 1886 and 1895, proponents of each of these theories became involved in unprecedented, intensely fierce controversies. In an attempt to reconcile the views of physiologists with those of philosophers and psychologists, Strong, then president of the American Psychological Association, suggested in 1895 that pain consisted of the original sensation and the psychic reaction or displeasure provoked by the sensation (52). This concept was later embraced by others, including Sherrington, who believed that pain was composed of sensory and affective (feeling) dimensions (53).

Pain Theories in the Twentieth Century

During the first six decades of the twentieth century, research on pain continued and the published data acquired were used, in part, to support either the specificity theory or the intensive theory, or a modification of these. The intense controversy between von Frey and Goldscheider continued until the late 1920s (54,55), and each rallied supporters. Thus, Weir Mitchell, Henry Head, and subsequently Adrian, Ranson, Waterston, Bishop, Sherrington, and Wolff and coworkers supported the specificity theory, whereas Lugaro, Leriche, and subsequently Livingston, Nafe, Hebb, Wedell, and Sinclair supported the intensive theory (7,56,57). By midcentury, however, the specificity theory prevailed and became widely taught.

Von Frey's theory, which dealt only with receptors, subsequently prompted others to believe that pain is subserved by specific fibers from the receptors to spinal cord and specific pain pathways in the neuraxis and even suggested the existence of a pain center. Experiments were carried out in peripheral nerves to show there is a one-to-one relationship between receptor type, fiber size, and quality of experience (58). Other animal experiments suggested that the anterolateral quadrant of the spinal cord was critically important for pain sensation, a concept that found support in the early observation by Spiller (59) of analgesia with pathologic lesions of this part of the cord, the early results with anterolateral cordotomy by Spiller and Martin (60), and subsequently by many others (61). In 1920, Head (62) proposed that a *pain center* is located in the thalamus because cortical lesions or excisions rarely abolish pain, but frequently make it worse, suggesting that the cortex exerts inhibitory control to the thalamic pain center.

Pattern Theories

In 1934, Nafe (63) suggested that all cutaneous qualities are produced by spatial and temporal patterns of nerve impulses, rather than by separate modality-specific transmission routes. On the basis of this suggestion and personal studies, Sinclair (64) and Weddell (65), two decades later, proposed a peripheral pattern theory that stated that all fiber endings, apart from those that innervate hair cells, are alike, so that the pattern of pain is produced by intense stimulation of nonspecific receptors. This theory ignored the physiologic evidence that shows a high degree of receptor fiber specialization.

Central Summation Theory

In 1943, Livingston (66) proposed his own theory of central summation in support of the intensive theory. He suggested that the intensive stimulation resulting from nerve and tissue damage activates fibers that project to internuncial neuron pools in the spinal cord, creating abnormal reverberatory activity in closed self-exciting neuron loops. This prolonged, abnormal activity bombards the spinal cord transmission (T) cells, which project to brain mechanisms that underlie pain perception. The abnormal internuncial activity spreads to lateral horn cells and ventral horn cells in the spinal cord, activating the sympathetic nervous system and somatic motor system, respectively, producing vasoconstriction, increased work of the heart, and skeletal muscle spasm. These, in turn, produce further abnormal input, thereby creating a vicious circle. Brain activities such as fear and anxiety evoked by pain also feed into and maintain the abnormal internuncial pool activity.

Eight years later, in 1951, Gerard (67) suggested a theory that is similar in concept but different in hypothetical mechanisms. He proposed that a peripheral nerve lesion may bring about temporary loss of sensory control of firing in spinal cord neurons, which then begin to fire in synchrony. Such synchronously firing pools "could recruit additional units, could move along in the grey matter, could be maintained by impulses different from and feebler than those needed to initiate it, and could discharge excessive and abnormally patterned volleys to the higher centers."

Fourth Theory of Pain

The controversy among the three groups of theorists continued, but by midcentury the specificity theory had prevailed and was taught universally. To take into account the psychological factors that have been shown to influence pain and consolidate these with the specificity theory, Hardy, Wolff, and Goodell (68) in the 1940s reintroduced the concept of the duality of pain that had been proposed by Strong and called it the *fourth theory of pain*. They believed that pain can be separated into two components: the perception of pain and the reaction to pain. The perception of pain, like the perception of other sensations such as temperature and touch, is a neurophysiologic process that has special structural, functional, and perceptual properties and is accomplished by means of "relatively simple and primitive" neural receptive and conductive mechanisms. The reaction to pain, on the other hand, is a complex physiopsychological process involving the cognitive functions of the individual and is influenced by past experience, culture, and various psychological factors that produce great variation in the *reaction pain threshold*. This concept assumes a one-to- one relationship between the intensity of the stimulus and pain perception and relegates the reaction to pain as a secondary response consequent to the sensation achieved in a straight-through push-button or alarm system fashion.

Sensory Interaction Theory

In 1959, Noordenbos (69) proposed the sensory interaction theory. This theory derived from Goldscheider's original concept and also subsequent proposals by Head, Bishop, and others of the existence of two systems involving transmission of pain and other sensory information: a slow system that involved the unmyelinated and thinly myelinated fibers and a fast system that involved the large myelinated fibers. He proposed that the small-diameter slowly conducting somatic afferent fibers and small visceral afferents project into the cells in the dorsal horn of the spinal cord and the summation of inputs from the small fibers produces the neural patterns that are transmitted to the brain to produce pain. The large-diameter fast-acting fibers inhibit transmission of impulses from the small fibers and prevent summation from occurring. Diseases that produce a selective loss of large fibers bring about a loss of inhibition and thereby increase the probability of summation and of abnormal pain phenomena. Noordenbos further proposed that one of the ascending systems that transmit pain signals is the short axon multisynaptic system in the core of the spinal cord.

Figure 1-2 presents schematically the most important conceptual models of pain mechanisms presented between 1900 and 1960.

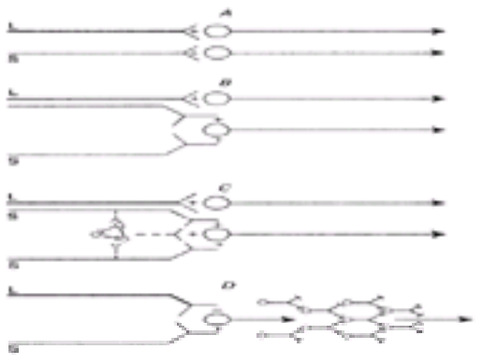

Figure 1-2. Schematic representation of conceptual models of pain mechanisms. **A:** The specificity theory espoused by von Frey, who believed that large fibers (*L*) transmitted touch, and small fibers (*S*) mediated pain impulses in separate, specific, straight-through pathways to touch and pain centers in the brain. **B:** The summation theory, first espoused by Goldscheider, who believed that convergence of small fibers onto a dorsal horn produced pain and that touch was transmitted by large fibers. **C:** Livingston's conceptual model of reverberatory circuits involved in chronic pathologic pain states in which nociceptive impulses initiate prolonged activity in the self-exciting chain of neurons and bombard dorsal horn cells, which then transmit abnormally patterned volleys of nerve impulses to the brain and also to anterior and anterolateral horn cells that become involved in abnormal reflexes, leading to skeletal muscle spasm and sympathetic hyperactivity. **D:** The interaction theory proposed by Noordenbos, who believes that large fibers inhibit (–) and small fibers excite (+) central transmission neurons, which project to a multisynaptic system that leads to the brain. Part of this theory was incorporated into the Melzack-Wall theory depicted in Figure 1-3. (Modified from Melzack R, Wall PD. Psychophysiology of pain. *Int Anesth Clin* 1970;8:3.)

Gate Control Theory

New data acquired during the 1950s led Melzack and Wall to reappraise the specificity and intensive theories in the following decade (70). They concluded that the specificity theory is strongly supported by physiologic evidence of specialization of the nervous system, but its psychological assumption that sensation is achieved via a fixed direct communication from the skin to the brain in a straight-through push-button fashion is its great weakness. The scientific evidence failed to support the assumption of a one-to-one relationship between the intensity of the stimulus and pain perception but instead suggested that the amount and quality of pain perceived are determined by many physiologic and psychological variables. Similarly, the intensive theory is strongly supported by the evidence on central summation and input control but is weakened by ignoring peripheral specificity. The scientific evidence suggests that pain is not caused by neural activity that resides exclusively in nociceptive pathways traditionally considered specific for pain, but is a result of activity in several interacting neural systems, each with its own specialized function. As a result of these considerations, Melzack and Wall published their own theory in 1965 (70) that took into account the evidence of physiologic specialization, central summation, patterning, modulation of input, and the influence of psychological factors.

The original Melzack-Wall theory of pain is illustrated in Figure 1-3. As noted, impulses evoked by peripheral stimulation are transmitted to three systems: the cells in the substantia gelatinosa, the dorsal column fibers that project toward the brain, and the spinal cord transmission (T) cells that mediate information to the brain. The theory is based on the following propositions: (a) The transmission of nerve impulses from afferent fibers to the spinal cord T cells is modulated by a spinal gating mechanism in the dorsal horn. (b) The spinal gating mechanism is influenced by the relative amount of activity in large-diameter (L) and small-diameter (S) fibers; activity in large fibers tends to inhibit transmission (closes the gate), whereas activity in small fibers tends to facilitate transmission (opens the gate). (c) The spinal gating mechanism is influenced by nerve impulses that descend from the brain. (d) A specialized system of large-diameter rapidly conducting fibers labeled the *central control trigger* activates selective cognitive processes that then influence by way of descending fibers the modulating properties of the spinal gating mechanisms. This system carries precise information about the nature and location of the stimulus and conducts so rapidly that it may not only set the receptivity of cortical neurons for subsequent afferent volleys, but also, by way of the descending fibers, influence the sensory input at the segmental gate control system and at other levels of the neuraxis. This rapid transmission makes it possible for the brain to identify, evaluate, localize, and selectively modulate the sensory input before the action system is activated. (e) When the output of the spinal cord transmission (T) cells exceeds a critical level, it activates the action system, those neural areas that underline the complex sequential pattern of behavior and experience characteristics of pain.

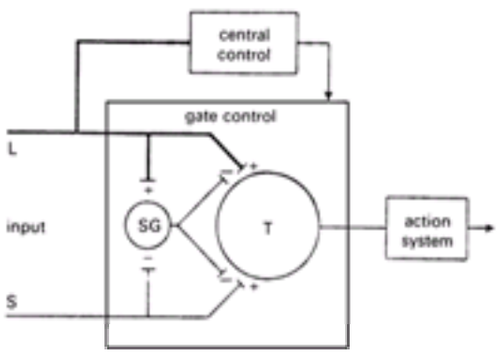

Figure 1-3. Schematic of the gate-control theory of pain (Mark I). L, large-diameter fibers; S, small-diameter fibers. The fibers project to the substantia gelatinosa (SG) and first central transmission (T) cells. The inhibitory effect exerted by the SG on the afferent fiber terminals is increased by activity in L fibers and decreased by activity in S fibers. The central control trigger is represented by a line running from the large-fiber system to the central control mechanisms; these mechanisms, in turn, project back to the gate-control system. The T cells project to the action system. +, excitation; –, inhibition. (From Melzack R, Wall PD. Pain mechanisms: a new theory. *Science* 1965;150:971, with permission.)

Three years later, Melzack and Casey (71) expanded the theory by taking into account subsequently acquired knowledge derived from physiologic and behavioral studies that further emphasize the motivational, affective, and cognitive aspects of the pain experience. These pertain to neural systems beyond the gate and involve interaction of the neospinothalamic and paleospinothalamic projecting systems and neocortical processes. They suggested that the neospinothalamic projecting system in the brain serves to process sensory discriminative information about the location, intensity, and duration of the stimulus, whereas impulses that pass through the paleospinothalamic tract and paramedial ascending system activate reticular and limbic structures that provoke the powerful motivational and aversive drive and unpleasant affect that triggers the organism into action. Neocortical higher central nervous system processes, such as evaluation of the input in terms of past experience, exert control over both discriminative and motivational systems.

In 1982, Melzack and Wall (72) modified their theory to take into account information acquired since the original proposal. The new model is depicted in Figure 1-4. As may be noted, this model includes excitatory and inhibitory links from the substantia gelatinosa to the transmission cells as well as descending inhibitory control from brainstem systems. Despite whatever deficiencies the Melzack-Wall-Casey models of pain may have, they have proven to be among the most important developments in the field of pain research and therapy. In addition to providing a comprehensive formulation of pain mechanisms, the theories have stimulated extensive physiologic and psychological research and have provoked the development of new approaches to pain therapy.

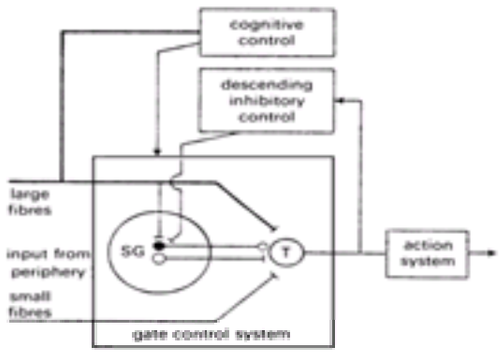

Figure 1-4. The gate-control theory (Mark II). The new model includes excitatory (*white circle*) and inhibitory (*black circle*) links from the substantia gelatinosa (SG) to the transmission (T) cells, as well as descending inhibitory control from brainstem systems. The round knob at the end of the inhibitory link implies that its actions may be presynaptic, postsynaptic, or both. All connections are excitatory, except the inhibitory link from SG to T cell. (Modified from Melzack R, Wall PD. *The challenge of pain*. New York: Basic Books, 1983.)

Psychological and Behavioral Theories

All of the preceding theories have been proposed to explain the mechanisms of pain caused by damage of body tissues or of peripheral nerves, the central nervous system, or both. Since the late 1960s, the literature has increased on chronic pain occurring in the absence of tissue damage or other *organic* pathology. The early reports by Engel and Walters on *psychogenic* pain were followed by studies of Merskey and collaborators and others of the incidence of pain in patients with a neurosis or psychosis and in whom no demonstrable pathology could be found. These studies, summarized in the book by Merskey and Spear (73), suggest that the highest incidence was found in patients with neurotic disorders, especially hysteria, and less frequently with reactive depression and other psychotic disorders.

One of the most important points made by Merskey and Spear (73) and later by Sternbach (74) is that these patients feel and describe their pain in the same terms as patients with demonstrable pathology and that their psychogenic pain is as real to these patients as pain caused by somatogenic disorders. This similarity of describing both types of pain is widely recognized and refutes the Cartesian concept of dichotomy of body and mind. This similarity is emphasized by the definition adopted and published by the Committee on Taxonomy of the International Association for the Study of Pain (IASP) discussed in the next chapter.

As part of the surge in pain research mentioned in the following discussion, studies by psychiatrists and psychologists have markedly expanded our knowledge of the role of learning, personality, culture, and cognition; psychological, emotional, and motivational factors; and environmental influences on pain and pain behavior. This knowledge has led to the development of other hypothesis and concepts to explain chronic pain behavior in patients with minimal or no demonstrable pathology. Among the most important of these are the concept of *chronic abnormal illness behavior*, first proposed by Pilowsky (75) and subsequently adopted by others, and the concept of *operant (behavioral) conditioning* developed by Fordyce (76), which is being applied in many chronic pain therapy programs. These hypotheses are discussed in detail in Chapter 24, Chapter 25 and Chapter 26.

STATUS OF PAIN THERAPY

Throughout the twentieth century, the methods used to treat acute and chronic pain conceived during the nineteenth century underwent remarkable advances. Because these are discussed in detail in Part V of this book, only brief comments on their historical development are made here. During this period, progressively greater advances were made in the development of systemic analgesics made possible by advances in synthetic chemistry. Consequently, a variety of nonnarcotic analgesics were developed, including acetaminophen (paracetamol), phenacetin, and other derivatives of paraminophenols and aminopyrine, phenylbutazone, and a variety of nonsteroidal anti-inflammatory drugs. Equally important advances were made in the development of various narcotic analgesics, including semisynthetic derivatives of morphine such as diacetylmorphine (heroin), hydromorphone (Dilaudid), and oxymorphone (Numorphan); later, wholly synthetic narcotic analgesics were developed, of which meperidine (pethidine, Demerol) was the first. Subsequently, methadone (Dolophine) and morphinan were synthesized, and from these a large number of derivatives that constitute important synthetic opioids were developed. In addition to nonnarcotic and narcotic analgesics, another heterogeneous group of drugs usually labeled adjuvants are used in conjunction with one or both of the other classes. These drugs constitute the most frequently used method for the relief of pain because they are readily available, inexpensive, simple to administer, and if properly used are reasonably effective in relieving various types of pain.

The widespread acceptance of the specificity theory led to the development and widespread use of regional analgesia and neurosurgical operations for the treatment of nonsurgical pain. During the early part of the century, techniques were developed for the injection of local anesthetic into tissues or around virtually every major nerve and various nerve plexuses and into the subarachnoid and epidural spaces to produce nerve block or regional analgesia and anesthesia. Although these procedures were first developed for surgical anesthesia, it was not long before physicians began to use them as diagnostic, prognostic, and therapeutic aids in the management of patients with acute or chronic pain syndromes (57,58). Moreover, the intentional destruction of peripheral nerves or sensory roots of spinal and cranial nerves by injecting alcohol, phenol, or other neurolytic agents became widely used for the relief of severe intractable pain of cancer and other chronic conditions. Similarly, neurosurgical procedures were developed and refined that were intended to interrupt pain pathways in various parts of the peripheral and central nervous system. As is emphasized throughout this book and is considered in detail in Chapter 104, Chapter 105, Chapter 106, Chapter 107 and Chapter 108, more recently acquired information has caused a marked decrease in the use of these destructive chemical and surgical procedures.

During the first decade of the twentieth century, the use of hypnosis for pain therapy underwent periods of enthusiastic acclaim and total neglect. Psychotherapy also was used from time to time in treating persistent pain. Other psychological techniques of controlling pain that have been proposed included relaxation and a variety of cognitive-behavioral procedures, but these did not gain widespread acceptance and application until the pioneering work of Fordyce made multidisciplinary pain management popular after 1970. Moreover, a variety of physical therapeutic techniques and radiation therapy were refined and widely applied for the treatment of acute and chronic pain syndromes.

In the introduction to the first edition of this book, published in 1953 (56), after reviewing the advances in pain theory and pain therapy achieved up to that time, Bonica made the following statement:

> In spite of all the aforementioned achievements, and in spite of the many efforts that have been made by so many investigators regarding all of its phases, we are far from our goal of understanding pain. . . . Moreover, more than superficial thought on this problem reveals that our methods of management, while effective in some patients, are nevertheless not as refined as they can be, and entail procedures which frequently are destructive.

Throughout the book he repeatedly emphasized that many patients with various types of acute pain and most patients with chronic pain were not relieved effectively. Subsequently, he reassessed the status of pain research and therapy at frequent intervals, and each time he found that the statements he made in 1953 continued to be valid (6,7,56,57,77,78,79 and 80).

On each occasion of reassessment, Bonica found impressive evidence that a large percentage of patients with acute postoperative pain, or other post-traumatic pain, and those with severe acute pain associated with visceral disease, and most patients with acute postburn pain were inadequately relieved. Moreover, as detailed in Chapter 10, many patients with nonmalignant chronic pain did not respond to the usual medical therapy and an impressive number have been exposed to the high risks of iatrogenic complications including drug toxicity, drug dependence, and multiple, often useless, and at times mutilating operations. A significant number of these patients gave up medical care and consulted quacks who not only depleted their economic resources, but also did them harm. Patients with cancer pain have often fared no better; indeed there have been numerous reports indicating that many patients with advanced cancer live the last months of their lives in unrelieved severe pain (see Chapter 35, Chapter 36, Chapter 37, Chapter 38, Chapter 39 and Chapter 40). One of the most gratifying events of the 1990s has been the significant improvement in cancer pain and end of life palliative care; this contrasts with the slow progress in the prior 25 years.

Reasons for Deficiencies

On each occasion of reassessing pain diagnosis and therapy, Bonica looked into the reasons for these deficiencies and found them to remain the same. These can

be grouped into three major categories: (a) great voids in knowledge about pain and its mechanisms because of insufficient research; (b) inadequate or improper application of the available knowledge and therapies; and (c) problems with communications. Although he discussed these issues on numerous occasions and in several dozen publications (6,7,56,57; see 80 for other references), they deserve reemphasis here because they serve as an important framework for many of the chapters that follow.

Voids in Knowledge

A careful review and analysis of the history of pain research reveals that, after the surge of interest and activities evidenced during the last part of the nineteenth century and the early part of the twentieth century, the degree of interest and participation in this field was not commensurate with the clinical importance of the problem. Until the 1960s or so, pain research was relatively neglected by the scientific community, and only a few basic and clinical scientists devoted efforts to this field. Moreover, of those basic scientists who studied pain, most did so in the isolation of the animal laboratory, and many were not concerned with clinically relevant issues. The failure to study animals with injuries to somatic tissues or nerves was a major impediment to the development of valid models for clinical pain states, especially those that were chronic. Indeed, almost all studies that purported to be related to pain involved transient stimuli designed to be insufficient to damage tissues. The advent of reasonable animal models in the 1990s has greatly advanced studies of the mechanisms of chronic pain. As previously mentioned, most of the new data acquired during the first half of the twentieth century were used to support either the specificity theory or the intensive theory or subsequent modifications.

Until the early 1970s, the scientific community did not take advantage of great advances in medical research, medical science, and technology and apply them to pain research. This was especially true of the investigation of the mechanisms and pathophysiology of chronic pain states. Perhaps this was caused in part by the fact that most scientists, like most clinicians, did not appreciate differences between acute and chronic pain. Consequently, no effort was devoted to development of animal models for chronic pain. As a result of fragmented independent research efforts on artificially induced acute pain, hypotheses and concepts were developed that, although reasonable for the times and the scientific data available, were not relevant to chronic pain.

The predominant concern with anatomic and physiologic research on pain, consequent to the widespread assumption that pain was a purely sensory experience, caused emotional and psychological factors to be relegated to secondary roles or to be considered by-products of the sensation. These and other factors discouraged experimental and clinical psychologists and behavioral scientists from becoming involved in pain research. Consequently, the crucial roles of psychological and environmental factors in causing chronic pain behavior in a significant number of patients were not studied and defined until recently. In regard to this issue and to the widespread acceptance of the specificity theory by midcentury, Bonica stated in the first edition of this book that: “As a consequence, there has emerged a sketch plan of pain apparatus with its receptors, conducting fibers, its centers of elaboration, and its standard function, which is supposed to be applicable to all circumstances. But . . . in doing so, medicine has overlooked the fact that the activity of this apparatus is subject to a constantly changing influence of the mind.”

As emphasized in Chapter 9 and Chapter 10, a serious research-related deficiency has been the lack of accurate data from large-scale national epidemiologic studies on the incidence and prevalence of various types of pain and their socioeconomic effect. Another critically important reason for the voids in our knowledge of pain has been the lack of research training programs focused on pain of the type that has existed for the study of other important health problems. Consequently, there has been an insufficient number of basic and clinical scientists devoting their time to pain research. Related to these problems has been the meager amount, or total lack, of funds allocated for pain research and research training even in so-called developed and medically advanced countries.

The explosion in neurosciences research in the last quarter of the twentieth century has led to increased understanding of the nervous system in general and mechanisms of acute and chronic pain in particular. Entire laboratories have been established to undertake pain research and have received significant funding from governmental and commercial sources. A significant fraction of the papers at the annual Society for Neurosciences meeting focuses on aspects of pain. Numerous other meetings take place every year that lead to increased communications among pain researchers and attract neuroscientists to this field. Pain research is better funded at the end of the twentieth century than at any time in the past.

Inadequate Application of Available Knowledge and Therapies

Improper or inadequate application of current knowledge and therapies has been caused by a number of interrelated factors including (a) lack of organized teaching of medical students, physicians, and other health professionals involved in the clinical management of patients with acute and chronic pain; (b) inadequate sources of other information, such as books and journals available for the education of students, physicians in training, and practitioners; and (c) the lack of appreciation by investigators, teachers, and clinicians of the differences between acute pain and chronic pain in regard to etiology, function, mechanisms, pathophysiology, and approach to diagnosis and therapy. Consequently, students have been taught to use pain as a diagnostic aid and have been given little, if any, instruction in the basic principles of the management of acute and chronic pain.

As a result of this lack of education, many physicians have treated acute pain and cancer pain in an empiric manner, relying on nonnarcotic and narcotic analgesics and related drugs, not infrequently administering them improperly. A number of studies have shown that house officers and some physicians prescribe narcotics at two-thirds or three-fourths of the dose required to relieve severe pain, and that nurses underadminister drugs by another one-third to one-half (81,82). These studies revealed that the reasons for such underdosing included inadequate knowledge of the pharmacology of these drugs so that physicians underestimated the effective dose range and overestimated the duration of action and that nurses and physicians had an exaggerated opinion of addiction potential and the dangers of respiratory depression. As is emphasized in many parts of this book, these are not valid reasons for underdosing patients with pain.

Inadequate application of available knowledge and therapies has played an even greater role in the improper treatment of patients with chronic pain syndromes. The lack of organized teaching and appreciation of the difference between acute and chronic pain have caused many physicians to apply the same therapeutic modalities that are used in treating acute pain to the management of patients with chronic pain. Moreover, as previously mentioned, until the last quarter of the twentieth century, the critical influence of environmental and psychological factors as primary causes of chronic pain behavior was not known or appreciated. Treatment of patients with chronic pain, caused by such factors, with traditional medical therapy has proved totally ineffective and has often led to iatrogenic complications.

As a result of the deficiencies in teaching and transfer of information, some physicians have not appreciated that, because most patients with chronic pain develop complex emotional and behavioral changes, they require extensive psychological evaluation as well as detailed general physical, neurologic, orthopedic, and other special examinations as discussed in Part II of this book. Finally, many physicians do not have a broad perspective of all the available therapeutic modalities, including their indications and advantages and their disadvantages and complications, essential requisites for their proper application.

The inability (or unwillingness) of some physicians and other health professionals to spend several hours for the initial workup of the patient has probably been caused by the pressure of their large clinical practices and lack of interest in, and knowledge of, chronic pain syndromes. Consequently, a correct diagnosis is not made and the patient is started on a course of empirical therapy that usually ends in drug toxicity and other iatrogenic complications and in an endless series of experiences of hopefulness and then disappointments, frustrations, and hopelessness. Many of the patients seen at the University of Washington Pain Center could have been spared the prolonged suffering and disability if, at the initial contact, the physicians could have spent more time to do a proper workup of the patient, or if the patient had been referred to someone who could do so.

The progressive trend toward specialization has led practitioners in the various specialties to concern themselves only with their own narrow approaches to pain. Thus, the anesthesiologist attempts to treat all patients with chronic pain with nerve blocks, the neurosurgeon by cutting pain pathways, the orthopedic surgeon by surgical operations, the general practitioner and internist by prescribing drugs, and the psychiatrist by traditional psychotherapy. This tunnel vision is particularly likely to occur when a specialist practices alone and sees these patients in the isolation of the office. This approach precludes viewing the pain problem within the perspective of the many diagnostic and therapeutic strategies that may be applicable to the particular problem and choosing which are best for the particular patient.

A related causative factor is that many chronic pain syndromes are composed of such complex arrays of sensory, perceptual, psychological, psychosocial, environmental, and other factors as to require the concerted and well-coordinated efforts of the patient's physician and a number of specialists from different disciplines working as a closely knit team to make a correct diagnosis and develop the most appropriate therapeutic strategy. Although Bonica first conceived and practiced this multidisciplinary team approach to complex pain problems in 1945, and subsequently spoke and wrote extensively about it until the late 1960s and early 1970s (see Chapter 11 for references), the pattern of traditional medical practice was not conducive to such team efforts. This concept is discussed in detail in Chapter 11, Chapter 18, and Chapter 109.

The aforementioned deficiencies are not the fault of physicians, nurses, and other health professionals, but of educators who, because of lack of appreciation and concern about the symptomatic treatment of acute pain, cancer pain, and nonmalignant chronic pain, have not included ample education and training in this subject in

the curricula of undergraduate and graduate (residency) programs and in postgraduate (continuing) educational courses. This thesis is strongly supported in part by the fact that review of the 10 textbooks on medicine and surgery (83,84,85,86,87,88,89,90,91 and 92) and 11 on oncology (93,94,95,96,97,98,99,100,101,102 and 103) published in the United States, which are used as standard texts for medical students, house officers, and practitioners, in 1985 revealed that of a total of nearly 27,000 pages, only 0.6% are devoted to the description of symptomatic therapy of acute and chronic pain (i.e., therapy not directed at removing the cause of the pain by medical or surgical means). Similar deficiencies have existed in texts in other countries. Since 1980, journals and books devoted to pain diagnosis and treatment have dramatically increased in number, both in the English language and in many other languages. Furthermore, many comprehensive textbooks have included chapters on pain management. Although few medical schools provide their students with adequate education about pain, some have developed good curricula. In general, nursing schools have done a better job with this subject matter. In some countries, the government has recognized the discipline of pain management as a bona fide specialty; this has greatly improved educational opportunities for medical students and advanced trainees. Some of the improvements are related to the recognition of palliative care as a medical specialty and the inclusion of pain management as an essential part of palliation of illness.

Communication

A matrix common to all of these causative factors has been the poor, and indeed at times total, lack of communication among investigators and between this group and clinicians. Until the mid-1970s, the usual mechanisms for disseminating new information were publications in highly specialized journals limited to specific fields and meetings generally limited to specific groups. These specialized publications and meetings precluded cross-fertilization of ideas and dissemination of information among the various basic scientists and clinicians. The poor interaction among basic scientists of different disciplines has impaired the application of vitally important new information acquired by biochemists, for example, to the pain research programs of neurophysiologists. Moreover, it has impaired interaction and collaboration between basic and clinical scientists, which is essential to solve clinical problems. This lack of communication also has resulted in a great lag in clinical application of new information useful and pertinent to the care of patients with chronic pain. Other major communication problems have included a lack of an international standard terminology (taxonomy) of pain and pain syndromes, and lack of national and international pain data banks or data pools, essential requisites to optimal communication and evaluation of old and new methods of therapy.

ADVANCES

Since the early 1970s, several developments have taken place that, if sustained and expanded, hold the promise of helping to rectify some of the previously mentioned deficiencies. One has been a surge of interest among many basic scientists concerning the mechanisms of acute and chronic pain syndromes, and in collaborating with clinical investigators and practitioners to begin to solve some of the major clinical problems. This has resulted in the acquisition of much new knowledge on the anatomy, physiology, biochemistry, and psychology of acute pain and some new information on the pathophysiologic, psychological, and environmental substrates of chronic pain, most of which are summarized in this textbook. This new knowledge has changed our concept of sensory processing and sensory coding, and, together with recent clinical experience, it has changed our concepts and approaches to diagnosis and therapy of acute and chronic pain.

An important spin-off of recent research has been to bring into sharper focus a point that Bonica made in the first edition of this book, but which was ignored by many investigators and clinicians: that there are significant differences between acute pain and chronic pain in regard to etiology, mechanisms, pathophysiology, function, diagnosis, and therapy. In a paper published in 1981, Sternbach (74) described the contrasting characteristics of acute pain and those of chronic pain and developed, in an intriguing way and an impressively logical sequence, convincing evidence that whereas in acute pain the pain is a symptom of disease or injury, in chronic pain the pain itself is the disease. These differences are emphasized in the next two sections and throughout the book.

Some progress has also been made in some areas of pain diagnosis and therapy. A number of physicians and other health professionals have manifested interest in acquiring more knowledge about pain and its treatment. This has been reflected in part by the large attendance at numerous postgraduate seminars, international, national, and regional symposia and meetings, and at nine World Congresses on Pain sponsored by the IASP, and by the large number of textbooks on pain published during the 1990s and purchased by health professionals. Another encouraging trend has been the surge of interest in the multidisciplinary approach to diagnosis and therapy of chronic pain and in the hospice concept of managing patients with terminal cancer, two developments that Melzack and Wall (72) believe are the most important advances in patient care. These are discussed further in Chapter 11, Chapter 12, Chapter 40, and Chapter 109.

There has also been some progress with regard to communication and transfer of information. The founding of the IASP in 1974 and publication of its journal *Pain* since 1975 must be considered among the most important developments in the field of pain research and therapy. The goals of the IASP are to foster and encourage research on pain mechanisms and pain syndromes and to help improve the management of patients with acute and chronic pain by bringing together basic scientists, physicians, and other health professionals in various disciplines and backgrounds; to promote education and training in the field of pain; to facilitate dissemination of information; to promote triennial World Congresses; to encourage the formation of national chapters; to develop a classification of pain syndromes; and to encourage development of national and international data banks.

IASP has grown (up to 1999) to a membership of some 7,000 persons representing every biomedical science, clinical discipline, and health profession from 95 countries and has fulfilled most of its purposes. The journal *Pain* has acquired a reputation as a prestigious multidisciplinary international publication that publishes high-quality reports of original pain research and therapy, review articles, and other types of information relative to pain. The first nine World Congresses sponsored by IASP attracted the largest number of scientists and health professionals interested in pain research and therapy ever assembled. Through the scientific programs of these Congresses, publication of *Pain*, and publication of the Congress proceedings, IASP has done much to enhance the dissemination of basic and clinical information of multidisciplinary interest.

Through these programs, the IASP has made major contributions to promoting research and disseminating research knowledge and clinically relevant information. IASP's success in bringing together large numbers of research scientists from many disciplines, all having an interest in pain research and maintaining and promoting the high standards of these research areas, is a major achievement. Equally important has been its effectiveness in bringing together scientists and clinicians, thus bridging the gap that heretofore was partly responsible for the great lag in application of new knowledge to the care of patients. The Committee on Taxonomy completed its original task of developing definitions and a classification of various pain syndromes and an initial revision has been accomplished (presented in the next chapter), and the Committee on Research and Ethical Issues has developed guidelines for animal and human experimentation that have received international acclaim. Moreover, most of the 56 chapters of the association, composed of members from 65 countries, have had impressive growth, are active, and contribute to the achievements of the association. Chapter development and other professional societies also have been important in disseminating clinical information. Many other local, regional, national, international, single discipline, or multidisciplinary societies focusing on pain have been established. Some are purely clinical; others have a research focus. These often sponsor journals and meetings that have brought new interest to the problems of pain mechanisms and treatment. Their existence is a sign of the healthy growth in pain research and management.

If one attempts to characterize the last quarter of the twentieth century in contrast to the prior 5,000 years of study and treatment of pain, it is the cross-fertilization of different domains of thought that has led to dramatic advances. Only since 1975 have physicians, philosophers, psychologists, physiologists, moralists, and others who consider the human condition realized the need to study pain from multiple perspectives to move forward in the reduction of human suffering. We no longer accept the inevitability of pain or the suffering it engenders; scientists and clinicians are determined to develop knowledge of mechanisms of pain and effective diagnostic and treatment strategies. Predicting the future is always perilous, but we seem to be close to major breakthroughs in the relief of pain and suffering. The changes that can be documented since 1975 are in no small measure because of the crusading efforts of John J. Bonica, who first made the study of pain and its treatment a goal for twentieth-century physicians and scientists.

FUTURE NEEDS AND GOALS

We end this chapter with the same theme as the end of the introduction to the first edition of this book (77). What is our present position, and what are our needs and goals in improving the management of patients with pain? In the future, we must not only sustain but also markedly increase the current momentum and rapidly expand the gains we have made. The challenge to the biomedical scientific community, health professionals, and society as a whole is to organize, mount, and support a multipronged program. We must exert greater efforts and expend greater energy to solve the mystery of pain and to carry out more effective therapy. Doing so requires that the anatomist, neurophysiologist, psychologist, pharmacologist, and other laboratory investigators join forces with clinical scientists and clinicians to further elucidate the intimate nature of this most vexing perennial human problem. We must also markedly increase our efforts in the education and training of students, house officers, physicians, nurses, and other health professionals to improve the care of patients suffering from pain. We must concern ourselves with this problem, because pain is the day to day business of most physicians, nurses, and other health professionals. We must apply effectively the available knowledge and therapies so that we can reduce prolonged suffering and disability and thus improve the quality of life and social usefulness of millions of patients with pain. The proper management of patients with pain remains one of the most important responsibilities and obligations and can be the crowning achievement of biomedical

scientists and clinicians. It is hoped that this book will contribute to the attainment of this vital human and professional objective.

CHAPTER 2

Pain Terms and Taxonomies of Pain

Dennis C. Turk and Akiko Okifuji

The inherent subjectivity of pain presents a fundamental impediment to increased understanding of its mechanisms and control. The language used by two individuals attempting to describe a similar injury often varies markedly, but appropriate communication requires a common language and classification system used in a consistent fashion. Clinicians and clinical investigators commonly use multiple terms that at times have idiosyncratic meanings. Thus, we have two primary goals in this chapter: (a) to provide definitions for many commonly used terms in the pain literature in an effort to bring about consistency and thereby to improve communication, and (b) to describe and discuss different classification systems or taxonomies, in an attempt to improve communication and to bring consistency to research and treatment of patients reporting pain.

DEFINITION OF COMMONLY USED PAIN TERMS

Discussions of pain involve many terms. The meaning and connotation of these different terms may vary widely. Some authors use the term *pain* to relate to a stimulus, others to a thing, and still others to a response. Such inconsistent usage creates difficulties in communication. As Merskey noted (1), it would be most convenient and helpful if there were some consensus on technical meanings and usage. Based on this belief, the editors of the two editions of the *International Association for the Study of Pain (IASP) Classification of Chronic Pain* included a set of definitions of commonly used pain terms (2,3). In the second edition of this text, Bonica reproduced a list of the terms and, in some cases, provided annotations. We adopt a similar strategy. We follow the convention of IASP, begin with the definition of pain, and then proceed alphabetically. Terms followed by an asterisk come directly from the IASP descriptions of pain terms.

*Pain**: An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.

Pain, acute/pain, chronic[†]*:* Definitions of acute, chronic, recurrent, and cancer pain are not included in the IASP list of pain terms. We believe, however, that it is important to clarify these as they are commonly used in the literature.

Traditionally, the distinction between acute and chronic pain has relied on a single continuum of time with some interval since the onset of pain used to designate the onset of acute pain or the transition point when acute pain becomes chronic. The two most commonly used chronologic markers used to denote chronic pain have been 3 months and 6 months since the initiation of pain; however, these distinctions are arbitrary.

Another criterion for chronic pain is “pain that extends beyond the expected period of healing.” This is relatively independent of time because it considers pain as chronic even when it has persisted for a relatively brief duration. Unfortunately, how long the process of healing will (should) take is ambiguous.

Some hold that pain that persists for long periods of time, in the presence of ongoing pathology, should be considered an extended acute pain state. In this case, treatment targets the underlying pathology. This is not to encourage a Cartesian perspective of pain that distinguishes between mind and body. As the IASP definition clearly states, any pain, acute or chronic, regardless of the presence of identifiable tissue damage, is an unpleasant experience, inherently influenced by various cognitive, affective, and environmental factors. We hold that the weighting of the psychological factors is often greater in chronic pain than acute pain.

We propose conceptualizing acute and chronic pain on two dimensions: time and physical pathology dimensions. Figure 2-1 schematically depicts this two-dimensional conceptualization of acute and chronic pain. From this perspective, any case falling above the diagonal line (short duration or high physical pathology) is acute pain, whereas cases falling below the diagonal line (low physical pathology or long duration) are chronic pain. The perspective presented in Figure 2-1 leads to the following definitions of acute and chronic pain.

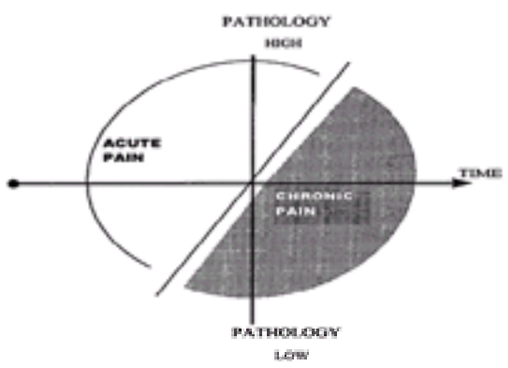

Figure 2-1. Figurative representation of acute and chronic pain.

Acute pain: Pain elicited by the injury of body tissues and activation of nociceptive transducers at the site of local tissue damage. The local injury alters the response characteristics of the nociceptors and perhaps their central connections and the autonomic nervous system in the region. In general, the state of acute pain lasts for a relatively limited time and generally remits when the underlying pathology resolves. This type of pain is often a reason to seek health care, and it occurs after trauma, surgical interventions, and some disease processes.

Chronic pain: It is usually elicited by an injury but may be perpetuated by factors that are both pathogenetically and physically remote from the originating cause. Chronic pain extends for a long period of time, represents low levels of underlying pathology that does not explain the presence and extent of pain, or both. This type of pain prompts patients frequently to seek health care, and it is rarely effectively treated. Because the pain persists, it is likely that environmental and affective factors eventually interact with the tissue damage, contributing to the persistence of pain and illness behaviors. It is also possible that, just as the brain is modified by experience, especially in early life, the brain may alter the way noxious information is processed to reduce or augment its effect on subjective awareness.

Cancer pain: Pain associated with cancer includes pain associated with disease progression as well as treatments. Although some contend that pain associated with

neoplastic disease is unique, we view it as fitting within our description of acute and chronic pain as depicted in Figure 2-1. Moreover, pain associated with cancer can have multiple causes—namely, disease progression, treatment (e.g., neuropathic pain resulting from radiation therapy), and co-occurring diseases (e.g., arthritis). Regardless of whether the pain associated with cancer stems from disease progression, treatment, or a co-occurring disease, it may be either acute or chronic. Thus, we do not advocate a separate classification of cancer pain as distinct from acute and chronic pain.

Recurrent pain: Recurrent pain is episodic or intermittent occurrences of pain, with each episode lasting for a relatively short period of time but recurring across an extended period of time. Our distinction between acute and chronic pain using the integration of the dimensions of time and pathology does not include recurrent pain (e.g., migraine headaches, tic douloureux, sickle cell crisis). In the case of recurrent pain, patients may suffer from episodes of pain interspersed with periods of being completely pain free. Although recurrent pain may seem acute because each pain episode (e.g., sickle cell crisis) is of short duration, the pathophysiology of many recurrent pain disorders (e.g., migraine) is not well understood. Syndromes characterized by recurrent acute pain share features in common with acute and chronic pain. The fact that these syndromes extend over time, however, suggests that psychosocial and behavioral factors, not only physical pathology, may be major determinants of illness behavior.

Transient pain: Transient pain is elicited by activation of nociceptors in the absence of any significant local tissue damage. This type of pain is ubiquitous in everyday life and rarely is a reason to seek heath care. It is seen in the clinical setting only in incidental or procedural pain, such as during a venipuncture or injection for immunization. This type of pain ceases as soon as the stimulus is removed.

Addiction: A behavioral pattern of psychoactive substance abuse, addiction is characterized by overwhelming involvement with the use of a drug (i.e., compulsive use), the securing of its supply, and the high tendency to relapse. The compulsive use of the drug results in physical, psychological, and social harm to the user and use continues despite this harm (see also Physical Dependency).

*Allodynia**: This is pain caused by a stimulus that does not normally provoke pain.

Analgesia: Absence of the spontaneous report of pain or pain behaviors in response to stimulation that would normally be painful. The term implies a defined stimulus and a defined response. Analgesic responses can be tested in animals as well as humans.

*Anesthesia dolorosa**: This refers to spontaneous pain in an area or region that is anesthetic.

*Central pain**: Pain initiated or caused by a primary lesion or dysfunction in the central nervous system.

Central sensitization: This is an increase in the excitability and responsiveness of neurons in the spinal cord.

*Complex regional pain syndrome type 1 (formerly reflex sympathetic dystrophy)**: A syndrome that usually develops after an initiating noxious event, is not limited to the distribution of a single peripheral nerve, and is apparently disproportionate to the inciting event. It is associated at some point with evidence of edema, changes in skin blood flow, abnormal sudomotor activity in the region of the pain, or allodynia or hyperalgesia.

*Complex regional pain syndrome type 2 (formerly causalgia)**: A syndrome of sustained burning pain, allodynia, and hyperpathia after a traumatic nerve lesion, often combined with vasomotor dysfunction and later trophic changes.

Cost-benefit analysis: An evaluation of the costs and effects of an intervention in a common, usually monetary, unit. The standardization of unit has an advantage because it permits comparisons across dissimilar intervention programs. On the other hand, the conversion of treatment effects to monetary units may not always be feasible. Estimation of the cost to outcome ratio is possible, as are comparisons between interventions using the rates of improvement (e.g., return to work) with common denominators.

Cost-effectiveness analysis: An estimation of treatment outcome entails criteria other than monetary terms, such as lives saved or return to work. An intervention is cost effective when it satisfies one of the following conditions: It is more effective than an alternative modality at the same cost; it is less costly and at least as effective as an alternative modality; it is more effective and more costly than an alternative treatment, but the benefit exceeds the added cost; or it is less effective and less costly, but the added benefit of the alternative is not worth the additional cost.

Disability: Any restriction or loss of capacity to perform an activity in the manner or within the range considered normal for a human being, such as climbing stairs, lifting groceries, or talking on a telephone. It is a task-based concept that involves the person and the environment. Disability is essentially a social and not a medical term or classification. Level of disability should be determined only after a patient has reached maximum medical improvement following appropriate treatment and rehabilitation.

*Dysesthesia**: An unpleasant abnormal sensation, whether spontaneous or evoked.

*Hyperalgesia**: An increased response to a stimulus that is normally painful.

*Hyperesthesia**: Increased sensitivity to stimulation, excluding special senses.

*Hyperpathia**: A painful syndrome characterized by increased reaction to a stimulus, especially a repetitive stimulus, as well as an increased threshold.

*Hypoalgesia**: Diminished pain in response to a normally painful stimulus.

Hypochondriasis: An excessive preoccupation that bodily sensations and fears represent serious disease despite reassurance to the contrary.

Impairment: Any loss of use of, or abnormality of psychological, physiologic, or anatomic structure or function that is quantifiable. It is not equivalent to disability. Impairment is to disability as disease is to illness.

Malingering: A conscious and willful feigning or exaggeration of a disease or effect of an injury in order to obtain a specific external gain. It is usually motivated by external incentives such as financial compensation, avoiding work, or obtaining drugs.

Maximum medical improvement: The state beyond which additional medical treatment is unlikely to produce an improvement in function.

Multidisciplinary (interdisciplinary) pain center: An organization of health care professionals and basic and applied scientists that includes research, teaching, and patient care related to acute and chronic pain. It includes a wide array of health care professionals including physicians, psychologists, nurses, physical therapists, occupational therapists, and other specialty health care providers. Multiple therapeutic modalities are available. These centers provide evaluation and treatment and are usually affiliated with major health science institutions.

*Neuralgia**: Pain in the distribution of a nerve or nerves.

*Neuritis**: Inflammation or a nerve or nerves.

*Neurogenic pain**: Pain initiated or caused by a primary lesion, dysfunction, or transitory perturbation in the peripheral or central nervous system.

*Neuropathic pain**: Pain initiated or caused by a primary lesion or dysfunction in the nervous system.

*Neuropathy**: A disturbance of function or pathologic change in a nerve: in one nerve, mononeuropathy; in several nerves, mononeuropathy multiplex; if diffuse and

bilateral, polyneuropathy.

Nocebo: Negative treatment effects induced by a substance or procedure containing no toxic or detrimental substance.

*Nociceptor**: A receptor preferentially sensitive to tissue trauma or to a stimulus that would damage tissue if prolonged.

Nociception: Activation of sensory transduction in nerves by thermal, mechanical, or clinical energy impinging on specialized nerve endings. The nerve(s) involved conveys information about tissue damage to the central nervous system.

*Noxious stimulus**: A stimulus that is capable of activating receptors for tissue damage.

Pain behavior: Verbal or nonverbal actions understood by observers to indicate that a person may be experiencing pain and suffering. These actions may include audible complaints, facial expressions, abnormal postures or gait, use of prosthetic devices, avoidance of activities, overt expressions, and verbal or nonverbal complaints of pain, distress, and suffering.

Pain clinic: Facilities focusing on diagnosis and management of patients with pain problems. It may specialize in specific diagnoses or pain related to a specific area of the body.

Pain relief: Report of reduced pain after a treatment. It does not require reduced response to a noxious stimulus and is not a synonym for analgesia. The term applies only to humans.

Pain threshold: The least level of stimulus intensity perceived as painful. In psychophysics, pain threshold is defined as a level of stimulus intensity that a person recognizes as painful 50% of the time.

*Pain tolerance level**: The greatest level of noxious stimulation that an individual is willing to tolerate.

Pain sensitivity range: The difference between the pain threshold and the pain tolerance level.

*Paresthesia**: An abnormal sensation, whether spontaneous or evoked.

*Peripheral neurogenic pain**: Pain initiated or caused by a primary lesion or dysfunction or transitory perturbation in the peripheral nervous system.

Physical dependence: A pharmacologic property of a drug (e.g., opioid) characterized by the occurrence of an abstinence syndrome following abrupt discontinuation of the substance or administration of an antagonist. It does not imply an aberrant psychological state or behavior or addiction.

Placebo: A substance or procedure without therapeutic effect that is provided as a treatment. It is frequently used to control patients' expectations for the efficacy in testing a treatment intervention.

Placebo effects: Refers to the positive benefit(s) from a placebo preparation or procedure that is generally achieved only with an active treatment intervention.

Plasticity, neural: Nociceptive input leading to structural and functional changes that may cause altered perceptual processing and contribute to pain chronicity.

Pseudoaddiction: Refers to the perception by observers of drug-seeking behavior in patients who have severe pain and are undermedicated or who have not received other effective pain treatment interventions. Such patients may appear preoccupied with obtaining opioids, but the preoccupation reflects a need for pain relief and not drug addiction. Pseudoaddictive behavior differs from true addictive behavior because when higher doses of opioid are provided, the patient does not use these in a manner that persistently causes sedation or euphoria, the level of function is increased rather than decreased, and that medications are used as prescribed without loss of control over use.

Psychogenic pain: Report of pain attributable primarily to psychological factors usually in the absence of any objective physical pathology that could account for pain. This term is commonly used in a pejorative sense. It often suggests a cartesian dualism and is not usually an effective method of describing a patient.

Rehabilitation: Restoration of an individual to maximal physical and mental functioning in light of his or her impairment.

Residual functional capacity: The capacity to perform specific social and work-related physical and mental activities after rehabilitation related to an impairment or when a condition has reached a point of maximum medical improvement.

Symptom magnification: Conscious or unconscious exaggeration of symptom severity in an attempt to convince an observer that one is truly experiencing some level of pain. It differs from malingering as it is an effort to be believed not necessarily to achieve a positive outcome (i.e., secondary gain) such as financial compensation.

Suffering: Reaction to the physical or emotional components of pain with a feeling of uncontrollability, helplessness, hopelessness, intolerability, and interminableness. Suffering implies a threat to the wholeness of an individual's self-concept, self-identify, and integrity.

Tolerance: A physiologic state in which a person requires an increased dosage of a psychoactive substance to sustain a desired effect.

Wind-up, second pain: Slow temporal summation of pain mediated by C fibers. Repetitive noxious stimulation at a rate less than one stimulus per 3 seconds. It may cause the person to experience a gradual increase in the perceived magnitude of pain.

TAXONOMIES

The lack of a classification of chronic pain syndromes that is used on a consistent basis inhibits the advancement of knowledge and treatment of chronic pain and makes it hard for investigators as well as practitioners to compare observations and results of research. Bonica (4) referred to this language ambiguity as “a modern tower of Babel.”

To identify target groups, conduct research, prescribe treatment, evaluate treatment efficacy, and for policy and decision making, it is essential that some consensually validated criteria are used to distinguish groups of individuals who share a common set of relevant attributes. The primary purpose of such classification is to describe the relationships of constituent members based on their equivalence along a set of basic dimensions that represent the structure of a particular domain. Infinite classification systems are possible, depending on the rationale about common factors and the variables believed to discriminate among individuals. The majority of the current taxonomies of pain are *expert-based* classifications.

Expert-Based Classifications of Pain

Classifications of disease are usually based on a preconceived combination of characteristics (e.g., symptoms, signs, diagnostic test results), with no single characteristic being both necessary and sufficient for every member of the category, yet the group as a whole possesses a certain unity (5). Most classification systems used in pain medicine [e.g., International Classification of Diseases (ICD-10) (6), Classification and Diagnostic Criteria for Headache Disorders, Cranial Neuralgias, and Facial Pain (7), International Association for the Study of Pain Classification of Chronic Pain (2)] and dentistry [i.e., Research Diagnostic Criteria for Temporomandibular Disorders (8)] are based on the consensus arrived at by a group of experts. In this sense they reflect the inclusion or elimination of certain diagnostic features depending on agreement.

Expert-based classifications develop preconceived categories and *force* individuals into the most appropriate one, even if not all characteristics defining the category

are present. Expert-based classification systems do not explicitly state the mathematical rules that should exist among the variables used to assign a case to a specific category.

In an ideal classification, the categories comprising the taxonomy should be mutually exclusive and completely exhaustive for the data to be incorporated. Every element in a classification should fit into one and only one place and no other element should fit into that place. An example of such an ideal, natural taxonomy is the periodic table in chemistry. We can also develop artificial classifications such as a telephone directory. The criterion for the classification—namely, the sequence of letters in the alphabet, has no relation to the people, addresses, and telephone numbers being classified; but it is quite satisfactory for the intended purpose (3). No classification in medicine or dentistry has achieved such aims. For example, the Research Diagnostic Criteria for Temporomandibular Disorders (8) includes eight different diagnoses. In one study, more than 50% of the sample received three or more Research Diagnostic Criteria diagnoses (9). Thus, the classifications or diagnoses are not mutually exclusive.

The most commonly used classification system of pain is the ICD published by the World Health Organization. In the most recent edition, the ICD-10 (6), conditions are classified along a number of different dimensions including causal agent, body system involved, pattern and type of symptoms; and whether they are related to the artificial intervention of an operation, time of occurrence, or grouped as signs, symptoms, and abnormal clinical and laboratory findings. Within major groups there are subdivisions by symptom pattern, the presence of hereditary or degenerative disease, extrapyramidal and movement disorders, location, and etiology. Overlapping occurs repeatedly in such approaches to categorization and thus is not ideal even if they serve a useful function.

Further complications arise when clinicians require a separate coding system. In the United States, for example, in addition to the ICD codes a clinician must select Current Procedural Terminology coding schemes for billing purposes. This has created a tendency whereby the fulfillment of the Current Procedural Terminology coding may dictate the ICD selections to justify the procedures. Such practices often needlessly create many diagnoses and additional treatments for billing purposes.

It is clear that the classification of pain cannot approach the ideal found in chemistry or telephone books, but this is not unique to pain; it characterizes medical classification systems in general. Classification in medicine, dentistry, and psychology is a pragmatic activity. It does not provide absolute truth but rather provides categories with which we can work to identify individuals with similar phenomena, prognoses, or causes (3). Currently, the majority of pain classifications in pain medicine rely on various parameters of pain experience such as anatomy, system, severity, duration, and etiology.

Classification Based on Anatomy

Several pain syndromes are classified by body location. For example, low back pain, pelvic pain, and headache each refer to the specific location of symptoms. However, the extent for which the anatomy-based classification of pain is clinically meaningful is limited, at least partially, because of the lack of anatomically defined specificity in the neurophysiology of pain.

Classification Based on Duration

As previously discussed, one common way to classify pain is to consider it along a continuum of duration. Thus, pain associated with tissue damage, inflammation, or a disease process that is of relatively brief duration (i.e., hours, days, or even weeks), regardless of how intense, is frequently referred to as acute pain (e.g., postsurgical pain). Many pain problems can be classified as chronic. For example, pain that persists for extended periods of time (i.e., months or years), that accompanies a disease process (e.g., rheumatoid arthritis), or that is associated with an injury that has not resolved within an expected period of time (e.g., low back pain, phantom limb pain) are all referred to as chronic. As noted, however, a single dimension of duration is inadequate because pathologic factors may be relatively independent of duration.

Classification Based on the Etiology of Pain

Another way to classify pain is based on etiology. The crudest classification of this kind is simply to distinguish somatogenic pain from psychogenic pain (pain of psychological origin). Simply put, when a range of physical examination, diagnostic imaging, and laboratory tests fail to identify the physical basis for the report of pain, pain is automatically believed to have originated from psychic conflict or psychopathology. Variations on the dichotomous somatogenic versus psychogenic classification exist. For example, Portenoy (10) proposed that three primary categories of pain be used—namely, nociceptive, neuropathic, and psychogenic. In this system, somatogenic pain is subdivided into two subtypes that contrast with psychogenic pain.

It is interesting to note that the processes by which clinicians determine whether pain is somatogenic or psychogenic are distinctive. The classification of somatogenic pain is established by identification of positive organic findings, whereas psychogenic pain is indicated only in the absence of positive signs. We question the utility of such a classification scheme.

Classification Based on Body System

Classification may focus on the body system involved. For example, Fricton (11) proposed the use of five categories—namely, myofascial, rheumatic, causalgic, neurologic, or vascular. In this case patients are assigned to one of five rather than two or three categories. However, the decision regarding classification still is based on a single dimension: system for the experience of pain.

Classification Based on Severity

Frequently, pain is classified unidimensionally on the basis of severity (0- to 10-point scale, with 0 being no pain and 10 being the worst pain that can be imagined). Therefore, regardless of the scale's level of measurement, nominal, ordinal, or interval, the construct involves a single dimension.

Mechanism-Based Classification of Pain

The conventional classifications of pain disorders based on anatomy, duration, and systems have drawn criticism for their deficiency in sensibility for guiding treatment or research (12). Woolf et al. (12) support developing a mechanism-based classification of pain, proposing a potential list of pain mechanisms (Table 2-1). They argue that the list needs to include affective, behavioral, and cognitive factors relevant to pain, although they do not specify what these factors may be.

Transient pain
Nociceptor specialization
Tissue injury pain
Primary afferent
Sensitization
Recruitment of silent nociceptors
Alteration in phenotype
Hyperinnervation
Central nervous system mediated
Central sensitization recruitment, summation, amplification
Nervous system injury pain
Primary afferent
Acquisition of spontaneous and stimulus-evoked activity by nociceptor axons and somata at loci other than peripheral terminals
Alteration in phenotype
Central nervous system mediated
Central sensitization
Deafferentation of second-order neurons
Disinhibition
Structural reorganization

Adapted from Woolf C, Bennett G, Doherty M, et al. Towards a mechanism-based classification of pain. Int J Pain 1998;77:227–229.

TABLE 2-1. Categories of pain and possible mechanisms

The mechanism-based classifications of pain differ from the conventional classification in that the former frees pain from diseases that may accompany pain complaints. Mechanism-based classification groups patients who are homogeneous in pain mechanisms but heterogeneous in disease conditions or diagnoses. Woolf

et al. (12) emphasize that their proposal is not to replace but rather to supplement the current system.

The basic premise underlying the mechanism-based classification of pain is helpful, both in guiding treatment and in bridging research to clinical practice in pain medicine. However, the mechanism-based system is still at the conceptual stage. Ongoing efforts to synthesize findings from various areas of pain research will help to formulate this new classification system.

This approach contrasts with our use of two dimensions, time and severity, to distinguish acute and chronic pain (Fig. 2-1). The description of attempts to develop multidimensional classification systems incorporating features of several of the classifications is reviewed in the next section.

Multidimensional Classification of Pain: International Association for the Study of Pain Taxonomy

An alternative to the unidimensional approaches is a multidimensional approach that uses several relevant dimensions rather than a single dimension as the basis for developing the classification system and for assigning patients to a particular subgroup or diagnosis. The IASP has published an expert-based multiaxial classification of chronic pain (1,2) intended to standardize descriptions of relevant pain syndromes and to provide a point of reference. The published taxonomy classifies chronic pain patients according to five axes based on the best published information and consensus: (a) region of the body (axis I), (b) system whose abnormal functioning could conceivably produce the pain (axis II), (c) temporal characteristics of pain and pattern of occurrence (axis III), (d) patient's statement of intensity and time since onset of pain (axis IV), and (e) presumed etiology (axis V) (Table 2-2).

TABLE 2-2. International Association for the Study of Pain: scheme for coding chronic pain syndromes

This system establishes a five-digit code that assigns a unique number to each chronic pain diagnosis. For example, the code for carpal tunnel syndrome is 204.X6. Thus,

200 = Region: upper shoulder and upper limbs
00 = System: the abnormal functioning is attributed to the nervous system
4 = Temporal characteristics: symptoms occur irregularly
X = Patient's statement of intensity and time since onset: this varies by patient
06 = Etiology: degenerative, mechanical

Table 2-3 contains the IASP scheme developed for the coding of chronic pain diagnoses. The IASP classification is the most comprehensive approach to classification of chronic pain syndromes. By design, the IASP classification is a heuristic, multiaxial guide that emphasizes the consideration of signs and symptoms. It excludes assessment of psychosocial or behavioral data.

Definition
Site
System(s) involved
Main features of the pain including its prevalence, age of onset, sex ratio if known, duration, severity, and quality
Associated features; aggravating and relieving agents
Signs
Laboratory findings
Natural course
Complications
Social and physical disability
Pathology or other contributing factors
Essential features and diagnostic criteria
Differential diagnosis
Code based on the five axes
References (optional)

TABLE 2-3. List of descriptions in each syndrome in the International Association for the Study of Pain Classification

To be useful, any classification system must be reliable and valid, but as yet little published research has evaluated the reliability, validity, or utility of the IASP classification. Existing evidence (13) indicates that, although axis I (body region) demonstrated reliable coding across examiners, axis V (etiology) failed to achieve acceptable interrater reliability. The consistency (test-retest reliability) of the IASP taxonomy has yet to be established. Further research is needed to evaluate the psychometric properties of the classification system and to facilitate refinements of the system.

The classifications we have described are only a few examples and are definitely not exhaustive. Various specialists can arrive at classification categories based on clinical experience, published data, and consensus. However, no single system exists for classifying pain patients that is universally accepted by clinicians or researchers. Furthermore, several problems associated with the current classification systems have generated debates and research concerning an alternative classification of pain. We provide several examples to illustrate different attempts to devise alternative taxonomies of pain and chronic pain patients.

Empirically Based Classifications of Pain

Those who advocate the use of empirically derived taxonomies maintain that quantitative analysis should define the relationships of contiguity and similarity among individuals (i.e., the taxonomic system must reflect clinically relevant characteristics that exist in nature, defined by empirical methods rather than based on expert judgment and consensus).

The American College of Rheumatology provides an empirical diagnosis for the classification of fibromyalgia syndrome (FMS). In a multicenter study (14), a group of FMS experts at several medical centers collected FMS-related variables and used those variables in an attempt to differentiate FMS patients from patients with other types of chronic pain syndromes. The acceptable sensitivity and specificity were achieved by two criteria, presence of widespread pain (i.e., above and below the waist, right and left side of the body, and along the midline) and at least 11 of 18 positive tender points on palpation. Other symptoms commonly reported by FMS patients, such as fatigue and stiffness, did not differentiate between FMS and other types of chronic pain. Since publication, most subsequent research seems to conform to this classification system, making it a bit easier to compare results across studies. Nonetheless, debate remains about the extent that this classification contributes to clinical practice.

Several types of empirical methods statistically (e.g., cluster analysis) can identify categories that share relationships derived directly from data rather than hypothesized relationships. This is the case with more traditional consensus-based deductive systems. The results of identification analyses can lead to explicit,

mathematical categories. Physicians can assign patients to specific categories on an objective basis.

Although quantification, replication, and objectivity are the hallmarks of the inductive approach, it is important to acknowledge that all relevant factors cannot be measured by a single classification system. The use of an inductive approach depends on what the investigator chooses to include within the statistical analysis. Thus, in practice, the inductive approach to classification is not a totally objective process that is completely atheoretical. In light of this notion, some advocate the dual-diagnostic approach, using the two loosely defined domains, biophysiologic and psychosocial domains (8,15). In this framework, physiologically homogeneous patients may exhibit a range of psychosocial heterogeneity.

Multiaxial Classification of Pain

Ever since the gate-control model underscored the importance of cognitive-evaluative and motivational-affective factors in the process of pain experience, the importance of integrating the psychosocial domains in the classification of pain has been proposed by a number of clinical investigators. However, as in other domains of pain medicine, the psychosocial classifications of pain have largely depended on the traditionally defined diagnosis system, in this case, identification of psychopathology. Although the psychiatrically defined classification of pain patients may help identify patients with specific psychiatric disorders, thereby directing treatments for those disorders, psychologists have introduced psychological classification systems to identify the specific psychological components (affective, evaluative, motivational) of pain.

Emory Pain Estimate Model

The Emory Pain Estimate Model (EPEM) was the first attempt to integrate the biophysiologic and psychosocial domains in classifying pain patients (16,17). Brena and colleagues arbitrarily labeled the dimensions *pathology* and *behavior*. The pathology dimension includes the quantification of physical examination procedures (e.g., ratings of joint mobility, muscle strength) as well as assigning numerical indices to reflect the extent of abnormalities determined from diagnostic procedures such as radiographic studies. The behavioral dimension comprises a composite of activity levels, pain verbalizations, drug use, and measures of psychopathology based on the elevations of the Minnesota Multiphasic Personality Inventory scales.

Using median divisions on the pathology and behavior dimensions, the EPEM defines four classes of chronic pain patients (Fig. 2-2). Class I patients are characterized by higher scores on the behavior dimension and lower scores on the pathology dimension. It describes these patients as displaying low activity levels, high verbalizations of pain, prominent social and psychological malfunctions, and frequent misuse of medications. Class II patients are those who display lower scores on the pathology and behavioral dimensions. These patients are described as displaying dramatized pain complaints with ill-defined anatomic patterns. However, they do not display significant behavioral dysfunction. Class III represents patients with higher scores on both dimensions, characterized as showing clear evidence of physical pathology and high-intensity illness behavior. Finally, class IV patients are those who have higher scores on the pathology dimension and lower scores on the behavior dimension and thus demonstrate “competent” coping in the presence of a physical pathologic condition.

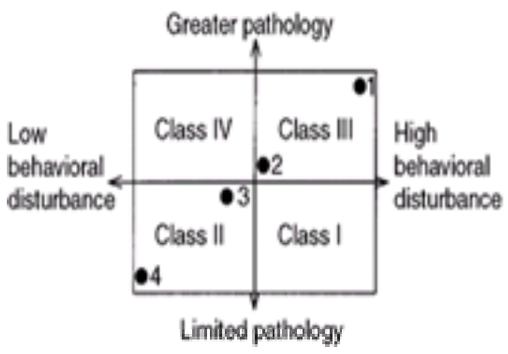

Figure 2-2. The Emory pain estimate model. (From Turk DC, Rudy TE. Classification logic and strategies in chronic pain. In: Turk DC, Melzack R, eds. *Handbook of pain assessment*. New York: Guilford, 1992:409–428, with permission.)

Although Brena and colleagues (16,17) appropriately emphasized the importance of integrating physical and psychological data to develop a classification system for chronic pain patients, some of the basic theoretical and quantitative characteristics of the EPEM are problematic. We see this framework as a conceptual model rather than an adequately operationalized empirical one. For example, from a theoretical standpoint, the inclusion of activity levels, pain verbalizations, and measures of psychopathology under a single dimension labeled *behavioral* is troubling because research shows that little association exists between pain behaviors and psychopathology. Thus, the behavioral dimension is most likely not unidimensional and, therefore, cannot measure behavior directly.

Examination of the empirical aspects of the scoring and classification system used in the EPEM identifies additional problems. For example, the weights assigned to specific medical and physical findings are *a priori* and were not empirically derived. Moreover, applying median divisions to the two dimensions, although intuitively appealing, artificially creates four classes of patients, so no statistical demonstration exists that four nonoverlapping groups of pain patients naturally exist in these data or that, in fact, the pathology and behavioral dimensions are independent. Review of the 2 × 2 grid displayed in Figure 2-2 reveals that within the EPEM extreme scores are treated the same as scores near the medians. For example, the scores of patients 1 and 2, depicted as points in Figure 2-2, would both be assigned to class III, whereas those of patients 3 and 4 would be classified in class II. In reality, however, the scores of patients 2 and 3 are more similar than they are with the scores of patient 1 or patient 4. Thus, this method of establishing classification rules may lead to erroneous or nonindependent patient assignments because it is derived from artificial and external mathematical criteria rather than from divisions or clustering of groups that occur naturally within patients' scores.

Empirically Based Classification of the Psychological Components of Pain

Many taxonomies of pain recognize that the conceptualization and operationalization of cognitive, affective, and behavioral factors associated with pain merit consideration. Numerous instruments assess pain-related psychosocial constructs, but most are unidimensional or inadequate for pain populations, or they lack predictive validity for treatment outcomes. We describe one specific multidimensional psychosocial classification system used primarily with patients with chronic pain conditions.

The Multidimensional Pain Inventory (MPI) (18) consists of a set of empirically derived scales designed to assess chronic pain patients' (a) reports of pain severity and suffering; (b) perceptions of how pain interferes with their lives, including interference with family and marital functioning, work, and social and recreational activities; (c) dissatisfaction with present levels of functioning in family, marriage, work, and social life; (d) appraisals of support received from significant others; (e) perceived life control incorporating perceived ability to solve problems and feelings of personal mastery and competence; (f) affective distress including depressed mood, irritability, and tension; and (g) activity levels. Using the MPI, Turk and Rudy (19) were able to group patients within three relatively homogeneous sets.

Turk and Rudy (19) performed cluster analyses on a heterogeneous sample of chronic pain patients' responses on the MPI scales. Three distinct profiles were identified: (a) dysfunctional (DYS), patients who perceived the severity of their pain to be high, reported that pain interfered with much of their lives, reported a higher degree of psychological distress caused by pain, and reported low levels of activity; (b) interpersonally distressed (ID), patients with a common perception that significant others were not very supportive of their pain problems; and (c) adaptive copers (AC), patients who reported high levels of social support, relatively low levels of pain and perceived interference, and relatively high levels of activity. Reliable, external scales supported the uniqueness of each of the three subgroups of patients. Performing a 12-dimension Bayesian calculation to test goodness of fit can identify the profile that best fits a patient.

In addition to categorical classification that assigns an individual patient to a specific diagnosis, the empirical-statistical approach permits judgments about how well a patient matches the central features of that diagnosis. This is especially useful in complex pain syndromes that involve various clinical characteristics with rather large individual variability, even within a single diagnostic group. Using an empirical method, one can not only establish whether a patient fits the diagnostic classification but also determine how good a fit to the diagnosis the patient is. For example, based on a set of patient characteristics, signs, and symptoms, a prototype for a diagnosis is established. It is possible to determine statistically how close an individual case matches that prototype. Assume that a perfect match to a prototype is

0.99. A particular case may fit within the diagnosis but not be a perfect fit; thus the fit might be 0.80. Some statistical rule can decide the minimum fit to the characteristics of the diagnosis—say, for example, 0.67. Thus, any two individuals with the same diagnosis must share certain characteristics but not necessarily all; the similarity of two patients with the same diagnosis has a statistical definition.

Subsequent testing of the MPI profiles across various pain disorders suggests that the MPI psychosocial classification is independent of the conventionally defined pain syndromes, such as low back pain, migraine headaches, fibromyalgia syndrome, and pain associated with cancer. In other words, two patients whose pain pathologies are likely to differ (e.g., those with cancer and migraine headaches) could have a homogeneous psychological classification of pain. On the other hand, two patients, both having same type of temporomandibular pain, based on the Research Diagnostic Criteria for comparable duration (8), may fare differently in the psychological classification of pain. Clinical trials using the MPI-based classification have consistently yielded differential responses to a cognitive-behavioral approach (20,21). Such results strongly suggest that the psychosocial treatment components need to conform to the psychological classification of pain.

We suggest that disease classification should reflect physical assessment and treatment (e.g., 2) and that a psychosocial-behavioral taxonomy should determine complementary psychological treatment strategies. Physical and psychosocial diagnoses are important in the person suffering from a chronic pain syndrome. Several groups (8,15,22) have proposed the use of a dual-diagnostic approach, whereby two diagnoses are assigned concurrently, physical and psychosocial-behavioral. Treatment could then target both simultaneously. A chronic pain patient might have diagnoses on two different but complementary taxonomies (e.g., IASP and MPI-based classification). Thus, a patient might be classified as having Complex Regional Pain Syndrome, Type 1 (CRPS-1) of the upper extremity (203.X1, Axis I Region = Upper Shoulder and Upper Limbs; Axis II System = Nervous; Axis III Temporal Characteristics of Pain: Pattern of Occurrence = none of the codes listed; Axis IV Intensity and Time of Onset = based on patient report; Axis V Etiology = Trauma) on the IASP taxonomy and be classified DYS on the MPI-based taxonomy. Note not all CRPS-1 patients would be classified as DYS and not all DYS patients would have CRPS-1. A second patient might have the same IASP diagnosis, CRPS-1, but be ID on the MPI-based classification. Conversely, patients might have quite different classifications on the IASP system but have the identical MPI-based classification. The most appropriate treatment for these different groups might vary, with different complementary components of treatments addressing the physical diagnosis (IASP) and the psychosocial diagnosis (MPI-based).

Psychometric Considerations

The general utility of any proposed empirical taxonomy links closely to the psychometric properties (i.e., reliability, validity, and utility) of the measures, scales, or instruments used to derive the classification system. Because these are the building blocks used to generate profiles or clusters, the reliability and validity of the classification system depend, in part, on the psychometric quality of the measures used. Because reliability and validity coefficients are generic terms, the specific psychometric techniques used to evaluate a measure's *psychometric properties* require consideration. Multiple ways exist to demonstrate the reliability and validity of measures. Therefore, the more psychometric support there is for a measure, the more likely it will perform well when used in taxonometric identification and classification procedures. Additionally, replication of classification accuracy on new samples and demonstrating substantial, statistically significant differences across patient profiles for conceptually related measures external to the measures used to develop the profiles are some of the best ways to demonstrate the reliability and validity of empirically derived profiles. Evaluation of any classification should demonstrate reliability, validity, and utility before widespread adoption.

CONCLUDING COMMENTS

Pain management specialists have witnessed rapid advances in the basic sciences and clinical arenas of pain medicine since the 1970s. Many pain-related terms, once a major source of confusion, have received clear definitions, aiding efficient and productive communications among researchers and clinicians. The classification systems that direct our research and clinical practice need to reflect the progress in our understanding of mechanisms, multifactorial integration, and outcome predictability of classification criteria. In this chapter, we reviewed several conventional classifications as well as emerging classification systems that can supplement the conventional ones. The review of various classification systems suggests that the comprehensive taxonomy of pain requires multifactorial assessments (Table 2-4).

Pain parameters
Anatomy/system
Duration/intensity/quality
Associated abnormality (physical/psychological)
Underlying diseases
Signs/symptoms
Pain mechanisms
NEUROPHYSIOLOGIC
Primary afferent involvement
Central nervous system involvement
PSYCHOLOGICAL
Cognitive-affective-behavioral involvement
Cognitive appraisal of pain
Coping
Affect/mood
Environment

TABLE 2-4. Taxonomy of pain based on multifactorial assessment: a proposal

The multiaxial approach to the assessment of pain and dysfunction described earlier appears to be a reasonable strategy to adopt. Given a comprehensive set of physical, psychosocial, and behavioral measures, the strategy of matching patients to existing classification systems could provide a basis for treatment decisions. The use of the dual-diagnostic approach holds promise because it incorporates biomedical, psychosocial, and behavioral data in the assignment of patients to empirically derived categories. Future research needs to relate patient classification to performance on standardized physical capacity assessment protocols, rehabilitation, and ability to engage in gainful employment and regular homemaking activities.

The utility of any classification system depends on application. The important question is whether assignment of an individual to a class truly facilitates treatment decisions or predictions of future behavior. Few of the taxometric systems have demonstrated their utility to predict treatment outcome (15). Preliminary results on the MPI-based classification demonstrate the potential of such an approach (20,21). Research efforts to evaluate the predictive value of any classification of pain need to demonstrate the validity of that classification system or taxonomy.

[†]The discussion describing the distinction between acute and chronic pain reflects on deliberations among the editors of this volume.

CHAPTER 3

Peripheral Pain Mechanisms and Nociceptor Plasticity

Margaret R. Byers and John J. Bonica

This chapter summarizes the structure, physiology, pharmacology, cytochemistry, molecular biology, tissue interactions, and plasticity of the peripheral nervous system in relation to nociception. Until the early 1980s, the peripheral components of pain have been explained primarily in terms of a specific, twofold wiring system (A-d nociceptors for faster sharper *first* pain, and C fibers for the slower conduction of dull ache or *second* pain). This was based on the concepts of Sherrington (1) and included subdivisions for thresholds and modalities within those two groups, sensitization following injury, sympathetic interactions, and distinctive features for skin, compared with deep, visceral, and articular tissues. However, mismatches between that simple afferent scheme and the complex nature of clinical pain were apparent to pioneers such as Lewis (2) and Bonica (3) in their analyses of chronic pain and conditions such as causalgia and other sympathetically mediated pains. These complexities began to be explained in the 1960s and 1970s (4,5,6,7 and 8) with better understanding of polymodal mechanisms, sympathetic and sensory interactions, endogenous pain modulation, neuronal plasticity, and more detailed information about neural events in the periphery in relation to nociception and pain perception (9,10,11,12,13,14,15,16,17,18,19,20).

Since the 1980s and especially the late 1990s, there have been enormous advances in understanding the cellular interactions, neuroplasticity, and molecular mechanisms that support the nervous system in general. Many of the mechanisms that underlie peripheral aspects of acute nociception, chronic inflammatory and neuropathic pain, sensory neural efferent functions, sympathetic interactions, and sensory contributions to inflammation, immune defense, and wound healing are now becoming clear (21,22,23,24,25,26,27 and 28). The discovery of complex growth factor regulation of nociceptor development and mature function now suggests that two different classes of C fibers exist: (a) the polymodal receptors that are regulated by nerve growth factor (NGF) and (b) the more specific nociceptors that are regulated by glial-derived neurotrophic factor (29), with the former more affected by tissue inflammation and the latter by nerve injury (30,31).

The tidal wave of discovery concerning nociceptive molecular and cellular neurobiology has begun to suggest that the peripheral endings of nociceptors rival the complexity of the dorsal horn for processing afferent information (22,28,32). The nociceptors serve as gatekeepers that survey peripheral information to send to the central nervous system (CNS). Numerous specific molecules in the membranes of the nociceptors affect signal generation, and their actions excite or inhibit the endings, thus providing a composite picture of tissue conditions via the patterns and volume of signals that arrive at the dorsal root ganglion and CNS. For example, nociceptive neurons have specific receptors for excitatory amino acids, capsaicin, adenosine triphosphate (ATP), tachykinins, protons, prostaglandins, opoids, noradrenalin, neurotrophins, and bradykinin (28,32,33) with which they can *read* the tissue and convey an edited report to the CNS. When a tissue becomes inflamed or a nerve is injured, many of those specific molecules change expression or activity, and others, such as the a_2-adrenergic receptor (34) or cyclooxygenase-2 enzyme (35), are inducible.

The C, A-d, and A-b nociceptive neurons each have a repertoire of different functional phenotypes that are elicited by different tissue conditions. Those conditions include the various stages and intensities of inflammation, neuropathic injuries and metabolic disease, or regeneration and healing to provide optimal neural functions and tissue integrations for each of those conditions. Their thresholds and other physiologic and pharmacologic properties differ for each phenotype, so that the CNS can receive different types of information for each condition. One subgroup of the C and A-d primary afferents makes up the polymodal receptors, described in detail in the section Polymodal Receptors, later in this chapter. Those have the widest set of stimulus energies to which they respond, a wide dynamic range, and a variety of phenotypic shifts to match tissue condition. However, most of the rest of the primary afferents involved in pain also respond to multiple types of stimuli, they are affected by injury and inflammation to alter their cytochemistry and function, and they have different phenotypes. Even the mechanically silent nociceptors, which are difficult to activate from healthy tissues but become increasingly active during inflammation, can be considered to have a quiet phenotype related to healthy conditions and an active one for inflammation. Finally, the A-b fibers that are sensitized by inflammation to drive mechanical allodynia have a different phenotype during inflammation when compared with their resting state.

This expansion of our understanding of specific mechanisms of nociceptive pharmacology is leading to important new drugs and strategies for pain management (26,36,37,38,39,40 and 41). In addition, much of the mystery for the efficacy of placebo and alternative medicine procedures is beginning to make sense in relation to modulation of tissue conditions and nociceptors by stress or relaxation, endogenous opiates, endocannabinoids, hormones, nutrition, massage, acupuncture, and exercise (42). Indeed, plasticity of nociceptor mechanisms, the sympathetic and nociceptor interactions after nerve injury compared with those during tissue inflammation, and the powerful effects of complex afferent input (including afferent immune information) on central mechanisms have been major missing pieces of the puzzle of pain. Research during the 1990s is beginning to elucidate this multifaceted story, with significant effects on development of new therapeutic drugs.

In this chapter, we have retained much of Bonica's encyclopedic overview of the anatomy, physiology, biochemistry, and pharmacology of nociception while adding new information from the 1990s that greatly expands our knowledge of the peripheral neural contributions to pain. The chapter is accordingly reorganized into sections on the (a) peripheral nervous system, (b) physiology of nociception, (c) polymodal receptors, (d) pharmacology and modulation of nociception, (e) peripheral mechanisms of persistent pain, including a discussion of experimental models of pain, (f) genetics of pain, and (g) conclusions and therapeutic horizons. The types of afferent electrophysiologic, cytochemical, endocrine, and immune information that flow into the CNS after injury are obviously modulated by interactions in the spinal or medullary dorsal horn before further transmission to the brain (Fig. 3-1 and Fig. 3-2). The specific details of spinal and supraspinal basic mechanisms for pain and plasticity, as well as descending controls and other central modulating systems, are presented in Chapter 4 and Chapter 5. Additional discussion of basic peripheral neural components related to pain, including the autonomic system, can be found in Chapter 8, Chapter 9 and Chapter 10, and in the many chapters on general and regional pain syndromes, especially those that concern neuropathic pains. Much greater detail about this vast and rapidly evolving story is presented in the review by Millan (28).

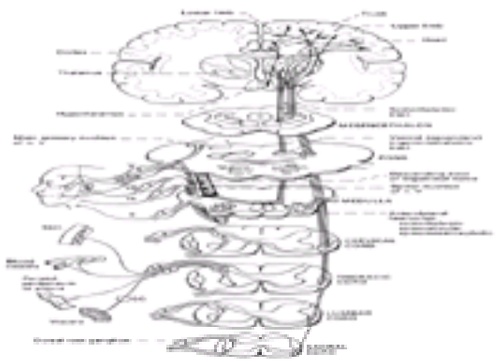

Figure 3-1. Schema of the primary neural pathways for transmission of nociceptive information from various body structures to the brain. The figure forms the basis for detailed discussion of various parts of the *pain* system in Chapter 3, Chapter 4 and Chapter 5. (n., nerve; SG, sympathetic ganglion; V, VII, IX, X, cranial nerves.)

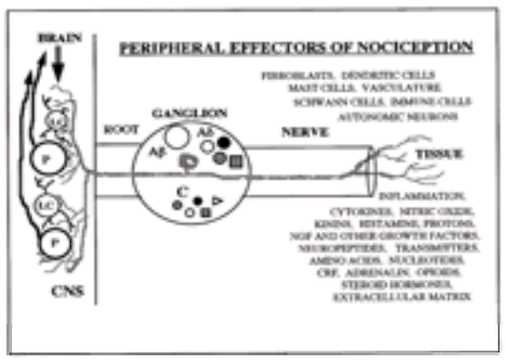

Figure 3-2. Overview of the peripheral cells and factors that modify the flow of information in sensory nerves from tissues through the sensory ganglion (dorsal root, trigeminal, or visceral) and into the central nervous system. Sensory neuronal types that affect pain are represented in each group (A-b, A-d, C) as follows: *Open circles* represent normally mechanoreceptive or thermoreceptive neurons that have altered cytochemistry and activity in inflamed tissue; *black circles*, nociceptive-specific; *gray squares*, silent nociceptors; *gray circles*, polymodal nociceptors; and *open triangle*, GDNF (glial derived neurotrophic factor)-dependent C fibers. Each projection neuron (*P*) is modulated by local circuit (*LC*) neurons and by descending input from supraspinal centers, both of which can also affect primary afferent endings. Many of the key peripheral cell types and factors that affect primary afferent function are listed.

PERIPHERAL SYSTEM

Nociception and Antinociception

Pain is a complex constellation of unpleasant sensory, emotional, and mental experiences and certain autonomic (involuntary) responses and psychological and behavioral reactions provoked by tissue damage. Injury to tissues, whether induced by disease, inflammation, or accident (or provoked by surgical operation or other therapeutic measures) constitutes a noxious stimulus and causes cellular breakdown with liberation of biochemical substances. These activate special receptors on nociceptors that can be sensitive to heat, cold, mechanical stimuli, or chemical mediators. All tissues are also innervated by polymodal C and A-d receptors that have (a) extensive branching of their peripheral endings, (b) a wide range of effective stimuli, (c) a wide dynamic range that includes nonnoxious thresholds, (d) numerous unperceived neuroeffector functions that regulate tissue homeostasis and affect inflammation and wound healing, and (e) a versatile ability to shift their functional and cytochemical phenotype depending on tissue conditions (23). In addition, all tissues also have many afferents that are unresponsive in normal tissues, but that become active during inflammation, called *silent nociceptors* (43,44) as well as some A-b fibers that become chemosensitive during inflammation and affect CNS pain pathways (45). All of these different peripheral nerve fibers exhibit plasticity that can be rapid (seconds) or delayed (hours to days) and is dependent on electrophysiologic properties, growth factors, cytokines, or other tissue factors (see Fig. 3-2).

Although nociceptive impulses are often called *pain* impulses, pain is not experienced until information reaches the brain in normally conscious persons, in which the sensory and emotional experience takes place. Early systems of nociceptor classification used terms such as *acute* versus *chronic pain* or spoke in terms of specific tissues or body regions. However, it has been suggested that nociception categories should be redesigned to reflect basic mechanisms (46). In this chapter, nociceptive activity is subdivided into three levels of injury: *transient* (no significant tissue or nerve damage); *reversible* (moderate damage to tissue, nerve, or both, but healing or regeneration occurs within days or weeks by local defense mechanisms, without persistent pain); and *irreversible* (persistent tissue inflammation, tissue loss, and/or neuropathic injury that induce persisting alterations in peripheral and central nerves and pain mechanisms) (Fig. 3-3). Nociception also is discussed here in terms of various neuronal features: (a) cell body size and cytochemistry, (b) peripheral receptor structure and tissue specificity, (c) physiologic parameters, (d) pharmacology of the peripheral endings, and (e) pharmacology and distribution of the central endings. In addition, polymodal receptor functions are discussed separately.

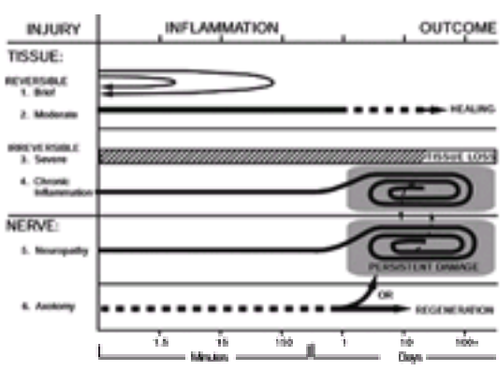

Figure 3-3. Six different outcomes of tissue or nerve injury are diagrammed in relation to a log time scale from minutes to more than 100 days. Reversible tissue injury is either (1) transient, with no long-term effects, or (2) moderate, with successful healing but some scarring and alterations. Irreversible tissue injury includes (3) tissue amputation and (4) persistent damage caused by chronic inflammation. Nerve injury can be reversible (not shown), (5) persistently damaged, or (6) partially or completely regenerated.

Nociceptive and polymodal impulses from tissues below the head are transmitted via fibers in spinal nerves and the vagus nerve that synapse with interneurons or second-order neurons in the dorsal horn of the spinal cord. Afferent information from the head related to pain is carried in fibers that synapse with neurons in the trigeminal sensory nuclei, in particular the spinal subnucleus caudalis (see Fig. 3-1). At this first synapse, the nociceptive impulses are subjected to other influences coming from the periphery, from interneurons of the spinal cord or the trigeminal subnuclei, and from the supraspinal control systems, all of which determine the further processing of these afferent signals of tissue damage. After being subjected to these modulating influences in the dorsal (posterior) horn, some of the nociceptive impulses pass directly or through interneurons to the ventral and ventrolateral horn cells of the same and adjacent spinal cord segments, in which they stimulate somatomotor and preganglionic sympathetic neurons, respectively, and provoke segmental nocifensive reflex responses. Nociceptive impulses also activate other neurons, the axons of which make up the ascending systems that pass cephalad to the brainstem and the brain to provoke suprasegmental reflex responses, the powerful motivational drive and unpleasant affect and other psychological reactions, and activate the motor systems that determine behavior discussed in Chapter

4 and Chapter 5. Pain provoked by injury or disease is the net effect of many simultaneously interacting biochemical, physiologic, and psychological mechanisms that involve activity in most parts of the nervous system concerned with sensory, motivational, and cognitive processes and psychodynamic mechanisms. More recent work also has demonstrated that cytokine signaling from the immune system affects sensory afferents, especially those in the vagus nerve, with important influences on the brain, illness behavior, intensity, and duration of pain (27,47). These interactions are modulated in complex ways during persisting tissue inflammation, neuropathic injury, or metabolic diseases, with profound changes in neural mechanisms in the tissue, nerve, ganglion, root, and central endings (see Fig. 3-2) and at autonomic ganglia, in the afferent immune system, in the dorsal horn or trigeminal nuclei, and in supraspinal and modulatory systems.

Just as the CNS has a range of modulatory systems that either facilitate pain or inhibit it, the peripheral primary afferents not only signal tissue damage and become sensitized by inflammatory mediators, but they also can be inhibited by endogenous analgesic mechanisms. This phenomenon has been called *antinociception*, and several categories of endogenous antinociceptive agents now exist, such as endocannabinoids, opioid peptides, adenosine, and the cytokine leukocyte inhibitory factor (48,49,50,51 and 52). The primary afferents also produce a set of peptides that counteract their own hypersensitivity and excitotoxicity, such as galanin, vasoactive intestinal peptide, and neuropeptide Y (53,54 and 55) . The pharmacology and modulation of peripheral neurons are exceedingly complex, as indicated in Pharmacology and Modulation of Nociception, later in this chapter. The great advances in our understanding of the pharmacology of pain during the 1990s offer a variety of avenues for the management of pain, because each of the excitatory mechanisms can be a target for custom-designed analgesic drugs, and it should be feasible to selectively activate the inhibitory antinociceptive systems for enhanced endogenous analgesia (22,26). Indeed, the efficacy of acupuncture and other alternative medical treatments appears to involve some activation of endogenous antinociceptive pharmacology (42).

Peripheral Nerves

Peripheral nerves consist of somatic motor axons, autonomic axons, and somatic and visceral afferent sensory axons that are connected to the CNS via the dorsal or ventral roots (Fig. 3-4). A cross-section of a peripheral nerve shows various sizes of single myelinated axons (outside diameter ranging from 1.5µ to 20.0 µ) and clustered unmyelinated axons (diameter range, 0.2µ to 2.0µ), each with a basal lamina outside the Schwann cell and collagen of the endoneurium beyond that, plus endoneurial capillaries, and a special perineurium barrier around each fascicle (see Fig. 3-5). The outermost sheath of a peripheral nerve, the epineurium, serves to protect and cushion the nerve, and it contains loose strands of collagenous fascia, blood vessels, fat, and an important neural innervation, the *nervi nervorum* (Fig. 3-5) made up of noradrenergic sympathetic fibers and peptidergic polymodal receptor axons (56,57 and 58). The nervi nervorum play an important role in neuropathic pain conditions and neuritis (59,60). They can have different local pathologic reactions depending on their particular nerve (61), and they also include the sympathetic axons that sprout around sensory cell bodies after peripheral nerve lesions (62,63). Different peripheral nerves have different proportions of nociceptive, polymodal, and nonnociceptive somatic axons, as well as visceral sensory, somatic motor, and autonomic motor axons; those differences confer different peptide expression profiles on normal nerves (64). Thus, an injury affects quite different populations of axons depending on which nerve is involved and where the injury occurs along its course.

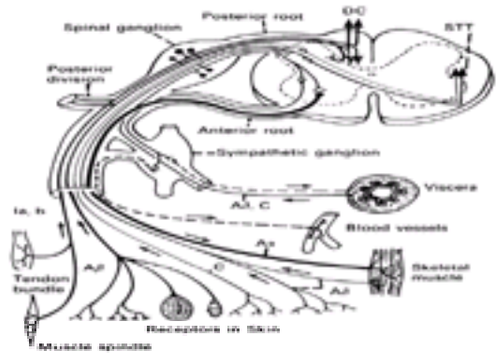

Figure 3-4. A simplified schema of a spinal nerve and the different types of fibers contained therein. (DC, dorsal columns; STT, spinothalamic tract; see Table 3-1 for fiber type.)

Lloyd/Hunt system	Diameter (µm)	Latter system	Conduction velocity (m/sec)	Myelin	Receptor/ending type
Ia*	12-20	–	70-120	+	Muscle spindle primary ending
Ib*	12-20	–	70-120	+	Golgi tendon organ
–	12-20	A_α	70-120	+	Muscle efferents (extrafusal)
II	6-12+	A_β†	30-70	+	Encapsulated ending (Meissner, Ruffini, Pacinian); interfal intrafusal muscle spindle secondary ending
–	3-10	A_γ	15-50	+	Muscle efferents (intrafusal)
III	1-6	A_δ	5-30	+	A_δ specific nociceptors; A_δ polymodal nociceptors; cold receptors; most hair receptors; some visceral receptors
–	<3	B	3-15	+	Preganglionic autonomic
IV	<1.5	C	0.5-2.0	No	C-nociceptors; C polymodal receptors; some visceral receptors; warmth receptors; some mechano-receptors; postganglionic autonomic motor/c nerve fibers

*Data mostly from cats. Velocity in primates and humans has been measured up to 80 m/sec.
†Some afferents in articular joint afferents can conduct up to 17 m/sec. These are sometimes classified as A_α, but sometimes all mammalian afferents are all considered to be A_β.

TABLE 3-1. Classification Of Fibers In Peripheral Nerves*

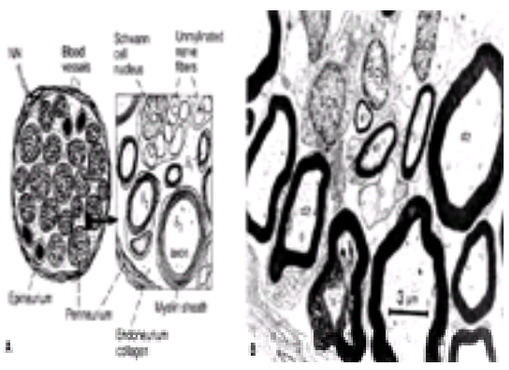

Figure 3-5. **A:** Diagram of a cross-sectioned peripheral nerve showing the many fascicles, each with its own endoneurium collagen and perineurium sheath. The whole nerve has its own innervation of epineurium and vasculature by the nervi nervorum (NN). The higher magnification panel shows details of the ensheathing Schwann cells and their nucleus (SCN) for groups of unmyelinated (C) axons or for single myelinated axons. The A-d axons can be thin and slow (d_1) or larger and faster (d_2). **B:** This electron micrograph of tibial nerve of rat shows a variety of myelinated axon sizes, including small (d1) and larger (d2) A-d fibers, and some bundles of unmyelinated C fibers of various sizes (*). Some of the Schwann cell nuclei are indicated (SCN) (magnification, × 7,000; scale, 3 µm).

A summary of the ranges of conduction velocities and stimulus specificities for axons in peripheral nerves is given in Table 3-1. Within each conduction group (A-a, A-b, A-d, and C) a wide range of rates and corresponding axon calibers occurs (see Fig. 3-5) to give a complex gradient of conduction information. The sensory data are usually recorded from peripheral axons in the proximal part of the nerve in which conduction is fastest. However, sensory axon caliber and conduction velocity decrease markedly in the peripheral branches and preterminal fibers (65), and the central axons are thinner and slower than the peripheral axons, so that there is a set of differing conduction rates along a sensory axon, as well as a range of maximal rates within each group (6). With injury or inflammation, changes in neuropharmacology affect all types of nociceptors (66), including recruitment of A-b fibers into the peripheral mechanisms of hypersensitivity (45). Evidence now

suggests that fundamental neuronal properties, such as duration of action potential (AP), afterhyperpolarization, or conduction velocity shift during inflammation (67), suggesting major changes in membrane channel distribution, type, and regulation (30,31).

Each axon in peripheral nerves requires ensheathment by support cells, called *Schwann cells*, to conduct potentials at the correct rates. Schwann support cells for unmyelinated axons enclose groups of axons, whereas the myelinating Schwann cells only ensheath one axon (Fig. 3-6; see Fig. 3-5). Special Schwann cells are associated with the receptive endings, called *terminal Schwann cells*. Special support cells that are derived from Schwann cells, called *satellite cells*, surround the cell body and its stem axon. Once the axon enters the CNS, it acquires glial sheath cells (Fig. 3-7). During development, the linear relationship between diameter and velocity persists while both increase fourfold, and internodal length is similarly correlated in young and mature animals with animal size (68).

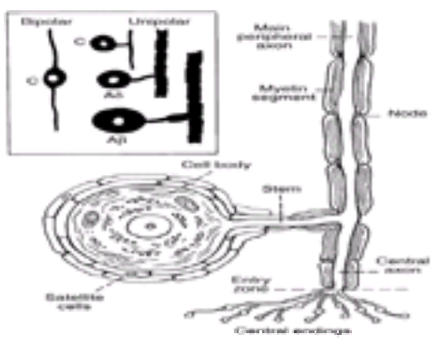

Figure 3-6. The associations of an A fiber with satellite cells, stem axon, peripheral and central branches of the main axon, myelin segments, nodes, and central nervous system entry zone are shown. At the entry zone the central axon switches from Schwann to oligodendroglial support cells (not shown). *Inset*: Primary afferent cell body shape is indicated for bipolar visceral C fibers, and unipolar cell bodies for somatic C, A-d, and A-b sensory neurons.

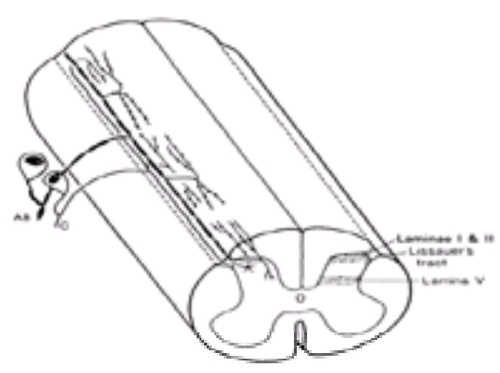

Figure 3-7. Three-dimensional diagram depicting the extensive field of A-d and C fibers after bifurcating at the point of entry in Lissauer's tract. The small-diameter fibers extend for several millimeters before terminating in the superficial dorsal horn (laminae I and II) where they contact dendrites and somas of many hundreds of spinal neurons. The A-dnociceptors and C-visceral afferents also have terminal branches that end in lamina V. (From Fields HL. *Pain*. New York: McGraw-Hill, 1987:45, with permission.)

The somatic motor nerve fibers have multipolar cell bodies located in the ventral (anterior) horn of the spinal cord or the motor nuclei of the cranial nerves, and their axons pass distally via the ventral root of spinal nerves, or the motor roots of the cranial nerves, to their motor end-plates in skeletal muscles (see Fig. 3-4). Skeletal muscle function depends on sensory signals from the annulospiral fibers and secondary sensory receptors in the spindles and the sensory Golgi tendon organs. As might be expected from the intricacy and speed of skeletal muscle reflexes and functions, the main motor fibers and the spindle and tendon sensory fibers are the fastest fibers in the body, conducting up to 120 M per sec, and can have diameters up to 20 µm (Table 3-1). Muscle function also requires gamma efferent motor fibers to the muscle spindles, for adjustment of spindle tension via contraction of the intrafusal muscle fibers, and it requires numerous sensory fibers in the muscle and tendon that include many thin polymodal receptors (Fig. 3-8) (69,70).

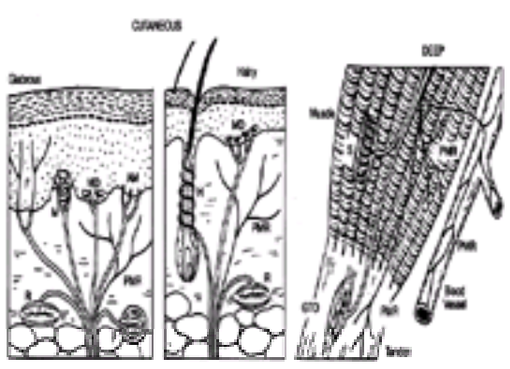

Figure 3-8. Schematic diagrams of the structure and position of various types of sensory receptors in integument (glabrous and hairy cutaneous skin) and a deep tissue (muscle and tendon). All tissues have polymodal receptors (PMR) in addition to their specialized sensory innervation. (AM, intraepithelial A-mechanoreceptors; F, free; GTO, Golgi tendon organ; H, hair mechanoreceptors; M, Meissner corpuscle with attachments to the epithelium; MD, Merkel disks; P, Pacinian corpuscle; R, Ruffini mechanoreceptors with open-ended capsule; S, various types of muscle spindle receptors.)

Autonomic sympathetic preganglionic neurons have their cell bodies in the intermediolateral horn of the thoracolumbar spinal cord and pass distally via the ventral (anterior) root of thoracolumbar spinal nerves and thence sequentially through the formed nerves, the white rami communicantes, and the paravertebral sympathetic ganglion chain to synapse there (or in the prevertebral ganglia) with postganglionic sympathetic neurons. The postganglionic sympathetic axons are unmyelinated and travel in cardiac or splanchnic nerves, via the gray rami to somatic nerves, or via the gray ramus and dorsal root to the vasculature of the sensory ganglia. The sympathetic fibers have extensive interactions with sensory fibers in nociception (34,62), as described below (see Sympathetic Interactions with Primary Afferents). The main parasympathetic preganglionic fibers travel via cranial (III, V, VII, IX, and X) or sacral nerves to their postganglionic neurons in various cranial, visceral, vascular, or urogenital tissues. Also, numerous small parasympathetic clusters of postganglionic neurons exist in some tissues, such as tongue or along blood vessels, and there can be important sensory and parasympathetic interactions in some pain conditions (71). The preganglionic and postganglionic autonomic neurons are multipolar cells that vary in size and form as well as numbers and lengths of their processes. The sympathetic and parasympathetic actions counterbalance each other to promote homeostatic control of involuntary functions such as circulation, respiration, digestion, elimination, and exocrine secretion. In most tissues, the sympathetic vasoregulatory actions are opposed by sensory neuropeptides. The autonomic modulation of nociception is described in greater detail in Pharmacology and Modulation of Nociception, later in this chapter, and in Chapter 8.

The somatic sensory nerve fibers have their unipolar cell body in the dorsal root ganglion of a spinal nerve and send axonal projections to sensory receptors in the periphery (see Fig. 3-8) and to presynaptic terminals in the dorsal horn (see Fig. 3-7). Visceral sensory afferents from cardiopulmonary, gastrointestinal tract, urogenital organs, and solid viscera are major components of the vagus nerve, with the somatic sensory cell bodies for that nerve located in the superior (jugular) ganglion and the numerous visceral sensory cell bodies in the large, inferior (nodose) ganglion. An auxiliary visceral sensory ganglion also is present on the

glossopharyngeal root (inferior ganglion). Other visceral afferent fibers are also part of the facial and trigeminal ganglia, and general visceral afferents make up approximately 10% of dorsal root ganglia.

An additional component of the peripheral nervous system is the enteric system, confined within the walls of the gastrointestinal tract. It contains as many neurons as the spinal cord, and it is primarily concerned with regulation of peristalsis, digestion, nutrient uptake, and fluid exchange. Interactions between the enteric neurons, the immune system, visceral afferents, and vasoregulatory innervation of the gut may contribute in important ways to pain conditions such as irritable bowel syndrome or Crohn's disease and need further research (72).

Finally, paraganglia exist along some peripheral nerves, notably the vagus nerve, that participate in modulation of pain by responding to the cytokines that are released during immune responses, such as interleukin-1b, and then activating afferent fibers either by direct synaptic connections or indirectly to affect pain and illness behavior (27,47). The chromaffin cells of those paraganglia, as well as peripheral cell types, such as mast cells, lymphocytes, and macrophages, function as important modulators or amplifiers of primary afferent neurons, especially during inflammatory or immune responses.

Morphology of Primary Afferent Neurons

Sensory Cell Body

Primary afferent neurons detect conditions outside the nervous system and convert stimuli into signals that reliably inform the CNS to promote survival, maturation, and reproduction of the animal. For the special senses, the receptors are designed to evaluate conditions outside the body, and they convert energy from light, sound, gravity, and airborne or fluid chemicals into meaningful nerve impulses. Somatosensory neurons detect alterations in thermal, mechanical, or chemical conditions in the body's tissues for conversion into nerve impulse information. The cell body of each primary afferent neuron has at least five challenges for maintaining the entire neuron. (a) It must deliver the correct macromolecular traffic from the cell body's synthetic organelles to the different specialized regions (central terminals, central axon in root, axonal branch points, nodes of Ranvier, stem axon and cell body in the ganglion, peripheral axon and branches, preterminal regions, and sensory receptor endings) at the right rates and targeted to the right places. (b) It must maintain correct interactions with the supporting Schwann cells for faithful transmission of signals from periphery to cell body and CNS. (c) It must maintain the correct degree of integration of the sensory receptors with the target tissue, whether that involves full encapsulation, partial separation from the tissue, or completely free endings. (d) It must establish and maintain appropriate central endings, often exceeding 1,000 synaptic boutons (73) distributed over several segments of the cord. (e) It also directs changes in pharmacologic, functional, and structural phenotype as needed to match the conditions of the innervated tissue and the excitatory or inhibitory influences along the axon and at the presynaptic central endings. The cell body learns about events in its distant extensions via APs, axonal transport traffic, and rapid phosphorylation systems. This combined electrophysiologic and cytochemical communication enables it to adjust its gene expression in relation to its far-flung extensions. For nociceptors and polymodal receptors, that adjustment can be extreme, because they express different neuropeptides, growth factors, ion channels, and other molecules, depending on conditions at their target tissue (normal, stressed, injured, inflamed, healing, or permanently damaged) and at their central endings.

Somatic sensory neurons have a bipolar form early in development, but the cell body becomes unipolar (no dendrites) with a short stem connection between the cell body and the main peripheral and central axon branches (see Fig. 3-6). The mature visceral sensory cell bodies often remain bipolar and are either in the spinal and cranial ganglia (making up approximately 2% to 10% of those cells) (62,64) or are in the geniculate ganglion, the distal (petrosal) ganglion, or the distal (nodose) ganglion of the VII, IX, or X cranial nerves, respectively. The sensory cell bodies are located in spinal and trigeminal ganglia or in the proximal ganglia (jugular, superior) of the IX and X cranial nerves, and they are supported by layers of satellite cells at the cell body and Schwann cells on the stem axon (see Fig. 3-6). The satellite cells are derived from the neural crest, and they form overlapping layers around each cell body. The cell bodies vary significantly in size, but can be divided into two general groups. Type A cells are large and light staining, are associated with large-diameter myelinated fibers, and have a cell body diameter of 60 µ to 120 µ. Type B cells are small (10- to 30-µ diameter), are darker staining, and give rise to small-diameter myelinated and unmyelinated primary afferent axons. Of the total population of dorsal root ganglion cells, approximately 60% to 70% are of the small type, a fact that agrees with the preponderance of unmyelinated over myelinated fibers in the dorsal root. Those two groups now also have been shown to have different timetables for programmed cell death during development (74) and different growth factor dependencies (29,75). Immunocytochemistry has shown a complex variety of subtypes in sensory ganglia (64,76,77 and 78), also discussed in Pharmacology and Modulation of Nociception, later in this chapter. Because of the position of the sensory ganglion, the peripheral axon and its branches are a much greater proportion of the neuron than the central axon and endings, and the peripheral axon has a larger caliber (79) and, therefore, a greater volume of axonal transport and faster conduction.

Peripheral Receptor Endings

From the bifurcation of the stem axon, the peripheral process(es) passes distally through the spinal (or cranial) nerves and thence through the somatic nerve branches or autonomic nerves to end as sensory receptors. The peripheral part of a spinal (or cranial) axon takes one of two pathways to reach its sensory endings. Most course through a formed spinal nerve (in its dorsal or ventral division) to reach the sensory endings (receptors) in a somatic tissue such as the skin, subcutaneous tissue, muscles, bones, or joints and are accordingly called somatic sensory fibers. The rest accompany peripheral sympathetic or parasympathetic nerves to reach the viscera or urogenital organs and are known as visceral afferent fibers. Although visceral afferent fibers (including many that mediate pain) use autonomic pathways, their cell bodies are in the spinal dorsal root ganglia, trigeminal ganglion, or the visceral sensory ganglia of the VII, IX, and X cranial nerves.

Peripheral terminations of sensory axons end in the skin and other somatic or visceral tissues by ramifying to varying extents and forming encapsulated, partially covered or free nerve endings. As they near their destinations they branch, shed their perineurial sheaths, and move beyond their myelinated or unmyelinated Schwann cells to associate with specialized terminal Schwann cells (Fig. 3-9 and Fig. 3-10; see Fig. 3-8). The larger myelinated fibers end in specialized encapsulated structures made up of nonneural and neural elements (80,81 and 82) that permit the nerve endings to act as transducers of low-intensity mechanical stimuli.

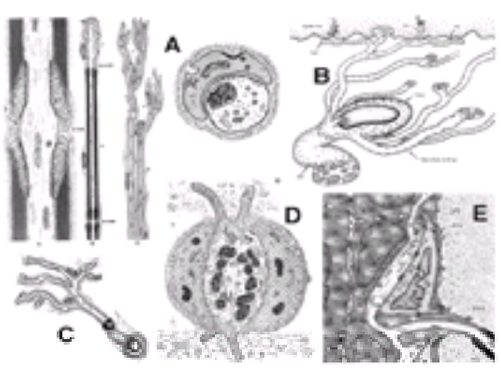

Figure 3-9. Axonal and receptive ending ultrastructure for free endings. **A:** The three left-hand drawings show (A) the complex Schwann and axonal ultrastructure at a node of Ranvier (*arrow*), (B) the last myelin segment and the terminal Schwann cell of a small A fiber, and (C) an unmyelinated fiber bundle and individual endings. The enlargement shows the partial covering of Schwann cell (sz) and a C-fiber receptor terminal, with an extracellular basal lamina separating the ending from the tissue. **B:** Termination of unmyelinated nerve fibers of the penicillate form in human hairy skin. A terminal Schwann cell (T.Sch) is associated with a number of endings and provides them with sheaths for their course through the corium. The endings terminate either in the subepidermal zone (Sub) or intradermally (Int). At intervals, there is attachment (Att) between the basal lamina of the epidermis and the nerve endings. Modified from Cauna N. The free penicillate nerve endings of the human hairy skin. J Anat 1973;115:277–288. **C,D:** Small and large endings of Ruffinilike endings that extend small protrusions or larger fingers to contact the collagen of the tissue. The ultrastructural details of the terminal Schwann cell are shown in **D**, including numerous active caveoli (budding vesicles). **E:** Intraepithelial Merkel ending (pale) contacting a Merkel cell on its right side. [a, axon; ax, axon; r, receptor endings; sy, synapse; sz, Schwann cell; tm, terminal. For other abbreviations in **E**, see Andres and von Düring (80), cited here.] (**A** and **C–E** modified from Andres KH, von Düring M. Morphology of cutaneous receptors. In: Iggo A, ed. *Somatosensory system. Handbook of sensory physiology*. Berlin: Springer-Verlag 1973;II:3– 28, with permission.)

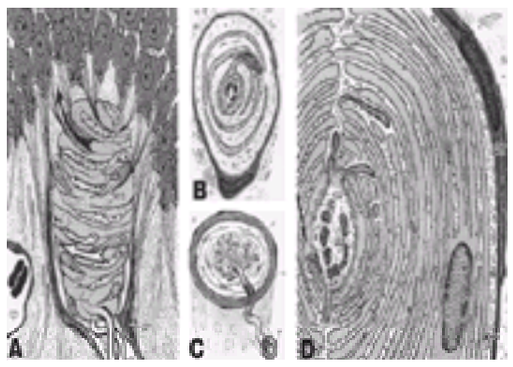

Figure 3-10. Terminal ultrastructure for various encapsulated endings. **A:** The Meissner corpuscle is ensheathed at its base, but its coiled endings are exposed to the tissue near its tip, and extracellular fibers attach it to the epithelium. **B,C:** Two varieties of small corpuscle. **D:** Portion of the central neural ending and layers of support structure within a pacinian corpuscle. [ax, axon; cp, capillary; pn, perineurium; ra, receptor axon; sc, terminal Schwann cell. For other abbreviations, see Andres and von During (80), cited here.] (From Andres KH, von Düring M. Morphology of cutaneous receptors. In: Iggo A, ed. *Somatosensory system. Handbook of sensory physiology*. Berlin: Springer-Verlag 1973;II:3–28, with permission.)

The endings of A-d and C fibers do not make encapsulated receptors in their peripheral tissues, but rather branch extensively and then end with different tissue associations depending on whether they are located in intraepithelial, subcutaneous, musculoskeletal, visceral, vascular, deep, or special target tissues. Many intraepithelial endings are completely free between the epithelial cells, having shed their Schwann cell and basal lamina (see Fig. 3-8 and Fig. 3-9) (83), and those in teeth are also completely free where they end in the dentinal tubules (see Chapter 50). Other intraepithelial nociceptive endings have been shown in serial reconstructions to have only a small exposed ending just after their axon has entered the epithelium (84). A-d axons in deep or visceral tissues can have extensive branching that then shifts to unmyelinated terminal fibers and finally beaded endings with partial Schwann covering, but a basal lamina is usually retained (85,86). Clusters of C fibers that have a single Schwann cell sheath in the main nerve branch to many smaller bundles and often appear to end as small groups of thin axons, still with a Schwann cell and basal lamina (see Fig. 3-9) (60,80,87). Thus, the A-d and C fiber *free nerve endings* usually retain a Schwann and basal lamina barrier between them and the tissue. By contrast, the Ruffini stretch mechanoreceptors form large endings in ligaments, joint sheaths, vessel walls, and deep tissue from which branches extend out to contact the collagen of the tissue (see Fig. 3-10) (80,86,88), so that these appear to have the greatest actual contact with subepithelial tissue.

Central Endings

Dorsal Root. From the stem axon bifurcation, the central axonal process passes through the dorsal (posterior) roots and into the dorsal horn, in which it makes extensive branches, beaded terminal fibers, and many synaptic endings in specific laminae of the dorsal horn (Fig. 3-11 and Fig. 3-12; see Fig. 3-2 and Fig. 3-7). Many sensory axons reach the CNS without branching, but others can form more than one central axon, and in one quantitative study, the number of central processes in the dorsal root exceeded the number of ganglion cells by 43% (89). In many cases, the axon also sends branch(es) into the ventral root, as discussed in the following section. In the nineteenth century, Lissauer and Bechterew noted that the smaller myelinated fibers congregated on the lateral side of the dorsal rootlets as they entered the cord, whereas the larger axons were in the center and medial part of the rootlets (19). Lissauer further noted that the small lateral fibers pass to the apex of the dorsal horn, thus forming the pathway that bears his name, whereas the larger fibers pass centrally to travel in the dorsal columns. In the ensuing half-century, these findings were confirmed in animal studies by Cajal, Ranson, Ingvar, O'Leary and their associates, and others (19), including demonstrations that in experimental animals pain could not be elicited after cutting the lateral bundle. More recently, this notion of segregation of the fibers as the root entry zone was confirmed by some, but disputed by others (90). Snyder (91) and Kerr (90) showed that this segregation does not occur in the cat but does in monkeys, raising the important issue of species variation. Kerr (90) found a random distribution of large and small fibers in a rootlet at 5 mm from the entry zone into the cord that continued until approximately 1 mm from the cord, in which the majority of the small fibers shifted to the periphery of the rootlet, forming a conspicuous marginal ring. Just before joining the cord, however, the fine fibers shifted from the circumferential ring to a clear lateral position and in the cord merged with the tract of Lissauer, in which the medial division was composed of large fibers.

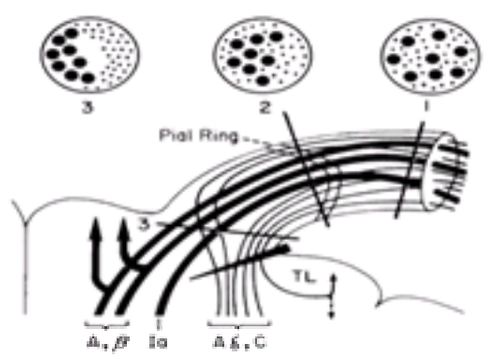

Figure 3-11. Schema of dorsal root entry zone based on anatomic findings. In the peripheral portion of the root (cross-section 1), the large and small fibers are intermingled. At the pial ring (cross-section 2) the fine afferent fibers are situated on the rootlet surface, predominantly in the ventrolateral portion but some dorsomedial. At the entry zone (section 3), the C and A-d fibers cross large myelinated fiber bundles and follow an oblique course to enter the tract of Lissauer (TL) and the dorsal horn. Some of the large A fibers are situated centrally and proceed to the anterior horn, whereas many are medial and proceed toward the dorsal columns. (From Sindou M, Goutelle A. Surgical posterior rhizotomies for the treatment of pain. In: Krayenbühl H, ed. *Advances and technical standards in neurosurgery*. Vol 10. New York: Springer-Verlag, 1983:147–185, with permission.)

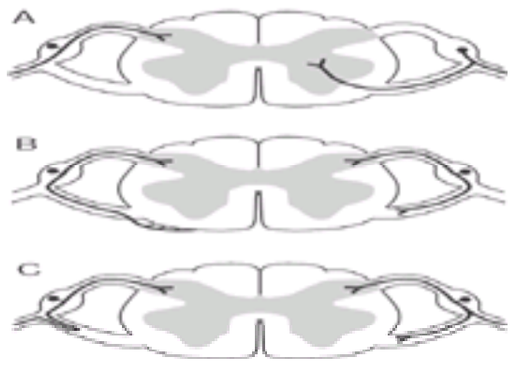

Figure 3-12. Various pathways of primary afferent central axons are diagrammed. **A:** The central axon can follow the dorsal or ventral root into the spinal cord. **B:** Some neurons send their peripheral axon into the ventral root, from which it may innervate the meningeal blood vessels, and in some cases lacks an axon in the peripheral nerve. **C:** Some neurons have a branch into the ventral root as well as a peripheral nerve branch. (Modified from Hildebrand C, Karlsson M, Risling M. Ganglionic axons in motor roots and pia mater. *Prog Neurobiol* 1997;51:89–128.)

In humans, Sindou and colleagues (92) have found that in the rootlet the small and large fibers are randomly situated, but as they near the dorsal root entry zone (DREZ), the small fibers become situated on the surface, mostly in the lateral region, although some are in the medial region. In the DREZ, the small fibers in the

medial aspect cross to join those in the lateral bundle to enter the tract of Lissauer (see Fig. 3-11). These findings have prompted Sindou and associates to develop a *selective posterior rhizotomy* or what is sometimes called *rhizidiotomy* (see Chapter 106).

An interesting challenge for neural regeneration in mature animals after dorsal root injury or avulsion is the difficulty of peripheral fiber regrowth across the mature DREZ into the CNS, because astrocytes and their various cytochemical markers inhibit ingrowth by peripheral fibers in mature animals (93,94 and 95). That barrier can be overcome if peripheral nerves or roots are implanted to provide a conduit across the DREZ, with some success in both afferent and motor regeneration. In some cases, the regenerating afferent central axons bypass the DREZ by following the pia mater from the dorsal root into the CNS (96).

Ventral Root. In the early nineteenth century, Bell and Majendie proposed that ventral roots contain axons of motor fibers and dorsal roots contain axons of sensory fibers. Although most fibers follow this law, evidence has been accumulating for more than a century and a half that afferent fibers also exist in ventral roots. Majendie himself noted that manipulation of the ventral root caused an animal to behave as if it were experiencing pain and that this behavior could be eliminated by section of the dorsal roots, and he labeled this phenomenon *recurrent sensibility*. Frykholm and associates (97) noted that stimulation of ventral roots in conscious humans caused pain, and that this could be abolished by applying a local anesthetic to the dorsal root. Coggeshall and associates (98) have used electron microscopic and electrophysiologic methods to demonstrate that ventral roots in mammals (including humans) contain a large proportion of unmyelinated axons, amounting to 30% of the total fiber count. They clearly demonstrated that many of these ventral root unmyelinated afferents are nociceptors and that most of them have their cell body in the dorsal root ganglion and ultimately enter the cord through the dorsal root. Nerve tracing studies (96) show that many of those fibers end in the sheath of the root and its blood vessels or end blindly. Those endings have neuropeptides consistent with polymodal nociceptor properties. In some cases, the axons may double back and enter the cord at the dorsal root, but some also enter through the ventral root in a variety of different types of pathways (see Fig. 3-12). These findings reinforce the old assumption that such an alternate route accounts for failure of dorsal rhizotomy to relieve pain permanently. Moreover, they have provoked the use of ganglionectomy, alone or in combination with rhizotomy, in the attempt to ensure greater success in relieving pain (see Chapter 106).

The different functions, sources, and pathways of sensory axons in ventral roots are summarized in Figure 3-12, taken from the extensive review by Hildebrand and colleagues (96) in which data supporting each of the suggested possibilities are discussed. Not only do the axons have different physiologic properties and come from somatic and visceral neurons, but some ventral axons also are third branches of a dorsal root afferent, some end in the root and lack a CNS projection, and some come from the ganglion without a branch into the peripheral nerve (99). The blood vessels and pia of the roots receive some of this sensory innervation as well as sympathetic endings, and both types of nerve fibers can branch extensively after nerve injuries. Much of the vascular and nonvascular innervation of the spinal pia appears to derive from sensory afferents in the ventral roots (96,99). The trigeminal nerve presents an unusual case in which some of the sensory unmyelinated fibers in the motor root enter the brainstem via that pathway (100). The ventral root sensory fibers may have important functions in acute and chronic pain conditions, inflammatory and neuropathic pain, and regeneration.

Lissauer's Tract. Lissauer's tract is a tightly packed system of longitudinally running fine fibers that extend from the periphery of the dorsal horn to the cord's surface. Lissauer's original view of the tract was that it consisted chiefly of small primary afferent fibers en route to the synaptic terminals in the dorsal horn, and Ranson (101) proposed that most of these conduct nociceptive impulses. Subsequent degeneration studies indicated that, at most, only 25% of the fibers were afferents located in the most medial part of the tract; the rest were considered propriospinal (19). Detailed anatomic studies (19,102) have shown that (a) primary A-d and C fibers make up two-thirds of the axons in the rat, 50% in cat, and 80% in monkey; (b) the ratio of unmyelinated to myelinated fibers within the tract in rat is 3.8:1; (c) primary afferent fibers ascend several segments in the lumbosacral cord of rat but terminate within a single segment in the thoracic cord; and (d) in monkey there are more primary afferents in the medial part than in the lateral part of the tract. A detailed study of the terminal arbors of individual lectin-labeled and functionally identified visceral afferents found that some axons make terminal presynaptic swellings within Lissauer's tract before reaching the neurons of the dorsal horn (103). The proportions of those endings ranged from 5.9% to 20.3% of the total, with the rest located in specific dorsal laminae. Electrophysiology studies by Wall and colleagues show that specific interactions between fibers in Lissauer's tract and subsets of dorsal horn neurons are the basis for the prolonged depolarizations of the dorsal root potential (104).

Somatic and Visceral Central Terminations. The specific organization of laminae in dorsal horn and typical terminal locations for somatic A-b, A-d, and C fibers are illustrated generally in Figure 3-13, Fig. 3-14, Fig. 3-15 and then considered in detail in the next chapter. The pathways of A-b fibers in dorsal horn are shown in Figure 3-13 with their terminations in laminae III through V and their axonal branches into the dorsal columns. As indicated in Figure 3-14, the nociceptive A-d fibers have a different set of pathways and endings, with their terminations mainly in laminae I, II $_o$, V, and X. Capsaicin-sensitive somatic C nociceptors and thermoreceptors end mainly in lamina II, and visceral C fibers in lamina V (see Fig. 3-15).

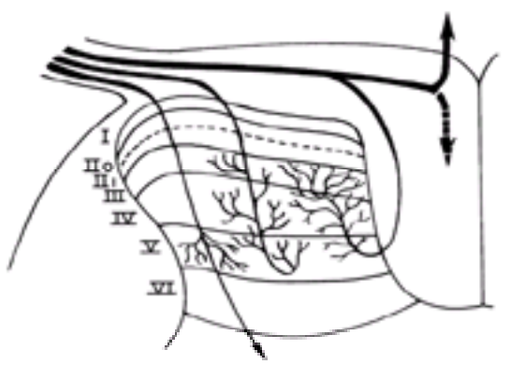

Figure 3-13. Cross-section of the spinal cord showing the course and termination of large beta afferent fibers. On entering the spinal cord these fibers proceed medially and bifurcate into short descending and long ascending branches in the dorsal column. Before entering the dorsal column, they give off the collaterals, some of which penetrate the dorsal horn. Others pass ventrally in the white matter medial to the medial side of the dorsal horn. At the level of lamina IV or V they reverse their direction, enter the gray matter, and pass dorsally as far as lamina III. In this lamina they divide into long (200-µm to 700-µm) ascending and descending branches that give off flame-shaped arborizations that in transverse sections appear to separate the neuropil into lobuli. Although the most dense arborization occurs in lamina III, there are also arborizations in laminae IV and V. The largest sensory afferents from the specialized muscle-stretch receptors have collateral branches that pass ventrally to make synaptic connections with neurons of laminae V, VI, and VII, thus making monosynaptic activation of these possible. Some even penetrate into the ventral horn (laminae VIII and IX), where they terminate directly on motor neurons and form the basis of the monosynaptic reflexes such as the knee jerk.

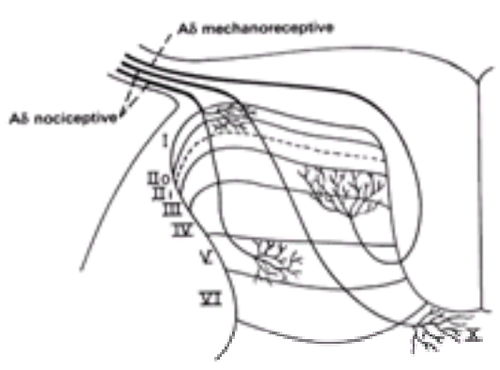

Figure 3-14. A schematic diagram of the course and termination of collaterals of A-d cutaneous fibers in the dorsal horn of the spinal cord.

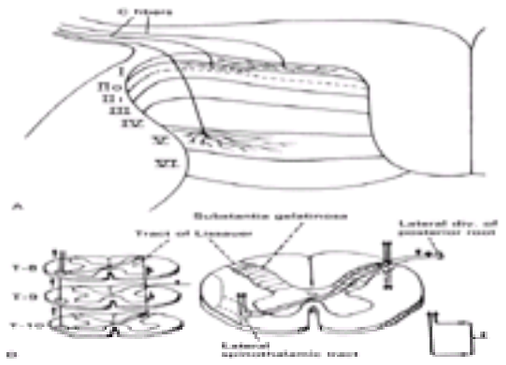

Figure 3-15. Schematic diagrams of the course and termination of collaterals of unmyelinated (C) cutaneous visceral afferents in the dorsal horn. **A:** Simple cross-section. **B:** On entering the spinal cord, the thin fibers divide into short ascending and descending branches and make up Lissauer's tract before they enter the dorsal horn, where they synapse with interneurons and cells of spinothalamic tract fibers. The insets on the left and right are schematic representations of this arrangement. Evidence suggests that C visceral afferents terminate in lamina V. (From Cervero F, *personal communication*, 1989.)

Single cell labeling studies have correlated the physiology of somatic and visceral afferents with the distribution and synaptic ultrastructure of their central presynaptic endings. The rostrocaudal extent, laminar termination fields, ipsilateral endings compared with those with both ipsilateral and contralateral arbors, and the overall shape of the central terminal clusters are different for somatic and visceral fibers, as demonstrated by Sugiura and colleagues (73,103) (Fig. 3-16 and Table 3-2). Individually identified thoracic somatic afferents made approximately 1,400 terminal swellings within its few terminal arbors, whereas individual visceral afferents could form as many as 20 different arbors, with an aggregate total of 5,000 to 6,000 terminal swellings. The challenges for sensory neuronal development and maintenance of such complex central endings for a somatic or visceral afferent fiber are impressive, especially because the pharmacology and functional dynamics are so different for the central endings of primary afferent neurons compared with their peripheral endings (see Pharmacology and Modulation of Nociception, later in this chapter), and because of complex inhibitory mechanisms that shunt APs to only some of the endings (105).

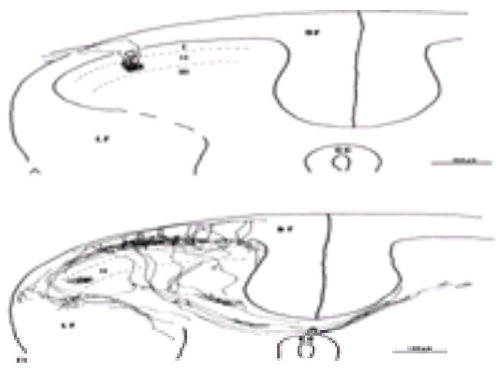

Figure 3-16. The different extents of central terminal fields are shown here for an individual somatic neuron **(A)** and a visceral neuron **(B)** from guinea pigs that were injected with phaseolus vulgaris leucoagglutenin after functional identification. The visceral neuron had many more central branches and numerous arbors that include contralateral projections, whereas the somatic neuron had just one main terminal field. (CC, central canal; DF, dorsal funiculus; LF, lateral funiculus.) [From Sugiura Y, Terui N, Hosoya Y. Difference in distribution of central terminals between visceral and somatic unmyelinated (C) primary afferent fibers. *J Neurophysiol* 1989;62:834–840, with permission.]

Per neuron	Somatic	Visceral
Terminal fields	Narrow	Dispersed

TABLE 3-2. Somatic and visceral C-fiber central arbor structure

Trigeminal and Other Cranial Nerves

Nerve impulses encoding head pain originate primarily in the peripheral sensory distribution of four cranial nerves—V (trigeminal), and to a lesser extent VII (facial), IX (glossopharyngeal), and X (vagus)—and also in terminations of the upper three cervical nerves. These nociceptive impulses activate neurons in the trigeminal brainstem nuclei and cervical dorsal horn. Signals are then relayed to other CNS sites, including brainstem reticular nuclei, solitary nucleus, thalamus, and cerebral cortex. In many respects the anatomy, physiology, and biochemistry of cranial nociception and pain pathways are homologous to those involved in transmitting pain signals originating in the body below the head (106,107,108,109,110,111,112,113 and 114) and the main termination region for trigeminal primary afferents is called the medullary dorsal horn.

The sensory input of the trigeminal nerve to the brainstem is diagrammed in Figure 3-17 (also see Chapter 50). The trigeminal mesencephalic nucleus is actually a collection of sensory cell bodies of primary neurons, which instead of being localized in the gasserian ganglion with other somatic cell bodies, have migrated into the midbrain and are thought to be associated functionally with proprioception, especially from oral mucous membrane, temporomandibular joint, masticatory and ocular muscle spindles, and periodontal ligament receptors (88,108,114,115 and 116). The pseudounipolar cell bodies in the mesencephalic nucleus give off peripheral branches that reach the muscles and other structures, and the central branches project to the motor trigeminal nucleus and make monosynaptic contact with somatomotor neurons to complete a two-neuron arc for the jaw-jerk reflex, which is homologous with the spinal reflexes. The other primary afferents of the trigeminal system are like those of the spinal nerves: They are composed of pseudounipolar cell bodies in the gasserian ganglion and have peripheral and central axons. The peripheral axons make up the ophthalmic, maxillary, and mandibular divisions of the ganglion and peripheral nerves, and the central axons make up the sensory root, which becomes attached to the ventral surface of the pons.

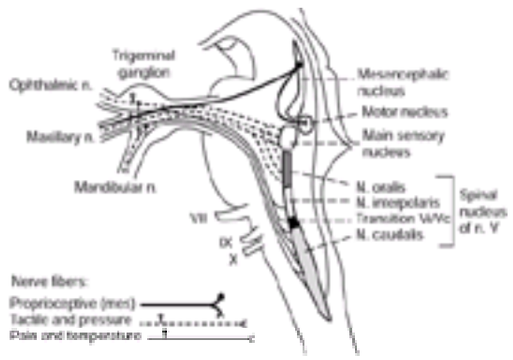

Figure 3-17. Schematic diagram of the neuroanatomy of the trigeminal system in sagittal section. The large A-b fibers, which transmit proprioceptive information from the anterior two-thirds of the head, have their central endings in the motor nucleus and either have their cell body in the gasserian ganglion (not shown), or their cell body is in the mesencephalic nucleus. Tactile and pressure afferents have their cell body in the ganglion and their endings in the main sensory nucleus and the subnuclei oralis and interpolaris. The thin nociceptive and thermoreceptive fibers pass caudally to end in the transition zone between subnuclei interpolaris and caudalis and in the subnucleus caudalis. (n, nerve; N, nucleus; V, VII, IX, X, cranial nerves.)

On entering the brainstem, these central processes pass through the spinal trigeminal tract to terminate in the trigeminal nuclear complex, composed of the main sensory nucleus and the spinal trigeminal nucleus, as well as in auxiliary sites (Table 3-3). The main sensory nucleus is located at the level of the pons, whereas the spinal trigeminal nucleus is deep to the descending trigeminal tract and extends as far caudad as the third or fourth cervical segments (117,118). The spinal subnucleus is further subdivided into three parts: subnucleus oralis, subnucleus interpolaris, and subnucleus caudalis (108,109,110,111,112,113,114 and 115,119). An additional important termination site for nociceptive trigeminal afferents from regions of the head is the overlap *transition* zone between interpolaris and caudalis subnuclei (120,121 and 122). In addition, some trigeminal afferents extend their central axons to the paratrigeminal nucleus, solitary nucleus, and cerebellum; some afferents cross in the caudalis region to terminate on the contralateral side of the brainstem (114,117,118,123,124). On entering the brainstem, the A-d and C fibers pass to the spinal tract and descend in it to terminate mainly within the subnucleus caudalis (see Fig. 3-17). In contrast, the large myelinated fibers divide into short ascending branches that terminate in the main sensory nucleus and long descending branches that pass through the trigeminal tract and give off collaterals to various parts of the underlying spinal nucleus. As these fibers pass caudad and give off collaterals they become smaller, so that by the time they reach the subnucleus caudalis, 75% of them are smaller than 2 µm in diameter, with a consequent progressive slowing of impulse conduction (108).

Trigeminal subnuclei	Auxillary sites
Mesencephalic	Cerebellum
Main (principalis)	Supratrigeminal nerve
Oralis	Trigeminal motor nerve
Interpolaris	Vestibular nerve
Vi/Vc transition zone	Solitary nerve
Caudalis	Reticular parvocellular
Cervical C-1–C-5	Paratrigeminal nerve
	Contralateral C-1–C-5

Data from Pfaller K, Arvidsson J. Central distribution of trigeminal and upper cervical primary afferents in the rat studied by anterograde transport of horseradish peroxidase conjugated to wheat germ agglutinin. *J Comp Neurol* 1988; 268:91–108; and Marfurt CF, Rajchert DM. Trigeminal primary afferent projections to "non-trigeminal" areas of the rat central nervous system. *J Comp Neurol* 1991;303:489–511.

TABLE 3-3. Central distribution of trigeminal afferents

Somatotopic organization is one of the most important and clinically relevant characteristics of the trigeminal system and exists throughout the gasserian ganglion, sensory root, spinal tract, and spinal nucleus. In the ganglion, the cell bodies of the mechanoreceptive and nociceptive afferents within the ophthalmic division are concentrated medially and somewhat anteriorly. Those of the mandibular division are caudal and lateral, and the cell bodies of the maxillary nerve lie between those of the other two divisions. Moreover, cell bodies of neurons that innervate the perioral and oral areas are located more ventrally, whereas those that supply the structures remote from the mouth are located more dorsally. In the sensory root, the afferents are also somatotopically organized in a medial to lateral fashion, such that the central processes of the mandibular division are posteromedially positioned, those of the ophthalmic division are located anterolaterally, and those of the maxillary branch are situated in an intermediate position (108,109,110,111,112 and 113,115,119) (Fig. 3-18). Complementary experimental and clinical studies have shown a similar somatotopic organization in the trigeminal spinal tract.

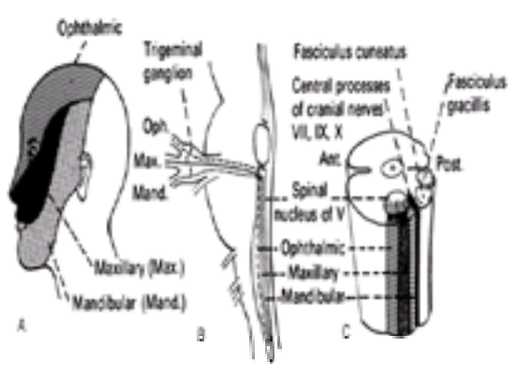

Figure 3-18. **A:** The cutaneous distribution of the three major divisions of the trigeminal nerve. **B:** The somatotopic position of the central processes of the three divisions in the descending trigeminal tract and in the spinal nucleus. **C:** The somatotopic organization of the descending spinal trigeminal tract, and its relation to the spinal nucleus and to the wedge in the medulla that contains the central processes of the VII, IX, and X cranial nerves, located between fasciculus cuneatus and the mandibular division. (Modified from Brodal A. *Neurological anatomy in relation to clinical medicine*, 3rd ed. New York: Oxford University Press, 1981.)

Another important and clinically relevant somatotopic pattern occurs along the rostrocaudal axis of the subnucleus caudalis, showing the *onion peel* pattern first described by Déjérine (125) on the basis of the sensory deficit caused by certain pathologic lesions of the brainstem (Fig. 3-19). Sensory innervation near the midline around the mouth and nose is represented in the most rostral

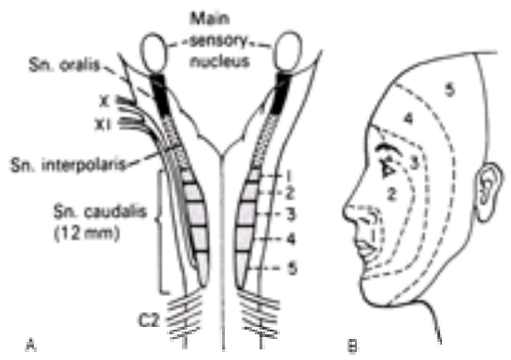

Figure 3-19. **A:** The rostrocaudal somatotopic organization of the subnucleus caudalis. **B:** The relation of the subnucleus caudalis to input from primary afferents on the face. The fibers nearest to the lips and lower nose (area 1) terminate highest in the subnucleus caudalis; the innervation of successively more lateral regions of the face ends progressively in more caudal parts of the subnucleus caudalis. This rostrocaudal somatotopic organization applies to all three divisions of the trigeminal nerves and produces the *onion peel* pattern in the face. (sn, subnucleus.) (Modified from Kunc Z. Significance of fresh anatomic data on spinal trigeminal tract for possibility of selective tractotomies. In: Knighton RS, Dumke PR, eds. *Pain*. Boston: Little, Brown and Company, 1966:351–366.)

part of the subnucleus caudalis, whereas the innervation of successively more lateral regions of the face ends progressively in more caudal parts of the subnucleus caudalis. The most impressive clinical evidence for this has been produced by Kunc (126) based on trigeminal tractotomy for facial pain. This operation, which has been done since 1938, permits the production of analgesia without significant effects on tactile sensation. If the lesion is placed above the upper pole of the subnucleus caudalis, analgesia of the whole ipsilateral trigeminal nerve territory occurs. On the other hand, if the tractotomy is performed more caudally, the analgesia is incomplete, with sensory sparing of the center of the face. With more caudal sections, these areas expand concentrically. These results lead Kunc to conclude that whereas all three divisions of the trigeminal nerve terminate in all segments of the spinal nucleus, the terminations of the primary afferents from the center of the face are most intense in the highest level and those from the periphery in the lowest level. This clinical conclusion was subsequently confirmed by the electrophysiologic studies of Yokota (111). More recent studies have used the expression of the proto-oncogene c-*fos* as an indicator of central neurons that are contacted by trigeminal afferents. Those studies demonstrate some endings in the interpolaris and caudalis transition zone for polymodal nociceptors from all head regions (120,121 and 122).

The classical technique of medullary trigeminal tractotomy can be extended somewhat medially to produce analgesia of the posterior third of the tongue, tonsil, pharynx, tympanic membrane, and external auditory canal. Tactile sensibility in these areas is not noticeably altered after the operation. These results strongly suggest that the central processes of cranial nerves VII, IX, and X end in and synapse with cells of the dorsomedial part of the subnucleus caudalis and the spinal dorsal horn at levels of C-1 and C-2, and sometimes even C-3. The general visceral afferent input traveling in cranial nerves V, VII, IX, and X terminates mainly in the nucleus of the tractus solitarius (115). Although some neurosurgeons believe it is necessary to cut the whole spinal tract to interrupt nociceptive fibers in the other three cranial nerves, Kunc (126) believed it possible to obtain analgesia in the distribution of these nerves and the third division of the trigeminal while sparing the first and second division. He achieved this result by making a precise, narrow incision, extending from the lateral boundary of the cuneate fasciculus to the medial boundary of the spinal trigeminal tract.

Central axons from the spinal afferents ascend and terminate in the subnucleus caudalis. Dorsal root axons from upper cervical nerves can send branches to terminate in the spinal trigeminal nuclei. These overlapping trigeminal and spinal terminations provide a morphologic basis for the substantial interaction between the upper cervical dermatomes and cranial nerve nervatomes revealed after brain lesions or pharmacologic manipulations (110). They also complement evidence indicating a major homology between the trigeminal subnucleus caudalis and the spinal dorsal horn. Finally, the convergence of cranial and upper cervical primary afferents into a common synaptic region in the caudal medullary and upper cervical cord provides a logical explanation for the phenomenon of referred pain from the head to the neck and vice versa.

NOCICEPTOR PHYSIOLOGY

In the preceding section, we have already used several different categorizations for primary afferent neurons: (a) nociceptive subtypes in the ganglion (see Fig. 3-2), (b) conduction velocities (see Table 3-1), (c) type of receptor ending structure (see Fig. 3-8, Fig. 3-9, Fig. 3-10), and (d) central terminal morphology (arbor shape, rostrocaudal extent, ipsilateral and contralateral distribution, and laminar location) (see Fig. 3-13, Fig. 3-14, Fig. 3-15 and Fig. 3-16). To further understand the physiology of nociception, it is important to discuss nociceptor signal detection and integration, information flow in primary afferent neurons, basic physiologic properties of nociception, sensitization and hyperalgesia, reflex activities that affect pain, and tissue specificity of nociception. The special properties of polymodal receptors and their efferent actions are considered in Polymodal Receptors, later in this chapter. The cytochemistry, pharmacology and modulation of the primary afferents are reviewed in the sections on Pharmacology and Modulation of Nociception and Peripheral Mechanisms of Persistent Pain, later in this chapter. Much of the information described here comes from the extensive reviews by Meyer and colleagues, Levine and Taiwo, Rang and colleagues, Woolf, Fitzgerald, Bennett, Yaksh and Malmberg, Dubner and Basbaum, and Devor in the third edition of Wall and Melzack's *Textbook of Pain* (21), as well as more recent reviews by Stein (22), Dray (127), Devor (128), Kumazawa (129), Cesaro and McNaughton (39), Woolf and colleagues (130), Carlton and Coggeshall (32), Dray and Rang (41), Millan (28), Willis (142), and books edited by Kumazawa and colleagues (23), Belmonte and Cervero (131), and Dickenson and Besson (26). The basic principles of neurobiology and neurophysiology that concern pain can be studied further in works by Zigmond and colleagues (132), Nolte (133), Hille (134), Hall (135), and Siegel and colleagues (136).

Detection of cytochemical signals by the peripheral endings is driven by specific molecular systems using ligand-receptor mechanisms or ion channels. The endings are able to respond to many different types of signals, only some of which are allowed to move beyond the endings to reach the cell body and affect gene expression. Thus, it has been proposed that screening of tissue conditions by nociceptors is as sophisticated as that of the dorsal horn for regulating access of peripheral information to the CNS (22,32). Whereas information through-put in the dorsal horn depends on a series of gating and modulating mechanisms at the synaptic connections with central neurons (4), the peripheral signals do not reach the CNS at all unless they exceed physiologic, pharmacologic, and molecular threshold requirements of the peripheral endings, and their access to the CNS may be further regulated within the sensory ganglion (137). The peripheral endings are therefore critical primary *gatekeepers* that select, limit, or enhance access of neural signals to the CNS. In addition, the signal-generating properties of the nociceptive neurons shift to different functional levels or phenotypes depending on whether the tissue is normal, inflamed, invaded by foreign agents, healing, or irretrievably damaged. Those changes in functional and cytochemical phenotype are triggered at the peripheral endings of nociceptors by membrane receptors, ion channels and transporters, G- protein systems, second messenger cascades [cyclic nucleotides, calcium, phosphatidyl inositol, nitric oxide (NO), eicosanoids], various effectors (kinases, phosphatases, enzymatic arrays), and other axonally transported proteins, as described in Pharmacology and Modulation of Nociception, later in this chapter. Whether tissue events produce algesic or analgesic responses depends on how the primary afferent neurons read and respond to their environment, and on how their functions are modulated by neuroinflammatory, neuroimmune, and neuroendocrine interactions.

Information Systems in Peripheral Neurons

The detection systems of primary afferents (whether at their peripheral endings, central endings, along the axon, or at the cell body) are converted into at least four different intraneuronal information pathways (Fig. 3-20): (a) fast electrophysiologic signaling via sensory potentials, conducted APs, and their ion channel mechanisms; (b) the slower cytochemical delivery systems via axonal transport; (c) rapid retrograde phosphorylation signals from nerve endings to cell body; and (d) diffusion of membrane-permeable molecules such as NO. It is the combined effects of the complex messages that are carried by these intraneuronal information systems that underlie phenotypic changes in nociceptive peripheral neurons after injury, at different stages of inflammation and wound healing, and after neuropathic injury.

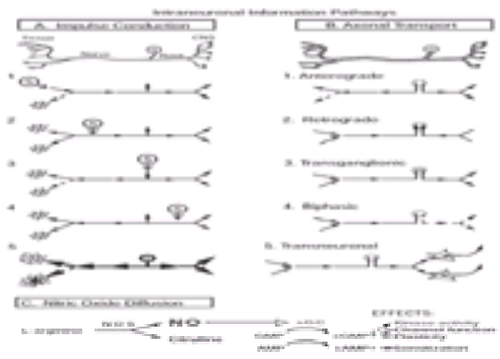

Figure 3-20. Schema depicting the flow of information via action potentials **(A)**, and various types of axonal transport **(B)**. Local intraneuronal signals also involve nitric oxide **(C)**. See text for details.

Electrophysiologic Information

Although the sensory neurons are called primary afferents, their conducted APs can move either in the afferent direction (from the tissue toward the ganglion and CNS) or in the efferent direction (out to the peripheral endings), depending on the type and location of stimulation. Five examples of efferent movement of APs in sensory neurons are shown in Figure 3-20 and include (a) the axon reflex, in which a stimulation of some of the branches of a peripheral arbor reverberate back out to unstimulated branches. (b) Mechanical or electrical stimulation of a nerve can generate APs that move in efferent and afferent directions away from the stimulus. (c) Stimulation of the sensory cell body causes movement of potentials out to the peripheral endings as well as to the central endings. (d) Stimuli to the dorsal horn can generate signals that move back out the peripheral axon, called the *dorsal root reflex*. (e) Endogenous spontaneous signal generation in the sensory cell body sends APs out to the peripheral endings as well as to the central endings. When efferent potentials arrive in the peripheral endings, the voltage change can induce release of neuropeptides that then have paracrine effects on neighboring cells, autocrine effects on the sensory neurons, or both. An interesting feature of AP movement in sensory neurons is that the signals bifurcate to be carried via the stem axon to the cell body when passing through the ganglion, thus enabling the cell body to have a record of the electrical traffic in the main axon and to respond to that traffic with relevant adjustments in gene expression and transcription.

The electrophysiology of nociceptors has some unusual properties. For example, it is now known that conduction velocity increases and AP duration decreases for C and A-d fibers after 2 days of tissue inflammation, and the afterhyperpolarization of A fibers also decreases (67). Many A-d and C fibers have an inflection on the falling phase of their AP and a prolonged afterhyperpolarization, both involving calcium channels. The after-hyperpolarization is enhanced during periods of activity and counterbalanced by excitatory cross- depolarization from adjacent active fibers (138,139) (Fig. 3-21). Evidence suggests that bursts of spontaneous impulse generation occur periodically in normal dorsal root ganglia, and that after nerve injury there are periods of increased frequency followed by periods of suppression and hyperpolarization (128,139). Gradual excitatory summation of low-intensity stimuli in C fibers can cause extended bursts of APs that contribute to central sensitization (140). When antidromic potentials are triggered during dorsal root reflex, they affect all calibers of sensory fiber (141) and can modify sensitivity of peripheral endings as reviewed by Willis (142). For example, one study shows that the peripheral axons to the primary and secondary spindle afferents of muscles are differentially affected by antidromic APs. At low signal frequency, only the secondary afferents are inhibited, but both are affected at high frequency (143), thereby causing different effects on muscle afferent sensitivity depending on the rate of reflex potentials. Release of substance P by C-fiber activity in the ganglion has been shown to vary, depending on tissue condition, and to inhibit subsequent A-fiber AP traffic through the ganglion (137), providing further complexity to passage of electrophysiologic information from the periphery to the CNS.

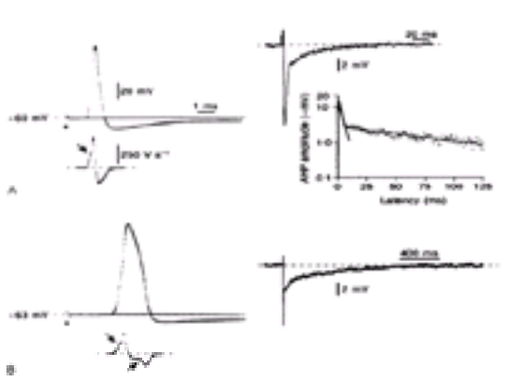

Figure 3-21. Spike waveform and afterhyperpolarization in A fibers. In **(A)** and **(B)** the axon was stimulated (*) just below and just above threshold (single sweeps). **A:** Upper trace shows the spike waveform of A_0 fibers with standard action potentials and the lower trace shows the differentiated voltage signal illustrating spike inflections (*arrows*). **B:** Lower traces show A_{inf} fibers with an extra inflection on the falling phase and prolonged afterhyperpolarization. The higher gain, slower time base records on the right illustrate the two phases of the afterhyperpolarization, including a log plot for the cell in **(A)**, with linear regression plots for the two phases (1.5 and 0.2 mV ms^{-1}). [From Amir R, Devor M. Spike-evoked suppression and burst patterning in dorsal root ganglion neurons of the rat. *J Physiol (Lond)* 1997;501: 183–196, with permission.]

Axonal Transport

Although electrophysiologic signals move from one end of a neuron to another within seconds, the axonally transported cytochemical signaling systems take hours or days to reach their intraneuronal destinations. At least five pathways of axonally transported information in primary afferent neurons exist (see Fig. 3-20): (a) Anterograde transported molecules go from the cell body into the peripheral axon to the receptive endings and into the central axon to the central synaptic terminals. (b) Retrograde transport from the receptors in peripheral tissues travels back to the cell body, or from the presynaptic central terminals back to the cell body. (c) Transganglionic transported materials are picked up by the peripheral endings and move all the way to the central synaptic terminals. (d) Biphasic relay signaling occurs, in which a molecule such as NGF is transported retrograde from a peripheral injury site or from the CNS to the cell body, in which it elicits expression of another neurotrophin [brain-derived neurotrophic factor (BDNF)] that is then conveyed by anterograde transport to peripheral and central endings (144,145). That arrival of BDNF at central terminals may be a key trophic agent in driving persistent plasticity in the dorsal horn, because its expression and delivery only happen when significant injury occurs to drive increased NGF retrograde transport (144). (e) Finally, transneuronal transport occurs when transported materials, such as WGA-HRP (wheat germ agglutinen–bound horseradish peroxidase) or herpes virus, which were picked up in a peripheral tissue, such as cornea or tooth pulp, move into the next neuron in the CNS (146,147). Also, exocytosis and transfer of nerve labels into nonneuronal cells occurs after transport out to the peripheral nerve endings (148).

The anterograde and retrograde systems carry different materials at different rates for different purposes: (a) Rapid anterograde transport carries vesicle-packaged material from the Nissl body endoplasmic reticulum and Golgi organelles to the sensory and synaptic nerve endings or other specialized regions (e.g., nodes of Ranvier), traveling at relatively fast 200 mm per day to 400 mm per day rates, with specific molecular guidance systems to ensure delivery to the correct subcellular domain. (b) Slow anterograde transport moves cytoplasmic cytoskeletal materials such as microtubules and neurofilaments into the axons from the cell body at rates of 1 mm per day to 5 mm per day to resupply and maintains the axon and its endings. (c) Intermediate anterograde transport rates occur for mitochondria and other special cytoplasmic organelles that move within the axon. (d) Retrograde axonal transport carries retrograde signals from the central and peripheral endings back to the cell body at rates of 70 mm per day to 100 mm per day to return exhausted axonal materials to the lysosomal systems of the cell body for recycling or removal. The retrograde signals also trigger altered gene expression for altered nociceptor phenotype.

The extensive mapping of neural pathways in the periphery and CNS that occurred in the 1970s and 1980s (135,149) depended on the discovery of the anterograde and retrograde axonal transport systems in the 1960s and 1970s and on development of the wide variety of general transport labels such as anterograde

radioactive-labeled protein, bidirectional horseradish peroxidase, fluorescent labels, lipophilic hemocyanin dyes such as Di-I, and lectin-labels such as WGA-HRP. Some labels such as biocytin or phaseolus hemoagglutinin lectin have been extremely useful for marking neural form after electrophysiologic recording (see Fig. 3-16). In addition, some labels are specific for axonal subtypes, such as anterograde labeling of small intraepithelial fibers with WGA-HRP but not choleragenoid B-HRP (150) or transganglionic retrograde labeling of terminals of thin fibers by WGA-HRP and of large fibers using choleragenoid-HRP (151). However, combinations of labels can produce puzzling results, such as failure of transganglionic labeling when WGA-HRP is combined with choleragenoid-HRP (151) or failure of herpes virus retrograde transport when combined with Fluoro- Gold label (152); there is still much to learn about the subtleties of axonal transport mechanisms and the targeting of molecular traffic to the correct intraneuronal subcellular regions (153).

Rapid Retrograde Phosphorylation

Until the mid-1990s, the signaling cascades in mature neurons in response to application of ligands such as NGF to the nerve endings have been thought to require retrograde transport of endocytotic vesicles containing ligand and receptor to the cell body (154). However, ultrafast retrograde signaling by phosphorylated tyrosine kinase A (trkA) receptors for NGF has now been demonstrated to produce molecular reactions in the cell body at rates that are at least an order of magnitude faster than possible by standard retrograde transport (155,156). In addition to trkA, other proteins in the cell body also are phosphorylated quickly in response to NGF at the nerve endings. This mechanism appears to bypass internalization of ligand-receptor complexes, a process that requires too much time for the observed effects. Instead it somehow initiates a propagated signal that may involve calcium mechanisms (155). The slower retrograde transport of vesicles that do not have an effect until they reach the cell body many hours later is also important, but would elicit a different set of biologic responses from the ultrafast phosphorylation system.

Intracellular Nitric Oxide

NO is a diffusable gas with numerous local biologic actions that can be intracellular [e.g., stimulation of cyclic guanosine monophosphate (cGMP)–dependent kinases, ion channels, or phosphodiesterase] or extracellular (neurally induced relaxation of vascular smooth muscle, anterograde and retrograde signaling between presynaptic and postsynaptic units, or enhancement of spontaneous discharges in injured neurons involving satellite cell and neuronal interactions) (157,158,159 and 160). NO is generated when the enzyme NO synthase (NOS), in the presence of calmodulin, catalyzes conversion of l-arginine to citrulline, thereby releasing NO. The NO then diffuses short distances in cytosol or through nearby membranes, to activate soluble guanyl cyclase enzymes. These enzymes generate cGMP, thereby promoting cGMP-dependent actions in the donor cell or in nearby target cells, or both (see Fig. 3-20). NO signals are activity dependent, local, and short-lived, with NO amounts regulated first by their production followed by inactivation after binding to guanyl cyclase. More recent work shows that NO also can enhance nociceptor hyperalgesia induced by prostaglandin E_2, adenosine, or serotonin, by activating intracellular cyclic adenosine monophosphate (cAMP)–dependent mechanisms and protein kinase A (161). The NO that is generated at sites of inflammation or ischemia comes from a variety of cell types (neural, endothelial, immune) at different stages of the pathology, and it may potentiate the effects of other agents, such as prostaglandins at low concentration, but have its own direct effects at higher concentrations (161).

Much still remains to be learned about the specific local functions of NO in nociceptive neurons. So far, they involve enhancement of sensitization of peripheral endings (161), increased discharges from ganglia of injured nerves (158), activity-dependent retrograde effects on presynaptic cGMP functions at central endings (162), and inhibition of *N*-methyl-d-aspartate (NMDA)–driven excitotoxicity (159,160). Immunocytochemical studies have found that many visceral afferent neurons normally contain NO synthase, whereas only a few dorsal root ganglia or trigeminal neurons have it, suggesting different functions for NO in normal visceral afferent functions. However, after axotomy, the neurons of nodose, dorsal root, and trigeminal ganglia showed similar upregulation of the enzyme (53). That increased enzyme must then be transported to sites of action, in which it will induce local production of NO. Injured neurons would differ from normal not only in their amount of NO, but also in the specific NO-dependent cGMP or cAMP-driven reactions, and in their axonal transport traffic dynamics.

Basic Physiologic Properties

Chapter 2 defines many terms that are relevant to the neurobiology of pain. Several other physiologic properties are briefly defined here, to facilitate discussion of their contributions to transient, acute, and persistent pain, and the molecular mechanisms of nociceptor modulation and plasticity. These properties occur in primary afferent neurons and in central neurons, but with different mechanisms and significance at each successive level in pain pathways. Further information about fundamental aspects of neurophysiology can be found in reviews and books by Hall (135), Hille (134), Treede and colleagues (163), Meyer and colleagues (164), Devor (128), Nolte (133), Siegel and colleagues (136), Zigmond and colleagues (132), and Willis (142).

Action Potentials

APs are generated when gradual depolarization of the membrane potential causes enough inward sodium current flow through sodium channels to reach threshold for the all-or-none AP. At that time, a transient opening of voltage-gated sodium channels and inward sodium current occur that rapidly shifts the membrane potential to a positive value, followed by closing of the sodium channels and opening of voltage-gated potassium channels. The subsequent outflow of potassium ions brings the membrane potential back to its resting level, with important involvement of calcium and chloride currents in the afterhyperpolarization that precedes resetting of normal resting potential, and of calcium currents for an inflection on the falling phase of some A-d and C-fiber AP (see Fig. 3-21). Successive opening of voltage-gated sodium channels allows an AP to propagate at characteristic rates along the axon, as indicated in Table 3-1. The size of the peripheral axon correlates with conduction velocity to define the A, B, and C components of the compound AP. Primary afferent neurons that contribute to nociception are mostly in A-d and C groups, but some A-b neurons have nociceptorlike properties, and A-bmechanoreceptors in inflamed tissue have altered conduction properties (44,67,78), cytochemistry, and central connections (45). Although voltage and patch clamp technologies have shown that AP mechanisms are roughly similar in all neurons, important variations occur in resting potentials and AP size and shape (67) for different neurons and for different normal physiologic conditions, such as sleep (132,133,134 and 135,165), or after injury. For example, inflammation induces changes in conduction properties of nociceptive C, A-d, and A-b fibers (67), as well as blockade of A-fiber conduction through sensory ganglia if there has been release of substance P by prior C-fiber activity (137). Active fibers may cross-excite many of their neighbors, and neurotrophin growth factors affect conduction properties in some important ways (166,167).

Adaptation

Adaptation denotes the duration of physiologic response by a sensory neuron in relation to the stimulus. Slowly adapting mechanoreceptors continue to fire for the duration of a stimulus to give tonic information, whereas rapidly adapting receptors give phasic information about onset of stimuli (or their cessation). For many of the C fibers, their adaptation is slow and can outlast the stimulus, allowing for the temporal and spatial summation that underlie many of the features of inflammatory and pathologic pain.

Adequate Stimulus

For each somatosensory receptor, there is a preferred type of stimulus energy (mechanical, thermal, cytochemical, or a combination of those modalities) to which the neuron is most sensitive, called the *adequate stimulus*. Specific mechanosensitive and thermosensitive (heat or cold) receptor channels have been identified (164), as well as a variety of chemosensitive receptor mechanisms, such as those driven by bradykinin receptors, capsaicin-sensitive vanilloid receptors, purinergic receptors, or proton-sensitive receptors (127). The adequate stimulus depends on the complement of molecular mechanisms in the membrane of the primary afferents, and it differs for the different functional states (phenotypes) of a nociceptive neuron because the membrane chemistry changes. Each tissue has characteristic adequate stimuli for its custom-designed nociceptive apparatus, as discussed at the end of this section.

Dynamic Range

The range of stimulus intensities to which a sensory neuron responds is called its *dynamic range*. For polymodal receptors, it extends from the innocuous far into noxious levels of stimulation, whereas specific nociceptors have their dynamic range more narrowly confined to the noxious range. The dynamic range for central neurons can be wide or nociceptive specific, and it is affected by unmasking of auxiliary inputs during peripheral inflammation.

Receptive Field

Receptive field indicates the region of the body from which a particular sensory or central neuron is activated. The receptive field of a primary afferent neuron depends on the distribution of its terminals, their receptor properties, the presence or absence of inflammatory agents, and the type and location of the stimulus. The receptive field of a primary afferent expands during inflammation (163,164) (Fig. 3-22). The receptive field of a second-order neuron in spinal cord or brainstem depends on the

types of peripheral inputs and on complex central modulation. The receptive fields of central neurons are much larger than those of the primary afferents, and they expand if their target tissue is inflamed because of integration of many peripheral afferent inputs and central mechanisms. Central receptive fields can be altered within seconds via unmasking of ineffective afferent connections (168).

Spontaneous Discharge

Spontaneous discharge refers to APs that are generated, usually at the sensory cell body, without exogenous stimulation. Those APs then propagate distally and centrally to affect function of the peripheral and central endings. Daily fluctuations in spontaneous discharge rate have been demonstrated in normal conditions, and they are enhanced after neuropathic injury or inflammation (128,138,139). Spontaneous discharges in sensory neurons are often found as bursts of signals with intervening quiescent periods, and the intervals between signal bursts are altered by injury.

Stimulus Modalities

Mechanical, heat, cold, and chemical energy modalities activate sensory neurons via specific ion channels or receptors. Nociceptive C fibers exist that are specific for each of those modalities, as well as a large group that responds to noxious mechanical and heat stimuli [C-fiber mechanoheat nociceptors (CMH)]. Many other C fibers respond to chemical as well as mechanical and heat stimuli and are called *polymodal nociceptors* (see Polymodal Receptors, later in this chapter). The most common type of A-fiber nociceptor responds to high threshold mechanical stimuli in normal skin and becomes sensitive to heat also after injury (A-fiber mechanoheat nociceptors, AMH). Polymodal A-fibers also exist that are responsive to chemicals such as capsaicin in addition to mechanical and or heat sensitivity. Many A-d and C primary afferents cannot be mechanically activated in healthy tissue (mechanically insensitive or *silent* afferents) but become active in inflamed tissue (44,163,164) and might best be considered to be inflammation detectors.

Summation

Changes in the membrane potential at sensory endings (sensory potentials) or at postsynaptic regions (synaptic potentials) do not propagate actively, but dissipate over short distances. Successive potentials can combine to give a progressively more positive (excitatory) or more negative (inhibitory) membrane potential, with the integration of multiple inputs affecting AP generation in the axon. Neurons vary in the duration of their nonpropagating potentials and in the distance over which they can travel. Nociceptive endings have particularly long duration and effective distance, so that temporal and spatial summations are important mechanisms by which the nociceptive endings evaluate the severity of noxious or inflammatory events and titrate their signal frequency accordingly.

Sensitization and Hyperalgesia

Sensitization

Peripheral sensitization occurs when the stimulus threshold of a nociceptive neuron is lowered and the stimulus and response curve shifts to the left (Fig. 3-23). Perl and others (66,164,169) demonstrated that with repeated stimulation, high-threshold polymodal C fibers display enhanced sensitivity, lower stimulus threshold, and prolonged, enhanced afterdischarge. Not only are most C and A-d fibers sensitized by inflammatory mediators (Fig. 3-24), but some A-b fibers also become sensitized (44,45). Other agents, such as endocannabinoids and opioid peptides, decrease nociceptive responsiveness and therefore desensitize the neurons (161,170).

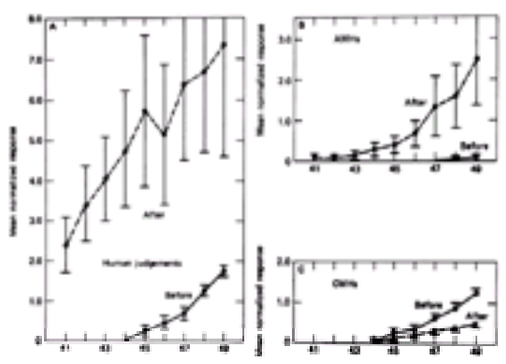

Figure 3-23. Hyperalgesia and nociceptor sensitization after a cutaneous burn injury. Responses to heat stimuli were obtained 5 minutes before and 10 minutes after a 53° C, 30-second burn to the glabrous skin of the hand. The burn resulted in increases in the magnitude of pain (hyperalgesia) in human subjects that were matched by enhanced responses (sensitization) in type I A mechanoheat receptive fibers (AMHs) in monkey. In contrast, C mechanoheat receptive fibers (CMHs) exhibited decreased sensitivity after the burn. **A:** Human judgments of pain (n = 8). **B:** Response of A-fiber nociceptive afferents (type I AMHs) in monkeys (n = 14). **C:** Responses of C-fiber nociceptive afferents (CMHs) in monkeys (n = 15). Because the AMHs did not respond to the 45°C stimulus before the burn, the AMH data were normalized by dividing by the response to the first 45° C after the burn. (From Meyer RA, Campbell JN. Myelinated nociceptive afferents account for the hyperalgesia that follows a burn to the hand. *Science* 1981;213:1527–1529, with permission.)

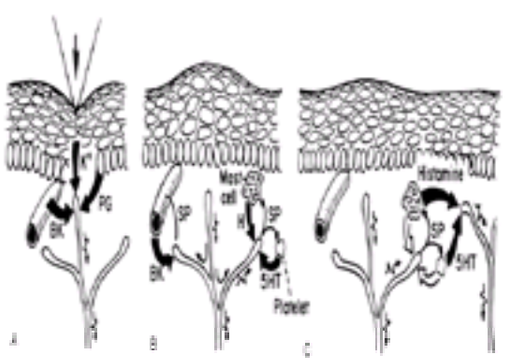

Figure 3-24. Events leading to activation, sensitization, and spread of sensitization of primary afferent nociceptor terminals. **A:** Direct activation of intense pressure and consequent cell damage, which leads to the release of potassium (K^+) and the synthesis of prostaglandins (PG) and bradykinin (BK). Prostaglandins increase the sensitivity of the terminal to bradykinin and other pain-producing substances. **B:** Secondary activation, showing that impulses generated in the stimulated terminal propagate not only to the spinal cord but into other terminal branches, where they induce the release of peptides including substance P (SP). Substance P causes vasodilation and neurogenic edema with further accumulation of bradykinin and also causes release of histamines (H) from mast cells and serotonin (5HT) from platelets. **C:** With continued liberation of substance P, the levels of histamine and serotonin continue to increase in the extracellular fluid and indirectly mildly sensitize nearby nociceptors. Sensitization leads to a gradual spread of hyperalgesia, tenderness, or both. (Modified from Fields HL. *Pain*. New York: McGraw-Hill, 1987:36.)

Central sensitization also occurs after tissue or nerve injury in an activity-dependent fashion (140,171). Both voltage-dependent NMDA receptors and metabotropic (neuropeptide or excitatory amino acid) receptors are involved, and protein kinase C activity is necessary to produce the characteristic increased intracellular calcium (172,173). Repetitive C-fiber stimuli that cause *windup* (increasing amplitude of central neuronal response) drive central sensitization, but other mechanisms that elevate intracellular calcium, such as summation of synaptic potentials below the firing threshold, can also lead to increased intracellular calcium and central sensitization. This is discussed in Chapter 4.

Hyperalgesia

Primary hyperalgesia involves altered physiology and pharmacology of the sensory endings to produce a leftward shift in the stimulus and response curve for injured tissue. It is triggered by inflammatory mediators, persisting noxious stimuli, or both, and it is characterized by lowered threshold, increased rate of APs, spontaneous activity, and increased pain sensation to suprathreshold stimuli. Its specific characteristics depend on the energy that caused the injury (heat has different effects than mechanical injury), on the type of tissue, the energy of the test stimulus, and the time after injury (2,128,163,164). Hypoalgesia is the opposite phenomenon, with increased threshold of primary afferent sensory endings and decreased pain from the stimulated tissue.

Secondary hyperalgesia involves increased pain and allodynia from uninjured tissue surrounding the injury (see Fig. 3-22). It is driven mainly by increased excitability of central neurons via activated NMDA receptors, elevated intracellular calcium, and increased sensitivity to glutamate. The mechanisms for secondary hyperalgesia share many central neuronal plasticity responses with referred hyperalgesia and neuropathic hyperalgesia (163) (see Chapter 4).

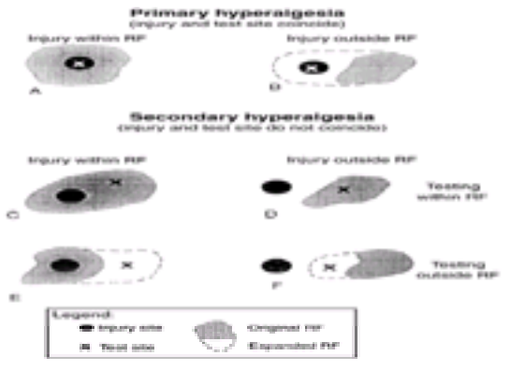

Figure 3-22. Experimental configurations for testing the neural mechanisms of primary and secondary hyperalgesia. For primary hyperalgesia, the site of injury (*filled circle*) and the site of testing (*X*) must coincide. Alterations of the stimulus-response functions within the original receptive field **(A)** or receptive field expansions toward the injury site **(B)** are correlates of primary hyperalgesia. For secondary hyperalgesia, the site of injury and the site of testing must not coincide **(C–F)**. A sensitization of the stimulus-response function revealed by testing within the original receptive field may occur following injuries within **(C)** or outside **(D)** the receptive field. An expansion of the receptive field to include a test site outside the original receptive field may occur for injuries within **(E)** or outside **(F)** the receptive field. (From Treede RD, Meyer RA, Raja SN, et al. Peripheral and central mechanisms of cutaneous hyperalgesia. *Prog Neurobiol* 1992;38:397–421, with permission.)

Reflexes That Affect Nociception

Spinal Motor and Autonomic Reflexes

It has long been known that when tissue damage initiates nociceptive impulses, some of those signals are transmitted to the anterior horn cells to stimulate somatic motor nerves, whereas others are transmitted to the anterolateral horn to stimulate cell bodies of preganglionic neurons (Fig. 3-25). Somatomotor stimulation produces increased tension or spasm of skeletal muscles, which, in turn, can give rise to positive feedback loops that enhance the spasm, which then becomes a new source of nociceptive impulses to reinforce the already existing nociception. Those reflexes can be driven by somatic, visceral, or both kinds of motor spasms. The increase in sympathetic tone leads to peripheral vasoconstriction, with consequent decrease of the microcirculation in the injured tissue and adjacent muscles. That induced ischemia may further enhance sensitization of nociceptors and thus increase nociceptive input. Moreover, this reflex sympathetic response often plays an important role in certain types of persistent pain.

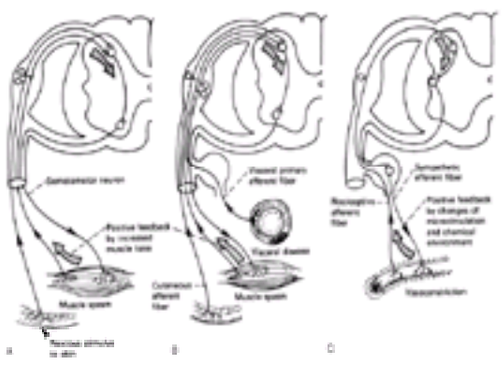

Figure 3-25. Diagram indicating some possible mechanisms of self-excitation nociceptors by spinal reflexes. **A:** A somatomotor reflex induced by stimulation of cutaneous or muscle nociceptors causes reflex contraction of skeletal muscles, which, in turn, act as positive feedback to further excite and sensitize the dorsal and ventral horns' neurons (*arrows*) and to produce an abnormal reflex mechanism, resulting in further increase in tension of the muscle. **B:** A similar mechanism of producing skeletal muscle spasm, initiated by a convergence of cutaneous and visceral primary afferents on viscerosomatic spinothalamic tract neurons. Stimulation of the somatomotor neurons in the anterior horn produces reflex skeletal muscle spasm, which acts as positive feedback to create and sustain a vicious circle. **C:** Noxious stimulation of primary afferent fibers produces nociceptive input, some of which is transmitted to spinothalamic tract neurons. Other impulses go to the anterolateral horn to stimulate sympathetic preganglionic (efferent) fibers, causing vasoconstriction, increased smooth muscle tone, and change in the chemical environment. The latter, in turn, acts as positive feedback to further increase nociceptive input.

The efficacy of relaxation techniques, massage, peripheral vibration, transcutaneous electrical nerve stimulation, and other therapeutic methods that manipulate the peripheral tissues to counteract pain problems must depend in part on inhibiting the reflex muscle spasms and promoting blood flow to counteract sympathetic vasoconstriction. In addition, such activity can affect information processing in the dorsal horn to inhibit the effect of the nociceptive messages and short circuit the positive feedback loops, as proposed originally by Melzack and Wall (4) and modified by the numerous studies of dorsal horn mechanisms since the 1970s (24,26) and discussed in Chapter 4.

Dorsal Root Reflexes

The sensory barrages to the dorsal horn that are triggered by inflammation or neuropathic injury induce reflexive efferent conduction back out the sensory axons in fibers of all size (141,142). The specific efferent effects of dorsal root reflexes on sensory systems need further examination. Those reflexes may play important roles in contralateral sensory sequelae to unilateral injury, such as a mirror-image inflamed knee (174). In addition, it has been shown that sensory fibers of skeletal muscle are differentially affected by dorsal root reflexes, so that they would each acquire a new relationship that would alter the sensory receptor balance in the muscle and, in turn, affect motor reflexes (143).

Neuroimmune Reflexes

Research during the 1990s has shown that important afferent signals to the brain occur via the vagus nerve that drive *illness behaviors* (guarding behavior, hyperalgesia, loss of appetite), physiologic changes such as fever and activation of hypothalamic- pituitary-adrenal system, and cytochemical changes in central neurons. Immune defense after intraperitoneal injections of agents such as lipopolysaccharide causes release of interleukin-1b (IL) or other cytokines such as tumor necrosis factor in the affected tissue, that in turn stimulate paraneurons along the vagus to activate visceral sensory fibers via direct synapses. Subdiaphragmatic

vagotomy completely eliminates the afferent branch of these powerful reflexes, so that all of the central neural cytochemical, physiologic, and behavioral responses except for increased corticosterone are interrupted. This type of experiment shows the importance of the vagus nerve pathway for cytokine-brain communications (27,175,176). When the vagus is intact, it is a conduit for afferent information that has profound effects on pain perceptions and behavioral reactions that in turn affect peripheral tissues. For somatic nerves outside the territory of the vagus nerve, nerve-associated lymphoid tissue can respond to inflammation and then affect nociceptor activity via release of modulators such as IL-1b (177).

Neuroendocrine Reflexes

Tissue injury also induces neuroendocrine responses that feed back to modulate the sensitivity of primary afferent neurons. For example, stress induces release of corticotropin-releasing factor and corticosterone reduces nociceptor sensitivity, as seen during stress-induced analgesia (32). Similarly, increased systemic amounts of opioids and other antinociceptive factors can inhibit activity in nociceptive pathways at central sites and via peripheral opioid receptors. It has been demonstrated that the phospholipid- and calcium- binding protein, annexin I, blocks the phospholipase A_2 pathway and the production of arachidonic acid metabolites such as prostaglandin E_2 and leukotriene B_4 (178). That modulation inhibits the actions of inflammatory mediators such as bradykinin-induced increases in prostaglandin E_2. In addition to inhibitory feedback neuroendocrine reflex modulation of pain, also endocrine enhancement of pain may occur, as during chronic inflammatory conditions, that may elevate systemic NGF (179).

Tissue Specificity of Nociception

The specificity of nociceptive innervation is reviewed here, with emphasis on nerve pathways, types of primary afferent neurons, and adequate stimuli per organ system. The sensory and protective requirements of skin are different from those of muscle or vasculature or gastrointestinal tract or urogenital system or teeth or other tissues, because each tissue has its own types of low and high threshold innervation, adequate natural stimuli, and responses to inflammation. In all cases, there are polymodal receptors with different properties from the specific nociceptors and different functions for different tissues. We know more about skin and joints than some other tissues, because they have been particularly well studied in animal models, but the 1990s have seen many advances in understanding other tissues as indicated throughout this book. In addition to the specific nociceptors and the polymodal receptors, numerous silent nociceptors exist that also are only responsive to experimental stimulation during inflammation (43,164). The polymodal receptors and silent nociceptors have critical importance for persistent inflammatory and neuropathic pain, as described in Peripheral Mechanisms of Persistent Pain, later in this chapter.

Microneurographic recordings from awake humans have given ample evidence that all the general nociceptive properties documented in animals from rat, to cat, to monkey also occur in humans after mechanical, thermal, chemical, or electrical stimulation (180,181). However, some species differences exist in the proportions of each type of nociceptor in particular organs, and there must be some variations within a species that contribute to individual differences in pain threshold and tolerance. Much greater details on the specific nociceptive innervation of skin, joints, muscle, bone, viscera, blood vessels, teeth, temporomandibular joint, and regional pain are considered in the chapters specifically devoted to those areas. Some of the differences in innervation of skin, muscle, and viscera are demonstrated by the different proportions of substance P, calcitonin gene–related peptide (CGRP), and somatostatinlike immunoreactivity of sensory cell bodies labeled by retrograde transport from the saphenous nerve, gastrocnemius nerve, or splanchnic nerve (64) and showing that neuropathic injury affects different sensory neuropeptide subgroups depending on the type of nerve.

Most nociceptive afferent units in uninflamed tissue conduct impulses in the A-d or C-fiber range, although for each type of myelinated nociceptor there are some that conduct up to 50 M per sec, which is well into the A-b range. Some of the nociceptors respond only to intense forms of mechanical stimuli and are known as *mechanical nociceptors*, many of the cutaneous receptors respond to noxious mechanical and heat stimuli and are known as *mechanoheat nociceptors*, and some A-d fibers respond only to intense heat stimuli, called *heat nociceptors*, or to intense cold stimuli, called *cold nociceptors*. Those that respond to noxious mechanical, thermal, and chemical stimuli were initially called *polymodal nociceptors* or, more recently, *polymodal receptors*, (23,129) as discussed in Polymodal Receptors, later in this chapter. Acute nociceptors are characterized by their restricted receptive fields and their ability to respond differentially or exclusively to noxious stimulation. Some nociceptors respond to stimuli that are not noxious or perceived as painful, but are most effectively excited by stimuli in the noxious range. This is not unexpected, because their function is to provoke protective responses that need to be initiated before irreversible tissue damage has occurred. It is thus clear that the afferent units that signal acute tissue injury also signal levels of stimulation that only threaten such damage.

Cutaneous Nociceptors

Skin, subcutaneous tissue, and fascia are supplied by all the categories of nociceptor described previously, with important differences in the distribution and subgroups found in glabrous skin compared with hairy skin (see Fig. 3-8). A-d myelinated mechanical nociceptors, also referred to as *high-threshold mechanoreceptors*, respond only to moderately intense or noxious mechanical stimuli; they do not respond to heat or algesic chemicals. They have been demonstrated in the skin of the body and face of the cat and monkey and in the human forearm (see Fig. 3-22 and Fig. 3-23) (163). They terminate in the epidermis close to the basal keratinocytes (84). Their receptive fields consist of collections of from 3 to 20 discrete spots, each with an area of less than 1 mm^3. These are interspersed among regions unresponsive to equivalent stimuli and are distributed over areas ranging from 1 cm^2 to 8 cm^2 on the body surface and 1 mm^2 to 2 mm^2 on the face. Their stimulus thresholds are 5 to 1,000 times higher than those of the various low-threshold mechanoreceptors. In the absence of stimulation, these receptors are silent, although repeated stimulation leads to a slow background firing that is important for activating central hyperalgesia mechanisms (182). Most high-threshold mechanoreceptor units have axons that conduct in the range of A- d fibers (mean velocity of 15 m/s to 25 m/s, but wide range of 5 m/s to 50 m/s). It is clinically important that approximately 20% of cutaneous high-threshold mechanoreceptors supplying the skin also have receptive fields in the subcutaneous tissue, usually fascia (66,164).

The mechanoheat nociceptors include myelinated AMH fibers and unmyelinated CMH fibers (164). Two types of AMH fibers exist. Type I has high threshold levels of at least 50°C and usually greater than 53°C, with a mean conduction velocity of 30 M per s, and a maximum of 55 M per s. Type II AMH units have lower thresholds and slower conduction velocity (mean, 15 M/s). The CMH mechanoheat nociceptors have the lowest thresholds in the 38° to 50° C range, and their responses increase with stimulus intensity over that temperature range, which includes the pain threshold range for humans. The AMH and CMH fibers have an important role in coding pain intensity.

Some exclusively thermoreceptive nociceptors have been described (163). The cold nociceptors are insensitive to noxious mechanical stimuli and A- and C-caliber groups have been described. They typically are silent over the temperature ranges that excite low-threshold cold receptors. Much of the response to noxious cold stimulation of skin appears to come from vascular receptors, based on ability of local circulating anesthetic to block that pain in humans (164,183). Specific heat nociceptors that have been described are insensitive to mechanical stimulation under normal healthy conditions.

Finally, polymodal nociceptors have variable responses over a range of chemical, mechanical, and thermal noxious stimuli, and they make up a majority of the fibers in many peripheral nerves. They are characterized by their responsiveness to intense mechanical (greater than 1 g), thermal (maximal firing range, 45° to 53°C) and chemical stimuli. Their receptive fields comprise one to two spots in the nonprimates that have been studied, but may be much larger in humans, suggesting extensive peripheral branching (6).

Data from the 1980s and 1990s confirm the earlier suggestion by Zottermann and others that both A-d and C fibers are essential for transient pain (184). The wealth of more recent experiments confirms the century-old concept that brief noxious stimulation to the skin with a pinprick or application of brief noxious heat provokes a double pain response: a fast first pain that has a pricking quality and lasts less than 50 milliseconds, followed by a painless interval of 1 second or longer, after which a slow second pain occurs that has a burning quality and lasts for 1 second or longer. It has long been established that the first pain is mediated by A-d fibers and the second pain by C fibers, and that the double pain response is most easily elicited in the upper and lower limbs and the anterior wall of the trunk below T-3.

The A-d group in skin is mainly specialized for detecting dangerous mechanical or thermal stresses and for triggering a rapid nociceptive response and protective reflexes. The C-polymodal nociceptors also respond to strong mechanical, thermal, and chemical stimuli and are sensitized by chemical agents released in damaged or inflamed skin. Therefore, in addition to reinforcing the immediate response of the A-d fibers to mechanical or thermal stress, the C-polymodal fibers signal the presence of damaged or inflamed tissue, and they contribute to guarding behavior to promotion of healing. The sensitivity of all classes of nociceptor increase following mild injury, and this is a factor in producing primary hyperalgesia, defined previously.

Finally, there have been suggestions that the sensation of itch is simply a different pattern of signals from neurons that can otherwise signal pain (164). However, some specific itch receptors have been identified that react to histamine stimulation of human skin (185).

Noncutaneous Integument

Most of the mucosa of the mouth, nasopharynx and its sinuses (including the middle ear), and mucous membrane of the larynx, upper trachea, and the anal canal are sites of pain consequent to noxious stimulation in the form of extreme cold or heat, chemical, or mechanical stimuli. A high proportion of the nociceptive innervation is of the polymodal receptor type, so inflammation significantly lowers the pain threshold. The oral and nasal mucous membranes have a dense sensory innervation, with a high incidence of polymodal receptors and many fine intraepithelial endings (186,187).

The cornea is innervated by A-d and C fibers that contribute fine axonal terminals that respond readily to mechanical, thermal, and chemical stimuli and can be sensitized by heating (188). Most have characteristics of polymodal receptors. Thus, they are well suited for providing information about potential damaging conditions and are presumably responsible for triggering reflex reactions, such as blinking and tear secretion, as well as transmitting nociceptive impulses, which produce the excruciating pain characteristic of corneal inflammation or injury. Those responses are eliminated in experimental animals by capsaicin treatment, and loss of the blink reflex is the standard indicator of capsaicin denervation in the adult. Trophic efferent actions of corneal polymodal innervation is shown by the persistent keratitis in capsaicin-denervated rats (189).

Other special integument regions, such as tympanic membrane, nails, and external genitalia, have sensory innervation with a high proportion of the polymodal receptors and distinctive pain characteristics (23,60,129).

Visceral Nociceptors

It has long been widely recognized that stimuli that damage skin and deep somatic structures produce pain, but when they are applied to the viscera they usually do not provoke pain. However, Cervero has pointed out that typical cutaneous mechanical or thermal stimuli are not adequate stimuli for viscera, and that one must choose natural stimuli, such as increased biliary pressure, to detect specific nociception in viscera (190) (Fig. 3-26). All of the abdominal and thoracic viscera have afferent innervation associated with parasympathetic or sympathetic nerves, participating in reflex control of cardiopulmonary, gastrointestinal, and genitourinary functions, and changes caused by these reflexes are not perceived. However, when viscera are distended or inflamed, as in the extensive research of the last decade on colorectal pain (191), vaginal and uterine pain (192), or bladder inflammation (193), sophisticated polymodal nociceptive mechanisms are detected.

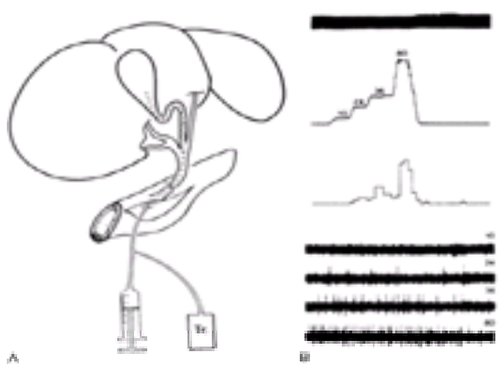

Figure 3-26. Demonstration of the effect of increasing the biliary pressure on high-threshold biliary afferents. **A:** One method of mechanical stimulation of the biliary system. A catheter is inserted through the major duodenal papilla to cannulate the common bile duct, and a ligature is placed around the bile duct to fix the catheter in position. The catheter is connected to a transducer (Tr) and to a syringe for the injection of warm saline into the biliary system. **B:** The response of one high-threshold biliary afferent to increasing biliary pressure. From top to bottom are shown blood pressure, biliary pressure (with numeric values), rate of firing of the afferent, and a recording of electrical activity at different biliary pressures. Activity begins to appear at higher pressures, which evoke transient increases in systemic blood pressure. (From Cervero F. Afferent activity evoked by natural stimulation of the biliary system in the ferret. *Pain* 1982;13:137–151, with permission.)

In general, the afferent fibers from the thoracic and abdominal viscera, except those from the pelvis, run in association with sympathetic fibers. Although the range of fiber size is comparable with that of cutaneous fibers, a considerably higher proportion of C fibers to A fibers exists, with a ratio of approximately 10:1 rather than the 2:1 that is found in cutaneous nerves. Visceral afferents constitute less than 10% of afferent fibers in dorsal roots. However, myelinated and unmyelinated visceral afferents ramify so extensively that there is great overlap between the fields of adjacent dorsal roots. A much larger proportion of the visceral afferents have polymodal receptor properties than is found for cutaneous afferents (23,129,194).

Cardiac. It has long been established that reversible ischemia of ventricular muscle by occlusion of the coronary artery produces pain in humans and in animals via A-d and C visceral afferent fibers that accompany the sympathetic nerves to the heart (195,196). Single-unit recording from the rami communicantes or dorsal roots of sympathetic afferents has shown that activity of A-d and C fibers increases significantly during coronary occlusion. The mechanosensitivity of some slowly responding A-d and C fibers is involved with cardiovascular reflexes. The faster-responding C fibers are chemonociceptors that can be activated by serotonin, histamine, bradykinin, acids, and prostaglandins. It has been suggested that angina results from the combined stimulation of bradykinin and prostaglandins on cardiac polymodal receptors (196).

Respiratory. In the lungs, two types of receptors have been described that probably have nociceptive functions: the type J receptors, with C afferents, and the *lung-irritant receptors*, with afferents in the A-d range, all running in the vagus nerve (197). The type J receptors are located in the interstitial space close to the capillaries, whereas the lung-irritant receptors are in the epithelial lining of the lung and its airways. These are activated by a variety of stimuli that produce mechanical distortion within the lung, such as pulmonary congestion, microembolism, atelectasis, and pneumothorax, and by chemical irritants. The peptide contents of the visceral sensory fibers in lung and airways and their responses to inflammatory mediators suggest that they are in the polymodal receptor category of nociceptor (198).

Gastrointestinal. The gastrointestinal tract has slowly adapting and rapidly adapting mechanoreceptors and chemoreceptors. Sensory impulses from the upper two-thirds of the esophagus are carried by A-d and C fibers in the vagus, whereas in the lower one-third, the afferent fibers travel in sympathetic nerves and enter the cord at T5–8 inclusive (see Chapter 60 and Chapter 65). The stomach, small intestine, and large intestine as far as the splenic flexure are supplied by sympathetic afferents that enter the spinal cord between T-(5)6 and L-2 inclusive. The primary afferents that supply the descending colon and rectum pass through the pelvic nerves and enter the spinal cord via ventral and some dorsal roots of S2–4. Mechanoreceptors of A-d and C fibers are found in smooth muscles of the hollow viscera. Morrison has described splanchnic afferents whose receptive fields contain up to eight punctate mechanosensitive sites distributed along walls of the viscera. They responded not only to light mechanical stimuli but also to tension applied to the peritoneum, to smooth muscle contraction, and to visceral distension. C-polymodal afferents with multiple spotlike receptive fields in the mucosal lining of the rectum and perhaps other parts of the gastrointestinal tract have been found with polymodal properties. For reviews of gastrointestinal and abdominal visceral sensory functions, see Cervero and Morrison (199), Koltzenburg and McMahon (193), and Gebhart (191,194).

Biliary. The gallbladder and bile ducts are supplied by splanchnic afferent units excited by distension and with small receptive fields. Cervero (200) used controlled pressure stimulation to distend the gallbladder and ducts and noted that there were two distinct types of units: low-threshold and high-threshold fibers. The high-threshold groups required pressure in excess of 25 mm Hg, as is likely to occur when obstruction exists in the ductal system, and these responses were accompanied by reflex vascular changes (Fig. 3-26).

Urinary. Visceral afferents that supply the kidney travel via sympathetic nerves and enter the spinal cord at T-10–L-2. Some of these have a nociceptive function because distension of the fascia of the kidney, irritation of distension of the kidney pelvis, or distension of the ureter (kidney stone) causes pain, and extensive peptidergic sensory innervation of kidney and ureter occurs (201). The urinary bladder is supplied by C and A-d fibers that are sensitive to stretch and contraction, some of them passing through the lumbar and sacral splanchnic nerves and others passing through the pelvic nerves (193). As for other viscera, rapid distension, contraction, or pressure of the kidney, ureters, or bladder causes severe pain. The involvement of polymodal receptors in bladder pain is indicated by the peptide

content of bladder afferents and their responses to inflammatory mediators (193).

Peritoneal. Lipopolysaccharide or inflammatory challenge to the peritoneal cavity causes pain and causes immunocytes to release IL-1b. If experimental animals have received a subdiaphragm vagotomy, the pain behavior is reduced, showing involvement of vagal afferents in initiating pain and illness behavior via the nucleus tractus solitarius (27).

Intraabdominal Solid Organs. The liver is supplied with vagal afferents within the parenchyma or along the hepatic arterial system that are primarily concerned with regulating osmotic pressure, glucose concentration, and temperature of the organ. However, they also respond to cytokines such as IL-1b that are produced by the resident immunocytes or by the vagal paraganglia during an immune response (27), and thereby trigger pain-related physiologic responses via their connections with the nucleus tractus solitarius. In addition, afferents that travel via sympathetic nerves innervate the capsule of the liver, and those fibers initiate pain in response to distension of the organ. Similarly, the spleen and the pancreas are innervated by afferents that travel in the sympathetic nerves and that innervate the capsules of the organs and their blood vessels and ductal systems. These mechanoreceptors, like those supplying the other viscera, normally have a reflex function, but in the presence of inflammation their threshold is greatly reduced and their activation causes pain. The sensitivity of visceral afferents from the vagus nerve to inflammatory mediators or to cytokines released by immunocytes in the solid viscera contributes significantly to the quality of pain from these organs (27).

Reproductive Systems

The reproductive systems include integument structures and deeper visceral organs that have complex innervation by visceral, somatic, and autonomic nerves. Those afferents travel in multiple peripheral nerves to enter the CNS through many dorsal roots, and they have extensive divergence of their central arbors, to give a diffuse somatosensory system that is integrated with autonomic and endocrine information (129, 192, 202, 203 and 204). For example, nociceptive and polymodal afferents in women have pathways via (a) the pudendal nerve projecting via L-6–S-2 (for perineal structures), (b) the pelvic nerve and plexuses via S2–4 (for cervix and lower uterine region), (c) the thoracolumbar splanchnic nerves and the cervical, uterine, and inferior hypogastric plexuses and nerves (for upper vagina, cervix, uterine body, inner third of the fallopian tubes and ligaments) that travel via the hypergastric plexus, through the sympathetic chain and then into dorsal roots T-10–L-1, and (d) afferents from the ovary and distal fallopian tube that enter the sympathetic chain at L-4 and then the spinal cord at T9–10 (Fig. 3-27). With increasing study of individual afferents, the richly detailed stimulus characteristics and polymodal properties of these visceral afferents are becoming apparent (23, 129, 192). The mechanisms of acute reproductive pain are becoming clear, but those for chronic pelvic pain have not usually correlated with specific peripheral pathology, suggesting the importance of complex central mechanisms (204) and neuroimmune reflexes via the vagus nerve (27).

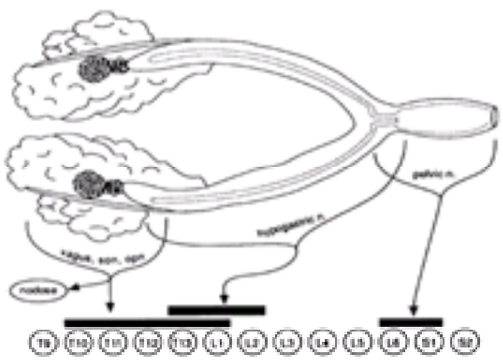

Figure 3-27. Summary of the sensory afferent innervation of female internal reproductive organs in the rat. The upper part of the figure is a diagram of, from left to right, the ovary, oviduct, ovarian ligament, and surrounding fat pads, the uterine horn, cervix, and vaginal canal. The middle part of the figure shows the nerves through which afferent fibers travel from different parts of the reproductive tract to reach nodose and dorsal root ganglia shown at the bottom of the figure. Note overlap of hypogastric and pelvic nerve innervation of the cervix so that primary afferent input from this region enters through two separated sets of dorsal root ganglia (T-13–L-2 and L-6–S-1). (son, superior ovarian nerve; opn, ovarian plexus nerve.) (From Berkley KJ, Hubscher CH. Visceral and somatic sensory tracks through the neuraxis and their relation to pain: lessons from the rat female reproductive system. In: Gebhart GF. *Visceral pain. Progress in pain research and management*. Vol 5. Seattle: IASP Press, 1995:195–216, with permission.)

Deep Somatic Tissues

Skeletal Muscle and Tendon. The stretch receptors of muscle comprise only approximately 25% of the sensory innervation, and the other 75% consists of free endings in fascia of the muscles, between muscle fibers, and in the walls of blood vessels and tendons (see Fig. 3-8) (69, 205). These endings are supplied by thin A-d myelinated axons (group III) and unmyelinated C fibers (group IV). After losing their myelination, the terminal branches of the A-d fibers may extend 1 mm, supplying a field as large as 25 mm × 200 mm. A majority of them respond to inflammatory mediators and also to innocuous to noxious pressure and thermal stimuli and are therefore clearly polymodal receptors (70). They also can be activated by muscle stretch or contraction. Approximately 80% of the C fibers are polymodal (70), but their threshold to mechanical stimuli is higher than that of the A fibers, their receptive fields are small areas within muscle or tendon, adaptation is slow, and few respond to stretch and none to contraction.

Joints. Joints are usually supplied by two types of nerves: articular branches derived directly from major nerves that supply the joint exclusively, and accessory nerves that are short branches from nerves supplying the muscles near or surrounding the joint. The large (group I) and medium (group II) A fibers terminate in mechanoreceptive endings that detect the torque that develops as a joint is extended, flexed, or rotated to the extreme of its range. Most of the A-d (group III) and all of the C fibers (group IV) end as free nerve endings that form a widespread plexus in the joint capsule, ligament, fat pads, and adventitia of blood vessels that supply the joint. The detailed examination of joint innervation in normal and inflamed conditions has been one of the best model systems for understanding polymodal receptors and their functions, including identification of the properties of silent nociceptors, defining the complex variations in chemosensitivity of polymodal receptors, and showing sensitization of some group II thick myelinated fibers by inflammatory agents (44) (Fig. 3-28).

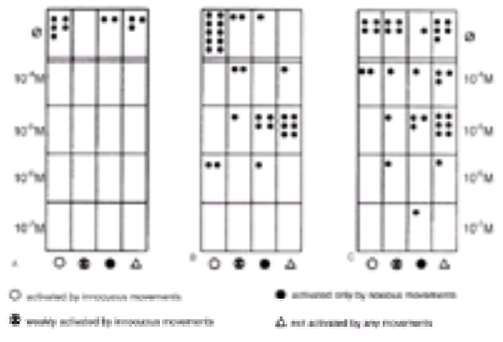

Figure 3-28. Sensitivity to capsaicin of a population of 84 fine afferents recorded from the knee joints of 24 cats. The units were classified based on conduction velocity [**(A)** group III with velocity > 11.3 m/s; **(B)** group III with velocity <11.3 m/s; **(C)** group IV] in regard to their responses to passive movements of the knee joint (left to right in each panel according to the key given at the bottom of the figure). The study included only units that were readily excited by a close intra-arterial bolus injection of 0.3-mL twice isotonic KCl solution. Units that did not respond to a 0.3-mL bolus injection of 10^{-4} M capsaicin were classified as unresponsive (uppermost row in each panel). Notice that many group III fibers with conduction velocity slower than 11.3 m/s were responsive. (From Schmidt RF. The articular polymodal nociceptor in health and disease. In: Kumazawa T, ed. *The polymodal receptor—a gateway to pathological pain. Progress in brain research*. Vol 113. Amsterdam: Elsevier, 1996:53–81; as modified from data in Herbert MK, Schmidt RF. Activation of normal and inflamed fine articular afferent units by serotonin. *Pain* 1992;50:79–88.)

Bone. Among the deep somatic structures, periosteum of bone is a frequent site of pain. Bone is a dynamic tissue capable of responses to injury, stress, and metabolism, and it has sensory innervation that responds to external stimuli and to internal pressure. The periosteum receives nerve endings of thinly myelinated A-d and unmyelinated C fibers, the terminals of which form a plexus that is especially extensive in the periosteum of long bones and that mostly contains neuropeptide-rich polymodal receptors. In the bone, nerve fibers run along with blood vessels in the haversian canals and are mostly vasomotor. The cancellous portion of the bone also receives free nerve endings of C and A-d fibers that are nociceptors, whereas the cortex and marrow of the bone receive mostly vasomotor fibers and normally are not pain sensitive (206).

Teeth and Periodontal Ligament. Teeth are richly innervated by C, A-d, and A-b fibers that are primarily nociceptive, whereas periodontal ligament has both a nociceptive innervation and an elaborate set of Ruffini mechanoreceptors that provide the tooth touch sensitivity, as described in Chapter 50 and several reviews (207,208 and 209). The sharp acute pain from an injured tooth depends on fast A-d and A-b fibers that terminate in dentin and adjacent pulp, whereas the more diffuse pain of toothache depends mainly on capsaicin-sensitive polymodal C and slow A-d fibers in pulp reacting to pulpal damage and inflammatory mediators (209,210). There is also an important A-b innervation of teeth that has the lowest threshold. Those fibers have prepain and vibration-detection functions (211) as well as involvement in dentinal pain (208). Silent nociceptors also have been identified in tooth pulp (209). Much of the dense innervation of teeth is needed to protect against excessive forces that can crack enamel and dentin and to regulate pulpal blood flow and interstitial fluid pressure, in partnership with sympathetic fibers. The nerves in teeth are, therefore, mainly polymodal with important efferent regulatory functions in addition to their responses to injury and inflammation, as discussed in Chapter 50.

Blood Vessels, Meninges, and Pleura. Numerous primary afferents and especially polymodal receptors innervate the blood vessels in all tissues of the body and exert important control over vasodilation via neuropeptide release at arterioles and extravasation of plasma protein and cells at venules after injury. The major vessels of the meninges also receive important sensory innervation, and the trigeminal afferents to the dura have been shown to exhibit sensitization, suggesting their importance for headache pain (212). Many of the nerve endings along the transverse sinus within the dura were found to be A-d or C-fiber mechanically sensitive units, of which subsets also responded to various agents, such as hypertonic sodium chloride, low pH, capsaicin, histamine, serotonin, bradykinin, or prostaglandin E_2, when applied directly or via intravascular infusion. The meningeal afferents also have been shown to induce degranulation of dural mast cells and could be important sources of intracranial neurogenic inflammation (213). The electrophysiologic properties of those meningeal afferents make them likely to respond to the normally innocuous head movements that become painful during conditions that cause headache. Finally, electrophysiologic and structural studies have found many A-d and C polymodal receptors in the pleura with widely distributed receptor arbors that have mechanical and chemical sensitivities as well as responses to noxious cold (214).

POLYMODAL RECEPTORS

Polymodal receptors, also called *polymodal nociceptors* or *neuroeffectors*, participate in regulation of tissue homeostasis, along with autonomic and endocrine systems, via efferent release of neuropeptides and afferent transport of cytokines and growth factors to inform the sensory cell body and CNS about tissue conditions. Organisms need specific nociceptors to detect tissue injury to elicit reflex escape for preservation of tissues and life, and the specific nociceptors that were discussed in the previous section are designed for that type of activity. The polymodal receptor system is quite different in that it interacts with many different cell types to monitor and facilitate local physiology and to shift neural behavior in ways that promote normal health, regeneration, and wound healing (Fig. 3-29). The reflex responses of polymodal receptors to changes in tissue chemistry (whether the minor shifts in efferent neurokine release during normal functions, or the dramatic changes in cytochemistry after injury and during inflammation) contribute to the tissue chemistry, for example, via release of proinflammatory peptides (CGRP, substance P) to cause neurogenic inflammation. Many of the mediators, such as capsaicin, neurotrophins, or inflammatory agents, that affect polymodal receptor function are discussed in Pharmacology and Modulation of Nociception, later in this chapter (Table 3-4,Table 3-5, and Table 3-6), as are the many local and circulating defense systems that amplify polymodal receptor responses to match the extent of injury.

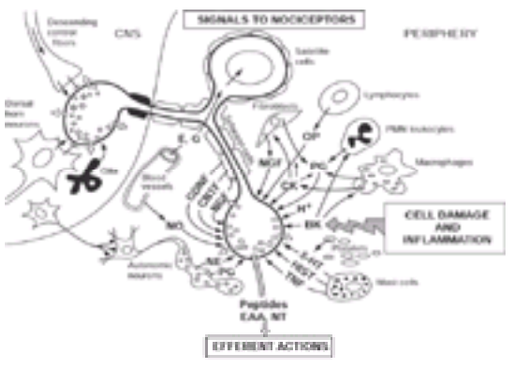

Figure 3-29. Diagram showing *some* of the peripheral cells and factors that interact with nociceptors via specific membrane receptors. Afferent signals to the neuron come from the indicated cells, all of which are affected by efferent release of neuropeptides, excitatory amino acids (EAA), or both and neurotransmitters from the neurons. Systemic hormones such as estrogen (E) or glucocorticoids (G) regulate neural function via receptors in the soma cytoplasm. In the central nervous system there are equally complex interactions with the central neurons and glia as well as with descending control fibers. (BK, bradykinin; CK, cytokines; CNTF, ciliary neurotrophic factor; GDNF, glial-derived neurotrophic factor; H+, protons; Hist, histamine; NE, norepinephrine; NGF, nerve growth factor; NO, nitric oxide; OP, opioid peptides; PG, prostaglandins; TNF, tumor necrosis factor; 5-HT, serotonin.)

TABLE 3-6. Sensory cytochemical changes with inflammation versus axotomy

The polymodal receptors ordinarily function to prevent or reduce injury and enhance healing, but under some pathologic conditions they may enhance pain and pathology, especially related to chronic pain as described in detail by Kumazawa and colleagues (23,129). The key features of polymodal receptors are (a) widely branched preterminal axons and dispersed endings in the target tissue, (b) wide variety of adequate stimuli, (c) wide dynamic range from nonnoxious to noxious thresholds, (d) numerous efferent (neuroeffector) functions that promote regulation of tissue homeostasis, inflammation, and wound healing via release of neuropeptides, and (e) an ability to shift among different functional phenotypes depending on the conditions of the tissue. Although much research since 1970 has documented the functional flexibility of these neurons, it is only during the 1990s that their close partnership with other defense systems of the body has been appreciated (23,27,129).

The polymodal receptor is especially designed for titrating its electrophysiologic and cytochemical signaling through sensitization or desensitization to mirror the local conditions in the peripheral tissues, thus forming a surveillance system that informs the CNS about the health of the body, while acting to promote survival and healing. Proportions and properties of polymodal receptors in different tissues (e.g., viscera, skin, joints, and muscle) are different (Fig. 3-30) and match the homeostatic and defense needs of each region. In many ways, the polymodal receptor system should be considered to be a dispersed peripheral organ that normally promotes tissue functions but that requisitions altered phenotype in relation to the degree of pathology or healing.

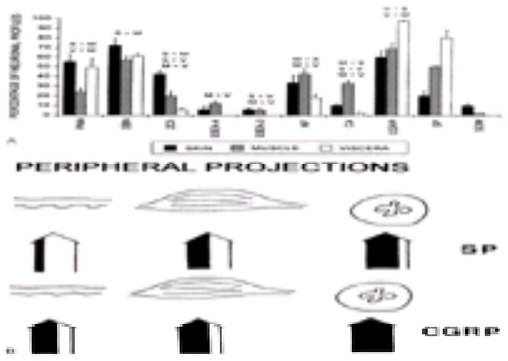

Figure 3-30. **A:** A summary histogram of mean percentages of skin (saphenous nerve), muscle (gastrocnemius nerve), or visceral (splanchnic nerve) afferent neuronal profiles in rat that were labeled by a range of antibodies. Error bars indicate standard error of the mean. Statistical differences and the directions of those differences are shown above the bars for each marker (too few rats for substance P and somatostatin for statistical significance). Specific antibodies identified lectins: PNA (peanut agglutinin), SBA (soybean agglutinin); oligosaccharides: 2C5 (lactoseries), SSEA-3, SSEA-4 (globoseries); neurofilaments (NF); carbonic anhydrase (CA); and neuropeptides: CGRP (calcitonin gene-related peptide), SP (substance P), and SOM (somatostatin). From Perry MJ, Lawson SN. Differences in expression of oligosaccharides, neuropeptides, carbonic anhydrase and neurofilament in rat primary afferent neurons retrogradely labeled via skin, muscle, or visceral nerves. *Neuroscience* 1998;85:293–310, with permission. **B:** Cartoons represent the proportions of dorsal root ganglion neurons of rat that project to skin, muscle, or viscera, as in **A**. The total width of the arrow in each case represents 100% of the retrogradely labeled dorsal root ganglion counted per nerve, whereas the proportion of the width of the arrow filled in black indicates the retrogradely labeled profiles that showed detectable substance P-like or CGRP-like immunoreactivity. Note that neuropeptide content of splanchnic visceral afferent neurons was greater than for muscle afferents, skin had the least proportion of neuropeptide-rich afferents, and higher proportions of neurons projecting to all tissues expressed CGRP-like than substance P-like immunoreactivity. (From Lawson SN. Peptides and cutaneous polymodal nociceptor neurons. In: Kumazawa T, ed. *The polymodal receptor—a gateway to pathological pain. Progress in brain research*. Vol 113. Amsterdam: Elsevier, 1996:369–385, with permission.)

The polymodal receptors were first identified electrophysiologically in skin by their high thresholds to mechanical and heat stimuli plus their sensitivity to algesic chemicals (5). They have since been studied extensively in skeletal muscle, joints, colon, urinary bladder, cornea, and especially in the scrotum, with other investigations in dura, perineurium, vasculature, dental tissues, gastrointestinal tract, gallbladder, andurogenital organs, as described in detail by Kumazawa, Perl, Handwerker, Schmidt, Mense, Gebhart, Mizumura, Kumazawa, and others (23,66,129). The proportion of A- and C-polymodal receptors varies among species and tissues. For example, almost all C fibers in skin are polymodal receptors in humans, but only approximately 70% of cutaneous C fibers are polymodal receptors in rabbits and rats, and only 35% to 40% in cats. By contrast, 90% of the spermatic nerve A and C fibers are polymodal receptors (23,129). Even the articular A-b (group II) fibers sensitize and have some polymodal properties in addition to the large and small A-d group III fibers and the unmyelinated group IV (44).

Within the C-fiber (group IV) axons, a variety of polymodal receptor subtypes exist with different algesic sensitivities and temperatures. For example, some cutaneous C-polymodal receptors are especially sensitive to histamine, whereas others are not (66), and in skeletal muscle or joints, individual units can be especially sensitive to bradykinin but not to serotonin and potassium ions, whereas others are responsive all three agents, and still others are mechanically sensitive and respond to one or more of the algesic compounds (44,70). In addition, fast A-d (group III) fibers differ from slower A-d fibers. Complex subcategories of algesic and mechanical sensitivities exist (44) (see Fig. 3-28), with capsaicin sensitivity demonstrated for the slower A-d fibers that innervate joints (44) and teeth (210). Finally, in the A and C groups there are some polymodal receptors that are mechanically insensitive in healthy tissue, but can be activated by algesic agents, thus providing innervation that only signals to the CNS during inflammation or pathologic conditions (44).

The polymodal receptor neurons release neuropeptides to enhance the functions of many different cells that are important for tissue defense and repair functions, including arterioles (vasodilation), venules (extravasation of plasma proteins and cells), mast cells (histamine release), macrophages (phagocytosis), monocytes (cytokine release), neutrophils (chemotaxis), T lymphocytes (proliferation and cytokine release), fibroblasts (proliferation and scar formation), and visceral and cardiac smooth muscle (contraction or relaxation) (see Fig. 3-29). In addition, they have powerful effects on central neurons (hyperexcitation), as well as on peripheral nerve fibers, both autonomic and sensory, and can have autocrine effects on their own peripheral endings (23,129). These actions are used to coordinate and amplify local inflammatory events at sites of tissue injury and in neighboring regions via the axon reflex.

PHARMACOLOGY AND MODULATION OF NOCICEPTION

Molecular Pharmacology

The phenomenal progress during the 1990s in understanding neurochemistry, neuropharmacology, membrane receptor and ion channel mechanisms, signal transduction, neuronal gene regulation, and neuroplasticity make it clear that all neurons, including peripheral nociceptors, use an enormous molecular repertoire to detect changes in their environment and to respond appropriately. The peripheral endings of nociceptive neurons are continually communicating with inflammatory, vascular, immune, and local cells, as well as analyzing and responding to tissue chemistry (pH, K^+, ATP, cell breakdown products), extracellular matrix, their own products or those of other neurons, and endocrine or other systemic signals. The sensory endings also synthesize, transport, and release neuropeptides and neurotransmitters by specific exocytotic molecular mechanisms that in turn affect their neighbors, with subsequent cellular reactions, alterations in the local environment, and new conditions that further affect the nerve endings. This interactive cytochemical conversation is in constant flux and can operate at different levels depending on the tissue conditions. Of course, the central endings of the sensory neurons are also affecting and responding to the cells of the CNS using similar mechanisms, but via a somewhat different set of agents and membrane receptors and channels. Finally, the primary afferent neurons are also in molecular communication with their different supporting cell types, such as terminal Schwann cells in the periphery, Schwann cells (myelinating or unmyelinated) along their peripheral axons, satellite cells of the ganglion, and CNS glia along their central branches. Each of these different interactions depends on specific mechanisms of signal detection, evaluation, and response, all of which offer possible targets for new drugs to manage pain by blocking excitatory mechanisms or enhancing the inhibitory ones (28,33,37,41,127,215,216).

This section gives a brief overview of signal detection and signal production mechanisms. It also reviews the importance of pharmacologic location, concentration,

timing, and plasticity for nociceptor and polymodal functions that is followed by a discussion of the varieties of nociceptor modulation (excitatory, inhibitory, sensitizing, desensitizing, facilitating, amplifying, or neuroprotective), and by a summary of modulating cells and autonomic and sensory interactions of some of the many ways that neurotrophin growth factors affect inflammation, nociception, and polymodal receptor plasticity. These mechanisms and their pharmacologic manipulation can only be touched on superficially here, and books by Hall (135), Hille (134), Wall and Melzack (21), Dickenson and Besson (26), Zigmond and colleagues (132), and Nolte (133) offer introductions to these topics.

Signal Detection

Membrane Detectors as First Messengers

Receptors. Extracellular agents for which specific receptor molecules have been found so far on nociceptor cell membranes include (a) endogenous chemicals (tissue breakdown products such as protons, ATP, or bradykinin), (b) arachidonic acid metabolites (membrane phospholipase-derived agents such as leukotriene B_4 and prostaglandin E_2), (c) exogenous chemicals (e.g., capsaicin and other vanilloid agents), (d) excitatory agents [glutamate, aspartate, g-aminobutyric acid (GABA), norepinephrine, ATP, histamine, and serotonin], (e) inhibitory agents (opioid peptides), (f) sensitizing agents (IL-1b or IL-6, histamine, serotonin, NGF), or (g) desensitizing agents (leukocyte inhibitory factor, interferon-g, and opioid peptides). Table 3-4 lists some of the specific receptors that have been identified so far, organized by type of ligand. Many of the receptors initiate ion flow after binding their ligand (ionotropic) and are a type of ion channel (see following discussion), whereas others convert extracellular stimuli to intracellular responses by G-protein–driven second messenger systems (metabotropic) or by trk mechanisms that induce a succession of protein phosphorylations (Fig. 3-31). The latter type is found for many growth factors such as the neurotrophin family, described in the following section. Many ligands have ionotropic and metabotropic receptors, and the more recently discovered ones have systematic abbreviations that are indicated by *X* for the ionotropic subtypes and by *Y* for metabotropic (e.g., the $P2X_{1\text{-}n}$ and $P2Y_{1\text{-}n}$ sets of receptors for ATP). However, the nomenclature is less systematic for many ligands discovered earlier; for example, ionotropic glutamate receptors include at least N-methyl- d-aspartate (NMDA)- $_{1,2}$, 2-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA) ($GluR_{1\text{–}3}$) and kainate ($GluR_{4\text{–}7}$) receptors, each of which has distinct ion permeabilities and pharmacologic properties; whereas metabotropic glutamate receptors are designated $mGluR_{1\text{–}4}$ and induce effects via G proteins. For further details see current texts on pharmacology.

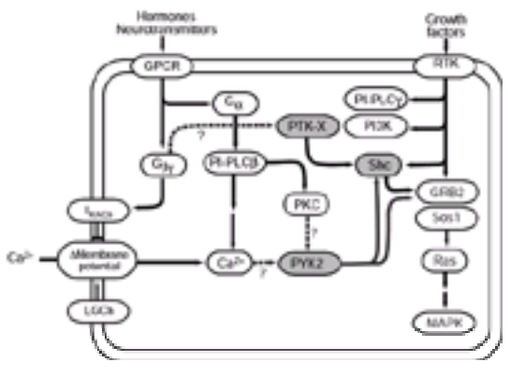

Figure 3-31. Cross-talk between G protein-coupled receptors (GPCR), ligand-gated ion channels (LGCh) and receptor protein tyrosine kinases (RTK). GPCRs, via activation of PTK-X or PYK2, can activate the mitogen-activated protein kinase (MAPK) pathway. LGChs, via an increase in [Ca^{2+}], may also activate PYK2. Note that the key *go-between* molecule is the adaptor protein Shc, which in turn can interact with growth factor receptor-binding protein 2 (GRB2)/son of sevenless (Sos1) to activate the MAPK pathway. Question marks indicate that the pathways of activation still need to be firmly established. (I_{KACh}, inwardly rectifying, acetylcholine-regulated potassium channel; PI3K, phosphatidylinositol 3-kinase; PKC, protein kinase C; PI-PLC, phosphoinositide-specific phospholipase C.) (Adapted from Holz RW, Fisher SK. Synaptic transmission and cellular signaling: an overview. Team blue sees red. *Nature* 1995;376:727–729, with permission.)

TABLE 3-4. Some factors that affect nociceptors via membrane receptors*a*

Ion Channels and Ion Transporters. The four main types of voltage-gated ion channels (sodium, potassium, chloride, and calcium) allow ions to flow down their electrochemical gradients when they are open, whereas the transporters actively pump ions against their gradient. The Na, K, and Cl channels induce changes in membrane potential when they are activated electrically, mechanically, or chemically. The altered membrane voltage then affects other voltage-sensitive (voltage-gated) molecules. Ion flow through calcium channels not only affects membrane potential, but also alters calcium concentration, thereby driving most intracellular responses to neuronal stimulation. Calcium is therefore the key transducer of membrane potential changes into specific cellular actions. For each type (*family*) of channel or transporter, many isoforms exist for different tissues and different activation mechanisms, voltages, or types of ion flow. Channel families can be divided into the voltage-gated channels, such as sodium, potassium, and calcium channels, and the ligand-gated ionotropic receptors, such as glycine, $GABA_A$, and glutamate-NMDA receptors. The cloning, pharmacologic analyses, and identified actions of each of the many members of each family of ion channels and their subunits are vast topics of increasing importance for understanding the subtleties of nociception and devising new antinociceptive drugs. Some of the important features of the voltage-gated channels for nociceptor function are summarized here.

Sodium channels, when open, permit the flow of sodium ions into the cell, thereby raising the membrane potential and bringing the neuron closer to its firing threshold. On axonal membranes their brief opening provides the initial positive phase of the all-or-none AP. However, at receptive or postsynaptic membranes they induce local excitatory potentials that extend for variable distances and times before dissipating, and they form the excitatory components of temporal and spatial summation. Neurons that respond to noxious stimulation of normal tissues primarily express the tetrodotoxin-sensitive types of sodium channels (TTXs), whereas inflammation induces the expression of a TTX-resistant variety (SNS/PN3) that is also prominent in the silent nociceptive fibers that are activated by inflammation. Because the lidocaine family of local anesthetics works mainly by blocking sodium channels that are TTX-sensitive, it is clearly important to find new agents that can block the TTX-resistant PN3 type that is so important in nerves responding to inflammation. Analysis of sodium channel subtypes and nociception is progressing rapidly, boosted by molecular and genetic techniques and the avalanche of genome information. For example, a second type of sodium channel (NaN) has been cloned that is preferentially downregulated after axotomy and whose molecular structure predicts it to be voltage dependent and TTX resistant (217).

Potassium channels allow passive flow of potassium ions out of the cell, and their delayed opening after onset of the AP is responsible for bringing axonal membrane potential back to a hyperpolarized negative level that causes a refractory period after each AP before the resting potential is restored. The duration of that afterhyperpolarization is regulated by a variety of potassium channels (134) and can shift its properties during inflammation (67). A large number of potassium channels exist, and they have great importance in controlling the excitability of the neurons during restoration of the resting potential. Many important regulators of nociceptor activity, such as inhibitory mu-opioids, act via interactions between their receptor G proteins and associated potassium channels (218), thereby driving

membrane potential away from threshold and reducing neural activity.

Virtually all cellular responses to ion flow and membrane potential changes involve altered cytoplasmic concentrations of calcium ions, via entry of extracellular calcium or release from intracellular calcium storage compartments. For example, docking of synaptic vesicles with the membrane to allow for exocytosis of neurotransmitters or neuropeptides requires a boost in the local Ca^{2+} concentration, as does the glutamate- or aspartate-driven neuroplasticity via the ionotropic NMDA receptor (134,172). In addition to the many functions of nociceptors that depend on calcium flux, the high-voltage P/Q-type of Ca channel has been implicated in responses of nociceptive neurons to persistent injury (219,220), and responses to substance P and CGRP involve increased Ca influx via voltage-gated Ca channels (221). These observations are just the tip of the iceberg concerning important regulation of and by calcium channels in nociceptor function and plasticity.

Work on ion transporters (molecules that actively pump ions against their electrochemical gradients) has found that membrane conductance is regulated in important ways by transporter activity (216,222) so that modulation of transporter function also could contribute to antinociceptive treatments. Some examples of ion transporters are the Na^+/K^+ pump, the Ca^{2+} pump, the Na^+/Ca^{2+} exchange, and the $Cl–/HCO^{3–}$ exchange (134,135).

Macromolecular Arrays. Most membrane receptors, ion channels, and associated enzymes are clustered and coregulated, as has been found for the NMDA excitatory amino acid receptor and NO synthase, MAP kinase signaling systems, targeting protein PSD-95 and other associated molecules (216,223). Similarly, a newly identified proton-gated ion channel (ASIC-1) appears to interact with other molecules for detection of acidosis by noncapsaicin-type nociceptors (224). Interactions of receptors, G proteins, and second messenger systems can integrate many signals into a single response or convert a single signal into multiple effects (Fig. 3-32). Differential expression of the component molecules and their regulation by growth factors and hormones adds enormous complexity to the ability of the membrane to integrate information and tailor responses to signals in sophisticated ways. Thus, antinociceptive drugs might indirectly target channels or receptors via inhibition of the associated molecules or their regulators.

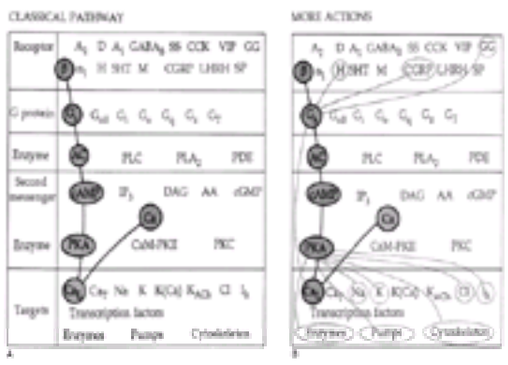

Figure 3-32. Signaling systems arranged as a menu showing at successive levels the abbreviated names of many receptors, G proteins, G-protein–coupled enzymes, second messengers, protein kinases, and target proteins. **A:** Menu filled in with the classical description of b-adrenergic action in the heart leading to the phosphorylation of l-type Ca channels and enhanced Ca^{2+} entry. **B:** A more complete description shows histamine (H), glucagon (CG), and CGRP receptors activating the same pathway, the Gs protein acting on Ca channels directly, and prokininogenase acting on many targets including six kinds of channels. (From Hille B. *Ionic channels of excitable membranes*, 2nd ed. Sunderland, MA: Sinauer Associates, 1992:191. After Hille B. Ionic channels: evolutionary origins and modern roles. *Q J Exp Physiol* 1989;74:785–804, with permission.)

Signal Transduction and Second Messengers. The ionotropic receptors have a conformational change after binding their ligand that then triggers a specific ion flow to produce a local cellular effect (see Fig. 3-31). For example, glutamate binding to the excitatory NMDA receptor causes Ca^{2+} flux into the cell at that site, that in turn initiates neuroplasticity via the protein kinase C-g signal pathway (225). The metabotropic receptors initially induce a conformational change in their associated G-protein structure that causes specific second messenger cascades for specific metabolic responses. Those second messengers include cAMP, cGMP, calcium ions, diacylglycerol, inositol triphosphate, arachidonic acid and its metabolites, and NO. The metabotropic receptors can also induce current flow indirectly by activating associated ion channels, as when the mu-opioid receptor and its G protein trigger potassium flow to inhibit neuronal firing (218). For the trk receptors, binding of the ligand triggers phosphorylation of the trk that then leads to a series of protein phosphorylations via multiple pathways (see Fig. 3-31). An interesting situation in nociception is that many signal cascades that are involved in the development of neuropathic pain funnel through the protein kinase C-gamma pathway. Thus, when protein kinase C-gamma is deleted from mice, neuropathic pain responses are inhibited or missing, even though there is still specific response to acute noxious stimuli (225).

Transcription Factors, the Third Messengers. The ultimate effect of signals that induce alterations in gene expression is the activation of transcription factors that then turn genes on or off. There has been much research during the 1990s of the functions of transcription factors such as c- *fos*, c-*jun*, and NFk B in driving nociceptor and dorsal horn plasticity. Nociceptors shift their functional and cytochemical phenotypes depending on conditions in their target tissue (or in the nerve, the ganglion, or the CNS), and those shifts require activation of transcription factors, as described in more detail by Hall (135) and others (132,133,171,226).

Signal Production

An important aspect of nociceptor function is the efferent delivery of neuropeptide and neurotransmitter signals to the peripheral tissue and to the CNS. This involves synthesis of the signal molecules, packaging into vesicles, targeting and delivery to the right region, regulation of the exocytosis location and timing, and reuptake and recycling. The elegant molecular details of exocytosis are now largely identified (132,135,153), and the importance of Ca^{2+} concentration for triggering the final merging of the vesicle and membrane is clear. The sophistication of signal vesicles was revealed by the demonstration that delta-opioid receptors are clustered inside neuropeptide-containing dense-core vesicles. Those receptors would only be exposed to the external opioid signals when the vesicle has merged with the membrane and so may only function briefly following exocytosis (227). The transient exposure and activity of some receptors reveal an additional complexity to receptor and signal production mechanisms.

Another kind of signaling involves NO. In addition to intracellular signaling (see Fig. 3-20C), it also has important extracellular signaling functions that are activity-dependent, short-lived, and local. NO diffuses readily from donor cells to nearby target cells, and it is a key intercellular regulator of neural, vascular, inflammatory, and immune defense reactions (157,159). In inflammatory pain, the actions of NO depend on the stages of inflammation and the cellular sources and targets. Levels of NO increase quickly in inflamed tissue with activation of the NO synthase enzyme and have complex actions. It is an important agent in sensory neuronal efferent regulation of vasodilation (e.g., in cerebral arteries) (228), so that at early stages of inflammation, neural and endothelial NO have important effects on blood flow and plasma extravasation. The peripheral actions of NO are mostly protective during the first few hours (facilitating blood flow, limiting excitotoxicity and scavenging reactive oxygen species) but become cytotoxic later (oxidative damage, inhibition of energy metabolism, DNA damage) (160). The exact balance of protective and toxic actions would depend on the severity and stages of inflammation and the available targets of NO. The importance of NO signal production is seen in the inhibition of neuropathic pain behavior in various animal models when NO is inhibited pharmacologically (229). The ongoing discharges of dorsal root ganglion neurons that occur after neuroma development in sciatic nerve in rats also appear to be regulated by NO, using mechanisms via signaling between satellite cells and injured neurons (158).

Signal Location, Concentration, Timing, and Plasticity

As is true for all pharmacologic agents, the location and concentration of the receptors and the duration of response are of critical importance. Differential targeting of molecules within the primary afferent neuron is exceedingly complex and specific. These cells can deliver subsets of signal-detection molecules to different regions, such as peripheral endings, axons, cell body, or central endings, or to smaller subregions, such as nodes of Ranvier. The local concentration can differ greatly, as for the 15-fold greater sodium channel density at nodes of Ranvier compared with unmyelinated axons (134), and can be affected in important ways by inflammation or nerve injury. For example, the TTX-resistant sodium channel PN3 expression decreases in large neurons while staying the same or increasing in small neurons affected by paw inflammation, whereas after axotomy the expression stays the same but there is an increased shipment of PN3 out into the axons (41). The complexity of pain pharmacology often includes opposite actions of an agent at different concentrations, as when NO potentiates prostaglandin actions at low concentration while having inhibitory actions at higher concentrations. In other cases, two different agents can affect each other's actions by interactions at the same

second messenger system downstream from their individual receptor binding, as with opioid and adenosine antinociception (161). For each signal, important issues of timing also exist, both for duration of agent activity and duration of neural response. For example, substance P is rapidly degraded in normal tissue by a specific endopeptidase enzyme, so that it is only active for a few minutes. However, if the neuropeptide CGRP is also present, the peptidase is blocked for approximately 30 minutes, thereby prolonging substance P action (230). Not only can the longevity of an agent vary greatly, but the neuronal responses differ depending on which receptors, channels, enzymes, and so forth are constituitively present or induced by inflammation.

Modulation of Nociception

In Table 3-4, we listed some of the types of factors that affect nociceptive peripheral endings via specific membrane receptors. Primary afferent neurons have interactions with other peripheral cells via release of neuropeptides, neurotransmitters, or neurotrophins, or via diffusion of arachidonic acid metabolites or NO to neighboring cells, and via uptake of growth factors, cytokines, and other signals. The nerve fibers are important participants in inflammation, immune responses, vascular regulation, and wound healing via neuroinflammatory, neuroimmune, neurovascular, neurofibroblastic, neuroleukocytic, and neuroendocrine interactions. Nociceptive fibers, and especially the polymodal receptors, are in constant chemical conversation with their neighbors, including some epithelial cells, fibroblasts, dendritic macrophages, mast cells, vascular endothelium, circulating monocytes, immunocytes, paraneurons, other sensory neurons, and Schwann cells. They also respond to signals from extracellular matrix, interstitial fluid and tissue chemistry, circulating agents, hormones, and invading pathogens. This information allows neural participation in coordinated cellular actions to reduce damage and facilitate repair.

The interactions between nociceptive neurons and other cells can be direct, via ligand-receptor mechanisms, or indirect, via an intervening cell that enhances or overrides tissue signals. For example, nociceptive neurons have IL-1 receptors and can respond directly to that cytokine, but the IL-1 also triggers NGF production by monocytes that further stimulate the neuron, or b-endorphin production by invading immunocytes that inhibit the primary afferent neurons (231). With indirect modulation, the intervening cell's amplification contributes to the cytokine portrait of the extent of tissue damage, whereas the inhibitory agents help protect the neurons from excitotoxicity. In addition to the paracrine signals from local and invading cells, important interactions occur with the endocrine and autonomic systems, whose participation and regulation of primary afferents contribute yet another indication of the extent and duration of tissue pathology.

Modulating Nociceptor Membrane Potential

Excitatory and Inhibitory Factors. The peripheral receptive endings of nociceptors do not conduct APs, but their integration of excitatory or inhibitory inputs to their sensory membrane determines whether there is enough summation of positive deflections in the membrane potential for the axon to exceed its depolarization threshold and generate a propagated AP. Depending on the molecular components of the ending and the factors in the extracellular space, the stimulus needed to reach the AP threshold may range from low to high. Excitatory factors that depolarize nociceptive endings at specific receptors include excitatory amino acids, acetylcholine, and ATP. In addition, thermal and polymodal nociceptors are activated by heat or vanilloid compounds at the VR1 receptor. Some of the inflammatory mediators, such as bradykinin, serotonin, NGF, or low pH, also directly excite some of the endings by directly shifting the potential closer to the AP threshold. Inhibitory agents include the opioid peptides whose receptors are linked to potassium channels and cause negative shifts in potential when the opioid receptor binding opens the potassium channels.

Sensitizing and Desensitizing Factors

Other factors induce molecular changes in the endings so that they are more easily (sensitized) or less easily (desensitized) excited. Those effects take minutes or hours to occur and effectively raise or lower the gain of the system. The neuronal membrane threshold remains standard, but the endings shift closer to that threshold when sensitized by inflammatory agents such as serotonin, histamine, prostaglandin, bradykinin, IL-1b, or NGF, or they are moved farther into the hyperpolarized range by factors such as leukocyte inhibitory factor, adenosine, or IL-6. These are mechanisms that help to match the responsiveness of the nociceptive endings to the conditions of their local environment, and the sensitizing and desensitizing agents are augmented or reduced by systemic factors such as gonadal or glucocorticoid steroids or hormones.

Neuroprotective Peptides

With prolonged injury or inflammation, some types of primary afferents increase synthesis of some neuropeptides such as galanin, neuropeptide Y, or vasoactive intestinal peptide that are thought to have neuroprotective functions, while downregulating others (232,233) (Table 3-6). The timing of those changes can be quite variable, as with the transient expression of galanin in large neurons compared with the prolonged increase (many months) in the smaller neurons after neuropathic injury. The neurons also increase production of peptide receptors for circulating agents such as neuropeptide Y (produced by the adrenal and by sympathetic fibers in response to stress), thus giving additional protection to that from its own altered peptide array. The targeting of receptors and detailed local actions at different sites along the neuron are quite sophisticated, as indicated by the concentration of the neuropeptide Y1 receptor at the cell body and the Y2 receptor at endings (232,233,233a).

Sensory-Sensory Interactions

Table 3-4 indicates that the sources of many of the ligands that affect nociceptor function are other nociceptive neurons or autocrine effects by the neuron on itself. These nociceptor-nociceptor interactions follow the exocytotic release of neuropeptides, neurotransmitters, or other agents from normal or injured nerve fibers. They can occur in the periphery following efferent APs (axon reflex or other mechanism; see Fig. 3-20A), along the nerve at sites of damage or neuritis, in the ganglion, or in the central root and dorsal horn. Evidence now exists that neuropeptide release by C fibers during a barrage passing through the ganglion can cause blockage of subsequent A-fiber activity (137), so that the nociceptor-nociceptor interactions during signal propagation in the periphery may be quite complex. That complexity extends into the central branches of the primary afferent in which inhibition of signaling in many terminal branches appears to be a fundamental and powerful mechanism for regulation of the incoming signal traffic (36,234). For some agents, such as CGRP, receptors have not been found on the nociceptive neurons, so that its release may only affect other neurons (or other cells, such as mast cells or vascular smooth muscle). For other agents that are released by the nociceptors (e.g., substance P, glutamate, glycine, GABA, acetylcholine, serotonin, ATP, bombesin, neuropeptide Y, and neurotrophins), receptors are also present and offer the possibility of autocrine regulation (32,235). Data also suggest that specific interactions between A and C fibers in the dorsal horn contribute to dorsal root reflexes that then drive axon reflexes, flare, and pain in areas of tactile allodynia (236).

Sympathetic Interactions with Primary Afferents

It was known for most of the twentieth century that the sympathetic nervous system can initiate or maintain pain after various nerve injuries and during inflammatory pain (2,21). The clinical symptoms of burning pain, allodynia, hyperalgesia, and hyperaesthesia during causalgia and other complex regional pain syndromes clearly had sympathetic involvement, because sympathetic blocks or sympatholytic treatments relieved the conditions, especially if used in the first few months of the initial neuropathic lesion, and noradrenalin exacerbated those pains. The sympathetic-sensory interactions differ for neuropathic and inflammatory pain, and dissection of each of those the molecular mechanisms is leading to much improved clinical treatment, as discussed later in this book. Extensive reviews provide much greater detail than can be given here 34,62,237,238 and 239). The general features of sympathetic modulation of sensory function are summarized in Figure 3-33.

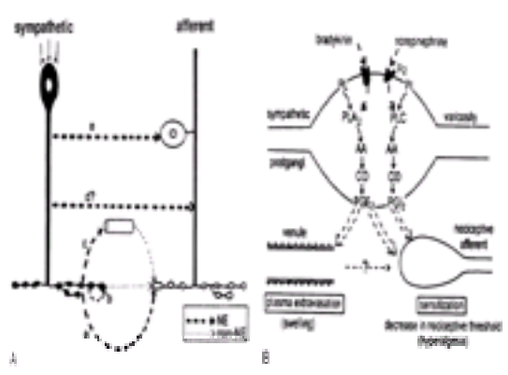

Figure 3-33. **A:** Possible ways of coupling between sympathetic postganglionic neurons and afferent neurons under pathologic conditions. (*a*) Noradrenergic (NE) and possibly also nonnoradrenergic (non-NE) chemical coupling between peripheral endings. This may preferentially occur after nerve lesions. (*b*) Indirect chemical

coupling. As believed by Levine et al. (*Nature* 1986;323:158–160), norepinephrine acts prejunctionally at postganglionic varicosities via a $_2$-adrenoreceptors triggering the release of other substances (e.g., prostaglandins). This may be relevant during states of chronic inflammation. (*c*) Indirect coupling via the vascular bed (change of neurovascular transmission, development of hyperreactivity of the vascular bed). This may occur after various forms of trauma with or without nerve lesion. (*d*) Interaction along the nerve. This may occur after nerve lesions during regeneration and sprouting in the nerve. (*e*) Noradrenergic coupling in the dorsal root ganglion. This may occur after a remote nerve lesion. [From Jänig W, Levine JD, Michaelis M. Interactions of sympathetic and primary afferent neurons following nerve injury and tissue trauma. In: Kumazawa T, ed. *The polymodal receptor—a gateway to pathological pain. Progress in brain research*. Vol 113. Amsterdam: Elsevier, 1996:161–184; as modified from Jänig and Koltzenburg (237,348).] **B:** Idea on the role of the varicosities of sympathetic postganglionic noradrenergic fibers in venular plasma extravasation and sensitization of nociceptive afferents induced by bradykinin (BK) and in sensitization of nociceptive afferents induced by norepinephrine (NE). Venular plasma extravasation may also contribute to sensitization of nociceptors. Both processes are mediated indirectly via different metabolic arachidonic pathways and are principally independent of the neural activity in the sympathetic neurons: BK reacts with b $_2$-receptors on the varicosities and leads to release of prostaglandin E_2 (PGE_2) via activation of phospholipase A_2 (PLA_2). NE reacts with a_2-adrenoceptors in the varicosities and leads to release of prostaglandin I_2 (PGI_2) via activation of phospholipase C (PLC). Although BK-induced decrease of nociceptive threshold and plasma extravasation occurs in normal tissue, norepinephrine-induced sensitization of nociceptors only occurs in injured tissues. AA, arachidonic acid; CO, cyclooxygenase; PI, phosphatidyl inositol; PL, phospholipid. [From Jänig W, Levine JD, Michaelis M. Interactions of sympathetic and primary afferent neurons following nerve injury and tissue trauma. In: Kumazawa T, ed. *The polymodal receptor—a gateway to pathological pain. Progress in brain research*. Vol 113. Amsterdam: Elsevier, 1996:161–184; as modified from Levine and Taiwo (169).]

The sympathetic fibers coexist with primary afferents throughout peripheral tissues, especially along the vasculature. The associations are more complex in viscera and in endocrine and exocrine organs in which there are general and special visceral afferents near the sympathetic, parasympathetic, enteric, or all three kinds of nerve fibers. Sensory and sympathetic fibers also exist among the nervi nervorum of the peripheral nerves and ganglia. Most investigators have found that the two systems do not significantly affect one another's electrophysiologic activity in healthy tissues (62). However, they counterbalance each other for efferent regulation of vasculature constriction [norepinephrine (NE) from sympathetics] and dilation (CGRP/substance P from sensory fibers) in many tissues, so that loss of one of the vasoregulatory partners alters the effects of the other on blood flow.

After injury to a peripheral nerve, several different changes occur in sensory-sympathetic interactions, some of which depend on the type of injury. After nerve ligation, A-fiber afferents increase their a_2-adrenoreceptor activity and thereby become sensitized to systemic or local release of noradrenalin (34,62). Initiation or maintenance of some complex regional pain syndromes is primarily via this altered sensory adrenergic receptor activity in large fibers. Those axotomized neurons also attract sprouting intraganglionic sympathetic fibers that form *baskets* of endings around their cell bodies, but it is not clear whether those sprouted sympathetics contribute to sensory activation or have another function (62). When a cut nerve is trapped in a neuroma, many of the sensory sprouts for axons of all sizes develop sensitivity to sympathetic stimulation (240). In partial nerve lesions approximately one-third of the C-polymodal receptor fibers whose fibers are not injured increase their a_2-adrenoreceptor activity to become sensitized to heat and noradrenalin, as demonstrated by their responses to local administration of noradrenalin and inhibition of the effects by a_2-adrenoreceptor antagonists (66). In many neuropathic injuries there would be ligation effects for some fibers, partial injury effects for others, perhaps some small neuromas, and local neuritis for a variety of mechanisms inducing sympathetic activation of sensory fibers. Additional complexities are introduced at the central endings of the primary afferents where there are also a $_2$-receptors; however, their function is mainly inhibited by hyperpolarization responses to descending noradrenergic fibers in the dorsal horn (239).

When a tissue becomes inflamed, a specific set of direct and indirect interactions occurs between sympathetics and the affected primary afferents (see Fig. 3-33). The sympathetic fibers increase their release of norepinephrine, which then has an autocrine feedback effect that stimulates production and release of prostaglandin I_2 from the sympathetic endings, which in turn sensitizes the afferents (62). In addition, the bradykinin in the inflamed tissue stimulates the sympathetic fiber to produce and release prostaglandin E_2, which further sensitizes the afferent, as well as enhancing serum extravasation from postcapillary venules. These direct and indirect actions of sympathetic mediators on primary afferents are the best documented, and undoubtedly others exist (e.g., the hyperpolarizing actions of another sympathetic mediator neuropeptide Y) (232,233).

Parasympathetic Involvement in Pain

Research shows that trigeminal afferents and parasympathetic fibers affect each other during certain kinds of cluster headache and paroxysmal hemicrania (71). Patients with this pain condition, which usually lasts for a few minutes, have typical accompanying lacrimation and rhinorrhea. Evaluation of cranial circulation shows elevated levels of CGRP and vasoactive intestinal polypeptide during the attack, and treatment with indomethacin is successful. Thus, the parasympathetic system also must be included in analyses of neuropathic pain mechanisms for some tissues.

Nerve Growth Factor and Other Neurotrophin Growth Factors

A prolific effort since the mid-1980s has been undertaken to identify the factors that drive neuronal plasticity and persistent pain, especially concerning NGF and other neurotrophin growth factors (30,31,241,242). The role of NGF in stimulating neural outgrowth and survival during development of sympathetic and sensory nerve fibers has been known since the work of Hamburger, Levi-Montalcini, and Cohen in the 1930s to 1950s (243). It is now clear from studies of knockout mice (244,245,246 and 247) that development of each type of peripheral nerve fiber depends on specific members of the neurotrophin growth factor family and their corresponding trk high-affinity receptors, as well as the p75 low-affinity neurotrophin receptor (see Table 3-5). Peripheral neurons shift to somewhat different neurotrophin requirements in mature animals, with some work showing that NGF, BDNF, and glial-derived neurotrophic factor (GDNF) affect different groups of nociceptive primary afferents (75). Those effects include subtle regulations of conduction properties and of sodium channels (30,31,241).

All neurotrophin-dependent neurons also respond to the low-affinity (p75) neurotrophin receptor that also has homologies with the tumor necrosis growth factor family (248). Its functions are still not entirely clear, but, in addition to modulating the functions of the high-affinity receptors, it also initiates apoptosis or survival depending on NGF levels during development, with the proliferative activity involving signaling through the phosphorylated transcription factor NFkB. Its regulatory activities are partly tissue specific, because cutaneous and oral and dental nociceptive afferents are affected differently in p75 knockout mice (244,249).

Many of the neuroplastic effects of nerve injury and inflammation depend on alterations in amount, origin, and distribution of NGF (Fig. 3-34). Nerve injury obviously cuts off NGF and other signals from tissues, and the nociceptive neurons that expresses trkA and neuropeptides substance P and CGRP are most affected after axotomy, and rescued by administration of exogenous NGF. Conversely, inflamed tissues have greatly elevated NGF, made especially by local fibroblasts, which signals the extent of the inflammatory cellular responses when arriving in the sensory ganglion by retrograde transport (241). Altered sodium channel distribution and function are prominent mechanisms in neuropathic pain (250), and work shows that NGF (and GDNF, see following discussion) regulates sodium channel expression and function (30). NGF also has direct involvement in acute pain (179,251,252 and 253), and when animals are depleted of NGF by autoimmunization, they develop thermal hypoalgesia (254,255) under conditions that also alter sodium channels (Fig. 3-35). The effects of NGF on sodium channels differ in rats for sciatic nerve transection (256), tight ligature of L-5/L-6 (257), and carrageenan injections of paw (258), and include effects on the SNS/PN3 and the NaN channel subtypes (30,31). The complexity of neurotrophin effects on nociceptors is seen in the differential effects of estrogen on NGF receptors of dorsal root ganglion (259).

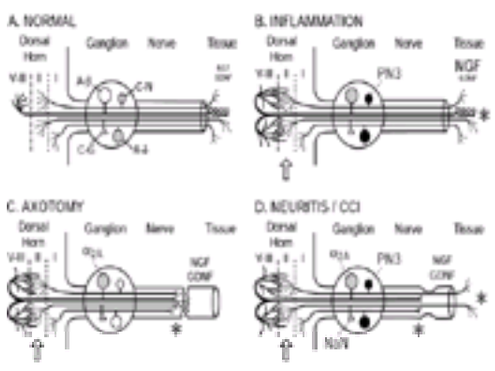

Figure 3-34. Some data support this diagram of four different sensory neurons, (A-b, A-d, C-N [nerve growth factor (NGF)–dependent C fibers], and C-G [glial-derived neurotrophic factor (GDNF)–dependent C fibers]) and their altered peptide expression (gray tone), or expression of the NaN or PN3 tetrodotoxin resistant (TTX-R) sodium channels for four different conditions: **A,** normal; **B,** tissue inflammation; **C,** axotomy; and **D,** chronic nerve constriction with neuritis. The levels of peptide expression in neuronal cell bodies are represented as little or none (*clear*), moderate (*gray*), or high (*dark gray*). The neurons that have the most change in expression or distribution of TTX-R sodium channel are indicated. Altered growth factors at peripheral sites (*) affect neuronal gene expression via axonal transport. Although each of the three pathologic conditions has different combinations of sensory alteration, the sprouting of A-bcentral arbors (*arrow*) into lamina II has been found for all. See text for references.

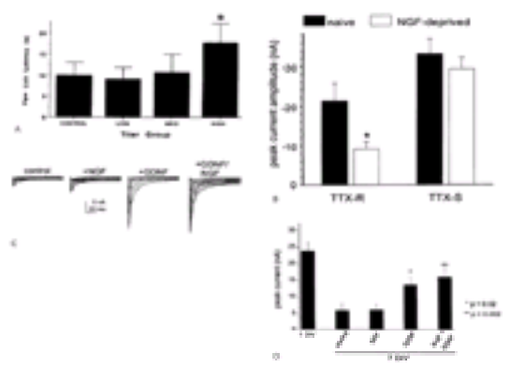

Figure 3-35. **A:** Effects of nerve growth factor (NGF) depletion in rats on heat nociception. High titer animals had a significant hypoalgesia for the paw lick latency test. From Chudler EH, Anderson LC, Byers MR. Nerve growth factor depletion by autoimmunization produces hypoalgesia in adult rats. *Brain Res* 1997;765:327–330. With permission. **B:** Specific effects of NGF depletion in rats on current amplitude for sodium channels of the TTX-R subtype but not TTX-s. From Fjell J, Cummins TR, Fried K, et al. *In vivo* NGF deprivation reduces SNS expression and TTX-R sodium currents in IB4-negative DRG neurons. *J Neurophysiol* 1999;81:803–810, with permission. **C,D:** *In vitro* studies of patch-clamped neurons of the IB4+/glial- derived neurotrophic factor type. Current peaks are affected especially by glial-derived neurotrophic factor (GDNF), not by NGF alone, but with some augmentation of the glial-derived neurotrophic factor effect when NGF is coadministered. (From Fjell J, Cummins TR, Dib-Hajj SD, et al. Differential role of GDNF and NGF in the maintenance of two TTX-resistant sodium channels in adult DRG neurons. *Mol Brain Res* 1999;67:267–282, with permission.)

In addition to the NGF/trkA system that regulates the capsaicin-sensitive, neuropeptide-rich small A-d and C-fiber system, another major set of nociceptive C fibers express the isolectin IB4 that are not neuropeptide-rich, that have specific receptors for GDNF (see Table 3-5), and that make up approximately one-third of the nociceptive population (29,75). GDNF is produced by Schwann cells and is increased after nerve injury, whereas its receptors (a molecular complex of Ret and GDNFRa) are made by the GDNF-dependent neurons and are also affected in injured neurons (260,261). GDNF regulates both the SNS/PN3 and NaN subgroups of sodium channel in the IB4+ neurons (31).

BDNF appears to have different functions in cutaneous and visceral afferents (28). In the former, elevated NGF then stimulates expression of BDNF, as a possible amplification signal when peripheral damage is extensive (262). In visceral afferents, most coexpress trkA and trkB receptors, and many mature visceral neurons express BDNF (263). In addition, BDNF enhances the sensitivity of sensory vagal neurons to capsaicin (264). BDNF exhibits extensive effects on central neural function, but the sprouting of A-fiber central endings into lamina II was not prevented by intrathecal injections of either BDNF or NT3, whereas injections of NGF did prevent that response (265).

Ciliary neurotrophic factor is a neurokine whose molecular structure and actions are similar to the cytokines IL-6 and leukocyte inhibitory factor, and it has important actions via the gp130 receptor after nerve injury and demyelination (28,266,267,268 and 269). Other growth factors are certain to be added to this set of nociceptive modulators in the near future (e.g., the newly described neurturin in the GDNF growth factor family). In addition, to the neurotrophin growth factors there are many others, such as fibroblast growth factors and insulinlike growth factors, that have important regulatory effects on some primary afferents during development, inflammation, and nerve regeneration. The molecular mechanisms of the neurotrophins are critical to regulation of peripheral phenotypes of nociception, and intense research is under way to understand their functions and develop pharmacologic therapies targeted to those mechanisms (28).

PERIPHERAL MECHANISMS OF PERSISTENT PAIN

Experimental Models for Studying Pain

The development of animal models has been an essential step, in combination with molecular and clinical studies, for understanding of pathologic mechanisms of most diseases. The study of pain also has benefited greatly from a variety of animal models, each of which is useful for improving knowledge about and management of particular features of pain and for development of new pharmacologic treatments. Of course, many questions concerning pain mechanisms can be addressed using *in vitro* paradigms such as the isolated skin-nerve preparation (270) or sensory ganglion cell cultures (271,272), and acute studies under general anesthesia or decerebration are conducted without any sensory experience being possible for the animal (273). Indeed, many important molecular mechanisms related to neuroplasticity and pain are being discovered in simple organisms such as the nematode *Caenorhabditis elegans*, in oocytes or other cells *in vitro*, or using patch clamp technology to study ion channels in isolated cell membrane (134,274).

However, studies of pain and analgesia in awake animals also have been necessary to reveal the neurobiology of activity- dependent interactions of the peripheral nervous system and CNS and their effects on behavior *in vivo*. These studies present special challenges for animal care, because some pain is usually unavoidable, and analgesics sometimes cannot be given when their antinociceptive effects counteract the goals of the experiment. The ethical considerations and guidelines for experimental studies of pain in awake animals have been discussed and reviewed in detail (275,276), with special emphasis on the need for careful planning to have an experimental design that allows valid behavioral tests while keeping stress, discomfort, and duration to a minimum. In general, this means that stimulus intensity and duration should give measurable nociceptive responses in comparison with sham controls, but not reach the levels of discomfort that disturb normal eating, drinking, grooming, or other behaviors. Careful attention is needed for choice of species, gender, age, diurnal variations in nociceptive sensitivity, minimal numbers of animals, type of tissue being stimulated, size of stimulus area, and interstimulus interval (277,278,279 and 280). Adaptation of an approved paradigm to a different tissue, species, age group, or gender needs careful scrutiny to be sure that behavioral responses remain in an acceptable range for the new conditions.

Because perception of pain is a psychological event that cannot be directly assessed in animals, its presence must be inferred indirectly from the animal's behavioral responses, and by correlation with parallel studies in human subjects. The investigator has a special responsibility to use adequate behavioral tests and monitoring to ensure that the animal's behavior remains above threshold but well below intolerable levels. Many patients still have intractable persistent pain. However, it is not necessary to duplicate those conditions in an animal, because the properties of neuroplasticity and their reduction by pharmacologic treatment have been shown to occur within the tolerable range (278).

The Committee for Research and Ethical Issues of the International Association for the Study of Pain (281) identified the following guidelines for pain research in conscious animals: (a) Experiments must be reviewed beforehand by scientists and lay persons to clarify the potential benefits for improved understanding of pain, and there must be continuing justification for the investigations. (b) If possible, the investigator should try the pain stimulus on him- or herself. (c) Physiologic and behavioral assessments of any deviations from normal behavior should be measured. (d) The pain stimulus should be the minimum necessary for the purposes of the experiment. (e) Pain-relieving agents or procedures should be used, as long as this does not interfere with the aims of the investigation. (f) Paralytic agents should not be used without a general anesthetic. (g) The duration of the study must be as short as possible, and the number of animals kept to a minimum. Some experimental conditions cannot be self-tested by the investigator, but in most cases there are parallel studies in humans for comparison. In addition, all animal research is monitored by each institution's Animal Care and Use Committee, which has overall responsibility for the humane treatment of animals in research and for minimizing

their discomfort (282).

Development of many animal models for studying acute and persistent pain during the 1980s and 1990s has led to enormous insight into mechanisms of peripheral and central neuroplasticity, especially concerning chronic inflammatory and neuropathic conditions and the phenomena of sensitization, hyperalgesia, allodynia, spontaneous pain, bilateral spread from unilateral lesions, and activity-dependent plasticity. That work has already produced improved treatment for postoperative and inflammatory pain, and a new pharmacology is rapidly emerging for treatment of chronic pain (26,283). In many studies, the animal has control over the intensity and duration of the stimulus by being free to escape it, as in the reflex paw withdrawal or tail-flick tests, or with more complex learned escape responses for which latencies can be measured. In other cases, a persistent pain is initiated (e.g., by intradermal injection of inflammatory agents, moderate distension of hollow viscera, or partial injury to a peripheral nerve), and then the specific features of behavioral, functional, and molecular plasticity are tested. In those cases, keeping the stimulus within the tolerable range can be inferred if the animal maintains normal feeding, grooming, drinking, social behaviors, and mobility (278) or if aversive behaviors provide the end-point for the stimulus (190,194). Combined studies exist in which neuropathy is established *in vivo*, but then the analysis is done with *in vitro* paradigms such as the isolated nerve-skin preparation (284) or patch clamp physiology of labeled sensory ganglion cells (285). Many of the models developed in rats have been successfully adapted to transgenic or knockout mice (225,286).

Important benefits from the animal studies include the detailed testing of syndrome-specific drugs and the development of new treatment strategies to dampen the peripheral barrages that drive CNS plasticity, to discover new anesthetics based on better understanding of peripheral neuroplasticity, and to reduce the effect of immune and endocrine signaling on persistent pain, as described throughout this text and reviewed elsewhere (21,26,287). In addition, sophisticated genetic analyses are now feasible in animals and humans that address important aspects of pain, as discussed in Genetics of Pain, later in this chapter.

Neuropathic Pain

Neuropathic pain syndromes involve injury to the nervous system and have different mechanisms from pain caused by chronic tissue inflammation (see Fig. 3-34). For the latter, the nerve fibers are intact and have reactions to inflammatory mediators and cell breakdown products at their peripheral endings that then alter the afferent and efferent functions of the sensory nerve fibers, both in the periphery and at central connections. For nerve injury, the fibers are disconnected from the periphery and respond to axonal damage, local neuritis, atrophy, altered Schwann cell activity, and their own altered signaling. For inflammatory and neuropathic conditions, there are phenotypic changes in the peripheral nerve cells; increased excitation, disinhibition, or both of dorsal horn and pain pathways; altered immune signals into the CNS; and usually some activation of stress endocrinology and alterations in sensory-sympathetic interactions (46).

For neuropathic injury, important differences exist in symptoms, persistence, and underlying neuroplasticity for each of the animal models, of which more than 30 have been developed so far to address specifically different mechanisms in different nerves and for different causal agents (278,279,288). The main characteristics are summarized in Table 3-7 for (a) the neuroma model for analgesia dolorosa and phantom limb pain (240,289); (b) the chronic constriction injury that causes a partial nerve lesion with neuritis (284,290,291); (c) partial nerve ligation (292); (d) tight ligature and degeneration of the L-5, L-6, or both spinal nerves, but preservation of the L-4 components of the sciatic nerve (293); (e) peripheral neuritis (294); (f) cryoneurolytic injury (295); and (g) diabetic neuropathy (296). In addition, spinal injury models (297) affect the central terminals of the sensory fibers that terminate in the injured spinal segments, and dorsal rhizotomy also destroys central terminals and causes neuropathic behavior. Each of these neuropathic injuries mimics some features of specific clinical conditions, and the differences among the various animal models help us to understand how to devise syndrome-specific pain medications.

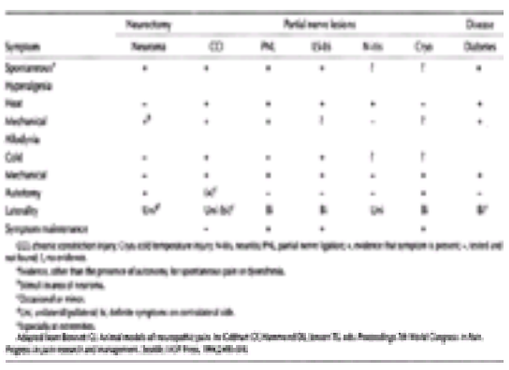

TABLE 3-7. Comparison of animal models of neuropathic pain

Important anatomic considerations exist for neuropathic pain mechanisms. First, the location of injury along a peripheral nerve elicits different intensities of response and types of neuroplasticity depending on whether it is near the periphery, along the nerve, close to the ganglion, in the root, or affecting the central terminals in the cord. Second, different peripheral nerves, such as cutaneous, articular, muscular, or visceral, can have quite different sets of somatosensory fiber types and different proportions of polymodal nerve fibers, as indicated in Figure 3-30 (64), and would therefore have different capacities to react to injury. In addition, special somatic or visceral sensory fibers can exist in the injured group, as well as different access to afferent immune and CNS pathways and different degrees of sympathetic-sensory interaction. Finally, the anatomic location of the pain in humans and animals can differ from the distribution of the injured nerve, including contralateral symptoms for unilateral injury (288). Although that depends on some important central mechanisms, evidence also exists that neighboring uninjured peripheral nerves may contribute to the neuropathy, perhaps by collateral sprouting into the injured territory (298). Chronic pains that become independent of the anatomic triggering site are considered to be maladaptive and tend to persist for long periods and resist standard therapies (46,299)

The physiologic and pharmacologic reactions of peripheral nerves to injury or inflammation have been discussed generally in Nociceptor Physiology, previously in this chapter, and have been reviewed in much more detail elsewhere (21,130,142,232,240,274). Although central plasticity is a key factor in neuropathic pains, many important functional and cytochemical changes in the peripheral nerves help drive the central changes and initiate their own abnormal sensations. The main pathologic changes in the nerves are spontaneous ectopic discharge, increased excitability, and altered pharmacology, and these are driven by different subsets of peripheral fibers during different postinjury times. For example, after the initial injury discharge at experimental neuromas, 10% to 15% of the A fibers have spontaneous discharge at 1 to 2 weeks, subsiding to 2% to 3% by the end of the first month, whereas the C fibers have only 1% to 2% spontaneously active fibers in the first week, gradually increasing to 4% to 6% by 1 month (240). Thus, central sequelae of C-fiber neuropathic activity should intensify during the first month, whereas those related to A-fiber spontaneous discharge should weaken. Other complex abnormal firing patterns that have been recorded from the sensory ganglion include periods of spontaneous bursting followed by suppression of that activity, cross-excitation of quiescent neurons by impulse activity in nearby neighboring neurons possibly via chemical signals, and altered sensory spontaneous activity by sympathetic input after neuropathic injury (138,139,300). These are just a few of the amazingly varied and subtle physiologic changes induced by nerve injury or tissue inflammation, some of which vary for the trigeminal ganglion compared with dorsal root ganglia (301,302).

More recent work has begun to show interesting changes in expression, distribution, and function of specific ion channels, receptors, and other key membrane molecules in primary afferents (30,31 and 32,258,271,303) for each neuropathic condition for each subgroup of nociceptive neuron. The molecules in Table 3-4 and Table 3-5, as well as others not on the list, may all be affected in complex ways depending on the type of nerve injury or tissue conditions. For example, altered expression and distribution of the peripheral type of sodium channel (PN3) is implicated in many neuropathic syndromes, but shows different patterns for different injuries. Some that have been identified so far include downregulation of PN3 after axotomy (217), unaltered PN3 mRNA after chronic constriction injury (CCI) injury but redistribution of the protein from cell body to the injury site for both CCI and axotomy (304), increased expression by 4 days after injections of carrageenan into the rat hind paw (258), and increased expression in large sensory cells after L5-6 ligation (41). These examples of expression plasticity for one sodium channel represent the tip of the molecular iceberg for which current research is intense (Fig. 3-35).

Some of the main changes in expression of neuropeptides, neurotransmitters, and neurotrophin receptors by sensory neurons after axotomy compared with inflammation are indicated in Table 3-6 (232,233,305). Some of those changes are related to protective needs of the injured neurons (upregulation of galanin, vasoactive intestinal peptide, neuropeptide Y), some relate to regeneration (Gap-43, tubulin), some to loss of retrograde signals such as NGF from the target tissue (downregulation of CGRP and substance P), and others could be in response to retrogradely transported inflammatory or vascular agents, immune signals, or Schwann factors generated at the injury site. The smaller fibers can have quite different cytochemical responses from larger ones, and it has been shown that even the A-b fibers begin to express substance P and neuropeptide Y when they become involved in inflammatory pathophysiology (45,306). The sophistication and

molecular intricacy of differences in cytochemical mechanisms for different types of neuropathic pain are just beginning to be appreciated and are the subject of intense current research (41).

Inflammatory Pain

Immediately after tissue injury, sensory nerve endings are suddenly exposed to a variety of cellular breakdown products and inflammatory mediators that trigger acute nociceptive activity. This *inflammatory soup* includes prostaglandins, protons, serotonin, histamine, bradykinin, purines, cytokines, eicosanoids, and neuropeptides that act at specific receptors on the sensory fibers (see Fig. 3-29) and also have important synergistic interactions (233,305). The initial injury and inflammation cause C and A-d fibers to undergo changes such as sensitization, increased activity in normally silent nociceptors, and altered activity of ion channels and membrane receptors (307). If inflammation is short lived, nerve function should return to normal quickly. With increasing severity and duration, those conditions are reflected in the set of growth factors and cytokines produced by the local cells, invading monocytes, and vascular cells that are conveyed to the sensory cell body by retrograde axonal transport. Those then induce myriad changes in neuronal function that are being identified for each subgroup of peripheral axon (see Table 3-6) (233). Some of the most surprising have been the demonstration of substance P production by A-b fibers that normally make little or none of that peptide, the central sprouting of their terminals into lamina II of the dorsal horn (Fig. 3-36), and their increased expression of a $_{2A}$-adrenergic receptors (45,308,309).

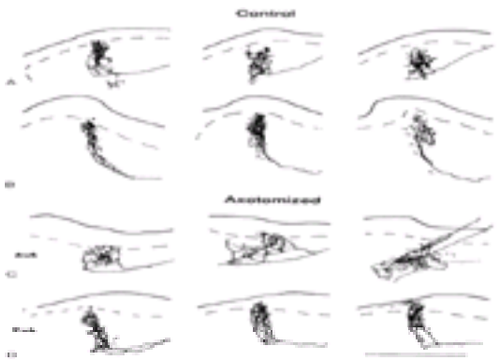

Figure 3-36. Camera lucida reconstructions from transverse sections of the spinal cord of the complex terminal arbors of four single sural Ab afferent fibers. Each row shows three adjacent arbors from a single afferent fiber, two controls (**A** and **B**), and two from axotomized sural nerves (**C** and **D**). Solid line above each drawing is the dorsal-most surface of the dorsal horn; dotted line, the lamina II-III border. Each arbor has a collateral axon arising from a stem axon running longitudinally in the dorsal columns (not shown). This collateral axon for hair follicle afferent fibers terminated in a flame-shaped branching pattern (**A** and **B**). **C** and **D**, arbors that have branching patterns not seen in control animals that extend into the superficial laminae. Scale, 250 µm. (From Woolf CJ, Shortland P, Coggeshall RE. Peripheral nerve injury triggers central sprouting of myelinated afferents. *Nature* 1992;355:75–78, with permission.)

This plasticity induced by chronic tissue inflammation differs from neuropathic injury in the types of cytochemical responses (see Fig. 3-34) and because it does not cause ectopic signal generation, increased adrenergic sensitivity of myelinated fibers, sprouting of sympathetic fibers in the ganglion, cell death in the ganglion, or transganglionic degeneration of the central endings (46,305). It is a different challenge to the peripheral nervous system and causes somewhat different reactions in the CNS, although many of the NMDA-based excitatory mechanisms, central modulation, and immune and endocrine responses may be similar. Certainly some of the problems in neuropathic injury are compounded by chronic inflammatory stimulation at the injury site, with important reactions by the local neural innervation (nervi nervorum) that are only just beginning to be appreciated (57,60,287), and other types of persistent pain (cancer pain, postherpetic neuralgia) may involve important combinations of neuritis and neuropathic mechanisms.

Developmental and Aging Aspects

Just as great variation occurs in the response of peripheral nerves to different types of peripheral pathology, much variation exists among individuals in their specific neural reactions and neuroimmune and endocrine responses to injury and inflammation. Those differences are more extreme in infants because of their immature peripheral nervous systems and CNSs. The fetal acute noxious reflex patterns that begin during the first trimester are exaggerated, hypersensitive, whole body responses that continue into the early neonatal period, and gradually become more specific and localized as central and peripheral inhibitory mechanisms become established (310,311). Thresholds to mechanical stimuli increase during the first few weeks, whereas those for noxious chemical or heat stimuli are initially elevated and gradually decrease. The polymodal receptors have fairly mature afferent thresholds and firing patterns at birth in rats, whereas their efferent neurogenic functions take longer to appear, A-d high-threshold fibers take longer to develop, and low-threshold mechanoreceptors are most immature at birth. Establishment of functional central endings for C and A fibers occurs at different rates, development of local circuit neurons extends into the neonatal period, and the important descending inhibitory controls are immature at birth. In addition, the excitatory NMDA mechanisms in the neonatal dorsal horn appear to be hyperactive, and fos responses in the dorsal horn are different (312), so that wind-up and central excitation after C-fiber stimulation may be greater than in adults. Other important pharmacologic aspects of pain, such as opioid and neuropeptide functions, can also be quite different in infants than in adults, and many kinds of receptors are overexpressed initially or occur in areas not found in the adult. Thus, it is not surprising that analgesics have different efficacy for infants than for children and adults.

When infants experience pain from surgeries or prolonged intensive care, there may be persistent changes in neural connections that affect their subsequent acute pain pharmacology and behavior (267). However, it is rare for chronic pain patients to be younger than 20 years, suggesting that nerve injury and tissue inflammation in children elicit central plasticity that easily reverts to normal during peripheral healing. The elderly are also rare among chronic pain populations, but for different reasons. They have been shown to be less stressed emotionally by painful stimuli, to have somewhat reduced acute pain sensations (e.g., during myocardial ischemia), and to have less perception of pain when experiencing dementias (313). In addition, the peripheral nervous system gradually loses some of its fibers with aging and has altered expression and distribution of neuropeptides and growth factor receptors (314), as well as altered protein kinase/phosphatase activities and altered synaptic efficacy (315). If those changes occur at different rates in different fibers, there may be important shifts in the balance among inputs to the CNS, in the capacity of peripheral nerves to drive long-term central plasticity, as well as in central modulatory mechanisms (316).

The prevalence of shingles and postherpetic neuralgia in the elderly (317) may depend primarily on increased longevity with greater opportunity for viral reactivation, but some of the alterations in the aging peripheral nervous system, its proportion of nociceptive subgroups, its interaction with immune and endocrine factors, and its tissue interactions may facilitate that reactivation. Obviously, some changes in tissue chemistry, structure, endocrinology, and circulation occur with age, as well as increased wear and tear, especially for joint and muscle pain.

GENETICS OF PAIN

During the 1990s, there has been extensive interest in genetic approaches to understanding pain mechanisms in animals and humans, as reviewed by Mogil and colleagues (318,319,320,321,322 and 323). The wide variations in clinical pain sensitivity and analgesia (324,325) and evidence for gender differences in pain (319,326,327,328,329 and 330) have shown that there are definite heritable traits for pain. For example, it is now known that five hereditary sensory neuropathies have five different deficits in the peripheral nociceptive apparatus (331) (Table 3-8). One of those neuropathies (type IV, congenital lack of pain sensibility with anhidrosis) has been found to have a defective gene for the high affinity (trkA) NGF receptor (331), which would prevent development of the trkA-dependent nociceptors (see earlier discussion of NGF and peripheral pharmacology of pain). The rapid progress in mapping the human genome, and its associated evolving molecular technologies (332), makes it likely that genetic traits for pain and analgesia, whether they have large phenotypic features as for the conditions mentioned previously or much more subtle properties, may soon be easily detected. When that happens, it should be possible to diagnose an individual's pain-related genes and then custom-design pharmacologic treatment (332).

Type	Characteristics
I. Dominant hereditary sensory neuropathy	Degeneration of dorsal root ganglia
II. Recessive hereditary sensory neuropathy	Loss of myelinated A fibers
III. Dysautonomia	Loss of unmyelinated C fibers
IV. Congenital insensitivity to pain with anhydrosis	Defective tyrosine kinase A gene, loss of C fibers
V. Congenital insensitivity to pain without anhydrosis	Loss of small A-δ fibers

Adapted from Wood JN. No pain, some gain. *Nat Genet* 1996;13:382–383; and Indo Y, Tsuruta M, Hayashida Y, et al. Mutations in the TRKA/NGF receptor gene in patients with congenial insensitivity to pain with anhidrosis. *Nat Genet* 1996;13:485–488.

TABLE 3-8. Peripheral deficits in hereditary sensory neuropathies

Studies in animals using recombinant inbred strains, selective breeding, and targeted or spontaneous mutations have made it clear that some interesting aspects of pain are heritable, such as high or low sensitivity to opiates (319,328,329,333,334), high and low analgesia in swim stress tests (335,336), or high and low autotomy behavior (337). In addition, animal models for other conditions with associated pain problems, such as rheumatoid arthritis, show genetic based traits for severity and chronicity (338). Defects in genes for tissue signals, such as those of IL-6 (286) or b-endorphin and other products of the proopiomelanocortin gene (339) are another way in which peripheral mechanisms of pain are affected by genetic traits.

The extensive work with animal models of persistent pain during the 1980s and 1990s set the stage for the remarkable demonstration that removing the protein kinase C-gamma gene from mice eliminates their neuropathic pain response to partial ligation of the sciatic nerve but does not affect their acute reflexes to noxious thermal or mechanical stimuli (225) (Fig. 3-37). This discovery has stimulated intense research to discover effective treatments based on procedures to either delete appropriate genes, selectively remove key neurons in the dorsal horn that drive neuropathic pain, or design drugs or gene therapies with selective neurotoxic effects (340,341). The mapping of human genetic trait loci, in combination with the animal genetic studies and the new technologies for nucleic acid microarrays (321,322 and 323,332,342) should rapidly change the clinical landscape for pain diagnosis and treatment.

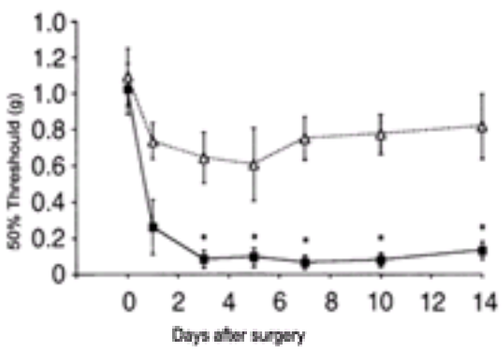

Figure 3-37. Constriction injury to the sciatic nerve produced a significant decrease in paw withdrawal thresholds to von Frey hair stimulation on the injured side in wild-type (n p <.05, Friedman test) but not in PKC-g mutant mice (D p > .05) compared with baseline thresholds. Asterisks indicate significantly lower thresholds on the injured site in wild-type mice compared with the injured side of mutant mice (* p <.05, Mann-Whitney test). No change in withdrawal latency was observed on the contralateral side. (Modified from Malmberg AB, Chen C, Tonegawa S, et al. Preserved acute pain and reduced neuropathic pain in mice lacking PKCg. *Science* 1997;278:279–283, with permission.)

CONCLUSIONS AND THERAPEUTIC HORIZONS

Treatments for peripheral pain mechanisms since the nineteenth century have included inhibitors of inflammation (aspirin, corticosteroids), opiate inhibition of nociceptive pathways in the periphery and CNS (morphine), inhibition of AP signaling (local anesthetics such as cocaine and lidocaine), and use of massage and relaxation therapies to reduce pain. The combined molecular, genetic, animal, clinical, and psychological studies by thousands of pain researchers during the 1980s and 1990s have now opened up new therapeutic possibilities in each of these areas, as summarized in this book. Revolutions in pain management during the 1990s can be expected based on the escalating pace of discovery in the genetics (320,321,322 and 323), pharmacology, and physiology of pain (28,142). Major pharmaceutical efforts to improve anti-inflammatory drugs by making drugs that block membrane receptors, inducible enzymes such as cyclooxygenase 2, membrane ion channels, or that facilitate endogenous antinociceptive mechanisms should soon provide alternatives to the traditional medications for persistent pain. The discoveries of peripheral actions of endorphins, endocannabinoids, and the new orphanin/nociceptin opiate suggest that other endogenous antinociceptive agents and actions are still waiting to be found and brought into service as pain treatments. The many studies on mechanisms of persistent pain have revolutionized knowledge of neuroplasticity and led to the concept of preemptive analgesia and to new strategies for preventing persistent pain or reducing its effect (234,343,344). Precise definition of these phenomena and education of the health professions about their applications for pain management should flourish in the first decade of the new millennium.

The reader is warned that the information presented in this and the next two chapters is a snapshot of the vast topic of basic biologic mechanisms of pain. The database is growing daily, as thousands of neuroscientists tackle the challenge of defining the cellular, molecular, and genetic mechanisms of pain. Many fascinating discoveries of basic and clinical mechanisms are just around the corner. In 1974, at the First World Congress on Pain, Dr. John Bonica encouraged scientists and clinicians to focus their attention on the frustratingly mysterious mechanisms of chronic pain to make its treatment as effective as that for acute pain (8). At that time, the nervous system was thought to have mostly stable wiring and relatively simple neurochemistry, so that mechanisms of neuroplasticity and the complex long- term interactions of the peripheral nervous system and CNS were not even imagined. The remarkable revolution that was set in motion by the vision of Bonica and other pioneers has already achieved much better understanding and treatment for most types of pain, as indicated in this book, and we can anticipate many further improvements as the tidal wave of pain research engulfs and fascinates us.

CHAPTER 4

Spinal Mechanisms and Their Modulation

Gregory W. Terman and John J. Bonica

This chapter provides an overview of the anatomic and physiologic substrates of nociceptive transmission at the spinal level. The last edition required only a few paragraphs to describe the literature addressing animal models of chronic pain (e.g., inflammatory and neuropathic pain) and the changes that take place in spinal cord physiology and pharmacology as a result of repeated afferent input. This chapter significantly updates this information. Nonetheless, much of the neuroanatomy and neurophysiology described in the last edition pertains, and it is supplemented, not supplanted, here by the extensive research of the 1990s.

Pain is a complex constellation of unpleasant sensory, emotional, and cognitive experiences provoked by real or perceived tissue damage and manifested by certain autonomic, psychological, and behavioral reactions. Thus, this chapter concerning spinal mechanisms attempts to avoid the simplistic and potentially misleading tendency to write about pain in the spinal cord. Nonetheless, the spinal cord is the site of considerable information processing for stimuli normally perceived as painful, termed *nociception*. Injury to tissues, whether induced by disease, inflammation, surgical trespass, or other environmental hazards, constitutes a noxious stimulus and causes cellular breakdown with liberation of biochemical substances from intracellular stores. These, in turn, activate specialized high-threshold receptors, called *nociceptors*, and the primary afferent nerve fibers to which they are attached, to transmit action potentials to the dorsal horn of the spinal cord (or its trigeminal analog above the neck) (see Fig. 3-1). It is here, in the spinal cord dorsal horn, that information from nociceptors is modulated by other incoming primary afferent inputs, descending facilitatory and inhibitory influences from the brain, local interneurons, and the activity-dependent state of *transmission readiness* of the dorsal horn neurons themselves. Moreover, it is likely that in the spinal dorsal horn, information from nonnociceptive specialized receptors in skin (activated by touch, for instance), under certain disease states becomes misinterpreted as noxious and consequently perceived as painful. In this chapter we examine what we know about this process, looking first at the basic anatomy and physiology of the system and then at its remarkable plasticity.

SPINAL CORD ANATOMY

The spinal cord is a long cylindrical structure covered by pial, arachnoid, and dural meninges that lies within the vertebral canal (see Fig. 8-1). It extends from the foramen magnum to the first lumbar vertebra in adult humans. Thirty-one pairs of spinal nerves (one on each side of the body), associated with localized peripheral regions, segregate into dorsal and ventral roots as they approach the spinal cord from the periphery. The entrance of these roots into the spinal cord produces a pseudosegmentation. The spinal cord is the only remaining part of the adult nervous system that retains the segmental features of the developing embryo. Despite this gross appearance, the spinal cord in the adult is not truly segmented, and axon fibers from a particular dorsal root can actually travel to many levels of the spinal cord or brain stem before synapsing. Spinal roots are grouped as cervical, thoracic, lumbar, and sacral/coccygeal roots based on their regions of innervation. Because the spinal cord occupies only the upper two-thirds of the vertebral canal, the lumbar and sacral roots descend for a much longer distance in the cerebrospinal fluid-filled meningeal sac before leaving the vertebral canal via intervertebral foramina. Physicians make use of this offset (see Fig. 8-2) between spinal cord and vertebral levels by placing needles either subarachnoid or epidurally at the lumbar vertebral levels to administer medications or withdraw samples without fear of damaging the spinal cord. For pain management, this offset is important to remember because medications, such as opiates, given at the lumbar vertebral level are some distance from their receptors in the substance of the spinal cord.

The internal structure of the spinal cord comprises the external white matter and internal gray matter, all surrounding the small central canal. The size of the white and gray matter changes as a function of the spinal segment in question. In general, white matter represents the ascending and descending tracts of the spinal cord, communicating with the brain and to a lesser extent between spinal cord segments. Thus, it is not surprising that the white matter is larger the closer to the brain (rostral) one looks (i.e., the more rostral one goes in the spinal cord, the more white matter is present because it represents all of the brain's afferents from and efferents to increasing numbers of caudal spinal segments) (Fig. 4-1). In contrast, the gray matter represents the region of synaptic activity in the spinal cord and thus contains not only neuronal axons but also dendrites and synaptic terminals, supported by a matrix of glia and capillaries. The size of the gray matter, unsurprisingly, is largest in areas in which spinal neural processing is greatest, those segments representing the extremities. The cervical and lumbar enlargements in the human are directly related to the arms and legs, respectively, and the brachial and lumbar and sacral plexes in the periphery (see Fig. 4-1). Gray matter anatomy grossly resembles the shape of the letter H with the dorsal and ventral horns separated by the crossbar of the H and the midpoint of this crossbar representing the central canal. At the microscopic level, gray matter anatomy was, for many years, filled with eponyms and nuclei, and conflicting names for similar locations between, and even within, species. A landmark series of papers by Rexed (1) described a cytoarchitectural organization of the gray matter called laminae in the cat spinal cord. Similar laminar, gray matter divisions have now been described in a variety of species including humans and have provided a framework from which anatomic and physiologic findings within the spinal cord can be compared and contrasted.

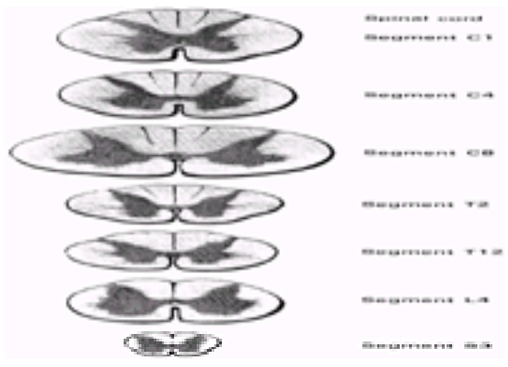

Figure 4-1. Spinal cord segments at different levels of the neuraxis show variations in size and shape of gray and white matter (see discussion in text). (From

Carpenter MB. *Human neuroanatomy*, 7th ed. Baltimore: Williams & Wilkins, 1976:218, with permission.)

Specifically, Rexed (1) divided the spinal gray matter into 10 laminae (Fig. 4-2). Laminae I through VI make up the dorsal horn; laminae VII through IX, the ventral horn; and lamina X is composed of a column of cells clustered around the central canal. We discuss the known differences between the various laminae and their importance in nociceptive processing in the section Dorsal Horn Morphology, later in this chapter. In short, lamina I of the dorsal horn is called the *marginal layer*. This lamina has the largest incidence of cells that send their axons to the thalamus, thereby forming much of the white matter known as the spinothalamic tract (STT). This tract is thought most important for the transmission of nociceptive information from spinal cord to brain. Cells in lamina V are also commonly found to project to the brain via the STT. Lamina II cells rarely project to thalamus or anywhere else outside a particular spinal segment, and are termed *interneurons*. Lamina II and its interneurons are known to modulate the activity of laminae I and V cells. Lamina II, which is subdivided into outer (II_o) and inner (II_i) parts, was originally labeled *substantia gelatinosa* (SG) because of its gelatinous gross appearance. A few authors adhere to Rolando's original description and include laminae I and II as SG, whereas others consider SG as including laminae II and III (2). Rexed's laminae run the entire length of the spinal cord, and the spinal dorsal horn laminae fuse with similar structures in the medulla called the medullary dorsal horn.

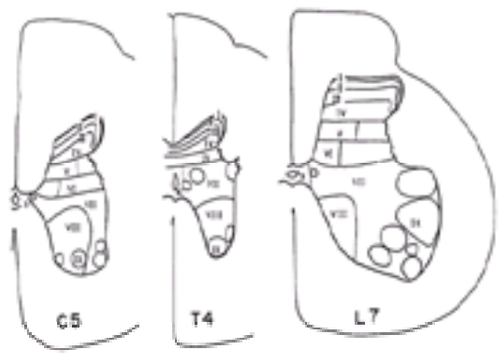

Figure 4-2. Diagrams showing Rexed's laminar histologic organization of the cat spinal cord gray matter at three levels. The dorsal horn corresponds to laminae I through VI inclusive, lamina I being the marginal zone, lamina II the substantia gelatinosa, laminae III and IV the nucleus proprius, and lamina V the neck of the dorsal horn. Lamina VI is more readily demonstrated in the cervical and lumbosacral enlargements of the spinal cord. (From Rexed B. The cytoarchitectonic organisation of the spinal cord in the cat. *J Comp Neurol* 1952;96:415–495, with permission.)

PRIMARY AFFERENT CENTRAL PROJECTIONS

Nociceptive primary afferents (discussed in depth in Chapter 3), whose peripheral processes innervate skin, muscle, or viscera and whose cell bodies are found in a dorsal root ganglion, project centrally via the dorsal root corresponding to that ganglion into the spinal cord. Each dorsal root breaks up into 12 to 15 rootlets that connect with the spinal cord. At the beginning of the twentieth century, Lissauer and Bechterew noted that the smaller myelinated fibers congregate on the lateral side of the rootlets as they enter the cord, whereas the larger axons were in the center and medial part of the rootlets [see (2) for references]. Lissauer further noted that the small lateral fibers pass to the apex of the dorsal horn, thus forming the tract that bears his name, whereas the larger fibers pass centrally to travel in the dorsal columns. In the ensuing half century, these findings were confirmed in animal studies by Cajal, Ranson, Ingvar, O'Leary, and others (2). Ranson (3), agreeing with Lissauer's anatomic studies, also noted that, in experimental animals, pain could not be elicited after cutting the lateral bundle. Snyder (4) and Kerr (5) showed that this segregation does not occur in the cat but does occur in monkeys. Kerr (5) found a random distribution of large and small fibers of a rootlet at 5 mm from the entry zone into the cord that continued until approximately 1 mm from the cord, where the majority of the small fibers shifted to the periphery of the rootlet, forming a conspicuous marginal ring. Just before the rootlet joined the cord, however, the fine fibers shifted from the circumferential ring to a clear lateral position and in the cord merged with the tract of Lissauer, whereas the medial division was composed of large fibers. Similarly, in humans, Sindou and colleagues (6) found small and large fibers to be randomly situated in the rootlet, but that the small fibers shift laterally as they near the dorsal root entry zone. In the dorsal root entry zone, the small fibers in the medial aspect cross to join those in the lateral bundle to enter the tract of Lissauer (see Chapter 3 for more detailed discussion). These findings prompted Sindou and associates to develop a “selective posterior rhizotomy” and others to use dorsal root entry zone lesions as neurosurgical approaches to eliminating certain pain conditions (see Chapter 106).

Lissauer's tract is a tight collection of fine fibers, longitudinally oriented in the spinal cord, that extends between the periphery of the dorsal horn and the cord's surface. Lissauer's original view of the tract was that it consists chiefly of small primary afferent fibers en route to the synaptic terminals in the dorsal horn, and Ranson (3) proposed that most of these conduct nociceptive impulses. Subsequent degeneration studies suggest that as few as 25% of the fibers in the most medial part of the tract are primary afferents, the rest being intersegmental propriospinal fibers (for review see 2). LaMotte (7) found that lesions restricted to Lissauer's tract produced degeneration in laminae I, II, and III of the dorsal horn (Fig. 4-3), the degeneration extending only a few millimeters rostral and caudal to the lesions. The primary afferent fibers are located throughout the tract at the level of their entry, but they shift medially at more rostral and more caudal levels. She concluded that fine primary afferents project to these superficial laminae by way of Lissauer's tract. Coggeshall and colleagues (8) have quantified these studies across species: (a) primary A-d and C fibers make up two-thirds of the axons in rat, 50% in cat, and 80% in monkey; (b) the ratio of unmyelinated to myelinated fibers within the tract in rat is 4:1; (c) primary afferent fibers ascend several segments in the lumbosacral cord of rat, but terminate within a single segment in the thoracic cord; and (d) in monkey there are more primary afferents in the medial part than in the lateral part of the tract.

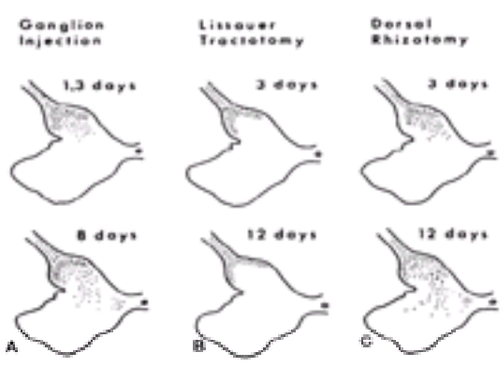

Figure 4-3. Summary diagrams of the results of Lissauer's tractotomy and dorsal rhizotomy in the monkey, suggesting that fine primary afferents pass through Lissauer's tract and terminate in the superficial dorsal horn. **A:** Distribution of radioactive amino acid 1.3 and 8.0 days after injection into the dorsal root ganglion of the monkey showing normal terminations of primary afferents. **B:** Three days after Lissauer's tractotomy, fibers terminating in laminae II and III degenerated, whereas those that terminated in laminae I and II_o required 12 days to degenerate. **C:** Three days after dorsal rhizotomy, dorsal column collaterals to laminae IV through VI and laminae in the ventral horn began to degenerate. The degeneration was prominent by 12 days. (From LaMotte C. Distribution of the tract of Lissauer and the dorsal root fibers in the primate spinal cord. *J Comp Neurol* 1977;172: 529–561, with permission.)

On entering the spinal cord, primary afferents take different courses depending on their size and function. Many dorsal roots, on entering the spinal cord, bifurcate in a Y-shaped fashion into a long ascending and a shorter descending branch. From each of these branches, large numbers of collaterals leave at right angles to enter and distribute in the spinal gray. Although the overwhelming majority of primary afferents terminating in the dorsal horn do so ipsilaterally, some course dorsal to the central canal and terminate in the contralateral horn. As mentioned previously, the small C fibers appear to travel in the most lateral part of the dorsal white matter,

including Lissauer's tract, and large A fibers more medially in the dorsal column. The dorsal root afferents of all sizes issue most collaterals in their segment of entry, but the rostral-caudal spread varies. A-d fibers spread three to six segments rostrally and an equal number caudally, whereas the collaterals of C fibers spread two to three segments above and below the level of entry (Fig. 4-4).

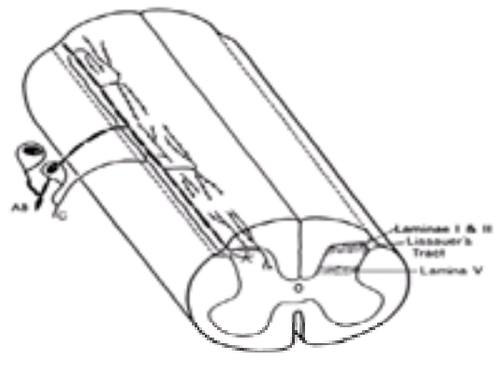

Figure 4-4. Three-dimensional diagram to depict the extensive field of A-d and C fibers after bifurcating at the point of entry into Lissauer's tract. The small-diameter fibers penetrate the spinal gray matter and terminate in the superficial dorsal horn (laminae I and II), and the A-d nociceptors and C visceral afferents also terminate in lamina V. The terminal axons of both types of small-diameter primary afferents are close and have a longitudinal orientation extending for several millimeters in laminae I and II, contacting hundreds of spinal neurons. (From Fields HL. *Pain*. New York: McGraw- Hill, 1987:45, with permission.)

The termination of primary afferents in dorsal horn has been studied by numerous investigators. Light and Perl (9), using the anterograde transport of horseradish peroxidase (HRP), showed that the concentration of fine fibers and their terminals ended in the superficial part of the dorsal horn of rat, cat, and monkey, whereas the large fibers ended in the deeper parts. They examined the number and distribution of HRP-stained terminal enlargements (en passant and boutons) for whole dorsal rootlets and for rootlets whose medial or lateral division had been sectioned. Figure 4-5 shows the results. As noted, the stained terminals in the whole- rootlet preparations were distributed evenly through the gray matter. Section of the lateral division, which contained small primary afferents before application of HRP, caused a dramatic elimination of most of the terminals in the marginal zone and in the SG, whereas the projections to deeper layers remained extensive. Conversely, section of the medial division containing large primary afferents eliminated virtually all terminals in the nucleus proprius and the deeper laminae (most terminals remained unstained), whereas a large number of terminals in the marginal zone and SG were marked.

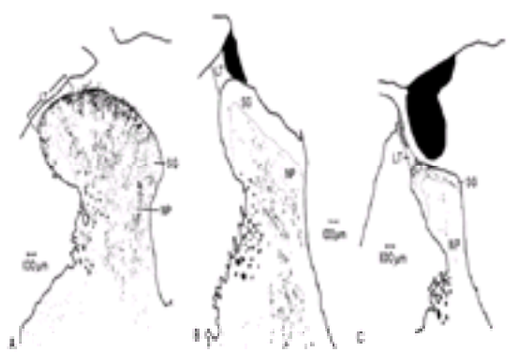

Figure 4-5. Pattern of projection of large and small primary afferent fibers in the spinal cord of rhesus monkey. **A:** Normal distribution. (LT, Lissauer's tract; NP, nucleus proprius; SG, substantia gelatinosa.) **B:** The lateral divisions of the root fibers were cut (lesion shown in solid black) at the junction between the dorsal root and the spinal cord before horseradish peroxidase was applied. Most of the terminals in the marginal zone and the substantia gelatinosa were eliminated, whereas the projection to deeper layers remained extensive. **C:** Lesion of the medial division of the root left most terminals in the nucleus proprius and deeper regions unstained, whereas a large number of terminals were marked in the marginal zone and in the substantia gelatinosa. (Modified from Light AR, Perl ER. Reexamination of the dorsal root projection to the spinal dorsal horn including observations on the differential termination of coarse and fine fibers. *J Comp Neurol* 1979;186:117–131.)

Termination of Collaterals from Large Myelinated (A-b) Fibers

A-b fibers terminate primarily in lamina III but also, to a lesser extent, in laminae IV through IX (including presumed monosynaptic primary afferent–motor neuron contacts) (see Chapter 3 and Fig. 3-13).

Termination of Collaterals of Small Myelinated (A-d) Fibers

The course followed by the fine fibers in the lateral division of the dorsal rootlets is entirely different from that followed by the large fibers. They run laterally into the medial aspect of the tract of Lissauer, in which they divide into short ascending and descending branches that may run for several segments. Collaterals of the A-d nociceptors penetrate the lateral aspect of the dorsal horn and terminate at four sites: lamina I via tortuous paths and ending in terminal arbors in laminae I and II $_{o}$, and others penetrate deeper to end in laminae V and X (see Chapter 3 and Fig. 3-14).

Termination of Collaterals of Small Thinly Myelinated (C) Fibers

Collaterals of C fibers penetrate the dorsal gray matter from the medial Lissauer tract and appear to terminate exclusively in laminae I, II, and V of the dorsal horn (see Fig. 3-15) in two ways: a capping tangential plexus of fibers over the marginal layer oriented longitudinally, and bushy terminal arbors in the SG forming thin sagittally oriented slabs (4). The mediolateral dimension of a C-fiber arbor is much smaller than this dimension of the A-d type B hair fiber. The terminal arbors of C fibers cluster together to make foci curving in their side branches. Figure 4-4 depicts the extensive terminal field of A-d and C fibers along the length of the spinal cord. Studies have described a dichotomy in C-fiber nociceptor anatomy (10). Using immunohistochemical techniques the subpopulation of C fibers terminating in lamina II$_{i}$ have been found to differ biochemically from C fibers terminating elsewhere (e.g., laminae I and II $_{o}$). C fibers terminating in lamina II$_{i}$ do not appear to contain calcitonin gene–related peptide (CGRP) or substance P, instead staining selectively for the enzymes fluoride-resistant acid phosphatase and thiamine monophosphatase as well as the binding site for the lectin IB4 (Fig. 4-6). As discussed in a following section, these two subsets of C-fiber nociceptors have distinct developmental and perhaps functional characteristics as well.

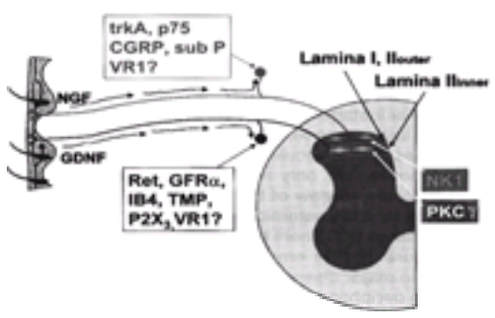

Figure 4-6. Schematic of peripheral and central target fields, trophic factor dependence, and biochemical characterization of two classes of cutaneous C fibers. The class expressing calcitonin gene–related peptide (CGRP) and trkA receptor [a nerve growth factor (NGF) receptor] represents roughly 40% of dorsal root ganglion neurons in rodents. The IB4 lectin binding class represents approximately 30%. Both classes are sensitive to capsaicin probably via the VR1 vanilloid receptor for capsaicin. (GDNF, glial cell line–derived neurotrophic factor; GFRa, GDNF family receptor a; p75, another low-affinity neurotrophin receptor; $P2X_3$, an adenosine triphosphate receptor subtype; PKC, protein kinase C; Ret, receptor tyrosine kinase; sub P, substance P; TMP, thiamine monophosphatase.) (From Snyder WD. Tackling pain at the source: new ideas about nociceptors. *Neuron* 1998;20:630, with permission.)

Termination of Fine Muscle Afferents

Small-diameter muscle afferents (groups III and IV) terminate primarily in dorsal horn laminae and resemble cutaneous small- diameter afferents more than large muscle afferents discussed previously. Mense and associates (11) found that high-threshold myelinated mechanoreceptors (type III) from tail muscle, fascia, and joint capsules sent collaterals to laminae I and V and longer branches to the region of the central canal, as well as to laminae I and V of the contralateral dorsal horn. No terminals were found in laminae III and IV. Craig and Mense (12) have shown that C-fiber muscle afferents terminate in laminae I and V but not in the SG.

Visceral Afferents

Termination of visceral afferents in the spinal cord is of great importance in considering the mechanism of visceral pain. A-d and C afferents, which run with sympathetic autonomic nervous system efferents (termed sympathetic afferents), terminate predominantly in laminae I and V, although they also terminate in laminae IV, VI, VII, and X.

Using the N wave as a signal of the site of afferent termination after stimulation of the sympathetic chain, Selzer and Spencer (13) found that lamina V was the major termination site in the upper two lumbar segments of the cat. Morgan and associates (14), using HRP technique, studied the spinal termination of visceral afferents of the pelvic nerve and noted that the input was largely in S2, less in S1 and S3, still less in L1-4, and contralateral in S1 and S3. The densest staining was in Lissauer's tract, and from this structure two bands of collaterals appeared, one lateral pathway and one medial pathway, thus forming a horseshoe-shaped pattern around the dorsal gray matter. Collaterals from both pathways projected into laminae I, V, VI, and VII, and some from the medial pathway terminated in lamina X (Fig. 4-7). A similar pattern of fiber termination was noted at the L-3 spinal level in the cat after labeling of the sympathetic hypogastric nerve and by Cervero (15) in the cat thoracic cord after splanchnic nerve labeling. None of the visceral afferents was found to terminate in lamina II, a finding whose functional significance is unknown.

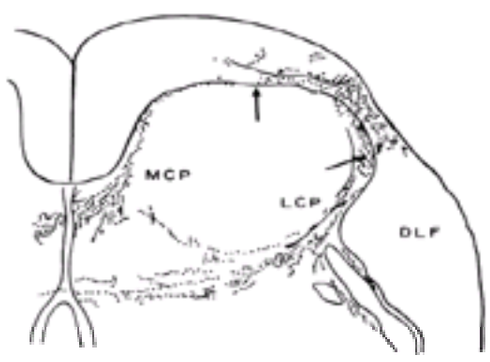

Figure 4-7. Pattern of distribution of collaterals of primary afferents of the pelvic nerve in the S2 segment of cat spinal cord. The pelvic nerve was labeled with horseradish peroxidase, and the ventral roots were cut to eliminate efferent labeling. The densest labeling is in the tract of Lissauer, and from here two bands of collaterals appeared, a lateral pathway (LCP) and a medial pathway (MCP). See text for details. (DLF, dorsolateral funiculus.) (From Morgan C, Nadelhaft I, de Groat WC. The distribution of visceral primary afferents from the pelvic nerve to Lissauer's tract and the spinal gray matter and its relationship to the sacral parasympathetic nucleus. *J Comp Neurol* 1981;201:415–440, with permission.)

Thus, visceral afferents terminate primarily on cells in laminae I, V, and X. Up to 95% of spinal neurons that respond to visceral stimulation, however, also respond to somatic stimuli, thus showing viscerosomatic convergence (16). This convergence was first demonstrated in 1968 by Pomeranz and colleagues (17) in the thoracic cord of cat, and a year later by Selzer and Spencer (13) in the lumbar cord of the same species. Both groups demonstrated that many neurons within the gray matter of the spinal cord responded to electrical stimulation of cutaneous nerves and also could be driven by stimulation of the splanchnic nerve, and, furthermore, that these were visceral A-d and C afferents. Since then, many others have shown this somatovisceral and viscerosomatic convergence at all levels of the spinal cord. Convergence among multiple visceral inputs is also seen, in that stimulation of multiple viscus organs can activate the same lamina I, V, or X neuron (18). These neurons can project to the ventrolateral funiculus of the spinal cord and become part of the spinothalamic and spinoreticular tracts (15). The Willis group has reported a separate visceral ascending pathway in rat (19), monkey (20), and humans (21). Visceral afferents are thought to synapse in the spinal cord (particularly in lamina X) on second-order neurons that then project via the dorsal columns to the dorsal column nuclei and then on to higher brain areas. A lesion of this pathway has been found to inhibit visceral pain behaviors and may underlie the clinical use of myelotomy for visceral pain (see Chapter 106).

Convergence of visceral and cutaneous afferent fibers and muscle and cutaneous afferents onto second-order dorsal horn neurons is the most cited mechanism for referred pain; a phenomenon in which visceral pain is sensed at a somatic site. The site of referral is innervated by the same segmental nerve roots as those innervating the visceral structure (e.g., pain of pleuritic origin referred to the shoulder or angina referred to the chest wall or arm). Although the phenomenon could be explained by single primary afferents innervating both somatic and visceral structures, the low incidence of such primary afferents suggests a central site for referred pain (22). The precise site at which somatic and visceral converging information causes a misrepresentation of pain location is not yet known. The high frequency of somatovisceral convergence in dorsal horn cells may, in fact, argue against the dorsal horn as the critical site because many visceral pains are not referred. The finding of specific visceral nociceptive pathways gives renewed credence to older theories (23) that referred pain is primarily caused by convergence at thalamic or cortical levels at which visceral pain representations, although present (24,25), seem much less detailed than somatic representations.

DORSAL HORN

Enormous advances have been made in knowledge of the complex circuitry, biochemistry, and function of the spinal dorsal horn and its brain stem homologue, the trigeminal subnucleus caudalis (medullary dorsal horn). A number of techniques have made possible physiologic and pharmacologic studies that previously were impossible. For example, the combined use of anatomic (intracellular dyes and ultrastructural analysis) and single cell electrophysiology (*in vitro* and *in vivo*) has permitted precise correlations of structure and function and lent new insight into the synaptic interactions that underlie processing within the dorsal horn. Moreover, immunohistochemical characterization of the dorsal horn has provided a wealth of pharmacologic information including the neurochemical profiles of various sized afferents, their distribution within the dorsal horn, and changes in these profiles with development, activity, or injury (see Chapter 3 for examples in the dorsal root ganglia). This section highlights such work on the morphology, physiology, and biochemistry of the spinal dorsal horn (and its less studied medullary analogue, the medullary dorsal horn). Numerous more specific reviews of the dorsal horn also have been published including those by Wall (26), Cervero (27), Dubner and Bennett (28), Basbaum (29), Yaksh (30), Coderre (31), Coggeshall and Carlton (32), and Millan (33), among others.

Dorsal Horn Morphology

Although it is convenient to subdivide the spinal cord into the various laminae described by Rexed on the basis of shape, size, and distribution of cell bodies, these laminae clearly do not have rigid, exact edges and, furthermore, the dendrites of the cell bodies in one lamina can range widely into neighboring laminae and sometimes into white matter. Nonetheless, we now look more closely at the spinal cord laminae and what is known about their functions as evidenced by their differing cytoarchitecture and electrophysiologic characteristics. Recall that, in this book, lamina I corresponds to the marginal zone, lamina II to the SG, laminae III through V

to the nucleus proprius, and lamina VI to the base of the dorsal horn.

Lamina I

The marginal zone is a thin band that caps the dorsal horn and contains a variety of neuronal types. These include the large cells of Waldeyer, whose dendrites appear parallel to the surface of the lamina. In the cat medullary dorsal horn, Gobel (34) was able to distinguish four types of cells: smooth and spiny pyramidal cells and two types of multipolar neurons. He emphasized that dendrites of these neurons are restricted to the marginal zone and are set to receive direct input from only a restricted population of primary afferent fibers or projections from relay of action of interneurons in deeper laminae. In contrast, Beal and colleagues (35) found in the spinal cord of monkey that the dendrites of cells in the medial part of the marginal zone project ventrally at least to SG and even to lamina III. Therefore, they can receive direct synaptic input from primary afferents that terminate exclusively in marginal zone or SG (as well as presumed relayed activity). Zhang and Craig have looked specifically at lamina I cells projecting to thalamus in cats (36) and monkeys (37,38) and noted three major morphologic types of cells: pyramidal, fusiform, and multipolar. Like Gobel, they noted that the dendritic fields of these cells tended to stay within lamina I (with few exceptions) and emphasized the importance of using horizontal sections, rather than transverse sections, for these morphologic studies (39). Marginal cells located in the lateral part of lamina I often have dendrites that enter into Lissauer's tract. Some of the cell bodies are located within the tract and thus can have synaptic input from axons in the tract (Fig. 4-8).

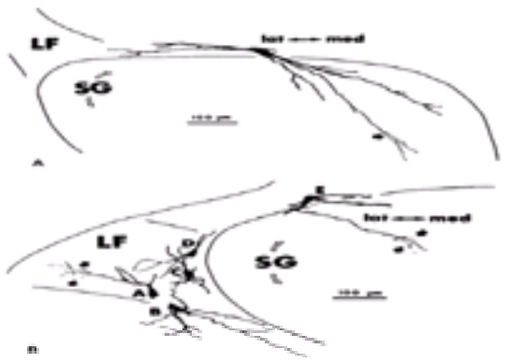

Figure 4-8. Marginal (lamina I) neurons in monkey spinal cord. **A:** The neuron sends a major dendritic projection through lamina II substantia gelatinosa (SG) and into lamina III. **B:** Marginal cells, including a cluster with dendrites extending into Lissauer's tract fibers (LF) (A through D) and a medially located neuron with dendrites (E) descending into the SG. [From Beal JA. The ventral dendritic arbor of marginal (lamina I) neurons in the adult primate spinal cord. *Neurosci Lett* 1979;14:201–206, with permission.]

Lamina I has special function regarding nociception because it is the termination zone of nociceptive afferents and because it contains cells that respond only to noxious stimuli, the so-called nociceptive-specific (NS) neurons (also called *class 3 cells*). Cervero and colleagues (40) reported that marginal NS neurons responding to A-d and C-fiber input from the skin also could be activated by group III and IV muscle afferents, indicating convergence of cutaneous and muscle input. Other neurons in lamina I respond only to innocuous thermal stimuli (class 1), and a third type responds to both noxious and innocuous stimulation and can differentiate between these two by discharging at higher frequency to noxious stimuli. These last cells are called *wide dynamic range* (WDR), *multireceptive*, or *class* 2 neurons. Fewer WDR neurons exist in lamina I than in deeper laminae (particularly lamina V).

Many of the cells in lamina I are projection cells. Many of these have long axons that cross the midline and enter ascending spinal pathways, some projecting to the thalamus, some to the brain stem, and others to the cerebellum. Roughly one-half of the lateral STT, critical for normal pain and temperature sensation, is made up of projecting axons from lamina I cells (37). Other projections interconnect with near and distant spinal segments and are involved in the segmental organization of sensory transmission (41). Attempts to correlate the varied morphology of lamina I cells with their response characteristics (i.e., NS or WDR cells) in lamina I projecting cells has not been very successful, although undertaken by a number of laboratories (39,42,43). In the cat, Craig and colleagues (44) have reported the most success in this regard, recording intracellularly from spinothalamic projecting neurons in lamina I and then morphologically classifying these same cells using biocytin staining. They find a strong correlation between structure and function. Fusiform-shaped cells were found to be NS, responding solely to heat or pinch. Pyramidal-shaped cells were classified as *cold* cells in that they responded to innocuous cooling (and were inhibited by warming). Multipolar cell responses were both NS and polymodal nociceptive, meaning that they responded to cold (called *HPC cells*, signifying responses to heat, pinch, and cold). These interesting structure and function correlations (Fig. 4-9), according to the authors, may have been missed by others because of a failure to test cold responsiveness or because of the use of transverse rather than horizontal spinal cord sections. WDR lamina I spinothalamic cells are rare in the cat and thus were not studied by these authors.

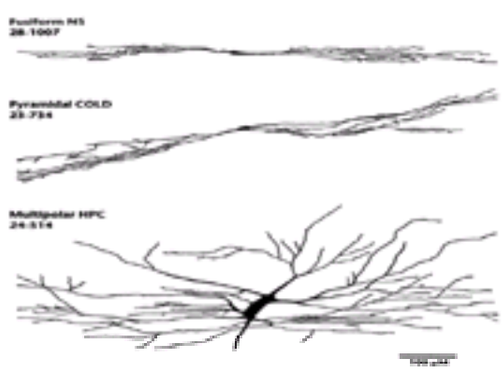

Figure 4-9. Camera lucida reconstructions of examples of three types of morphologically distinct lamina I neurons and their correlated activating stimuli in the cat. Fusiform-shaped cells were found to be nociceptive specific (NS). Pyramidal-shaped cells were *cold* cells in that they responded to innocuous cooling and were inhibited by warming. Multipolar cells were called *HPC cells*, signifying responses to heat, pinch, and cold. Cells and their dendrites were generally contained within two or three serial 50-µm horizontal sections. Rostral is left and medial is up. (From Han ZS, Zhang ET, Craig AD. Nociceptive and thermoreceptive lamina I neurons are anatomically distinct. *Nature Neurosci* 1998;1:223, with permission.)

Lamina II

Most of the neurons in the SG are small, with dendrites arborizing in a rostrocaudal plane. In the early part of the twentieth century, Cajal (45) described two major types of cells in the SG: central cells, which appear to have a radial orientation when viewed in transverse section, a large rostrocaudal orientation in sagittal section, and are found throughout SG; and limotrophe (limiting) cells, which are located in the outer part of the SG (Fig. 4-10). More recently, Gobel (46), on the basis of a detailed study of the cat medullary dorsal horn, described four types of cells: stalked cells, which he believes to be equivalent to Cajal's limiting cells; islet cells, equivalent to Cajal's central cells; arboreal cells; and II to III border cells. Of these, the first two are considered as important dorsal horn nociceptive local-circuit neurons. The stalked cells have cell somata at the border of laminae II and III, dendrites that fan out ventrally in lamina II and occasionally laminae III and IV, and axons that arborize extensively in lamina I among the dendrites of projection neurons (Fig. 4-11). Gobel (46) proposed that they function as excitatory local-circuit neurons, collecting and relaying nociceptive inputs from terminals of primary nociceptive afferents in lamina II to projecting neurons in lamina I. Stalked cell dendrites receive synapses from primary afferents and from dome-shaped axon terminals that resemble the terminals from descending serotonergic axons (28).

Figure 4-10. Transverse section of the dorsal horn of the spinal cord stained with the Golgi technique. C and F are limiting cells, and cells D and H are central cells. (From Cajal SR. *Histologie du systéme nerveux de I'homme et des vertebrés*. Vol 1. Paris: Maloine, 1909, with permission.)

Figure 4-11. A stalked cell of the caudal spinal trigeminal nucleus in the cat. The cell body is in the outer part of lamina II, whereas the dendrites extend into lamina III and even deeper and the axon enters lamina I. The dendrites bear spines and stalklike branches (*arrows*) for which the cells have been named. [From Gobel S. Golgi studies of the neurons in layer II of the dorsal horn of the medulla (trigeminal nucleus caudalis). *J Comp Neurol* 1978;180:395–413, with permission.]

Islet cells, the second major type of local-circuit neurons, are found throughout the SG. Seen in a sagittal section, these have a fusiform cell body and dendritic arbor that is elongated rostral-caudally, and those in lamina II_i extend for well over a millimeter. Islet cell axons are unmyelinated and arborize profusely within and near their dendritic trees. Gobel (46) has proposed that islet cells are inhibitory local interneurons. Some islet cells contain the inhibitory neurotransmitter gamma-aminobutyric acid (GABA), and others are enkephalinergic (28,47). Ultrastructural analysis of electrophysiologically characterized and HRP-filled islet cells indicates that their spine heads and dendritic shafts contain aggregates of round and oval synaptic vesicles that synapse with scallop-shaped primary afferent terminals (28,47) (Fig. 4-12). Thus, dendroaxonic synapses may regulate the activity of primary afferent terminals, but the nature of this regulation remains unknown. Islet cell dendrites also synapse on other dendrites, which do not contain vesicles and are thought to come from stalked cells. Islet cells also receive synapses from dome-shaped axon terminals of descending serotonergic axons.

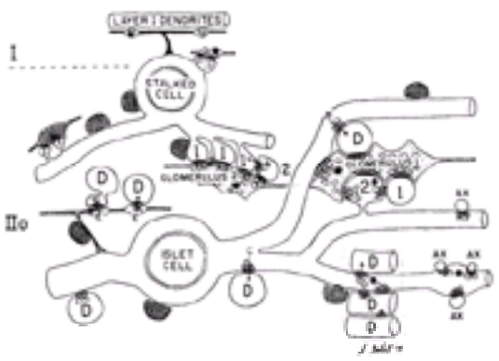

Figure 4-12. Synaptic connections of a lamina II_o islet cell and a stalked cell. Both cells receive axodendritic synapses from primary endings (*stippled*) and nonprimary inputs (*cross-hatched*), which include descending aminergic terminals on their dendrites and cell bodies. The islet cell, with synaptic vesicles in its dendrites, forms dendrodendritic synapses with type I spines and dendritic shafts (D) in glomerulus 1, on dendritic shafts in dendrite bundles (*dotted enclosure*), and with individual dendritic shafts that pass alongside the primary and higher order islet cell dendrites. The islet cell also forms dendroaxonic synapses on the primary ending in glomerulus 1 (*arrowhead*) and on unmyelinated axonal shafts (AX) outside of glomeruli. The islet cell axon (*striped*) receives an axoaxonic synapse on its initial segment from a nonprimary ending, and its endings synapse on dendritic shafts and type I spines. The stalked cell axon (*black*) synapses with layer I dendrites. Potential sites where layer II_o islet cells could synapse with stalked cell dendrites include dendrodendritic synapses with type I spines (*arrow A*) and dendritic shafts (*arrow B*) in glomeruli, with dendritic shafts outside of glomeruli (*arrow C*), and with dendrite bundles (*arrow D*), as well as axodendritic synapses (*arrow E*) at its axonal termination. (From Gobel S, Falls WM, Bennett GJ, et al. An EM analysis of the synaptic connections of horseradish peroxidase filled stalked cells and islet cells in the substantia gelatinosa of adult cat spinal cord. *J Comp Neurol* 1980;194:781–807, with permission.)

The physiologic characteristics of SG cells have been studied by a number of groups. Although both NS and WDR cells have been identified in II_o, only WDR nociceptive cells (48) (and low-threshold mechanical neurons) (28) have been reported in II_i. Of particular value for functional conclusions, in this area containing both excitatory and inhibitory cells, are studies combining anatomic and electrophysiologic methods.

Bennett, Dubner, and coworkers (28), using intracellular HRP techniques, found that both NS and WDR responses were seen in both stalked cells and islet cells in lamina II_o (Fig. 4-13). Islet cells in lamina II_i responded only to innocuous stimuli and no WDR cells in this region were observed in these experiments. The nociceptive inputs could be conveyed by A-d fibers or by A-d and C fibers, whereas the tactile inputs could be mediated by A-d down-hair receptors or A-b guard-hair receptors. They concluded that the patterns of primary afferent excitation of SG neurons were comparable with WDR, NS, and low- threshold mechanoreceptor patterns seen elsewhere in dorsal horn.

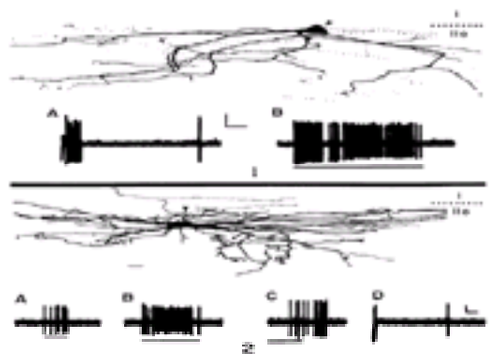

Figure 4-13. Responses of stalked cells and islet cells whose cell bodies are located in the outer part of lamina II $_o$. **1:** Nociceptive-specific stalked cell labeled with intracellular injection of horseradish peroxidase. *Inset A* shows the response of the cell to electrical shocks applied to the receptive field and indicates a convergent input from A-d and C fibers. *Inset B* shows the response to pinch with toothed forceps. **2:** A wide dynamic range islet cell labeled with horseradish peroxidase. *Inset A* shows responses to brushing; *B*, responses to pinching with toothed forceps; *C*, responses to noxious heat; and *D*, responses to electrical shock applied to the skin. (From Bennett GJ, Abdelmoumene M, Hayashi H, et al. Physiology and morphology of substantia gelatinosa neurons intracellularly stained with horseradish peroxidase. *J Comp Neurol* 1980;194:809–827, with permission.)

In other respects, the response of SG neurons to continuous stimulation is quite different from that seen elsewhere in dorsal horn, with many SG neurons showing a powerful habituation to repeated stimuli (28). In addition, Cervero and colleagues (49) reported that SG cells had a tonic discharge that could be inhibited by cutaneous stimulation. A variety of responses were noted: Some cells were inhibited by innocuous mechanical stimuli but excited by noxious input, others were inhibited by both innocuous and noxious stimuli, and still others were inhibited by noxious stimuli but excited by innocuous stimulation. The complexity of the circuitry of this area with its inhibitory and excitatory cells modulating other laminar inputs and outputs has made the functional implications of SG difficult to assess *in vivo*. As noted in the gate-control theory in 1965, the SG seems ideally suited to modulate pain responses. Little evidence of such a role has been demonstrated as yet, however. The development of *in vitro* electrophysiologic techniques applied to spinal cord circuitry may help to unravel the complexity of this region.

Laminae III and IV

Lamina III is distinguished from lamina II by the larger number of myelinated axons and from lamina IV by the appearance of large cell bodies in the latter lamina. Moreover, its anatomy is dominated by the extensive dendritic arbors arising from cells in deeper layers and by *antenna-type* neurons thought to be cells of origin of the spinocervical tract and whose dendrites divide horizontally before pushing dorsally into lamina II (50). Willis and associates (38) found spinothalamic projection cells in laminae III and IV in monkeys that send dendrites through the SG and into lamina I. Beal and Cooper (51) noted that lamina III also contains many central or islet cells that are similar to the neurons found in lamina II. Some small cells have small, low-threshold excitatory receptive fields that make up part of the larger receptive field of the nearest large cell. Although no specific function has yet emerged for lamina III, which may well represent a transition between lamina II and IV, studies by Bennett and colleagues (28) have demonstrated that the cells are particularly responsive to low-threshold afferents that terminate in this region. As we discuss in Modulatory Mechanisms: Structural Reorganization, sprouting of low threshold primary afferent terminals from lamina III into more superficial areas of the dorsal horn (more commonly associated with nociception) may be a mechanism for the development of neuropathic pain (52).

Lamina IV contains some large cells that send dendrites into more superficial layers of the dorsal horn. Many of these neurons project their axons in the dorsal column white matter to the dorsal column nuclei. This lamina also contains small stellate cells. By far the most common cell type is excited only by light mechanical stimuli to the skin, and the response of these cells does not increase with increases in pressure intensity (53). However, several investigators have observed lamina IV WDR cells, and Besson and colleagues noted a few lamina IV cells that are excited by intraarterial injection of bradykinin into the limb (2).

Lamina V

Lamina V is important in nociception and pain because it receives input from A-d and C nociceptors and contains cells whose axons contribute to long ascending tracts, including the spinothalamic and spinomesencephalic, and, to a lesser extent, the spinoreticular tracts (see Ascending Systems, later in this chapter). The most common cells in lamina V are the WDR or multireceptive neurons. By definition they respond to a variety of inputs from low-threshold and high-threshold mechanical, thermal, and chemical stimuli by way of large and small afferent fibers. Evidence exists that these WDR neurons and those in lamina I constitute one-third to one-half of the long ascending nociceptive systems (28). WDR neurons often have large cutaneous receptive fields with a central area responsive to both tactile and noxious stimuli, surrounded by a larger area with ill-defined borders that is responsive only to noxious stimuli. The excitatory receptive field is surrounded by an inhibitory receptive field. Some lamina V neurons have other response properties, including tactile and NS responses.

Certain cells in lamina V respond to A-d and C fibers of visceral origin as well as to cutaneous low- and high-threshold mechanical stimuli, which, as previously mentioned, may constitute the neural substrate of referred pain (17). As we discuss later, the organization of these WDR receptive fields and their responsiveness to different kinds of primary afferent inputs are modulated by descending controls and spinal circuitry. A large body of evidence indicates that WDR neurons contribute to the perception of pain, including the finding that selective activation of human WDR neurons is sufficient to produce pain (28).

Lamina VI

According to Rexed (1), lamina VI cells exist only at certain levels of the spinal cord: They are present in the lumbosacral and cervical enlargements, but not in most of the thoracic cord or lower sacral and coccygeal segments. Lamina VI cells are somewhat smaller than those found in lamina V, and Wall (53) characterized them as responsive to both low-threshold muscle afferents and low- and high-threshold cutaneous afferents. In medullary dorsal horn the homologue to spinal lamina VI consists of neurons (receiving tactile and low-threshold muscle afferents) located at the junction between the subnucleus caudalis and the cuneate nucleus (38,54).

Intermediate Region and Ventral Horn

Cells of the intermediate region and ventral horn contribute a small percentage of axons to nociceptive ascending tracts, including the spinothalamic and spinoreticular (2,26). Lamina VII and VIII make up the majority of the ventral horn and surround clusters of motor neurons (lamina IX). Lamina VII is continuous with the medullary reticular formation. It includes cells with large, often bilateral, receptive fields that are excited (presumably indirectly) by a wide range of stimuli. Many neurons in laminae VII and VIII respond to high-threshold input.

Lamina X

Lamina X consists of a group of specialized cells gathered around the central canal, some of which respond to high-intensity bilateral stimuli and are considered NS. This group of cells may constitute one of the polysynaptic chains linking the entire length of the cord and brain stem that is believed to be involved in transmission of nociceptive information. Lamina X cells have been suggested to be particularly sensitive to visceral nociceptive stimulation (55). However, such selectivity, if it exists, is likely to be a matter of degree only, in that like other lamina of the spinal cord (I and V), a great deal of convergence between somatic and visceral input takes place in lamina X, and a small minority of cells are responsive solely to visceral stimulation (56). Nevertheless, this region does contain neurons that receive input from visceral primary afferents and project cephalad as part of the dorsal column postsynaptic pathway found to be particularly important in transmitting visceral nociceptive information supraspinally (41).

Trigeminal System

Sensory innervation of the face is more highly specialized than any other body region. Like the spinal nerves and the dorsal root ganglia, the primary afferents of the face are pseudounipolar cell bodies in the gasserian ganglion that have peripheral and central processes. The peripheral processes make up the ophthalmic, maxillary, and mandibular trigeminal divisions, and the central processes make up the sensory root, which enters the central nervous system (CNS) on the ventral surface of the pons (see additional discussion in Chapter 3 including Fig. 3-17). On entering the brain stem, these central processes pass through the spinal trigeminal tract to terminate in the trigeminal nuclear complex, composed of the main sensory nucleus and the spinal trigeminal nucleus (see Fig. 3-17). The main sensory nucleus is located at the level of the pons, whereas the spinal trigeminal nucleus is deep to the descending trigeminal tract and extends as far caudad as the second, and often the third, cervical segment (Fig. 4-14). The spinal nucleus is further subdivided into three parts: subnucleus oralis, subnucleus interpolaris, and subnucleus caudalis (57,58,59,60 and 61).

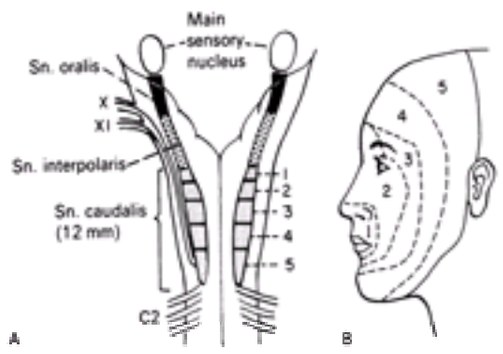

Figure 4-14. **A:** The rostrocaudal somatotopic organization of the subnucleus caudalis. **B:** The relation of the subnucleus caudalis to input from primary afferents on the face. The fibers nearest to the lips and lower nose (area 1) terminate highest in the subnucleus caudalis; the innervation of successively more lateral regions of the face ends progressively in more caudal parts of the subnucleus caudalis. This rostrocaudal somatotopic organization applies to all three divisions of the trigeminal nerves and produces an *onion peel* pattern. (Modified from Kunc Z. Significance of fresh anatomic data on spinal trigeminal tract for possibility of selective tractotomies. In: Knighton RS, Dumke PR, eds. *Pain*. Boston: Little, Brown, 1966:351–366.)

On entering the brain stem, the A-d and C fibers pass to the spinal tract and descend in it to terminate within the subnucleus caudalis (Fig. 4-15). In contrast, the large myelinated fibers divide into short ascending branches that terminate in the main sensory nucleus and long descending branches that pass through the trigeminal tract and give off collaterals to various parts of the underlying spinal nucleus. As these fibers pass caudad and give off collaterals, they become smaller so that by the time they reach the subnucleus caudalis 75% of them are less than 2 µm in diameter, with a consequent progressive slowing of impulse conduction (57).

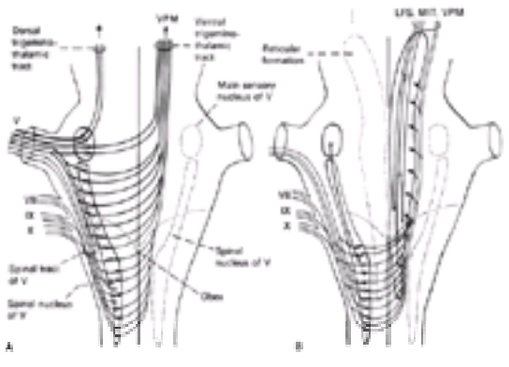

Figure 4-15. **A:** Detailed depiction of primary afferent input into the trigeminal main sensory nucleus and the spinal nucleus, as well as input from primary afferents of the VIIth, IXth, and Xth cranial nerves. The descending fibers from the four cranial nerves make up the descending spinal tract, and their collaterals end in the spinal nucleus, where they synapse with *second-order* neurons. The latter cross to the opposite side to make up the ventral trigeminothalamic tract. Some of the fibers from the main sensory nucleus and subnucleus oralis ascend ipsilaterally as the dorsal trigeminothalamic tract. **B:** Origin and initial course of the paleotrigeminothalamic tract. The fibers cross to the opposite side, and some ascend to reach the thalamic ventroposteromedial (VPM) and medial/intralaminar nuclei (MIT), whereas others pass into the reticular formation, where they synapse with ascending reticulothalamic fibers. (LFS, limbic forebrain structure.)

An important difference between the trigeminal and spinal afferent systems is the separate anatomy of the proprioceptive system of the face. The trigeminal mesencephalic nucleus is actually a collection of cell bodies of primary neurons, which instead of being localized in the gasserian ganglion with other somatic primary cell bodies, have migrated into the midbrain and presumably mediate proprioception from oral mucous membrane, temporomandibular joint, masticatory and ocular muscle spindles, and periodontal ligament receptors (57). The pseudounipolar cell bodies in the trigeminal mesencephalic nucleus give off peripheral branches that reach the muscles and other structures, and the central branches project to the trigeminal motor nucleus. The monosynaptic contact with somatomotor neurons made there completes a two-neuron arc mediating the jaw-jerk reflex and is homologous to monosynaptic spinal reflexes.

Trigeminal Somatotopic Organization. Strict somatotopic organization is one of the most important and clinically relevant characteristics of the trigeminal system and exists throughout the gasserian ganglion, sensory root, spinal tract, and spinal nucleus. In the gasserian ganglion the cell bodies of the mechanoreceptive afferents within the ophthalmic division are concentrated medially and somewhat anteriorly. Those of the mandibular division are caudal and lateral, and the cell bodies of the maxillary nerve lie between those of the other two divisions. Moreover, cell bodies of neurons that innervate the perioral and oral areas are located ventrally in the ganglion, whereas those that supply the structures remote from the mouth are located in the dorsum of the ganglion. In the sensory root, the afferents are also somatotopically organized in a medial to lateral fashion, such that the central processes of the mandibular division are posteromedially positioned, those of the ophthalmic division are located anterolaterally, and those of the maxillary branch are situated in an intermediate position (57) (see additional discussion in Chapter 3 and Fig. 3-18).

Complementary experimental and clinical studies have shown a similar somatotopic organization in the trigeminal spinal tract. The central processes of the ophthalmic division are situated ventrolaterally, those of the mandibular division are situated dorsomedially, and those of the maxillary division lie in between. This somatotopic laminar organization involves myelinated and unmyelinated fibers. Degeneration studies have shown that the collaterals of the myelinated fibers terminate in the underlying main sensory and spinal nucleus, distributed in sharply defined sectors extending deeply into the nucleus and overlapping only slightly with neighboring projections (57). This organization is in contrast to that of the small diameter nociceptive afferents. Although some nociceptive afferent collaterals arise at the level of the subnucleus interpolaris, most nociceptive terminal axonal arbors are found in the subnucleus caudalis (59,62,63).

Another important and clinically relevant somatotopic pattern occurs along the rostrocaudal axis of the subnucleus caudalis. The *onion peel* was first described by Dejerine (63) on the basis of the sensory deficit caused by certain pathologic lesions of the brain stem. Figure 4-14 depicts this pattern in which sensory innervation near the midline around the mouth and nose is represented in the most rostral part of the subnucleus caudalis, whereas the innervation of successively more lateral regions of the face maps to progressively more caudal parts of the subnucleus caudalis. Much of our knowledge of this somatopy comes from electrophysiology studies of Yokota (60). The clinical importance of this somatotopy is seen in the results of trigeminal tractotomy by Kunc for facial pain. Kunc (64) produced lesions at different levels of the subnucleus caudalis and then compared the distribution of the resultant analgesia from the tractotomy with the scheme published by Dejerine. He noted that if the lesion was placed above the upper pole of the subnucleus caudalis, analgesia of the whole ipsilateral trigeminal nerve territory resulted. On the other hand, if the tractotomy was performed more caudally, the analgesia was incomplete, with sensory sparing of the center of the face. With more caudal sections, these areas expanded concentrically. These results led Kunc to conclude that whereas all three divisions of the trigeminal nerve terminate in all segments of the spinal nucleus, the terminations of the primary afferents from the center of the face are most intense in the highest level and those from the periphery are most intense in the lowest level.

Relation of Trigeminal Fibers with Nociceptors in Other Cranial Nerves. The classic technique of medullary trigeminal tractotomy can be extended somewhat medially to produce analgesia of the posterior one-third of the tongue, tonsil, pharynx, tympanic membrane, and external auditory canal. Tactile sensibility in these areas is not noticeably altered after the operation. These results suggest that the central processes of cranial nerves VII, IX, and X terminate and synapse with cells in the dorsomedial part of the subnucleus caudalis and the spinal dorsal horn at levels C1, C2, and perhaps C3 (Fig. 4-16). General visceral afferent input traveling in cranial nerves IX and X relays in nucleus tractus solitarius (65).

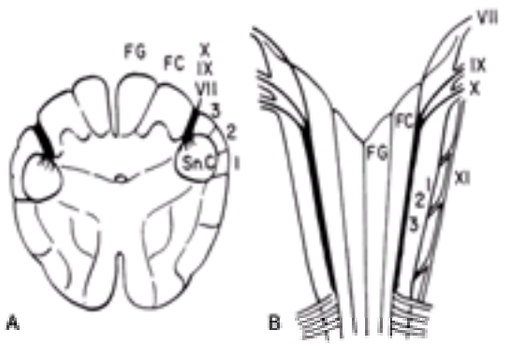

Figure 4-16. Schema depicting the distribution of the central processes of primary afferents of the VIIth, IXth, and Xth cranial nerves, which make up a bundle that is wedged between the fasciculus cuneatus and the mandibular division of the trigeminal nerve. These fibers descend and enter the subnucleus caudalis (SnC), in which they synapse with the second-order trigeminothalamic neurons. **A:** Transverse section. **B:** Dorsal view. (FC, fasciculus cuneatis; FG, fasciculus gracilis; 1, 2, and 3, the divisions of the trigeminal nerve.) See text for details.

Relation of Trigeminal System with Cervical Nerves. Dorsal root fibers from upper cervical nerves also ascend and terminate in the subnucleus caudalis. These overlapping terminations provide a morphologic basis for the substantial interaction between the upper cervical dermatomes and cranial nerve dermatomes revealed after brain lesions or pharmacologic manipulations (59). They also complement evidence indicating a major homology between the trigeminal subnucleus caudalis and the spinal dorsal horn. Finally, this convergence of cranial and upper cervical primary afferents into a common synaptic region in the caudal medulla and upper cervical cord provides a logical explanation for the phenomenon of referred pain in the head and neck.

Morphology of the Medullary Dorsal Horn. On the basis of cytoarchitectonic structure, Olszewski (61) proposed a subdivision of the trigeminal subnucleus caudalis into three layers: the marginal layer, SG, and magnocellular layer. Most investigators (47,59,60,62) now agree that the marginal layer corresponds to Rexed's lamina I; the SG to Rexed's lamina II; and the magnocellular layer, although much expanded, to laminae III and IV of the spinal dorsal horn. The neck region of the dorsolateral gray matter, which is ventromedially adjacent to the magnocellular layer and is part of the lateral reticular formation, is homologous to spinal lamina V, wherein most of the trigeminal WDR neurons are located. This region is the lateral portion of the subnucleus reticularis dorsalis (Fig. 4-17).

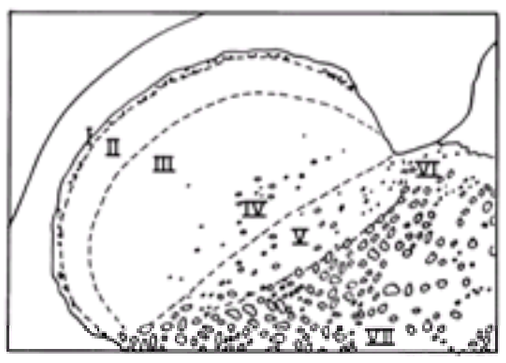

Figure 4-17. Laminar structure of the dorsolateral gray matter of the caudal medulla oblongata at the level of the subnucleus caudalis, more properly called the *medullary dorsal horn*. See text for details. (From Yokota T. Neural mechanism of trigeminal pain. In: Fields HL, Dubner R, Cervero F, eds. *Advances in pain research and therapy*. Vol 9. New York: Raven, 1985:211–232, with permission.)

Neurons receiving tactile and low-threshold muscle afferents, which in the spinal cord are located in lamina VI, in the caudal medulla are located at the junction between the trigeminal subnucleus caudalis and the cuneate nucleus, an area that is continuous with lamina VI of the first cervical segment (60). Finally, the dorsolateral part of the subnucleus reticularis ventralis is probably the homologue of lamina VII of the spinal cord, and this region also contains trigeminal nociceptive neurons (60).

Just above the level of the obex, the subnucleus caudalis makes an abrupt transition to an entirely different structure, which constitutes the subnucleus interpolaris. In contrast, at its caudal end, the subnucleus caudalis and the adjacent reticular formation are directly continuous with the dorsal horn in the cervical spinal cord.

Primary Afferent Input to the Medullary Dorsal Horn. As previously mentioned, the primary afferents projecting to the subnucleus caudalis include myelinated and unmyelinated fibers, the caliber of individual myelinated fibers in the spinal tract decreasing markedly below the level of the obex (57). Both groups of fibers penetrate the subnucleus caudalis from the spinal tract in a spatially ordered radial pattern, in contrast to the terminal projections in the dorsal horn, in which myelinated fibers enter medially (57,59). A-d mechanical nociceptors and C nociceptors terminate in laminae I, II $_o$, and V. A-d low-threshold mechanoreceptive afferents terminate in laminae II$_i$ and III, whereas functionally distinct large A-b low-threshold mechanoreceptive afferents have overlapping distributions in laminae III through VI (62,66).

Intrinsic Neurons of the Medullary Dorsal Horn. Although less studied, the anatomic, physiologic, and pharmacologic characteristics of intrinsic medullary dorsal horn cells are quite similar to those seen in spinal dorsal horn cells. NS (Fig. 4-18) and WDR (Fig. 4-19) cells are evident (34,60,62). Lamina I contains multipolar and fusiform or bipolar trigeminothalamic neurons (34,40,62). The same two major types of dorsal horn local-circuit neurons, the stalked and the islet cells, are found in the SG of the medullary dorsal horn. Multipolar and bipolar thalamic projecting neurons are present in lamina V (62).

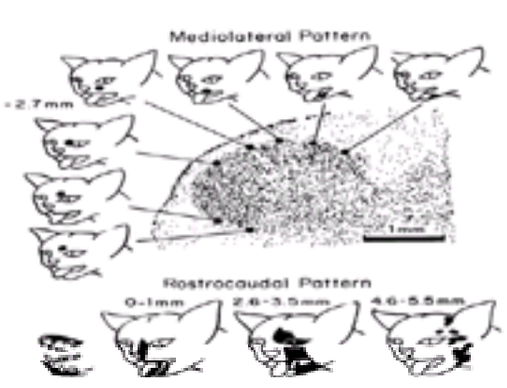

Figure 4-18. Somatotopic organization of nociceptive-specific neurons in the superficial layers of the subnucleus caudalis in the cat. The upper panel shows the locations and receptive fields of marginal layer nociceptive-specific neurons obtained from a transverse section 2.7 mm caudal to the obex. The lower plane shows the receptive fields of nociceptive-specific neurons within the superficial layers at various levels of the subnucleus caudalis. A concentric shift of receptive field representation exists along the rostrocaudal axis of the caudal medulla oblongata. (From Yokota T. Neural mechanism of trigeminal pain. In: Fields HL, Dubner R, Cervero F, eds. *Advances in pain research and therapy*. Vol 9. New York: Raven, 1985, 211–232, with permission.)

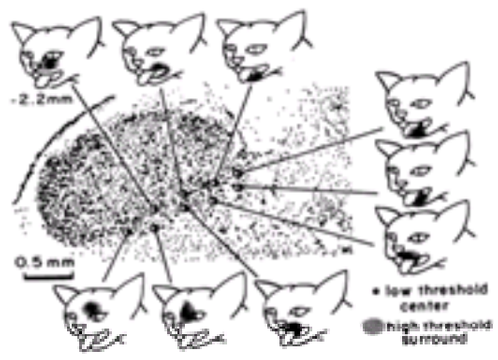

Figure 4-19. Locations and receptive fields of trigeminal wide dynamic range neurons obtained from a transverse section 2.2 mm caudal to the obex in the cat. Trigeminal wide dynamic range neurons are located in the lateral part of the subnucleus reticularis dorsalis and show a somatotopic organization. (From Yokota T. Neural mechanism of trigeminal pain. In: Fields HL, Dubner R, Cervero F, eds. *Advances in pain research and therapy*. Vol 9. New York: Raven, 1985, 211–232, with permission.)

Behavioral and electrophysiologic studies indicate that the more rostral subnuclei of the spinal trigeminal nucleus also receive nociceptive input (57). Terminals of primary afferents and nonnociceptive afferents are found in the subnucleus interpolaris just rostral to the medullary dorsal horn (MDH) (66). A tonic ascending influence of the medullary dorsal horn on more rostral trigeminal neurons has been demonstrated both anatomically and physiologically (47). The afferent neurons projecting rostrally are predominantly from the nucleus proprius (laminae III and IV). These are primarily tactile sensitive neurons that have collateral projections to the thalamus (59). Behavioral studies in cat and monkey suggest that pain sensations from the tooth pulp are intact after trigeminal tractotomy at the level of the obex (67).

Dorsal Horn Nociceptive Physiology

The dorsal horn neurons described previously (summarized in Fig. 4-20) that are excited by natural forms of cutaneous stimulation include (a) low-threshold mechanoreceptive and low-threshold thermoreceptive neurons (class 1); (b) NS neurons (class 3); and (c) WDR or multireceptive neurons (class 2). Low-threshold mechanoreceptor neurons are excited only by touch, hair movement, and other types of innocuous tactile stimulation, whereas low-threshold thermoreceptive neurons are excited by innocuous thermal stimulation. NS (class 3) neurons respond only to stimuli that threaten or actually produce tissue damage, and they are of two types: 3a, which can be excited by A-d nociceptive afferents, and 3b, which can be excited by both A-d and C afferents from the skin and from muscle (40). The WDR (class 2) neurons respond to hair movement and weak mechanical stimuli but respond maximally to intense and potentially tissue-damaging or actually damaging stimuli (Fig. 4-21).

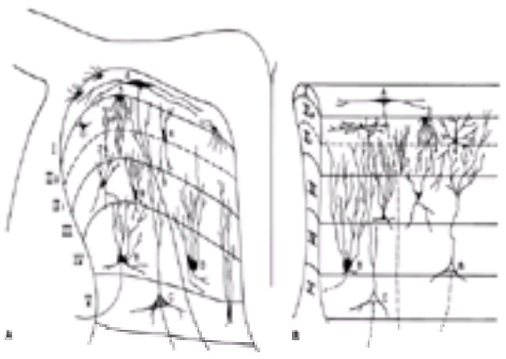

Figure 4-20. A schematic arrangement of various cell types found in the upper five laminae of the dorsal horn of the human spinal cord. **A:** A transverse view. **B:** A sagittal view. Cell types: *A*, a large marginal neuron with output to the anterolateral ascending systems; *B*, two large antenna cells in lamina IV and a smaller one in lamina III, which are low-threshold mechanoreceptive neurons; *C*, a wide dynamic range neuron in lamina V. In the substantia gelatinosa (II_o, II_i), *1* is an islet cell, *2* is a filamentous cell, *3* is a stalked cell, and *4* is a stellate cell. The axons of neurons in **A** are shown solid, whereas in **B** they are indicated by a dotted line. (Modified from Schoenen J. *Organisations Neuronale de la Moelle Epiniére de l'Homme*. Thesis, Faculty of Medicine, Universite de Liége, 1980.)

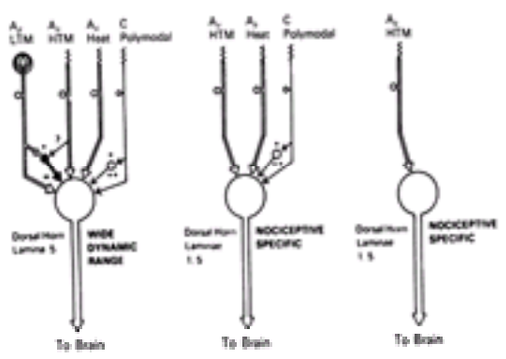

Figure 4-21. Three types of nociceptive cells in the dorsal horn, their inputs from primary afferents, their location in the spinal cord, and their output to ascending systems. Some wide dynamic range neurons are also found in lamina I. Wide dynamic range neurons receive inputs from low-threshold mechanoreceptive primary afferents (LTMs), A-d thermoreceptive afferents, high-threshold mechanoreceptive afferents (HTMs), and C-polymodal nociceptive afferents. The nociceptive-specific dorsal horn neurons receive input exclusively from nociceptive afferents. (From Price DD, Dubner R. Mechanisms of first and second pain in the peripheral and central nervous system. *J Invest Dermatol* 1977;69:167–171, with permission of Blackwell Science, Inc., Oxford, UK.)

Low-threshold thermoreceptive neurons are located in the superficial dorsal horn laminae, whereas low-threshold mechanoreceptor neurons are located in all laminae except lamina I. These low-threshold cells have small receptive fields with sharp boundaries; receptive field characteristics suggest that the cells encode stimulus location. Receptive fields in distal parts are smaller than those in proximal body parts. NS neurons are located mainly in laminae I, II_o, V, and X. NS neurons have receptive fields similar to those of low-threshold groups and therefore presumably also encode stimulus location. WDR or multireceptive neurons have larger and more complex receptive fields with central areas that are responsive to both tactile and noxious stimuli and are surrounded by a larger area with ill-defined borders responsive only to noxious stimuli. The WDR cell excitatory receptive field is often surrounded entirely by an inhibitory receptive field.

Despite these generalities in receptive field properties for nociceptive cells in the spinal cord, it has become clear that receptive field characteristics of a particular cell can change dramatically as a function of pharmacologic and physiologic modulation. Increases in receptive field size, for example, have been correlated with repeated nociceptor activation by tissue injury (68), the mechanisms of which are likely caused by changes in both the peripheral (see Chapter 3) and central (see Central Sensitization, later in this chapter) nervous system. Similarly, it is important to note that anesthetics may change the response properties of nociceptive cells and that most of the studies of spinal cord neurons discussed previously were gathered in anesthetized animals. Collins' group has reported a dramatic effect of barbiturate anesthesia in increasing the incidence of spinal WDR cells in the cat (69). This effect appears to be caused by barbiturate-induced increases in responses to noxious stimuli by cells that normally only respond to low-threshold stimuli (70). An increase in responses of dorsal horn cells to noxious stimuli with low doses of barbiturates

also has been reported in monkeys (71). Spinal or decerebrate preparations, which avoid the need for anesthesia, are no less complicated in that the descending modulation of spinal cord nociceptive cells is considerable. Despite these concerns, Dubner and his colleagues (72) recorded from NS and WDR neurons in awake-behaving monkeys and their results, in general, supported those previously reported in anesthetized and spinalized animals. Indeed, the Dubner group (73), using the same awake-behaving primate model, demonstrated that WDR neurons may be more involved in encoding of the perceived intensity of noxious stimuli than previously thought. Their studies showed that WDR neurons are more precise in detecting small increments of noxious heat intensities than NS neurons. Thus, although an important effect of anesthesia on spinal nociceptive cells cannot be denied, the much more difficult studies in awake animals have thus far not negated the findings in the anesthetized preparation.

Modulation of nociceptive cell activity also may be mediated by small SG cells that receive intrasegmental primary afferent nociceptive input. Moreover, axons from these SG cells project up and down the spinal cord by way of the tract of Lissauer, enabling extrasegmental effects, and to the opposite SG by way of the dorsal commissure. Short propriospinal fibers run in white matter bundles close to the gray matter and may link spinal segments to the brain as well as to each other. Activity in these and other ascending nociceptive systems provoke inhibitory and facilitatory effects on dorsal horn nociceptive responses via descending systems projecting from brain to spinal cord. A number of spinal reflexes can also modulate dorsal horn nociceptive response properties. Direct or indirect peripheral nociceptor activation of anterior and anterolateral horn cells stimulates somatomotor neurons and preganglionic sympathetic neurons, respectively, to provoke autonomic segmental and extrasegmental nocifensive reflex responses (Fig. 4-22). These reflexes, in turn, can give feedback to modulate subsequent nociceptor activity via effects on blood flow or muscle tension (see further discussion in Chapter 3 and Fig. 3-25).

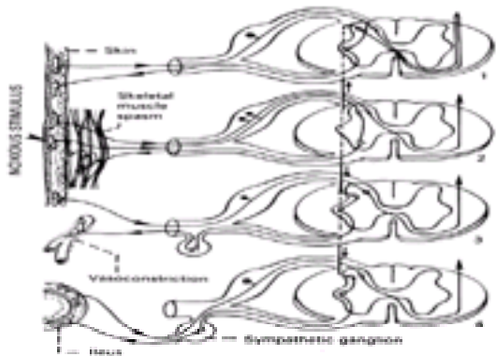

Figure 4-22. Simple diagram to depict the neural pathways for segmental reflex responses to noxious stimulation. Input from the site of injury spreads to the same and adjacent segments of the spinal cord and thus stimulates somatomotor neurons in the anterior horn, which produce skeletal muscle reflex contraction (2). Profound contraction can lead to muscle ischemia and resultant additional nociceptor activation; giving rise to a positive feedback loop referred to as spasm. Other impulses stimulate preganglionic sympathetic neurons in the intermediolateral column to produce vasoconstriction in the skin and splanchnic region (1 and 3). This also produces increased sympathetic tone, which results in an increase in cardiac output and blood pressure and a decrease in the tone of the gastrointestinal tract (4) that may progress to ileus (dashed line indicates normal size of the gut).

Neuropharmacology of Dorsal Horn Inputs

Discussion of the response characteristics of medullary or spinal dorsal horn neurons to noxious stimuli leads naturally into the question of what neurotransmitters mediate or modulate those responses. An explosion of research has investigated the neuropharmacology of nociceptive neurotransmission, particularly that involving the primary afferent (see Chapter 3). Neurochemicals modulating nociception at the level of the dorsal horn could include excitatory and inhibitory agents released by terminals of primary afferents, interneurons of the dorsal horn, and descending axonal projections from supraspinal sites. Minimum criteria necessary for identification of a substance as a neurotransmitter include (a) the candidate neurotransmitter or its *immediate* precursor must be present presynaptically (e.g., within dorsal root ganglion cells or primary afferent terminals); (b) the putative agent must be released by stimulation of a presynaptic terminal (e.g., by a painful stimulus); and (c) the effects of the exogenously applied agent must mimic the effect of the appropriate physiologic stimulus when applied to the terminal field of the unanesthetized animal (e.g., must produce pain behaviors).

An ever-growing list of neuroactive substances has met these criteria for classification as a neurotransmitter in the spinal cord. Probably most important are the excitatory amino acids glutamate and aspartate. However, a number of peptides including substance P, vasoactive intestinal polypeptide, cholecystokinin (CCK), and CGRP also fulfill these criteria. Peptide-mediated effects differ in several ways from more classical, *fast* neurotransmitters (named for their rapid onset and offset of action) such as glutamate. The term *neuromodulation* describes the often slow onset and slow offset effects of a substance, frequently a peptide, that may occur some distance from the place at which it was released (volume transmission). In this way, these neuromodulators resemble hormones in their wide-reaching effects (although the latter term is usually reserved for blood-borne agents). In contemporary neurobiology, these terms are used less frequently as it has become clear that the hormonal, neuromodulator, or neurotransmitter characteristics of a particular released neuroactive substance may vary as a function of site of release, neurochemical environment, and previous stimulus history. In general, onset and offset times of a released neuroactive agent depend on the amount released, its degradation or uptake (e.g., via transporters), its receptor location, and its mechanism of action (e.g., effects on ion channels, enzyme activation, or gene induction). All of these factors can show considerable plasticity in their effects as a result of prior or concurrent neural activity.

Thus, it is likely that numerous substances contained within the central terminals of primary afferents can act as nociceptive neurotransmitters. Moreover, it is now clear that more than one releasable neurotransmitter can coexist in the same or different terminals of a single neuron. This is in contrast to what was believed for many years (Dale's law). For instance, in a single primary afferent terminal at the ultrastructural level both substance P (dense core vesicles that frequently contain peptides) and amino acid transmitters (smaller, clear vesicles) can be identified (74). The release of such primary afferent transmitters may also be modulated by postsynaptically released substances, so-called retrograde neurotransmission. The opioid peptide dynorphin in dendritic vesicles in the hippocampus, for example, can be released by synaptic excitation and retrogradely inhibit further synaptic activity via inhibition of excitatory amino acid release (75). Furthermore, diffusible neurotransmitters (e.g., the gas nitric oxide) can act retrogradely to increase synaptic excitation when synthesized in postsynaptic or other neighboring cells (76). The multiple levels of feedback in tightly regulating neurotransmitter concentrations in the synaptic cleft are further exemplified by the well-known role of presynaptic autoreceptors and their role in inhibiting (or rarely, facilitating) further transmitter release.

Thus, neurotransmission in the CNS is a complex process with multiple mechanisms interacting, all aimed at tightly controlling the release and action of neuroactive substances. The adaptive advantages of pain sensation to the survival of an animal suggests that nociceptive neurotransmission is as tightly regulated as any mechanism. With this overview in mind, we begin to examine the known neuropharmacology of nociception in the spinal dorsal horn. We then look at the modulation of this system by pharmacologic, morphologic, developmental, and descending influences and their hypothesized importance in regulating the perception of pain.

Glutamate Neurotransmission in the Dorsal Horn

Like the majority of excitatory transmission in the CNS, excitatory transmission in the dorsal horn and specifically that involved in nociception is mediated largely via excitatory amino acids (including glutamate and aspartate). Glutamate, in particular, is released from depolarized primary afferent terminals in the dorsal horn; it binds to receptors postsynaptically to depolarize dorsal horn second-order cells and thus transmits the nociceptive signal to the CNS. Glutamate concentrations in the synaptic cleft are tightly controlled by glutamate transporters that quickly remove glutamate from the synapse. The effects of glutamate on neurotransmission are complicated by the variety of characterized receptors that bind glutamate. Much is known about glutamate receptors including their molecular structure, anatomy, physiology, and function in a variety of brain areas. We briefly discuss these receptors as examples of CNS receptors before focusing on their role in pain.

Glutamate receptors, like all receptors, are proteins that bind an agonist and thereby initiate a cellular response. Receptors can be classified on the basis of a number of different structural or functional criteria. With the development of molecular biologic techniques, we now have the ability to describe a large number of glutamate receptor subtypes based on minor alterations in the amino acid sequences or subunit composition of these proteins. Historically, receptors have been classified based more on their pharmacologic properties (i.e., different receptor types bind different drugs, including the ligand in question, with different affinities or with different effects). For example, many years before the opiate receptors were cloned, opiate receptors were subclassified based on responses of animals to different opiate drugs. Similarly, muscarinic and nicotinic acetylcholine (ACh) receptors were defined by differing effects of ACh and the effects being mimicked by two exogenous

chemicals, nicotine and muscarine.

This is clearly a much less precise approach than molecular biology in receptor characterization because one is limited to the pharmacologic tools already available. For instance, the delta opiate receptors were not identified until the endogenous opiates that bind them with high affinity were identified. The pharmaceutical industry, then, is excited about receptor molecular biology because such techniques provide specific targets for their chemical development. Moreover, neuroscientists can, for example, use these molecular targets to grow antibodies specific to various receptor types, ultimately allowing much greater resolution for anatomic localization of receptors than previously possible. Nonetheless, functional end-points, not just binding sites, are important for classification of receptors.

Once the amino acid structure of a receptor is known, physiologists can add these receptors, or the messenger RNA instructions for producing them, to simple systems (frog oocytes or various tumor cell lines) to study their pharmacology or physiology reproducibly and efficiently. More than 30 genes have been identified as important for expressing the various subunits and subtypes that make up the known glutamate receptors (77,78). Minor alterations in the subunits that form a particular receptor in a particular CNS region could allow drug targeting of that receptor in that region with high specificity and a resultant high therapeutic index. Few examples exist of such pharmacologic magic bullets, and most drugs even at the preclinical testing stages are still the result of bioassay rather than molecular biology screening. Nonetheless, the more molecular biology is combined with anatomy and physiology, the more important molecular biologic classification schemes will become in receptor discussion. At present, the classification of glutamate receptors is still largely based on more general functional criteria, as discussed here.

All receptors are loosely classified into two general functional categories, ionotropic and metabotropic (Fig. 4-23). Ionotropic receptors form a channel in the membrane of the cell, and when agonist binds to such receptors a conformational change takes place, allowing ions (e.g., Na^+ or Cl–) to pass through the cell membrane. Such ion movement changes the charge difference across the cell membrane (depolarizing or hyperpolarizing). The size and direction of this depolarization depend on the receptor's permeability to specific ions and on electrical and ion concentration gradients across the cell membrane. Three ionotropic glutamate receptors are named for the compounds that are known to bind them most selectively, kainate, a-amino-3- hydroxy-5-methyl-4-isoxazoleproprionate (AMPA), and *N*-methyl-d-aspartate (NMDA). Kainate and AMPA receptors have been difficult to differentiate pharmacologically until recently because of (a) kainate acting as an agonist at both types of receptors; (b) rapid desensitization of kainate's effects at the kainate receptor, leaving only its AMPA effects to study; and (c) a lack of specific kainate receptor agonists and antagonists. More pharmacologic tools are becoming available to look more specifically at kainate receptors and their role in nociception. Kainate receptors have been localized on C-fiber primary afferent neurons in the dorsal root ganglia (78). Furthermore, kainate receptor-mediated responses from electrical stimulation of primary afferents (particularly C-fiber afferents) have been reported in dorsal horn neurons (79). Finally, intrathecal kainate antagonists have been shown (79,80) to inhibit nociception in laboratory animals (see, however, 81). The possible role of kainate receptors in mediating nociception will likely receive great research attention in the coming years as pharmacologic tools allow.

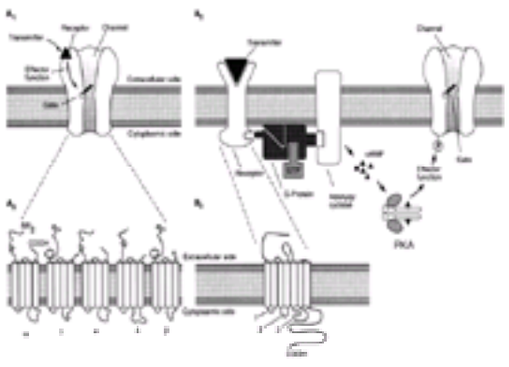

Figure 4-23. Two classes of neurotransmitter receptors. **A:** 1. Ionotropic receptors demonstrate ligand gating of an ion channel that is part of the receptor protein complex. 2. These receptors are composed of four or five subunits, each of which contains four or five membrane-spanning alpha helical regions. **B:** 1. Metabotropic receptors have separate binding and effector complexes. For example, G protein–coupled receptors: The receptor when activated by the transmitter in turn activates a GTP-binding protein (G protein) that transduces a change in an effector molecule (adenylyl cyclase here). In this case, adenylyl cyclase converts ATP to cAMP (a second messenger), which activates cAMP-dependent protein kinase (PKA), which phosphorylates an ion channel (P), leading to a change in channel function. 2. The typical G protein linked receptor is a composed of a single protein with seven membrane-spanning alpha helical regions that bind the ligand within the plane of the membrane. (From Kandel ER, Schwartz JH, Jessell TM, eds. *Principles of neural science*, 3rd ed. New York: McGraw-Hill, 1991:133, with permission.)

Much more information has already been gathered concerning the importance of the AMPA receptor throughout the nervous system in general and in nociceptive processing specifically. This receptor subtype is known to be a common mechanism of excitatory neurotransmission throughout the brain and spinal cord. A number of *in vivo* and *in vitro* studies have demonstrated the importance of glutamate acting at AMPA receptors in mediating fast neurotransmission in laminae I, II, and V electrophysiologically (82,83). Behaviorally, AMPA antagonists have been found to decrease pain behaviors in rats and humans (84), specifically considering the ubiquitous distribution and function of these receptors in the CNS. This could be caused by differences in sensitivity to AMPA antagonists of AMPA receptors in nociceptive pathways or in differences in drug concentrations reaching nociceptive-related receptors in comparison with other receptors (e.g., intrathecal administration might ensure significantly increased concentrations of drug in lamina I compared with lamina IV or IX).

The third ionotropic glutamate receptor, the NMDA receptor, differs in several ways from the other two. Most important, in normal extracellular fluid ionic concentrations and at normal neuronal resting potentials, the NMDA receptor does not allow ions to pass through it even when bound by glutamate because of a block of the ion channel by a magnesium ion. It is only with depolarization that the NMDA receptor becomes unblocked and able to be activated by glutamate. Thus, NMDA effects tend to follow periods of depolarization or several excitatory events in a train of excitatory stimuli. Unlike the majority of kainate and AMPA glutamate receptor actions (in which sodium is the most important ion passing through the receptor), calcium ions are of utmost importance passing through an open NMDA receptor. As we discuss more thoroughly in the section Modulatory Mechanisms: Increases in Synaptic Efficacy, calcium is an important intracellular ionic signal, not only because of its charge but also because of its effects on calcium-dependent enzymes important in the cell's metabolism. The complex structure of the NMDA receptor makes it sensitive to antagonism through several different mechanisms (Fig. 4-24). The first is competitive blockade of the glutamate- (or NMDA) binding site (e.g., AP5). The second is noncompetitive blockade of the ion channel itself (e.g., MK-801 or ketamine). The third is via blockade of the strychnine-insensitive binding site for glycine (e.g., with 5,7-di-Cl-kyurenic acid). Glycine acts as a coagonist at this excitatory receptor unlike the inhibitory effects it has at strychnine-sensitive glycine receptors. Finally, NMDA receptor function can be modulated by several other receptor sites (or their blockers) including proton sensitive sites, re-dox modulatory sites, zinc-binding sites, and polyamine-binding sites. We discuss the extensive evidence for a role of NMDA receptors in nociception in the section Modulatory Mechanisms: Increases in Synaptic Efficacy. As the previous discussion would suggest, these receptors are particularly important in mediating nociceptive responses to repeated noxious stimuli and may be an important mechanism in the development of chronic pain from acute injury.

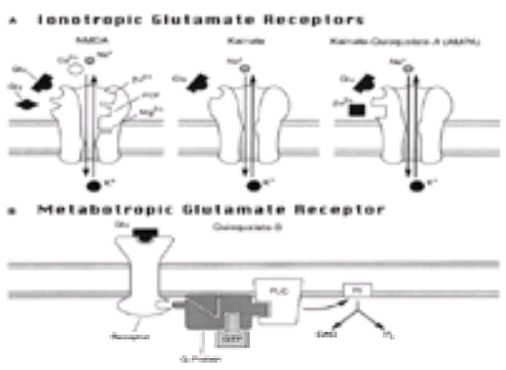

Figure 4-24. Four classes of glutamate receptors. **A:** Ionotropic or ligand gated receptors including *N*-methyl-d-aspartate (NMDA), kainate, and AMPA receptors. The NMDA receptor regulates a channel permeable to Na^+ and Ca^{2+} in particular. It has several different binding sites, including those for glycine, Zn^{2+}, PCP or ketamine, MK801, and Mg^{2+}, which regulate the channel function in separate ways. The kainate and AMPA (also binds kainate) receptors regulate channels primarily permeable to Na^+. **B:** A metabotropic glutamate receptor activated by quisqualate-B activates phospholipase C (PLC), leading to the formation of the second messengers inositol 1,4,5-triphosphate (IP3) and diacylglycerol (DAG) from phosphatidylinositol-4,5-bisphosphate (PI). (From Kandel ER, Schwartz JH, Jessell TM, eds. *Principles of*

neural science, 3rd ed. New York: McGraw-Hill, 1991:157, with permission.)

Such hypotheses and the numerous targets available on the NMDA receptor for antagonism of NMDA effects have raised hopes of finding unique analgesic drugs for chronic pain. Most of the NMDA antagonists investigated thus far produce intolerable side effects in humans, however (e.g., dysphoria). In addition, no differences between spinal cord and supraspinal NMDA receptors have been identified as yet. As mentioned previously, such a difference might allow targeting one site-specific receptor subtype to inhibit spinal nociception without supraspinal dysphoria, for instance; thus increasing the therapeutic ratio for such drugs.

Metabotropic receptors, in contrast to ionotropic receptors, do not directly mediate ionic fluxes across excitable membranes but instead act on intracellular metabolic processes (see Fig. 4-23). This definition suggests the pharmacology of metabotropic receptors is somewhat more complex than with ionotropic receptors. It is much harder to rule out a receptor's interaction with one of many possible metabolic pathways than to rule out its ability to conduct one of a few physiologic ions. Indeed, AMPA glutamate receptors have now been found to have metabotropic effects in addition to and independent of their ionotropic effects (85).

Many metabotropic receptor effects are transduced by guanosine nucleotide-binding proteins (G proteins) acting on an *effector molecule*, often an enzyme such as adenylyl cyclase (see Fig. 4-23). Some metabotropic receptors, such as tyrosine kinase (Trk) receptors for neurotrophins are enzymes themselves. The final cellular target (e.g., an ion channel) may be acted on directly by the effector molecule or via a diffusible second messenger [e.g., cyclic adenosine monophosphate (cAMP) or ionized calcium]. A number of different receptors can use the same G protein and thereby produce the same second messengers, thus integrating complex extracellular pharmacologic activity. However, the same receptor type can also use multiple G proteins and a single G protein can regulate several different effectors. This provides the framework for a complex network of convergent and divergent biochemical interactions, allowing for almost unlimited versatility in cell function regulation.

The metabotropic glutamate receptor has been molecularly classified into eight subtypes. These subtypes have been found to differ dramatically from each other in regard to the effectors to which they couple. Some are coupled to phospholipase C and even receptors in this subgroup differ from one another in the type of G protein used. The phospholipase C activation can produce inositol-1,4,5-trisphosphate and diacylglycerol (see Fig. 4-24), which leads to release of intracellular calcium stores and activation of calcium-dependent protein kinase (PKC), respectively. Phosphorylation (by PKC or other kinases) can alter the conformation of a protein enough to modify the function of an enzyme, a cytoskeletal protein, a channel subunit or a transcription factor (involved in gene expression). Thus, such a metabotropic receptor may have many effects on-cell function after agonist binding with a time course far outlasting the millisecond responses of ionotropic receptors. Glutamate metabotropic receptors also have been linked to other signal transduction pathways, including stimulation and inhibition of adenylyl cyclases with resultant changes in cAMP (e.g., Fig. 4-23) and cAMP-dependent protein kinase (protein kinase A or PKA) as well as phospholipase A_2. A comprehensive review of second messenger systems is beyond the scope of this book and is only described as relates to their increasing relevance to nociception.

Much of the research describing the second messenger effects of metabotropic glutamate receptors are in *in vitro* expression systems in which cells are genetically altered to produce these receptors. It is not yet known whether these effects are relevant to the *in vivo* preparation in which gene expression and biochemical sequelae may be quite different. Moreover, *in vivo* work has been hampered by the lack of specific pharmacologic tools and the related difficulty in knowing the drug concentration that reaches a receptor *in vivo* after either parenteral or intrathecal drug administration. Nonetheless, glutamate metabotropic receptors have been reported to be involved in nociception (86,87,88 and 89). The generally slower effects of these receptors make them more likely to play a role in pain modulation than fast nociceptive transmission *per se*. Thus, glutamate acting at AMPA and, perhaps, kainate receptors is the most likely neurochemical candidate to mediate nociceptive neurotransmission.

Other Excitatory Neurotransmitters

The finding that glutamate excites nearly 100% of dorsal horn neurons involved in nociceptive processing (83,90,91 and 92), via AMPA/kainate, NMDA, or both receptors does not rule out other neurotransmitter involvement. Other known fast excitatory transmitters in the CNS include ACh at nicotinic receptors, serotonin (5-HT) at 5-HT_3 receptors, and adenosine triphosphate (ATP) at P2X receptors.

Acetylcholine. ACh nicotinic receptors, most carefully studied at the neuromuscular junction, have been molecularly characterized and their CNS subtypes have been described. Although all of these channels conduct cations and therefore should be depolarizing, nicotine has been characterized as producing analgesia since 1932. CNS subtype-specific nicotinic agonists also produce analgesia, when administered either peripherally, intrathecally, or in the brain stem (93,94 and 95). Such agonists have been reported to show no analgesic tolerance or dependence in rodents (94). The most likely explanation for antinociceptive effects of a depolarizing compound is in the location of the receptor, either on primary afferent terminals via presynaptic inhibition or on inhibitory interneurons. Indeed, both mechanisms appear to take place in the spinal cord. Presynaptic nicotinic receptors on primary afferent terminals have been well described (96). Acetylcholine-induced increases in the release of the inhibitory neurotransmitter GABA also have been demonstrated (i.e., excitation of inhibitory neurons). In the spinal cord this effect is best documented for ACh acting at its metabotropic, muscarinic receptor, however (97). Discovering the details of ACh physiology in the spinal cord is complicated by its dual receptors, both of which have pain modulatory effects, and by its primarily interneuronal location (98) (and the complex circuitry of these cells). Nonetheless, the finding that interference with ACh metabolism via anticholinesterase inhibitors such as neostigmine produces analgesia in laboratory animals and humans suggests a tonic role of ACh in inhibiting nociception (99). Moreover, other spinal analgesics, including opioids and a $_2$-noradrenergic receptor agonists, may act in part via release of ACh in the cord (99). In any event, no evidence exists that ACh mediates fast nociceptive transmission and indeed ACh receptors seem to be positioned to inhibit such transmission instead.

Serotonin (5-Hydroxytryptamine). 5-HT receptors also have a complex pharmacology, with four major groups of receptors (5-HT 1 through 4) and multiple subtypes within these groups (e.g., 5-HT_{1A} receptor). The only ionotropic serotonin receptor identified thus far is the 5-HT $_3$ receptor. Like nicotinic receptors, 5-HT_3 receptors are fairly nonselective cation channels and depolarize neurons. Like nicotinic agonists, 5-HT $_3$ agonists can produce analgesia (100). However, this is controversial and 5-HT_3 agonists also have been shown to potentiate nociception (101). Perhaps this is simply reflective of the variety of neurons on which 5-HT $_3$ receptors are located. For instance, 5-HT_3 receptors located on primary afferent terminals may, like nicotinic receptors, act to presynaptically inhibit nociception (as is more fully described for GABA receptors; see Gamma-Aminobutyric Acid, later in this chapter) (102). On the other hand, 5-HT_3 receptors on nociceptive neurons in dorsal horn could potentiate their nociceptive responses. We discuss further the role of serotonin in modulating nociceptive transmission when we discuss descending modulation later in this chapter (see Descending Systems that Modulate Nociception). For the purposes of this discussion, the fact that most, if not all, spinal 5-HT comes from supraspinal sites makes 5-HT_3 receptors more likely to modulate than mediate nociception.

Adenosine Triphosphate. ATP is probably the best nonglutamate candidate for mediating primary afferent and dorsal horn neurotransmission. ATP can both potentiate glutamatergic neurotransmission within the dorsal horn (103,104 and 105) and act directly at neuronal ligand-gated (ionotropic) P2X receptors (in contrast to the metabotropic P2Y ATP receptors) to produce *fast transmission* (104,105,106 and 107), relevant to nociception (108,109). The ATP P2X3 receptor subtype, specifically expressed in sensory neurons (110), has been implicated in nociception both by anatomic localization to small dorsal root ganglion neurons that project to the spinal cord via small-diameter C and A-d fibers (10) and by pharmacologic studies with available, rather nonselective, agonists and antagonists (104,108,111). Immunohistochemical co-localization studies suggest that primary afferents expressing P2X3 receptors project predominately to lamina II_i of the dorsal horn. This is one finding in an emerging literature suggesting that there may be important anatomic, neurochemical, and physiologic differences between nociceptive circuitry in laminae I and II_i of the spinal cord (10). For example, C-fiber primary afferents, which synapse in lamina I of the spinal cord and are likely to be involved in nociception, contain substance P and CGRP and are responsive to nerve growth factor via its trkA receptor (112). A separate subset of C-fiber primary afferents that synapse in the inner portion of lamina II_i, on the other hand, contains less substance P and CGRP and instead stains heavily for the enzymes fluoride-resistant acid phosphatase and thiamine monophosphatase and responds to glial cell-line derived neurotrophic factor (112) and presumably ATP via P2X receptors (107). Moreover, laminae I and II_i circuitry has been differentially implicated in inflammatory and neuropathic pain sensitization, respectively. We discuss more of the possible functional implications of this seeming anatomic and pharmacologic dichotomy in nociceptive processing in the section Modulatory Mechanisms: Increases in Synaptic Efficacy. We underscore here the changing understanding of spinal cord primary afferent and dorsal horn neurotransmission to introduce the important concept that nociceptive mechanisms differ across pain states.

Modulation of Dorsal Horn Neurotransmission

Until the late 1980s, virtually all small animal studies of nociceptive processes involved threshold changes in response to some nociceptive stimulus (usually heat).

This approach likely grew out of a preconception that the CNS, in general, and nociceptive transmission circuitry, in specific, normally underwent little change during an organism's adult life and was essentially hard-wired. Since that time, an explosion of neuroscience research has demonstrated the amazing plasticity of the adult brain and spinal cord. Correspondingly (and really since the Melzack-Wall Gate Control Theory in 1965), preclinical pain researchers have developed and investigated a number of innovative pain tests and animal models demonstrating that the basic nociceptive circuitry described thus far in this chapter is subject to complex modulatory influences. Much of this research has attempted to mimic clinically relevant pain states, such as inflammatory (e.g., formalin, capsaicin, complete Freund's adjuvant, or carrageenan injection responses) or nerve injury (e.g., Bennett, Chung, and Selzer models) pains. Studies of such models have shown that the mechanisms underlying inflammatory and neuropathic pain differ considerably and that both differ from more acute or *transient* [pains represented by threshold studies in the previously untreated animal (113)]. In particular, it has become clear that the pain responses elicited by noxious stimuli are integrally dependent on the prior nociceptive experiences of an animal.

Central Sensitization

The previous chapter thoroughly describes the mechanisms underlying inflammation and peripheral sensitization. A host of neurochemical changes takes place in primary afferents after inflammation, nerve damage, or both, which make them more responsive to nociceptive stimuli (hyperalgesia) or produce a nociceptive response to normally nonnociceptive stimuli (allodynia). Changes also take place in the spinal cord in primary afferent and spinal neurons that can produce such changes in nociceptive responses. These changes have collectively been termed *central sensitization*.

Although Hardy in 1950 suggested that hyperalgesia after tissue injury or inflammation was caused by changes in the spinal cord dorsal horn (secondary hyperalgesia), it was the work of Woolf and colleagues more than 30 years later that dramatically consolidated this concept. In 1966, Mendell noted a sequential increase in the number of dorsal horn action potentials elicited by a C-fiber stimulation given repeatedly at certain rates (at least 1 stimulation per second) (114). This effect was termed *wind- up* (Fig. 4-25). In 1983, Woolf reported (115) that tissue injury caused an increase in responses (measured by motor reflexes or motoneuron activity) that persisted even after local anesthetic blockade of the damaged tissue, suggesting central mediation of this sensitivity (Fig. 4-26). Despite their similarities, central sensitization is not simply wind-up (116) in that wind-up outlasts the initiating stimulus by only a few seconds (see Fig. 4-25), whereas other forms of sensitization may last many minutes to hours after a repeated afferent input ceases or is blocked (Fig. 4-26). Central sensitization has now been demonstrated in a number of laboratories using a variety of response end-points (threshold stimuli, response frequency, receptor field size) and eliciting stimuli (thermal, chemical, acute joint inflammation, and C-fiber electrical stimulation) (31).

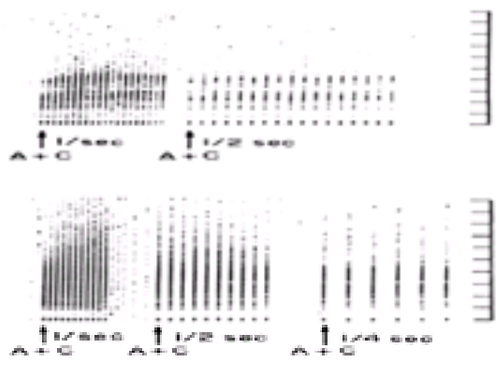

Figure 4-25. Wind-up responses of single units to repeated stimulation of sufficient intensity to activate A and C fibers (no wind-up seen with A- fiber stimulation by itself). The vertical time markers on the far right represent 100 msec. Each mark at the bottom of the time line represents the stimulation artifact, and the burst of activity immediately above each of these stimulations is the response to A-fiber stimulation (each dot represents an action potential). The more delayed responses to the more slowly conducting C-fiber stimulation are above that. *Top panel*: Response of dorsolateral column axon to stimulation of ipsilateral sural nerve at a stimulation rate of 1 per second (left) and 1 per 2 seconds (right). An increase in C-fiber responses is seen but only in response to the 1 per second stimulation rate. *Bottom panel*: Response of a separate dorsolateral axon to ipsilateral nerve again shows wind-up only to 1 per second stimulation. Here, wind-up lasts for several seconds, as seen by an increase in spontaneous activity and a more prolonged than normal response to the 1 per 2 seconds stimulation initially. This increased excitability resolves in spite of 1 per 2 seconds stimulation resulting in apparent *wind down* and normal responses to the 1 per 4 seconds stimulation. (From Mendell LM. Physiological properties of unmyelinated fiber projection to the spinal cord. *Exp Neurol* 1966;16:316–332, with permission.)

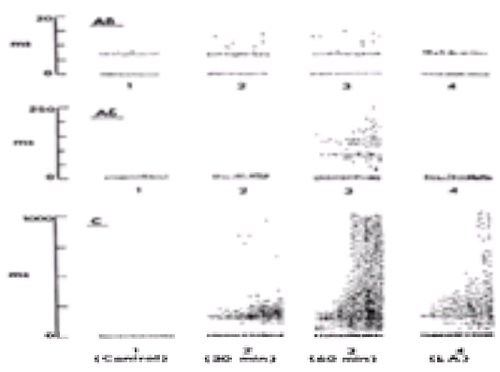

Figure 4-26. Rastor dot displays of a single biceps femoris unit activated by stimulation of the sural nerve 1 every 2 seconds before an ipsilateral thermal injury (control), 30 and 60 minutes postinjury, and 10 minutes after the injured foot has been completely anesthetized with local anesthetic. Each dot represents an action potential. The vertical scale is the latency of the responses after sural nerve stimulation, and the stimulus artifact can be seen at time 0. Stimulation strengths were given to activate A-b fibers (100 µA, 50 µs; top panel), A-b and A-d fibers (250 µA, 50 µs; middle panel), or A-b, A-d, and C fibers (5 µA, 500 µs; bottom panel). Note the different time scales used in the three panels to record the activity evoked by the three different fiber populations. In the preinjury state, only an A-b input was evoked. Thirty minutes after injury a C-fiber response begins to occur, whereas at 60 minutes both A-d and C-evoked responses are present. Note the development of wind-up of C responses. Ten minutes after the local anesthetic (administered 80 minutes postinjury) the sural C-evoked responses remain higher than before the injury, suggesting a central component of the sensitization. (From Woolf CJ. Evidence for a central component of post-injury pain hypersensitivity. *Nature* 1983;306:687, with permission.)

Several chronic pain models have evolved with the goal of, or as a result of, studying central sensitization. Although a complete review of pain models is not possible here, they generally fall into two major categories: (a) inflammatory (some have suggested this category be labeled *tissue injury*) and (b) neuropathic (damage to nerves). The interaction between the immune and nervous systems makes this a somewhat arbitrary distinction in that immune cells can mediate nerve damage and nerve damage may activate immune cells. Nonetheless, the experimental manipulations that create these models tend to be one or the other.

Inflammatory agents, such as acetic acid, carrageenan, capsaicin, formalin, mustard oil, and Freund's adjuvant, have all been given on or in the skin or viscera to produce pain responses or facilitations in pain responses developing within seconds to days. On the other hand, animal models of neuropathy include cutting or ligating (tightly or loosely) nerves, or depriving nerves of blood flow. These manipulations increase pain responses localized to corresponding or adjacent dermatomes. Although important differences exist in the responses and mechanisms underlying these models, they are more similar to each other than they are to any of the threshold animal pain models that came before (e.g., paw or tail withdrawal from heat, pressure, or an electric shock) if only in their temporal dimension. Inflammatory and neuropathic pain models rely on mechanisms of central sensitization, although ongoing peripheral mechanisms also contribute to pain behaviors in many of these models (117).

A number of mechanisms can account for increased sensitivity of spinal nociceptive neurons to nociceptive stimulation: (a) an increase in activity at excitatory synapses, (b) an increase in excitatory synaptic connections (e.g., sprouting), and (c) a decrease in inhibitory tone in the spinal cord. Each of these mechanisms has been reported in the spinal cord, attesting to the remarkable plasticity of the adult CNS. Obviously, the rapid time course of certain models of central sensitization

cannot be explained by slower mechanisms such as sprouting of new axons. However, this may say more about the model than the mechanism in regard to the etiology of clinical pain states. Indeed, the primary weakness of most of the models of sensitization in trying to explain possible sensitization phenomena in humans is the short time course of most of the models and the sadly long time course of many neuropathic or inflammatory chronic pain states that the animal studies purportedly model. Nonetheless, it is only relatively recently that such models have been extensively used and despite their flaws they have already made important conceptual contributions to the study of pain mechanisms.

Modulatory Mechanisms: Increases in Synaptic Efficacy

Many of the studies of central sensitization have been patterned after the studies of long-term potentiation (LTP) in the hippocampus. This model of learning involves intense stimulation of afferent input to cells of the hippocampus and involves increases in synaptic efficacy of the synapses activated (118). This potentiation, which can last for several weeks after stimulation, has received extensive study, in part because of the intrinsic interest in studying learning at the molecular level and in part because the laminar cytoarchitecture of the hippocampus allows researchers easy access to the region for *in vivo* and *in vitro* electrophysiologic studies. As in the spinal cord, glutamate has proven to be a potent excitatory transmitter in the hippocampus, acting at AMPA (119), NMDA (120,121), and metabotropic (122) receptors to initiate a host of ionic, second messenger, and gene-expression processes, which with repeated stimulation mediate the induction, expression, and maintenance of LTP (Fig. 4-27 and Fig. 4-28). In particular, reports of presynaptic and postsynaptic changes in synaptic efficacy thought to underlie LTP provide a ready source for hypotheses concerning the mechanisms of nociceptive central sensitization.

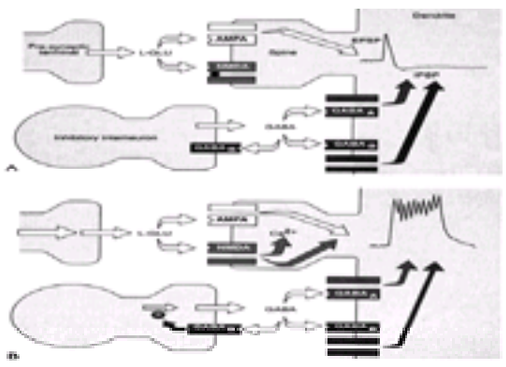

Figure 4-27. Excitatory amino acid–mediated induction of long-term potentiation. **A:** Low-frequency transmission: A single stimulus depolarizing an afferent terminal causes release of a neurotransmitter (e.g., l-glutamate or l-GLU), which binds to postsynaptic ionotropic receptors. In this example, the glutamate AMPA type receptor is activated, evoking an influx of sodium ions, a depolarization, and an excitatory postsynaptic potential (EPSP). Stimulation of afferent activity may also activate inhibitory interneurons in parallel or in series to release inhibitory neurotransmitters. In this example gamma-aminobutyric acid (GABA) is released and binds to postsynaptic $GABA_A$ receptors to activate chloride currents that produce an inhibitory postsynaptic potential (IPSP) and cause the delayed phase of the biphasic electrophysiologic response, which curtails excitation. Moreover, GABA is shown binding to presynaptic and postsynaptic $GABA_B$ receptors that can activate potassium channels via G-protein coupling to subsequently further limit excitation. *N*-methyl-d-aspartate (NMDA) receptors contribute little to the synaptic response, because by the time that the NMDA receptors become activated by depolarization (losing their shown magnesium block), IPSP-induced hyperpolarization has already begun. **B:** High-frequency transmission: The contribution of NMDA receptors to synaptic transmission alters radically to a high-frequency input. This is because a rapid rate of afferent glutamate release maintains the neuron in a more depolarized state (reducing magnesium block), while at the same time providing a more prolonged release of glutamate that activates the NMDA receptor. Several factors may contribute to sustained depolarization seen in this example. These include summation of AMPA receptor–mediated EPSPs and depolarizing shifts in the chloride or potassium reversal potentials because of buildup of intracellular chloride or extracellular potassium, which may interfere with the usual IPSP-producing mechanisms. The long duration of NMDA receptor–mediated EPSPs means that they summate effectively during high-frequency transmission, as shown. (From Bliss TVP, Collinridge GL. A synaptic model of memory: long-term potentiation in the hippocampus. *Nature* 1993;361:35, with permission.)

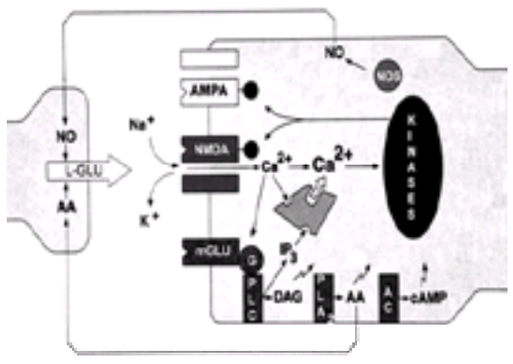

Figure 4-28. Schematic showing several ways in which glutamate can activate signal transduction mechanisms involved in long-term potentiation. Calcium influx through *N*-methyl-d-aspartate (NMDA) receptors can be supplemented by an additional calcium elevation via inositol trisphosphate (IP3) sensitive intracellular stores. A parallel pathway, perhaps important in certain forms of long-term potentiation is via activation of metabotropic glutamate receptors (mGLU). These receptors can couple through G proteins with a number of effectors, including phosphoinositide- specific phospholipase C (PLC), phospholipase A_2 (PLA_2), and adenylate cyclase (AC) to produce diacylglycerol (DAG) and arachidonic acid (AA) and to regulate the levels of cAMP, respectively. As shown, an intracellular calcium increase may be important for the activation of these mGLU signal transduction cascades. The amplified increase in calcium, in association with the other activators of a number of protein kinases (*zigzag arrows*), then leads to the phosphorylation of substrate proteins, including AMPA and NMDA receptors. Other enzymes, such as nitric oxide synthase (NOS), if present, also may be activated by the calcium transient. Biochemical changes in the presynaptic terminal also may be initiated by the action of retrograde messengers such as nitric oxide (NO), AA, and potassium (K), perhaps in conjunction with the action of glutamate on presynaptic mGLU or NMDA receptors (not shown). (From Bliss TVP, Collinridge GL. A synaptic model of memory: long-term potentiation in the hippocampus. *Nature* 1993;361:36, with permission.)

Clinical observations suggesting that patients really do *learn to hurt* provided further support for mechanistic similarities between LTP and central sensitization. Anecdotes that phantom limb pain is more common in patients who have pain in the limb before amputation led to confirming studies: Patients with ischemic extremity pain scheduled for extremity amputation develop less phantom limb pain postamputation if they are made comfortable preoperatively with intraspinal analgesics (123). Moreover, reports that aggressive preoperative pain treatment significantly decreased pain and analgesic use for many days after the anesthetic or analgesic effects subsided (124,125,126 and 127) have led to the concept of *preemptive analgesia* and in some cases changes in anesthesiology practice as a strategy to avoid activity-dependent neuroplastic changes in nociception.

The true clinical significance of preemptive analgesia (i.e., whether preoperative analgesic therapy provides greater benefit than normal postoperative analgesic therapy independent of a simple increase in drug dosage) is controversial. The disparate results of these studies may stem from the varied quality of the investigators' normal (control) pain management practices. Unlike animal studies, even control patients in clinical studies receive some analgesics for their pain, including intraoperative analgesic use in almost all surgeries. It is not surprising, then, that additional analgesics given to the experimental group of patients before a 2- or 3-hour surgery might not significantly distinguish them from a group given normal analgesic intraoperative therapies, when both groups are given impeccable analgesic management beginning postoperatively for their 4- to 5-day hospital stay.

That aggressive pain management (e.g., with preoperative nerve blocks) can produce long-term benefits in pain control, compared with little (clinical studies) or no (animal studies) pain treatment, perhaps via an inhibition of central sensitization, is not controversial. Although this may seem a rather modest finding to many readers of this book and therefore of little clinical use, it is worth noting that the medical community in general is not so far removed from using muscle relaxants as the sole

“anesthetic” for heart surgery in neonates and b-blockade, rather than analgesics, to treat procedure-induced tachycardias in the operating room or intensive care unit.

N-*Methyl-d-Aspartate Glutamate Receptors.* Regardless of their current clinical application, animal studies of central sensitization have made important contributions to our understanding of nociception and its modulation. Returning to the LTP model of central sensitization, considerable evidence suggests that, like LTP in many brain regions, activity-dependent increases in excitation in the spinal cord depend on NMDA receptors. Numerous models of central sensitization are inhibited by NMDA antagonists. These include wind-up of dorsal horn neuronal activity (128), increases in dorsal horn neuron nociceptive responses or receptive field size by acute and chronic inflammation (129,130), increases in flexion responses from C-fiber stimulation or mustard oil irritation (131), hyperalgesia from thermal burn (132), peripheral nerve ligation (133) or chronic inflammation (134), autotomy behavior after nerve section (135), and pain behaviors in the second phase of the formalin test (136,137).

The clinically available weak NMDA antagonists, ketamine or dextromethorphan, can improve control of ischemic, postoperative or posttraumatic chronic pains in humans (138,139). However, side effects (particularly dysphoria) have limited their clinical use. The complicated structure of the NMDA receptor including its various modulatory binding sites (e.g., glycine's coactivating site) and subunits (e.g., the NR2B subunit) are probably the best hope for NMDA antagonists, playing an important role in clinical pain management. Possible nociceptor or spinal cord–specific NMDA receptor structures or functions (140) fuel the search for analgesic pharmacologic agents with NMDA antagonist activity and an improved therapeutic ratio.

The mechanism of NMDA's central sensitizing activity is less well studied in the spinal cord, but it probably resembles NMDA- dependent LTP in the hippocampus. Voltage-dependent magnesium blockade of the NMDA receptor, explains the lack of effect of antagonists on initial afferent activation (transient or acute pain thresholds). After initial depolarization of a cell (via glutamate's actions on AMPA or kainate receptors) unblocks the NMDA receptor, subsequent glutamate release also activates NMDA receptors, leading to a calcium influx and thereby modulation of a cascade of enzyme activities and genetic sequelae (see Fig. 4-27 and Fig. 4-28). Presumably, these latter effects make wind-up of a few seconds different from sensitization of many minutes, hours or days. Moreover, this difference, together with any ongoing primary afferent activity (117), probably defines the role of NMDA receptors in maintenance of sensitization, accounting for reports of efficacy of NMDA receptors in reversing, rather than simply preventing, sensitization (133).

In the hippocampus a number of second messengers facilitate postsynaptic responses, even after repolarization and presumed NMDA receptor magnesium blockade recurs. Phosphorylation of AMPA (141), NMDA (142), or both receptors potentiates subsequent responses, and a variety of calcium-modulated kinases have been implicated in mediating LTP (e.g., PKC, calcium/calmodulin kinase II, Trks). In dorsal horn neurons activation of PKC has been seen to increase NMDA currents (143,144) and nociceptive behaviors to subcutaneous formalin (145). Conversely, inhibition of PKC (145) or inhibition of PKC translocation from the cytoplasm to the cell membrane (146) blocks sensitization. Finally, and perhaps most interesting from a clinical perspective, mice lacking the PKC-g isoform, which is found exclusively in lamina II_i of the spinal cord, did not develop sensitization in a nerve injury model (147). Protein kinase A also has been implicated in the development of hyperalgesia although peripheral, rather than central, mechanisms have been shown to be primarily involved (148,149). The Trks, including those activated by neurotrophins such as nerve growth factor (Trk A) or brain-derived neurotrophic factor (Trk B), also may play a role in sensitization at peripheral and spinal levels. Indeed, new biologically relevant kinases are being identified, sequenced, and targeted pharmacologically or through transgenic technology at a rapid rate. Although many have wide-ranging functions making them unlikely for successful clinical inhibitory manipulations, some, or isoforms of some such as the PKC-g example, might conceivably be targeted therapeutically if found to be specific to nociceptive processes.

In addition to changes mediated by the second messengers mentioned previously, modulation of gene transcription, translation, or both as a result of movement of messages to the nucleus also may be an important consequence of NMDA activation and may mediate sensitization. Generally, only LTP observed 4 hours or longer after LTP induction relies on protein synthesis (150). Central sensitization has not been studied as carefully. Calcium-dependent increased expression of nitric oxide synthase has been associated with the development of thermal hyperalgesia (151). This enzyme produces nitric oxide, a gas that may mediate some forms of LTP by acting as a retrograde transmitter, diffusing from the postsynaptic to the presynaptic cell and potentiating presynaptic glutamate release (76). Similarly, inhibition of nitric oxide inhibits NMDA-mediated central sensitization in the spinal cord (152,153,154,155 and 156).

Another example of activity-dependent gene expression is the proto-oncogene c-*fos* or its protein product fos (31). Fos expression can be increased by a variety of noxious stimuli, many of which, though not all, can produce central sensitization. Moreover, fos expression can be inhibited by drugs that inhibit central sensitization including NMDA antagonists. Transcriptional activation of c-*fos* is calcium dependent, and thus it is not surprising that activation of NMDA receptors would be correlated with fos production. The function of fos or c-*fos* is largely unknown, but it may help regulate neuropeptide gene expression. Although c-*fos* immunohistochemistry has become a useful anatomic technique indicating cellular activity, it is quite sensitive to such activity and conclusions regarding sensitization induction or inhibition caused by c-*fos* activity merit caution.

Substance P. In 1931, von Euler and Gaddum discovered a potent vasodilator in extracts from horse intestine and named it substance P (the *P* perhaps indicating *precipitate*). In the mid-1970s, Leeman and colleagues sequenced this same compound in the hypothalamus (an 11 amino acid peptide that caused salivation in laboratory animals) and its ensuing mass production has led to many experiments detailing the anatomy, pharmacology, and physiology of this compound. Its subsequent localization in small primary afferents (see Chapter 3) synapsing on lamina I projection neurons (157) and other dorsal horn nociceptive cells (Fig. 4-29 and Fig. 4-30) linked substance P to the field of pain. The release of substance P with small-fiber stimulation and its potent depolarizing effects on dorsal horn neurons (200 times more potent than glutamate on a molar basis) have made substance P an obvious candidate as a nociceptive neurotransmitter. Nonetheless, the relatively slow onset and offset of its effects, relative to glutamate, for example, suggest that substance P functions as a modulator of nociception rather than a transmitter *per se*. The precise role of substance P in nociception has been difficult to define because of the absence of specific antagonists for the neurokinin 1 (NK1) G protein–coupled receptor to which it binds. Important advances have been made in this regard (158), and clinical trials are beginning to dissect the use of these antagonists in a variety of pain states. One such possible clinical use, the treatment of migraine (159), may take the study of substance P physiology back to its vasodilatory roots in hopes of alleviating this pain often linked to vascular pathogenesis. As yet, substance P antagonists, even when effective, have had only moderate efficacy in relieving pain in clinical trials (160). Perhaps no other area of pain research so clearly demonstrates the distinctions between differing types of nociception.

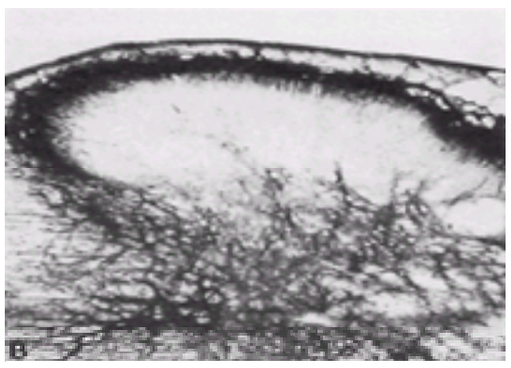

Figure 4-29. Immunocytochemical staining for substance P in the medullary dorsal horn of the cat. The substance P band is densest in laminae I and II_o; in lamina II_i there are few substance P axons; and in laminae V and VI the density of substance P is significant. Compare with Figure 4-35, which depicts the distribution of enkephalin in the same laminae. (From Ruda MA. The pattern of nociceptive modulation in the dorsal horn. In: Yaksh TL, ed. *Spinal afferent processing*. New York: Plenum, 1986:141–164, with permission.)

Figure 4-30. Camera lucida drawing of a lamina II stalked cell labeled with the intracellular horseradish peroxidase method. The tissue section was subsequently stained with substance P antisera. Arrows represent sites of substance P–like immunoreactivity contacts on dendritic shafts; asterisks denote sites of substance P–like immunoreactivity contacts on spines. Note the predominance of contacts on spines. Inset is an enlargement of the area outlined in dots and shows a substance P–like immunoreactivity axon with its varicosities contacting a spine and the dendritic shaft. *Dotted horizontal line* represents the border between laminae I and II. Scale bar represents 10 µm. (From Ruda MA, Bennett GJ, Dubner R. Neurochemistry and neurocircuitry in the dorsal horn. *Progr Brain Res* 1986;66:219–231, with permission.)

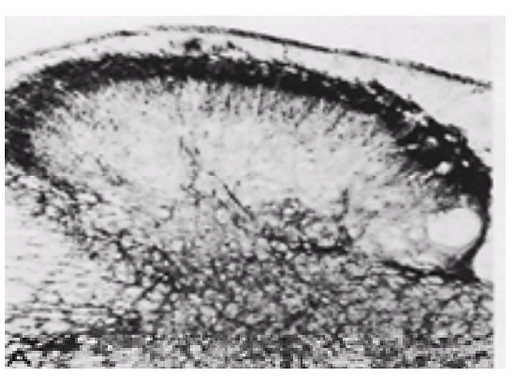

Figure 4-35. Immunocytochemical labeling of enkephalin in the medullary dorsal horn of the cat. Dense enkephalin-staining band is found in laminae I, II_o, and II_i, whereas laminae VI and VII have less staining. Compare with Figure 4-29, which depicts staining of substance P taken from a neighboring section of medullary dorsal horn of the same animal. (From Ruda MA. The pattern of nociceptive modulation in the dorsal horn. In: Yaksh TL, ed. *Spinal afferent processing*. New York: Plenum Press, 1986:141–164, with permission.)

Substance P antagonists have, in general, proven to have little analgesic efficacy in animal studies looking at tests of threshold pain responses (161). In contrast, animals lacking substance P or NK1 receptors, or given an NK1 antagonist, do differ from controls in their nociceptive responses to higher intensity or longer duration pain tests (e.g., high temperature stimuli, the second phase of the formalin test or writhing responses after intraperitoneal acetic acid) (162,163). Similarly, substance P is most reliably released from primary afferents by intense or prolonged stimuli (164). Indeed, substance P can not only be released in greater amounts, but by greater numbers of primary afferents during prolonged noxious conditions. After inflammation, for example, large (A-b) fibers, in addition to small (A-d and C) fibers, produce (165) and presumably release substance P, thereby contributing to inflammatory hyperalgesia.

Other important insights into the physiology of substance P have been provided by Mantyh and colleagues in a series of studies investigating the internalization of substance P receptors. Internalization of NK1 receptors and many other G protein–coupled receptors is common after agonist binding. Mantyh and colleagues used antibodies specific for the NK1 receptor and confocal microscopy to visualize internalized substance P receptors as a measure of substance P effects. They have seen that substance P receptor internalization takes place after repeated C-fiber stimulation (166), primarily in lamina I, but that after inflammation, internalization of substance P receptors becomes near maximal in lamina I and spreads to deeper laminae (III through IV) (167). This spread of agonist-induced activity is likely caused primarily by increases in substance P release and spread by diffusion to deeper laminae, called *volume transmission*. Large-fiber stimulation is still insufficient to induce internalization. This is true, even in allodynia models (produced by nerve injury), in which activation of large fibers by light touch produces pain behaviors (166).

Supplementary to these findings are the same group's use of intrathecal injections of the neurotoxin saporin bound to substance P. This compound, like substance P itself, is internalized and cleaved by intracellular enzymes to release the toxin and kill the cells into which it has been taken. Thus, this technique can be used to kill many of the cells expressing substance P receptors, particularly in lamina I, in which the compound diffuses most readily from the intrathecal space. Rats given this selective neurotoxin have unchanged pain thresholds but inflammation-induced hyperalgesia is attenuated (168). Substance P appears, then, to have an important role in central sensitization, at least during inflammation.

Wind-up from repeated C-fiber stimulation is correlated with a slow, long-lasting excitatory potential, which is partially reversed by NK1 antagonists and may represent a substance P–mediated central sensitization (89). However, given the importance of glutamate in nociceptive transmission, including central sensitization, we primarily focus on the synergistic interaction between NK1 and glutamate receptors in producing central sensitization (169,170). The majority of this work has been done in the spinal cord, although substance P can enhance LTP in other areas of the CNS (171). The interaction between glutamate and substance P is both presynaptic and postsynaptic. For instance, glutamate binding at presynaptic NMDA receptors has been reported to release additional substance P (172). Postsynaptically, the long-lasting (i.e., seconds) depolarizing effects of substance P may unblock NMDA receptors, thereby potentiating NMDA effects (173). Prior depolarization can also potentiate substance P effects (89), presumably by facilitating NK1 activation of voltage-dependent calcium channels or NK1-coupled inhibition of potassium channels.

Finally, NK1-activated second messengers interact with glutamate receptors in several important ways. Substance P binding to NK1 receptors as well as glutamate binding to metabotropic receptors stimulates the hydrolysis of polyphosphatidylinositol by phospholipase C into inositol trisphosphate and diacylglycerol. Inhibition of phospholipase C reduces sensitization in the formalin test (145). Inositol trisphosphate stimulates the release of calcium from intracellular stores, and this release is potentiated by high intracellular calcium levels as might occur with concurrent NMDA activity. In addition, diacylglycerol stimulates the cytosol to membrane translocation and resultant activation of PKC thought important in NMDA-mediated central sensitization.

Whatever the mechanism, the synergism between NMDA and NK1 receptors seen in the induction of central sensitization in the laboratory remains to be tested in the clinic. Important in this testing is the differentiation of effects on induction, expression, or maintenance of central sensitization only rarely addressed in laboratory and clinical studies. Induction, expression, and maintenance in clinical terms are analogous to preventative, symptomatic, and curative therapies, respectively. The finding that a drug can block central sensitization induction as most NMDA studies report may have little usefulness to the clinician treating a pain of 30 years' duration even if it is entirely mediated by sensitization mechanisms. Similarly, although reduction of the expression of nociceptive sensitization by high-dose opioids or local anesthetics is useful in the short term, blockade of maintenance mechanisms is clearly the goal. Unlike most hippocampal LTP, evidence suggests that NMDA antagonists given after induction of central sensitization can still decrease this altered nociception. This may result from an importance of continued peripheral input and corresponding NMDA receptor activity in at least a portion of central sensitization maintenance (117). The ideal analgesic would block maintenance of sensitization only, leaving other nociceptive processing (e.g., in other regions of the body) intact. In this regard, it is noteworthy that PKC-g knockout mice and rats lacking NK1-expressing lamina I neurons caused by saporin–substance P intrathecal injections both had normal nociceptive thresholds for transient noxious stimuli.

Modulatory Mechanisms: Other Pronociceptive Neurochemicals

As described in detail in Chapter 3 of this text, substance P and other peptides are produced in dorsal root ganglion cell bodies by ribosomal synthesis of large

precursor peptides. These precursors are then cleaved and transported to the peripheral and central terminals, in which they are stored in vesicles in a form amenable to release on appropriate stimulation (30). A number of peptides besides substance P have been implicated in nociceptive modulation by (a) their specific distribution in small primary afferents, (b) their quantity correlating with pain behaviors, or (c) their effects on nociception with intrathecal administration or antagonism.

Interpretation of behavioral effects of intrathecal drugs is complicated by possible nonspecific effects, caused, in large part, by an inability in such studies to definitively know the concentration of a compound reaching the receptor (174). For example, even oxygen and water, given at too high a concentration, can have toxic effects. Thus, some behavioral effects may be caused by toxicity of a drug. Moreover, even nontoxic agonists or antagonists at a specific peptide receptor may differ in their effects because of differences in drug distribution. Some compounds given intrathecally, for example, may be limited in their ability to reach receptors in deeper laminae and thus have concentration-dependent effects there, caused by rapid metabolism, poor diffusion, or both (175).

Clearly, the biggest problems in behavioral experiments examining peptide effects on nociception are the frequent lack of specific antagonists. Antisense studies, in which administration of specific oligonucleotides specifically disrupt a peptide's synthesis and thereby function, have been used to circumvent the lack of peptide antagonists. Such studies also experience issues of distribution as well as unknown mechanisms of cellular uptake of oligonucleotides. Knockout and other transgenic studies of animals genetically altered to have abnormal peptide levels also attempt to bypass pharmacologic limitations. These studies also are not a panacea, in that effects of a planned genetic manipulation may be confounded by unknown compensatory or accompanying (hitchhiking) genetic changes (161,176).

In our discussion, we try to focus primarily on compounds whose effects on nociception are antagonized by currently available receptor antagonists.

Neurokinins. Neurokinin A (NKA) and neurokinin B (NKB) are, like substance P, tachykinins and bind to NK2 and NK3 receptors, respectively. Little evidence exists for a role of NKB in nociception (although it is a weak agonist at the NK1 receptor normally associated with substance P effects). NKA (sometimes referred to as *substance K*) is produced by a gene closely associated with that producing substance P in mice (preprotachykinin), making the effects described previously from knockout experiments of substance P difficult to differentiate from an NKA knockout effect. Moreover, like substance P, NKA is found in fine primary afferents.

Studies of the nociceptive effects of NKA have been hampered by a lack of receptor antagonists. Nonetheless, several studies suggest an involvement of NKA in heat- (but not mechanically) induced nociceptive responses (177). Whether these selective NKA effects on noxious heat are specific to capsaicin receptor (vanilloid receptor or VR) expressing primary afferents, which also respond selectively to heat (see Chapter 3), is not yet known. However, NK2 antagonists at the spinal level inhibit peripheral capsaicin-induced STT neuronal responses in the primate (178). Such research also demonstrates an increase in capsaicin-induced sensitization of STT cells to mechanical stimuli after NK2 antagonism. This seeming difference between thermal and mechanical nociception and their respective sensitizations has been proposed by other investigators (88,152). However, difficulties in differentiating peripheral and central sensitization mechanisms have impeded progress in testing this hypothesis.

Calcitonin Gene-Related Peptide. CGRP is a prominent peptide in small primary afferents and thus has been of considerable interest for its possible role in nociceptive modulation. CGRP receptors are widely dispersed in the dorsal horn wherever primary afferent terminals are found. They appear to be predominantly postsynaptic, however. In laminae I, II, and V their number is unaffected or actually increased after dorsal rhizotomy. CGRP spinally administered exerts hyperalgesic effects, but the absence of an antagonist makes the interpretation of such data difficult. Indeed, knockout mice lacking a-CGRP do not differ from wild type in their heat nociceptive thresholds and paradoxically show reduced morphine analgesia in the tail-flick test (179). This latter finding contrasts with a study using CGRP antagonists that noted morphine potentiation (180). The role of CGRP, then, in nociceptive modulation awaits further investigation.

Bradykinin. Bradykinin is well known for its role in peripheral nociceptive mechanisms (Chapter 3). However, it may also play a part in modulating nociception in the spinal cord (181). Intrathecal bradykinin, binding at the B2 receptor, produces antagonist-reversible hyperalgesia. This effect probably takes place at the primary afferent terminals because two-thirds of bradykinin receptors disappear with rhizotomy (32). However, an effect on descending noradrenergic fibers cannot be ruled out because bradykinin receptors are also localized there. The source of endogenous bradykinin, which might mediate such hyperalgesia, physiologically is another matter. Bradykinin is primarily produced at sites of tissue damage from blood-borne precursors. Whether some peripherally produced bradykinin might make its way to the spinal cord or whether bradykinin might instead be produced within the spinal cord in the absence of gross spinal damage is unknown.

Pro-nociceptive Neuromedins. The amphibian peptide bombesin and its mammalian homologue gastrin-releasing peptide, as well as the structurally related neuromedin B and neuromedin C, have been most studied in the gastrointestinal tract but also produce CNS effects. Bombesin appears to bind to the neuromedin C receptor predominately, on presynaptic primary afferent terminals (32), and can facilitate nociceptive responses that are blocked by a neuromedin C antagonist (182,183). These facilitatory effects also can be blocked by an NMDA but not an AMPA receptor antagonist, suggesting an interaction of the neuromedin C receptor and glutamate NMDA receptors. The neuromedin C receptor in gut is coupled to a variety of second messenger systems that could facilitate NMDA receptors or their effects (184), but nothing is known of such mechanisms in the spinal cord as yet.

Vasoactive Intestinal Peptide. Another peptide initially isolated from the intestine, vasoactive intestinal peptide, in spinal cord is principally found in lamina I, with some sparse staining in the medial part of lamina V (185), and this is particularly evident in small primary afferents. In a spinal superfusion model (186), electrical stimulation of A-d/C, but not A-b primary afferents releases vasoactive intestinal polypeptide in addition to substance P and CCK *in vivo*. Postsynaptic excitatory effects of this peptide are clearly demonstrated by its iontophoretic administration onto dorsal horn cells (187). Nonetheless, vasoactive intestinal polypeptide is an important example of a peptide that, despite the anatomy and physiology, may have little role in normal or sensitized nociception in the spinal cord (188). Acceptable antagonists have been discovered, used experimentally, and found to have little effect. Naturally other receptor subtypes or related CNS peptides (e.g., pituitary adenylate cyclase–activating peptide) might still mediate pronociceptive effects of vasoactive intestinal polypeptide.

Cholecystokinin. CCK is an eight amino acid peptide that has been studied extensively for its effects on nociception. Although, we return to the effects of CCK when we talk about descending inhibition and facilitation of nociception, much spinal CCK is located in interneurons. CCK-like immunoreactivity is distributed in lamina IV and the central canal region, and its distribution is similar to that of substance P (185). CCK has been localized in axons descending from the brain stem and primary afferents in addition to the interneuronal pool. A coexistence of CCK and substance P is common, but a population of primary afferent somata contains either CCK or substance P without the other peptide (185). CCK receptors are divided into CCK-A and a CCK-B receptor subtypes. The former is the most common CCK receptor type in human and monkey spinal cord, and the latter is most common in the rodent (32). Rodents and primates show exclusively CCK-B receptors in dorsal root ganglion, however, so the CCK-A receptors in primate cord must be on cells intrinsic to the CNS.

Unlike the peptides discussed previously, CCK produces little potentiation of nociceptive responses in previously untreated animals when applied to the spinal cord. However, CCK attenuates several antinociceptive treatments, in particular opioid antinociception (189). Conversely, CCK antagonists in rodents and humans potentiate opiate analgesia and may slow the development of morphine tolerance. The mechanism for this inhibition has not been determined. In addition to its effects on morphine analgesia, CCK may be an important mediator of sensitization after nerve injury. After nerve section a dramatic increase occurs in CCK receptors and CCK in dorsal root ganglia (see Chapter 3). Autotomy behavior after nerve section can be significantly decreased by CCK antagonists, and this suggests a role for CCK in mediating this model of neuropathic pain. Indeed, the increase in CCK-mediated neurotransmission in neuropathic pains may be responsible for their relative insensitivity to opiate analgesics. The analgesia produced by CCK antagonists in neuropathic pain models, for example, is blocked by the opiate antagonist naloxone, as if endogenous opioids are being released to alleviate the neuropathic pain but that concurrently released CCK antagonizes these (189). Whether such rodent experiments will generalize to primates, and specifically humans, with their different CCK receptor subtype distributions awaits further investigation.

Thyrotropin-Releasing Hormone. The tripeptide thyrotropin-releasing hormone (TRH) binds to receptors in the superficial dorsal horn and like CCK also has been reported to inhibit opioid analgesia (190) and facilitate nociceptive responses. These effects may be caused by NMDA-facilitating effects of TRH (191). As we will discuss, TRH has effects on nociception via descending pathways as well. Nevertheless, the spinal nociceptive facilitatory effects have been shown to be independent of these descending effects by several investigators (191,192).

Prostanoids. The role of prostaglandins in modulating nociception has already been discussed in regard to the peripheral nervous system (see Chapter 3). Spinal prostaglandins and particularly prostaglandin E_2 (193) have been associated with the development of central sensitization as well, particularly in inflammatory pain states (194). Spinal administration of cyclo-oxygenase inhibitors can inhibit sensitized primary afferent increases in peptide release (195). Sensitization from spinal glutamate, substance P, or administration of both is also blocked by these drugs (196). The neurons and mechanism involved in this effect is not yet known, although an interaction with nitric oxide has been hypothesized and a presumably indirect inhibition of nitric oxide synthesis has been reported (197). Different mechanisms may be involved for different prostaglandins. Whereas prostaglandin E_2–produced hyperalgesia is absent in knockout mice missing an NMDA receptor subunit, prostaglandin D_2–produced hyperalgesia is not (198). In contrast, prostaglandin D_2, but not prostaglandin E_2, hyperalgesia is blocked by NK1 antagonists.

The clinical application of these findings awaits appropriate toxicology and dosing studies to determine whether the intrathecal versus the oral or intravenous routes of administering cyclooxygenase-inhibiting antiinflammatory drugs improves the therapeutic ratio. The development of cyclooxygenase II inhibitors specifically targeting the inducible isoform of cyclooxygenase is hoped to improve therapeutic ratios at least after systemic delivery. The cyclooxygenase II isoform predominates in dorsal horn; however, at least some CNS cyclooxygenase analgesic activity has been tied to the constituently active cyclooxygenase I isoform (199).

Cytokines. The role of CNS glial cells has classically been considered as primarily providing structural support to neurons, particularly within the gray matter. More recently, it has become clear that glia share several characteristics with neurons, including release and uptake of neuroactive chemicals (including glutamate, ATP, prostanoids, and nitric oxide). An example of possible neuromodulation by glia, which could play a role in nociception, is the finding that CNS glia synthesize, store, and presumably release d-serine, a coagonist at the glycine binding site on the NMDA receptor (200). At the very least, glia function to provide environmental homeostasis for CNS neurons, including those in the dorsal horn. Other homeostatic cells, including microglia and other immune-competent cells, contain a variety of neurochemicals important in mediating nociception. For instance, these cells contain and release chemicals called *cytokines*. Intrathecal interleukin-6 (IL-6), for example, produces hyperalgesia, whereas another IL, IL-1b, can enhance substance P release (201,202). Dorsal horn levels of these, as well as other cytokines (including leukemia inhibitory factor and tumor necrosis factor-a), all increase after nerve injury (201,202). Although research on the role of cytokines in the modulation of nociception in the spinal cord still lags behind that in the periphery (203), work is likely to continue as pharmacologic and genetic tools allow.

Modulatory Mechanisms: Inhibition and Disinhibition

In addition to the previously mentioned mechanisms of facilitated nociception, another hypothetical mechanism for central sensitization might be a loss of inhibitory tone. This could occur from a loss of inhibitory interneurons or depletion of, or tolerance to, antinociceptive neurochemicals. We briefly describe the major inhibitory systems in the spinal cord, including effects of their disruption, and then discuss the known peptidergic modulators usually classified as antinociceptive, including the opioid peptides.

Gamma-Aminobutyric Acid. GABA is the most prevalent inhibitory neurotransmitter system in the CNS. It has been known for many years that GABA exerts a presynaptic control of large primary afferent fibers, particularly Ia afferents from muscle (96,102). High concentrations of GABA are also found in laminae I and II of the superficial dorsal horn, in which there is dense input from small-diameter primary afferents. The pharmacology of the GABA system includes two receptor subtypes, the $GABA_A$ and $GABA_B$ receptors. $GABA_A$ and $GABA_B$ receptors are decreased, although not eliminated, in the spinal cord by dorsal rhizotomy, suggesting a presynaptic primary afferent locus for a significant portion of these receptors (32). The $GABA_A$ receptor is an ionotropic receptor complex composed of three subunits including barbiturate and benzodiazepine binding sites that modulate GABA-activated chloride currents. In adult CNS neurons, GABA-activated chloride currents flow into the neuron because of the low chloride concentration intracellularly. This current hyperpolarizes the neuron or inhibits depolarizing currents passing through other channels or receptors. On the other hand, $GABA_A$ effects on young hippocampal or primary afferent neurons differ in that intracellular chloride concentrations are kept high in these cells by active co-transport of chloride (along with sodium and potassium) into the neuron, and thus GABA-mediated chloride currents flow in an outward direction, depolarizing the cell. $GABA_A$-mediated primary afferent depolarization (PAD) is a mechanism of presynaptic inhibition associated with a decrease in excitatory transmitter release. Indeed, substance P release is under tonic inhibitory control by GABA, and GABA antagonists have been shown to produce allodynia. Interestingly, however, such PAD has an equilibrium potential (approximately –30 mv) more depolarized than the action potential threshold for primary afferents. In short, this means that excessive $GABA_A$-mediated depolarization could conceivably produce rather than inhibit excitatory transmitter release. Indeed, in one inflammatory pain model, $GABA_A$ antagonists inhibit hyperalgesia, suggesting that just such a potentiated PAD is responsible. Moreover, peripheral signs of inflammation (e.g., edema, flare) are reduced, suggesting that a PAD- initiated action potential can propagate antidromically from the spinal cord terminals to the periphery (dorsal root reflex) (102). In contrast, PAD has been found to be decreased in an axotomy model of neuropathic pain, implying that a loss of $GABA_A$ tone may facilitate pain behavior in this model.

$GABA_B$ receptor activation, although capable of causing presynaptic inhibition does not produce PAD. The $GABA_B$ receptor is a metabotropic receptor that inhibits depolarization via G protein–coupled effects on calcium or potassium currents. Much more information is available regarding the function of $GABA_A$ receptors in modulating nociception than $GABA_B$ receptors, primarily because of the better pharmacologic tools available for studying $GABA_A$ receptors. Indeed, much of the research on the spinal effects of $GABA_B$ agonists such as baclofen have focused on the inhibition of motor reflexes, particularly in laboratory animals or humans with spinal cord injuries. Nonetheless, a role for $GABA_B$ receptors is likely in the dorsal horn as well, if only because this region is virtually unique in the CNS for $GABA_B$ receptors outnumbering $GABA_A$ receptors.

In addition to the effects of GABA on presynaptic primary afferent inhibition, much evidence of postsynaptic inhibition in the spinal cord also exists. Some stalked cells contain GABA and inhibit the activity of STT neurons near their lamina I axonal arbors. GABA-containing layer II_i islet cells also have been identified. Based on their nonnociceptive inputs, some propose that these cells serve as the inhibitory interneurons of the inner SG, mediating nonnociceptive inhibition of second–order nociceptors (29,54).

Its inhibition of motor reflexes suggests that GABA's effects are unlikely to be selective to nociceptive processes. Even in the dorsal horn GABA (and particularly $GABA_B$) receptors densely populate laminae III and IV, as well as more superficial laminae. Nonetheless, $GABA_A$ (204) and particularly $GABA_B$ agonists inhibit sensitized responses to low-threshold mechanical stimulation (allodynia) in a number of neuropathic pain models (189). Such a model, the chronic constriction injury model, produces degenerated or *dark* neurons in laminae I and II of the dorsal horn. These dark neurons may be the result of excitotoxicity of inhibitory interneurons, and the mechanical sensitization may result from a loss of inhibitory, presumably GABAergic tone.

Initial clinical reports of $GABA_B$ agonists such as baclofen inhibiting allodynic pain have been hopeful (205). Such pain relief may prove short-lived because baclofen's inhibitory effects on muscle spasms have demonstrated rapid tolerance clinically. More than most receptors, $GABA_B$ receptors show dramatic increases and decreases in receptor number as a result of $GABA_B$ antagonist and agonist exposure, respectively (32). This is a possible mechanism for tolerance to these drugs.

Glycine. Like GABA, glycine is an important inhibitory neurotransmitter in the CNS. Glycine binding sites divide into two groups, strychnine-sensitive and strychnine-insensitive. We briefly discussed strychnine-insensitive glycine sites in discussing the NMDA glutamate receptor.

Glycine acts as a coagonist at the NMDA receptor. This action is not blocked by strychnine and is generally excitatory. In contrast, glycine's strychnine-sensitive effects are inhibitory, caused by anionic currents and the receptor itself is molecularly similar (35% to 40% sequence homology) to $GABA_A$ receptors. Glycine inhibition seems to be much more important in brain stem and spinal cord than at more rostral sites in the CNS. Like GABA receptors, strychnine-sensitive glycine receptors are definitely not restricted to the superficial laminae and, although common in lamina II, they are scattered from laminae II through VIII. Nonetheless, glycine does not seem to mediate PAD (102) and, indeed, dorsal rhizotomy has no significant effect on glycine binding. This suggests that glycine receptors are intrinsic to the CNS.

Strychnine given intrathecally causes impressive sensitization to light touch (allodynia) (206), implying that tonic glycine inhibition is important in normal somatosensation. Humans also show allodynia in strychnine toxicity. Central sensitization of STT cells in the deep dorsal horn has been associated with decreases in glycine and GABA inhibition. This takes place postsynaptically via effects of the nitric oxide/guanosine 3',5'-cyclic monophosphate pathway (154,207) activated by, in this case, capsaicin, presumably on the receptors themselves. Moreover, blockade of glycine facilitates dark neuron production after chronic constriction injury, suggesting that glycine is important in inhibiting excitotoxicity.

In summary, GABA and glycine appear important in modulating nociception in the spinal cord. These inhibitory transmitters appear particularly important in inhibiting allodynia in a variety of neuropathic pain models. Perhaps counterintuitively, increases in $GABA_A$ activity may potentiate inflammatory pain.

Adenosine. Adenosine administered intrathecally can produce potent analgesia in a variety of threshold, inflammatory, and neuropathic pain tests (208). Interestingly, adenosine is a metabolite of ATP, which we suggested previously might be pronociceptive. A1 and A2 adenosine receptors are implicated in producing analgesia, although the most convincing data implicate A1 receptors primarily. Adenosine receptors are present in the spinal dorsal cord and particularly in the SG. Postsynaptic adenosine inhibitory effects, including activating potassium currents, are probably most common because few adenosine receptors have been localized to primary afferent terminals. Nonetheless, adenosine inhibits substance P release from primary afferent electrical stimulation, presumably via a presynaptic effect.

Adenosine is a potent inhibitor of excitable cells throughout the body, including spinal motoneurons. Possible motor side effects confound several of the studies purporting to demonstrate adenosine analgesia. Dose-response studies, however, demonstrate a five- to tenfold increase in doses needed to inhibit motor responses over doses that inhibit pain. Human studies of the analgesic effects of adenosine are complicated by a $_2$-mediated algesic effects in the periphery. Nonetheless, intrathecal trials have been initially promising (209).

In animal models, no effect on nociception has been reported with adenosine antagonists, suggesting that endogenous adenosine does not tonically act to produce antinociception, at least not with its rapid metabolic pathways intact. Specific adenosine kinase inhibitors (210) may prove therapeutic by prolonging the actions of endogenous adenosine and by decreasing the side effects seen with administration of the drug. On the other hand, adenosine is an example of an agent that may have particular use in the sensitized pain state, particularly allodynia. Even when pain threshold tests demonstrate little analgesia, antihyperalgesic, or antiallodynic effects of adenosine (211), a_2-noradrenergic (212), cholinergic (212,213), and kappa opiate agonists (214) may have important clinical implications.

Inhibitory Synaptic Plasticity. We discussed previously the hypothesis that nociceptive sensitization may be caused by an LTP- like phenomenon strengthening or even unmasking previously silent (215) excitatory synapses in the spinal cord. Conversely, LTP of inhibitory synapses could counteract sensitization or inhibit nociception itself. Such inhibitory LTP has not been reported as yet in the nociceptive system, although it has been demonstrated in the hippocampus (216). In both the hippocampus and in the spinal cord the conceptually similar phenomenon of long-term depression has been reported. Long-term depression is similar to LTP in that it frequently depends on NMDA receptors and calcium influx through those receptors. In general, afferent stimulation just subthreshold for producing LTP (either because of the stimulus parameters used or partial pharmacologic blockade) results in long-term depression (217,218). Little work has been done in the spinal cord with this interesting phenomenon, which may well have therapeutic implications for reversing the maintenance of sensitization (219,220). This is likely caused by the need for single-cell analysis to rule out neural damage as the mechanism for a long-lasting inhibition of nociception after repeated excitation and the technical difficulties of such studies in the spinal cord. Indeed, in the hippocampus the most convincing studies are whole-cell voltage clamp studies in which induction of long-term depression is followed by induction of LTP at a single synapse or set of synapses. Whether long-term depression ultimately proves relevant to spinal cord nociception is unknown. However, if it does, the much-maligned NMDA receptor might prove an integral part of therapy for central sensitization.

Modulatory Mechanisms: Other Antinociceptive Neurochemicals

In addition to the mechanisms of inhibitory nociceptive modulation described above, several other neurochemicals inhibit nociceptive responses. As with the excitatory neuropeptides, research on inhibitory peptides has been hampered by a lack of selective receptor antagonists. Prominent exceptions to this are the opioid peptides or endorphins, whose receptor pharmacology is well worked out and exogenous agonists and antagonists abound.

Opioid Peptides and Their Receptors

Opiate Receptors. As previously mentioned, Martin (221) first subclassified opiate receptors into mu, kappa, and sigma groups using differing responses to the opiates morphine, ketocyclazacine, and SKF-10047, respectively (Table 4-1). Shortly thereafter, binding sites for these opiate agonists were identified pharmacologically and anatomically (222). With the discovery of the endogenous opioids by Hughes, Kosterlitz, and colleagues (223) new tools became available to identify specific targets. The delta opiate receptor was described as binding the two 5 amino acid opioid peptides methionine (met-) and leucine (leu-) enkephalin (ENK) with high affinity. Similarly, the 17 amino acid endogenous opioid dynorphin A was found to bind kappa receptors with relatively high affinity (224,225). Finally, two 4 amino acid peptides, the endomorphins, have been reported to have high affinity for the mu receptor (226), although ENKs and particularly dynorphin can also bind to these receptors. An epsilon receptor also has been hypothesized and is thought to bind the 31 amino acid b-endorphin. The sigma receptor proposed by Martin (see Table 4-1), although still a topic of interest to psychopharmacologists (227), is no longer thought to mediate opiate effects of endogenous or exogenous ligands.

	Receptor		
Organ/effect	Mu	Kappa	Sigma
Pupil	Miosis	Miosis	Mydriasis
Respiratory rate	Stimulation, then depression	No change	Stimulation
Heart rate	Bradycardia	No change	Tachycardia
Body temperature	Hypothermia	No change	No change
Affect	Indifference	Sedation	Delirium
Nociceptive flexor reflexes	Decrease	Decrease	Modest decrease

The effects of morphine- and nalorphine-like drugs in the nondependent and morphine-dependent chronic spinal dog. *J Pharmacol Exp Ther* 1976;197:517–532.

TABLE 4-1. Opiate receptor classification and action (studies in spinal dogs)

Pharmacologic agents have been developed to specifically act on or inhibit actions at mu, kappa, and delta receptors. Binding studies and behavioral pharmacology experiments suggested subtypes of these receptors and even more selective agonists and antagonists were developed to focus on the differential effects of these opiate receptor subtypes. The most highly cited example of such differential effects of receptor subtypes is the work of Pasternak's group on mu $_1$ and mu$_2$ receptor subtypes. Using an antagonist specific for the mu$_1$ receptor, the analgesic effects of morphine could be blocked without effect on the lethal dose of morphine (228). This finding gave great hope that the analgesic effects and the most serious side effect (respiratory depression) of mu agonists could be differentiated pharmacologically if a mu$_1$-specific agonist could be developed. Despite considerable effort, no one has produced such a drug.

Kappa and particularly delta opiate receptor subtypes also have been reported, based on binding affinities or behavioral studies using microinjections within the CNS. Several specific delta$_1$ and delta$_2$ agonists and antagonists have been produced, and the differential importance of these receptor subtypes in spinal (delta $_1$) and supraspinal (delta$_2$) antinociception has been reported.

With the cloning of the mu, delta, and kappa receptors in 1992 (Fig. 4-31), the biologic importance of opiate receptor subtypes became a topic of some controversy. At present, no generally accepted direct evidence exists for molecularly distinct subtypes of delta receptors or any other opiate receptor. Indeed, *in vitro*, specific delta$_1$ and delta$_2$ agonists act identically on delta receptors in cells from which the delta receptor amino acid sequence was cloned (229). Intrathecal antisense studies (230) suggest that, if a molecular difference exists between delta$_1$ and delta$_2$ receptors, it should lie in the amino, or extracellular, terminal of the seven transmembrane opiate receptor structure characteristic of G protein–linked receptors. Such an extracellular difference could explain a difference in binding affinities for various agonists and antagonists. Even if no molecular differences between delta $_1$ and delta$_2$ receptors are identified, differences in effects of specific delta $_1$ and delta$_2$ agonists could still result from different pharmacokinetic or pharmacodynamic influences on these drugs when centrally administered *in vivo*. For instance, differences in a drug's ability to penetrate the spinal cord to the receptor sites could produce differential effects, particularly if receptors at different depths had different functions. Moreover, differences in metabolism or activity at other opioid or nonopioid receptors might produce reliably different pharmacologic effects without molecularly different receptors. Another possible explanation for pharmacologically distinct opiate receptor subtypes has been reported. Devi and colleagues have shown that individual opiate receptors can bind to one another to produce a receptor dimer whose binding affinities and functions differ from those of monomeric mu, kappa, or delta receptors (231). The opiate receptor dimer made up of delta and kappa$_1$ receptor subunits, for example, acts *in vitro* (231) much like the kappa$_2$ receptor subtype described *in vivo* (232). This phenomenon, if it holds true *in vivo* for opiate receptors and is extended to other G protein–linked metabotropic receptors, will have important implications for mechanisms of synaptic plasticity in the field of pain and throughout neuroscience.

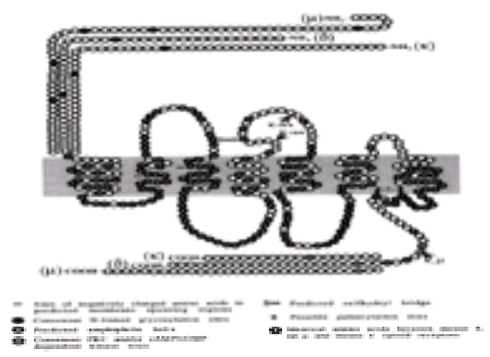

Figure 4-31. Structural homology among the delta, mu, and kappa opioid receptors. Amino acid sequences of opiate receptors show remarkable similarities to one another (approximately 60%) and across species (more than 95%). This homology is particularly evident in the transmembrane regions of the receptors. Arrows indicate where there are additional amino acids in the kappa or mu receptor. (From Miotto K, Magendzo K, Evans CJ. Molecular characterization of opioid receptors. In: Tseng LF, ed. *The pharmacology of opioid peptides*. Singapore: Harwood Academic, 1995:64, with permission.)

Clinically, opiate receptor *subtype* effects and agents may prove useful, regardless of the molecular events underlying their distinct pharmacologies. Subtype-specific effects might be limited to certain administration routes (e.g., intrathecal) or to combination therapy with other interacting drugs. Nonetheless, these effects would be of great use if tied to differential side effect profiles. For example, delta agonists have epileptogenic side effects and the kappa opiates are poorly tolerated because of dysphoric effects. If subtype-specific agonists could produce antinociception without the usual receptor-mediated side effects or analgesic tolerance, then the absence of receptor subtype clones would not reduce the importance of these results. Thus far, few such studies have been published, with the notable exception of the mu $_1$ and mu$_2$ investigations.

Spinal opiate receptors are 70% mu, 24% delta, and 6% kappa receptors. Antibodies to specific amino acid sequences of mu, kappa, and delta receptors permit study of the anatomic location of these receptors with much greater resolution than was possible previously with radiolabeled receptor autoradiography techniques. Presynaptic and postsynaptic mu and delta receptors have been identified with co-localization of these two receptor types, a common occurrence (74). Presynaptic receptors make up approximately 70% of all mu and delta receptors. Kappa receptors, although less studied, thus far appear to be more commonly located on postsynaptic structures in the dorsal horn (233). In accordance with the anatomy, both presynaptic and postsynaptic mu opioid effects inhibit primary afferent input to the spinal cord (234,235).

Another mechanism of opiate activity in other areas of the CNS (e.g., the hippocampus) is disinhibition: inhibition of inhibitory interneurons resulting in a net excitation of the system. Such excitatory effects of opiates in spinal cord nociception have not been demonstrated. Although suggestions of kappa opiate–mediated sensitization exist (236), this phenomenon is probably mediated by nonspecific NMDA receptor activation by dynorphin rather than a kappa-mediated disinhibition (237). Reports of opiate activation of SG cells have unclear significance to nociception (238). Presumably, opiate-induced disinhibition of SG inhibitory interneurons would be antinociceptive, whereas disinhibition of excitatory interneurons might potentiate nociceptive transmission. Regardless of their effects on any given neural circuit throughout the nervous system, opiates are inhibitory at the cellular level with few exceptions (239). The molecular mechanisms underlying this inhibition depend on the ion channels linked to the G protein–coupled opiate receptor. Opiates open potassium channels or close calcium channels. In either case, these actions cause less transmitter release presynaptically and make it more difficult for neurons to reach their action potential thresholds postsynaptically.

Mu receptors are predominately localized on small primary afferent terminals. This may account for mu agonist effects on nociception without affecting touch sensations carried by larger fibers. Indeed, it may be this selectivity that makes the allodynia (pain from light touch) experienced by some patients and laboratory animals after nerve injury less responsive to opioid therapy. Postsynaptically, second messengers can be inhibited (e.g., PKA and cAMP) or activated (e.g., inositol triphosphate, PKC, and Ca^{2+}) by opiates (240) (Fig. 4-32).

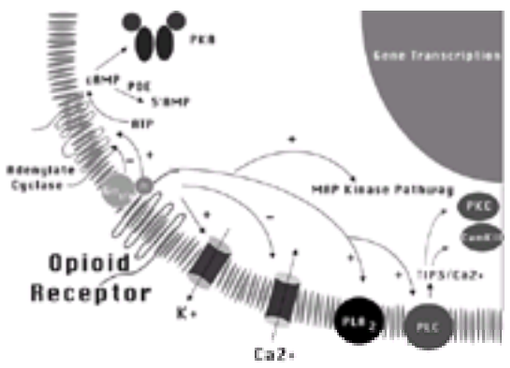

Figure 4-32. Opioid receptor effects on enzymes and second messengers. The opiate receptor is a G-protein–coupled receptor that can work via a number of effectors and second messengers to influence a variety of neuronal processes from resting membrane potential to gene transcription. Through G protein coupling, opiate receptors can activate potassium (K) channels, close calcium (Ca) channels, or both. Mu, delta, and kappa opiates have all been reported to have these effects. Opiate receptors can also act via i and o alpha G protein subunits (Ga $_{i/o}$) to inhibit adenylate cyclase and thus cAMP production from ATP. This in turn can inhibit cAMP-dependent protein kinase (PKA). Conversely, via s alpha subunits (Ga $_s$, not shown) or certain beta/gamma G protein subunits (bg) opiate receptors can activate cAMP production and PKA activity. Other kinases can also be activated by opiate receptors including G protein receptor kinases (not shown), mitogen activated protein kinases (MAP kinase), and via phospholipase C (PLC)- mediated increases in inositol triphosphate (IP3) and intracellular calcium, protein kinase C (PKC), and calmodulin-dependent kinase (CamK). Phosphorylation of the opiate receptor by these kinases can inhibit its function and may provide a mechanism for opiate tolerance. Opiate receptors can also activate phospholipase A $_2$ (PLA_2) and activate certain potassium channels via a 12-lipoxygenase–produced metabolite of arachidonic acid (see discussion in periaqueductal gray part of Descending Modulation section of this chapter). Phosphodiesterase (PDE) metabolizes cAMP to 5'AMP. (From Appleyard S. *Agonist dependent desensitization and opioid receptor phosphorylation: a potential role in the development of opioid tolerance*. Seattle: University of Washington Doctoral Thesis, 1998:14, with permission.)

Cross-talk by second messenger systems activated by other receptors may modulate opiate actions as well. One example of such cross-talk is the interaction of NMDA and opiate receptors. Calcium entering the cell via NMDA receptors can activate PKC. Phosphorylation of NMDA receptors can potentiate activity of these receptors, causing a positive feedback loop (241). In contrast, opiate receptors can also activate PKC, and phosphorylation of opiate receptors (by PKC or other kinases) can decrease the activity of those receptors causing opiate desensitization or tolerance (242). Mao and colleagues (243) have proposed that this cross-talk mediates morphine tolerance in cells with both activated NMDA receptors and opiate receptors. This explains why NMDA antagonists inhibit mu opiate tolerance in several animal models and why NMDA-mediated nociceptive phenomena are poorly responsive to opiates (Fig. 4-33 and Fig. 4-34). Whether enough dorsal horn cells with co-localized mu and NMDA receptors exist to allow this mechanism to mediate a significant portion of opiate tolerance is still under investigation. Nonetheless, NMDA antagonists are already being studied in humans for their ability to block or reverse opiate tolerance. Facilitated NMDA receptors may be responsible for the effects of opiate withdrawal. Fundytus and Coderre have implicated cross-talk between opiate receptors and metabotropic glutamate receptors in mediating opiate withdrawal excitability (87). In their model, desensitization of metabotropic receptors by opiate-induced kinase activity would increase excitability of the circuit (in the absence of opiate inhibition) via a loss of metabotropic glutamate autoreceptors presynaptically or via a postsynaptic increase in cAMP and subsequent activation of cation channels (see Fig. 4-34).

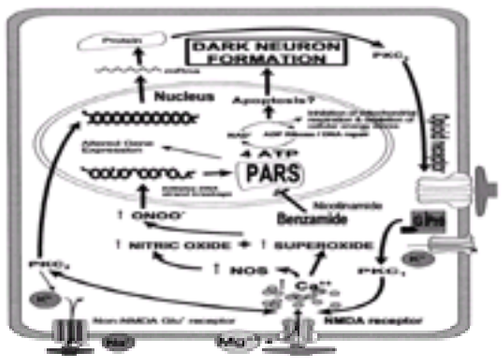

Figure 4-33. A model of the development of opioid tolerance in the dorsal horn of the spinal cord. Activation of the mu-opioid receptor initiates protein kinase C (PKC) activation (translocation to the membrane), which phosphorylates an *N*-methyl-d-aspartate (NMDA) receptor, activating it (by removal of the Mg^{2+} block) and allowing an increased influx of Ca^{2+}. The increased Ca^{2+} activates additional PKC [either the same pool (PKC_1) or a new pool (PKC_2), which can diffuse to the nucleus to alter gene transcription]. Increased Ca^{2+} also activates nitric oxide synthase (NOS), increasing nitric oxide, and the production of mitochondrial superoxide. The simultaneous generation of NO and superoxide produces peroxynitrite (ONOO–). ONOO– can initiate DNA damage and subsequent production of nuclear repair enzyme (PARS). PARS activation can deplete energy stores and lead to cell dysfunction and perhaps death (dark neuron formation?). (From Mayer DJ, Mao J. Mechanisms of opioid tolerance: a current view of cellular mechanisms. *Pain Forum* 1999;8:16, with permission.)

Endogenous Opioids (Endorphins). The discovery of leu-enkephalin and met-enkephalin, the two 5 amino acid peptides with opiate-like activity, suggested that these ligands, found in high concentration at the spinal and medullary dorsal horn and in various other parts of the CNS, might normally act on intrinsic opioid systems to inhibit nociception. That opiate antagonists such as naloxone generally have no effect on pain thresholds suggests that endogenous opioid systems are not tonically active (244). However, some studies, including one in postoperative patients, do report reduced pain thresholds after naloxone (245).

Three classes of endogenous opioids have been most thoroughly studied: the ENKs, dynorphins, and b-endorphin. These three distinct families of opioid peptides are cleaved from different precursors (Table 4-2), and each has a distinct anatomic distribution. The two 4-amino endomorphins described in 1997, have been less studied but also have a distinct anatomy and pharmacology (246,247,248 and 249).

Prohormone	Peptide	Sequence*		No. of amino acids
		L	M	
Proopiomelanocortin	β-Endorphin		X	31
	γ-Endorphin		X	17
Proenkephalin A	Leu-enkephalin	X		5
	Met-enkephalin		X	5
	Heptapeptide		X	7
	Methorphamide		X	7
Proenkephalin B	Dynorphin	X		17
	$Dynorphin_{1-8}$	X		8
	α-Neoendorphin	X		10
	Dynorphin B	X		13

*Indicates the end terminus is either identical to leu-enkephalin (L) or met-enkephalin (M).

TABLE 4-2. Amino acid sequences of major opioid peptides and their respective precursors (prohormones)

ENKEPHALIN. ENKs have a wide distribution throughout the CNS. However, their presence in several regions are consistent with their contribution to antinociceptive mechanisms (29,186). The most important and clinically relevant location is the dorsal horn, in which there are opiate-binding sites on central terminals of primary afferents and dorsal horn neurons. ENK also occurs in supraspinal regions implicated in nociceptive modulation, including the midbrain periaqueductal gray (PAG) and the medullary nucleus raphe magnus (NRM) and adjacent nucleus reticularis paragigantocellularis (250).

Although some spinal ENK immunoreactivity is from axons projecting to the spinal cord from the medulla (bulbospinal), the vast majority of ENK derives from intrinsic dorsal horn neurons (29). Immunohistochemical studies reveal that dense accumulation of ENK is in the superficial layers of laminae I and II and also in lamina V, most notably in the lateral part, as well as in laminae VII and X (29) (Fig. 4-35). Because these regions contain cells responsive to noxious input, the ENK axons and their terminals are strategically situated for direct postsynaptic inhibition of nociceptive neurons projecting rostrally toward the brain.

Combined immunochemical and retrograde HRP studies indicate that ENK immunoreactive endings make direct synaptic contact with the soma and proximal dendrites of approximately one-third of lamina I thalamic-projecting neurons (185). Lamina II_o stalked cells and some lamina II_i islet cells are ENK containing (185) (Fig. 4-36). Because the axons of stalked cells arborize in lamina I among dendrites of lamina I, ENK-containing stalked cells are a potential source of ENK input on thalamic projection neurons (185). Dubner and colleagues (54) suggested that, although some stalked cells that are not ENK-containing neurons may be excitatory local-circuit neurons as Gobel proposed, the ENK stalked cells are inhibitory local-circuit neurons that suppress the activity of lamina I thalamic projection neurons. Dubner and associates (185) further noted that, although lamina II_i cell axons and dendrites are confined to lamina II and therefore cannot directly influence output systems in lamina I, the islet cell dendrites are presynaptic to stalked cell dendrites. Thus, islet cells may indirectly modulate the activity of lamina I thalamic projecting neurons via the stalked cell–lamina I linkage. The most densely innervated lamina I neurons often are large Waldeyer's cells.

Figure 4-36. A composite from several sagittal sections of camera lucida drawings of lamina II enkephalin-immunoreactive stalked cells (a through d) and lamina IIb (II_i) islet cells (e through g) in cat lumbar spinal cord pretreated with colchicine. The dashed line at the top indicates that border between lamina I and the overlying white matter. The rapidly tapering processes (*arrowheads*) arising from the stalked cell somata resemble axon initial segments. *Arrow* beside (e) indicates a recurrent islet cell dendrite. (From Bennett GJ, Ruda MA, Gobel S, et al. Enkephalin immunoreactive stalked cells and lamina IIb islet cells in cat substantia gelatinosa. *Brain Res* 1982;240:162–166, with permission.)

ENK-containing local-circuit neurons are also present in deeper laminae of the dorsal horn (28). Lamina III contains small ENK-containing cells that have somata and dendritic patterns characteristic of intracellular HRP-filled lamina III neurons, which receive only low-threshold mechanoreceptor input. The ENK-containing lamina III neurons are ideally located to provide ENK input to the dorsal column postsynaptic neurons whose dendrites ramify throughout lamina III, and their axons project in the dorsal columns. Based on the importance of this pathway in visceral pain, one might hypothesize a role for these cells in modulating this visceral nociception.

ENK-containing neurons located in lamina V are situated well for providing ENK input to lamina V projecting neurons and, indeed, more than 50% of lamina V thalamic-projecting STT neurons receive ENK contacts (185). Evidence exists for a local negative feedback circuit that is turned on by arriving nociceptive impulses. Such impulses cause the local release of ENK, which modulates the output of ascending nociceptive neurons. In addition to these postsynaptic actions, the evidence for presynaptic opiate receptors points to possible opioid-mediated presynaptic control of primary afferents. Interestingly, this hypothesis for presynaptic control of primary afferents by ENK lacks support of ultrastructural evidence. Electron microscopic studies have generally revealed that the ENK terminals are primarily presynaptic to dendritic or somatic profiles, not primary afferent or other axons. Nonetheless, as previously mentioned, much electrophysiologic evidence suggests a pharmacologic presynaptic effect, if not a physiologic one.

DYNORPHIN. As noted in Table 4-2, dynorphin and a-neoendorphin are cleaved from proenkephalin B. Dynorphin-containing cell bodies are found in the PAG, mesencephalic reticular formation, and spinal and medullary dorsal horns (251). More than 80% of labeled medullary and spinal dorsal horn dynorphin cells are located in laminae I and V. After the discovery of dynorphin, evidence emerged that intrathecal, but not intracerebral, injections of the peptide produce profound and prolonged analgesia (252). Dynorphin's paralytic effects confound some of these studies. These effects are mediated via NMDA receptors, rather than opiate receptors, and they are a high-dose effect (253).

Cruz and Basbaum (251) suggested that because the axonal arborization of spinal dynorphin neurons is not in the immediate vicinity of the cell, some of the spinal dynorphin neurons project elsewhere. They also concluded that dynorphin neurons of the dorsal horn might provide a presynaptic opioid peptide input onto the primary afferent neurons. Again, studies showing considerable postsynaptic kappa opiate receptor immunoreactivity (233) appear to demonstrate a mismatch between peptide and receptor. Indeed, the role of dynorphin in nociception has been complicated by studies showing that inflammation and nerve injury produce a prominent increase in spinal dynorphin immunoreactivity with a time course associated (although slightly behind) hyperalgesia in these models (254). The elevation of dynorphin is localized in laminae I, II, V, and VI of the ipsilateral (but not the contralateral) dorsal horn. This suggests the involvement of dynorphin-containing neurons in nociceptive processing. Whether this correlation of dynorphin level and hyperalgesia implies a causative role for dynorphin (perhaps at NMDA receptors) or, in contrast, represents a negative feedback mechanism whereby dynorphin inhibits further hyperalgesia, is controversial. Indeed, dynorphin could do both in a dose-dependent way.

b-ENDORPHINS. Proopiomelanocortin is the precursor for b-endorphin, adrenocorticotropic hormone, and three forms of melanocyte-stimulating hormone. Unlike the ENKs and dynorphin, which are widely distributed in the neuraxis, proopiomelanocortin neurons are concentrated in the basal hypothalamus (infundibular nucleus) with their axons extending rostrally to the limbic system or caudally along the wall of the third ventricle toward the midbrain, PAG, and locus coeruleus. b-endorphins can produce analgesia and have been implicated in mediating certain forms of stress-induced analgesia (SIA) (255), although this is controversial. We discuss SIA later in this chapter (see Descending Systems that Modulate Nociception).

Opiate Inhibition of Sensitization. As mentioned, opiates can inhibit AMPA (234) and NMDA-receptor-mediated primary afferent neurotransmission (82) in the dorsal horn via presynaptic (82) and postsynaptic (235) mechanisms. This may explain their potent analgesic actions. Mu opiates can also inhibit induction of LTP in dorsal horn cells after repeated primary afferent activation (256), perhaps explaining their preemptive effects on sensitization in rodents (31) and humans (257). Mu opiates have proven less effective in providing antinociception in the sensitized state, particularly in neuropathic pain. Mu opiate receptors decrease in the spinal cord after nerve injury, perhaps providing a mechanism for this effect (240).

In contrast, kappa opioids seem particularly effective in inhibiting sensitized nociception after dorsal horn cell LTP (258), inflammation (259), surgery (260), or nerve injury (214), sometimes without effect on baseline nociception. This suggests that kappa agents interfere preferentially with maintenance, expression, or both, rather than induction of sensitized nociception. As previously mentioned, the therapy of most pain conditions would benefit from the targeting of sensitization without sacrificing normal nociception, by kappa opiate or other antinociceptive drugs.

Neuropeptide FF. The eight amino acid neuropeptide FF has complex effects on nociception, varying in its effects depending on the site of injection and prior nociceptive sensitization. Supraspinally administered neuropeptide FF lowers nociceptive thresholds and reverses morphine analgesia (261). After nerve injury, however, supraspinal neuropeptide FF inhibited mechanical (though not thermal) thresholds while still blocking morphine's antinociceptive effects (262). In contrast, intrathecal neuropeptide FF induces a long lasting, opioid-dependent analgesia and potentiates opioid analgesia (261), except after carrageenan-induced sensitization when neuropeptide FF had no effect on mechanical or thermal nociception (263). The mechanism for these differential effects of neuropeptide FF after sensitization is not known. Receptors for neuropeptide FF are present in laminae I and II of the dorsal horn and are unaffected by dorsal rhizotomy, suggesting that the peptide's spinal effects are on intrinsic, perhaps ENKergic, cells. Indeed, neuropeptide FF can potentiate delta opiate analgesia (264). Endogenous neuropeptide FF is present in the superficial dorsal horn and around the central canal. It increases after peripheral inflammation (263). Perhaps neuropeptide FF normally acts at the spinal cord to release ENK and produce analgesia, but tolerance develops to these effects after long-lasting noxious stimulation.

Neuropeptide Y. The 36 amino acid neuropeptide Y (NPY), and the structurally related avian pancreatic polypeptide, when administered intrathecally, also produces differential effects on sensitized and normal animals. NPY normally inhibits thermal nociception, although it has little effect on mechanical nociceptive thresholds. Presumably, this indicates that the NPY receptors located on small-caliber primary afferent terminals in laminae I and II (32) are located on thermal sensitive nociceptors specifically (e.g., capsaicin-sensitive afferents). There, NPY receptors produce presynaptic inhibition of these nociceptors (265), via G protein–dependent inhibition of calcium channels or activation of potassium channels. After nerve ligation (266) or inflammation (267), however, NPY potentiates nociceptive responses. As discussed in Chapter 3, primary afferent NPY and NPY receptors increase (147) after inflammation or nerve injury. Spinal cord laminae II and III NPY receptors also increase, at least after inflammation (32). These laminae are known to contain GABA interneurons that also contain NPY and synapse on cells expressing the NK1 (substance P) receptor (268). NPY inhibition of these presumably inhibitory interneurons, by way of newly expressed NPY receptors, might account for changes in NPY pronociceptive effects after sensitization. Moreover, five subtypes of NPY receptors have thus far been identified (269). NPY1 and NPY2 receptors are normally expressed in large and small dorsal root ganglion (DRG) cells, respectively, although changes with nerve injury and inflammation on receptor subtype distribution have not been well characterized. A change in NPY subtype phenotype could underlie the differences seen in NPY nociceptive modulation after sensitization.

Galanin. Galanin, a 29 amino acid peptide discovered from intestine in 1983, inhibits nociception. It is cleaved from a prepropeptide along with a 60 amino acid fragment called *galanin message-associated peptide*, which inhibits C-fiber wind-up (270). Galanin binds to specific receptors, three of which have been cloned,

Gal-R1, R2, and R3. Gal-R1 and R2 receptors have been identified in CGRP-containing DRG, in large and small neurons, respectively, as well as on central terminals of these cells (271). GAL-R1 receptors, the most prevalent receptor subtype on dorsal horn neurons, are located in lamina I and II. Galanin itself is also seen in laminae I and II, around the central canal, and is contained both in primary afferent terminals and in small second-order neurons coexisting with GABA, ENK, NPY, or all three.

Low doses of galanin given intrathecally facilitate nociceptive reflexes, whereas larger doses inhibit them (272). An antagonist to galanin blocks intrathecal morphine analgesia and potentiates wind-up, suggesting a normal role for galanin in modulating opioid action and sensitization. In this latter regard, galanin and galanin receptors are greatly affected by inflammation and nerve injury, as mentioned in Chapter 3. The effects are complex and we refer the reader to reviews on the topic (271) for detailed anatomic analyses. In short, intrathecal galanin inhibits allodynia after axotomy. This inhibition is probably postsynaptic because presynaptic (primary afferent nerve terminal) galanin receptors decrease after nerve injury.

Galanin antagonists potentiate pain behaviors after nerve injury, and increases in DRG galanin after nerve injury suggests this as the most important source of peptide mediating the effect (189). Galanin antagonists also can greatly increase nociceptive responses after inflammation, although increases in dorsal horn galanin suggest this as the predominant source of galanin for this effect. Whether presynaptic or postsynaptic galanin receptors are most important in this effect is unknown.

Neurotensin. Neurotensin, a 13 amino acid peptide, produces analgesia in certain pain tests after intrathecal injection (273). Neurotensin and its receptors are localized to spinal neurons intrinsic to the cord (29,32). Cell bodies containing neurotensin concentrate in laminae II and III of the dorsal horn, and their terminals extend through laminae I, II, and III (274). Like ENK, terminals containing neurotensin predominantly form axosomatic and axodendritic synapses with dorsal horn neurons, although some neurotensin terminals are located presynaptically to unidentified vesicle-containing structures (29). Neurotensin's effects are primarily excitatory at the cellular level, so its antinociceptive effects probably stem from excitation of inhibitory cells or presynaptic inhibition of excitatory interneurons (although neither mechanism has been demonstrated). Indeed, neurotensin's effects on nociception are much better characterized at supraspinal sites and a supraspinal site of action for its intrathecal effects has not been ruled out. Nonetheless, neurotensin-containing cells are heavily innervated by descending serotonergic input usually associated with antinociception (275) and thus its spinal action seems more likely to be facilitated by its supraspinal action than confounded by it.

Somatostatin. Like neurotensin, somatostatin (a tetradecapeptide) and its more metabolically stable analogues have been reported to mediate supraspinal and spinal analgesic effects (276). Moreover, several case reports suggest that both systemic and spinal administration of analogues of somatostatin can produce analgesia in humans; particularly for migraine (277) and cancer pain resistant to other forms of therapy (278). Somatostatin occurs predominantly in lamina II_o, but there is also some staining in lamina II_i and the dorsal part of lamina III. Sparse innervation is also seen in the rest of lamina III, lamina IV, the reticulated region of lamina V, and in the central canal region (185) (Fig. 4-37). Somatostatin receptors are located in laminae I and II and in the adult animal are not observed on primary afferents (279). Somatostatin derives from a population of small-diameter dorsal root ganglion cells and from somatostatin cell bodies within lamina II_i and exerts a predominantly inhibitory effect on nociceptors in electrophysiology studies (280). Somatostatin has also been found to have neurotoxic effects in some animal species (281) and perhaps humans (282). Whether these effects are caused specifically by somatostatin receptors is not known because of the absence of a selective somatostatin antagonist. Regardless, such effects underline the difficulty facing clinicians who attempt to alleviate their patients' pain without doing them harm. Clearly, a rat may stop flicking its tail away from a hot light for many reasons. The physician must be armed with toxicology and drug dosing information, not simply a new drug, before extrapolating preclinical results to his or her patient's pain complaints. At present, the jury is still out on somatostatin's role in the physiology and pharmacology of pain modulation.

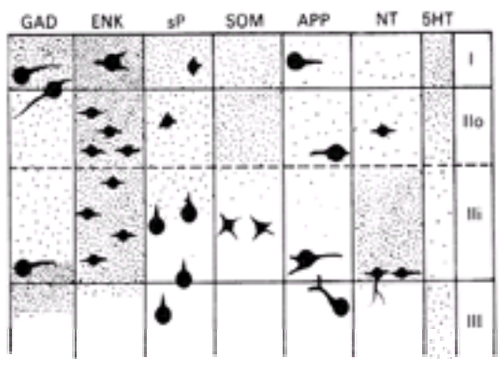

Figure 4-37. Diagram showing the location of neurons and of terminal zones in the upper three laminae of the dorsal horn that show immunoreactive staining for the following substances: glutamate decarboxylase (GAD), enkephalin (ENK), substance P (sP), somatostatin (SOM), avian pancreatic polypeptide (APP) (similar structurally to neuropeptide Y), neurotensin (NT), and 5-hydroxytryptamine (5-HT). (From Hunt SP, Kelly JS, Emson PC, et al. An immunohistochemical study of neuronal populations containing neuropeptides or gamma-aminobutyrate within the superficial layers of the rat dorsal horn. *Neuroscience* 1981;6:1883–1898, with permission.)

Ion Channel Blockers. A variety of ion channel blockers have neuronal effects and inhibit nociception. Sodium channel blockers, such as tetrodotoxin, for example, can be deadly, and local anesthetics (including analgesic oral antiarrythmic drugs such as mexiletene) share this characteristic as well as their sodium channel blocking properties. Other analgesic adjuvant drugs, such as phenytoin and carbamazepine (283), probably work by this mechanism. The small therapeutic ratios of these drugs, particularly with systemic administration, are quite reasonable, considering that sodium channels mediate all active neural transmission. However, the discovery of tetrodotoxin-resistant sodium channels (SNS/PN3), which are located predominately in small primary afferents and are increased coincident with neuropathic pain in some animal models (284,285), gives hope for the development of more selective antinociceptive sodium channel blocking agents, at least in the periphery.

Calcium channels are involved in all synaptic transmission by mediating exocytosis of neurotransmitter-containing vesicles. Thus, calcium channel blockers, of which there are many laboratory examples gathered from poisons throughout nature (e.g., conotoxins from cone snails), are dangerous drugs, at least systemically. Nonetheless, several subtypes of calcium channels have been identified and antagonists at several of these subtypes produce analgesia; these include *L*-type, *N*-type, *P*-type, and *Q*-type channel blockers (168,169,170,171,172,173 and 174). For example, in humans, analgesia from intrathecal SNX-111 (286) and, perhaps, gabapentin (287,288) is mediated via inhibition of calcium channels. Indeed, SNX-111 acts on the *N*-type calcium channel, and this is particularly important for vesicular release. If intrathecal doses of SNX-111 are identified that provide relatively specific antinociceptive effects, poor penetration into the spinal cord by peptides and the importance of lamina I in nociception may be responsible. Gabapentin appears to bind to a portion of the *L*-type calcium channel (289), thought less important in fast transmitter release. As discussed in Chapter 3, studies of inflammatory and nerve injury effects on calcium channel subtype expression may lead the way to better therapeutic options using calcium channel blockers for specific pain states. The tricyclic antidepressant adjuvant analgesic drugs have both sodium and calcium channel blocking properties (290,291), as well as monoaminergic reuptake blocking effects. They may be useful in certain pain states because of their mechanistic nonspecificity. Likewise, gabapentin, in addition to its channel blocking effects, also can potentiate GABA release (289). A myriad of ion channels exist that allow ions to flow down their electrical or concentration gradients to determine the electrical activity of a neuron. These may be ligand gated, voltage dependent, dependent on the concentration of a separate ion, and/or modulated by a host of G protein–coupled receptors or second messengers. Blockade or activation of any one of these channels or their modulators may be the key to pain management in the future. At present, however, our most useful antinociceptive pharmacologic tools have multiple mechanistic effects.

Nociceptive Modulation: Alternate Delivery Systems

The discovery of an increasing number of neurochemicals that modulate nociception at the spinal level in animals and in humans has led, not only to an increasing search for analogues with greater nociceptive specificity, but also to new methods of delivering these chemicals to their spinal targets. The studies by Yaksh and colleagues (174), demonstrating enhanced efficacy and potency of administering opiates directly to the spinal cord via intrathecal catheters in animals, have revolutionized clinical pain management through the routine use of intraspinal opiates. Other therapeutic agents also have been administered successfully via this route (Table 4-3) and a number of commercially available catheters and pumps are approved for spinal use in humans. Intrathecal drug administration allows targeting of the highest concentrations of drug at a site of high receptor number, thus theoretically increasing drug effect while minimizing drug side effects that might result

from actions in other areas of the brain or extranervous tissue (e.g., intestine). In addition, this technique allows drugs with minimal lipid solubility (e.g., peptides) to reach spinal sites by bypassing the blood–brain barrier and metabolism in liver or other peripheral sites. Investigators are now using other methods to achieve similar goals. Sagen and colleagues have shown that cells (such as adrenal medullary cells) that normally produce and excrete antinociceptive chemicals, when transplanted to the intrathecal space, can produce decreases in behavioral pain responses in rats (292,293) and humans (294). Other cells have been implanted intrathecally that have been genetically altered to excrete a number of antinociceptive neurochemicals (295,296). Carrying this reasoning one step further, genetically altered viral vectors have been used to induce opioid peptide production in primary afferent and meningeal cells and inhibit nociception in rodents (297,298). It remains to be seen whether such therapies using largely uncontrolled dosing and dosing regimens will be useful for treating clinical pain, whose intensity can fluctuate day to day and even hour to hour. However, molecular biology techniques exist to allow conditional changes in gene expression that might prove useful for overcoming these concerns.

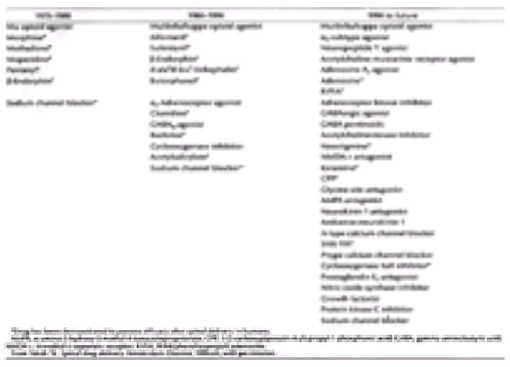

TABLE 4-3. Summary of drug classes that regulate nociceptive processing in preclinical and clinical models after spinal delivery

Overview of Neuropharmacologic Nociceptive Modulation

As is apparent from the preceding paragraphs, the pharmacologic modulation of spinal nociception is a complex topic. Many neurochemicals appear capable of inhibiting or facilitating nociception in animal and even human models (Fig. 4-38). Thus far, few of these compounds (or their antagonists) have been demonstrated to provide clinical benefit. A time lag always exists between basic science discoveries and clinical utilization, appropriately so, in order for toxicology and dose ranging studies to be done. Nonetheless, it is important to point out some of the possible incompatibilities between clinical pain studies and, for example, rodent pain studies that might lead to disparate results.

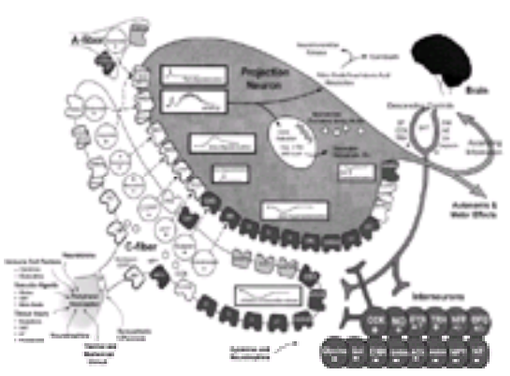

Figure 4-38. Pharmacologic systems thought to contribute to transmission and modulation of nociception in the dorsal horn of the spinal cord. The various neurochemicals and receptors depicted each has its own pharmacologic profile and may represent independent populations of individual neurons and fibers but more commonly interact with one another at any given synapse. Interactions can take place at presynaptic terminals, dendrites, and somata. Nonetheless, all of these neuromodulators are unlikely to be present at any one synapse. Not shown are interactions that can take place between interneurons [e.g., acetylcholine-induced gamma-aminobutyric acid (GABA) release]. Examples of A-fiber modulation are shown suggesting possible presynaptic antiallodynic mechanisms. Dark receptors (or –) indicate reported antinociceptive and white receptors (or +) pronociceptive effects. Gray receptors indicate presynaptic inhibitory effects. [Ach, acetylcholine (m and nAChR, muscarinic and nicotinic acetylcholine receptors); AMPA, a-amino-3-hydroxy-5-methyl-4-isoxazoleproprionate; ATP, adenosine triphosphate; B2, bradykinin receptor subtype; CB1, cannabinoid receptor subtype; CCK, cholecystokinin; CGRP, calcitonin gene–related peptide; DA, dopamine; DYN, dynorphin; ENK, enkephalin; 5HT, serotonin; Gal, galanin (Gal1 and 2, galanin 1 and 2 receptor subtypes); GRP, gastrin-releasing peptide; mGlu, metabotropic receptor; NE, norepinephrine; NFF, neuropeptide FF; NK1 and 2, neurokinin 1 and 2 receptor subtypes; NM, neuromedin (bombesin) receptor; NO, nitric oxide; NPY, neuropeptide Y; NT, neurotensin; OFQ, orphanin FQ (nociceptin); ORL, orphanin receptor; SP, substance P; TRH, thyrotropin-releasing hormone; VR, vanilloid (capsaicin) receptor.] (Adapted from Dickenson A. Pharmacology of pain. In: *Receptor and ion channel nomenclature supplement*, 4th ed. Cambridge: Elsevier, 1993.)

Pain Assessment. Dubner (299) and Vierck and Cooper (300) specified that ideal pain assessment in laboratory animals should (a) distinguish responses to noxious and innocuous stimuli, (b) vary in response magnitude with changes in stimulus intensity from threshold to tolerance, (c) use multiple threshold and suprathreshold behavioral measures to infer pain, (d) be altered by manipulations (e.g., drugs) that alter perceived stimulus intensity, (e) distinguish modifications in responses caused by nonsensory variables (e.g., motor or motivational factors) from those caused by sensory variables, and (f) cause little or no tissue damage. The last of these ideals has been the most hotly debated in the field; swayed in one direction by important ethical considerations and in the other by the development of inflammatory and neuropathic pain models, many of which, like their human analogues, are the result of some degree of tissue damage.

To understand these ideals better, let us consider an animal or a population of animals (including humans) exposed to a stimulus of increasing intensity or severity (see Fig. 4-39A). As the stimulus gradually becomes more severe, the nociceptive response of the animal becomes more pronounced (e.g., faster, more likely to occur, and so forth). The shape of this stimulus to response curve is sigmoidal, with only few responses occurring with innocuous stimuli until a stimulus threshold is reached and a rapid increase in responses occurs with increasing noxious stimulation until an asymptote is reached, followed by a nearly maximal response (see Fig. 4-39A). The curve itself can be defined by four lines. One line represents a low frequency of *nociceptive responses* occurring in response to innocuous stimuli (e.g., incidental responses) and it intersects a line describing the stimulus severity at which responses begin to rapidly increase (nociceptive threshold) (see Fig. 4-39A). A third line defines the response frequency at which nociceptive responses normally asymptote, and it crosses a fourth line describing the stimulus at which asymptote is reached, *nociceptive tolerance* (Fig. 4-39A).

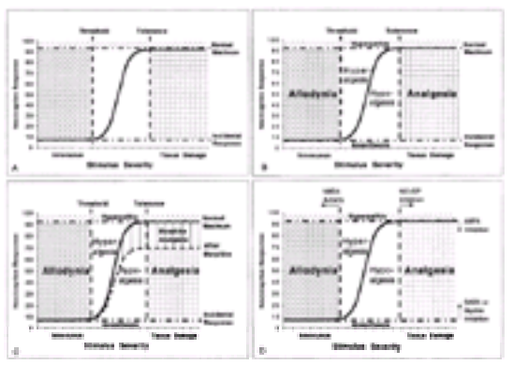

Figure 4-39. Stimulus/response curves for nociceptive responses and their modulation. **A:** A stimulus/response curve is sigmoidal and defined by four lines. One line

represents a low frequency of *nociceptive responses* occurring in response to innocuous stimuli (incidental responses). It intersects a line describing the stimulus severity where responses begin to rapidly increase (nociceptive threshold). A third line defines the response frequency where nociceptive responses normally asymptote (normal maximum), and it crosses a fourth line describing the stimulus intensity where asymptote is reached (nociceptive tolerance). **B:** An increased nociceptive response to normally innocuous stimuli is called *allodynia*. Increased responses to stimuli between nociceptive threshold and tolerance are hyperalgesic responses. Increases in responses over the normal maximum are called *hyperpathia* regardless of the intensity of the stimulus eliciting these responses. Response frequencies less than normal incidental responses (regardless of the stimulus severity) are seen primarily during anesthesia (or some motor impairment). Reduced responses to suprathreshold stimuli are best described as hypoalgesia. However, clinicians tend to describe reduced pain responses to stimuli beyond normal nociceptive tolerance as analgesia (even if some pain response is still present). **C:** Mu-opiate receptor agonists, such as morphine, seem to decrease maximum nociceptive responsiveness with much less effect on allodynia. **D:** An important mechanism by which mu opiates work is the inhibition of glutamate a-amino-3-hydroxy-5-methyl-4-isoxazoleproprionate (AMPA) (or kainate, or both) receptor activity. Perhaps decreases in AMPA act to decrease the asymptote of normal or hyperpathic nociceptive responses. On the other hand, modulators that act to inhibit activity of the inhibitory neurotransmitters gamma-aminobutyric acid (GABA), glycine, or both frequently cause allodynia, as if shifting up the incidental responses to innocuous stimuli. *N*- methyl-d-aspartate (NMDA) agonists and antagonists also produce and inhibit allodynia, respectively, but are also effective in modulating responses at greater stimulus severities. NMDA receptors may set the *pain threshold*. As illustrated, a facilitator of NMDA receptor activity would cause both hyperalgesia and allodynia. Finally, the effects of inhibiting substance P (SP), or its neurokinin 1 (NK1) receptors, are illustrated here as producing a shift of pain tolerance to the right, resulting in primary efficacy for stimuli of moderate severity. [Based on Cervero F and Laird JMA. Mechanisms of touch-evoked pain (allodynia): a new model. *Pain* 1996;68:13–23.]

This stimulus to response function is useful for demonstrating the meaning of several clinical terms. For example, an increased nociceptive response to normally innocuous stimuli is called *allodynia* (Fig. 4-39B). On the other hand, increases in responses to stimuli between nociceptive threshold and tolerance are *hyperalgesic responses* (Fig. 4-39B). Increased response above the normal maximum is called *hyperpathia*, regardless of the intensity of the stimulus eliciting this response (Fig. 4-39B). Similarly, response frequencies less than chance (regardless of the stimulus severity) are seen primarily during anesthesia (or some motor impairment) (Fig. 4-39B). Reduced responses to suprathreshold stimuli are best described as *hypoalgesia* (Fig. 4-39B); however, clinicians tend to describe reduced pain responses to stimuli beyond normal nociceptive tolerance as *analgesia* (Fig. 4-39B). A majority of animal pain studies (including those in human volunteers) measure hyperalgesic or hypoalgesic responses to heat, cold, or electric shock. Many clinical pain problems arise from allodynia or, at the other end of the curve, from severe stimuli (above pain tolerance levels). Thus, the shrewd pain researcher reserves judgment on a pharmacologic agent that is reported to inhibit nociceptive responses in a heat threshold test, for example, because few patients would benefit from such an effect. As suggested at the beginning of this section, pain assessment should ideally be done at a number of different stimulus severities.

Having used this stimulus/response approach to illustrate nociceptive problems, it may also be useful in examining pharmacologic solutions. Mu opiate receptor agonists such as morphine, for example, are clinically useful in inhibiting pain responses to an array of suprathreshold noxious stimuli. These drugs have been found to be much less effective for allodynia (often a hallmark of neuropathic pain). If we examine a stimulus/ response curve (Fig. 4-39C), we might conclude that morphine decreases maximum nociceptive responsiveness. An important mechanism by which mu opiates work is the inhibition of glutamate release. Initially, this inhibition would decrease AMPA (or kainate or both) glutamate receptor activation. Given this mechanism, and the role of glutamate in nociceptive fast transmission, other neuromodulators that either release endogenous opioids or inhibit AMPA and kainate receptor activation might be expected to have analgesic effects, even at high stimulus severities. For ethical reasons, severe noxious stimuli are not normally given to the awake animal. Nonetheless, AMPA receptor inhibition has been found to inhibit acute nociceptive responses to noxious heat (81,301,302) and formalin injection (303,304).

As described previously, antagonists of the inhibitory neurotransmitters GABA and glycine (e.g., bicuculline and strychnine) produce allodynia in laboratory animals and humans. This effect can be conceptualized in the stimulus/response figure by an increase in the basal level of pain responses. Modulators that act to inhibit or facilitate release of these transmitters might be particularly active in this region of the stimulus/response curve (Fig. 4-39D).

NMDA agonists and antagonists also are reported to produce and inhibit allodynia, respectively, with much less effect on pain responses at greater stimulus severity. Such effects might result from a selective involvement of NMDA receptors in setting the *pain threshold* on the curve. Inhibitors or facilitators of NMDA receptor activity (such as depolarizing exogenous or endogenous agents or repeated stimulation from nerve injury) might modulate nociceptive effects near threshold (see Fig. 4-39D).

Finally, the finding that substance P knockout mice show decreased responsiveness in moderate severity pain tests is modeled on the stimulus/response curve as a shift to the right of the pain tolerance line. Agents affecting substance P release (including prostaglandins) might be particularly effective in modulating pain from moderately noxious stimuli (see Fig. 4-39D). Indeed, the World Health Organization recommends nonsteroidal antiinflammatory drugs for “pain of moderate severity.”

This approach of conceptualizing modulation of spinal nociception by the effects that neuroactive agents exert on stimulus/ response curves is not presented as a comprehensive model of spinal pharmacologic mechanisms. Indeed, mu opiates, by presynaptic primary afferent inhibition, would ultimately also decrease NMDA glutamate receptor activity over time (not just AMPA activity) and can certainly inhibit substance P release as well. Moreover, opiates work by other mechanisms including postsynaptic effects, perhaps explaining their synergistic, not simply additive, effects with AMPA antagonists (302). Nonetheless, such a simplified scheme does prove useful as (a) a reiteration of the importance of behavioral pain tests using several stimulus intensities, (b) an illustration of differences between experimental and clinical pains studied, perhaps, even at the spinal level, and (c) an impetus for a more integrative and, it is hoped, mechanistic (113) understanding of spinal cord nociceptive pharmacology and physiology. Findings that many of the neurochemicals discussed previously interact with each other when exerting their effects (e.g., nicotinic and muscarinic ACh analgesia is associated with increased GABA activity and a $_2$-noradrenergic analgesia is associated with increased ACh release) give hope that neurochemical modulation of nociception, although seemingly complex, may result from a few primary mechanisms.

Modulatory Mechanisms: Structural Reorganization

In addition to the pharmacologic or physiologic modulation of excitatory or inhibitory synaptic strength, nociceptive modulation can theoretically result from anatomic changes. Such synaptic reorganization would likely be slower in onset than other mechanisms modeled *in vitro*. However, many of the nerve injury and inflammatory models of central sensitization develop over many hours to days, more than enough time for anatomic changes to take place.

We have already discussed the possibility that dark neurons that appear in the spinal cord in a neuropathic pain model (the Bennett model) represent dead or dying inhibitory interneurons and lead to sensitization via this mechanism. Similarly, the inhibition of nociception produced by large-fiber activation referred to in the gate control theory led to the hypothesis that selective large- fiber damage may mediate heat hyperalgesia in a neuropathic pain model in rats (305) and postherpetic neuralgia in humans (306). This hypothesis was complicated by the fact that most models of rat and monkey neuropathic pain resolve spontaneously without corresponding neuronal repair, and that pain-free patients after herpetic infection have been found to share much of the nerve damage as neuralgic patients (307). In short, little conclusive evidence exists to support this hypothesis, and indeed, nerve injury appears more likely to damage small fibers than large fibers (308).

Sensitization via structural reorganization might also result from an increase in excitatory synapses. As mentioned for several peptides and their receptors (see Chapter 3), nerve ligation or axotomy can produce changes in potential synaptic activity through changes in peptide levels, receptor number, or both. Fast transmitter receptor number, location, and subtype also can be dramatically altered by nerve damage. AMPA receptors (particularly those most permeable to calcium) increase in laminae III, IV, and V after rhizotomy, possibly leading to sensitization of STT projection cells located there (309).

Probably the best documented example of structural reorganization playing a role in central sensitization is that, as a result of nerve injury, A-b low-threshold mechanosensitive primary afferent fibers that normally terminate exclusively in laminae III and IV, sprout into lamina II (310). Here, in SG, they are in excellent position to affect nociceptive processing and perhaps ultimately lead to pain from nonnoxious stimuli-allodynia (311). Several groups have replicated these findings and found that the loss of C fibers in SG is critical for prompting A-b sprouting (52). Conversely, agents that rescue C-fiber terminals from axotomy-induced damage, such as nerve growth factor, can inhibit nerve injury–induced A-b sprouting (312) and allodynia. Woolf and colleagues also have demonstrated that an increased A-b synaptic input to lamina II is present after 48 hours of inflammation (from complete Freund's adjuvant) as well, without direct nerve injury (313).

We have not fully discussed the roles of neurotrophins, including nerve growth factor, brain-derived growth factor, or neurotrophin-3 or their trk receptors (trkA, trkB, and trkC, respectively) in nociceptive modulation. Much of their reported activity has been in the periphery or on the dorsal root ganglion. Nonetheless, neurotrophins and their receptors can be demonstrated in the dorsal horn (314), neurotrophin-3 has been reported to produce naloxone-reversible mechanical hypoalgesia and inhibit substance P release (315), and neurotrophins are clearly active in other regions of the CNS (316). Thus, it is likely that these agents, in years to come, will be

found to have important spinal effects on both short- and long-term nociceptive processing.

ASCENDING SYSTEMS

In the mid-1800s, Schiff provided evidence that nociceptive messages in animals were transmitted from the dorsal horn to the brain via pathways located in the anterolateral quadrant, often referred to as the ventrolateral quadrant. In general, the terms *anterior* and *posterior* apply to human anatomy, whereas the terms *ventral* and *dorsal* apply to the anatomy of lower animals. The contributions made during the ensuing years by Gowers, Edinger, Spiller, Martin, and Walker have been detailed by others (2) including in the first edition of this book (317). By the early part of the twentieth century, it was widely accepted that the STT and trigeminothalamic tract were the pathways that predominantly transmitted the signals that produced pain and temperature sensation. However, studies during the past several decades have provided evidence that (a) both the STT and trigeminothalamic tract are composed of anatomically and physiologically heterogeneous axons, many of which transmit touch and other sensory information; (b) these tracts are composed of two parts that have somewhat different anatomic and functional characteristics; and (c) in addition to the STT and the trigeminothalamic tract, a number of other pathways with distinctive sites of origin, conduction velocities, areas of termination and function are involved in transmitting information about the threat of tissue injury or actual injury.

The following systems are known to transmit nociceptive information from spinal cord to brain: (a) the lateral (and perhaps the ventral) STT; (b) the spinoreticular tract; (c) the spinomesencephalic tract; (d) the dorsal column postsynaptic spinomedullary system, otherwise known as the second-order dorsal column pathway; and (e) the propriospinal multisynaptic ascending systems. The first two are located in the ventrolateral quadrant (anterolateral quadrant in humans), the third in the ventrolateral quadrant and in the dorsolateral funiculus, the fourth in the dorsal column, and the propriospinal multisynaptic ascending systems are composed of a web of short-chain neurons criss-crossing the spinal cord. The origin, course, and known physiology of each of these pathways are discussed separately.

Spinothalamic Tract

The STT is generally regarded as the most important pathway for transmission of nociceptive impulses in humans and subhuman primates. Evidence for this conclusion has come from clinical and behavioral effects of lesions that interrupt the anterolateral quadrant of the spinal cord. After such a lesion, humans cannot experience pain in areas below the segmental level of the lesion on the contralateral side of the body. Responses to noxious stimuli are diminished in the contralateral side of monkeys. In addition, surgical section of the anterolateral quadrant also interrupts the spinoreticular and most of the spinomesencephalic tracts (318). On this basis, these separate tracts are sometimes collectively known as the spinal lemniscus or anterolateral fasciculus.

Cells of Origin of the Spinothalamic Tract

The cells of origin of the STT have been localized by examining (a) the chromatolytic reaction after section of the anterolateral quadrant of the spinal cord, (b) retrograde labeling of spinal cells with HRP or other dyes injected into the thalamus (319), and (c) antidromic activation of spinal neurons by stimulating electrodes situated in the thalamus. These studies have unequivocally localized the cells of origin of the STT in the monkey, cat, and rat. Although comparably definitive experimental evidence for cells of origin of the human STT is lacking, available evidence is consistent with a pattern similar to that of the monkey. On the basis of HRP labeling of STT cells in the sacral segment of the monkey spinal cord, Willis and associates (38) estimated that there were as many as 2,500 STT cells on each side of the lumbar cord and presumably several thousand more at the rostral levels of the cord. The STT is more prominent in the human than in the monkey, because of the proportionately greater size of the neospinothalamic tract (nSTT) (Fig. 4-40); thus it is likely that there are more than 5,000 STT cells in the human (2).

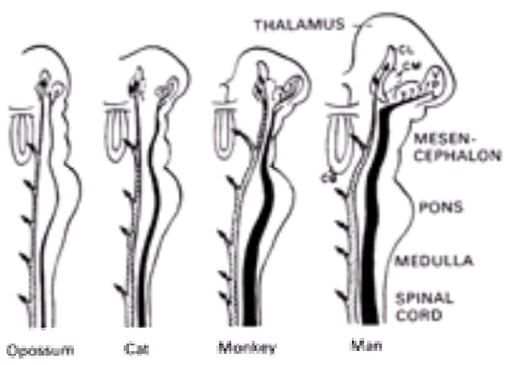

Figure 4-40. Schematic representation of the size, course, and distribution of the spinothalamic system in the opossum, cat, monkey, and humans. The neospinothalamic tract is shown in black, and the paleospinothalamic tract is shown stippled. (Modified from Mehler WR. Some observations on secondary ascending afferent systems in the central nervous system. In: Knighton RS, Dumke PR, eds. *Pain*. Boston: Little, Brown, 1966:11– 32.)

STT neurons exist throughout the entire gray matter except for the motoneuron pool (Fig. 4-41), but an obvious concentration occurs in laminae I, IV through VI, and, to a lesser extent, IX and X (6,38,41). Most of the STT cells project to the contralateral thalamus. Willis and associates (38) found in monkey that 95% of the STT cells labeled in the lumbosacral enlargement came from an injection in the region of the contralateral ventral basal complex, and 90% of the cells labeled from the region of the intralaminal complex were contralateral to the injection site. However, they also found that 26% of STT cells in the sacral cord were ipsilateral to the injection site and appeared to have a proprioceptive function. Moreover, STT cells in laminae VII and VIII of the upper cervical segments projected either ipsilaterally or contralaterally. Of the STT axons that project contralaterally, most cross within one or two segments and pass through the ventral white commissure to the opposite ventrolateral funiculus, at which they ascend rostrally as the lateral STT. This one- or two-segment delay in decussation explains the clinical finding that the uppermost level of analgesia after anterolateral cordotomy (section of the STT) is one or two levels caudal to the cordotomy site.

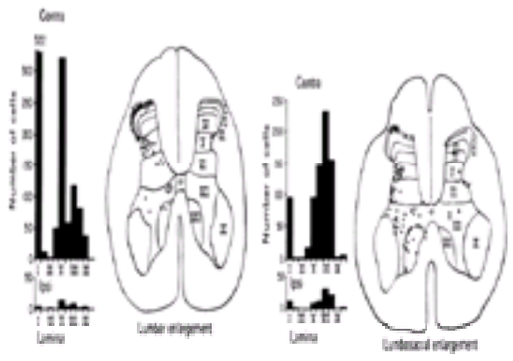

Figure 4-41. The locations of spinothalamic tract cells labeled with horseradish peroxidase transported retrogradely from the lateral thalamus **(A)** and from the medial thalamus **(B)** to the lumbosacral enlargement of the spinal cord in the monkey. On the left side of each diagram are histograms showing the number of spinothalamic tract cells in different laminae of the cord both contralateral (Contra) and ipsilateral (Ipsi) to the injection site. The diagrams are composite plots of all labeled cells found in 15 alternate serial sections. (Modified from Willis WD, Kenshalo DR, Leonard RB. The cells of origin of the primate spinothalamic tract. *J Comp Neurol* 1979;188:543–573.)

As mentioned previously, the axons of most STT cells in laminae I and V project directly to the ventrobasal and the posterior thalamus, where they synapse with cells that project to the somatosensory cortex (Fig. 4-42; see Chapter 5). This is often referred to as the nSTT (50,318,320,321,322 and 323). The cells in laminae IV through IX, as well as a subset of lamina I cells (324,325), project to nuclei of the reticular formation of the medulla, pons (spinoreticular tract), and the midbrain (spinomesencephalic tract), including the PAG, to the hypothalamus, or to the medial and intralaminar thalamic nuclei. These latter STT axons synapse with neurons

that connect with limbic forebrain structures via complex circuits and also with diffuse projections to other parts of the brain (see Fig. 4-42). This is often called the *paleospinothalamic tract* (pSTT) (65,326). Some STT cells form collaterals and project to both lateral and medial thalamus.

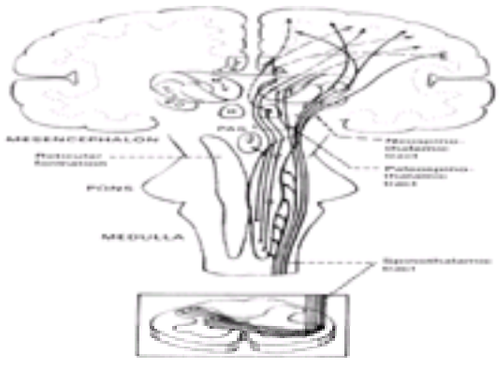

Figure 4-42. Simple diagram of the course and termination of the spinothalamic tract. Most of the fibers cross to the opposite side and ascend to the brain stem and brain, although some ascend ipsilaterally. The neospinothalamic part of the tract has cell bodies located primarily in laminae I and V of the dorsal horn, whereas the paleospinothalamic tract has its cell bodies in deeper laminae. The neospinothalamic fibers ascend in a more superficial part of the tract and project without interruption to the caudal part of the ventroposterolateral thalamic nucleus (VPLc), the oral part of this nucleus (VPLo), and the medial part of the posterior thalamus (POm). In these structures they synapse with a third relay of neurons, which project to the somatosensory cortex (SI, SII, and retroinsular cortex) (*solid lines*). Some of the fibers of the paleospinothalamic tract pass directly to the medial/intralaminar thalamic nuclei, and others project to the nuclei and the reticular formation of the brain stem and thence to the periaqueductal gray (PAG), hypothalamus (H), nucleus submedius, and medial/intralaminar thalamic nuclei. Once there, these axons synapse with neurons that connect with the limbic forebrain structure (LFS) via complex circuits and also send diffuse projections to various parts of the brain.

Axonal Distribution of the Spinothalamic Tract

Kerr (5) and Kerr and Lipman (318) examined the fiber composition of the lateral STT in the spinal cord of monkeys after midline myelotomy and found no unmyelinated axons. They concluded that C fiber nociceptive input from peripheral nerves must be transmitted onto the brain via myelinated fibers, although the presence of unmyelinated fibers could not be ruled out. When the larger fibers of the spinocerebellar tract (concentrated mainly in the periphery of the cord) were omitted, the fiber caliber spectrum ranged from 1 µm to 11 µm (318). However, most of the fibers had diameters between 3 µm and 6 µm with a peak concentration of 4 µm. These data confirmed those of an earlier study by Glees (321), who found that 60% of STT axons at the level of the superior colliculus had diameters between 2 µm and 4 µm, 35% had diameters between 4 µm and 6 µm, and only 5% had diameters between 8 µm and 10 µm. The spinoreticular and spinomesencephalic fibers are 1 µm to 5 µm in diameter (327). In the anterolateral quadrant, Bing (320) found that the thinner fibers are distributed more medially and the larger fibers more toward the periphery of the cord (318,322,328).

A number of studies of conduction velocity also have been carried out. One group found conduction velocities of 18 m per sec to 58 m per sec with an average of 36 m per sec; another reported conduction velocities of 7 m per sec to 74 m per sec with an average of 40.3 m per sec, and one reported an average rate of 37 m per sec (5). In monkeys, Albe-Fessard and associates (323) found that the conduction velocities of axons whose cell bodies are in lamina V range from 1 m per sec to 100 m per sec (with the majority at 50 m per sec to 60 m per sec, and they identified these neurons as part of the nSTT that projects without synapse to the ventroposterolateral nucleus of the thalamus. They further reported that the monkey nSTT is at least 20% composed of axons from lamina V cells. Mayer and Price (329) studied the physiologic properties of the anterolateral quadrant fibers in monkey and correlated these with studies in humans. They noted that lamina I nociceptive cells had a higher threshold, slower conduction velocity, and longer refractory period than cells in laminae IV through VI. They concluded that NS neurons in lamina I give rise to slow-conducting axons and the WDR neurons in laminae IV through VI give rise to faster conducting axons.

In the human (and monkey), as the STT ascends cephalad in the spinal cord, it continues to grow in size by the addition of fibers to its anteromedial borders. This results in a somatotopic layering or lamination: Axons arising from cells in the sacral region are outermost (dorsolaterally), those of cells in the lumbar and thoracic regions are more medial, and those from the cervical region are innermost. Some variation and significant overlap occur among the laminae from various levels. This lamination continues in the medulla, pons, and midbrain (Fig. 4-43). The course of the STTs (and the spinoreticular and spinomesencephalic tracts) through the spinal cord, brain stem, and their termination has been demonstrated in humans and monkey by anatomic studies using anterograde degeneration techniques (see Fig. 4-44, Fig. 4-45, Fig. 4-46, Fig. 4-47 and Fig. 4-48, including detailed descriptions in the legend) (318,328). In the spinal cord, white matter nociceptive ascending tracts are primarily intermingled in the anterolateral fasciculus and are situated medial to the anterior spinocerebellar tract (see Fig. 4-45). In its course through the brain stem, the STT gives off collaterals to nuclei and to the reticular formation, particularly to the nucleus cuneiformis and the PAG. At the rostral portion of the mesencephalic-diencephalic transition area, the STT separates into a medial component that projects to the medial thalamic region and a lateral component that projects to the ventrobasal and posterior thalamus (see Fig. 4-44, Fig. 4-46C, Fig. 4-47, and Fig. 4-48). Mehler and associates (106,107 and 108) pointed out that the medial portion is composed of fine fibers, and comparative studies on lower mammals indicate that these fibers represent a paleospinothalamic pathway distinct from the laterally deviating nSTT. In the thalamus (see Chapter 5), axons of neurons with cell bodies in lamina I project to both the caudal part of the ventroposterolateral nucleus (VPLc) (which also receives fibers from the medial lemniscus) and the oral part (2,5,41,322,330,331), as well as medial nuclei such as the ventral medial nucleus and nucleus submedius. The STT endings in the VPLc are in small patchlike zones, which Mehler (322) called *bursts* (see Fig. 4-46C). Neurons in laminae IV and V terminate in the medial part of the posterior complex and in the VPLc. Neurons in laminae VI through VIII terminate in the medial and the intralaminar thalamic nuclei (318,322,330,331 and 332) (see Fig. 4-46C). Spinothalamic terminations in the VPLc are somatotopically organized, whereas those in other thalamic nuclei are not (see Chapter 5 for more detailed discussion).

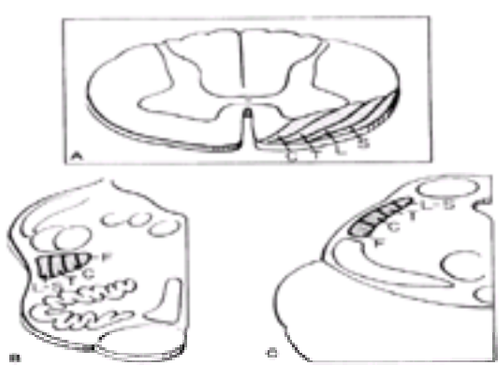

Figure 4-43. Schematic diagrams showing cross-section of the spinal cord, medulla, and midbrain, depicting the laminar arrangement of the ascending tracts in the anterolateral fasciculus in the upper part of the cervical spinal cord **(A)** and the anterolateral fasciculus and trigeminothalamic tract in the medulla **(B)** and midbrain **(C)**. **A:** In the cervical spinal cord the sacral segments (S) are most superficial, those from the cervical cord (C) are most medial and slightly anterior, and those from the thoracic (T) and lumbar (L) cord are in between. **B:** The section through the lower medulla shows that the fibers from the lower limb (L-S) are most superficial, followed by those of the trunk (T), arm (C), and finally the face (F), which is most medial. **C:** Diagram showing somatotopic pattern in the midbrain. (Modified from Brodal A. *Neurological anatomy in relation to clinical medicine*, 3rd ed. New York: Oxford University Press, 1981, and based on data by Walker, AE.)

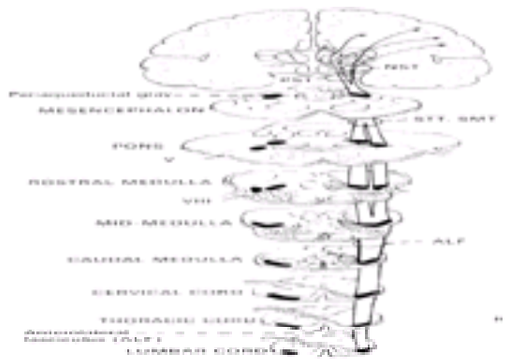

Figure 4-44. Diagram of the organization of the anterolateral fasciculus in the spinal cord, brain stem, thalamus, and brain. Note the separation into medial and lateral parts in the medulla and pons. This figure provides an overview of ascending nociceptive systems depicted in more detail in Figure 4-45 through Figure 4.48. (ALF, anterolateral fasciculus; NST, neospinothalamic tract; PST, paleospinothalamic tract; SMT, spinomesencephalic tract; STT, spinothalamic tract.)

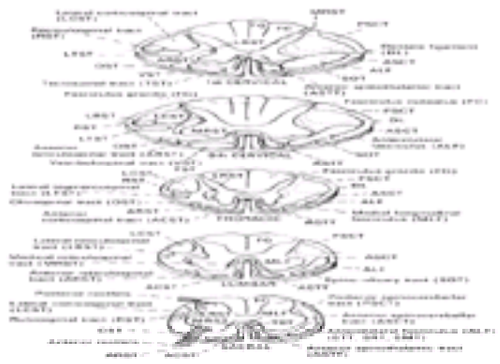

Figure 4-45. Diagram of the organization of the anterolateral fasciculus (ALF), composed of the spinothalamic (STT), spinoreticular (SRT), and spinomesencephalic (SMT) tracts in the spinal cord, and the relationship of the ALF to other important structures. The ascending tracts are emphasized on the right side and the descending tracts on the left side. As it ascends, the ALF becomes progressively larger, the largest part being in the upper cervical region. This is not only because the spinothalamic tract continues to add axons anteromedially, but also because there are more SRT cell bodies (and therefore axons) in the cervical enlargement than in the lumbosacral enlargement. Throughout the course of the ALF in the spinal cord the three nociceptive pathways are situated medial to the anterior (ventral) spinocerebellar tract, lateral to the anterolateral and anterior horns, and posterolateral to the spino-olivary tract. The anterior spinothalamic tract (ASTT), which may be an alternate nociceptive pathway, is separate from the three tracts in the ALF and is located deep in the ventral funiculus (not superficial, as sometimes written). Note the relation of various descending fibers to the ALF. Because a cordotomy lesion in the upper thoracic or cervical segments usually extends from the dentate ligament laterally to a few millimeters of the anterior sulcus medially (343), the ASTT and some of these descending tracts are likely to be interrupted with this operation. In the cervical region the ALF is shaped as a somewhat flat triangle with the apex medial and the base lateral. At successively higher cervical levels there is a gradual dorsolateral shift of the ALF.

Figure 4-46. Organization and course of the spinothalamic (STT), spinoreticular (SRT), and spinomesencephalic (SMT) tracts, collectively labeled the anterolateral fasciculus (ALF) in the medulla, pons, midbrain, and thalamus in humans (based on data in references 65, 157, and 322). On the right are emphasized the course of the ALF and its relationship to important structures and the termination of the tracts into the most important nuclei (shaded and named on the left). Large dots represent fibers of passage, and the thin lines depict projections to nuclei in which they terminate. The distribution and areas of terminations are not depicted on the left for the sake of clarity. **A:** Organization and course of the ALF in the medulla and caudal pons. 1. In the caudal medulla at the level of the pyramidal decussation, the dorsolateral shift of the ALF becomes progressively greater owing to withdrawal of the lateral corticospinal fibers into the pyramids. In this part of the medulla some SRT fibers course dorsomedially and terminate in nucleus medulla oblongata, nucleus supraspinalis, nucleus retroambiguus, and the commissural nucleus. 2. At midmedullary level, the inferior olivary nucleus causes a further dorsolateral displacement and flattening of the ALF triangle. At this level the more superficially placed STT fibers give collaterals, and a massive number of SRT fibers terminate medially in nucleus reticularis lateralis (NRL). The SRT fibers course medially and ascend between the NRL and the dorsal accessory olivary nucleus. Some of the medially coursing fibers terminate in nucleus gigantocellularis, nucleus Roller, nucleus interfascicularis hypoglossi, nucleus parvocellularis, nucleus raphe obscuruus, and nucleus paragigantocellularis lateralis and dorsalis (not shown in the diagram). 3. At the level of the rostral medulla and caudal pons the ALF in humans can be divided into a lateral superficial STT component and a medial SRT component more objectively than at any other level in the brain stem (322). This separation is caused by the intervention of the facial nucleus and superior olivary nucleus in the course of the ascending fibers. The fibers of the medial SRT lie ventral to the parvocellular reticular nucleus, and some terminate in the rostral pole of nucleus gigantocellularis, whereas others terminate in nucleus raphe magnus. **B:** Organization and course of the ALF in the pons and midbrain. 1. At the pontine level the medial SRT fibers lie ventral to the trigeminal motor nucleus, and its fibers course through the nucleus subcoeruleus. Many SRT fibers terminate in this nucleus and in nucleus pontis centralis caudalis and nucleus raphe pontis. The lateral component of the ALF (STT, SMT) lies ventral to the root of the trigeminal nerve, and its fibers pass through, and some terminate in, the processus tegmentosus lateralis of the pontine gray matter. More rostrally, the SRT fibers terminate in nucleus pontis centralis oralis and the subcoeruleus complex. 2. At the level of the isthmus, the ALF (composed of the SMT and STT) is dorsal to the medial lemniscus, ventrolateral to the lateral lemniscus, and lateral to the superior cerebellar peduncle. Fibers are given off to the nucleus pontis centralis oralis and nucleus raphe dorsalis. 3. In their course through the mesencephalon, the SMT fibers course medially and dorsally to reach their terminal zones, which include the subnucleus lateralis of the periaqueductal gray, nucleus intercollicularis, nucleus cuneiformis, the deep layer of the superior colliculus, nucleus Darkshevich, and nucleus Edinger-Westphal. **C:** Course and termination of the spinothalamic tract at the mesodiencephalic junction and in the thalamus. 1. As the STT continues rostrally through the mesodiencephalic junction (lower panel), it is surrounded by nucleus limitans on its dorsomedial side, the pulvinar dorsally, the medial geniculate body on its dorsolateral side, and the medial lemniscus ventrally. At this juncture some STT fibers end in the periaqueductal gray, in nucleus Darkshevich, the magnocellular part of nucleus medial geniculate body, and the superior geniculate nucleus (not shown). Just rostral to this level, at the caudal pole of the medial geniculate body, the STT fibers separate into a smaller medial component made up of thin fibers called the *paleospinothalamic tract*, and a much larger lateral component made up of thick fibers, the neospinothalamic tract. 2. The middle panel shows a frontal section of the caudal diencephalon and depicts the projection of STT fibers and medial lemniscus to the ventroposterolateral nucleus and the central lateral nucleus of the thalamus (not shown). Mehler includes in the central lateral nucleus the dorsolateral part of nucleus parafascicularis, the pars densocellularis, multiformis of the dorsomedial nucleus, and the entire central lateral nucleus (322). 3. The uppermost panel depicts terminal areas (fine stippling) and the fibers of passage (coarse stippling) of the STT in the ventroposterolateral nucleus and the other thalamic nuclei. Note the patchlike or burst pattern of the STT in the ventroposterolateral nucleus (see also Fig. 4-48 and Chapter 5). [The lower two panels were developed from data by Mehler WR, Feferman ME, Nauta WJN. Ascending axon degeneration following anterolateral cordotomy. An experimental study in the monkey. *Brain* 1960;83:718; and from Mehler WR: (a) The anatomy of the so-called “pain tract” in man: an analysis of the course and distribution of the ascending fibers of the fasciculus anterolateralis. In: French JD, Porter RW, eds. *Basic research in paraplegia*. Springfield, IL: Charles C Thomas, 1962:26–55; (b) Some observations on secondary ascending afferent systems in the central nervous system. In: Knighton RS, Dumke PR, eds. *Pain*. bilaterally.]

Figure 4-47. **A,B:** Sagittal sections of the brain stem and thalamus illustrating the course of ascending fibers and degeneration of the ALF after high cervical cordotomy (*inset*) in the monkey. Coarse stipple indicates degenerating fibers of passage, and fine stipple depicts areas of terminal degeneration. The most important structures related to the course of the neospinothalamic tract and paleospinothalamic tract are labeled, and their abbreviations are superimposed on the structures. **A:** Medial sagittal section depicting course and termination of the spinoreticular system. **B:** A more lateral section showing the more peripherally coursing spinothalamic tract. Terminal degeneration in the ventroposterolateral nucleus lies lateral to the plane shown in this figure. **C:** A horizontal composite diagram with a section through the dorsal thalamus and midbrain superimposed on a section through the pons and medulla, depicting the course and termination of the anterolateral fasciculus after thoracic (T6) cordotomy (*inset*) in the monkey. The superficial part of the anterolateral fasciculus passes out of the plane of section at the level of the lateral reticular nucleus (LR), but reappears at the level of the nucleus processus tegmentus lateralis (PTS). The spinothalamic component appears just lateral to the nucleus of the inferior colliculus (Ci) terminating in bursts in VPL and also in central lateral (CL) and parts of the dorsomedial (DM) and parafascicular (Pf) thalamic nuclei. (From Mehler WR, Feferman ME, Nauta WJN. Ascending axon degeneration following anterolateral cordotomy. An experimental study in the monkey. *Brain* 1960;83:718–750, with permission.)

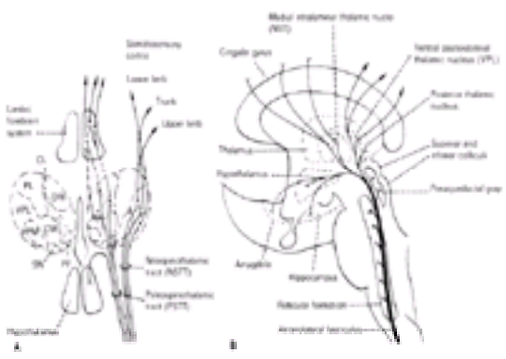

Figure 4-48. Schematic diagram showing the course and termination of the spinothalamic tract in the upper brain stem and thalamus. **A:** Coronal section showing the division of the system into the paleospinothalamic tract (pSTT) and neospinothalamic tract (nSTT). The nSTT terminates in the ventroposterolateral thalamic nucleus (VPLc), the oral part of this nucleus (VPLo), and the medial part of the posterior thalamus, where its fibers synapse with neurons that go to the somatosensory cortex in a somatotopically organized way. The pSTT projects to the reticular formation, the periaqueductal gray, the hypothalamus, nucleus submedius, and the medial and intralaminar thalamic nuclei [centromedial nucleus (CM), dorsomedial nucleus (DM), parafascicular nucleus (PF)]. There are also some spinothalamic terminals in parts of the paraventricular, paracentral, central medial, and reuniens thalamic nuclei. Some neurons, located primarily in lamina I, have a dense projection to the nucleus submedius. **B:** Sagittal section showing termination of nSTT and pSTT. (CL, central lateral; PL, pulvinar; SN, substantia nigra; VPM, ventral posteromedial nucleus.)

Physiology of the Spinothalamic Tract: Excitation

Spinothalamic projecting neurons are classified on the basis of their laminar location, response characteristics, and morphology. The response properties of these dorsal horn cells were discussed previously but are repeated here as specific to STT projecting neuron subtypes.

1. Neurons that respond uniquely to high-intensity stimuli, the NS neurons, are characterized by slowly adapting responses to either noxious pinch or heat and are located primarily in lamina I. Such cells have been found to have slower conduction velocities than other lamina I STT cells (1.8 m/sec in cats) (333) and as already mentioned in this chapter, Craig and colleagues have reported that such cells are often fusiform in shape (see Fig. 4-9) (44). The relatively recent use of noxious cold in animal pain studies (such studies, including the cold pressor test, had been used in human pain studies for years) has identified new categories of functionally discrete spinothalamic projecting cells that would otherwise have been labeled NS.
2. The so-called HPC lamina I STT projecting cells differ from the NS cells specifically in their activation by noxious cold. HPC cells also have been reported to have faster conduction velocities (approximately 4 m/sec) (333) than NS cells and have multipolar cell bodies (44). Like NS cells, HPC cells project to nucleus submedius and the ventral aspect of the ventrobasal complex of the thalamus (334) and their functional differences from NS cells in the awake behaving animal is unclear.
3. A third class of lamina I STT cell, the *cold* cell, is named for its activation by cooling (thermal stimuli less than body temperature) and is silent or inhibited by heat. These cells are primarily pyramidal in shape (see Fig. 4-9) (44), and although having conduction velocities similar to that of HPC cells (approximately 5 m/sec) (333), project to more dorsomedial locations in the thalamic ventrobasal complex (334). The importance of these cells in nociception seems minimal because they are most sensitive to innocuous or only mildly noxious cold temperatures. Nonetheless, these cells show increased responses to cold after morphine (335). Moreover, Craig and Bushnell (336) demonstrated a likely role for cold cells in mediating the thermal grill illusion described by Thunberg in 1896. In this illusion, simultaneous exposure to a grid composed of alternating cool and warm bars is perceived as hot. These investigators propose an inhibitory effect of cold cell activity on HPC-mediated thermal pain perception, presumably at a thalamic level (see Chapter 5). Their observations may explain not only the illusion but may underlie why cold pain is normally perceived as hot.
4. WDR (multireceptive) neurons respond in a frequency-dependent fashion to stimuli of increasing intensity and receive convergent input from cutaneous, visceral, and muscle afferents. They display a sustained discharge to pressure, a rapid adaptation to light tactile input, and they also respond to thermal and chemical stimuli in the noxious range. These WDR neurons are located primarily in lamina V, but also in lamina I and constitute one-third of STT cells (28).
5. Laminae IV and V contain STT neurons that respond only to innocuous tactile and thermal stimuli (low-threshold mechanoreceptors and low-threshold thermoreceptors). These constitute approximately 20% of the neurons in the STT (28).
6. Neurons situated in laminae IV and V are responsive to proprioceptive input.

In addition to transmission of nociception and temperature, the STT clearly carries information pertinent to tactile pressure and proprioception. Moreover, STT projecting cells are obviously classified somewhat arbitrarily as a function of whatever stimuli an investigator decides to use in studying a given cell or group of cells in a study. For example, the noxious stimuli that activate the STT include not only mechanical pinch and noxious heat but also the rarely studied noxious cold. Furthermore, few experiments thus far have systematically looked at STT cell responses to chemical noxious stimulation. Such experiments will likely result in still more functional classifications of STT projecting cells based on, for example, capsaicin, neurokinin, or cytokine differential responsiveness (see Chapter 3). In addition, apart from these cutaneous stimuli, muscle and visceral noxious stimuli also can activate STT cells (41). Finally, STT cells are well known to demonstrate synaptic modulation described previously for dorsal horn neurons in general. Whether all STT cell types show the same degree and neuropharmacology of such modulation is entirely speculative at present, but seems doubtful.

STT neurons that project to the VPLc are, in general, somatotopically organized and have small receptive fields. STT neurons that project to the medial thalamus, on the other hand, do not show this same somatotopic organization and have large receptive fields on much or all of the surface of the body and face (332). The receptive fields, apart from that on the ipsilateral limb, depend on a supraspinal loop believed (2) to exist in the reticular formation because stimulation in the reticular formation produces a powerful excitation of these, primarily WDR, cells. Giesler and colleagues (330) reported that nearly two-thirds of STT neurons projecting exclusively to the medial thalamus are excited only by noxious stimuli and are therefore NS neurons. In contrast to other NS neurons, however, these have large receptive fields, often including the skin of more than one limb, or the entire surface of the body. STT cells that branch and supply the VPL and the medial thalamic central lateral nucleus have receptive fields like those of cells that project only to the VPL (2). STT cells with small nociceptive fields may be involved in sensory-discriminative aspects of pain perception, whereas larger nociceptive fields are more suited for a role in the motivational-affective aspects of pain (41).

Physiology of the Spinothalamic Tract: Inhibition

In addition to excitatory receptive fields, STT cells often have inhibitory receptive fields. Inhibition is sometimes caused by activation of sensitive mechanoreceptors in the same region, but, more commonly, it is produced only by noxious stimuli delivered to areas remote from the excitatory field (2). Such inhibitory fields are more readily identified for WDR than for NS neurons. Although these effects may appear to be similar to those described as diffuse noxious inhibitory controls (337) (see Environmental Influences Modulating Nociception , later in this chapter), they differ in that the inhibition does not usually outlast stimulation and much of the inhibition remains after the spinal cord is transected. Nonetheless, such segmental mechanisms of STT neuronal inhibition have been proposed as mediating several clinical pain therapies, including transcutaneous electrical nerve stimulation (TENS), acupuncture, and dorsal column stimulation. The practice of stimulating or irritating the skin to provide relief of pain dates back to prehistoric times. Rubbing, massage, vibration, cupping, and even painful electrical stimulation of the skin as a means of relieving pain have stood the test of time. The mechanism of their efficacy has been more difficult to explain than their time-honored efficacy itself. Neither presumed peripheral mechanisms (e.g., increases in blood flow leading to enhancements in tissue repair) nor the proposed spinal gate of Melzack and Wall (see Chapter 1) has thus far collected much experimental evidence to support them. These mechanistic shortcomings may point to the limitations of such methods in acute pain models and highlight the complexity of counterirritation phenomena.

One such phenomenon, TENS, is an excellent example of a therapy that works well for certain patients and certain pains (see other chapters for fuller clinical detail). TENS produces analgesia that is not reversible by naloxone (thus, presumably does not involve endogenous opioids) when stimulation is given at high-frequency and low-intensity parameters. In contrast, stimulation using high intensity and low frequency (as used in acupuncture) produces analgesia that is partly reversible by naloxone and thus may involve these opioids. In monkeys, however, Willis' group (41) found that high-intensity, low-frequency TENS produced prolonged inhibition of STT neurons that was not affected by naloxone. They also demonstrated that the inhibition was not caused by peripheral nerve conduction failure. They concluded that inhibition of STT cells may mediate TENS analgesia but that the naloxone-reversible analgesia seen in humans is at another level of the nervous system than the STT. On the other hand, the same group did observe naloxone-reversible STT inhibition from repetitive stimulation of a peripheral nerve in a monkey (41,338). Because the inhibition occurred and was prolonged in animals with transected spinal cords, the mechanism is segmental. This inhibition was most effectively evoked by stimulation of A-d fibers, although there was also a contribution from A-b fibers. In short, although mechanisms of TENS' nociceptive inhibition can be demonstrated in animal models, and specifically on STT cells, whether these mechanisms are identical to those activated by TENS in the clinic is not clear.

Dorsal column stimulation has been suggested in some studies to inhibit nociception, primarily by activating dorsal roots rather than the dorsal columns (339). In either event, this therapeutic modality may also *close the pain gate* by tapping into intrinsic spinal inhibitory circuitry, activating large-diameter primary afferents terminating in the dorsal horn either orthodromically or antidromically. Because inhibitory effects by dorsal column stimulation on WDR neurons have been reported in animals with transected spinal cords, segmental spinal mechanisms appear to be sufficient for such inhibition (338). The neuropharmacology of dorsal column stimulation analgesia appears independent of endogenous opioids. It is not sensitive to naloxone. On the other hand, inhibition of nerve injury–induced allodynia by dorsal column stimulation relies on GABA release, consistent with other antiallodynic effects of GABA. The segmental analgesic effects seen on STT cells in animal models of therapies such as dorsal column stimulation or TENS should not be interpreted as ruling out a role for supraspinal, descending, or both modulatory roles in mediating these phenomena in the clinic (see Chapter 93).

Ventral Spinothalamic Tract

Most of the studies discussed previously refer to the lateral STT, although this distinction is rarely demonstrated experimentally. Kerr (340), believing that, like the lateral STT, the ventral or anterior STT might also be involved in transmission of nociceptive information, transected the ventral funiculus in the cervical area of macaque monkeys. By using an anterior transvertebral approach he was able to avoid damage to the fibers of the anterolateral quadrant and, in particular, to those of the lateral STT whose most medial axons lie among and slightly medial to the intra-axial ventral roots. On the basis of the pattern of degeneration, he concluded that the ventral STT is considerably smaller than the lateral STT, and its fibers appear to be distributed throughout the ventral funiculus, as determined by comparison of complete with superficial and deep lesions (see Fig. 4-45). Subsequent work suggests that the cells of origin of the ventral STT are located in laminae I, IV, V, VI, and VII (341). Although it was formerly believed that the ventral STT mediated only touch and pressure, evidence suggests that ventral STT axons of cells activated by tactile stimulation are intermingled with axons of cells that respond only to high-threshold stimulation (342).

Kerr (5,340) pointed out that although the ventral STT shares some of the structural features of the lateral STT, including a significant projection to nucleus cuneiformis in the mesencephalon, its connection to the brain stem and its course in the pons are different, and it should therefore be considered a separate tract. Kerr emphasized that the evidence that the ventral STT has a role in nociception is indirect, derived from its projection to cell groups that are known to be involved in pain mechanisms, including the ventrolateral PAG and the intralaminar nuclei of the thalamus. In carrying out cordotomy it is usually necessary to extend the incision from the dentate ligament to within 2 mm of the anterior sulcus (343), likely interrupting most, if not all, of the ventral STT in addition to the lateral STT.

Spinoreticular Tract

The reticular formation almost certainly plays an important role in pain mechanisms. The primary function of this loose collection of medullary, pontine, and mesencephalic nuclei triggers arousal to appropriate stimuli. Thus, it is probable that reticular activity accompanies pain, perhaps triggering motivational and affective responses to nociception as well as influencing somatic and particularly autonomic nociceptive reflexes. The spinoreticular tract is the most direct input from the spinal cord to the medullary and pontine reticular formation and indeed many spinoreticular tract neurons identified by antidromic activation are nociceptive (2).

The location of the cells of origin of the spinoreticular tract in the human is unknown. Monkey HRP studies indicate that spinoreticular tract projection cells are located predominantly in laminae VII and VIII, with some cells also scattered in other laminae, including I, V, and X (2,344,345) (Fig. 4-49). More spinoreticular cell bodies exist in the cervical than in the lumbosacral enlargement, the highest concentration being in the uppermost cervical segments. In monkey the number of spinoreticular tract cells is similar to the number of STT neurons (51,344), and the axons of spinoreticular tract are 1 µm to 5 µm in diameter (327), and thus are the same size as the thinner fibers of the STT. Approximately one-half of the spinoreticular tract neurons in the cervical enlargement project ipsilaterally and the other half project contralaterally (344,345), whereas in the lumbosacral enlargement more cells project contralaterally than ipsilaterally (318). Giok (327) estimated that the spinoreticular tract constitutes approximately 20% of all the fibers in the anterolateral quadrant and these axons are also likely damaged by cordotomy.

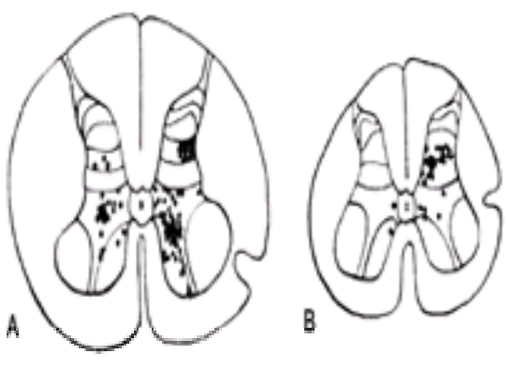

Figure 4-49. Location of spinoreticular tract cells labeled with horseradish peroxidase transported retrogradely from the medial reticular formation in the pontomedullary region of the monkey. **A:** Cross-section of the cervical enlargement. **B:** Cross-section of the lumbar enlargement. In the cervical enlargement slightly more cells are located contralaterally than ipsilaterally, but in the lumbar cord virtually all of the cells are located contralaterally (see Fig. 4-50). (Modified from

Kevetter GA, Haber LH, Yezierski RP, et al. Cells of origin of the spinoreticular tract in the monkey. *J Comp Neurol* 1982;207:61–74.)

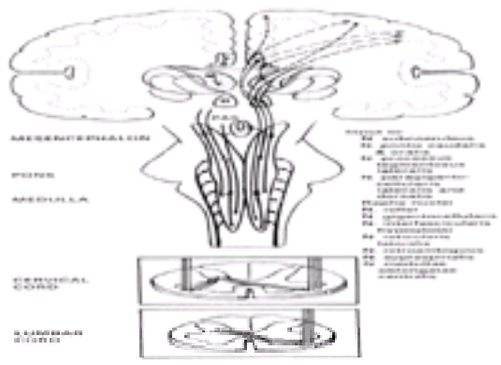

Figure 4-50. Schematic illustration showing the origin, course, and termination of the spinoreticular tract. Note its projection to the numerous nuclei and reticular formation of the medulla and pons (also see Fig. 4-46A for a description of the course and termination of the spinoreticular tract). (H, hypothalamus; LFS, limbic forebrain structure; MIT, medial/intralaminar nuclei; PAG, periaqueductal gray.)

In the spinal cord and brain stem the spinoreticular tract accompanies the STT and spinomesencephalic tract, taking a medial position to the other two tracts in the medulla and pons (346). Indeed some STT cells send collaterals to reticular nuclei. Figure 4-50 is a schematic depiction of the origin, course, and termination of the spinoreticular tract. No somatotopic organization has been reported for the spinoreticular tract. Spinoreticular projections terminate in nuclei of the caudal medulla, including nucleus superspinalis and the more rostral lateral reticularis, gigantocellularis, paragigantocellularis, parabrachial region, and nuclei pontis caudalis and oralis. Many of these nuclei play an important role in descending nociception modulatory pathways. Of particular importance in this regard are spinoreticular tract fibers from lamina I that ascend rather diffusely in the lateral funiculus of the spinal cord to synapse with a number of noradrenergic cell groups in the medulla and pons. Thus, the spinoreticular tract's role in nociception modulation is not only in its connections to more rostral brain regions stimulating arousal, but in its connections to cells thought important in mediating descending modulation.

Spinomesencephalic Tract

The spinomesencephalic tract is sometimes classified with the spinoreticular tract. Certainly, many of the aforementioned comments regarding the possible role of the medullary and pontine reticular formation in pain may also apply to the midbrain reticular formation.

Most of the spinomesencephalic tract cell bodies are in laminae I and V, but some are scattered in other laminae (2,51). Hylden and colleagues (347), in the cat, found that the majority of cell bodies of spinomesencephalic tract neurons were concentrated in lamina I and most were NS neurons (Fig. 4-51). Approximately 60% to 75% of these cells are contralateral to the side of the midbrain to which they project, and the rest are ipsilateral (347). Like the spinoreticular tract, the spinomesencephalic tract consists of relatively thin fibers (1 µm to 5 µm) (340) with conduction velocities of approximately 7 m per sec (2,347). Although human and monkey studies indicate that spinomesencephalic tract axons ascend in the anterolateral spinal cord and accompany the STT as far as the isthmus (328), McMahon and Wall and others found in rat, and Hylden and colleagues found in cat, that lamina I spinomesencephalic tract cells ascend in the contralateral dorsolateral funiculi (347). The spinomesencephalic tract cells in lamina V and in deeper laminae are scattered, and their axons ascend in the ventral and ventrolateral funiculi (347).

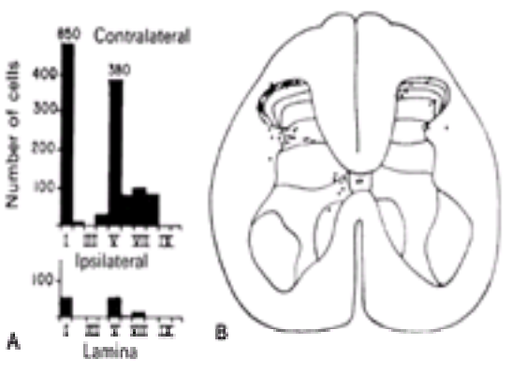

Figure 4-51. The location of spinomesencephalic tract cells in the various laminae of the lumbosacral enlargement after an injection of horseradish peroxidase into the midbrain. **A:** Histograms showing the number of cells in various laminae of the cord both contralateral and ipsilateral to the injection. **B:** Composite plot showing distribution of all labeled cells found in 15 alternate serial sections. (Modified from Willis WD, Kenshalo DR, Leonard RB. The cells of origin of the primate spinothalamic tract. *J Comp Neurol* 1979;188:543–573.)

The spinomesencephalic tract courses through the medulla and pons with the STT and spinoreticular tract. At the level of the mesencephalon, spinomesencephalic tract fibers course dorsomedially and terminate in the subnucleus lateralis of the PAG, in the nucleus intercolliculus (between the inferior and superior colliculi), nucleus cuneiformis, the superior colliculus, the nucleus Darkshevich, anterior and posterior pretectal nuclei, red nucleus, interstitial nucleus of Cajal, and the nucleus Edinger-Westphal (6,322,331,347) (Fig. 4-52). Spinomesencephalic projections are somatotopically organized with projections from more caudal parts of the body terminating more caudally in the midbrain (41).

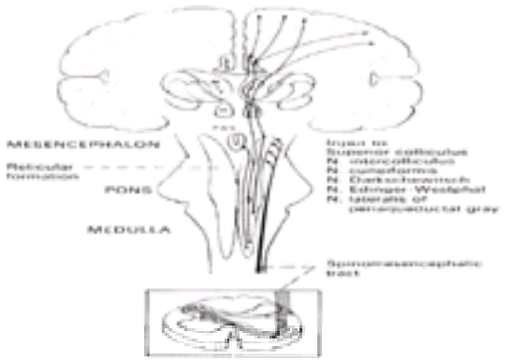

Figure 4-52. Diagram of the origin, course, and termination of the spinomesencephalic tract in primates. Note its projections to the nuclei and reticular formation of the midbrain (see Fig. 4-46B for detailed description of the course and termination of the SMT). (H, hypothalamus; LFS, limbic forebrain structure; MIT, medial/intralaminar nuclei; PAG, periaqueductal gray.)

Electrophysiologic and HRP studies in rat and cat suggest that spinomesencephalic tract neurons are largely nociceptive (347). In humans, electrical stimulation near

the PAG often causes the sensation of diffuse pain referred to the central part of the body or a feeling of fear (348). Comparable stimulation in animals often elicits rage reactions and vocalizations. Moreover, surgical lesions in humans at midbrain level made just medial to the location of the STT results in relief of chronic pain (343). Because ascending pathways from the midbrain project to the ventrobasal and medial thalamus and limbic system, it is likely that some spinomesencephalic tract neurons are involved in processing nociceptive impulses that have discriminative function and others provoke autonomic reflexes and motivational and affective responses. Termination of spinomesencephalic tract fibers in the PAG may be the course by which ascending impulses activate midbrain descending inhibitory systems that result in analgesia. Finally, projections to the collicular and cuneiformis nuclei may suggest a role for the spinomesencephalic tract in orienting and motor responses, respectively.

Other Ascending Pathways

Pain often returns several months after an initially successful cordotomy (at 1 year, 50% of subjects have neither pain relief nor analgesia). Moreover, subsequent cordotomy (including bilateral section) does not necessarily restore analgesia (343). This suggests that the renewed pain depends on pathways other than those in the anterolateral quadrant that have been discussed. The alternative pathways presumably have the potential to carry nociceptive signals but are not normally relied on for this function. Known pathways that might assume such an alternative role include the dorsal column postsynaptic system, the spinocervical tract (and portions of the spinomesencephalic tract and spinoreticular tract already mentioned) in the dorsolateral funiculi, and the propriospinal multisynaptic ascending system.

Dorsal Column Postsynaptic System

According to tradition, the dorsal column carries only fibers activated by innocuous stimuli such as touch and proprioception. However, several investigators have shown that cells in the dorsal column nuclei respond to noxious stimulation. Some of these responses are mediated by unmyelinated primary afferents that travel in the dorsal columns. However, second- or third-order neurons in the spinal cord also send axons into the dorsal columns and up to the dorsal column nuclei making up the dorsal column postsynaptic system, also called the *postsynaptic dorsal column pathway* (41). These dorsal column postsynaptic neurons constitute nearly 10% of the dorsal column. Approximately one-half of the dorsal column postsynaptic neurons respond differentially to both innocuous and noxious stimuli (349). Approximately 7% of dorsal column postsynaptic neurons respond only to noxious stimuli (350).

The cells of origin of the dorsal column postsynaptic neurons in the monkey are cells in laminae III and IV, including cells just lateral to or within lamina X (41,50,349,351). Most of the axons of the dorsal column postsynaptic neurons are deep within the dorsal column, but a few are found in the dorsolateral funiculus (41,50,351). The destinations of the dorsal column postsynaptic fibers, as already mentioned, are primarily the dorsal column nuclei, and the fibers are somatotopically organized: Those originating from cells in the lumbar cord project to the nucleus gracilis, and those from cells in the cervical cord project to the nucleus cuneatus (352). From the dorsal column nuclei they ascend to higher levels in the medial lemniscus and terminate principally in the VPL, but also in the zona inserta, the posterior thalamus, the superior and inferior colliculi, and the midbrain reticular formation (352). A few of the cells that project to the dorsal column nuclei also project to the contralateral thalamus, so that they are both postsynaptic dorsal column cells and STT cells (2) (Fig. 4-53).

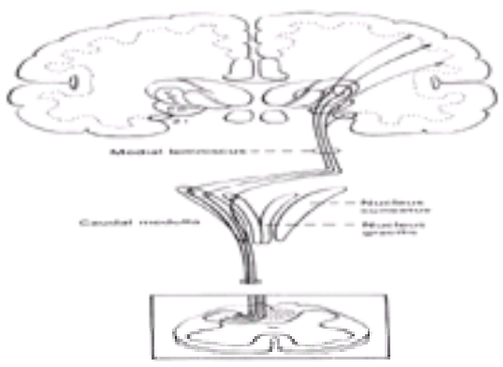

Figure 4-53. Diagram of the origin, course, and termination of the dorsal column postsynaptic system (also called the *postsynaptic dorsal column pathway*). The stippled area indicates the location of axons in the dorsal column. (PO, posterior thalmus; VPL, ventroposterolateral nucleus; ZI, zona inserta.)

The postulated role this system plays in nociception has expanded in response to demonstration of its importance in visceral pain, referred to previously in this chapter. Findings in rats and monkeys that dorsal column lesions block visceral pain behaviors and that noxious stimulation of visceral organs activates cells in the dorsal column nuclei reemphasize the importance of this pathway, and at the same time explain why previous researchers were unable to find effects of dorsal column lesions on standard nociceptive tests. Finally, these studies may give mechanistic explanations for the use of dorsal column lesions on visceral pain in humans.

Spinocervical Tract

The spinocervical tract comprises axons from dorsal horn neurons that travel in the dorsolateral funiculus to the lateral cervical nuclei at the first and second cervical levels, which in turn project to the contralateral thalamus (hence the alternate name, spinocervicothalamic tract) (352). The spinocervical tract is an important nociceptive pathway in the cat; it is much reduced in the lower primates and is considered absent or vestigial in humans (2,50,352). However, Truex and associates (353) carried out autopsies of 16 people and found the lateral cervical nucleus in nine, giving some evidence for the existence of a spinocervical tract in humans. One subject's lateral cervical nucleus contained nearly as many cells as that of the cat.

In the cat, the cells of origin are found chiefly in laminae I, III, V, and, particularly, IV (50) and have dendrites that project dorsally. At the border of III and IV they turn longitudinally (50). As mentioned, the axons ascend in the ipsilateral dorsolateral funiculus and terminate in the lateral cervical nucleus located in spinal segments C-1 and C-2. Second-order neurons in the lateral cervical nucleus send their axons to the contralateral ventral funiculus, wherein they run rostrally to reach the brain stem. At this level they join the medial lemniscus and ascend to terminate in the midbrain, VPL, and medial part of the posterior complex (Fig. 4-54).

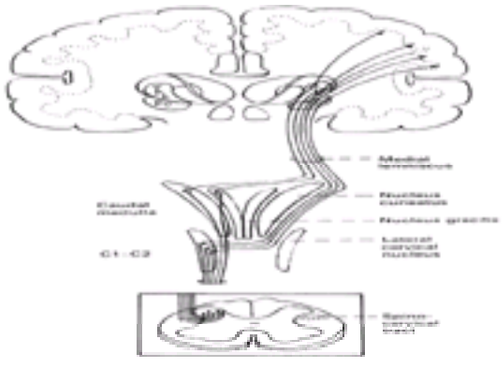

Figure 4-54. Diagram of the origin, course, and termination of the spinocervical tract. The stippled area indicates the location of axons in the dorsolateral funiculus. (PO, posterior thalmus; VPL, ventroposterolateral nucleus.)

Most of the spinocervical tract cells respond exclusively to tactile stimulation, but some cells respond to stimulation of C cutaneous nociceptors and fine muscle afferents. The paucity of spinocervical tract cells in humans argues against a significant role of this system in transmitting nociceptive information—at least in most humans.

Propriospinal Multisynaptic Ascending Systems

A concept first proposed by Goldscheider in 1898 (354) is that transmission of nerve impulses in humans takes place to a great extent via long chains of short neurons. Soon thereafter, a number of authorities attached great importance to the spinal-spinal fibers in the afferent conduction of sensory impulses. In 1914 Karplus and Kreidl (354) carried out simultaneous crossed hemisections at different levels of the spinal cord of the cat and noted that reaction times to “painful stimuli” were not decreased. They concluded that these impulses were conducted along multisynaptic pathways that crossed and recrossed the spinal cord and, furthermore, that in humans, in whom crossed pathways predominate, such an arrangement might still be present. Since the 1950s, a number of physiologists and neurosurgeons have repeated these types of experiments (354) and have restated the importance of such a system. The writings of Noordenbos (354) strongly support the notion that a multisynaptic ascending system plays a critical role in chronic pain states (Fig. 4-55). Basbaum (355) sectioned all of the long fiber tracts in rats, thereby isolating the short fiber system. He achieved this objective by hemisecting the thoracic spinal cord on one side, and later, at a slightly lower level, hemisecting the spinal cord on the other side. This operation did not abolish a learned response consisting of the rat turning its head to stop an electric shock. Moreover, he was able to train a rat to learn this response after the two hemisections. It was only when the cord was transected at a single level that the learned response was abolished (355). These findings may have important implications for the refractory nature of residual pain after bilateral cordotomies.

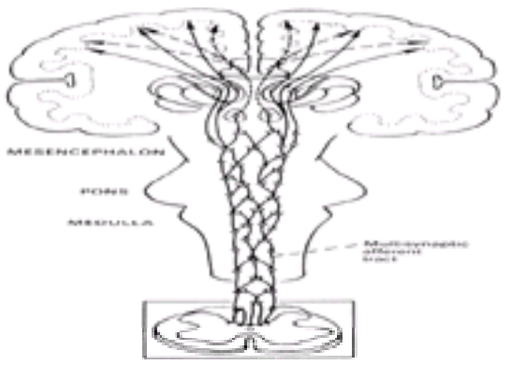

Figure 4-55. Schema of the multisynaptic ascending system, composed of neurons that have very short axons and have multiple synaptic contacts with other similar neurons. The cell bodies of this system are located in the medial aspect of the deeper laminae of the dorsal horn and in lamina X, which receives a prominent input from deep nociceptors and the viscera. This multisynaptic pathway, which has been called the *cornu commissural tract*, projects rostrally to the brain stem reticular formation and from there to the medial/intralaminar thalamic nuclei.

Ascending Trigeminal Pathways Mediating Head Pain

Nerve impulses contributing to head pain originate primarily in the peripheral sensory distribution of four cranial nerves, cranial nerve V (trigeminal), and, to a lesser extent, cranial nerve VII (facial), cranial nerve IX (glossopharyngeal), and cranial nerve X (vagus), and also in terminations of the upper three cervical nerves. These nociceptive impulses activate neurons in the trigeminal brain stem nuclei and spinal dorsal horn. Signals are then relayed to other CNS sites including brain stem reticular nuclei, the thalamus, and the cerebral cortex.

The ascending tracts that convey sensory information from the head divide into several functional types. One type is similar to the dorsal column pathways and receives input from large myelinated fibers that mediate touch, pressure, and proprioceptive information. Cell bodies of such neurons are located in the main sensory nucleus and the rostral (oralis) part of the spinal nucleus, and some proprioceptive fibers originate in the mesencephalic nucleus. The axons of most of these cells cross the midline at the level of the pons and become a defined fiber tract called the ventral (secondary) trigeminothalamic tract, also known as the ventral trigeminal lemniscus (65,356) (Fig. 4-56). It ascends in close relationship to the medial lemniscus and more rostrally also comes into close relationship with the spinal lemniscus. Some fibers from the main sensory nucleus do not cross but ascend ipsilaterally as the dorsal (secondary) trigeminothalamic tract or dorsal trigeminal lemniscus, which is associated also with the medial lemniscus of the same side. These lemniscal tracts terminate in the ventroposteromedial thalamic nucleus, in which a precise somatotopic organization is maintained (Fig. 4-57). After they synapse in the ventroposteromedial thalamic nucleus, a third relay of fibers passes to the extensive face area of the main sensory neocortex (S-1 and S-2). In addition to somatotopic organization, this system throughout has small receptive fields and modality specificity, which are consistent with its participation in fine sensory discrimination (57).

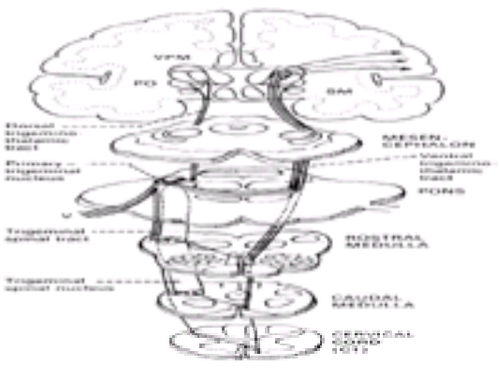

Figure 4-56. The *lemniscal* trigeminothalamic pathways transmitting tactile, thermal, and some proprioceptive and nociceptive information. The cell bodies are located in the main sensory nucleus and subnucleus oralis (some proprioceptive fibers originate in the mesencephalic nucleus). The axons of most of these cells cross the midline at the level of the pons and ascend rostrally as the ventral trigeminothalamic tract, but some ascend ipsilaterally as the dorsal trigeminothalamic tract. Second-order neurons from the subnucleus caudalis, which transmit touch, pressure, and thermal and noxious impulses also cross to the opposite side to join the ventral trigeminothalamic tract and project rostrally in company with the medial lemniscus to synapse in the ventroposteromedial nucleus (VPM) of the thalamus. (PO, posterior thalmus; SM, nucleus submedius.)

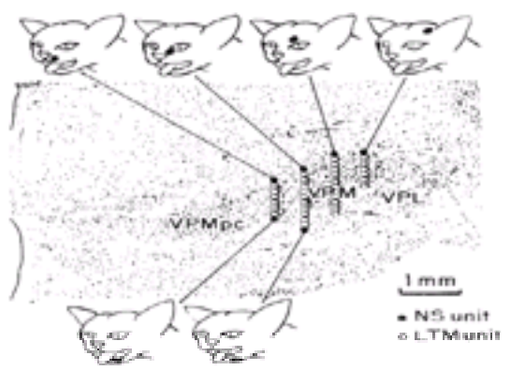

Figure 4-57. Somatotopic distribution of trigeminal nociceptive-specific (NS) neurons within the shell region of the ventroposteromedial nucleus (VPM) in the cat. Note that in the rostral part of the caudal third of the VPM, NS neurons having receptive fields in the ophthalmic division are found dorsolaterally, maxillary NS neurons are found dorsomedially, and mandibular NS neurons are encountered ventromedially along the border between the VPM proper and the parvocellular part of the ventroposteromedial nucleus (VPMpc). A similar somatotopic distribution of trigeminal wide dynamic range neurons is found in the shell region of the VPM proper. (VPL, ventroposterolateral thalamic nucleus.) (From Yokota T. Neural mechanism of trigeminal pain. In: Fields HL, Dubner R, Cervero F, eds. *Advances in pain*

research and therapy. Vol 9. New York: Raven, 1985:211–232, with permission.)

Neurons in the subnucleus caudalis, which, as previously noted, receive input from A-d and C fibers that carry touch, pressure, thermal, and noxious impulses, also project to the thalamus and ultimately the cortex via the ventral trigeminothalamic tract. One group of long fibers projects directly to the ventroposteromedial thalamic nucleus and medial part of the posterior complex and is analogous to the nSTT; hence it is the neotrigeminothalamic tract. Like the lemniscal tract, the neotrigeminothalamic tract is somatotopically organized and transmits discriminative information about tissue injury and temperature. The neotrigeminothalamic tract joins the trigeminal lemniscus and medial lemniscus to terminate in the ventroposteromedial thalamic nucleus (57).

Other neurons in the subnucleus caudalis send axons that project ipsilaterally and contralaterally and send terminals to the reticular formation, hypothalamus, PAG, and medial thalamic nuclei including nucleus submedius (Fig. 4-58). Neurons from these structures connect with limbic forebrain structures and with diffuse projections to many other parts of the brain. This system, like much of the paleospinothalamic tract, is not somatotopically organized and is considered a part of the nonlemniscal or paleotrigeminothalamic system (for summary see Fig. 4-59).

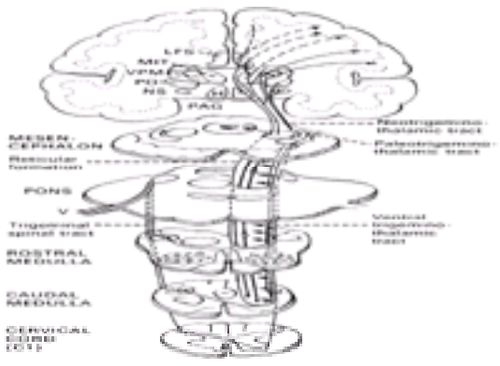

Figure 4-58. Schema of the ventral trigeminothalamic pathways, composed of neotrigeminothalamic and paleotrigeminothalamic axons. The cell bodies of these axons reside in the subnucleus caudalis, cross to the opposite side, and ascend rostrally. The lateral part of the tract comprises long axons that synapse in the ventroposteromedial nucleus (VPM) and medial part of the posterior thalamus (POm). The paleospinothalamic pathway consists of axons that pass into the reticular formation in the medulla, pons, and midbrain and there synapse with reticulothalamic fibers that project to the periaqueductal gray (PAG), hypothalamus (H), nucleus submedius, and medial and intralaminar thalamic nuclei (MIT). Within these structures they synapse with neurons that project to the limbic forebrain structures and with diffuse projection systems via complex circuits in the limbic system. (LFS, limbic forebrain structure; NS, nucleus submedius.)

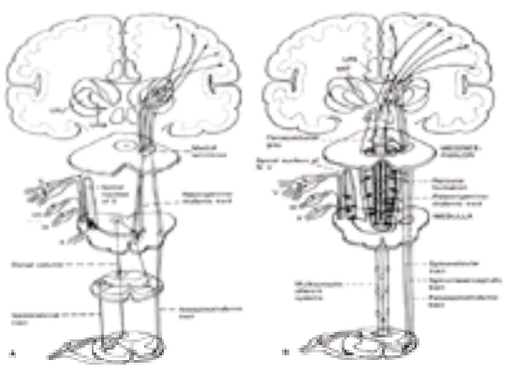

Figure 4-59. Diagrams illustrating the origin, course, and projection of the **(A)** lateral (lemniscal) and **(B)** medial (nonlemniscal) ascending systems. **A:** The lateral system includes the neospinothalamic tract, neotrigeminothalamic tract, dorsal column postsynaptic system, and spinocervical tract. These tracts are composed of long, relatively thick fibers that conduct rapidly, have a discrete somatotopic organization, and connect with the ventrobasal thalamus and thence with the somatosensory cortex. The evidence suggests that the lateral system is concerned with rapid transmission of phasic discriminative information about the onset of injury, its precise location, and its intensity and duration and can quickly bring about a response that prevents further damage. It has been suggested that these fast nociceptive pathways represent different sensory channels that are individually inhibited or facilitated, depending on the ongoing behavior or behavioral state of the organism (352). **B:** The medial system is composed of the phylogenetically older pathways, the paleospinothalamic tract, spinoreticular tract, spinomesencephalic tract, and multisynaptic ascending system, which transmit nociception from the body, and the neotrigeminothalamic tract and paleotrigeminothalamic tract for the head. Because of the thinness of these fibers, their multisynaptic nature, and the lack of somatotopic organization, impulses passing through the medial system are much slower in reaching the brain than those in the lateral system and are said to transmit tonic information about the state of the organism (352). Thus, an important although perhaps not exclusive role of these medial tracts may be to signal the actual presence of peripheral damage and to continue to send messages as long as the wound is susceptible to reinjury. In this way, the slow nociceptive pathways may, in part, determine the level of arousal or the general behavior state necessary to prevent further damage and to foster rest, protection, and care of the damaged area, thereby promoting healing and recuperative processes.

DESCENDING SYSTEMS THAT MODULATE NOCICEPTION

[Editor's note: The last edition of this book contained this section in a separate chapter cowritten by the late John C. Liebeskind, the father of this field of pain research. We have reproduced much of Liebeskind's work here, updating it with more recent findings as appropriate.]

Thus far we have discussed the multiple neuroanatomic, neurophysiologic, and neuropharmacologic pathways activated by a nociceptive stimulus. These pathways transmit information from the periphery to the brain, in which perception of the stimulus can take place. Activation of these pathways is neither necessary (e.g., in the case of thalamic pain syndromes) nor sufficient to produce pain perception. The modulation of these multiple transmission systems by inhibitory and excitatory neurochemicals as well as by their genetic and environmental (including prior activity) determinants offers a mechanism by which a certain stimulus may have remarkably disparate effects on pain perception. The previous discussion does not address why a biologic system would put so much energy into seemingly redundant nociceptive and pain modulatory circuitry. Indeed, *why* questions are difficult to answer scientifically, but pain is an adaptive warning signal and all animals have at least rudimentary nociceptive systems. The modulation of these systems must similarly provide some adaptive advantage. Mechanisms of central sensitization, for example, are unlikely to fully explain the development of chronic pain states after tissue injury (if they explain them at all) but more likely represent normally useful processes that can, on occasion, go wrong. A likely selective advantage to an animal in modulating pain perception is in ensuring that an organism's attention is directed to more biologically relevant sensation that is often, but not always, nociception. Such prioritization of incoming stimuli must be done at the highest levels of the neuraxis and communicated caudally to blunt or amplify the responses to noxious stimuli as a function of the appropriateness of the response for the organism as a whole. Perhaps it is less surprising, then, that there exist endogenous pain inhibitory and facilitatory systems descending from brain to spinal cord, whose normal function is the modulation of nociception as early as the first spinal synapse and perhaps, via autonomic outflow, at the nociceptors themselves.

The concept of descending pain modulation was proposed during the early part of the twentieth century by Sherrington (357), who emphasized that the interaction between excitatory and inhibitory systems was critical in the processing of sensory information from the body structures to the brain. In 1954 Hagbarth and Kerr (358) were the first to provide clear-cut evidence that corticospinal fibers influence afferent transmission and conduction at spinal levels. During the ensuing decade, others confirmed these observations and provided additional evidence that supraspinal mechanisms influence sensory input to ascending pathways in the spinal cord.

Nonetheless, the existence of specific nociceptive modulatory systems was first clearly proposed in 1965 by Melzack and Wall (359) as part of their gate-control

theory of pain. As discussed in Chapter 1, it included a proposal that modulation of dorsal horn cells could be affected by input coming from the periphery and also from supraspinal descending systems. At the time, the proposal for such a system was speculative, but this hypothesis received strong support from the report by Reynolds in 1969 (360) that electrical stimulation of the PAG (Fig. 4-60) resulted in sufficient analgesia to perform laparotomy in rats. These observations were soon confirmed and extended by Liebeskind and his students (361) in the early 1970s, who labeled the phenomenon *stimulation-produced analgesia* (SPA). Conversely, a number of laboratories have also reported descending pathways from brain to spinal cord that facilitate transmission of nociceptive information. We describe what is known about the neuroanatomy and neuropharmacology of these facilitatory and inhibitory descending systems and how they may normally function to modulate nociception in the spinal cord. It is likely that similar modulation, although perhaps by very different mechanisms, takes place at every rostral stop of the tissue trauma message on its way to consciousness.

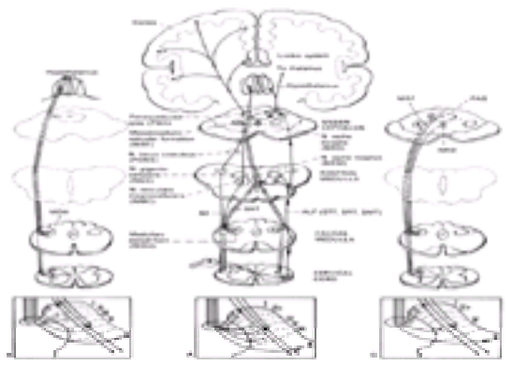

Figure 4-60. Descending endogenous pain inhibitory systems. **A:** The most extensively studied and probably the most important descending system, composed of four tiered parts, described in the text. The ascending anterolateral fasciculus (ALF), composed of the spinothalamic, spinoreticular, and spinomesencephalic tracts, has important inputs into the nucleus raphe magnus (NRM), nucleus magnocellularis (NMC), nucleus reticularis gigantocellularis (NGC), and the periaqueductal gray (PAG) via the nucleus cuneiformis. The ALF also has input to the medullary/pontine reticular formation, the nucleus raphe dorsalis (NRD), and the mesencephalic reticular formation (MRF). The PAG receives input from such rostral structures as the frontal and insular cortex and other parts of the cerebrum involved in cognition, and from the limbic system, thalamus, and hypothalamus, which sends b-endorphin axons to the PAG. The locus coeruleus in the pons is a major source of noradrenergic input to the PAG and dorsal horn (tract labeled NE). These mesencephalic structures (PAG, NRD, MRF) contain enkephalin (ENK), dynorphin (DYN), serotonin (5HT), and neurotensin (NT) neurons, but only the latter two send axons that project to NRM and NGC. Here, they synapse with neurons that are primarily serotonergic, whose axons project to the medullary dorsal horn and descend in the dorsolateral funiculus to send terminals to all laminae of the spinal gray (the densest populations are found in laminae I, II_o, and V of the dorsal horn and the motor neuron pools of lamina IX). The projection from NRM is bilateral, whereas the projection from NGC is ipsilateral. Noradrenergic fibers descend and project to the medullary dorsal horn and then descend in the dorsolateral funiculus of the spinal cord to send terminals to laminae I, II_o, IV through VI, and X. **B:** A simplistic schema to show the direct hypothalamospinal descending control system, which originates in the medial and paraventricular hypothalamic nuclei. This descending system consists of vasopressin and oxytocin neurons (and perhaps some enkephalinergic neurons), which send terminals predominantly to laminae I and X, but also provide sparse input into laminae II and III and the lateral part of lamina V, as well as the homologous area in the medullary dorsal horn. **C:** Direct PAG-spinal projection system, which bypasses the medullary nuclei and projects directly to the medullary dorsal horn and then descends in the dorsolateral funiculus to send terminals to laminae I, II_o, V, and X. Most of the axons are serotonergic and noradrenergic.

Stimulation-Produced Analgesia

The early studies by Liebeskind and associates (361) found SPA to be specifically antinociceptive, producing no generalized sensory, attentional, emotional, or motor deficits. They showed also that SPA could outlast the period of brain stimulation and that it occurred in a restricted peripheral field such that noxious stimuli applied outside that field elicited normal defensive reactions. They reported that during stimulation the sensation of light touch was intact, there was no indication of seizure activity, and animals were still capable of eating. Furthermore, rats could be trained to self-administer brain stimulation in the presence of noxious stimuli, and this self-administration did not recur when the noxious stimuli were terminated. These findings demonstrated the existence of a potent natural pain-inhibitory substrate in the PAG matter and were replicated by many other investigators (see 362 for comprehensive review of the early history of SPA). Subsequent demonstrations that stimulation of homologous brain regions in humans could relieve chronic pain provided even greater interest in this phenomenon (see Chapter 101).

In the rat, the analgesia produced by electrical stimulation of the PAG can be equipotent to that induced by high doses of morphine, and SPA completely inhibits withdrawal responses to noxious stimuli at even the severest intensities. These analgesic effects extend to spinal nociceptive reflexes, such as the tail-flick, clearly indicating a descending inhibition rather than a primarily supraspinal effect on ascending pathways. The observation, made somewhat later, that responses of spinal cord dorsal horn nociceptive cells to nociceptive stimuli were also inhibited by SPA validated this concept. SPA eliminates behavioral responses to such varied noxious somatic and visceral stimuli as electric shocks applied to the tooth pulp and limbs, heating of the skin, and injection of irritants into the skin and abdominal cavity (363). The analgesia elicited by brain stimulation can be observed within seconds after stimulation is begun and may last for minutes or even hours after stimulation is terminated. In human beings, relief from chronic pain outlasts the period of stimulation by up to 24 hours (see Chapter 101).

Another important characteristic of SPA found during these early studies was that analgesia induced by brain stimulation shared several characteristics with analgesia from opiate drugs (361,362). Concomitant with the first reports of SPA were the initial studies demonstrating the existence of specific opiate receptors in the neuraxis. Reports of these receptors in turn triggered an intense search to isolate endogenous ligands for them, ultimately culminating in the discovery of the ENKs in 1975 by Hughes, Kosterlitz, and associates (223). This search was reinforced by the emerging literature on SPA, demonstrating the existence of endogenous pain inhibitory systems. In turn, the discovery of ENKs greatly increased interest in the anatomic, physiologic, and pharmacologic bases of SPA and opiate analgesia. Areas of the brain from which SPA can be elicited are rich in opioid peptides and opiate receptors (364). Microinjection of morphine into these same brain regions produces analgesia (365), indicating that common brain sites support both SPA and opiate analgesia (see, however, 366). Systemically and centrally administered morphine increase the activity of some neurons in the PAG region, suggesting that opiate analgesia, like SPA, involves an active rather than a passive process of nociceptive inhibition. Like opiate analgesia, tolerance develops to the analgesic effects of repeated brain stimulation. Moreover, cross-tolerance is observed between opiate analgesia and SPA (367), suggesting a common underlying mechanism. Finally, opiate antagonists such as naloxone antagonize SPA (368), a crucial finding in encouraging the search for the “endorphins.” Ironically, the naloxone-sensitivity of SPA has proven controversial, and it is now clear that not all SPA is mediated by opioid peptides. Indeed, differential production of opioid and nonopioid forms of SPA result from stimulation of anatomically distinct sites within the PAG (363).

Early in the study of SPA, it became evident that if endogenous opioids play a role in this phenomenon, it is at the local level in brain stem and spinal cord rather than via long descending, opioid-containing pathways. ENK-containing cell bodies, fibers, and terminals and a high concentration of opiate receptors in the superficial dorsal horn (185,362) make this a probable site for stimulation-produced opioid activity. Moreover, anatomic and physiologic evidence of opiate inhibition of STT cells helped lead to the development of intraspinal opiate therapy in routine clinical use today. In addition to endogenous opioids, 5-HT proved important in mediating SPA. Even in the initial studies (28,252) inhibitors of serotonin synthesis and serotonin antagonists were found to antagonize SPA (369).

The serotonergic-rich raphe nuclei, particularly the NRM, were implicated in mediating SPA (Fig. 4-60). Stimulation of the NRM produced analgesia, whereas lesions of this structure inhibited SPA from PAG (252,370). Consequently, the NRM appeared to be a relay station that received descending input from the PAG and modulated spinal and medullary dorsal horn nociception via 5-HT–containing descending fibers. Basbaum and associates (371) went on to produce lesions of various quadrants of the spinal cord to determine the spinal locus of the brain stem to spinal cord descending inhibitory system. They found that lesions of the dorsal part of the lateral funiculus markedly reduced or abolished SPA (see Fig. 4-60). Once again, an analogous series of studies on opiate analgesia determined that lesions of the dorsal part of the lateral funiculus also interfered with morphine analgesia and that bilateral lesions were much more effective in this regard than unilateral lesions.

By the mid-1970s, sufficient knowledge had accumulated so that Mayer and Price (362) and Basbaum and Fields (370,372) could publish reviews of nearly 150 reports of stimulation-produced analgesia, including schematic diagrams of the anatomic and biochemical substrates of SPA and opiate analgesia.

Descending Nociceptive Modulation: Circuitry

Circuitry models of descending inhibitory systems consist of four tiers of CNS processing (see Fig. 4-60): (a) cortical and diencephalic systems; (b) mesencephalic

PAG sites, which are rich in ENKs and opiate receptors and when activated by opiates or electrical stimulation produce analgesia; (c) the rostroventral medulla, and especially the NRM, which receives excitatory input from the PAG and in turn sends serotonergic projections via the dorsolateral funiculus to the spinal and medullary dorsal horn; and (d) the spinal and medullary dorsal horn, which receives terminals of axons from the NRM and adjacent nuclei. Descending serotonergic fibers terminate among nociceptive transmission cells in laminae I, II_o, and V and can selectively inhibit nociceptive neurons, including interneurons and the rostrally projecting STT, spinoreticular tract, and spinomesencephalic tract cells. Evidence also suggests that norepinephrine-containing neurons originating in the locus coeruleus and other reticular brain stem sites contribute to endogenous pain inhibitory systems.

Cortical and Diencephalic Descending Systems

Stimulation of S-1 and S-2 and various other cortical and diencephalic structures inhibits afferent transmission in the spinal cord and medullary dorsal horn. We discuss these only briefly, in keeping with this chapter's focus on spinal mechanisms. Stimulation of S-1 cortex inhibits spontaneous activity of WDR STT neurons, as well as responses to C-fiber volleys in sural nerve and to noxious thermal and mechanical stimuli (373). Moreover, stimulation of S-1 and S-2 in the somatosensory cortex inhibits responses of WDR neurons of the trigeminal subnucleus caudalis to noxious and nonnoxious stimuli, although the effect on the latter is greater than that on the former. The corticospinal tract and extrapyramidal pathways mediate these effects. The axons of corticospinal neurons from S-1 and S-2 follow the major corticospinal tracts, which pass ipsilaterally in the brain stem and send collaterals to the trigeminal spinal nucleus. Most of these corticospinal fibers cross at the pyramidal structures and descend in the dorsolateral funiculus, whereas a smaller portion descend ipsilaterally as the anterior corticospinal tract (Fig. 4-61). Corticospinal afferents from the somatosensory cortex terminate in laminae I through VII, and axons from the motor control areas terminate in laminae VI through IX (Fig. 4-62). Corticospinal fibers in laminae I and II exert direct postsynaptic control on dorsal horn neurons, but the neurotransmitters involved are unknown (185). Because neurons of S-1 and S-2 cortex also project to the striatum, to the reticular ventrobasal posterior and intralaminar thalamic nuclei, and to the mesencephalon and reticular formation, descending fibers from these locations may mediate the analgesic effects of somatosensory cortical stimulation not involving the pyramidal tracts (373). The descending influence of cognitive and motivational processes on nociception are more difficult to study systematically because of the complex brain circuitry involved in these processes, but they are of equal importance. Limbic structures including amygdala and cingulate cortex are implicated in pain modulation and may be involved in analgesia resulting from hypnosis, learned helplessness, and uncontrollable stress.

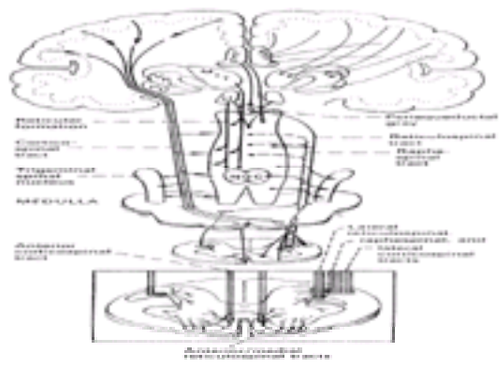

Figure 4-61. A simple diagram to depict descending pain-inhibitory systems. Note that the thalamus and the limbic system (LFS) receive afferents from the cerebral cortex, and they, in turn, send descending fibers to the brain stem and spinal cord. The corticospinal tracts modulate (excite or inhibit) various structures in the brain stem, trigeminal spinal nucleus, and dorsal and ventral horns. The raphespinal and the medullary reticulospinal tracts from each side project bilaterally, descend in the dorsolateral funiculus, and send terminals to laminae I, II_o, and V through VII. An exception to this is the reticulospinal fibers originating in the nucleus gigantocellularis (NGC) that terminate in laminae VII through VIII. The pontine reticulospinal tracts project ipsilaterally and descend in association with the medial longitudinal fasciculus in the anterior funiculus and terminate in laminae VII and VIII. See Figure 4-62 for a more detailed description of the termination of these descending fibers. (H, hypothalamus; MIT, medial/intralaminar nuclei; PO, posterior thalamus; VPL, ventroposterolateral thalamic nucleus.)

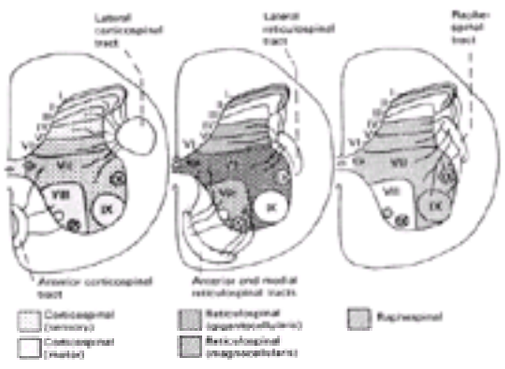

Figure 4-62. Schematic diagrams depicting the terminations of various descending systems in the gray matter of the spinal cord (and the spinal nucleus of the trigeminal complex). The corticospinal tract from the sensory cortex sends terminals to laminae I through VII, and the corticospinal tract from the motor cortex sends terminals to laminae VI through IX. The reticulospinal tract, which originates in the nucleus gigantocellularis, sends terminals to laminae VII and VIII, whereas the reticulospinal tract, which originates in nucleus magnocellularis, sends terminals to laminae I, II_o, and V through VIII. The raphespinal tract sends terminals to all laminae except III, IV, and VIII.

Diencephalic structures that participate in the centrifugal control of nociceptive information in the spinal cord and the trigeminal subnucleus caudalis include the periventricular gray, medial and lateral hypothalamus, medial preoptic/basal forebrain region, and somatosensory nuclei of the thalamus. Stimulation of the ventroposterolateral and medial nuclei of the thalamus inhibits evoked responses of identified WDR and high-threshold STT neurons (374). Although stimulation of these nuclei does not preferentially inhibit the responses to nonnoxious or noxious natural stimuli, the response to C-fiber volleys in the sural nerve is reduced to a greater extent than is the response to A-fiber volleys (374). Little evidence exists to suggest a direct projection of thalamic neurons to the spinal cord, and it has been suggested that stimulation of the ventrobasal thalamus produces antidromic activation of STT collaterals, synapsing in medullary reticular formation and PAG, which, in turn, activates neurons in these structures, which do project to the spinal cord (373).

A direct, predominantly ipsilateral projection to the spinal cord of the medial nuclei, and to a lesser extent, the lateral nuclei of the hypothalamus (373,374), travels principally in the dorsolateral funiculus and may mediate the antinociceptive effect of hypothalamic stimulation (see Fig. 4-60B). Although the spinal laminae in which these projections terminate have not been identified, it is known that oxytocin- and vasopressin-containing neurons of the hypothalamus terminate predominantly in laminae I and X, and that there are sparse inputs in laminae II, III, and V (185). Oxytocin (375,376) and vasopressin (377) have been reported to produce analgesia at the level of the spinal cord, although the effects of the latter, at least, may be confounded by paralytic motor effects (378). Another neurochemical possibly involved in such hypothalamic stimulation–induced analgesia is dopamine. Dopaminergic innervation terminates in lamina I and particularly laminae III and IV (379) of the spinal cord and dopamine has been found to reduce nociceptive responses in lamina I neurons (380) and behaviorally (381). Because both the medial and lateral hypothalamic nuclei project to the periventricular gray and medullary reticular formation, including the NRM, indirect pathways to the spinal cord may also mediate inhibition of nociceptive transmission by hypothalamic stimulation.

The experimental results cited previously are complemented by numerous clinical reports that electrical stimulation of the thalamus, septal area, caudate nucleus, medial forebrain bundle/lateral hypothalamic region, or internal capsule can produce analgesia in humans (382). The invasive nature of such SPA and the resultant risks involved in such therapy may make such reports of more scientific than therapeutic value. They show the mechanistic similarities between humans and laboratory animals without implying that such stimulation is recommended for either.

Mesencephalic Descending Systems

As mentioned previously, stimulating many areas of the CNS does not produce any direct or indirect SPA. On the other hand, the areas most sensitive to such stimulation appear to be concentrated in the periaqueductal and periventricular gray matter of the brain stem extending from the diencephalon to the medullary raphe nuclei (see Fig. 4-60 and Fig. 4-61). The nucleus raphe dorsalis in the midbrain and the mesencephalic reticular formation are also sensitive sites for electrical activation of descending inhibitory mechanisms.

Anatomy. The PAG is well positioned to relay messages from the forebrain to the hind brain. It receives inputs from such rostral structures as the frontal and insular cortex, limbic system, septum, amygdala, and hypothalamus (373,374,383) (see Fig. 4-60A; also see Fig. 5-10 and Fig. 5-11). Input from caudal structures includes those from nucleus cuneiformis, pontomedullary reticular formation, locus coeruleus, and spinal cord (see Fig. 5-2 and Fig. 5-3 for more detailed anatomy of brain stem nuclei). The locus coeruleus projection may contribute to norepinephrine's antagonism of opiate analgesia and SPA in this region. The PAG has descending connections to the rostral medulla, particularly its ventromedial part—the medullary reticular nuclei—and the NRM (383,384). These sites in the rostral medulla are a major source of axons projecting to the medullary and spinal dorsal horn, principally via the raphespinal and reticulospinal tracts that send fibers to the subnucleus caudalis or via the dorsolateral funiculus to laminae I, II, and V of the spinal cord. In addition to these descending relay systems, there are direct projections of the PAG and nucleus raphe dorsalis to the medullary and spinal dorsal horn via the dorsolateral funiculus (see Fig. 4-60C). Moreover, a direct projection of the mesencephalic reticular formation descends in the ventral and ventrolateral funiculi. Thus, at least a portion of the inhibitory effects of PAG stimulation is likely to depend on these direct projections from midbrain to the spinal and medullary dorsal horn. The PAG also sends ascending projections to the intralaminar nuclei of the thalamus in a pattern similar to that known for the paleospinothalamic tract (see Chapter 5).

As might be expected from its many inputs and outputs, the PAG is functionally not a unitary brain region. This area, apart from its role in pain modulation, has been implicated in controlling fear, anxiety, cardiovascular tone, lordosis, and vocalization (385). Indeed, even regarding its role in pain modulation, different subregions of the PAG differ markedly. For example, Liebeskind and colleagues reported that SPA was differentially sensitive to naloxone as a function of the stimulation site, with stimulation of much of the PAG producing naloxone-insensitive analgesia, but stimulation of the most ventral regions of the PAG, dorsal raphe, and subjacent tegmentum evoking analgesia blocked by naloxone (386).

Neurochemistry. The PAG contains ENKergic cells and terminals, dynorphin-containing cells, and b-endorphin–containing axon terminals. Like opiate actions elsewhere in the CNS, opiate actions in the PAG are largely inhibitory (or more accurately here, disinhibitory). Excitation of PAG output neurons, which initiates descending inhibitory controls, is thought to be caused by the endogenous opioids (ENK, dynorphin, b-endorphin, or all three) inhibiting a tonically active inhibitory interneuron (i.e., disinhibition) (Fig. 4-63).

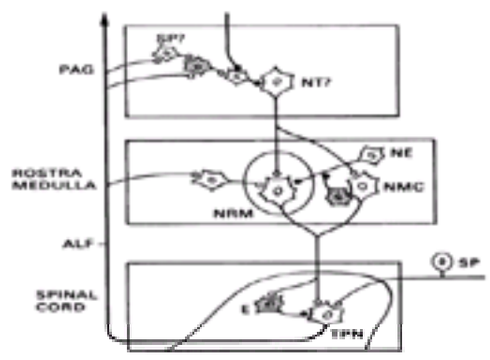

Figure 4-63. Schema modified from one by Basbaum and Fields (252) to depict the circuits in the periaqueductal gray (PAG), rostral medulla, and spinal cord. Unfilled boutons indicate release of excitatory transmitter, and shaded boutons indicate an inhibitory input. Stimulation from primary afferents activates thalamic projecting neurons (TPN), which transmit nociceptive impulses to the rostral medulla and PAG. The PAG receives input from cortical, thalamic, hypothalamic, or limbic sites. In the PAG, the output neuron is depicted as an excitatory neurotensinergic (NT) neuron that activates cells of nucleus raphe magnus (NRM) and nucleus magnocellularis (NMC) in the rostral medulla, although AMPA glutamate and nicotinic acetylcholine ionotropic receptors are also excitatory to rostral ventral medulla and perhaps more likely to mediate fast transmission (see text). An endogenous opioid peptide neuron (*shaded*) in the PAG presumably inhibits an inhibitory interneuron that in turn controls the PAG neuron. Input to the opioid interneuron may derive from ascending nociceptive pathways via substance P (SP) or histamine-containing local neurons. PAG output neurons also may be excited by neurotensin and nicotinic acetylcholine receptor activation. At the level of the rostral ventral medulla there is an inhibitory norepinephrine (NE) input to raphe bulbospinal neurons, although the importance of this inhibition for nociception is complicated by the functionally heterogeneous nature of rostral ventral medulla neurons. Included also is the possibility that local neurons presynaptically control the NE input to raphespinal axons. The bulbospinal 5-HT axons are shown to inhibit the projection neurons via two circuits: One is a direct postsynaptic inhibition, and the other involves an inhibitory opioid containing interneuron (E) (see further discussion in text). (ALF, anterolateral fasciculus.) (Modified from Basbaum AI, Fields HL. Endogenous pain control systems: brain stem spinal pathways and endorphin circuitry. *Ann Rev Neurosci* 1984;7:309–338.)

The $GABA_A$ antagonists bicuculline or picrotoxin can produce reliable antinociception when microinjected into the PAG, presumably via blocking the effects of such tonically active interneurons (387). The injection of glutamate or its analogues into the PAG, on the other hand, produces a much more complex behavioral response (e.g., antinociception, aversion behaviors, and so forth) depending on the dose and site injected (388). As in electrical stimulation experiments, results of such studies are likely to represent the sum of activating various ascending PAG inputs, inhibitory and excitatory interneurons, and descending and ascending PAG outputs because of the ubiquity of excitatory amino acid effects in the CNS.

The ionotropic and metabotropic effects of glutamate are implicated in PAG-mediated antinociception (389). Vaughan and Christie (390) reported that opiates (particularly ENKs), *in vitro* at least, have inhibitory effects on NMDA and non-NMDA glutamatergic excitation by both presynaptic and postsynaptic mechanisms. Disinhibitory effects of presynaptic mu receptors on GABA-releasing terminals were also reported in these studies, however.

Specifically, this inhibition appears to be mediated by a particular subtype of voltage-gated potassium channel (391). The function of this channel after mu receptor activation depends on arachidonic acid and its metabolites. Arachidonic acid (produced via phospholipases from cell membrane phospholipids) is metabolized via cyclooxygenases to prostaglandins and thromboxanes, via 5-lipoxygenase to leukotrienes or via 12-lipoxygenase to 12-HETE or 12-HPETE. Vaughan and colleagues (391) found the 12-lipoxygenase pathway to be critical in mediating the opiate inhibitory effects (disinhibition is blocked by a 12-lipoxygenase inhibitor). This finding is of obvious interest to cell biologists in understanding second-messenger effects of opiates (see Fig. 4-32). However, it also has clinical significance in that nonsteroidal antiinflammatory drugs may potentiate opiate analgesia, at least in part by this mechanism. Any inhibition of one metabolic pathway may shunt metabolism of arachidonic acid down alternate paths, producing more 12-lipoxygenase products and potentiated mu opiate effects. Whether this mechanism generalizes to sites other than the PAG is not known.

In addition to morphine and the endorphins, other putative neurotransmitters can produce analgesia when injected into the PAG including histamine (at the H_2 and perhaps H_1 receptors) (392) and substance P (at NK1 receptors) (252), although naloxone blocks these effects, pointing to an interaction with endogenous opioids. Nicotinic ACh agonists and the tridecapeptide neurotensin also produce analgesia in the PAG, but these effects are not blocked by naloxone. Carbachol-induced analgesia from dorsal PAG, but not ventral PAG, sites is blocked by systemic adrenergic antagonists, however. As mentioned previously, these are the sites that support nonopioid SPA. Ventral PAG SPA, in contrast, is naloxone sensitive and inhibited by NRM lesions (393), suggesting a serotonergic rather than a noradrenergic mechanism.

Neurotensin is a neural excitant in many areas of the CNS, and the PAG is no exception (394). PAG neurotensin-induced analgesia has also been reported to be blocked by NRM lesions (395) and opiates release neurotensin in the PAG (396). Investigation of neurotensin's role in pain modulation has been slowed by the paucity of selective antagonists and information regarding neurotensin receptor subtypes (397). TRH (398) and somatostatin (399) also produce antinociception when microinjected into the PAG. But again, the lack of specific antagonists has constrained research on these effects.

Another neurochemical of interest in this region is the peptide orphanin FQ (sometimes called *nociceptin*). Possibly the most interesting aspect of this chemical thus far is in the history of its discovery (400). Shortly after the opiate receptors were cloned, a receptor similar in its amino acid sequence, opiate receptor-like 1 (ORL1) was discovered that then led to the discovery of the endogenous ligand for that receptor, orphanin FQ. Despite its pedigree, the orphanin receptor is clearly not an opiate receptor in the usual sense (e.g., blockade by naloxone, binding of other opiates). Indeed, functionally, orphanin was originally labeled *nociceptin* by one group that first (401) described it because it blocked analgesia, and some have since proposed that it is an endogenous antiopiate (402). Orphanin has been studied electrophysiologically and is able to potently inhibit neural activity both by activating potassium channels (403) and by inhibiting calcium channels (404), and thus it is almost universally inhibitory. Its function primarily depends on the function of the cells it inhibits. In the PAG, it can inhibit analgesia from kainate or morphine injection, presumably by inhibiting descending pain inhibitory neurons. In the spinal cord it has nociception inhibitory effects (405), although its mechanism suggests that it has little nociceptive specificity. In the medulla, orphanin is both analgesic and hyperalgesic, depending on what population of cells it inhibits (406).

Pontine and Medullary Descending Systems

Anatomy. Since the earliest studies of descending modulatory circuitry, much anatomic, physiologic, and behavioral evidence has been published concerning the NRM (252). Raphe spinal neurons are excited by PAG opiate microinjection or PAG electrical stimulation, as well as by direct electrical stimulation of, or opiate microinjection into, the NRM. All produce inhibition of dorsal horn neurons. Subsequent findings suggest other important alternative descending paths activated by opiates and electrical stimulation. Raphe lesions have little effect on behavioral analgesia induced by morphine or PAG stimulation, unless the lesions are extended into the magnocellular reticular field (407). Electrical stimulation or lesions in the medullary reticular core activate or interfere with multiple descending pathways. These include rubrospinal, tectospinal, and pontine reticulospinal fibers of passage, including fibers originating from noradrenergic cell groups in the pons, all of which can influence dorsal horn activity (28) (Fig. 4-64).

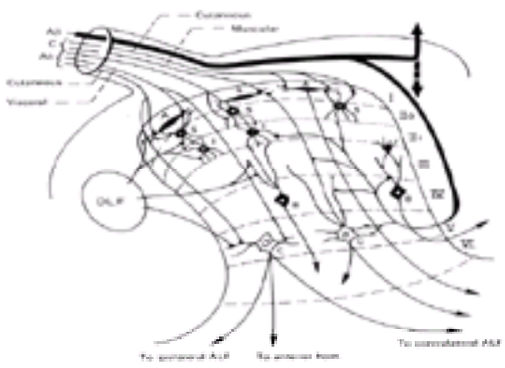

Figure 4-64. Simplified schematic cross-section diagram of input and output of the dorsal horn of the spinal cord, as well as interneurons and axonal terminals of descending control systems. A-d and C fibers transmit innocuous and nociceptive impulses. They synapse primarily in laminae I, II $_o$, and V, although they make synaptic contact through interneurons with cells in other laminae. Cutaneous nociceptive afferents project to laminae I, II $_o$, and V, whereas visceral and muscle nociceptive afferents project to laminae I and V but not to lamina II. Note the convergence of cutaneous and visceral afferents on viscerosomatic neurons in laminae I and V (C cells, which are wide dynamic range neurons), the axons of which pass to the anterolateral fasciculus (ALF) of the opposite side and project to the brain. Similarly, A-d and C muscle nociceptive afferents and cutaneous afferents also converge on neurons in laminae I and V, including some with long ascending axons that make part of the ALF. Although most of the axons ascend in the contralateral ALF, some ascend ipsilaterally. The collaterals from A-b fibers, which course along the medial side of the dorsal horn, take a retroflex course at the level of lamina V, ascend dorsally, and then branch out to make contact with interneurons and output neurons. In this way they modulate dorsal horn output. Note the interneurons in laminae II and III and an *antenna* cell in lamina IV (cells B) that may project rostrally as dorsal column postsynaptic fibers or as spinocervical fibers. Raphe spinal and reticulospinal fibers (from nucleus reticularis magnocellularis) descend in the lateral fasciculus to make contact with cells in laminae I, II, and V, and deeper laminae to exert modulating influences on dorsal horn function (see Fig. 4-61 and Fig. 4-62). The dorsolateral funiculus (DLF) contains descending axons of cells in the brain stem that are inhibitory (off-cells) and, perhaps, facilitatory (on-cells) to nociception. (S, stalk cell; I, islet cell.)

Clearly, the largest population of brain stem cells projecting to the spinal cord via the dorsal part of the lateral funiculus is located in the ventral tegmentum of the rostral medulla and caudal pons (408). In addition to the NRM, other nuclei in the adjacent reticular formation, all of which are located ventral to the nucleus reticularis gigantocellularis, are important in the modulation of nociception. These include the nucleus reticularis magnocellularis (in cat) and the nucleus reticularis paragigantocellularis lateralis (in rat). Fields (408) gives the label of rostral ventromedial medulla to the combination of NRM, reticularis paragigantocellularis lateralis, and nucleus reticularis gigantocellularis in the rat. All of these regions receive projections from the PAG, contain cells that can be activated by PAG stimulation (409), send axons to the spinal cord, and can produce antinociception (*analgesia*) when electrically stimulated (252) (see Fig. 4-60A). To completely block the effect of midbrain stimulation, NRM, nucleus reticularis magnocellularis, and reticularis paragigantocellularis lateralis must be simultaneously interrupted, either by lesion or by injection of local anesthetic (252,407). Thus, most researchers refer to the rostral ventromedial medulla as a unit rather than a collection of disparate nuclei. No one has suggested that these areas are functionally identical, however. To the contrary, these regions are probably grouped together primarily because even one such nucleus has cells within it that appear to have markedly differing effects.

The work of Fields and his colleagues best represents this diversity (410). Studying rostral ventromedial medulla cells in lightly anesthetized rats, they subclassified cells specifically by their response to a hot light during the tail-flick test. Among the cells that change their firing rates in temporal relation to the heat stimulus, two groups are evident. Some cells stop firing just before the animal flicks its tail away from the stimulus and are called *off-cells* in that they are thought to normally inhibit spinal nociceptive transmission. The other group of cells shows a burst of activity just before the tail-flick and these *on-cells* are hypothesized to facilitate spinal nociceptive transmission (Fig. 4-65). Thus, in addition to the descending inhibitory systems from this area, facilitatory descending systems may also exist.

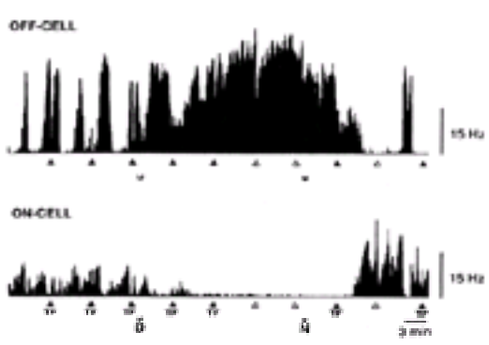

Figure 4-65. Examples of on- and off-cells in the rostral ventromedial medulla and their sensitivity to mu opioids. Rate meter recordings of the firing of an on-cell and an off-cell in rostral ventromedial medulla, recorded simultaneously from a single electrode in an experiment also accessing tail-flick in lightly anesthetized rats. Tail heat trials are indicated by triangles below the rate meter trace. Filled triangles (and TF) indicate that a tail-flick reflex occurred on that trial, whereas open triangles indicate no tail-flick response. Off-cells show a pause in their activity with tail flick, whereas on-cells show a burst of activity with tail flick. Administration of the mu opiate DAMGO [Tyr-D-Ala-Gly-(NMe)Phe-Gly-ol] (D) into the rostral ventromedial medulla produced a naloxone- (N) reversible change in the firing rate of both on and off-cells during the tail-flick stimulus preceding and then concurrent with the inhibition of the tail flick. Off-cell pause and on-cell burst were eliminated by DAMGO. (From Heinricher MM, Morgan MM, Tortorici V, et al. Disinhibition of off-cells and antinociception produced by an opioid action within the rostral ventromedial medulla. *Neuroscience* 1994;63:283, with permission.)

Several studies (410,411,412 and 413) have reported excitation, rather than inhibition, of WDR cells from electrical stimulation in the rostral ventromedial medulla. Indeed, neurochemical activation of cells in the rostral ventromedial medulla by neurotensin (414) and glutamate (413) also produces facilitatory and inhibitory effects on nociception, presumably depending on the particular subclass of cells primarily activated. In contrast, lidocaine injected into the rostral ventromedial medulla blocks allodynia from nerve ligation (415), suggesting a role of descending facilitatory pathways in sensitization phenomena.

Although nociceptive facilitatory and inhibitory descending systems project to the spinal cord from the rostral ventromedial medulla, inhibitory systems course primarily in the dorsolateral funiculus as described previously, whereas facilitatory systems project primarily in the ventrolateral funiculus (413,416).

Descending Inhibitory Neurochemistry. Descending axons that originate in raphe nuclei and reticular nuclei of the medulla or pons are primarily monoaminergic and release 5-HT or norepinephrine and, less commonly, ENK and other peptides as is discussed in the following section. As for rostral ventromedial medulla cells themselves, both excitatory amino acids (Fig. 4-66) and neurotensin (see Fig. 4-63) have excitatory effects and orphanin inhibitory effects, regardless of the on-cell or off-cell classification of any particular rostral ventromedial medulla cell. The nicotinic ACh agonist ABT-594 has analgesic effects when microinjected into NRM (94,417), presumably activating descending inhibitory pathways preferentially (perhaps via specific effects of on- and off-cells).

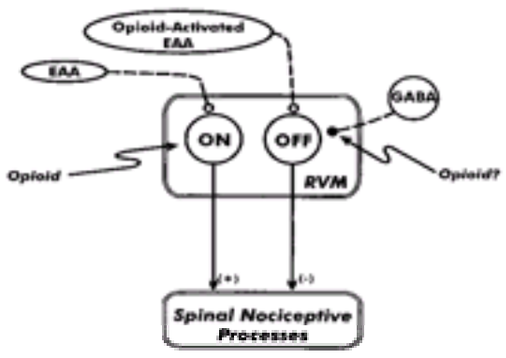

Figure 4-66. Circuitry diagram of the rostral ventromedial medulla (RVM). *Open circles* indicate excitatory and closed circles inhibitory connections. *Dashed lines* indicate possible multisynaptic pathways. The tail flick related on-cell burst is mediated by glutamate (or other excitatory amino acids) and is blocked by local application of mu opioids, which can inhibit on-cells directly. The glutamatergic input could be from spinal or periaqueductal gray projecting cells, both known to be inhibited by mu opioids at those sites as well. Glutamate-mediated inputs do not contribute to ongoing activity of off-cells (neurotensin also has excitatory effects in this region). Systemic morphine, however, does activate glutamate-mediated excitation of off-cells, perhaps via disinhibition of periaqueductal gray glutamatergic projecting cells. Mu opioids do disinhibit off-cells in the RVM, presumably by inhibiting gamma-aminobutyric acid (GABA) input on the off-cells. These GABA inhibitory inputs may be driven directly or indirectly by on-cell activity (not shown). Kappa opioids also have been reported to inhibit off-cells directly, thus providing a kappa physiologic antagonism of mu opioid effects (not shown). In contrast, cannabinoids have been found to increase off-cell activity, although the circuitry of this effect is unknown (see text for further discussion and references). (Adapted from Heinricher MM, McGaraughty S, Farr DA. The role of excitatory amino acids transmission within the rostral ventromedial medulla in the antinociceptive actions of systemically administered morphine. *Pain* 1999;81:63.)

Fields, Heinricher, Morgan, and others have intensively investigated the effects of opiates in this area. As previously mentioned, mu opiates microinjected into rostral ventromedial medulla produce inhibition of antinociceptive spinal reflexes. A correlation has been demonstrated between this analgesia and (a) inhibition of on or nociceptive facilitatory cells and (b) disinhibition (activation) of off or nociceptive inhibitory cells (418). Their model (see Fig. 4-66) (419,420) also includes an indirect or direct GABA-inhibitory influence on the off-cells that is caused by on-cell activation, mu receptor inhibition of both the on-cell and the GABA inhibition of the off-cell, and a kappa inhibition of off-cells. This last point suggests a physiologic antagonism between kappa and mu opiate activity in the rostral ventromedial medulla (419), although this antianalgesic effect is greater in male rats. Women are more sensitive to kappa opiate analgesia than men (421), although the mechanisms for this effect are still unknown.

Like mu opiate analgesia, cannabinoid analgesia (including that from endogenous cannabinoids such as anandamide) has been correlated in rostral ventromedial medulla with activation of descending inhibitory neural activity (off-cells) (422), although the cannabinoid effects are not blocked by opiate antagonists. Cannabinoid receptor antagonists, which do block the analgesia, also decrease pain thresholds, implicating endogenous cannabinoids in tonic pain inhibitory mechanisms at either spinal cord (423) or brain stem sites (422).

The brain-stem-to-spinal-cord connections and the neurochemistry underlying descending nociceptive modulation are much studied and have primarily focused on monoaminergic systems.

Serotonin. Cell bodies containing 5-HT are located in the NRM, nucleus raphe obscurus, nucleus raphe pallidus, nucleus raphe dorsalis, and other nuclei in the medulla and pons (B1 through B3, B7, and B9 cell groups) (Fig. 4-67). Indeed, almost all 5-HT–containing neurons in the dorsal horn must originate from descending brain stem neurons because chronic spinal cord transection results in complete depletion of 5-HT below the lesion (29,185,424) (Fig. 4-68). Most NRM 5-HT neurons project to spinal cord via the dorsolateral funiculus to terminate predominantly in laminae I, II $_o$, IV, and V of the spinal dorsal horn and near the central canal (185) (see Fig. 4-67). A similar termination is seen in the medullary dorsal horn. In contrast, the axons of 5-HT neurons located in nucleus raphe obscurus and nucleus raphe pallidus project near the ventral funiculus to the ventral horn. The 5-HT neurons of the NRM and other nuclei thus are presumed to provide the serotonergic link in the controls exerted by most rostral sites in the diencephalon and forebrain. Early studies of SPA from a number of brain stem sites, as well as systemic opiate analgesia, inhibited analgesia by inhibiting 5-HT synthesis (with parachlorophenylalanine) or by neurotoxic destruction of spinal 5-HT terminals (with 5-7-dihydroxytryptamine) or by lesions of the medullary 5-HT cells (407). Moreover, intrathecal methysergide, a serotonin antagonist, blocked analgesia produced by microinjection of morphine into the raphe nuclei (407). Iontophoresis of 5-HT was largely reported to inhibit the response of dorsal horn neurons to noxious stimulation, and when 5-HT is applied directly to the spinal cord it produces analgesia. Moreover, drugs that block 5-HT reuptake are effective analgesics in animals and humans (408). Microdialysis studies, in which the release of 5-HT into spinal cord or CSF has been measured, show that 5-HT levels increase after injection of morphine into the PAG, stimulation of the spinal dorsolateral funiculus, and intense sciatic nerve stimulation (407).

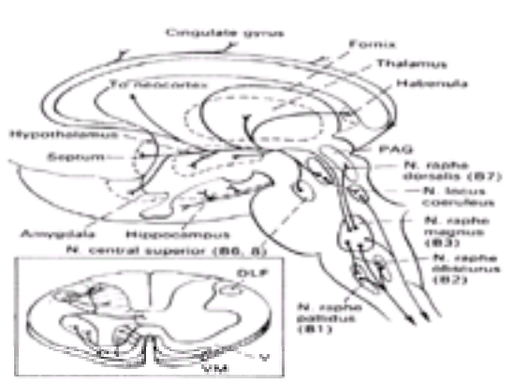

Figure 4-67. Diagram of the origin and projection of the serotonergic system. Serotonergic neurons are distributed within the midline raphe nuclei in medulla, pons, and mesencephalon. Rostrally projecting neurons are located in nucleus raphe dorsalis and nucleus centralis superior, and their axons project to various diencephalic structures as well as the cortex as depicted in the figure. From nucleus raphe magnus, rostrally projecting fibers pass to the periaqueductal gray (PAG) and the hypothalamus. The primary sources of raphespinal descending serotonergic neurons are in B1 through B3 nuclei and in B7 and B9 (not shown). The axons of these neurons project to the trigeminal spinal nucleus as well as to the spinal cord. 5-HT axons are found at the lumbar level throughout the white matter, with two areas of dense concentration: A well-defined wedge-shaped bundle occurs in the dorsolateral fasciculus (DLF), which sends terminals to laminae I, II $_o$, V, and X and a dense concentration is found in the ventral (V) and ventromedial (VM) white matter, and these send terminals to the motoneuron pools of lamina IX. At the thoracic level of the spinal cord the densest 5-HT concentrations are found in the intermediolateral cell column, which contains preganglionic sympathetic neurons. (Modified from

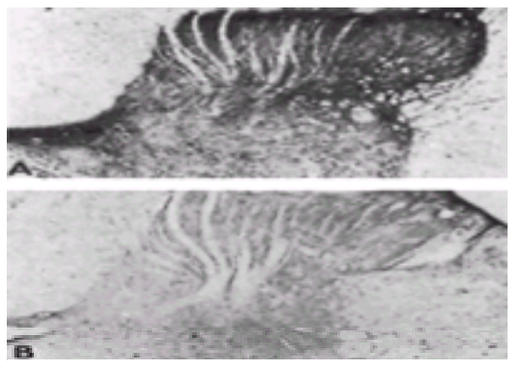

Figure 4-68. The contribution of descending 5-HT to the cat lumbar spinal cord evaluated immunocytochemically 8 weeks after transection of the spinal cord. **A:** View of the spinal cord processed for 5-HT. **B:** The 5-HT staining of the same cat after transection. All 5-HT-LI had disappeared 8 weeks after transection, indicating that all 5-HT axons are derived from the brain stem. (From Ruda MA, Bennett GJ, Dubner R. Neurochemistry and neural circuitry in the dorsal horn. *Progr Brain Res* 1986;66:219–268, with permission.)

Dubner, Ruda, and associates (54,185) examined sites of interaction between descending 5-HT axons and laminae I and II neurons in a series of experiments (Fig. 4-69). The majority of spinal 5-HT terminals form axosomatic and axodendritic synapses with neurons of the dorsal horn including STT neurons (54,185). In primates, evidence exists for a possible presynaptic 5-HT control of primary afferents (29). Stimulation of NRM inhibited all NS or WDR neurons identified, including STT cells, and all of these lamina I neurons exhibited many 5-HT immunoreactive contacts. As previously described, stalked cells (54,185) are either NS or WDR nociceptive neurons, and all stalked cells exhibit numerous 5-HT immunoreactive contacts. Stimulation of NRM inhibits all stalked cell neurons. These results suggest that direct descending 5-HT postsynaptic inhibition modifies the output of both lamina I projection neurons and stalked cells, which can directly modulate the output of lamina I projection neurons. In contrast, stimulation of NRM has no effect on lamina II_0 or II_i islet cells and has few or no 5-HT contacts (185).

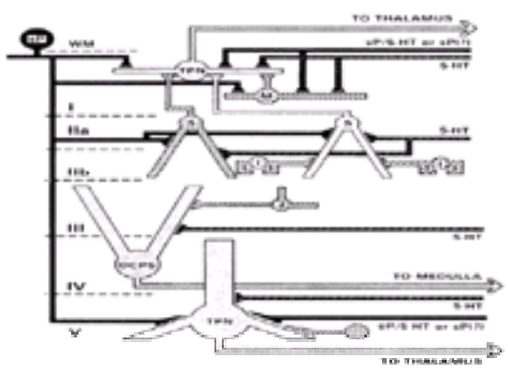

Figure 4-69. Diagram of dorsal horn circuitry, proposed by Dubner, Ruda, and coworkers. Laminae borders and white matter (WM) are represented at the left. Primary afferent axons enter at the left, and descending extrinsic axons enter at the right. (5-HT, serotonin; I, islet cell; M, lamina I local circuit neuron; S, stalked cell; sP, substance P; 3, lamina III local-circuit neuron; TPN, thalamic projection neuron; sP/5-HT or sP, descending axon that coexists in 5- HT and sP or sP only.) Striped cells are enkephalin-containing local-circuit neurons; cross-hatched cell is a gamma-aminobutyric acid–containing local- circuit neuron. (From Ruda MA, Bennett GJ, Dubner R. Neurochemistry and neural circuitry in the dorsal horn. *Progr Brain Res* 1986;66:219–268, with permission.)

Similar retrograde HRP and 5-HT immunocytochemical double-labeling studies have demonstrated 5-HT contacts on dorsal column postsynaptic neurons in lamina IV in both cat and monkey (54). All of the dorsal column postsynaptic system neurons in cat and 97% of those in monkey had 5-HT immunoreactive varicosities in contact with their somata and proximal dendrites. With the emerging importance of this pathway in visceral pain, the functional implications of such contacts might benefit from reevaluation, and 5- HT has already been implicated for some time in human visceral pain states (425,426) although primarily pronociceptive, rather than antinociceptive. Indeed, exceptions to the 5-HT antinociception story have been common over the years. Although most studies indicated that 5-HT iontophoresis inhibited laminae I and V dorsal horn neurons, excitatory effects were reported in deeper (lamina VI) neurons (29).

Descending serotonergic influences are now clearly implicated in nociceptive facilitation, not just in deeper laminae but in superficial dorsal horn as well. This difference from the antinociceptive role of 5-HT discussed previously may be primarily caused by differential effects of different serotonergic receptor subtypes (of which there are more than 10 cloned) or, instead, from differences in circuitry in the spinal cord.

Serotonin acting at 5-HT_{1A} receptors generally inhibits nociceptive activity in the spinal cord (427,428,429 and 430). 5-HT_2 (428) receptor effects, in contrast, have been reported to facilitate spinal nociception [see, however, (100)], and 5-HT_{1B} (431) and 5-HT_3 (100,101) receptors may have dual effects.

In terms of circuitry, serotonin has been seen *in vitro* to have fast synaptic effects on dorsal horn cells (432) and potentiates glutamate transmission (215). However, whether these effects are on excitatory or inhibitory neurons is unknown. For instance, 5-HT has been shown to release adenosine (433) presumably via an excitation of inhibitory interneurons. In addition, PAG stimulation-induced inhibition of STT cells also has been linked to excitation of spinal glycine and GABA-inhibitory interneurons (434). Finally, 5-HT_3 receptors located on primary afferent terminals should be able to mediate primary afferent presynaptic inhibition and thereby inhibit nociception, although pronociceptive 5-HT_3 effects are also seen (101). Zhuo and Gebhart (413) have found that NRM stimulation has excitatory or inhibitory effects on dorsal horn nociception at virtually overlapping stimulation sites dependent on the glutamate dose or electrical stimulation intensity administered (lower doses or intensities producing facilitation). Such findings emphasize the intermingling of nociceptive inhibitory and facilitatory cells in serotonin-rich rostral ventromedial medulla as described by Fields.

Norepinephrine. A second neurochemically distinct monoamine descending system involves noradrenergic neurons whose cell bodies are in A5, A6, and A7 cell groups and whose axons descend in dorsolateral, ventrolateral, and ventral funiculi to end in all of the laminae of the spinal cord (Fig. 4-70) (185). The A6 and A7 subgroups project most densely to the ventral horn to motor neurons but also to laminae I, II_0, IV through VI, and X. Neurons within A6 (nucleus locus coeruleus) have dense projections to the parasympathetic preganglionic cell column in the sacral cord, whereas the neurons in A7 (nucleus subcoeruleus) and medial parabrachial nucleus contribute axons to sympathetic preganglionic neurons in the intermediolateral cell column in T-1 to L-2 spinal cord (185,435).

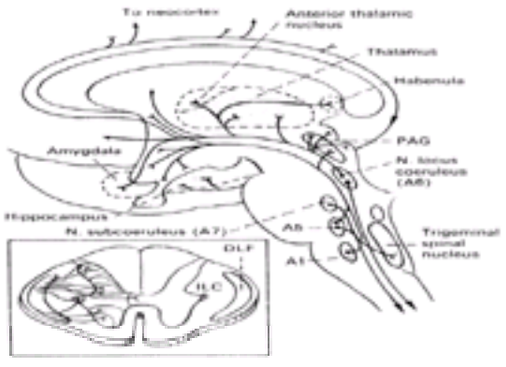

Figure 4-70. Schematic diagram of the noradrenergic system. The neurons that synthesize norepinephrine are located in the pontine and medullary tegmental regions; seven cell groups designated A-1 through A-7 have been described. Neurons that project rostrally to various parts of the diencephalon and the neocortex are found primarily in nucleus locus coeruleus (A-6) and in cell groups A-5, A-2, and A-7 (nucleus subcoeruleus). Dysfunction of the rostrally projecting norepinephrine system may play a role in pathologic anxiety, affective disorders, and schizophrenia. Neurons that have descending axons that project to the trigeminal spinal nucleus, especially the medullary dorsal horn and to the spinal cord, are found in A-5, A-6, and A-7 cell groups. In the spinal cord norepinephrine axons descend in the dorsal and ventral part of the lateral funiculus (DLF). A-6 and A-7 cell groups contribute afferents to laminae I, II $_o$, IV through VI, and X, and to motoneuron groups in the ventral horn. In addition, neurons in A-7 contribute axons to the intermediolateral cell column (ILC) of the thoracic and upper two lumbar segments of the spinal cord, whereas neurons in A-6 send a dense projection to the parasympathetic preganglionic cell column in the sacral spinal cord. (PAG, periaqueductal gray.) (Modified from Nieuwenhuys R, Voogd J, van Huijzen C. *The human central nervous system*, 2nd ed. New York: Springer-Verlag, 1981.)

Several studies indicate that a descending norepinephrine system can mediate analgesia and dorsal horn inhibition and that the norepinephrine descending system is critical for opiate-induced analgesia (28,407). Intrathecal phentolamine, an adrenergic blocker, attenuates the analgesia produced by systemic morphine administration or microinjection of morphine into the PAG. Intrathecal phenoxybenzamine, another adrenergic antagonist, blocks behavioral analgesia produced by morphine injected into the magnocellular tegmental field, and intrathecal phentolamine attenuates analgesia induced by electrical stimulation of the same region (373). Moreover, norepinephrine is released from the spinal cord after morphine microinjection or electrical stimulation in the magnocellular tegmental field, a procedure that does not release 5-HT (373). Norepinephrine is also released after electrical stimulation of the spinal cord dorsal part of the lateral funiculus or of the sciatic nerve. Anatomic evidence suggests that PAG stimulation may activate descending noradrenergic projections via the A-7 cell group (436).

Blockade of PAG SPA by intrathecal a_2-adrenergic antagonists underlines the importance of noradrenergic systems in descending nociceptive modulation (434). Intrathecal a_2-adrenergic agonists, of which clonidine is the prototype, produce analgesia in laboratory animals and humans, although such analgesia is associated with hemodynamic and sedative side effects. Much ongoing work attempts to identify a_2-adrenergic receptor subtypes that might mediate analgesia without inducing undesirable side effects. Studies in a_{2A}-receptor subtype knockout mice suggest that these receptors are primarily responsible for the spinal analgesic effects of a_2-agonists and for the synergism between spinal a_2-agonists and spinal morphine (437). Sedative and hemodynamic side effects also seem to be mediated by this receptor subtype.

The mechanism by which a_2-receptors inhibit nociception in the spinal cord is unclear. a_{2A}-Subtype receptors have been localized to substance P, presumably primary afferent, terminals in spinal cord (438). On the other hand, a number of anatomic studies have failed to show axoaxonic noradrenergic connections in spinal cord (379,439,440 and 441), making direct presynaptic primary afferent inhibitory effects unlikely. Instead, most of the anatomic evidence suggests that descending noradrenergic systems act postsynaptically on STT, trigeminothalamic tract, or dorsal horn local-circuit neurons (185). Indeed, analgesia from intrathecal injections of norepinephrine can be blocked by naloxone (442), suggesting a release of endogenous opioids, perhaps from local-circuit neurons, mediates this effect. Nonetheless, presynaptic inhibition may still take place on primary afferents, as a large number of *nonsynaptic* noradrenergic nerve terminals have been noted in the dorsal horn (379). Perhaps norepinephrine released from these terminals acts by volume transmission to inhibit primary afferent nociceptive activity (particularly with intense activation of descending fibers).

Microinjection of a_2-adrenergic agonists into the rostral ventromedial medulla also inhibits the tail-flick response, producing a long- lasting decrease in on-cell firing rate (443,444). Noradrenergic input to rostral ventromedial medulla is from A-1 to A-5 catecholamine cell groups (445) (and includes cells that also contain neurotensin). Interestingly, in contrast to the a_2 effects, rostral ventromedial medulla on- cells were excited by a_1-noradrenergic receptors (443). Thus, a_1 compounds might be expected to be facilitatory to nociception and therefore like serotonin, norepinephrine may have opposite effects on nociception depending on the specific receptor subtypes and the neural circuitry activated (412). Indeed, lesions of various noradrenergic cell groups (e.g., A5 and A7) have been found to both potentiate morphine analgesia and inhibit sensitization in the second phase of the formalin test (446), suggesting pronociceptive effects of norepinephrine in certain paradigms.

Enkephalin. Studies have demonstrated several brain stem sources of ENK-like immunoreactivity in or adjacent to NRM, including the midbrain nucleus cuneiformis, the nucleus of the solitary tract, and the dorsal parabrachial nucleus of the pons (252). Moreover, in some rostral ventromedial medulla neurons ENK and 5-HT coexist. Dynorphin-containing cells also project to the rostral ventromedial medulla (252), making the previously discussed physiologic inhibition of mu and kappa opiate receptors of more physiologic relevance. Despite the ENKergic cells projecting to and intrinsic to the spinal cord, little evidence has emerged to demonstrate the importance of spinal opioids in descending inhibition of nociception. Budai and Fields (387) find that descending inhibition of heat responses in dorsal horn cells from PAG is antagonized by iontophoresed mu antagonists. Their finding that descending dorsal horn antinociception had no effect on-cell responses to iontophoresed glutamate suggests a presynaptic antinociceptive effect, consistent with other *in vivo* and *in vitro* studies, suggesting presynaptic mu effects in the spinal cord (235) (Fig. 4-71).

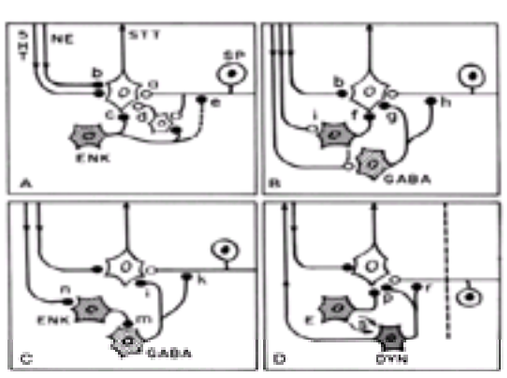

Figure 4-71. Cytochemical circuitry in the dorsal horn. Excitatory and inhibitory connections are represented by open circles and filled circles, respectively. **A:** Three major inputs to dorsal horn nociceptive neurons, some of which are at the origin of spinothalamic tract (STT) axons. Excitatory primary afferent inputs (a) are shown as originating from a substance P (SP)–containing primary afferent fiber. Descending inputs are by bulbospinal serotonin (5HT) and norepinephrine (NE) axons that postsynaptically inhibit an STT neuron (b). Local interneurons also converge onto the thalamic projection neurons, including enkephalinergic (ENK) interneurons that postsynaptically inhibit the STT neuron indicated by (c). The SP excitatory and ENK inhibitory controls may also be exerted through other excitatory interneurons of the dorsal horn (d). **B:** An example of interactions that may occur between bulbospinal axons and interneurons of the dorsal horn. Two inhibitory interneurons are shown: ENK (*cross-hatched*) and gamma- aminobutyric acid (GABA) (*dotted*) neurons postsynaptically inhibit the STT neuron (f, g, respectively). GABAergic neurons also presynaptically control the primary afferent input (h). Descending inhibitory control (from 5HT or NE axons) may be exerted either by direct postsynaptic inhibition of the STT neuron (b) or by excitation of the inhibitory interneurons (i, j). The bulbospinal inhibition and excitation derive from different populations of descending axons. Presynaptic inhibition of the primary afferent terminals also might be used by descending systems to inhibit nociception (as pictured for GABA interneurons). However, little anatomic evidence supports this mechanism, suggesting that if such effects take place (as is likely) they involve volume transmission rather than direct synaptic connections. **C:** A circuit demonstrating disinhibition by bulbospinal axons. GABAergic interneurons that presynaptically (k) or postsynaptically (i) inhibit STT projecting neurons are shown to be under tonic inhibitory control by ENK-containing interneurons (m). Activation of bulbospinal inhibition of these ENK neurons would disinhibit GABAergic cells with a net inhibition of the projection neurons. In this circuit, enkephalin would be hypothesized to cause a net excitation of spinal neurons, an action that has been reported, although not for identified STT cells. **D:** The effects of dynorphin (DYN) (fine stipple) on nociception. The action of the DYN-positive

neurons in the dorsal horn is complicated by the dual pharmacologic effects of DYN on kappa opiate and NMDA glutamate receptors. DYN, released from spinal interneurons, may inhibit primary afferent fibers (r) and projection neurons (p) via kappa opiate receptors. However, DYN also can excite nociceptive cells and increase SP release, probably via effects at the *N*-methyl-d-aspartate receptor (not shown). The interaction between dynorphinergic and enkephalinergic cells (s) is unknown. DYN-containing cells, although largely interneuronal, have also been reported to project rostrally (523). (Modified from Basbaum AI. Functional analysis of the cytochemistry of the spinal dorsal horn. In: Fields HL, Dubner R, Cervero F, eds. *Advances in pain research and therapy*. Vol 9. New York: Raven, 1985:149–175.)

Several studies report inhibitory effects of mu opioids (particularly with low doses) on descending pain inhibitory modulation produced by heterosynaptic noxious stimulation (so-called diffuse noxious inhibitory control). These findings may represent opioid inhibition of the noxious signaling that normally activates such inhibitory systems. We discuss more about the natural activation of such systems in the following sections.

Descending Facilitatory Neurochemistry. In addition to reports of monoaminergic nociceptive facilitatory effects, several other neurochemicals are implicated in mediating descending nociceptive facilitation. For example, substance P has been demonstrated in PAG and NRM somata, some of whose axons project to the superficial dorsal horn (447). Most substance P inputs to the spinal cord are still from primary afferents, however.

Descending release of TRH facilitates nociception, although, as mentioned previously, the absence of specific antagonists and the nonspecific effects of this compound (191,448) make interpretation of these findings difficult.

In contrast, several authors (100,449) have reported spinal release of CCK as underlying the nociceptive facilitatory effects of rostral ventromedial medulla stimulation, and the CCKB receptor antagonists block these effects in rodents. Moreover, spinal CCK inhibits opiate, intrathecal 5-HT_3 agonist and $GABA_B$ agonist (though not $GABA_A$ agonist) analgesia (100). Descending nociception facilitatory systems may also work by potentiating or disinhibiting spinal cord facilitatory mechanisms (e.g., glutamate or nitric oxide). Indeed, CCKB receptors are coupled to the production of arachidonic acid and presumably its cyclooxygenase and lipoxygenase metabolites, which modulate nociception. Glial activation and cytokine release also have been implicated in descending nociceptive facilitation (450).

Descending Nociceptive Modulation: Function and Physiologic Triggers

As already noted, the intricate modulation of nociception at the spinal level described thus far in this chapter must be adaptive for the animal despite the energy expended and the importance of nociception for survival. Why should an intrinsic nociception control system exist if the perception of pain is such an important life-preserving warning signal? The fact that injurious stimuli are generally perceived as hurting indicates that such a nociception-suppressive system is neither easily nor often fully activated. Little evidence suggests a tonic activity of these systems. Yet under some circumstances it might be more adaptive to inhibit pain than to perceive it. During sexual arousal, aggression, or fear, for example, perceiving pain could interfere with behaviors associated with these states, and pain suppression might have greater survival value to the organism and species than pain itself.

Teleologic speculation aside, what factors normally activate a pain-inhibitory system? A painful stimulus itself is one candidate. The firing of raphe neurons is augmented by noxious peripheral stimuli, and activation of raphe neurons by electrical stimulation can generate analgesia. David Livingstone, the Scottish missionary and explorer of Africa, reported a personal example of nociception-induced pain suppression when he was attacked by a lion during an early journey to find the source of the Nile:

> . . . I heard a shout. Starting, and looking half round, I saw the lion just in the act of springing upon me. I was upon a little height; he caught my shoulder as he sprang, and we both came to the ground below together. Growling horribly close to my ear, he shook me as a terrier does a rat. The shock produced a stupor similar to that which seems to be felt by a mouse after the first shake of the cat. It caused a sort of dreaminess in which there was no sense of pain nor feeling of terror, though quite conscious of all that was happening. It was like what patients partially under the influence of chloroform describe, who see all the operation, but feel not the knife . . . . The shake annihilated fear, and allowed no sense of horror in looking round at the beast. This peculiar state is probably produced in all animals killed by the carnivora; and if so, is a merciful provision by our benevolent creator for lessening the pain of death. [David Livingstone, *Missionary Travels*, 1857, as cited in (451).]

Much less dramatic environmental stimuli, not usually associated with pain, have been found to produce analgesia. Restraint, rotation, forced swim, and threat can all produce analgesia in laboratory animals. In humans, athletic competition, sexual stimulation, and battlefield exposure all produce substantial increases in pain thresholds. Many such situations are stressful, and stress may be a natural or physiologic trigger of intrinsic pain inhibitory systems. This phenomenon has been termed *stress-induced analgesia*.

Stress-Induced Analgesia

The first demonstrations of SIA were made in rats by Akil and collaborators (452) and Hayes and associates (453). Their results differed in one major respect, the sensitivity of SIA to antagonism by opiate antagonists. The analgesia observed by the Akil group was blocked by pretreatment with naloxone, suggesting that opioid peptides are involved in SIA as they are in SPA. The analgesia seen by the Hayes group, on the other hand, was not blocked by naloxone pretreatment, indicating a different, nonopioid, mechanism. Subsequently, SIA was studied in response to many varied stressors, but the question of the involvement of endogenous opioid peptides remained unclear. Some investigators reported naloxone blockade, and others did not see this effect. In addition, the Hayes group (453) noted that not all stressors, as defined by corticosterone release, elicit analgesia. Thus, what specific characteristics cause one type of stressor to elicit analgesia, whereas others do not, remained a mystery and is still not completely known.

Multiple Neural Mechanisms Mediating Stress-Induced Analgesia. A major problem in comparing the early studies of SIA was the variety of types of stressors used. Liebeskind's group (454) studying a single stressor, inescapable foot shock of constant intensity, found that they could elicit either naloxone-sensitive or naloxone-insensitive analgesia by varying the temporal pattern of the shock. Thus, like SPA, SIA has both an opioid form engaging endogenous opioid peptides and a nonopioid form, seemingly independent of opioid peptides. The naloxone-sensitive analgesic response met two other important criteria for inferring the involvement of opioid peptides: It showed development of tolerance with repeated administration of foot shock, and it was reduced in morphine-tolerant rats, indicating the presence of cross-tolerance (455). The nonopioid form of foot shock induced analgesia, in addition to revealing no inhibition by naloxone, and failed to show either tolerance or cross-tolerance with morphine. Further supporting the independence of these two forms of SIA is the lack of cross-tolerance between them (456).

Concurrent with the studies by Liebeskind and associates, Watkins and Mayer (457) observed that naloxone sensitivity of SIA has markedly different effects depending on the body region shocked. Low doses (0.1 mg/kg) of naloxone antagonized analgesia induced by shock to the front paw, indicating activation of an opiate system, whereas even high doses (20 mg/kg) did not reduce analgesia induced by shock to the hind paw, indicating that a nonopiate system was involved. The greater duration of stress analgesia from hind paw shock suggested that the two regionally discrete stimuli might not be equipotent stressors (458). Nonetheless, Watkins and Mayer, in a series of studies (457,459), carefully documented the anatomic and neurochemical pathways involved in SIA, finding important similarities between SIA and the SPA mechanisms supposedly activated by stress. Descending rostral ventromedial medulla to spinal cord projections in the dorsal part of the lateral funiculus proved important for mediating both opioid and nonopioid analgesia (460), and intrathecal naloxone reversal of opioid SIA suggested a spinal opioid receptor site of action. Supraspinal opiate receptors also have been found to be important in opioid SIA (461), and spinal and supraspinal opiate mechanisms may interact in a multiplicative way, just as spinal and supraspinal exogenous opiate analgesia mechanisms have been reported to do (462). A nonsegmental intraspinal inhibitory circuit is involved in nonopioid SIA; this is called a *propriospinal antinociceptive system* (409,463).

Hormonal and Autonomic Influences on Stress-Induced Analgesia. Even the opioid form of SIA has proven not to be a unitary phenomenon (464). Opioid SIA produced by numerous intermittent foot or tail shocks depends on higher brain functions: It is blocked by decerebration, muscarinic antagonists, amygdala lesions (465), and pentobarbital anesthesia, and it is correlated with the development of learned helplessness behavior. On the other hand, shorter duration shock produced opioid-mediated descending inhibition of spinal reflexes, even in the anesthetized animal. This shock-induced antinociception further muddies the use of the term *stress* in SIA, although no anesthesiologist would argue that even surgical levels of barbiturate anesthesia blocks stress.

The term *stress* as proposed by Selye (466) involved the body's response to increased physical or psychological demands by activation of the pituitary-adrenal-cortical and sympathetic-adrenal medullary axes. The hormonal products of these activations contribute to the adaptive responses of the organism to

stress by affecting energy production and the cardiovascular and immune systems (467). Because pain suppression can be viewed as an adaptive response to stress, it seems logical that these hormonal systems also play a role in SIA, and several lines of evidence support this hypothesis. b-Endorphin is highly concentrated in the pituitary, and stress causes the corelease of pituitary opioids (b-endorphin) and adrenocorticotropic hormone. In addition, the adrenal medulla contains opioid peptides that are released under the same circumstances of sympathetic activation that elicit the release of catecholamines (468). Stimuli that activate the pituitary-adrenal axis as well as the adrenal medulla cause the release of endogenous opioids from the pituitary and adrenal medulla. As might be expected, the form of opiate SIA insensitive to barbiturate anesthesia is also independent of the pituitary adrenal axis, being unaffected by adrenalectomy or hypophysectomy. Learned helplessness–linked opioid SIA, on the other hand, is blocked by hypophysectomy and adrenalectomy (454) and is mediated through adrenal medullary release of ENKs via sympathetic outflow (468). Activation of other autonomic pathways is also associated with descending nociceptive inhibition. Stimulation of vagal afferents via volume changes in the heart (469,470) or direct vagal stimulation (463,471,472,473 and 474) can activate descending inhibitory pathways, which are reported to involve opioid peptides (470,474) but that probably do not require rostral ventromedial medulla (470,471). In contrast, stimulation of sympathetic afferents has been reported to inhibit lumbar nociception without supraspinal involvement (463).

Whether various opiate SIA phenomena constitute completely independent analgesia substrates or, instead, represent different paths of access to a common neural core remains unknown. Evidence for the latter is that both opioid SIA linked to learned helplessness and opioid SIA insensitive to barbiturate anesthesia demonstrate mutual cross-tolerance. This suggests that they share a common receptor (464). Moreover, cross-tolerance develops between opioid forms of SPA and SIA (464). The effects of intrathecal naloxone in blocking opioid SIA points to a spinal opiate site of action; however, naloxone in the ventral tegmentum of the midbrain also inhibits SIA (475).

Nonopioid Stress-Induced Analgesia. The neurochemistry of nonopioid SIA is still poorly understood despite considerable study. It would be useful to activate pharmacologically the form (or forms) of SIA that shows less or no tolerance or cross-tolerance to morphine in the clinic. Although reserpine blocks nonopioid SIA (464), more specific dopamine, norepinephrine, and serotonin antagonists have proven inconsistent in inhibiting nonopioid SIA. Histamine, acting at the H_2 receptor, has been implicated in mediating nonopioid SIA (476,477). This effect most likely occurs in the PAG. Another line of evidence suggests that nonopioid analgesia may not really be nonopiate at all, but is really mediated by parallel opiate systems and, in particular, kappa opiate receptors and the kappa agonist dynorphin (478,479). Although kappa opiate–mediated analgesia has indeed been reported after or during stress (479,480,481 and 482), the large doses of naloxone normally given to define nonopiate analgesia should theoretically have been sufficient to block kappa opiate receptors as well.

$GABA_A$ (483) and $GABA_B$ (484) receptors have also been implicated in mediating SIA. Little is known of the spinal or supraspinal site of such an action.

Liebeskind and colleagues reported that nonopioid SIA, in particular that produced by swim stress, was blocked by NMDA antagonists (485). This NMDA-dependent SIA was sex specific, in that female mice demonstrated similarly potent *nonopioid* SIA not blocked by NMDA antagonists in an estrogen-dependent way (486). Kappa opiate analgesia also shows a sex difference, and endogenous kappa analgesia depends on female sex hormones (487). One wonders whether NMDA antagonist–resistant SIA in female mice might be kappa mediated. This speculation raises the issue of how various forms of SIA interact to produce nociceptive modulation.

Environmental Influences Modulating Nociception. Many stressors can produce SIA. Electric shock has been the first choice for most of the pharmacologic, anatomic, and hormonal investigations of SIA because of the ease of reproducible stress parameter manipulation without causing tissue damage. Forced swim stress has been intensively studied for similar reasons. Although neither stimulus is particularly relevant to the animal in the wild, these studies still reveal how natural stimuli might affect the organism and its nociceptive processing.

Continuous afferent stimulation via foot shock or swim stress produces opioid or nonopioid SIA differentially as a function of stress severity (464,488). The more severe the stress, the more likely that naloxone will not block the analgesia significantly.

The question of whether opioid and nonopioid mechanisms act independently has been posed, and the hypothesis put forward that they are mutually inhibitory (489,490), largely because of the potentiation of nonopiate SIA by naloxone in some studies. However, many nociceptive modulatory influences exist. Blocking opiate SIA might potentiate residual SIA simply by disinhibiting nociceptive circuitry, thereby increasing descending inhibitory influences by increasing ascending nociception.

Conversely, opiates might inhibit SIA by decreasing the nociceptive triggers for descending inhibition. Le Bars and colleagues, in a series of electrophysiologic studies of the anesthetized rat, find just such a phenomenon (337). Dorsal horn neuronal nociceptive responses are inhibited by noxious stimulation applied outside the neuron's receptive field. This phenomenon, termed *diffuse noxious inhibitory controls*, is blocked by low doses of morphine, perhaps because morphine inhibits the very nociceptive input that elicits diffuse noxious inhibitory controls. Similarly, SIA produced by severe afferent input may be sensitive to NMDA antagonists because NMDA receptors are especially likely to participate in the signaling of repeated nociceptive transmission. In addition, substance P knockout mice also have been reported to have reduced SIA (491). Thus, discriminating between a drug's effects on ascending and descending mechanisms underlying SIA is important; particularly if one hopes to activate descending nociception-inhibitory pathways without activating ascending nociceptive pathways, as would be clinically desirable. The NMDA sensitivity of SIA, then, may indicate the activation of descending feedback mechanisms when spinal NMDA receptors are activated, perhaps to keep NMDA sensitization at the spinal level to a minimum. Indeed, descending antinociceptive pathways block sensitization phenomena (492) and thresholds for sensitization are lower in spinalized (493) or animals with lesions on the dorsal part of the lateral funiculus (494).

Thus, forms of SIA elicited by continuous afferent input probably diminish nociceptive input in the behaving animal, allowing efficient escape behavior in the midst of ongoing nociception. Counterirritation analgesic therapies (including TENS, acupuncture, moxibustion, cupping, and so forth) in humans probably tap into these mechanisms to cause their pain-relieving effects. However, these forms of SIA are also important in decreasing inappropriate development of nociceptive sensitization at the spinal level.

In addition to the direct effects of noxious stimuli in producing analgesia, a large literature points to the importance of fear of such stimuli in activating pain inhibitory substrates (495,496). For example, the scent of an animal's natural predator can induce analgesia (497). One adaptive response to stress is learning to associate neutral environmental cues accompanying or preceding stress with its aversive qualities. Placing rats in a cage in which foot shock was previously received, but is not currently administered, elicits many of the responses formerly seen during shock presentation. One of these responses is analgesia, and this phenomenon has been termed *conditioned analgesia*. Evidently, animals can not only activate their intrinsic pain inhibitory systems in the presence of stress, but they can learn to activate them in anticipation of such stimuli (498) (Fig. 4-72).

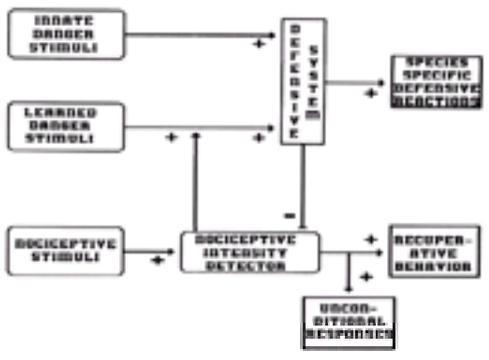

Figure 4-72. Illustration of the perceptual-defensive-recuperative model underlying descending nociceptive modulation. All links are excitatory (+) except for the link between the defensive system and the nociceptive intensity detector (–). This inhibitory link corresponds to an analgesic process. Presumably opposite processes (e.g., learned safety signal instead of learned danger) would produce opposite effects on nociception (i.e., facilitation instead of inhibition). (From Fanselow MS. Conditioned fear-induced opiate analgesia: a competing motivational state theory of stress analgesia. In: Kelly DD, ed. *Stress-induced analgesia*. New York: The New York Academy of Sciences, 1986:41, with permission.)

Most reports of conditioned analgesia have suggested that this phenomenon is mediated by endogenous opiates. The studies by Watkins and colleagues (459) have demonstrated a descending pathway mediating conditioned analgesia coursing from amygdala through PAG to lateral rostral ventromedial medulla (reticularis paragigantocellularis lateralis) and down the dorsal part of the lateral funiculus to the spinal cord. Much has been made of possible similarities between conditioned analgesia and the clinical phenomenon of placebo analgesia (499). Both, for instance, can be blocked by naloxone and CCK. Clearly, it is hard to draw comparisons between such different paradigms. In most studies of placebo, careful controls are used to avoid either SIA or conditioned analgesia (500) and unlike fear-elicited conditioned analgesia, hope is seemingly the expectation that elicits placebo analgesia. Nonetheless, conditioning greatly potentiates placebo analgesia, even when the placebo is described to the subject as being of no analgesic benefit (500).

In contrast to fear eliciting analgesia, Watkins and colleagues (416) have demonstrated that signals associated with safety after shock can block analgesia from opiate or $GABA_B$ receptor agonists. This phenomenon disappears with lesions of the midbrain dorsal raphe, NRM, and the dorsal part of the lateral funiculus (in contrast to other pain facilitatory spinal pathways suggested to lie in the ventral cord), and it is mediated by CCK. This is an antianalgesic phenomenon, rather than a nociceptive sensitization *per se* (Fig. 4-73). On the other hand, illness (450,483) activates a true descending pain facilitatory phenomenon (as anyone who has ever had a viral illness can attest) that shares many of the anatomic and neurochemical mechanisms of the antianalgesia system but over time also appears to activate spinal mechanisms of central sensitization (including NMDA and nitric oxide mechanisms). Indeed, descending facilitatory pathways have been implicated in mediating, at least partially, sensitization from mustard oil, subcutaneous formalin, carrageenan monoarthritis, and certain neuropathies (450).

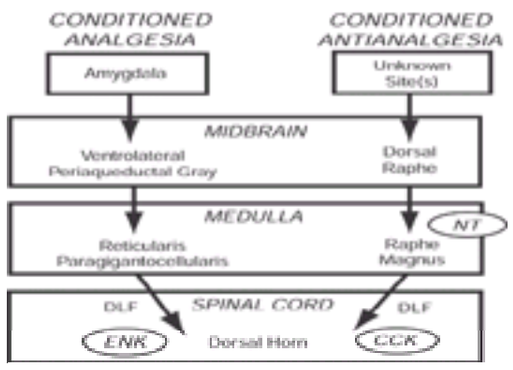

Figure 4-73. Neurocircuitry of conditioned analgesia and conditioned antianalgesia relies on distinct neural substrates that lie in close proximity throughout the neuraxis. Conditioned analgesia results from activation of the amygdala, leading to activation of the ventrolateral periaqueductal gray in the midbrain, to activation of the nucleus reticularis paragigantocellularis in the medulla through the dorsal lateral funiculus (DLF) to the spinal cord dorsal horn, where enkephalin (ENK) is released. Conditioned antianalgesia results from activation of unknown rostral brain sites that activate dorsal raphe in the midbrain, which, in turn, activates nucleus raphe magnus in the medulla, perhaps by the release of neurotensin (NT). The activated raphe magnus sends axons via the DLF to the dorsal horn where conditioned antianalgesia is produced, at least in part, by the release of cholecystokinin (CCK). (From Watkins LR, Wiertelak EP, McGorry M, et al. Neurocircuitry of conditioned inhibition of analgesia: effects of amygdala, dorsal raphe, ventral medullary and spinal cord lesions on antianalgesia in the rat. *Behav Neurosci* 1998;112:371, with permission of the American Psychological Association.)

Finally, after injury on the battlefield (or, in Livingstone's case, in the jungle), following prolonged electric shock or certain other SIA paradigms, all mechanisms of escape behavior may be exhausted. Maier and colleagues have demonstrated that animals learn to stop attempting escape from a shock: This is termed *learned helplessness*. These investigators also report a correlation of this behavior with activation of endogenous pain inhibitory mechanisms (501,502). This opioid SIA is dependent on pituitary and adrenal mechanisms and may be similarly activated by other intense forms of physical activity. Some hypothesize that this form of opioid SIA may occur in long-distance runners world-wide (503,504), who continue running even after the lions have quit chasing them.

Descending Nociceptive Modulation: Clinical Significance

Do studies of SIA have human applications? Demonstrations exist of opioid and nonopioid analgesia in humans provoked by various procedures that might be considered stressful, including acupuncture (505,506), TENS (507), and exercise (508). Perhaps such procedures activate areas of the human brain homologous to those activated by SPA and SIA in rats. Regardless, elucidating the neural basis of SIA might one day lead to the development of new approaches to pain management. Perhaps the greatest promise for such an advance lies in determining the neurochemistry of nonopioid analgesia. The similar efficacy of opioid and nonopioid SIA bode well for a nonopioid analgesic that shows no tolerance or cross-tolerance to mu opiates. A number of spinal and supraspinal nonopioid antinociceptive agents have been identified. However, in the past decade, the pharmacologic emphasis has swung subtly from investigating antinociceptive agonists to developing antagonists of certain forms of nociception.

In general, naloxone has no effect on pain thresholds, suggesting that opioid intrinsic pain inhibitory systems are not tonically active (244). Opiate antagonists can produce hyperalgesia in patients having postoperative pain, however, indicating that stress or nociception from surgery activates opioid intrinsic pain inhibitory systems (252). In this regard, to the extent that our intrinsic pain- inhibitory systems are mediated by endogenous opioid action, a consequence of prolonged opiate therapy might be a blunting of natural analgesic mechanisms through cross-tolerance. Just as opioid-mediated forms of SPA and SIA diminish in morphine-tolerant rats, so too might an opiate-tolerant pain patient's intrinsic capacity to modulate his or her own pain be reduced. Moreover, as research further defines the neurochemistry of pain and pain modulatory pathways, clinicians need to keep in mind that even nonopiate drugs appropriately prescribed for an ailment unrelated to pain might have a cost to the patient in terms of lessened pain tolerance by blocking some aspect of the intrinsic pain-inhibitory system.

Finally, the pain patient's knowledge of descending pain modulation provides a psychological double-edged sword. The existence of inhibitory systems can provide hope for overcoming debilitating nociception. Descending facilitatory systems, however, provide fodder for fears of patients (or their doctors) that their pain is “all in their heads.” Such psychological dilemmas (and their treatment) are well outside the scope of this chapter on spinal mechanisms of nociception but are integral to a full understanding of pain.

GENETIC AND DEVELOPMENTAL ASPECTS OF NOCICEPTIVE MODULATION

To this point in this chapter, we have discussed the modulation of nociception in terms of environmental influences on an organism producing a physiologic response. It is important to note, however, that modulation of nociceptive circuitry also may be under genetic preprogrammed control. We have mentioned the use of knockout mice and other genetic techniques, primarily as tools for investigating the molecular mechanisms that might be involved in producing certain nociceptive phenomena (e.g., sensitization or SIA). Investigators are also studying the genetics of nociception *per se*, however, in hopes of determining the heritability of nociception (i.e., how much of a mouse's, or human's, response to a noxious stimulus is caused by its genotype and, similarly, how much are response differences from its neighbor genetically determined). Mogil, for example, has shown that various inbred strains of mice differ dramatically in their responses to standard pain tests and their development of sensitization (509,510). Elmer (511) has, likewise, noted strain differences in opiate analgesia in mice. Although such genetic differences will be difficult to tease apart clinically from cultural and other environmental determinants, genetic risk for sensitization, for example, might one day alter pain management strategies in an individual.

Indeed, it is now clear that genetically defined modulation of nociception takes place in all of us as a function of ontogeny. For example, a decreased number of primary afferent nociceptors are found in the elderly (512). Nonetheless, an increase in pain complaints with age has been consistently reported in the clinical literature (513). Moreover, the aged appear particularly susceptible to sensitization phenomena such as postherpetic neuralgia. Two possible mechanisms for such an effect have emerged from animal models. In contrast to younger rats, aged rats have decreased neurogenesis and thus fewer cells in the dorsal root ganglia, as mentioned. Moreover, cells that remain may have increased ectopic discharges and potentiated cross-excitation of neighboring primary afferents (512). Such ectopic electrical activity is a well-studied peripheral mechanism for neuropathic pain after nerve injury decreases in DRG cell number (i.e., involution). Aged rats also contain decreased levels of spinal monoamines (serotonin and norepinephrine), possibly indicating a decrease in descending antinociceptive pathways (514). Such a decrease may also increase sensitization at the spinal level. Either or both of these hypotheses may ultimately prove correct in explaining the susceptibility of the elderly to neuropathic pain. In the meantime, research suggests that responses to therapy, including opiate pharmacodynamics (515), are not different in aged

patients.

The nociceptive processing of young animals is also quite different from animals of other ages. In general, the neonatal cord is more excitable than that of the adult, with larger reflexes and lower thresholds to noxious, particularly mechanical, stimuli (516). The A-b low-threshold mechanoreceptors, which in the adult terminate superficial to lamina III except in pathologic states associated with allodynia, normally synapse in lamina I and II of the rat until 3 weeks of age (517). Moreover, C fibers appear to facilitate their withdrawal at 3 weeks, just as in the adult, C-fiber damage appears to allow A-b return to lamina II through sprouting. Descending pain inhibitory pathways (and presumably descending facilitatory pathways as well) are absent or incomplete until 18 to 21 days of age (518).

Pharmacologically, the neonate spinal cord also differs considerably from that of the adult until 2 to 3 weeks of age. NMDA receptor responses are common in the neonatal spinal cord even without prior depolarization, and glycine and particularly GABA inhibition are greatly diminished during the first week (519). Substance P binding is nearly six times that of the adult, although normal primary afferent substance P levels are not present until day 14.

In short, the neonatal spinal cord is primed for central sensitization (519). Indeed, a number of inflammatory and neuropathic sensitization models have been described and some evidence suggests that early nociceptive experience can have long-lasting sensitizing effects in rats (520). With all of these data on the rat in hand, and similar data evident in the human neonate (521), it is tragic that there is, nevertheless, continued controversy over the importance of even minimal pain management for the child too young or too sick to complain (522).

GENERAL SUMMARY

The material presented in this chapter illustrates the concept that nociception at the spinal level, provoked by injury or disease, is the net effect of many interacting physiologic, biochemical, and even psychological mechanisms.

It is obvious that the concept of pain being transmitted via labeled line communications from body tissues to the brain is simplistic, and worse, it is wrong. A great variety of mechanisms modulate the transmission of information about tissue damage at virtually every synaptic relay station throughout the neuraxis. At the level of the STT cell (the gate-control theory's T-cell in Fig. 4-74), this is achieved through dynamic interactions between numerous neurotransmitters, their receptors, and the neural circuitry inputs from the periphery, spinal interneurons, and descending control systems from the brain. Through this process of modulation, the character of the nociceptive information received by the highest brain structures is determined. It is this low-fidelity signal that reaches the thalamus and contributes to autonomic reflexive, sensory-discriminative, motivational and affective, cognitive, and motor responses characteristic of pain behavior.

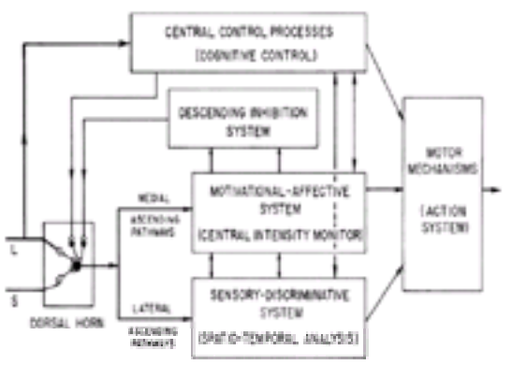

Figure 4-74. Model of the sensory, motivational, and central control of pain by Melzack and Casey. The output of the T cell in the dorsal horn projects to the sensory-discriminative system via the lateral ascending system and to the motivational-affective system via the medial ascending system. These systems interact supraspinally and eventually activate projections back to the spinal cord, modulating nociception via brain stem inhibitory and facilitatory systems as well as motor and autonomic efferent pathways. (Modified from Melzack R, Casey KL. Sensory, motivational and central control determinants of pain. In: Kenshalo DR Jr, ed. *The skin senses*. Springfield, IL: Charles C Thomas Publisher, 1968:423–443.)

CHAPTER 5

Supraspinal Mechanisms of Pain and Nociception

Eric H. Chudler and John J. Bonica

The two preceding chapters have discussed processing of nociceptive information at the peripheral and spinal levels of the nervous system. Electrophysiologic, neuropharmacologic, behavioral, and clinical data have suggested that numerous supraspinal structures process nociceptive information and may have varied roles in pain sensation and perception. Despite advancements in brain imaging methodologies that have provided new information about supraspinal pain mechanisms, a relative paucity of these data exist compared to the large body of literature pertaining to peripheral and spinal nociceptive mechanisms. This lack of data most likely is because of technical and ethical issues related to performing appropriate experiments. For example, supraspinal neuronal responses to noxious stimuli are affected by anesthetics requiring the use of awake animal preparations. This requires careful experimental planning to protect the animal from unnecessary exposure to painful stimuli.

Pain is a multidimensional experience that includes identification of somatic sensory events in terms of space, time, intensity, and submodality (mechanical, thermal, and chemical). It is associated with aversive motivational-emotional mechanisms leading to escape and other forms of aversive behavior. This complex multidimensional aspect of pain was implied by Melzack and Wall (1) and elaborated by Melzack and Casey (2), who took into account knowledge derived from physiologic and behavioral studies. Melzack and Casey (2) (Fig. 5-1) suggested three major psychological dimensions of pain: sensory-discriminative, motivational-affective, and cognitive-evaluative. Each influences motoric behavior in response to painful events. Physiologically specialized systems within the neuraxis are hypothesized to subserve these dimensions of pain. Although the Melzack-Casey conceptual model does not explain all questions regarding pain, it does provide a framework for investigating supraspinal pain processes.

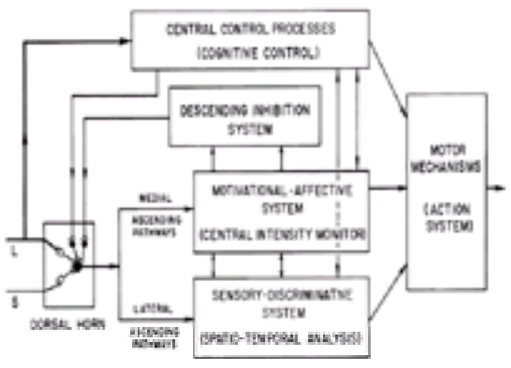

Figure 5-1. Conceptual model of the sensory, motivational, and central control determinants of pain, according to Melzack and Casey (2). The output of the T cell in the dorsal horn projects to the sensory-discriminative system via the lateral ascending system and to the dorsolateral projection systems and is represented by a heavy line running from the large fiber system of the central control processes that take place in the brain. These, in turn, project back to the dorsal horn and to the sensory-discriminative and motivational-affective systems. Added to the scheme of Melzack and Casey is the brainstem inhibitory control system activated by impulses in the medial descending system. It provides descending control on the dorsal horn. Much interaction occurs between the motivational-affective and the sensory-discriminative system, as indicated by the arrows. The net effect of all of these interacting systems is activation of the motor (action) system. (Modified from Melzack R, Casey KL. Sensory, motivational and central control determinants of pain. In: Kenshalo DR, ed. *The skin senses*. Springfield, IL: Charles C Thomas, 1968:423–443.)

RETICULAR FORMATION

The reticular formation has an important role in mediating motor, autonomic, and sensory functions. It also is involved with aversive drive and the motivational-affective dimensions of pain.

Anatomy

The reticular formation is composed of several nuclear groups each with cell bodies of distinctive sizes and shapes (Fig. 5-2, Fig. 5-3). However, as Casey (3,4) pointed out, silver stain studies reveal some common and unifying structural features superimposed on this morphologic heterogeneity. The reticular formation consists of core isodendritic neurons extending through the medulla, pons, and mesencephalon. The axonal projections of these cells are typically long, extending substantial distances along the rostral-caudal axis of the brainstem and brain. The number of short reticular formation neurons is small. Along their course, the axons send collaterals to (a) the spinal cord, (b) other reticular neurons, (c) various sensory and motor nuclei of the brainstem, (d) the diencephalon, and (e) the cerebral cortex (Fig. 5-4).

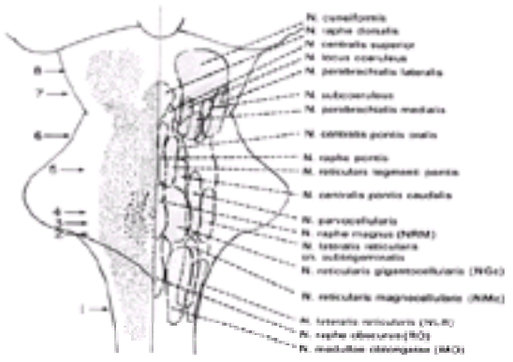

Figure 5-2. Semidiagrammatic representation of the dorsal view of the human brainstem depicts the cytoarchitecture of the reticular formation on the left and the most important subdivision of the right. The numbers to the left of the diagram indicate the sites of the cross sections shown in Figure 5-3. The abbreviations, derived from Mehler et al. (36,66), are used in Figure 5-3. (Modified from Nieuwenhuys R. *The human central nervous system: a synopsis and atlas*. New York: Springer-Verlag, 1981.)

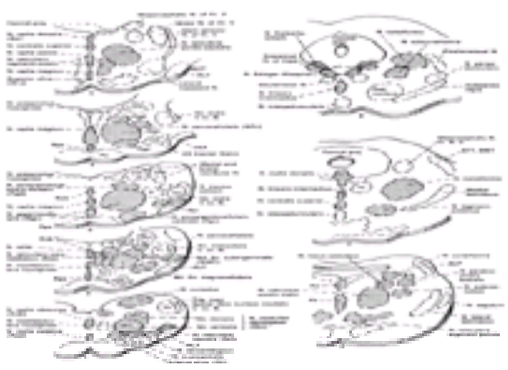

Figure 5-3. Right hemisections of eight different levels of the brainstem, indicated by the numbers on the left side of Figure 5-2, show the locations of the most important nuclei of the reticular formation and other important structures in the cat. The abbreviations in Figure 5-2 and in levels 1 to 5 are used in other levels to avoid overcrowding of the names of nuclei. (N., nucleus; Sn., subnucleus.) (Modified from Brodal A. *The reticular formation of the brain stem: anatomical aspects and functional correlations*. Springfield, IL: Charles C Thomas, 1957; and Taber J. The cytoarchitecture of the brain stem of the cat. *J Comp Neurol* 1961;116:27–52.)

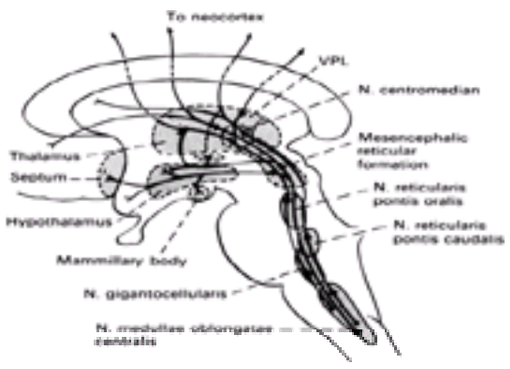

Figure 5-4. Sagittal section of the brainstem and the diencephalon shows the most important nuclei of the reticular formation and their projections to the thalamus, hypothalamus, septum, and mammillary body. (N., nucleus; VPL, ventroposterolateral nucleus.) (Modified from Nieuwenhuys R. *The human central nervous system: a synopsis and atlas*. New York: Springer-Verlag, 1981.)

Bulboreticular neurons with ascending axons send projections in the medial thalamic region, particularly in the nucleus parafascicularis, the nucleus centrum medianum, and to the more rostral mesencephalic reticular formation. Cells within the medial brainstem reticular formation of the caudal pons and the gigantocellular medial reticular area in the medulla send long ascending projections to the medial mesencephalic reticular formation and to the medial and intralaminar thalamic nuclei. Moreover, a direct relay exists from the nucleus gigantocellularis (NGC), in the medullary reticular formation, to posterior and medial thalamic nuclei. An especially massive projection exists from the mesencephalic tegmentum, particularly the central gray substance to the thalamus, subthalamus, and hypothalamus.

The periaqueductal central gray in the midbrain, a recipient of spinomesencephalic fibers, sends projections in the surrounding mesencephalic reticular formation and via the dorsal longitudinal fasciculus, in the dorsal and posterior hypothalamus, and in the midline and intralaminar thalamic nuclei and zona incerta of the subthalamus. A direct reticulocortical projection exists, and such fibers may be the longest axons in what is mainly a relay system. Therefore, at least five routes exist by which the midbrain reticular formation has access to the cerebral cortex: (a) direct, (b) via the medial forebrain bundle and hypothalamus, (c) through the thalamocortical pathway, (d) from the posterior thalamic group to the second somatosensory cortex (SII), and (e) through the ventral tier of thalamic nuclei. These ascending projections have important significance in pain-related behavior and responses. It is obvious that the reticular formation is not a diffuse network of short-axon neurons forming a multisynaptic chain, but rather a group of neurons that appears organized to distribute information quickly to multiple foci throughout a substantial portion of the neuraxis, extending from the spinal cord to the diencephalon and cerebral cortex.

Physiology and Behavior

Physiologic studies show that reticular formation neurons can mediate motor, autonomic, and sensory functions. Although circumscribed regions with specialized functions exist within the reticular formation, impressive evidence exists for substantial interaction that would provide the basis for unified operations of the reticular core (4). The reticular formation is essential for the coordination of motor behavior in animals experimentally deprived of forebrain function. Medullary and pontine reticular neurons also regulate various aspects of spinal motor activity and respiratory and other autonomic functions, including those carried out in the spinal cord. The reticular formation also has important sensory functions and is capable of modulating somatic, auditory, and visual sensory systems (4).

Electrophysiologic findings have clearly demonstrated that nociceptive afferents are among the most effective inputs that influence the discharge of a subpopulation of reticular formation neurons (3,4,5,6 and 7). Mechanical, thermal, electrical, and chemical stimuli are all capable of activating medullary and mesencephalic reticular formation neurons (3,4,5 and 6) in an exclusive or preferential manner. The receptive fields of nociceptive reticular formation neurons can be ipsilateral or bilateral. Often, the receptive fields are large and may include the entire body.

Within the medullary reticular formation, NGC neurons are most effectively activated by electrical stimulation of peripheral nerves sufficient to evoke A-d and C-nerve fibers (8). It also has been demonstrated that intraarterial injection of algogenic agents, such as bradykinin, or intense stimulation of the splanchnic nerve evokes discharge of neurons in the NGC. Neurons in the rat subnucleus reticularis dorsalis (SRD) of the reticular formation (caudal medulla) also respond to cutaneous and visceral nociceptive stimuli in the rat (9). Neurons in the monkey medullary reticular formation appear to have many of the same response properties as those in the rat SRD (10) (Fig. 5-5). Within the SRD, nociceptive neurons respond exclusively or preferentially to noxious mechanical, electrical, and thermal stimulation of the skin (11,12). Moreover, these neurons are capable of encoding the intensity of noxious stimulation in a linear fashion (12). However, the large whole body receptive fields of SRD nociceptive neurons suggest that this area may not be involved in localizing noxious stimulation. Rather, the electrophysiologic response properties and anatomic connectivity of neurons in the SRD have led Villaneuva and co-workers to hypothesize that the SRD is involved in a feedback loop that modulates spinal

outflow (9).

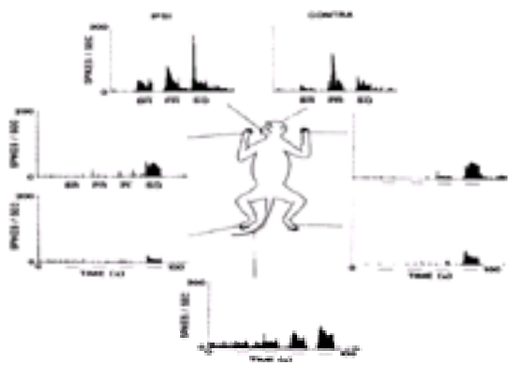

Figure 5-5. Responses of a medullary reticular formation neuron to graded mechanical stimulation of the skin on the indicated areas of the body (dorsal view). Stimuli included brushing with a soft-bristled brush (BR), pressure from a large arterial clip (PR), pinch from a small arterial clip (PI), and squeezing with forceps (SQ). Each stimulus lasted 10 seconds (*bars*). (IPSI, ipsilateral; CONTRA, contralateral.) [Reprinted from Villanueva L, Cliffer KD, Sorkin LS, et al. Convergence of heterotopic nociceptive information onto neurons of caudal medullary reticular formation in monkey (*Macaca fascicularis*). *J Neurophysiol* 1990;63:1118–1127, with permission.]

Casey and co-workers (7,8) correlated escape behavior of a cat with the neuronal activity of NGC neurons. As the intensity of electrical stimulation of radial nerve was increased, the discharge of NGC neurons increased and reached maximum levels when the cat performed a learned response that terminated the stimulus. Direct electrical stimulation of the NGC also elicited escape behaviors that were often accompanied by vocalization (13). Electrical stimulation of the mesencephalic reticular formation and central gray also have elicited aversive behavioral responses (13,14). Lesions within the medullary and mesencephalic reticular formation can produce marked decreases in the response to noxious stimuli. Melzack et al. (15) reported that medial mesencephalic lesions reduced pain behavior in cats immediately after the lesion but resulted in increased responsiveness to noxious stimuli at later postlesion periods.

Casey and associates (3,4,14) provide impressive evidence that the reticular formation is strongly influenced by nociceptive input. It also is an important determinant of pain behavior and, presumably, some aspects of the pain experience. Melzack and Casey (2) have suggested repeatedly that reticular formation neurons with ascending projections may mediate the affective-motivational dimension of the pain experience. With input from the reticular formation, the medial thalamus and hypothalamus project to limbic system forebrain structures, such as the cingulate gyrus and hippocampal formation. Both are known to play important roles in motivational and affective mechanisms. Casey (4) points out that selective lesions within limbic forebrain structures of humans and animals markedly attenuate the aversive quality of noxious stimuli without interfering with the discriminative aspects of somesthesia.

The effects of opioid analgesics on reticular formation neurons also may account in part for the reduction of suffering of clinical pain while preserving much of the discriminative ability to recognize noxious stimuli (4). Finally, the neural system mediating motivational and affective mechanisms is not simply a specialized pain pathway. Other inputs are important determinants of the affective state and can motivate behavior. Because pain is an especially compelling experience, however, nociceptive input has a major influence on the function of the reticular formation, which appears to be organized to play a critical integrating role in pain experience and behavior.

MIDBRAIN (SUPERIOR COLLICULUS)

The role of the superior colliculus (SC) in vision and sensory-motor behaviors is well established (16). Neurons in the SC receive multisensory (auditory, visual, and somatosensory) input (17,18,19 and 20) and form descending projections to the brainstem and spinal cord to influence facial, head, and neck movement (21,22 and 23). Data also suggest that the SC may be important in coordinating movements elicited by noxious stimuli (22,24).

Anatomy

Located in the mesencephalon, the superior colliculi are organized in a laminar fashion. The superficial (upper) layers of the SC receive direct input primarily from the retina and visual cortex. Neurons in the intermediate and deeper layers of the colliculi receive input from a variety of structures, including the spinal cord, basal ganglia, medullary nuclei, and cerebral cortex. Extensive crossed and uncrossed descending projections from the SC to areas in the pons, reticular formation, and spinal cord and ascending projections to the thalamus (25,26) suggest an important role of this midbrain structure in the control of sensorimotor behaviors (24).

Physiology and Behavior

Direct physiologic evidence for a role of the SC in pain comes from several laboratories. Stein and Dixon (27) first showed that neurons in the intermediate and deep layers of the SC were preferentially or exclusively activated by noxious mechanical and thermal stimulation. Moreover, intraperitoneal administration of etorphine suppressed the activity of 67% of these nociceptive neurons, and this inhibition was reversed by naloxone (27). Nociceptive SC neurons appear to be distributed in a somatotopic fashion and are found more often in the rostral SC (28). Telford et al. (29) demonstrated that noxious mechanical and chemical stimulation result in an even distribution of c-*fos* immunoreactivity along the rostrocaudal axis of the intermediate and deep layers of the SC. Nociceptive SC neurons [wide-dynamic-range (WDR)– and nociceptive-specific (NS)–type neurons] are capable of encoding mechanical and thermal stimulation intensity (23,28,30) (Fig. 5-6). The mechanical receptive field sizes of these SC neurons are often large. Within the receptive field area, a smaller, more sensitive region is usually found. It is possible that such a receptive field organization provides for location encoding of noxious stimuli.

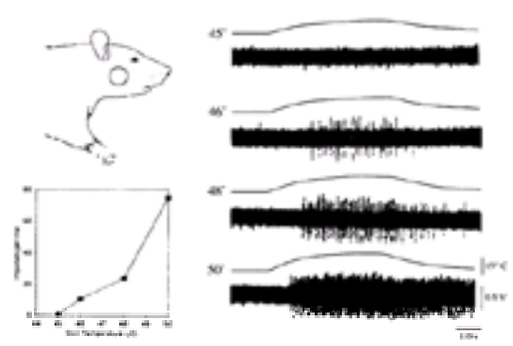

Figure 5-6. Example of the response of a nociceptive neuron in the superior colliculus. The number of impulses evoked by noxious stimuli was related to stimulus intensity. This nociceptive-specific neuron, which had a whole-body receptive field with no obvious best area, was responsive to the heat thermode placed on the face **(A)**. It showed a series of responses **(B)**, which were graded according to the intensity of the thermal stimulus. The baseline thermode temperature was matched with the ambient skin temperature (35°C). The values plotted in **C** show the number of impulses recorded during the 5- second duration of the heat pulse in each trial. (Reprinted from Redgrave P, McHaffie JG, Stein BE. Nociceptive neurones in rat superior colliculus. I. Antidromic activation from the contralateral predorsal bundle. *Exp Brain Res* 1996; 109:185–196, with permission.)

The existence of a nociceptive tectothalamic pathway has been demonstrated using electrophysiologic methods. Almost half of the SC neurons that are antidromically activated by stimulation of the intralaminar nuclei of the thalamus have been classified as nociceptive (25,26). Grunwerg and Krauthamer (26,31) found that 58% of the intralaminar thalamic neurons orthodromically activated by electrical stimulation of the intermediate and deep layers of SC were responsive to noxious mechanical

stimulation. Chemical lesions of this same region of the SC resulted in a significant reduction in the number of nociceptive intralaminar thalamic neurons (26). Redgrave and co-workers (23,32) also provided convincing evidence that chemical disruption of the SC and lesions of the descending pathway from the SC result in deficits to localize and respond to noxious mechanical and chemical stimuli while leaving general motor behavior unaffected.

The tectothalamic pathway and its extension to the striatum as well as tectofugal pathways may mediate withdrawal, orientation, and avoidance of noxious stimuli (28,33,34). The high incidence of neurons with trigeminal receptive fields within the SC, intralaminar nuclei of the thalamus, and striatum suggests that these neurons may play a role in controlling or coordinating head movement, orientation, and positioning during escape behavior (34).

THALAMUS

As a gateway and relay center for afferent input transmitted to the cerebral cortex, the thalamus makes refined cutaneous awareness of pain possible. It is subdivided into several anatomically or functionally distinct nuclei, most of which are linked to the cerebral cortex and limbic areas by ascending and descending tracts. Jones (35) defines the three major subdivisions of the thalamus as the (a) epithalamus (anterior and posterior paraventricular nuclei, habenular nuclei); (b) dorsal thalamus [ventrobasal (VB) nuclei and intralaminar nuclei]; and (c) ventral thalamus [reticular nucleus, ventral lateral (VL) geniculate nucleus, and zona incerta]. The majority of pain-related experiments in the diencephalon have focused on the role of the dorsal thalamus (Fig. 5-7).

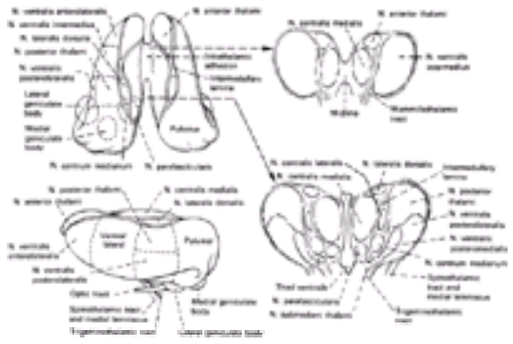

Figure 5-7. Schematic diagram of the human thalamus. **A:** Superior view. **B:** Lateral view shows the locations of the most important nuclei. **C:** Frontal section of the anterior part of the thalamus depicts the relationships of various nuclei. **D:** Frontal section of the middle part of the thalamus. Note that the spinothalamic tract and medial lemniscus terminate in nucleus (N.) ventralis posterolateralis, whereas the trigeminothalamic tract terminates in N. ventralis posteromedialis.

Ventrobasal Nuclei of the Thalamus

Anatomy

The VB nuclei comprise the ventral and posterior thalamic nuclei. These nuclei are subdivided into lateral and medial divisions called the *ventral posterior lateral* (VPL) (or *ventroposterolateral*) nucleus and the *ventral posterior medial* (VPM) (or *ventroposteromedial*) nucleus.

Ventroposterolateral Nucleus

The VPL nucleus receives fibers principally from the medial lemniscus formed, in part, by the second-order neurons of the dorsal column nuclei of the opposite site, which terminate on the VPL nucleus in basketlike clusters of terminal endings (see Fig. 5-7). Spinothalamic tract (STT) neurons that originate in laminae I and V terminate in the caudal and oral portions of the VPL nucleus in patchlike clusters that Mehler (36) called *bursts* in transverse sections or rod-like zones in three dimensions. The STT and medial lemniscal (dorsal column nuclei) projections to the VPL nucleus are organized somatotopically, with fibers from the lumbosacral cord (lower extremity) distributed laterally and fibers from the cervical cord (upper extremity) ending medially in the nucleus (Fig. 5-8). The VB nuclei also receive projections from the periaqueductal gray. The VPL nucleus projects to the first somatosensory (SI) cortex, the posterior parietal cortex, and may have a small projection to the SII cortex (37), and receives corticothalamic projections from these areas (38).

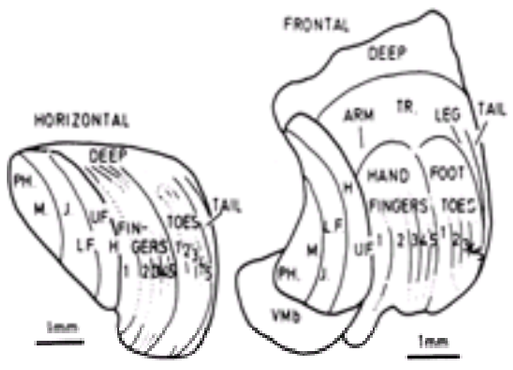

Figure 5-8. Schematic diagram of the left half of the thalamus shows on horizontal and frontal planes the overall lamellar pattern of representation in the cutaneous core of VPLc (the caudal division of the VPL) and ventroposteromedial nucleus and the anterodorsal deep shell of the ventrobasal complex in monkeys. The diagrams indicate a nearly complete separation of zones for cutaneous and deep modalities. The caudal body parts are represented laterally and the rostral body parts medially. The axial body parts are represented dorsally with the limbs represented progressively more ventrally. (H, head; J, jaws; LF, lower face; M, mouth; PH, pharynx; UF, upper face.) (Reprinted from Jones EG, Friedman DP. Projection pattern of functional components of the thalamic ventrobasal complex in monkey somatosensory cortex. *J Neurophysiol* 1982;48:521–544, with permission.)

Within the SI cortex, separate thalamic termination zones exist in areas 3a, 3b, 1, and 2 (38,39). Figure 5-9 illustrates the projection scheme by Jones and Friedman (39). The central core of the VPLc (the caudal division of the VPL), with neurons responsive to cutaneous stimuli, projects to areas 3b and 1 and the thinner anterodorsal shell of the VPLc, with neurons responsive to deep-tissue stimulation, projects to areas 2 and 3a. Penny et al. (40) presented evidence for a separate population of thalamic neurons that project to different cortical laminae in the SI cortex. Small VPL neurons project to lamina I, whereas large VPL neurons terminate in layers (40). Penny et al. suggest that large and small VPL neurons have separate functions based on inputs from large and small neurons in dorsal column nuclei. This may also apply to STT projections to the VPL nucleus.

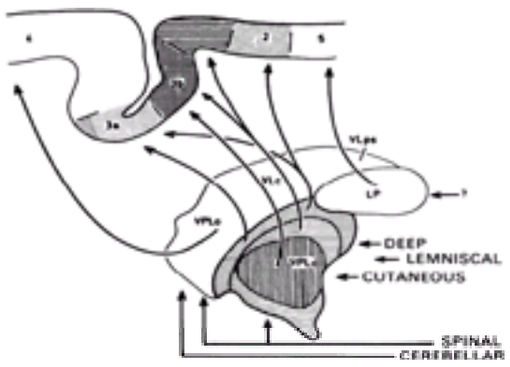

Figure 5-9. Schematic diagram shows on sagittal sections the pattern of input-output connections of the ventrobasal complex and adjacent thalamic nuclei in monkeys. Note the projection from the medial lemniscus to two components of the central cutaneous core of VPLc (the caudal division of the VPL), which projects to area 3b and 1 or area 3b only; projection of the anterodorsal deep shell is to area 3a and 2. The spinothalamic tract ends in the cutaneous core region that projects to area 3b and 1 and in the VPLo (the oral division of the VPL) nucleus, which is connected with the motor cortex (area 4). The cerebellar projections to VPLo are to separate neurons from those receiving spinothalamic projections. (Reprinted from Jones EG, Friedman DP. Projection pattern of functional components of the thalamic ventrobasal complex in monkey somatosensory cortex. *J Neurophysiol* 1982;48:521–544, with permission.)

Ventroposteromedial Nucleus

The VPM nucleus receives input from the main sensory trigeminal nucleus, from the pars interpolaris, and from the subnucleus caudalis via the trigeminothalamic tracts. VPM nucleus input from the main sensory nucleus and the subnucleus interpolaris is roughly analogous to the lemniscal input to the VPL nucleus, whereas the input from the subnucleus caudalis is roughly analogous to input from the neospinothalamic projection. VPM neurons project to the somatosensory cortex on the lateral part of the cerebral convexity in the postcentral gyrus. Corticofugal fibers descend from this region into the VPM nucleus.

Physiology and Behavior

Ventroposterolateral Nucleus

It is well established that the majority of neurons in the VB nuclei respond exclusively to somatic stimuli delivered to discrete regions of the contralateral body surface. Many investigators have emphasized that neurons respond to mechanoreceptive input either from tactile receptors, proprioceptors, or other deep receptors. A small percentage of VPL neurons in anesthetized and unanesthetized monkeys have either NS- or WDR-receptive field characteristics (41,42 and 43). Morrow and Casey (41) reported that only 13.1% of the recorded VPL neurons in awake monkeys were WDR-type neurons and none were NS-type neurons. Nociceptive VPL neurons have small receptive fields on the body and are arranged somatotopically within the VPL nucleus. More recently, in human subjects, thalamic neurons within the ventrocaudal nucleus (Vc), the human equivalent of the VPLc and VPM nucleus, have been identified that are preferentially or exclusively activated by noxious mechanical or thermal stimulation (44,45). This same area of the thalamus evokes pain sensations when stimulated (44,46,47). Moreover, abnormal spontaneous and evoked discharge patterns in some Vc neurons have been observed in patients with central pain during neurosurgical procedures (48,49).

In addition to receiving cutaneous input, the VPL nucleus receives visceral input. Colorectal distension and chemical irritation, urinary bladder distension, and electrical stimulation of the renal nerve all activate neurons in the VPL nucleus (50,51,52 and 53). Most neurons responsive to visceral stimuli have convergent somatic receptive fields. Lesions of the dorsal column reduce the neuronal response to visceral and cutaneous stimulation, but lesions of the ventrolateral column reduce only the response to cutaneous stimuli (52,53). These observations suggest that the dorsal columns play a critical role in the transmission of visceral nociceptive information to supraspinal structures.

Ventroposteromedial Nucleus

Like neurons in the VPL nucleus, VPM neurons are somatotopically organized and respond to innocuous and noxious input, but the majority of cells are classified as low-threshold mechanoreceptive neurons. These neurons are place specific: Each neuron responds only to stimulation of a restricted area of the contralateral side of the orofacial region. In awake monkeys trained on a thermal discrimination task, VPM neurons respond in a graded fashion to noxious cutaneous stimuli between 46°C and 49°C (54). Most VPM neurons in awake monkeys are multimodal because they respond to thermal and mechanical stimulation.

The role of the VPM nucleus in the sensory-discriminative aspect of pain is strengthened further by the observation that lidocaine microinjections in the VPM nucleus reduce the ability of monkeys to discriminate noxious cutaneous heat stimuli (55). Although inactivation of the VPM nucleus with lidocaine disrupted the monkey's ability to discriminate innocuous cooling and mechanical stimuli, the greatest effect was on noxious heat discrimination. Early attempts in humans to alleviate pain by surgical lesions focused on ventrocaudal nuclei of the thalamus (56). Neurosurgeons have abandoned this procedure because of the inconsistent results and a high complication rate (e.g., sensory loss, ataxia, and dysesthesia).

Summary

It is clear that the VPL and VPM nuclei play important roles in discriminative functions of pain. Electrophysiologic experiments have demonstrated that nociceptive neurons in these regions of the thalamus have small, somatotopically organized receptive fields. Furthermore, disruption of neural activity within the VB thalamus affects sensory discriminative abilities.

Posterior Group of Thalamic Nuclei

Anatomy

The posterolateral thalamus contains a cytoarchitecturally heterogeneous group of cells medial to the medial geniculate nucleus, extending rostrally to the nucleus ventralis posterior. This thalamic region, called the *posterior group* (PO) of thalamic nuclei, receives spinal somatic sensory input. This is contributed primarily by the spinothalamic system (57). It also receives lemniscal input from the dorsal column nuclei and from the spinocervical tract. Several projections arise from the posterior complex, but of principal interest is the projection of the medial portion of the posterior nuclear complex to the retroinsular cortex. This cortical zone is adjacent to the SII cortex and forms an additional somatosensory receiving area independent of SI and SII (see the section Cerebral Cortex). Cortical projections from the PO thalamic region include far fewer ascending axons than the extensive corticofugal input into the PO from the somatosensory cortical areas.

Physiology and Behavior

In lightly anesthetized cats, Poggio and Mountcastle (58) found a substantial proportion of PO neurons responded to noxious mechanical stimulation of the skin. They proposed that this region of the thalamus was a major relay center for neural activity subserving pain sensation. Subsequent studies failed to reveal a significant number of nociceptive neurons (59). This discrepancy may be because of the use of deeply anesthetized animals. Subsequent experiments have studied the response properties of PO neurons in lightly anesthetized and unanesthetized monkeys. Dong and Wagman (60), using lightly anesthetized cats, found a significant population of PO neurons that responded to noxious stimulation. Out of 258 somatosensory neurons studied, 16% were classified as NS and 14% were WDR. Guilbaud and co-workers (61), who worked with unanesthetized cats, found that 76 of 135 neurons (56.3%) were nociceptive. Furthermore, of these 76 nociceptive neurons, 41 neurons (53.9%) responded exclusively to noxious stimuli and 35 neurons (46.1%) were preferentially responsive to noxious stimuli.

In humans, Hassler (62) reported that stimulation of a region similar to the PO elicited reports of pain. Whether this effect was caused by excitation of PO neurons or ascending spinal fibers passing through the PO region toward other thalamic cells is uncertain. Destruction of the PO-like region in patients provides pain relief if the lesion is extensive enough to also involve some medial thalamic structures (63,64 and 65) (see Chapter 108). All authors agree that this region lacks somatotopic

organization and that receptive fields of neurons are often large and bilateral (5,59).

Medial and Intralaminar Thalamic Nuclei

Anatomy

The medial and intralaminar thalamic nuclei belong to the so-called diffuse or nonspecific thalamic system. This is so designated because electrophysiologic evidence suggests that these thalamic structures have widespread cortical influence in contrast to other thalamic nuclei, such as the VPL nucleus, which project directly to circumscribed cortical areas. (For a detailed discussion of the anatomic and physiologic properties of these nuclei, see reference 57.)

The intralaminar nuclei form a shell around the lateral aspect of the nucleus medialis dorsalis and are composed of five nuclear groups: the nucleus paracentralis, nucleus centralis medialis, nucleus centrum medianum, nucleus centralis later–alis, and nucleus parafascicularis (see Fig. 5-7). According to Mehler and associates (36,66), direct spinothalamic fibers from the ventrolateral spinal cord sweep over but do not terminate with the centrum medianum. They send terminals to the nucleus centralis lateralis and lateral portion of the dorsal medial nucleus, called *subnuclei multiformis* and *densocellularis*. Although endings of the STT in nucleus parafascicularis and nucleus centrum medianum are sparse (66), noxious inputs from the STT can gain access to these nuclei by way of the reticular formation (67,68). As mentioned previously, this part of the spinothalamic system originates from the deeper layers of the spinal gray and does not have somatotopic organization.

In addition to the direct spinothalamic input to the intralaminar complex, direct projections from the reticular formation relay impulses initiated by the spinoreticular projection from the ventrolateral spinal cord. Anatomic and electrophysiologic evidence exists for projections from the NGC to the centrum medianum and parafascicular region. Mancia et al. (69) have provided evidence that stimulation of the NGC excites intralaminar thalamic neurons directly. Finally, the intralaminar nuclei receive input from the mesencephalic reticular formation and central gray. Therefore, the posterior midline and intralaminar nuclei of the “diffuse projecting thalamic system” receive somatic input either directly from ascending spinal and trigeminal pathways or indirectly via reticular neurons that receive spinoreticular and trigeminoreticular input. The intralaminar thalamic nuclei also receive projections from the cerebral cortex, principally from areas rostral to the central sulcus.

Projections from the intralaminar thalamic nuclei are quite heterogeneous and diffuse. A major projection links the centrum medianum-parafascicular complex to the basal ganglia (caudate nucleus and putamen). This suggests that the role of this thalamic complex in pain is related to motor and emotional reactions and aversive drive (70). Although most of these thalamic nuclei are thought to have few direct projections to the cerebral cortex, electrophysiologic evidence leaves little doubt that electrical stimulation of the intralaminar area has widespread cortical effects. It appears to function as part of the “diffuse reticular activating system” studied extensively by Magoun (71). Neurons of this region project diffusely to wide areas of the cerebral cortex, including the frontal, parietal, and limbic regions (see the section Cerebral Cortex).

Physiology

In the unanesthetized monkey, Casey (72) noted that cells in the lateral part of the medialis dorsalis and in other medial and intralaminar nuclei responded to innocuous stimuli but responded much more vigorously to stimuli defined as noxious on the basis of the behavioral response of the animal. Other findings also show that neurons in this region of the rat respond to noxious visceral stimulation (73).

Dong et al. (60) found that a large proportion of neurons in these regions responded exclusively to noxious stimuli or to noxious and innocuous (tap) mechanical stimuli. Several investigations have made observations consistent with those of Dong et al.: Electrical stimulation of peripheral nerves at intensities necessary to recruit A-d and C nerve fibers evoke activity in medial and intralaminar nuclei neurons (59). The receptive fields of these thalamic neurons are large and often bilateral. Little evidence exists for somatotopic organization of input. This nuclear complex receives convergent input from skin, joint, and muscle (74).

Recordings from neurons in the intralaminar nuclei in humans are similar to those in animals. Thus, Ishijima et al. (75) demonstrated the existence of nociceptive neurons in the centrum medianum-parafascicular complex. These neurons possessed large receptive fields that occasionally included the contralateral half and ipsilateral upper part of the body. They observed two classes of neurons: Those with a short latency responses were found predominantly in the basomedial portion of the parafascicular nucleus; those with long latencies were located in the dorsal centromedian and parafascicular regions. They proposed that neurons responding with short latencies were activated by A-d nerve fiber input whereas those that respond with long latencies were activated by C nerve fibers.

Tasker et al. (76) reported that stimulation of the medial-intralaminar thalamus in normal individuals did not elicit pain, but in patients with deafferentation pain, stimulation of the mesencephalon and medial thalamus produced burning pain in the area of peripheral deafferentation. Sano et al. have reported similar observations (77). They also found that lesions within the medial and intralaminar system could relieve intractable pain caused by neoplastic disease. The centrum medianum-parafascicular-medialis dorsalis complex appears to be a critical determinant of the efficacy of the operation. These lesions appear to diminish the affective dimension of pain, while preserving somatosensory discriminative capacity. The effects of such lesions resemble those produced by frontal lobotomy on responses to painful stimulation, but they do not produce the same effects on cognition or social behaviors.

Nucleus Submedius

Anatomy

Craig and Burton (78) detailed the anatomic connections of a ventromedial thalamic area called the *nucleus submedius* (Sm), also called the *nucleus gelatinosus*. In the cat, lamina I neurons in the medullary and dorsal horn project directly to Sm (78,79,80 and 81). In contrast to these findings, the Sm in the rat receives projections from deep and superficial layers of the medullary and spinal dorsal horn (82,83 and 84). A reciprocal connection between Sm and the ventrolateral orbital (VLO) cortex has been demonstrated using anterograde and retrograde tracing methods (85,86) and electrophysiologic techniques (87).

Physiology and Behavior

The Sm contains a substantial number of neurons driven exclusively or preferentially by noxious cutaneous and visceral stimuli (79,87,88,89,90 and 91). The majority of nociceptive neurons in this region respond to noxious stimuli, but some are inhibited by noxious cutaneous stimuli. Many nociceptive Sm neurons respond to noxious stimulation with activity that outlasts the duration of the stimulus, and most nociceptive Sm neurons have large, bilateral receptive fields. Although spinal and trigeminal input terminate in the dorsal portion of Sm, nociceptive neurons extend throughout the dorsal-ventral extremes of the nucleus. These findings suggest that nociceptive neurons in the ventral portion of the Sm have dendrites in the dorsal portion of the nucleus or receive axons or axon collaterals from neurons in the dorsal region (88).

Two behavioral experiments have provided additional evidence regarding a possible role of Sm in pain modulation. Using an anesthetized rat preparation, Zhang et al. (92) demonstrated that bilateral, but not unilateral, destruction of the Sm facilitated the tail-flick reflex and reduced the analgesic effects of hindlimb stimulation as measured with the tail-flick test. Roberts and Dong (93), however, were unable to show any effect of bilateral Sm lesions on tail-flick latency 7 days after surgery. They did report significant decreases in the intensity of electrical shock necessary to evoke vocalization. Additional behavioral experiments are necessary to clarify the role of Sm in pain.

Ventral Medial Nucleus

Anatomic (94) and electrophysiologic studies (95) have demonstrated a projection from lamina I of the dorsal horn to the posterior part of the ventral medial (VMpo) nucleus of the thalamus. Anterograde tracing studies have revealed that the VMpo nucleus projects to the insular cortex (94). Unlike the majority of neurons in the VPL and VPM nuclei, most (97%) neurons in the VMpo nucleus responded to noxious or thermal (cold) stimuli (96). Thermally responsive VMpo neurons had small receptive fields and increased activity with increasing stimulus intensity. These data suggest an additional supraspinal pathway for nociceptive information that may function in the sensory-discriminative and affective-motivational dimensions of pain.

HYPOTHALAMUS AND LIMBIC SYSTEM (AMYGDALA, CINGULATE CORTEX)

Noxious stimuli that elicit pain often are highly motivating and tend to provoke strong autonomic arousal and emotional responses mediated by the hypothalamus and limbic system structures (97,98,99 and 100). The hypothalamus integrates and regulates the autonomic nervous system and the neuroendocrine response and helps to organize and coordinate visceral and somatic reaction patterns caused by tissue damage and pain.

As Jänig (97) described in a simplified view, the cerebrum consists of the neocortex and the limbic system (paleocortex). Goal- directed human behavior is generated by the cerebrum by integrating limbic and neocortical activity. In this process, the neocortex, which is clearly involved in sensory processing and integration, tends to regulate the precise spatiotemporal communication with the environment and formal intellectual and stereognostic capabilities. The reciprocal connection between the neocortex and many parts of the limbic system makes possible the interplay between these two systems that constitutes a functional anatomic substrate for behavior expression and regulation. The limbic system is concerned with mood and incentives to action, such as a person's motivational interaction and emotions (97). The limbic system endows the information derived from internal and external events with its particular significance to humans, and thus it determines each person's characteristic purposeful behavior.

The limbic system comprises the phylogenetic old parts of the telencephalon and the subcortical structures derived from them (99), as well as parts of the diencephalon and mesencephalon (Fig. 5-10). The telencephalic components of the limbic system include the amygdala, hippocampus, septal nuclei, nucleus accubens and diagonal band of Broca, bed nucleus of the stria terminalis, and the preoptic region. In addition, several transitional cortical areas also are involved in limbic circuitry: the parahippocampal, periamygdaloid, entorhinal and cingulate gyrus, insular and temporal cortex, and the orbitofrontal part of the neocortex. In the diencephalon, limbic structures include the hypothalamus and parts of the thalamus and “epithalamus,” or habenula. Limbic brain areas that occupy a paramedian position include the ventral tegmental area, dorsal tegmental nucleus, and parts of the periaqueductal gray and midbrain raphe nuclei.

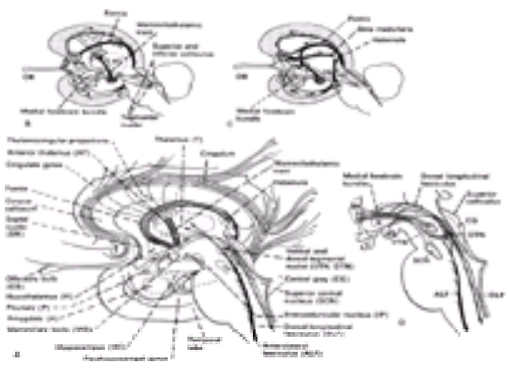

Figure 5-10. The limbic system. **A:** Sagittal section depicts the most important structures and connecting pathways. Note the projection of the anterolateral fasciculus containing the spinothalamic tract to the central gray of the mesencephalon and to the thalamus and the connections of the latter structure with other parts of the limbic system. The nucleus submedius also receives spinothalamic tract input and projects to the orbitofrontal cortex (not shown in this figure). **B, C:** Modifications of MacLean's schematic drawing, which placed emphasis on the medial forebrain bundle (MFB) as a major line of communication between the limbic cortex of the hypothalamus and the midbrain (262). Note the relationship between the fornix and cingulum, which become separated through the growth of the corpus callosum. **B** shows ascending pathways to the limbic cortex with emphasis on divergence of fibers from the MFB to the amygdala and septum and **C** shows descending pathways from the limbic cortex. (MT, medial thalamus; other abbreviations in **B** and **C** are listed in **A**.) **D:** Diagram to show connections made between the central gray (CG), the dorsal tegmental nucleus (DTN), the superior central nucleus (SCN), and the ventral tegmental nucleus (VTN) on the one hand, and the septal nuclei (SN) and mammillary body (MB) via the MFB on the other. The diagram also depicts the projection from the dorsal longitudinal fasciculus (DLF) from the hypothalamus to the brainstem and spinal cord, mediating sympathetic and parasympathetic and other autonomic information to these structures. (Developed from material in Isaacson RL. *The limbic system*. New York: Plenum Press, 1974; and MacLean PD. Contrasting functions of limbic and neocortical systems of the brain and their relevance to psychophysiological aspects of medicine. *Am J Med* 1958;25:611–626; Netter FH. Nervous system: anatomy and physiology. In: *CIBA collection of medical illustrations*. Vol. 1. CIBA, West Caldwell, NJ: 1983; and MacLean PD. The limbic system with respect to self- preservation and the preservation of the species. *J Nerv Ment Dis* 1958;127:1–11.)

Hypothalamus

Anatomy

The hypothalamus is a phylogenetically old part of the brain, considered essential in regulating the internal milieu. It is the diencephalic center of a group of structures forming a ring or “limbus” (border) of the medial forebrain structures around the rostral pole of the brainstem. As the ventral part of the diencephalon, the hypothalamus bounds the ventral half of the third ventricle, lying ventral to the thalamus and bounded caudally by the mesencephalon and rostrally by the laminae terminalis, the anterior commissure, and the optic chiasm. Lateral to the hypothalamus lie the optic tract, the internal capsule, and the subthalamic structures. Figure 5-11 depicts the anatomy and connectivity of the hypothalamus.

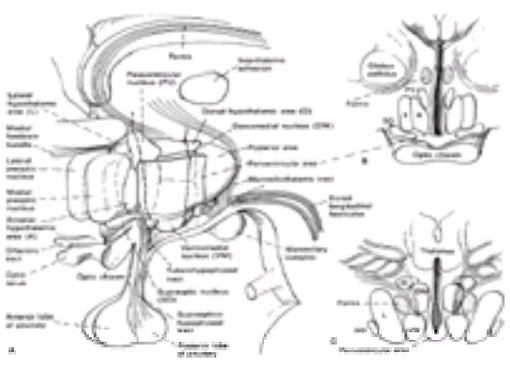

Figure 5-11. Schematic diagram of the hypothalamus. **A:** Sagittal view shows the most important nuclei and the pathways connecting the hypothalamus with the pituitary gland, fornix, brainstem, and spinal cord (dorsal longitudinal fasciculus). **B, C:** Frontal sections at sites 1 and 2 in **A** show the relationship of the various nuclei, named with abbreviations indicated in **A**. (Modified from Netter FH. Nervous system: anatomy and physiology. In: *CIBA collection of medical illustrations*. Vol. 1. West Caldwell, NJ: CIBA, 1983.)

Within the hypothalamus are three mediolaterally arranged parts: the periventricular zone, the medial hypothalamus, and the lateral hypothalamus. The periventricular zone is a thin sheet adjacent to the third ventricle. The medial hypothalamus contains various nuclear regions that control sympathetic and parasympathetic function. The ventromedial part of the hypothalamus gives rise to the hypophyseal stalk (infundibulum with the adenohypophysis and neurohypophysis). The lateral hypothalamus does not contain distinct nuclear regions. Instead, neurons disperse throughout it and surround the medial forebrain bundle (97,98).

The circuits that involve the hypothalamus include major pathways, such as the mammillothalamic tract and medial forebrain bundle in the lateral hypothalamic region, the fornix, and the stria terminalis (see Fig. 5-10). These fiber pathways interconnect the hypothalamus with limbic forebrain structures, such as the cingulate cortex, hippocampus and hippocampal gyrus, the amygdala, and the septal region. The hypothalamic region receives ascending input through the dorsal longitudinal fasciculus formed by fibers connecting the hypothalamus with the periaqueductal central gray and the dorsal tegmental nucleus of the midbrain, as well as visceral, sensory, and somatic motor autonomic centers in the caudal medulla (e.g., nucleus tractus solitarius and the dorsal motor nucleus of the vagus). The hypothalamic distribution of this pathway is mainly to the supramammillary, premammillary, and posterior hypothalamic group of cells, and the caudal end of the lateral

hypothalamus. The mammillary peduncle also carries ascending fibers from the caudal mesencephalic area via the medial forebrain bundle of the hypothalamus. In addition, more diffuse reticulohypothalamic connections exist by which activity of the brainstem reticular formation can influence hypothalamic and limbic forebrain function.

Neuroanatomic (101,102,103,104 and 105) and physiologic (106,107,108,109,110 and 111) tract tracing experiments have demonstrated a direct bilateral pathway from the spinal cord to the medial and lateral divisions of the hypothalamus (112,113). In rats, this spinohypothalamic tract (SHT) is almost the same size as the STT (102). The existence of the SHT in cats (114) and monkeys (115) also has been demonstrated. Within the spinal cord, the majority of cell bodies that give rise to the SHT are located in the marginal zone (lamina I), the lateral reticular area (lamina V), and the area around of the central canal (lamina X). Many SHT neurons provide collateral axons to structures in the brainstem and thalamus (92,109). A direct pathway from the medullary dorsal horn (nucleus caudalis) to the hypothalamus also has been demonstrated (113,116,117). Giesler et al. (112) have reviewed convincing evidence for a role of each of these spinal cord areas in nociception. Because of the anatomic connectivity and physiologic characteristics of SHT neurons, these authors suggest that the SHT has a role in emotional, autonomic, and neuroendocrine responses to nociceptive stimuli.

Physiology

Most SHT neurons in the cervical, lumbar, and sacral spinal cord respond preferentially or exclusively to noxious mechanical and thermal stimulation (107). SHT neurons in the sacral segments of the spinal cord also may respond to visceral stimulation (110,111). Approximately one-half of the SHT neurons recorded in the cervical spinal cord of rats have large or complex (e.g., discontinuous) receptive fields (106,107). In the lumbar spinal cord, however, all SHT neurons have small receptive fields incorporating only the ipsilateral hindpaw (118). SHT neurons encode the intensity of visceral stimulation (colorectal distension and vaginal distension) best described by a power function (111). Within the hypothalamus, some neurons respond to visceral and somatosensory (noxious and nonnoxious) stimuli (98). These neurons have bilateral receptive fields and may respond to multisensory input. Thus, it appears that the hypothalamus is not organized to provide spatial, temporal, or modality-specific information. The short- and long-latency hypothalamic responses to somatic stimulation suggest a rapidly conducting input (perhaps via the SHT) as well as a presumably polysynaptic input (119).

A few studies have shown that some hypothalamic neurons respond to nociceptive stimulation of the teeth and skin. Electrical tooth pulp stimulation activates some neurons in the lateral (120,121), anterior, posterior, and tuberal hypothalamus (122,123). Noxious mechanical stimulation of the skin also can activate some neurons in the paraventricular nucleus (124), lateral area (121,125), supraoptic area (126), preoptic area, and anterior hypothalamus (127). Sidar and Oomura (128) demonstrated that noxious radiant heat applied to the scrotum of rats was capable of inhibiting 69% of those lateral hypothalamic neurons that also were sensitive to glucose. These glucose-sensitive, nociceptive neurons were inhibited in a stimulus-dependent manner. Because all of these experiments have used anesthetized preparations, how the responsiveness of nociceptive hypothalamic neurons relates to nocifensive behavior remains unknown. Further quantitative investigations that study the response properties of hypothalamic neurons to nociceptive stimuli and that correlate these responses to behavioral indices of pain are warranted.

Lesion Studies

Electrolytic lesions of the hypothalamic periventricular nucleus (129) and posteromedial nucleus (130,131) have provided some relief for patients with cancer pain (see Chapter 108).

Amygdala

In primates, the amygdala occupies a large portion of the medial temporal lobe. The amygdala is subdivided into several distinct groups of nuclei, each having its own unique cytoarchitecture, afferent and efferent patterns, and histochemistry. The central nucleus of the amygdala (CEA) has received the most attention with regard to pain and nociception and is discussed in detail here.

Anatomy

The CEA is located in the caudal portion of the amygdala. It extends laterally to the external capsule and medially to the medial nucleus of the amygdala. The CEA can be separated into two divisions: the medial division, with small to medium-sized neurons; and the lateral division. In addition to receiving many intrinsic afferent projections from other nuclei of the amygdala, the CEA receives afferent input from the hypothalamus and thalamus. Anatomic studies have demonstrated that neurons in the lateral parabrachial area that receive spinal input project directly to the CEA (132,133,134,135 and 136).

Physiology and Behavior

Electrophysiologic studies have shown that some nociceptive neurons in the lateral parabrachial region can be antidromically activated by electrical stimulation of the CEA (137). In anesthetized rats, the activity of a large proportion (77%) of neurons in the CEA is altered by noxious mechanical and thermal stimulation of the skin (Fig. 5-12) (137). Many neurons in the lateral nucleus of the amygdala also can be activated by noxious electrical stimulation (138). CEA neurons have large cutaneous receptive fields, which suggests that the amygdala is not involved with the precise localization of noxious stimuli (137). On the other hand, the ability of CEA neurons to encode noxious stimulus intensity suggests that the amygdala may be involved in the intensive aspect of the sensory-discriminative dimension of pain.

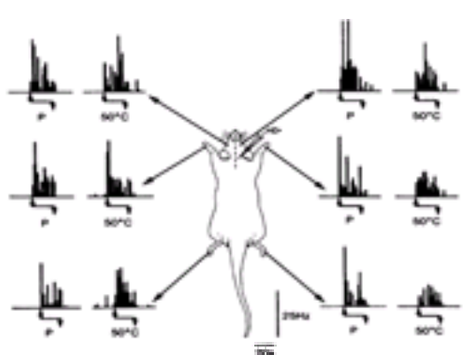

Figure 5-12. Response of a nociceptive-specific neuron located in the rostral lateral capsular subdivision of the nucleus centralis of the amygdala, with a very low spontaneous discharge (<0.1 Hz) and large receptive field. Thermal (50°C) and mechanical stimuli (P, pinch) were applied (duration between the two arrows) to the four paws and the face. (Reprinted from Bernard JF, Huang GF, Besson JM. Nucleus centralis of the amygdala and the globus pallidus ventralis: electrophysiological evidence for an involvement in pain processes. *J Neurophysiol* 1992;68:551–569, with permission.)

Although endogenous opioids play many roles in the central nervous system, the abundance of opiate receptors in the amygdala (139) suggests a role for the amygdala in pain. However, the reported effects of opiate injection in the amygdala on pain reactivity are equivocal. The injection of morphine or an enkephalinase inhibitor in the CEA has no effect on pain behavior when measured by the tail-flick and hot-plate tests (140,141 and 142). But supraspinal pain tests indicate that the amygdala may have a role in pain behavior. After bilateral amygdalar lesions, several behavioral effects occur, including (a) increased vocalization and jump thresholds, (b) apparent decreased pain sensation caused by trigeminal neuralgia, (c) reduced localization of painful electrical stimuli, (d) decreased aggressive behavior directed toward a noxious stimulus, and (e) reduced morphine- and stress-induced analgesia (140,143,144,145,146,147,148 and 149). Microinjection of neurotensin or an enkephalinase inhibitor in the CEA also results in analgesia as measured by the latency to paw lick and jump in response to a thermal stimulus (142,150).

Cingulate Cortex

Anatomy

The anterior cingulate cortex participates in motor, autonomic, and affective behaviors. It has attracted attention for its possible role in pain and nociception. This area of the limbic system is characterized by a high concentration of opioid receptors (151). Moreover, the anterior cingulate cortex receives direct input from several thalamic nuclei (e.g., nucleus parafasicularis, centrolateral nucleus, ventromedial nucleus, and Sm) known to process nociceptive information (152).

Physiology and Behavior

In the anterior cingulate cortex (area 24) of the rabbit, approximately 28%, 42%, and 19% of the tested neurons responded to noxious electrical, mechanical, and thermal stimuli, respectively (Fig. 5-13) (153). Many area 24 neurons that are responsive to noxious thermal stimuli also are activated by noxious mechanical stimuli. Nociceptive neurons in this area of the brain have bilateral, broad, mechanical receptive fields: In 12 of 15 tested neurons, noxious mechanical stimuli anywhere on the dorsal surface of the body elicited a response. These neurons apparently do not provide information pertaining to stimulus localization. In addition to noxious cutaneous stimuli, visceral stimulation delivered by colorectal distension can activate neurons in the anterior cingulate cortex of rats (154). In human subjects undergoing surgery for epilepsy, laser-evoked potentials are maximal in amplitude over area 24 (155).

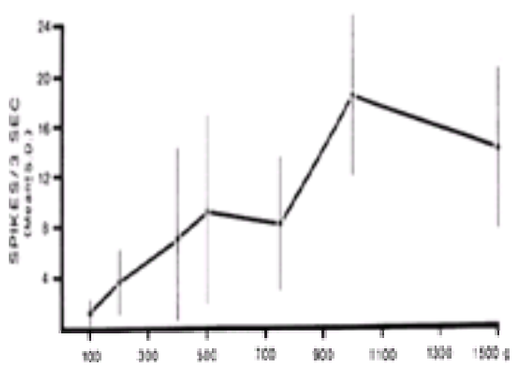

Figure 5-13. Responses to a graded series of mechanical stimuli for five units. The response was calculated by subtracting the average baseline activity previous to the stimulus from 3 seconds of the response. The mean value for each stimulus amplitude was calculated for each unit and the mean plus or minus the standard deviation (SD) calculated for all units. (Reprinted from Sikes RW, Vogt BA. Nociceptive neurons in area 24 of rabbit cingulate cortex. *J Neurophysiol* 1992; 68:1720–1732, with permission.)

Numerous studies show that lesions of the cingulate gyrus can decrease pain sensitivity. In the cat, bilateral destruction of the cingulate gyrus raised the escape threshold to electrical stimulation of the teeth (156). In the rat, an injection of local anesthetic in the cingulum bundle resulted in analgesia as measured by the formalin test (157) and reduced autotomy caused by a sciatic-saphenous nerve ligation (158). Pain arising from intractable cancer and reflex sympathetic dystrophy has diminished in human subjects after lesions of the cingulate gyrus (159,160), and electrical stimulation of the cingulate gyrus has resulted in a contralateral pain sensation in one patient (161). Devinsky et al. (152) hypothesize that the anterior cingulate cortex may participate in several aspects of pain, including the (a) affective nature of noxious stimuli, (b) motor response to noxious stimuli, and (c) learning associated with predicting and avoiding noxious stimuli.

Blood flow to the anterior cingulate cortex is increased by nonnoxious and noxious stimulation. However, numerous brain imaging studies have shown that the anterior cingulate area is one of the few supraspinal structures that consistently exhibits a significant increase in blood flow in response to noxious stimulation compared to that evoked by nonnoxious stimulation (Table 5-1). Noxious cutaneous thermal stimulation and intradermal chemical (capsaicin) administration result in a significant increase in blood flow to the anterior cingulate gyrus (162). Although it is possible that the alterations in anterior cingulate cortical blood flow evoked by noxious stimuli may be because of nonspecific attentional mechanisms, Derbyshire et al. (163) have shown a minimal overlap in the cingulate cortical area activated during an attentional-cognitive task (Stroop interference task) and noxious thermal stimuli.

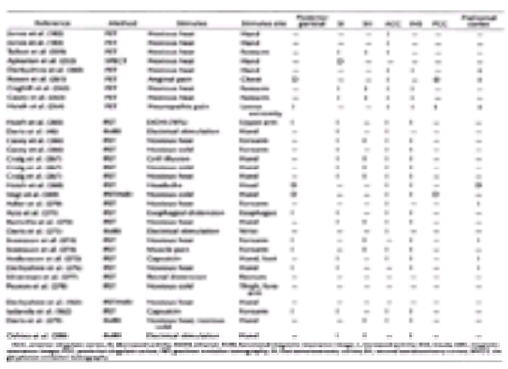

TABLE 5-1. Cortical areas activated by noxious cutaneous and visceral stimulation

Basal Ganglia

The role of the basal ganglia in movement has been studied for several decades. The functional organization and results from clinical studies suggest additional roles for the basal ganglia in higher order cognitive behaviors and sensory processes. Although it has been known since the 1950s that neurons within the basal ganglia may respond to visual, auditory, and somatosensory stimuli, some electrophysiologic, pharmacologic, behavioral, and clinical studies have implicated the basal ganglia in various dimensions of the pain experience (34).

Anatomy

The basal ganglia include a number of interconnected subcortical nuclei, including the caudate nucleus, putamen, globus pallidus (GP), substantia nigra, and subthalamic nucleus. The caudate nucleus and putamen collectively are known as the *neostriatum* or *striatum*. The striatum receives input primarily from the cerebral cortex, intralaminar nuclei of the thalamus, and substantia nigra pars compacta and projects to the GP. Efferents from the GP include those to the substantia nigra pars reticulata and thalamus (ventral anterior and VL nuclei). The substantia nigra pars reticulata also projects to ventral anterior and VL nuclei and has additional descending projections to the SC and pedunculopontine tegmental nucleus. The subthalamic nucleus receives input primarily from the cerebral cortex and GP and projects to the substantia nigra and back to the GP. Parent and Hazrati (164,165) provide an extensive review of the afferent and efferent pathways of the basal ganglia. Nociceptive information may reach the basal ganglia through several convergent pathways, including the cerebral cortex, medial and posterior thalamus, amygdala, parabrachial nucleus, and dorsal raphe nucleus (34). Direct spinostriatal and spinopallidal pathways may provide an additional source of nociceptive input to basal ganglia structures (105,115).

Physiology and Behavior

Although many neurons in the basal ganglia respond to low-intensity, nonnoxious, cutaneous stimulation, some neurons within the caudate nucleus, putamen, GP, and substantia nigra respond preferentially or exclusively to noxious thermal or mechanical stimulation (34). In rats and cats, a high proportion (44% to 97%) of the caudate-putamen (CPu) and GP neurons have been classified as nociceptive (33,166,167 and 168). Many of these nociceptive neurons are capable of encoding

noxious mechanical and thermal stimulus intensity (Fig. 5-14). The majority of nociceptive neurons in all basal ganglia structures have large receptive fields that may include the whole body (33,138,166,168,169,170 and 171), but orofacial structures appear to predominate within the receptive fields of CPu and GP nociceptive neurons (33,172,173,174 and 175).

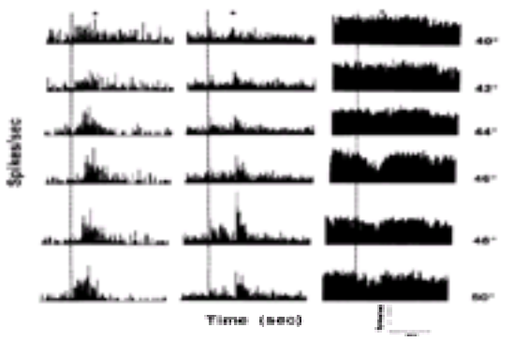

Figure 5-14. Thermal stimulus response functions of caudate-putamen (CPu) and globus pallidus (GP) neurons. The discharge frequency of some thermoreceptive CPu and GP neurons increased during the plateau stimulus temperature **(A)** while that of other neurons increased during the phasic rise, plateau, and phasic decrease in stimulus temperature **(B)**. Other neurons responded with a decrease in discharge frequency during the plateau stimulus phase **(C)**. The vertical dashes indicate the start of the stimulus increase. The down arrow indicates the start of the return of the stimulus to the baseline temperature of 38°C. The vertical scale bar represents 8, 40, and 32 spikes per sec in **A**, **B**, and **C**, respectively; horizontal scale bar represents 5 seconds in all figures. (Reprinted from Chudler EH. Response properties of neurons in the caudate-putamen and globus pallidus to noxious and non-noxious thermal stimulation in anesthetized rats. *Brain Res* 1998;812:283–288, with permission.)

Microinjection of opioid and dopaminergic agents in the CPu, GP, and SN have mixed effects on nociceptive behaviors (34). Administration of morphine in the GP and SN may produce dose-dependent, naloxone-reversible analgesia in rats as measured using the tail-flick test (176,177). On the other hand, intrastriatal morphine and beta-endorphin injections do not raise reflexive pain thresholds consistently. In primates, electrical stimulation of the caudate nucleus alters escape force without affecting escape latency or the number of escapes to electrical stimulation of the skin (178). In humans, electrical stimulation of the caudate nucleus can reduce chronic pain (179). Systemic administration of levodopa, the precursor of dopamine, has proven effective in relieving pain caused by diabetic polyneuropathy (180) and Parkinsonism (181), but the mechanisms responsible for the pain relief are unknown.

Brain imaging methodologies show that blood flow within several basal ganglia structures changes after experimentally induced pain and during several clinical pain states. Positron emission tomography studies have shown that noxious thermal stimulation of the skin (182,183) and an intradermal injection of capsaicin (162) increase blood flow to the putamen or GP, or both. Patients with pain caused by fibromyalgia and headache also show changes in blood flow to the caudate nucleus and putamen (184,185 and 186). In rats, neuropathic pain produced by a chronic constriction injury of the sciatic nerve produces an increase in glucose utilization within the CPu (187).

Several groups of patients with clinical conditions that affect the basal ganglia have been studied with regard to alterations in somatosensory function. A large proportion of patients with Parkinson's disease has sensory abnormalities, including pain. This pain may be contralateral to the side affected by motor tremor and may appear before the onset of motor symptoms. Although clinical pain testing of patients with Parkinson's disease may fail to uncover deficits in pain sensibility, careful psychophysical experimentation has revealed deficits in pain threshold and tolerance (188,189). Other neurologic conditions that affect the basal ganglia (i.e., neuroleptic-induced extrapyramidal syndrome, Huntington's disease, inherited peripheral neuropathy with extrapyramidal symptoms, torticollis, and “restless legs and pain toes”) also may present with alterations in pain perception (34,190,191).

These clinical and experimental data led Chudler and Dong (34) to hypothesize that the basal ganglia may play a role in the cognitive, motivational-affective, and sensory-discriminative dimensions of pain and participate in the motor response evoked by noxious stimuli and modulation of pain. Further experimentation with animal models of basal ganglia disease and human subjects afflicted with basal ganglia disease will help clarify the role of these areas in pain and nociception.

Cerebral Cortex

Anatomy

The VB thalamus and parts of the paleothalamus connect to the cerebral cortex by ascending (corticopetal) and descending (corticofugal) projections. The thalamus sends sensory input to the SI and SII cortices. The SI is located on the postcentral gyrus and extends from the longitudinal cerebral fissure superiorly to the lateral sulcus below (Fig. 5-15). The SII cortex is located on the superior bank of the lateral sulcus. Two other areas of the parietal lobe implicated in the processing of nociceptive information are the retroinsular cortex (Ri) and area 7b. Some electrophysiologic and brain imaging studies provide strong evidence that areas of the frontal and cingulate cortices play a role in the emotional dimension of pain. The thalamic Sm projects to the orbitofrontal cortex, which sends afferents to the cingulate gyrus. Gingold (192) used combined anterograde and retrograde tracing methods to show that the SI receives nociceptive information via a spinothalamocortical pathway through the VPL, VPI, and CL nuclei of the thalamus. Other work with these anatomic techniques indicates that nociceptive information from the spinal cord is relayed to the SII via the VPI, VPL, PO, and CL nuclei (193). Corticofugal afferents from these areas terminate in various thalamic nuclei and contribute to corticobulbar and corticospinal descending systems. Friedman et al. (37) have proposed that tactile learning and memory are mediated by serial processing of information from the SI to SII cortexes to the temporal lobe. Moreover, Pons et al. (194,195) have provided physiologic evidence for serial processing of somatosensory information in the SI and SII cortices. Stevens et al. (193) postulate that the STT may reach the SII directly through the VPI, VPL, and PO nuclei of the thalamus. Although it has not been demonstrated that learning and memory of painful events follow these pathways, Lenz et al. (196) hypothesize that a thalamic-parasylvian cortical-limbic pathway may be involved in some affective component of painful memories.

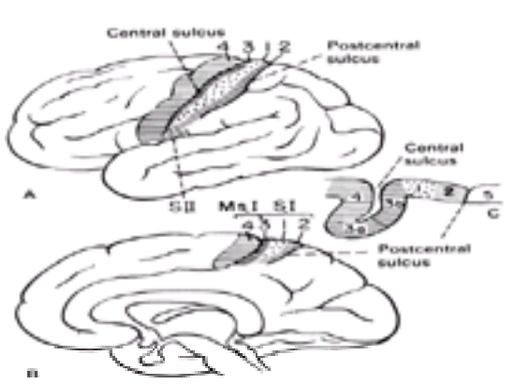

Figure 5-15. Diagrams of superolateral **(A)** and medial **(B)** surfaces of the human cerebral hemisphere to depict the cytoarchitectonic areas of the first (SI) and second (SII) somatosensory areas of the cerebral cortex. **C:** Sagittal section to show the relationship of the four areas of SI. Area 3 of SI extends through the floor of the central sulcus, where it becomes continuous with the primary motor cortex (area 4). This transitional zone is called *3a*, and the main part of area 3 is called *3b*. Area 2 extends along the posterior wall of the postcentral gyrus to the postcentral sulcus, which separates SI anteriorly from areas 5 and 7 in the superior parietal lobule posteriorly. (MsI, primary motor cortex.) (Modified from Jones EG, Friedman DP. Projection pattern of functional components of the thalamic ventrobasal complex in monkey somatosensory cortex. *J Neurophysiol* 1982;48:521–544; and Brodmann K. Dergleichende lokaliastionstehre der grosshirnde. In: *Ihren prinzipien dargestellt auf grund des zellendaues*. Leipzig: Barth, 1909.)

First Somatosensory Cortex (SI)

The SI consists of three distinct cytoarchitectonic subdivisions: areas 3, 1, and 2 (see Fig. 5-15). Area 3 is further subdivided into area 3a that is adjacent to the motor cortex (area 4) and area 3b. Posterior to 3b and oriented longitudinally along the crest of the postcentral gyrus is area 1, and behind this is area 2, which extends along the posterior wall of the postcentral gyrus to the postcentral sulcus. Neurons in SI are organized somatotopically: Each area of the body is represented in distinct, well-defined loci within the SI (197) (Fig. 5-16). Figure 5-16 illustrates that certain areas of the body have larger cortical surface area representation than other body parts. For example, the face and hands occupy more cortical area than the trunk and legs. This seemingly distorted map of the body on the cortical surface correlates with the peripheral density of somatosensory receptors in various body parts. Correlations between peripheral nociceptor density and cortical surface area have not been demonstrated.

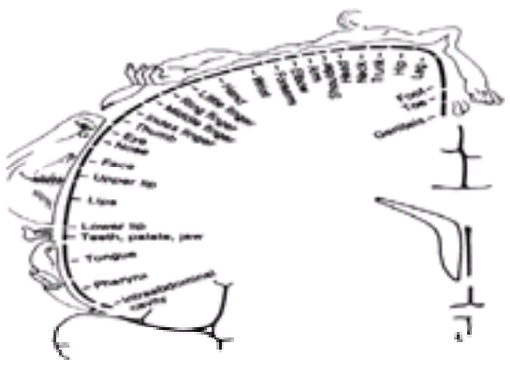

Figure 5-16. Somatotopic pattern of representation in the human first somatosensory (SI) cortex. Differences in relative size of body parts were determined by electrical stimulation of the SI cortex. Lesion Studies

In the early 1900s, Head and Holmes (198) and Head (199) examined patients with cortical injury, disease, or tumors. The persistence in the ability to appreciate pain in this population of patients led these authors to conclude that the cerebral cortex has a minimal role in pain perception. Nevertheless, many lesions of the SI do alter the ability to detect and discriminate painful stimuli and also may alleviate phantom limb pain and central pain syndromes (200,201). Sweet (65) cites studies in which patients underwent resection of the postcentral gyrus related to the painful site. Nearly 80% of the patients derived early relief, but the relief persisted in fewer than 25% of the cases. A widely cited report in support of the role of the SI in pain was published by Marshall in 1951 (202). Using rigid criteria, he selected patients who had penetrating brain wounds with permanent severe sensory loss. He examined these patients meticulously 5 years after their injuries, at which time the sensory findings were constant. All 11 patients had superficial wounds of the parietal cortex that produced contralateral, highly localized loss of superficial pain. Loss of deep pain was observed in some patients. Tactile sensation was markedly or moderately reduced.

Experimental lesions in nonhuman primates provide additional support for a role of the SI in the detection and discrimination of noxious stimuli. Impairments in the ability to localize or discriminate noxious mechanical and thermal stimuli have been demonstrated in monkeys with lesions of the SI (200,203,204). Kenshalo and Willis (200) (Fig. 5-17) have demonstrated that bilateral lesions of the SI produce deficits in the ability of trained monkeys to detect and discriminate noxious thermal stimuli. Because the monkeys' ability to detect cold and visual stimuli was unimpaired, the effects of the lesion were probably not the result of alterations in motor, attentional, or motivational factors. Recovery in the ability to detect and discriminate noxious stimuli occurred after approximately 24 weeks.

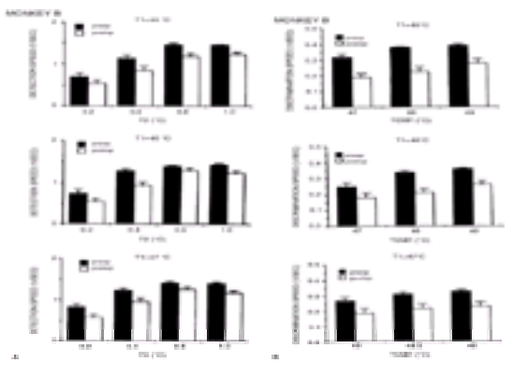

Figure 5-17. **A:** Effect of bilateral first somatosensory cortex (SI) lesions on the speed of the second temperature shift (T2) detection of noxious thermal stimuli is depicted for the first temperature change from a baseline of 38°C (T1) intensities of 45°C, 46°C, and 47°C. **B:** Effect of bilateral SI cortex lesions on discrimination of noxious thermal stimuli. The monkey's preoperative (preop) performance for 3 weeks is shown by the filled bars and postoperative (postop) performance for 3 weeks by the open bars. Error bars represent the standard error of the mean. (Reprinted from Kenshalo DR Jr, Willis WD Jr. The role of the cerebral cortex in pain sensation. In: Peters A, ed. *Cerebral cortex*. New York: Plenum Publishing 1991;9:153–212, with permission.)

Electrical Stimulation

Early experiments in which electrical stimulation was used to stimulate the exposed cerebral cortex of awake patients undergoing brain surgery failed to produce reports of pain (205,206). Although sensations, such as tingling and numbness, were reported, pain was rarely evoked by electrical stimuli. Sweet (65) has summarized this work, which led to the view that thalamic circuits, rather than the cerebral cortex, subserved pain sensation. Careful review of the literature, however, indicates that electrical stimulation of the SI can elicit pain (59,63,200). Moreover, excitation of the SI during epileptic seizure may result in an aura of pain (200). Young and Blume (207) reported that approximately 3% of those patients with an epileptic focus over the SI have painful seizures. Patients report such events as burning, tingling, shooting, cramping, and throbbing.

Electrophysiology

Evoked potential methodologies have been used since the 1960s in attempts to provide an objective measure of the cortical response to pain (208,209). The somatosensory evoked potential represents a time-locked alteration in the electroencephalogram produced by cutaneous stimulation. Technologies to detect magnetic fields originating from the brain also have afforded the opportunity to study pain-evoked responses from the cerebral cortex. In most cases, an averaged response evoked by multiple trials is used in the final analysis. Noxious thermal, mechanical, electrical, and chemical stimuli all have been used to generate evoked potentials in human subjects. Most studies have attempted to correlate the amplitude or latency of near-field components of the evoked potential with noxious stimulus intensity and pain report.

The tooth pulp, a structure comprised almost entirely of unmyelinated C and small myelinated A-d nerve fibers, was one of the first structures used to elicit pain-evoked potentials. Electrical stimulation of the tooth pulp in humans results in pain and a highly reliable series of positive and negative waveforms (208). Increases in stimulus intensity applied to the tooth result in increases in the pain report and in the amplitude of the evoked potential. Tooth pulp–evoked potentials also have been recorded over the SI of nonhuman primates (70,210,211).

Despite the positive correlation of evoked potential amplitude with pain report, several methodologic problems cloud the interpretation of the pain-evoked potential

studies. First, increases in stimulus intensity may result in the recruitment of additional nonnociceptive afferents in the nerve volley. This is especially true in studies using mechanical and electrical stimulation. Therefore, increases in evoked potential amplitude may reflect the recruitment of additional nonnociceptive neural activity rather than nociceptive activity. Second, the generator site of the evoked potentials elicited by noxious stimuli is not well understood. Often, only an electrode located at the vertex is used to record changes in the activity. Because the neural generator of the vertex potential is unclear, the origin of this waveform remains unknown. Magnetoencephalographic studies have indicated that painful electrical stimulation causes bilateral activation of the SI and SII cortices that may result in a maximal, electrically recorded, evoked potential at vertex (212). Other reports have attempted to map laser heat-evoked potentials in attempts to isolate the generator of pain-evoked potentials (213,214). Third, it is possible to dissociate the pain report and evoked potential amplitude. Chapman et al. (215) and Jacobson et al. (216) reported that increases in stimulus rate resulted in a reduction in the amplitude of the tooth pulp–evoked potential, but no change in pain report. Pain perception and evoked potential amplitude also are differentially affected by benzodiazepines (217). Small doses of benzodiazepine, which reduce anxiety without changing pain report, significantly reduce the amplitude of carbon dioxide laser–evoked potentials. Furthermore, hypnosis that reduces pain report has no effect on the amplitude of evoked potentials elicited by electrical stimulation (218). A dissociation between laser stimulus intensity, pain report, and the vertex response to noxious thermal stimulation has also been reported (219). These considerations indicate that evoked potentials elicited by noxious stimuli may reflect emotional or motivational components of pain, not just the sensory-discrimination aspects of pain.

Extracellular single-unit recording from the SI in rats, cats, and monkeys has provided convincing evidence that the SI plays a role in the sensory-discriminative aspect of pain. Noxious electrical and chemical tooth pulp stimulation (211,220,221) and noxious mechanical and thermal stimuli all are capable of preferentially or exclusively activating SI neurons (33,222,223). These nociceptive SI neurons have receptive fields that follow the same somatotopic organization of nonnociceptive neurons. Many nociceptive SI neurons in awake monkeys are capable of encoding the intensity of noxious tooth pulp stimuli (221) and noxious thermal stimuli applied to the face (Fig. 5-18) (223). Moreover, the discharge frequency of some nociceptive SI neurons is correlated to the perceived intensity of noxious stimuli (221,223). Chudler et al. (224) found that alterations in the interstimulus interval, which produced changes in the intensity of pain sensation, also affected the discharge rate of nociceptive SI neurons (Fig. 5-19). SI neurons in the primate (225) and rat (226) also can be activated by noxious stimulation of the viscera (bladder, colon, and esophagus).

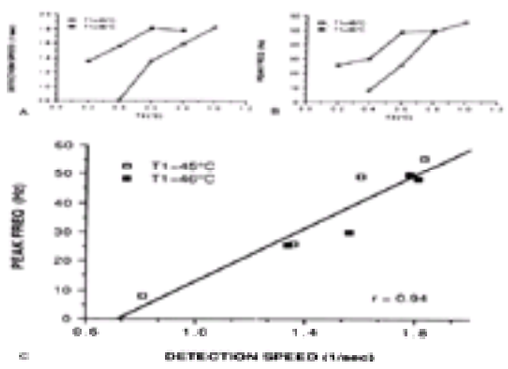

Figure 5-18. **A:** Average detection speed plotted as a function of the second temperature shift (T2) stimulus intensity from a first temperature change from a baseline of 38°C (T1) of either 45°C or 46°C. **B:** Peak frequency of neuronal discharge of a first somatosensory cortex neuron plotted as a function of T2 intensity for either a 45°C or 46°C T1. The peak frequency was determined from peristimulus time histograms (200-millisecond bin width) after the onset of T2 and before the monkey released the button. Each point represents the average of four trials. **C:** Peak frequency plotted as a function of detection speed for all T2 stimuli. The solid line represents the linear regression of the equation fit to the scatter plot. (r, regression coefficient.) (Reprinted from Kenshalo DR Jr, Chudler EH, Anton F, et al. SI nociceptive neurons participate in the encoding process by which monkeys perceive the intensity of noxious thermal stimulation. *Brain Res* 1988; 454:378–382, with permission.)

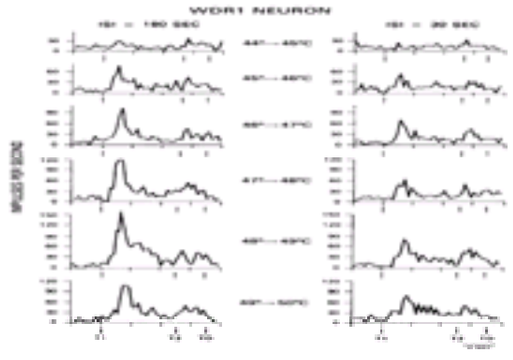

Figure 5-19. Averaged peristimulus time histograms of wide-dynamic-range type 1 (WDR1) neurons in first somatosensory cortex obtained when the interstimulus interval (ISI) was 180 seconds and 30 seconds. Each histogram was constructed by averaging two trials for each first temperature change from a baseline of 38°C (T1) and second temperature shift (T2) temperature for all neurons. Therefore, 28 pairs of T1 and T2 stimuli comprise each histogram. Numbers in the middle of the figure refer to the initial T1 and final T2 temperatures presented. Significant suppression of the T1 neuronal response observed within activity elicited with ISIs of 30 seconds is compared with that evoked when ISIs were 180 seconds (bin width, 100 milliseconds). (TD, temperature begins to return to baseline.) (Reprinted from Chudler EH, Anton F, Dubner R, et al. Responses of nociceptive SI neurons in monkeys and pain sensation in humans elicited by noxious thermal stimulation: effect of interstimulus interval. *J Neurophysiol* 1990;63:559–569, with permission.)

A few studies have examined the laminar distribution of nociceptive SI neurons. Kenshalo et al. (227) and Chudler et al. (224) reported that the majority of SI neurons that respond to noxious thermal stimulation of the face were located in cortical layers III and IV. In rats, however, cutaneous nociceptive neurons are located primarily in cortical layers V and VI (228,229), and visceral noxious neurons are located in layers IV and V (226).

Brain Imaging

Introduction of noninvasive brain-imaging methods has provided investigators with an additional tool to study cortical pain mechanisms (230). Several laboratories have demonstrated that activity in the SI is altered after noxious thermal, electrical, and chemical stimulation (see Table 5-1). Porro et al. (231) demonstrated that activity within the SI (and other areas) is positively correlated to the perceived intensity of noxious chemical stimulation. However, the SI is not activated consistently by noxious stimuli, and one study described a decrease in blood flow to the SI (232). Differences in stimulation procedures may partially account for the inconsistent observations that brain-imaging methods produce. It also is possible that the relatively low number and distribution of nociceptive neurons within the SI may contribute to the variable changes in cerebral blood flow after noxious stimulation. For example, SI nociceptive neurons appear to be distributed in discrete clusters scattered among nonnociceptive neurons (208,223). This arrangement of responsive neurons may impair the observation of change in blood flow using current brain-imaging methods.

A novel approach to understanding the role of the SI in nociception uses intrinsic optical signal imaging in nonhuman primates (233,234). Differences in the reflectance patterns over the anterior parietal cortex provide evidence that area 3a of the SI, not areas 3b or 1, are most important in the perceived intensity of noxious thermal stimulation. However, alterations in reflectance patterns over areas 3b and 1 after noxious thermal stimulation also suggest some interactions within SI subareas that may influence the processing of nociceptive information.

Second Somatosensory Cortex (SII)

The SII represents another complete somatotopic representation of the body within the parietal lobe. Located lateral and slightly posterior to the representation of the face in the SI cortex, the SII cortex is located on the superior bank of the Sylvian (lateral) fissure. Extracellular single-unit and evoked potential recordings from the

primate SII cortex have shown that this area of the parietal lobe is activated by noxious stimuli (210,235,236 and 237). Although the number of neurons responsive to nociceptive stimuli is small, the SII cortex participates in the encoding of noxious mechanical, thermal, and electrical stimuli. Dong et al. (237) reported that 4% of the neurons recorded from the SII/area 7b region responded exclusively to noxious mechanical stimulation and that one-half of these nociceptive neurons had bilateral receptive fields. These data agree favorably with those of Whitsel et al. (238) and Robinson and Burton (236), who also found a high percentage of SII neurons with bilateral receptive fields.

Acute Painful Stimuli

Acute painful stimuli activate the SII cortex in human subjects. Noxious electrical stimulation of the tooth pulp and painful stimulation of the nasal mucosa with humidified carbon dioxide evoke magnetic field changes that appear to originate in the SII cortex (239,240).

Electrical Stimulation

Few studies have examined sensory phenomena associated with electrical stimulation of the SII cortex. Sensations reported as quivering and unpleasant may be evoked by electrical stimulation (241), but reports of pain are rare (242). As with epileptic seizures involving the SI, abnormal electrical activity generated posterior to the SI in the SII may evoke painful sensations. Young et al. (243) and Balkan (244) described patients with painful epileptic seizures involving the SII. Salanova et al. (245) reexamined the records of 82 patients with parietal lobe epilepsy who were treated between 1929 and 1988. They reported that the most common aura produced was one of tingling or numbness. In 13 of 82 (16%) cases, however, the aura involved pain sensations. These aurae could be reproduced by electrical stimulation posterior to the SI.

Insula and Surrounding Regions

Several other regions of the parietal lobe in and around the lateral sulcus participate in the processing of nociceptive input: the insular cortex (Ri) and area 7b. The primate insula lies buried with the sylvian fissure in monkeys and humans. Ri also is found within the Sylvian fissure and is located immediately posterior to the insula. Area 7b (also known as *PF*) is located on the rostral inferior parietal lobe. These cortical areas each receive distinct thalamocortical projections and maintain extensive reciprocal corticocortical connections.

Area 7b

As indicated under Second Somatosensory Cortex, Dong et al. (237) identified a small number of neurons in the SII, area 7b region that responded to noxious mechanical stimulation. Later experiments by Dong et al. (246) extended these observations by demonstrating that some primate area 7b neurons can encode noxious thermal stimulation intensity, and that the neuronal discharge of these neurons is correlated to the perceived intensity of noxious stimulation (Fig. 5-20). Approximately 9% of the recorded neurons responded either exclusively or preferentially to noxious thermal stimuli. Of those neurons responsive to thermal stimulation, approximately 45% also were responsive to mechanical stimulation. Bilateral mechanical receptive fields were found in 40% of those neurons responsive to thermal and mechanical stimulation.

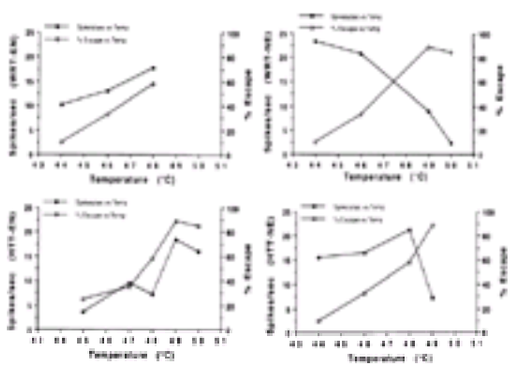

Figure 5-20. Relationships of noxious thermal stimulus intensity to the discharge frequency of wide-range thermoreceptive (WRT) and high- threshold thermoreceptive (HTT) neurons in area 7b and to escape frequency. All electrophysiologic and behavioral data illustrated were obtained from the same monkey. The mean discharge frequencies evoked during noxious plateau temperature are plotted for individual WRT and HTT neurons that did grade noxious thermal intensities (WRT-EN and HTT-EN) and that did not grade noxious thermal intensities (WRT-NE and HTT- NE). For each type of neuron, the mean discharge frequencies and mean escape frequencies (percentages) that were associated with the same thermal shifts are plotted. In these examples, note that the slopes of the stimulus intensity-discharge frequency function and stimulus intensity-percent escape function for WRT-EN and HTT-EN neurons are more alike than the slopes of the same functions for WRT-NE and HTT-NE neurons. (Temp, temperature; EN, encoding; NE, not encoding.) [Reprinted from Dong WK, Chudler EH, Sugiyama K, et al. Somatosensory multisensory and task-related neurons in cortical area 7b (PF) of unanesthetized monkeys. *J Neurophysiol* 1994;72:542–564, with permission.]

Of particular interest is the response of many nociceptive area 7b neurons to multisensory stimuli (246). One-third of the thermal nociceptive area 7b neurons also were responsive to visual stimulation. The most effective visual stimuli included the approach and withdrawal of novel or threatening objects in line with the most sensitive portion of the cutaneous receptive field.

Clinical and experimental lesions of area 7b provide additional evidence for the role of area 7b in pain and nociception. Greenspan and Winfield (247) reported changes in pain perception in one patient after a tumor compressed the posterior insula and parietal operculum, but spared the postcentral gyrus (Fig. 5-21). The patient had higher mechanical and heat pain thresholds and higher cold pain tolerance levels on the side contralateral to the tumor. No changes were observed in innocuous temperature perception in this patient. Removal of the tumor and alleviation of the cortical compression resulted in improvement of the sensory phenomena. Dong et al. (248) reported similar findings in a monkey who sustained compression of posterior parietal cortex, including area 7b, the SII cortex, and insula (Fig. 5-22). This monkey showed a dramatic increase in the pain tolerance as indicated by the absence of escape to noxious thermal stimuli. However, the ability of the monkey to detect changes in thermal stimulation intensity remained unchanged.

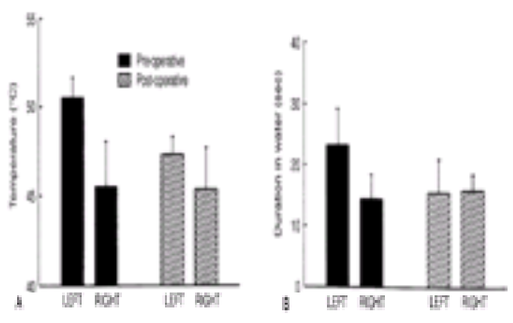

Figure 5-21. Means and standard deviations of thermal pain assessments. **A:** Heat pain thresholds based on 4 days of testing preoperatively and 4 days of testing postoperatively. **B:** Cold pain tolerance based on 4 days of testing preoperatively and 3 days of testing postoperatively. Ventrolateral Orbital Cortex

Anatomy

The VLO, an area thought to be homologous with the inferomedial orbital cortex in humans (249), has interested investigators in its role in pain and nociception based on the reciprocal connections it maintains with the thalamic Sm (85,86 and 87,250,251). In addition to these thalamic connections, the VLO is reciprocally connected with the somatosensory cortex.

Physiology and Behavior

Noxious electrical stimulation of the skin and bradykinin injection significantly increase blood flow to the frontal cortex in cats (252). VLO neurons in the rat and cat respond exclusively or preferentially to noxious mechanical, visceral, and cold stimuli (253,254) (Fig. 5-23). Nociceptive VLO neurons are activated in a graded fashion to cutaneous stimuli, and all have large, whole body receptive fields. Backonja et al. (255) found that compared to sham-operated rats, rats with a loose chronic constrictive nerve injury had a greater (80% vs. 61%) proportion of VLO neurons responsive to noxious cold stimuli. Although the magnitude of the VLO neuronal response was not significantly different in these two groups of rats, VLO neurons recorded from animals with nerve ligations exhibited a longer afterdischarge after cold stimulation. VLO neurons responsive to noxious colorectal distension in rats (256) and gallbladder distension in cats have large, bilateral cutaneous receptive fields (254).

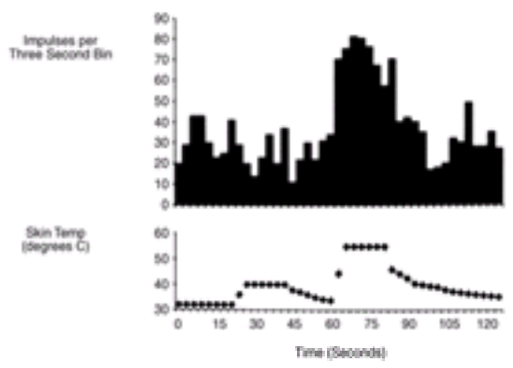

Figure 5-23. Response of a ventrolateral orbital cortex-alpha neuron to application of innocuous and noxious radiant heat pulses (40°C and 55°C) to the glabrous skin of the contralateral hind paw. (Reprinted from Snow PJ, Lumb BM, Cervero F. The representation of prolonged and intense, noxious somatic and visceral stimuli in the ventrolateral orbital cortex of the rat. *Pain* 1992;48:89–99, with permission.)

Clinical and experimental evidence suggests that the VLO may play a role in the modulation of pain. Prefrontal cortical lesions have relieved intractable pain in some cancer patients (257). More recently, Zhang et al. (258) reported that glutamate microinjections in the VLO significantly increased the rat tail-flick latency.

CONCLUSIONS

Pain is a subjective experience resulting from activity in many distinct areas of the brain. Complex patterns of activation are the reason why pain is multidimensional, including heightened emotions, increased motivational drive to reduce pain, cognitive and motoric strategies to reduce or prevent tissue damage, and memory of the sensory-discriminative and affective qualities of the painful event. Each supraspinal area plays an important role in the pain experience. The complex central processing that produces pain poses challenges to the study of supraspinal nociceptive processes and makes the treatment of chronic and acute pain difficult.

CHAPTER 6

Psychological Aspects of Pain

C. Richard Chapman and Judith A. Turner

Pain is a complex aversive experience normally associated with tissue trauma, inflammation, or a disease process. Because it is subjective and personal, pain is inherently psychological in nature. Bonica emphasized in the 1950s that psychology is important in the study of pain, and that psychological factors exert major causal influences in a person's experience and expression of pain. In the first edition of this book (1), he wrote,

> The crucial role of psychological and environmental factors in causing pain in a significant number of patients only recently received attention. As a consequence, there has emerged a sketch plan of pain apparatus with its receptors, conducting fibers, and its standard function, which is to be applicable to all circumstances. But . . . in so doing, medicine has overlooked the fact that the activity of this apparatus is subject to a constantly changing influence of the mind.

In other words, we could not then (and cannot today) reconcile a sensory neurophysiology model of pain with the typical patient's complex presentation of pain, which is often loosely related or unrelated to tissue damage. Nearly half a century ago, Bonica had identified a problem that then bedeviled the emerging field of pain management and continues to impede our understanding of pain and its control, even now.

Today, we understand the mind to which Bonica referred is an emergent property of the higher order, self-organizing processes of the brain (1). Protection of biological integrity is normally the mind's highest priority. As Chapter 24 indicates, injury-instigated physiologic processes involving the autonomic nervous system, the hypothalamo-pituitary-adrenocortical axis, and the immune system feed into the ongoing construction of somatic consciousness. Emotional responses to and cognitive appraisals of bodily changes that such processes create thread into the fabric of pain, along with sensory awareness. Severe pain typically involves shifting one's attention away from all else to one's body, experiencing strong negative emotion, having an urge to escape injury, and mental preoccupation with the meaning of the injury or disease. Pain is both a major mechanism for biological protection and a powerful psychological experience. Severe pain takes over the mind by dominating the higher order processes of the brain and the behavior that the brain directs.

This chapter addresses the psychological nature of pain, and it offers a perspective designed to help the practicing physician better understand the psychology of pain. Its purposes are to clarify the complex, subjective nature of pain and the importance of cognitive factors in the pain experience and to lay a groundwork for understanding subsequent chapters on psychological interventions. Because the history of neuroscience has shaped the thinking of many physicians about the brain and mental functions, we begin by reviewing some of the fundamental ideas about pain that come from past thinking in neuroscience and contrast them to the perspective of cognitive-behavioral psychology.

HISTORY AND CURRENT UNDERSTANDING OF PAIN

Although all physicians feel pain, many find the diagnosis and treatment of pain states perplexing and frustrating. In some cases, the root of the difficulty is the physician's fundamental understanding of pain. Medical education and the culture of medicine impose fundamental implicit beliefs and assumptions on young health care professionals in formative stages of career development, and these beliefs become the foundation for later clinical understanding and reasoning. Sometimes, the implicit beliefs are out of date, inappropriate for the situation at hand, or just plain wrong. Most have roots in the thinking of bygone eras. This section reviews some fundamental assumptions about pain from the past and emerging assumptions in contemporary thinking, particularly those that Freeman (2) has emphasized. Its purpose is to help the physician clarify his or her reasoning about pain and its psychological aspects.

Sensory Mechanisms: Energy or Information?

Our current understanding of pain reflects the influence of two dominating metaphors, each with deep roots in history: energy and information. A metaphor is a way of describing an unknown or complex process in familiar terms. We tend to think of metaphors in terms of language, but metaphors pervade our thinking and actions as well as our language (3). They do this by governing our concepts and shaping how we view the world. Metaphors in science often play key roles in the paradigms that guide inquiry.

Metaphors, as conceptual conveniences, provide approximations rather than perfect descriptions. Sometimes in science, knowledge outgrows an instantiated metaphor, and yet the metaphor remains in the language. When this happens, the metaphor can become an impediment rather than a facilitator of learning. We suggest that this has happened in the pain field with two metaphors in particular: the energy and information metaphors.

Energy Metaphor

Because of pain's sensory qualities, many neurophysiologists and physicians think of pain as a strong sensation that forms at the point of tissue damage, makes its way to the central nervous system (CNS), and elicits higher level psychological responses. This view has roots in historical concepts of the nervous system that used an energy metaphor. Energy is a force that flows from a source or reservoir, like water under pressure, running through conduits to some end point, where its release exerts some effect. Using this metaphor, we might reason that tissue injury via heat, for example, is a stimulus in the form of energy. Transduction at the nociceptor converts the heat to neural energy (electrochemical activity), and this neural energy moves from the periphery to the first cells of spinal transmission, and from there to the CNS, where it triggers higher levels of activity.

Descartes (1596–1650) initiated these ideas in his description of the nervous system (4,5). In *Traité de l'Homme*, he indicated that sensory messages ascended to the ventricles of the brain via little strings (petit filets). He described their actions using a mechanical metaphor: Pulling at one end of a rope rings a bell at the other. A control center housing the soul (the pineal body) acted as a pump for efferent fluids that Descartes called *animal spirits*. These, he said, flowed from the ventricles through the spinal cord and out into the muscles via the nerves in response to the tugging of the little strings. He envisioned the nerves as hollow conduits.

This notion implies that some sort of efferent life force moves along neural pathways in a feed-forward manner to activate muscles, an idea that resembles the ancient Chinese notion of vital life force flowing through meridians. Descartes thought that, in humans, the soul exerted control over this flow, but in animals, which lack souls, this process must be purely mechanical. Descartes was a good enough scientist to offer a testable hypothesis. Muscles, he proposed, should shorten and thicken during contraction, increasing in volume as they fill with animal spirits. Croone (1633–1684) extended and modified this idea, asserting that two types of spirit materials had to flow together for muscle swelling to occur. A spirituous liquid from the nerve had to interact with the nourishing juice of the muscle for the muscle to swell. Swammerdam (1637–1680) demonstrated the nonviability of this hypothesis in studies of frog muscle: Contracting muscles changed shape but not size (5). Willis (1621–1675) criticized the Cartesian principles that the pineal gland is the seat of the soul and that the cerebral ventricles are the origin of animal spirits and the loci of voluntary acts. Instead, he attributed acts of will to the brain. He also rejected the idea of muscles swelling as they filled with spirit substance, and he identified

fibers that ended in muscles (6). Willis retained the notion that animal spirits flow through tubules in nerves (albeit as heat or light), but he denied that they could perpetually inflate the fibers that end in the muscles. As the seventeenth century drew to a close, the question of how the soul could activate the body remained, and so did the notion of a force flowing through nerves.

The focus shifted to electrical energy in the eighteenth century after Galvani (1737–1798) demonstrated the intrinsic electricity of nerve and muscle. He believed that an electrical fluid flowed through nerves, and eventually he came to speak of animal electricity instead of animal spirits. Galvani postulated that the brain secreted animal electricity and the nerves distributed it (5). Thus, animal spirits gave way to electrical currents, but the notion of flow remained.

Matteuchi, Du Bois-Reymond, Mueller, von Helmholtz, and others further refined the concept of electricity in the nervous system in the nineteenth century (7). Despite his careful work on the electrical properties of nerves in frog muscle and electrical fish, Matteuchi continued to argue for a mysterious nerve force that was a specific form of energy. Du Bois-Reymond rejected this notion and tried to explain neurophysiology on purely chemical and physical grounds. He discovered the injury current and the action current of muscle. Mueller introduced the idea that a given kind of stimulus in a particular sensory pathway provokes only one sensation in a given sensory modality (*Doctrine of Specific Nerve Energies*), but others quickly disproved it. Mueller's thinking led to the notion of pain as a specific modality, an assumption that survives today in the thinking of many pain researchers, even though Mueller's short-lived theory of specific nerve energies long ago fell into disrepute. von Helmholtz measured the rate of conduction in a nerve and introduced the concept of conservation of energy. Observable conduction velocities seemed to support the idea that energy moves from the periphery to the brain: But what is the source of such energy? It seemed to the nineteenth century mind that centripetal energy flow is possible only if peripheral nerves pick up energy from an external source via transduction.

Freeman (2) described the understanding that emerged at this time in this way: Nerve energies enter the body from the environment via transduction at sensory receptors, flow to the brain, and then flow back out again to the muscles. He offered this quote from Spencer (8), which seems to echo von Helmholtz's notion of conservation of energy:

> [It is] . . . an unquestionable truth that, at any moment, the existing quantity of liberated nerve-force, which in an inscrutable way produces in us the state we call feeling, must expend itself in some direction—must generate an equivalent manifestation of force somewhere . . . [A]n overflow of nerve-force, undirected by any motive, will manifestly take the most habitual routes; and, if these do not suffice, will next overflow into the less habitual ones.

Researchers were equating energy with electricity. Energy flowed from some peripheral source via neural pathways to a central reservoir in the brain and then back again to muscle.

The energy metaphor led neurophysiologists to look toward physics as a model neuroscience. It generated various hypotheses about excesses and deficiencies in energy and models of energy discharge that applied at all levels of the nervous system, from the neuron to the brain. Freud's ideas of repressed energy probably originated in this intellectual climate. Neurologists saw epileptic fits as problems of energy discharge. Eventually, as Freeman (2) has explained, the energy flow paradigm failed to account for the phenomena at hand and fell into discredit. It became clear that the synapse was not a resistance barrier and that the nervous system was not an electrical circuit. Science outgrew the energy metaphor. Like a snake shedding its old skin, it should have dropped it and moved on. But new knowledge tends to build on old, even when the old knowledge is imperfect.

It is easy to find evidence of the energy metaphor in contemporary thinking. Duthie (9), for example, offered an energy flow model for pain:

> The appreciation of pain requires that the energy of a painful stimulus be transformed by peripheral receptors into impulses which are conducted along sensory neurones to the CNS. Onward transmission to higher centres triggers the appreciation of pain. Pain may be alleviated either by impeding the transmission of impulses or by enhancing the mechanisms which modulate onward transmission.

Duthie further noted that “pain appreciation has never been localized to a particular region of the brain. The post-central gyrus and parietal operculum are both possibilities.” An intriguing aspect of the energy flow model is the implication that the energy that is pain must somehow flow to a specific region in the brain. Because of nineteenth century preoccupations with localization of brain functions, many workers assumed that pain must flow to a specific brain region. As Chapter 24 notes, this assumption (which Duthie echoes) is inconsistent with the broad base of current evidence about pain, particularly brain imaging studies of persons in pain.

The energy metaphor itself is still with us in other, more subtle ways as well. It survives in contemporary science in studies of CNS activity, for example. Electroencephalography research associates brain activity with energy fields. Evoked-potential researchers try to identify dipole sources that create specific stimulus-related energy fields. Electroencephalography researchers examine spectral power densities of various electroencephalographic frequency bands (10,11). These sorts of pursuits are wholly concerned with changes in brain energy fields. However, they place less emphasis on flow of energy than do earlier paradigms.

Information Metaphor

In 1948, Shannon, an unassuming young mathematician at Bell Labs, introduced new ideas in a technical report that many would later call the *Magna Carta of the information age* (12). His notions of information began to affect many areas of science, including the life sciences. The formal introduction of information theory (13) greatly changed thinking about neural activity. It largely replaced energy flow concepts with the notion of information moving via signal transmission through the nervous system, limited by channel capacities and degraded by entropy. Bits combine to form words, and words combine to form symbols. Early thinkers contended that individual cells could act as binary switches that make possible Boolean algebra within neural networks. Memory processes, they contended, must store and retrieve information in mathematically specifiable ways. Information theory allowed for the conceptualization of higher order entities in the form of networks. This framework gave birth to a bold new vision of computer science, beginning with von Neumann's work (14) and moving forward into artificial intelligence and the neural network modeling of today. In the biological realm, investigators have defined DNA as the basis for the transmission of genetic information, and currently some investigators are pursuing the informational codes that control memory (15).

The neural network concept grew out of Hebb's (16) notion of cell assembly. Networks are simply higher order assemblies of cell assemblies. One could think of the spinal reflex as a neural network. Imagine a boy touching a hot stove accidentally and quickly withdrawing his hand. This spinal reflex requires neither higher order levels of processing nor conscious reflection. It is an assembly of sensory neurons, spinal cord intermediary neurons, and motor neurons (and each of these groups is itself an assembly). The highly efficient neural network serves an important protective function. Of course, current thinkers postulate the existence of far more complex neural networks in the brain (17,18). Neural networks perform computations, and consequently the neural network researcher delights in the computational modeling of brain functions.

The notion of information parallels that of energy in many ways, and some writers describe information flow. However, the information metaphor is far more powerful than the concept of energy flow. The transducer of the energy metaphor becomes a feature detector in the information model. The external or somatic environment contains information, not energy. Sensory end organs detect and gather information, sending it to the CNS for processing. A collection of feature detectors can fire in synchrony, thereby defining a cell assembly that feeds forward information that provides a basis for higher order computation. The notion of synchrony reemerges at higher levels of processing under the label of *resonance* (a term that remains popular despite the lack of biological evidence for resonating circuits in the brain).

By postulating neural networks as higher level organizational entities, information theorists can extend the metaphor to account for the complexity and nonlinearity of information transmission. The information metaphor has taken root in many areas of contemporary neurophysiology, ranging from the neurochemistry of synaptic transmission to studies of sensory coding and feature extraction. It still vies with the energy metaphor on some levels, but, by and large, it dominates thinking in neurophysiology and neuropharmacology. The energy metaphor still exists in our language and often becomes entangled, quite inappropriately, with that of neural information processing. The energy assumption still dominates receptor physiology, which concerns itself with stimulus transduction. This situation demonstrates that two competing metaphors can coexist in a single field, confounding reasoning.

The contemporary neural information metaphor represents nociception as information that originates with tissue trauma (recall that feature detection and coding correspond to transduction), follows various connections, undergoes redefinition by computation at many levels, and through resonant circuits in the brain generates the awareness called *pain*. The simplest information models (which resemble the energy metaphor) hold that information must exist in the periphery as a specific code, be transmitted from point to point, and, finally, undergo interpretation in the cortex. Emmers (19), for example, contended that pain was a spike-interval coded sensory message. In his framework, which carries forward Mueller's sensory specificity ideas, the nonuniform spacing of spikes leads to the decoding of highly specific messages.

Today, many writers mix the energy and information metaphors, referring to pain as a *specific sensory modality*. Some use the term *pain* as a synonym for tissue trauma, thus implying that pain is either a specific form of energy that exists in the periphery and is relayed to the brain or a specific message code that, when interpreted within the brain, invariably results in the sensation of pain. The concept of specificity tends to constrain thinking about pain to the realm of sensory neurophysiology.

Classical Metaphors and the Psychology of Pain

It is difficult to understand the psychology of pain from a historical neuroscience perspective. The notion of something, whether energy or information, flowing from one source to another is limiting for the description of behavior. One can build a cognitive psychology on the basis of information theory, but contemporary psychology contains many different paradigms and perspectives. It is difficult to address pain behavior in the framework of classical thinking, in large part because early thinkers such as Descartes attributed willful actions to the soul, a concept often equated with the mind. As described in the following section, the Cartesian dualism of mind and body still survives in neuroscience, and this dualism is incompatible with most frameworks in contemporary psychology.

Cartesian Thinking and the Mind

The easiest way for energy flow thinkers to account for the vagaries and complexity of pain, or any other complex human experience, was to postulate that the mind exists. Through the nineteenth century, neurophysiology implicitly accepted the ideas of René Descartes and others, who in the seventeenth century construed bodily processes within the metaphor of clockwork mechanics (4,20). Descartes proclaimed that body and mind were separate entities. He saw pain as a specific modality, a straight-through sensory projection system that moved injury messages from damaged tissue to the pineal body where the mind could appreciate them. Descartes held that the awareness of pain, like awareness of other bodily sensations, must occur in a special location where the mind observes the mechanistic body, namely the pineal gland. Dennett (21) and others concerned with the nature of conscious experience have characterized this concept as the *Cartesian theater*. The mind, like a small person watching a television in the control tower of the brain, observes and interprets the array of multimodality sensory input that the body produces, and decides how to respond.

Although the notions of neural activity evolved from the flow of animal spirit energy to the transmission of information, Cartesian dualism itself went unchallenged for two centuries. Sir John Eccles, probably the last formal dualist, died near the end of the twentieth century (22), but dualistic thinking has become endemic in our culture. Descartes left as his legacy the seemingly intransigent concept of dualism: The mind and body are separate entities.

Cartesian notions have deep roots in medicine and, although almost no one now formally accepts Cartesian dualism, it still exerts a strong, albeit subtle, influence. It does so, not because people still teach it explicitly, but because it has shaped our past in subtle ways. Consider, for example, the words of nineteenth-century neurologist J. Hughlings Jackson, “The doctrine I hold is: first, that states of consciousness . . . are utterly different from nervous states; second that the two things occur together—that for every mental state there is a correlative nervous state; third, that, although things occur in parallelism, there is no interference of one with the other” (23). Jackson refused to face the challenge of bridging the mental and physical. He chose the Cartesian way out.

Jackson's generation separated the disciplines of psychiatry and neurology, a contrived distinction that profoundly affects how patients are evaluated and treated today. Thinking in this period also laid the groundwork for the assumption that the psychological aspects of pain are separate from the neurology of pain (i.e., although they may confound medical diagnosis, psychological factors cannot alter the fidelity of the sensory message itself). Thus, our heritage predisposes us to separate mind and body and to see pain as either neurologic and therefore real or psychological and therefore mental. Like a conceptual boomerang thrown away whenever found, Cartesian dualism keeps coming back.

Do alternatives to Cartesian thinking exist? Today, some advocates of the neural-activity-as-information model argue for a functionalist concept based on a computer metaphor. Put simply and in its extreme form, computer hardware is to the brain as software is to the mind. The nervous system can never be the mind, because it is only the hardware. The software, programmed by environment and culture, constitutes the mind. The computer metaphor nicely evades the assumption of a separate mind or spirit operating a mechanical brain, and yet it preserves the limiting notion of dualism. As demonstrated in the following discussion, this metaphor is fatally flawed because it cannot account for neuroplasticity and self-organization in the nervous system.

Learning and Self-Organization

New information-based frameworks are evolving that recognize and emphasize neuroplasticity: Experience can alter synaptic connections and the presumed resonant processes at higher levels. Black (24), for example, offered a cogent and elegant argument for this position. In such models, information does not simply move through a passive and mechanical nervous system, it alters the structures and functions that its processing involves. Sensory input changes the neurotransmitter signals that neurons send, the nature and number of synapses, the structures of neurons, and the neural circuits themselves. In other words, the nervous system adapts to information and changes with it. In psychological language, we say that the organism learns from experience. This perspective contends that the nervous system is the mind: Mental phenomena are not somehow disembodied or separated from the underlying physiology.

The perspective that Black (24) provided is powerful: It accounts for learning and adaptation, it allows for cognition, and it dismisses the restricting Cartesian notions of dualism and a passive (clockwork mechanics) nervous system. However, it is locked to the idea that informational messages move from sources in the environment or the body into the brain. More important, perhaps, it stops short of accounting for an important feature of the brain: self-organization.

Self-organization is the tendency for highly complex, dynamic systems (in biology and nature as a whole) to form metastable states and to accommodate new information or disturbance by adjusting those states (25). Biology offers thousands of examples for how organisms, ranging from colonies of bacteria to herds of caribou, adapt to the environment by organizing themselves as a leaderless collective. The orderly assembly of a flock of geese illustrates the idea. One can argue that crowd behavior, traffic jams, and culture itself are human aspects of this process. Nonlinear systems dynamics, as a field, lends itself nicely as a descriptive framework for this process (26,27). Researchers can characterize seemingly chaotic phenomena as complex, self-organizing systems. The amount of information one needs to describe the behavior of such a system is a measure of the system's complexity.

Several variations of this notion exist. The autopoiesis (literally, self-forming) model that Varela et al. (28) introduced described systems that (a) maintain their defining organization over time despite environmental perturbation and structural change, and (b) regenerate their components in the course of their operation. All living systems, therefore, qualify as autopoietic systems. Every system has as one of its features an observer that distinguishes between itself and others and between itself and objects in the environment. The realm or sphere in which a system exists (its environment) is its domain. Systems constantly engage in self-regulation and self-reference, within the constraints of their domains.

Nervous systems are organs of physiologic self-organization. Chapter 24 describes the participation of the autonomic nervous system in physiologic self-organization, for example. At higher levels of CNS function, other forms of self-organization occur. These include cognitive functions, such as memory, attention, thinking, and affective functions. At a still higher level, the brain produces meaning, a sense of self, and suffering. These mental components are far from mechanical functions of a passive or mechanistic nervous system; they are the constructions of an active and self-organizing brain.

It seems reasonable to assume that pain, as a complex experience, is also a component of a self-organizing organism that detects damage to its biological integrity. Put another way, each person uniquely assembles the perception of pain from his or her complex and chaotic stimulus array of sensory input, emotional arousal, awareness of the present situation, memory, prior learning history, immediate goals, and social relationships (29). This is why pain varies markedly across persons with identical tissue damage, and the same tissue damage may affect a person differently depending on immediate circumstances.

If pain is the product of self-organization processes, then the brain must actively construct the experience of pain; it does not passively register it as a preformed sensory event. The psychology of pain is, in part, about how the process of construction happens.

Summary

This brief review of metaphors for neural function reminds us that science does not hold absolute truth but rather an approximation of the truth, often framed as a familiar metaphor. A good descriptive framework for explaining how the nervous system works is still lacking. This insight has important implications for understanding the psychology of pain. Evolving concepts of the nervous system and Cartesian dualism have hampered the integration of psychology into medicine. Physicians have

tended, and still tend, to see psychological factors as concepts that belong to a mental, nonneurologic realm. It is now clear that all pain is “in the mind,” inasmuch as all pain is the complex product of brain activity. It is equally clear that the mind is a product of the brain and not a separate entity. The psychological aspects of pain are highly complex patterns of neurophysiologic phenomena, best described in language different from that used in neurophysiology.

PLACE OF PSYCHOLOGY IN SCIENCE

Psychology offers a broader language for the description of experience and behavior than neurology and neurophysiology can provide, and thus it is better suited to account for complex CNS functions and behavior. The psychological aspects of pain refer to those higher CNS levels of processing that produce the perception of pain, including the emotional and cognitive aspects of pain, and the behaviors and expressions associated with the experience of pain. The language that psychology provides allows description of higher order processes and their reciprocal interactions with the environment and development of models and theories in this more abstract framework.

Science functions according to a hierarchy of knowledge organized by levels of inquiry (30). Figure 6-1 illustrates this point. The laws of science, language, and frames of reference differ at each level. Normally, little interchange exists among scientists across levels, apart from fields like pain research that emphasize cross-disciplinary cooperation. Scientists who attempt to work on more than one level typically find that they can reason linearly within levels but not across levels. This is because, at each lower level, new entities and complexities emerge that provide the basis for the next higher level.

Figure 6-1. Levels of inquiry in science. The bold topics and the associated bidirectional arrow represent some of the topic areas that psychology as a discipline covers. The longer area, indicated at the left margin, represents the levels at which one might investigate pain.

The concept of emergence simply means that combining certain elements produces a complex system that possesses properties lacking in the individual elements and unpredictable from knowledge of the individual elements (31,32). To express this as a familiar cliché, one can say that the whole is greater than the sum of the parts. Atoms of hydrogen and atoms of oxygen at room temperature are gases, but when one combines them, the curious property of liquidity emerges. Emergent properties are just this, the spontaneous emergence of hitherto nonexistent features. The apparent intelligence of an ant hill is an emergent property of the collective. No individual ant is intelligent, and nothing known about individual ants allows prediction of the astonishing intelligence that the colony displays. The concept of emergent property helps one escape the constrained thinking of Cartesian clockwork mechanics.

The emergent properties at one level of scientific inquiry become the focus of inquiry at the next highest level (30). Interesting, unprecedented properties emerge as one goes from lower to higher levels in the hierarchy portrayed in Figure 6-1. Emergent properties often define domains of study by specifying the boundaries of a given paradigm. The researcher who attempts to explain subjective reality from the activity of neurons and circuits in the brain simply arrives at the edge of the territory. To work with subjective reality, one needs the paradigms of psychology. Curiously, workers engaged at one level of scientific inquiry tend to ignore the efforts of colleagues working at higher or lower levels and sometimes consider them misguided or busy wasting time and effort. The ultimate goal of reductionist science, of course, is to build knowledge bases at each level and then extend explanatory bridges across levels. Ideally, pain researchers recognize the importance of building knowledge and bridges at all levels.

One of the important features of psychology as a field is that it concerns itself with more than one level of scientific inquiry, as Figure 6-1 shows. For this reason alone, any attempt to stereotype what psychologists think or do misrepresents the field. Psychologists contribute to pain research at basic science levels, through the study of perceptual and motor processes, with studies of cognition and emotion, via studies of drug effects, and in clinical research studies of many kinds.

What is the nature of contemporary psychology as a field? Robins et al. (33) described the current field of psychology as the product of competition across four competing schools of thought: psychoanalytic, behavioral, neuroscientific, and cognitive. To determine the relative influence of these four schools of thought at the close of the twentieth century, Robins and colleagues looked at the subject matter of articles published in the most influential (flagship) psychology journals, the subject matter of doctoral dissertations, and the degree to which flagship publications cite articles from the major journals of each school. Their inquiry indicated that psychoanalysis has slipped from prominence and now lies outside of the mainstream of contemporary psychology. It produces few, if any, scientific papers, and workers in other areas of psychology essentially ignore it. The Robins study suggested that behaviorists, too, are on the decline. Studies of a purely behavioral nature are becoming infrequent, and behavioral principles survive because of their integration into other perspectives rather than through the momentum of purely behavioral research. This area has largely succumbed to the cognitive revolution, and much of what was once behavioral has become cognitive-behavioral. To their surprise, Robins and coworkers (33) found little evidence that the rest of psychology was paying close attention to the strong neuroscience within its midst. Although neuroscience as a whole is rising in prominence, it does so outside of the ranks of mainstream psychology, and it would seem that psychologists engaging in neuroscience are beginning to see themselves as neuroscientists rather than psychologists. The area of greatest growth in the literature, and current prominence, is cognitive psychology. To provide a snapshot of the influence of psychological factors on pain, the following sections introduce the area of cognitive psychology and describe pain within this complex framework.

COGNITIVE PSYCHOLOGY AND PAIN

The field of cognitive psychology is complex and resists straightforward definition. In the broadest sense, cognition involves the construction of reality from moment to moment. The brain seeks and processes information from the external environment and the internal environment, attempting to define and meet the needs that arise in both. Unlike lower animals, humans possess the resource of a frontal lobe, and this makes possible planning, forecasting, abstract thinking, complex judgment, and a multidimensional sense of self. Cognition, overall, is a self-organizing process that gives coherence to life and one's sense of self across external settings and across long periods.

Figure 6-2 provides a rough overview of the content of the field, dividing it into two groups of processes: perception and ratiocination. The former class comprises processes that are normally transparent (i.e., processes that are used without awareness or deliberation). The latter group contains more complex processes that are normally used intentionally. Other subdivisions of cognitive science exist, such as computer modeling of intelligent processes, knowledge engineering, and decision process research. Indeed, some areas of cognitive science lie outside of psychology (engineering, computer science). For immediate purposes, however, the field consists of processes concerned with the perception of events in the internal (bodily) and external environments, along with higher order rational processes that involve reasoning and decision making.

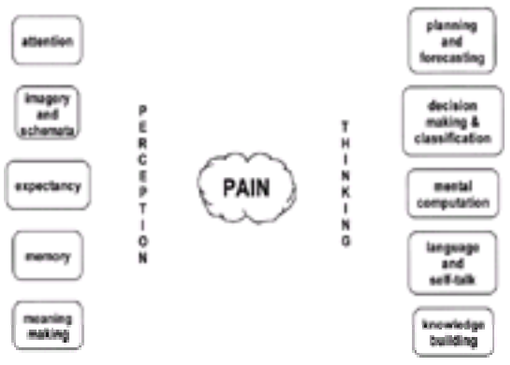

Figure 6-2. Cognitive factors influencing pain.

Classical views of cognition have held that cognition always entails conscious mental effort. Thinking, reasoning, and memory recall always occur within awareness and as a consequence of intentions that can be explained. More recent perspectives, however, emphasize the limitations of conscious processes (34,35). Rational thought, reasoning, purposeful memory recall, and the like are slow and singular processes. Much of what we do well in mental and physical performance seems to occur automatically in the service of conscious effort rather than from conscious effort itself. Greenwald (36) breaks such phenomena into two classes: (a) cognition outside of attention and (b) verbally unreportable cognition. Examples include balancing while riding a bicycle, estimating the passage of time, guessing distances, adjusting speed in a motor vehicle, keeping appointments, using rules of grammar, obeying laws, and exercising ethics. In general, unconscious cognition has severely limited analytic capability. Nonetheless, many people find that creative effort, problem solving, complex reasoning, and many other processes work best when attempted consciously and then relegated to unconscious levels. Solutions to difficult problems can then emerge as insights or “Aha!” experiences (37). Cognitive scientists now understand that mastery of knowledge, problem solving, and skilled performance always require rapid and powerful computational routines that occur at unconscious levels in the service of consciously maintained goals. These considerations indicate that cognition and conscious thinking are not one and the same. Some cognition depends on extensive unconscious, background processes.

Overview of Cognitive Processes in Pain

Attention

As Figure 6-2 shows, many cognitive factors affect the perception of pain. *Attention* refers to the selective filtering of relevant information from the internal and external environments, to the exclusion of other information. It relates closely to distraction, the blocking of certain sources of information from processing by narrowly focusing attention elsewhere. Some writers favor the spotlight metaphor for attention. Unable to process all of the information in the internal and external environments at a given moment, the brain spotlights certain things for processing and excludes others. Like someone sitting in a darkened theater, the brain only *sees* the lighted performers on the stage.

One of pain's cognitive features is that it captures and holds attention. A nonmedical writer described the qualities of severe pain as including extreme aversiveness, an ability to annihilate complex thoughts and other feelings, an ability to destroy language, and a strong resistance to objectification (38). The evolutionary purpose of this is clear: Injury threatens survival and requires adjustments in awareness and ongoing behavior. In contemporary human life, chronic pain normally provides no new information, and its domination of attention is more counterproductive than adaptive. Persons experiencing pain find it difficult to concentrate on normal work, recreation, social activities, or creative expression because the pain constantly intrudes on awareness.

Imagery

Awareness of pain is one of many types of somatic imagery. In everyday life, we think of an image as a visual experience, such as recalling a visual impression of the Mona Lisa painting. Clearly, however, we also have auditory images, such as a familiar tune or the sound of a train passing. Similarly, many can recall the feeling of a familiar low-grade pain localized in some part of their bodies. The feeling qualities of a pain, its personal and subjective nature, constitute a somatic image. Hebb (39) described the image associated with a pain as a mental representation of the actual sensory activity associated with an injurious external event. He emphasized that an image does not always correspond faithfully to an external stimulus. Visual afterimages associated with bright lights, for example, are poor representations of the lights that evoked them. Similarly, pains need not correspond accurately to features of an injurious stimulus.

Strange though it may seem, the brain does not deal with reality *per se* because it has no direct access to it. Rather, it deals with sensory images and creates models of the internal and external environments from patterns of sensory information. Ellis (40) contended that images can occur at a low level of consciousness and that they are the basic building material of concepts. To this we would add that complex images are multidimensional. When a friend's face is seen, the brain creates a visual image. Interacting with that friend involves multidimensional imagery that has an auditory dimension, sometimes an olfactory dimension, and, if we shake hands or otherwise touch the friend, a somatic dimension.

Pain, too, is an image, and it is no less complex. We construct somatic images, drawing not only on the sensory information provided via the spotlight of attention but also from memory. Autonomic nervous system arousal produces strong somatic images that contribute to emotion and feed the development of elaborate somatosensory schemata, which are complex patterns of images and associations (these are described in greater detail under Schemata).

Expectation

Because the brain constructs its reality, imagination sometimes enters into the process. Imagination often builds on expectations. Knowing, for example, that one's mother had breast cancer or that one's father died prematurely from a myocardial infarction may make a person hypervigilant for certain symptoms. The female patient who feels soreness in one breast and imagines a tumor has embellished the somatic image of the pain substantially and attached additional expectations and meanings. The hyperventilating middle-aged male patient who appears in the emergency room with severe chest pain and the conviction that he is experiencing a heart attack may have constructed a personal reality that does not fit objective reality. Physicians should keep in mind that their interactions with patients shape and embellish patients' thinking by shaping understanding and expectations.

Schemata

A schema is a normally nonconscious pattern of concepts, assumptions, images, affects, and associations that reflects a person's past experience as well as expectations for the present and future (41,42). Thinking of baseball, for example, brings a host of associations forward for most Americans: stadiums, game rules, famous players, umpires, balls, bats, and so forth. Note that thinking of baseball does not bring to mind the focused image of a particular player in a specific game engaging in a specific play. Rather, the baseball schema is a nonspecific frame of reference that assists the brain in dealing with a complex area by activating a learned network of associations. In a similar way, the patient with chronic pain, when thinking about the pain, activates a complex schema that involves past medical history, present fears, social consequences, and more. Rumelhart and colleagues (42) described the highly abstract nature of the schema concept as follows:

> Schemata are not single things. There is no representational object which is a schema. Rather schemata emerge at the moment they are needed from the interaction of large numbers of much simpler elements, all working in concert with one another. Schemata are not explicit entities, but rather are implicit in our knowledge and are created by the very environment that they are trying to interpret as it is interpreting them. . . .

Thus, a schema is the basis for screening out and organizing the stimuli surrounding an individual. It directs attention, brings images forward from memory, and organizes expectations. People categorize and evaluate their experiences through their schemata.

Some schemata are partially preformed patterns of multidimensional imagery that emerge from memory and adapt to fit the immediate environment. They are never simple memory traces. A schema can include a postural and motor pattern formed from learning processes that involved extensive repetition (e.g., riding a bicycle).

Beck and colleagues have emphasized the role of schemata in psychological dysfunction (43). A schema may be inactive for long periods, then activated by specific situations. The schemata activated in a particular situation determine the person's responses. In states of psychological dysfunction (e.g., depression), dysfunctional and idiosyncratic schemata distort patients' interpretations of specific events. In cases of severe psychopathology, patients cannot recognize that their thinking is erroneous or illogical, and their thinking may become dominated by idiosyncratic schemata. Such individuals may find it extremely difficult to concentrate on external stimuli or engage in voluntary mental activities (e.g., problem solving). A person's cognitive organization may become increasingly independent of external stimulation so that he or she is unresponsive to changes in the immediate environment.

Schemata depend heavily on memory of past experience. Presumably, the brain stores certain images and motor patterns associated with visual, auditory, proprioceptive, somatosensory, and visceral sensory awareness. As it periodically retrieves, uses, and restores this information, the brain alters and refines schemata. In other words, retrieving and using memory contents (which are more akin to networks of association than stored computer records) change those contents and associations to some degree. This idea is consistent with those of Black (24).

Repeatedly accessing and using a schema expands that schema and makes it readily available. The practice of medicine, for example, requires the formation of multiple schemata that continue to expand and develop with repeated use and degrade with disuse. Airway management for anesthesiologists is but one of many possible examples. An anesthesiologist doing airway management on a daily basis has every detail and maneuver readily available, but one who long ago left the operating room and shifted to a pain practice has to stop and recall principles and actions before managing an airway. In the same way, having a chronic disease, such as cancer or arthritis, leads patients to many repeated experiences that generate and revise schemata. Patients think, feel, and act as they do because of past experience, current appraisals and expectations, goals, and other cognitive factors.

Some schemata become learned (i.e., they survive indefinitely in memory as relatively stable working perceptual hypotheses). Learned schemata are readily available for recall. Importantly, certain sensory events or other schemata can act as triggers for a particular schema. The appearance of a trigger in the environment (any conditioned stimulus) can bring a schema to the foreground of a person's immediate awareness and experience.

The schema concept helps explain a painful, trigger-sensitive condition known as *phantom limb pain* that exists across individuals and cultures. Phantom body parts tend to appear in consciousness after a person has lost a limb. They are kinesthetically vivid realizations of a body part that is physically absent. Sometimes a phantom limb hurts, and treatment directed at the stump or administered systemically may not relieve it (44).

In a study of 68 patients with phantom limb pain, Katz and Melzack (45) found that patients had experienced various postamputation pains, all localized to the missing limbs. The patients described these pains as immediate and real, quite unlike recollection of a past pain state. The patients seemed to be reproducing or recreating the pain and not simply recalling a past event. Some of the phantom experiences involved painless experience (e.g., feeling a shoe on a missing foot) and some had multimodal sensory qualities. Katz and Melzack (45) speculated that a higher order somatosensory memory component, once formed, can be activated when only some of its elements are present in the sensory input. Their description captures the concept of schema trigger. This concept may help explain the experience of some chronic pain patients.

The schema concept underscores the fact that the human brain can generate its own patterns of awareness and imagery in the absence of extrinsic signaling. Moreover, it can store these patterns in memory, retrieve them selectively, modify them, and put them back into storage. This means that perception is more an act of constantly building and remodeling one's view of the world than it is of passively receiving and registering information. Pain, therefore, is rarely a passive experience of tissue trauma, but rather a complex construction that involves multiple cognitive dimensions.

Meaning

Meaning making is an important feature of pain schema formation. Meaning involves causal attribution and the fitting of an experience or circumstance in to a greater framework of purpose and global coherence. One way to assess meaning is through measuring sense of coherence (whether life seems to hold together, make sense). Buchi and colleagues, for example, found that low sense of coherence was associated with depression in rheumatoid arthritis patients (46).

Most people find it difficult to experience pain without attributing it to some physical cause. In cases in which patients experience severe debilitating disease, such as rheumatoid arthritis, or life-threatening disease, such as cancer, patients often need to create a framework that gives meaning to their condition. Sometimes, the schema of self (“who I am”) becomes a part of the search for meaning. Attributing pain to a physical cause sometimes proves difficult or impossible when pain is chronic and medical evaluation fails to identify pathology.

Because meaning and emotion are closely related, the search for meaning typically involves strong feelings. In dealing with physicians, some patients seek information about the cause of the painful condition or the disease, and some raise the “Why me?” question. It is important to identify and address patient questions and concerns, but the physician must recognize that he or she cannot dispense meaning. The patient must construct it. Ordinarily, the physician can only recognize and affirm the value of the process of meaning making.

In some cases, patients engage in inappropriate or maladaptive meaning making. Some tend to fit the pain into a larger life schema in which they define themselves as innocent victims in a cruel world. Sometimes, the pain is linked to rage against a spouse or parent. Negative schemata of this sort impede the patient's ability to respond to intervention or rehabilitation. In cases in which the patient appears to have created a maladaptive meaning framework for the pain, psychotherapy can sometimes help. Schemata are powerful factors in the treatment and rehabilitation of the patient with chronic pain. They are dynamic in nature, and motivated patients can change maladaptive schemata to more adaptive schemata.

Multiple Drafts

How does the brain handle variation in subjective experience across time? Dennett and Kinsborne (47) asserted that one's mental representation of reality changes constantly in a nonlinear way, relatively independent of time (i.e., instead of generating conscious representation of stimulus events in a chronologically serial fashion, the brain constantly produces revised drafts of awareness, mixing old and newer sensory, affective, and cognitive representations without particular regard for time). Put another way, elements of memory and expectation compete for, and eventually integrate with, recent sensory messages from the environment in constructing a representation of reality.

Because this is the case, schemata emerging from unconscious processing into immediate awareness need not carry the most recent information that the brain has processed. A part of the immediate representation of reality comes from memory. Some anesthesiologists have performed diagnostic nerve blocks on patients with chronic pain and found, in frustration, that the patient cannot say whether the pain has disappeared as a function of the nerve block. This is a genuine and reasonable response on the patient's part, because the awareness of pain depends on a complex cognitive process that constructs a model of reality and not simply on a sensory signal from the periphery.

The multiple drafts concept of consciousness suggests that the most remarkable feature of consciousness formation is its extraordinary plasticity. The brain creates a representation of immediate reality by interweaving records of the past with sensory input from the immediate present, and it forecasts images of the future. Far from being a passive entity that merely registers information that arrives from various sensory channels, the brain is an active, complex adaptive system that constantly simulates the world and the body in which it dwells. Nociceptive signals may trigger complex responses and schemata, leading to elaborate experiences of pain with sensory, affective, cognitive, and motor dimensions.

Patients with chronic pain sometimes develop elaborate presentations of pain that involve abnormal body postures and movements. The patient's immediate social environment can shape such behaviors, and this process may occur outside of the patient's awareness. For example, pain behaviors may increase in the presence of a physician or a spouse just as blood pressure sometimes increases when measured in a physician's office. Most physicians view a patient's description of pain as directly reflecting a sensory experience that has potentially important diagnostic value. In the case of acute pain, this view is usually appropriate. In the case of chronic pain, it is more useful to view pain as a cognitive schema that involves multiple determinants and complex patterns of association.

For a subset of patients with chronic pain, certain schemata may lead to persistent doctor shopping and an obsession with finding and eliminating the organic cause of pain. On the face of it, such patients seek help for a relentless, unpleasant sensory experience that seems to have no adequately defined origin. A complex history of suffering, discouragement, physical exhaustion, and emotional upheaval that may include mood problems or anger is often integrally associated with this

experience, as are limitations in social, role, and vocational functioning. Many such patients fail to recognize or acknowledge the other stressors and problem areas in their lives, and they focus solely on their pain as the reason for their limitations and problems. In such cases, when patient and physician alike look only to biomedical explanations and treatments for the pain, long-term pain relief from any treatment is unlikely.

Physicians have difficulties in treating patients whose pain problems are influenced in important ways by environmental factors. Today, many physicians refer difficult cases to multidisciplinary pain centers, but some still prefer to think of such pain problems as psychogenic. Historically, this means that the pain stems from deep-seated, unconscious conflicts, such as one might see with Briquet's syndrome (48,49). Labeling as psychogenic patients whose pains reflect environmental factors serves little purpose beyond protecting patients from risky intervention, and it wrongly denies the genuineness of the patients' suffering. Psychological assessment and intervention can help alleviate suffering and disability in many such patients (see Chapter 89).

How Pain Impairs Normal Cognition

In day-to-day practice, most physicians think of pain as a simple aversive sensation that a patient feels. Cognitively, as already indicated, it is much more. At the perceptual level, pain is a somatic image that captures or narrows attention (i.e., pain is felt as a focus of distress in a bodily area). The person trying to work while experiencing the pain of a kidney stone has major problems with concentration. Because pain represents a threat to biological integrity in the most fundamental emotional sense (see Chapter 24), it normally involves thinking about the origin of the tissue trauma and the meaning that this has for the immediate and long- range well-being of the person. These complex processes draw on memory, may involve forecasting and planning, and often entail decisions about activity, medication use, or self-care.

Because of pain's cognitive complexity, most patients who seek medical help for pain want more than simple pain relief. They typically wish to achieve some or all of the following goals: (a) understand the cause of the pain, (b) obtain a diagnosis for it, (c) gain a forecast for the pain (how long it will last, whether it will worsen), (d) acquire information about how to control or relieve the pain, (e) learn how to treat or eliminate the cause of the pain, and (f) obtain information about whether certain activities will cause damage or harm. Identifying and addressing such needs is a part of optimal pain medicine. It is important to provide realistic information, when available, about the natural history of the patient's pain problems. For example, current knowledge on back pain reveals that an acute episode of low back pain persists longer than what was once thought and that low back pain is a recurrent condition for most patients. Knowing this can reassure patients whose pain does not resolve within 1 or 2 weeks. The timely offering of such information may motivate patients to engage in behaviors that reduce the chances of future back pain episodes, and it may reduce unnecessary health care use. Some patients worry that persistent or recurrent pain means physical examination has failed to detect a serious cause of the pain.

At sensory and emotional levels, pain feels unpleasant, causes fatigue, and impairs sleep (see Chapter 24), and it probably interferes with cognitive memory (50). Sleep disturbance degrades normal cognitive ability, impairing concentration, and at times pain can interfere with productive mental effort by dominating immediate awareness and causing somatic preoccupation. What is the nature of pain's deleterious effect on the patient's cognitive well-being and functional capability?

Mandler (51), while ostensibly describing stress in cognitive terms, essentially identified the mechanism by which pain impairs cognitive function. Pain captures or narrows attention and thereby disrupts organized action and thought. In other words, it disturbs and eventually controls self-organization and self-reference. When it is chronic, pain becomes the theme around which the patient organizes thinking and action. Pain biases memory, and it may cause the patient to preferentially recall negative ideas and feelings (52,53,54,55 and 56). Pain can sometimes bias perception of the external environment such that everyone and everything in the environment are selected and evaluated for their relevance to pain relief. Moreover, it creates a preoccupation with somatic well-being, causing the patient to dwell on signs and symptoms. Often, patients seek information about pain and its relief, information about other patients like themselves, and information that suggests overlooked or withheld cures. Naturally, the experience of pain in the absence of cancer or another serious disease is incomprehensible to patients and families alike, and most patients engage in a search for meaning and personal dignity. In all of these respects, pain becomes a dominant influence on the patient's cognition. The cognitive and emotional associations that surround the experience of pain are major features of most patients' presentations.

Because pain can interfere with a person's ability to see his or her own situation and life stressors clearly, it tends to create vicious circle situations. The development of a painful condition causes a host of life problems and depletes the person's normal coping resources. The person with chronic pain forms elaborate and negative schemata related to the pain and the search for relief. Often, people with unrelieved pain become preoccupied with the pain and somatic processes. Pain may disrupt sleep; cause depression, irritability, and social withdrawal; sap energy; and limit the sufferer's ability to engage in customary recreational, social, household, and vocational activities. These changes further deplete the person's coping resources and increase his or her focus on pain and its relief, sometimes to the exclusion of all else. Such cases require a multidisciplinary rehabilitation approach that facilitates the patient's return to normal activities, the formation of more adaptive beliefs about the pain, and the application of adaptive pain and stress coping skills (see Chapter 11).

Cognition and Coping with Pain

Persons with pain problems vary widely in the beliefs they hold about their pain and in the ways they cope with or manage their pain. Beliefs and coping strategies are associated importantly with their physical and psychosocial adjustment. Among the beliefs particularly important in adjustment to chronic pain problems are one's perceived ability to control one's pain and one's tendency to think catastrophically (i.e., to expect or worry about major negative consequences from a situation, even one of minor importance). For example, patients who believe they have little control over their pain and who think catastrophically frequently are more likely to exhibit physical and psychosocial dysfunction (57,58 and 59). Close associations exist between thinking catastrophically, fear of pain and of reinjury, and attention (hypervigilance) to pain and other unpleasant somatic sensations (60). People who think catastrophically frequently may attend excessively to pain and have difficulty using coping strategies that involve distraction or attention diversion (60).

Coping refers to “constantly changing cognitive and behavioral efforts to manage specific external and/or internal demands that are appraised as taxing or exceeding the resources of the person” (61). Coping involves two fundamental tasks: the management of affect or emotional states, and planning and problem solving (62). Pain-coping strategies can include cognitive strategies (e.g., self-statements such as “I can deal with this”), and behavioral strategies such as increasing or decreasing specific activities (e.g., resting, exercising, and using heat or ice).

Numerous studies have shown that patients' beliefs about their pain (such as perceived ability to control the pain) and the strategies they use to cope with their pain are associated with their pain intensity ratings and psychosocial and physical functioning (57,63,64,65,66,67,68,69,70,71,72 and 73). Most of this work addresses chronic pain problems, but the principles also apply to acute pain, as Ulmer's study of coping in burn trauma patients shows (74). She measured pain, coping, and depressed mood in patients with moderate to severe burn injuries. Patients' tendency to think the worst or to think catastrophically was positively associated with pain intensity and pain distress. Conversely, personal belief in one's ability to control and decrease pain correlated negatively with depressed mood.

Awareness of the importance of patients' cognitions and coping strategies in their physical and psychosocial adjustment to chronic pain has led to the widespread application of cognitive-behavioral therapy approaches in multidisciplinary pain centers (see Chapter 89). However, such approaches have yet to find their way into most primary care settings.

Chapter 89 discusses and provides examples of negative cognitions that patients frequently have about their pain and how a therapist might work with a patient to identify such negative cognitions and generate alternative, more adaptive cognitions. Most physicians do not have the time necessary to use such an approach with their patients. However, physician awareness of the importance of these cognitive and behavioral factors may result in improved treatment of patients with chronic persistent or recurrent pain problems in a variety of health care settings. For example, identifying and addressing patient concerns about the pain problem; providing accurate information concerning the likely course of the pain problem; encouraging patient use of self-management strategies rather than continued pursuit of a medical cure; and assisting the patient in return to normal functional, vocational, and social and recreational activities that the pain has interfered with may help reverse and prevent the negative effect of pain on patient psychological and physical functioning.

CONCLUSIONS

The psychology of pain is a rapidly growing field with roots in behavioral and cognitive psychology. This field's fundamental assumptions differ markedly from those of neurology, psychiatry, and anesthesiology because these medical disciplines build on the field of neurophysiology. Classical lines of thinking in neurophysiology, particularly the energy metaphor and Cartesian dualism, are conceptually incompatible with much of the work in current psychology, although information theory provides some potential for interaction. Achieving a full integration of pain medicine and pain psychology requires reconsideration of fundamental assumptions on

both sides and intensive dialogue. The possibilities that such integration would offer for multidisciplinary care are exciting and unprecedented.

CHAPTER 7

Gender, Cultural, and Environmental Aspects of Pain

Linda LeResche

This chapter focuses on several socially related aspects of pain—specifically, gender, culture, and the social environment. Gender and ethnicity are aspects of personal identity that are rooted in biology, but develop over the course of the lifetime within the context of the individual's social milieu. For example, an individual may be born female and of Japanese heritage, but how she responds to pain as an adult depends not only on those biologic characteristics bestowed by virtue of having two X chromosomes and certain genes associated with racial origin, but also on whether she grows up in Tokyo or Toronto, behavioral expectations for women and girls within the context of her family and culture, and even how persons with her cultural background are viewed by persons in other cultures. Gender, the proximate social environment of family and friends, and social role within the context of the larger culture all have the potential to influence the individual's perception and appraisal of a pain problem and his or her behavior in response to pain experiences. At an even more basic level, because different social and occupational roles expose people to different risk factors for disease and injury, a person's gender, culture, and social environment also influence the very probability of developing any specific clinical pain problem.

GENDER

Gender differences in pain have been the focus of a number of review articles (1,2 and 3) and a major conference (4). In attempting to understand how gender can affect pain, one must consider that biological differences may exist in the nociceptive and perceptual systems of males and females. Work with rodents suggests differences in the pain modulation systems of males and females in some species (5,6) that appear to be related to hormonal factors, specifically estrogen. Moreover, Mogil (7) and colleagues have shown that gender differences in pain responsiveness vary for different strains of mice.

In humans, laboratory studies of gender differences in pain perception are usually designed to compare pain threshold and tolerance measures in men and women. The bulk of these studies seems to indicate slightly higher pain sensitivity in women than in men (2). However, gender differences in pain threshold and tolerance measures appear to vary with the type of experimental pain stimulus applied (e.g., larger and more consistent differences are found for pressure than for thermal stimuli) (2). In addition, different study designs can yield differing results, and even those studies that show statistically significant differences by gender find overlapping distributions of pain sensitivity for men and women (1). A further complicating factor in these studies is that phase of the menstrual cycle in reproductive-aged women is rarely taken into account (8). Although numerous studies have attempted to determine how pain sensitivity might vary with menstrual cycle phase (9,10,11,12,13,14 and 15), they have reached somewhat contradictory conclusions about when sensitivity is highest, perhaps because of different study designs, use of different pain stimuli, and different definitions of phase. Furthermore, sample sizes for most of these studies are quite small, and few studies have provided corroborative evidence of hormonal state.

Despite the difficulties with human laboratory experiments on pain sensitivity, many investigators are willing to draw the inference from these studies that women are, in general, more sensitive to painful stimuli than men, and that this difference is biologically based (1,2). Although this conclusion is plausible, it may be premature, not only for the methodologic reasons just mentioned, but, perhaps more important, also because information on pain sensitivity in these human experimental studies is gathered via self-report or behavior (e.g., terminating exposure to the stimulus). Thus, the findings could reflect willingness or propensity to report pain, rather than biological differences. In addition, nearly all of the experimental studies have been conducted on European or North American subjects, and the majority of them have investigated only pain responses of young adult men and women, not those of the elderly or of children (16). Thus, as yet, little evidence exists to indicate the extent to which the (usually small) gender differences observed in these studies are a product of human biology, and the extent to which they reflect social and cultural influences on pain report.

For many common pain conditions, including migraine and tension-type headache, facial pain, and abdominal pain, population-based studies indicate higher prevalence rates in adult women than in men (17). However, higher pain prevalence in women is not a universal finding. For example, epidemiologic research on back pain is contradictory, with some studies finding higher rates of pain report in men and other studies showing higher rates in women of the same age (18,19 and 20). For some pain conditions, women show a higher prevalence at some points in the life cycle, but not at others. Migraine and temporomandibular pain, for example, tend to show a female predominance only after puberty (21,22), and joint pain shows a female predominance only after approximately age 50 years (23).

Higher prevalence rates for pain in women could be related to a number of factors. First, as has been mentioned, socialization of children in European societies may be such that less stigma is associated with reporting pain for women than for men. Because most of the epidemiologic research, like the experimental research, has been conducted in Europe and in persons of European origin in North America, there have been few opportunities to test whether different socialization patterns could influence gender- specific prevalence patterns. However, at least one cross-national study of primary care patients (24) found that the higher prevalence of persistent pain among women was not confined to Western societies. Second, men and women may have different benchmarks for reporting pain related to their prior pain experience. For example, boys, at least in earlier generations, were more likely to experience pain from sports injuries than girls. On the other hand, after puberty, women's monthly menstrual cycles provide them with a set of physiologic signals from their bodies that are not experienced by men. These sometimes painful physiologic signals could have a sensitizing effect on pain perception (1) or result in behavioral and social role responses (e.g., taking medication, staying in bed) that can generalize to other types of pain. Finally, the prevalence of a pain condition (i.e., the number of cases in the population at a given point in time) is a product of the rate of onset of the pain condition, as well as its duration. If pain prevalence rates for women are higher than for men, this could occur either because women are more likely to experience pain in the first place, or because pain, once present, tends to last longer for women. Few data are available on differential rates of onset and duration for chronic and recurrent pain conditions in men and women.

Whatever the pain prevalence differences for men and women, most studies show that women seek health care for pain at a higher rate than men (3). The predominance of women in treatment settings is not surprising, given that women are more likely than men to seek care for most medical conditions (25). Although there has been little research concerning the factors associated with seeking care among persons with pain in the population, one study found that the major predictors of health care in both genders were pain severity and persistence (26) (i.e., persons with more severe, persistent pain were more likely to seek care). For some pain conditions, such as temporomandibular pain, women experience pain of higher average severity than do men. If it is true that pain severity drives treatment seeking and that women, on average, experience pain of higher severity than men, we would expect that the levels of pain and pain-related symptoms among men and women seeking pain treatment would be fairly comparable, although women could outnumber men in treatment settings. The few studies that have examined this question have, in fact, found that levels of pain, pain-related signs and symptoms, and psychosocial profiles are roughly comparable for men and women seen in the same treatment setting (27,28).

Some research suggests that women and men with pain problems differ in their patterns of coping with pain. For example, in a sample of patients from a pain management center, Buckelew and colleagues (29) found women more likely than men to report the use of cognitive restructuring and information seeking. A daily diary study (30) found that women with arthritis reported greater pain, but also used more pain-coping strategies on a daily basis than men. Furthermore, men showed a greater carryover effect of intensifying pain on the presence of negative mood the next day. Thus, although women may experience more intense pain, they may also be better able to limit its negative emotional consequences.

Only a few studies have explored possible differences in how men and women respond to pain treatment. Clinical experiments have found differential response to some pain medications among men and women (31), with some drugs, notably kappa opioids, being more effective in women than in men. Although little reported research exists on the effectiveness of nonpharmacologic therapies by sex, one study found that women were more likely than men to be successful in a cognitive-behavioral program of the type frequently used in multidisciplinary pain centers (32). Finally, in a study of injured workers with musculoskeletal pain, Crook and Moldofsky (33) found that patterns of return to work after injury differed for men and women. Although men returned to work sooner than women, they were more likely to experience recurrent disability. Women, possibly because of additional duties at home, took more time than men to return to employment, but were more

likely to stay on the job once back in the work force.

Thus, it appears that gender affects not only pain perception, pain coping, and pain report, but also pain-related behaviors, including use of health care and the social welfare system. It is also probable that men and women differ systematically in their responses to pain treatments, although further research is needed in this area.

CULTURE

The influence of culture and ethnicity on pain perception and expression has been a focus of research attention since the pioneering work of Zborowski in the 1950s and 1960s (34). However, summarizing the body of research in this area systematically is difficult, because a wide variety of research approaches have been used, including direct observation; in-depth, open-ended interviews with a small number of informants; the administration of structured questionnaires; and experimental studies of responses to painful stimuli. Furthermore, although a wide variety of cultures have been examined across the various studies, little replication has occurred in the cultural groups investigated from study to study, so it is difficult to know whether findings about a given culture reported in one study are generalizable to other research settings. Some research investigates persons of a given culture living in their native land, where they are usually the predominant culture, and other studies focus on persons of specific ethnic backgrounds living in a multicultural society such as the United States, where they are frequently cultural minorities. Although some studies carefully control for factors such as socioeconomic status, degree of acculturation to the predominant culture, and age and gender of the subjects, and report intracultural as well as intercultural variation, others fail to do so. Given these concerns, a comprehensive review of the literature on culture and pain is beyond the scope of this chapter. Instead, I highlight some of the more important issues in this area by reviewing selected studies that have taken a variety of approaches to studying culture and pain.

Moore and colleagues have used qualitative and quantitative methods to examine the words used by persons in Anglo-American and Chinese cultures to describe specific pains (35,36 and 37). These studies of pain language reveal that different concepts are applied to the same types of pain in different cultures. For example, muscle pain was viewed as *deep* by nearly all Anglo-Americans, but only approximately one-half of Mandarin Chinese. Eighty-two percent of Chinese described the pain of tooth drilling as *sourish*, whereas only 8% of Americans agreed that this was an accurate descriptor (37). In the same study, dentists' views of the appropriate words to describe various kinds of pains did not differ from those of laypeople in their respective culture, indicating that professional socialization may not have a strong influence on basic concepts of the qualities of pain. In contrast, earlier studies of coping with pain among ethnic Chinese, Anglo-Americans, and Scandinavians in a U.S. city found that although pain remedies endorsed by patients showed ethnic differences, dentists in all three cultures seemed to have similar views of appropriate remedies, suggesting that professional socialization had a larger influence in this domain than did ethnicity (38).

In 1990, Zatzick and Dimsdale (39) systematically reviewed the literature on cultural differences in responses to experimentally induced pain and located 13 studies published between 1943 and 1989. The studies were diverse with regard to the racial and ethnic groups studied, as well as the pain stimuli applied and the outcomes measured (i.e., pain threshold and/or pain tolerance). The authors concluded that although there appear to be no racial or ethnic differences in the ability to differentiate painful stimuli, the experimental evidence is not consistent with regard to cultural differences in pain response. They suggested that future laboratory investigations focus on behavioral pain tolerance measures, rather than pain threshold measures (which are likely to be influenced by language), and stressed the importance of assessing intragroup as well as intergroup differences. Perhaps because some have questioned the relevance of such laboratory studies for understanding how culture influences pain in clinical contexts, I was not able to locate additional human experimental studies published since 1990.

In contrast, a number of studies have been published investigating the perception of acute and chronic pain in daily life and clinical contexts. For example, menstrual and premenstrual symptoms were assessed using daily symptom diaries in Afro-Caribbean, white, and Chinese women recruited through a community center in London (40). Relative to the Afro-Caribbean subjects, white women reported more pain in both the premenstrual and menstrual periods. Similar results were found in analysis of retrospective report of menstrual distress. Another study investigated ratings of the pain of ear piercing in 84 young women and men, aged 15 years to 25 years. Again, the study was carried out in London and investigated Afro–Caribbean, Anglo-Saxon, and Asian subjects. One-half the subjects of each gender in each ethnic group were told that they were participating in a study of pain, and one-half were told the study involved sensory experience. Significant effects were found for ethnicity, and for pain versus sensory experience conditions, but no significant sex differences were found. Afro–Caribbean subjects reported significantly lower pain levels than the Anglo-Saxon and Asian subjects; although Asians reported the highest pain levels, no significant difference was found between the Asians and Anglo-Saxons.

A few studies have examined differences in the levels of chronic pain reported by patients of different cultures in pain treatment centers. In a well-controlled study in a single multidisciplinary pain management center, Bates and colleagues (41) examined variability in pain report on the total Pain Rating Index of the McGill Pain Questionnaire among “Old American” (at least third-generation United States–born non-Hispanic whites), Hispanic, Irish, Italian, French Canadian, and Polish subjects. The majority of subjects in all groups had chronic low back pain, and no significant differences existed in diagnosis, mean number of medications, or types of medications by ethnic group. Hispanics reported the highest pain levels and were also more likely than the other groups to have an *external* locus of control. In multiple regression analyses, both ethnic group identity and perceived locus of control were significantly associated with pain intensity after controlling for the influence of age. The significant ethnic group differences were between Hispanics and Old Americans, Hispanics and French Canadians, and Hispanics and Polish subjects. Intraethnic group variation in pain intensity was also investigated and found to be related, albeit in a complex way, to locus of control and to the degree to which the individual identified with his or her ethnic group. Although this study provides a wealth of interesting information regarding ethnic group differences, it represents findings from only a single health facility. Caution should also be taken in attributing differences between Hispanics and other ethnic groups solely to cultural factors, as the level of education of the Hispanic sample was significantly lower than that of other groups in the study.

A few investigators have examined the prevalence of specific pain conditions in different ethnic groups in large, well-controlled epidemiologic studies. Using International Headache Society criteria for migraine, Stewart and colleagues (42) examined migraine prevalence in more than 12,000 residents of Baltimore County, Maryland, aged 18 years to 65 years. In women, migraine prevalence was significantly higher among whites than among African-Americans or Asian-Americans (prevalence rates of 20.4%, 16.2%, and 9.2%, respectively). A similar pattern was shown for men (rates of 8.6% for whites, 7.2% for African-Americans, and 4.2% for Asian-Americans), although absolute rates were lower than for women. In models adjusting for age and education, African-American and Asian women showed significantly lower prevalence ratios when compared with white women. African-American men also displayed significantly lower adjusted prevalence than white men. Although the adjusted prevalence for Asian men was only 60% of that of white men, this difference was not statistically significant, because of the very small number of Asian men with migraine. These findings are particularly interesting in light of the fact that meta-analyses of studies of migraine prevalence using International Headache Society criteria indicate lower migraine prevalence rates in Asia and Africa than in Europe or the Americas (43). The authors speculate that genetic differences between races are likely to account for the observed variability, although other factors, such as dietary and symptom-reporting differences, cannot be ruled out.

Skovron and colleagues (44) assessed the prevalence of back pain among Flemish and French speakers in Belgium, a bicultural, economically diverse society that has a national social security system and single-payer health care reimbursement. In multivariate analyses controlling for several variables (social class, rural-urban location, occupation, and work status), increasing age, female gender, and French language were associated with reporting a history of back pain (i.e., ever having had back pain). Only female gender and French language predicted being in a first episode of back pain, with language being the stronger predictor. However, when predictors of daily back pain were examined, the factors that emerged as predictors, other than age and sex, were largely social, rather than cultural (i.e., social class, living in a large city, and being an unskilled worker). Thus, it appears that cultural factors may have influenced rates of reporting a history or a first episode of back pain in this study; however, pain persistence was unrelated to culture.

Finally, a few large multinational studies have examined the effects of pain across cultures. One set of studies (45,46) examined the consequences of pain in more than 1,800 patients with metastatic cancer and pain in four countries, the United States, France, the Philippines, and China. Patients rated their worst pain on a 1 to 10 numeric rating scale and the degree to which pain interfered with enjoyment of life, activity, walking, mood, sleep, work, and relations with others on 0 to 10 scales. It was found that, based on the degree of interference with function, pain ratings of 1 to 4 corresponded with mild pain, 5 to 6 with moderate pain, and 7 to 10 with severe pain. These cut points were the same for each of the national samples, although the specific interference items affected by pain differed from country to country.

Gureje and colleagues (24) examined measures of well-being for more than 5,400 persons with persistent pain in primary care settings in 15 countries in Asia, Africa, Europe, and the Americas, compared with persons in the same settings who did not experience persistent pain. Across all the centers, the prevalence of persistent pain was 22%, but there was wide variation in prevalence from center to center, with a range of 5.5% to 33.0%. No cultural reasons for the variability in prevalence were apparent. Relative to patients without persistent pain, patients with persistent pain were more likely to experience an anxiety or depressive disorder, to experience significant activity limitations, and to rate their general health status as fair or poor. For all 15 centers, the difference in rates of depressive and anxiety disorders for those with versus without pain was statistically significant. However, statistical differences in self-rated health status, self-rated interference, and interviewer-rated work-related interference did not emerge in all centers, and there was no straightforward interpretation of the pattern of results that emerged across

cultures. This lack of consistency across settings in a well-controlled study with substantial sample sizes at each center suggests that caution should be used in drawing conclusions about cultural differences in the effects of persistent pain when samples are drawn from a limited number of health care settings in each culture.

ENVIRONMENT

Two classic experimental studies illustrate the role that the environment theoretically can play in the perception of pain. Dworkin and Chen (47) tested young women's sensation threshold, pain threshold, and pain tolerance levels in a laboratory situation using tooth pulp stimulation and then retested one-half of the subjects in a dental operatory setting and one-half in the original laboratory setting. The salience of the dental environment was enhanced by the experimenter's introducing himself as a dentist and telling the subject that information on her pain responses was relevant to her risk of dental health problems. Those subjects tested in the dental environment had significantly increased anxiety and not only had significantly reduced pain threshold and pain tolerance levels, but also had significantly reduced thresholds for reporting the presence of any sensation compared with their original measures and with the levels of those subjects retested in the original laboratory environment. Craig and Best (48) exposed young female subjects to electrical stimulation in the presence of a confederate who modeled either tolerance or intolerance to pain (i.e., systematically gave ratings either lower or higher than those of the subject) or was inactive. Subjects exposed to tolerant models exhibited significantly higher pain tolerance than those exposed to the intolerant model, whereas the tolerance levels of subjects in the inactive control condition were intermediate. When the model was removed and subjects were informed of the model's role, they continued to respond in the same manner as when the model was present. Thus, it appears that, at least in some circumstances, the social environment in which a pain response is learned may have a lasting effect on pain behavior.

Does the social environment influence the tendency to report clinical, as well as experimental, pain? Because the family is the primary agent of socialization about health and illness, if there are social environmental influences on pain perception and pain reporting, it seems logical to look for these influences within the family. Turk and colleagues (49) reviewed a fair amount of empirical evidence supporting the view that children and adults with chronic pain are likely to have individuals in their families with chronic pain (i.e., models for chronic pain). However, these authors also point out that most of the reported studies of chronic pain in families suffer from one or more significant methodologic problems, including reliance on retrospective self- report of patients and families, lack of control groups, and potential for recall bias among persons with pain. Thus, although a strong role for the family, as well as the larger social and cultural environment, in shaping an individual's perception and appraisal of pain is highly plausible, detailed longitudinal research is necessary to confirm or refute the suspected relationships. Until such research findings are available, it may be best for the clinician to be aware that the behavior of individual patients presenting with pain is likely to be influenced by a range of social factors, including their gender, culture, and family upbringing; yet, none of these factors is sufficient to determine the individual's experience of pain.

CHAPTER 8

Applied Anatomy Relevant to Pain

John J. Bonica and John D. Loeser

This chapter contains information about those aspects of the gross anatomy and neuroanatomy relevant to painful disorders and is intended to complement the information contained in Chapter 3 and Chapter 4. The material is presented in two parts. The first section contains a description of the segmental and peripheral nerve supply to the skin, muscles, and bones and the segmental sensory and autonomic nerve supply to viscera. The second section is devoted to a general discussion of the autonomic nervous system (ANS) as relevant to its role in pain. The sensory supply of each region is discussed in more detail in the introductory chapter of each section of Part IV of the book and is also considered briefly in the introduction to some of the chapters. For example, Chapter 46, the first chapter of the section on pain in the head, contains a detailed discussion of the nerve supply to the head and precedes the chapters in which the various head pain syndromes are discussed. Some of the information is also repeated in the sections on neurologic and orthopedic examination of Part II and in connection with those chapters in Part V dealing with therapeutic modalities that require full knowledge of the relevant anatomy and physiology. The material is derived in part from updated reviews and other reliable sources (1,2,3 and 4).

SEGMENTAL AND PERIPHERAL NERVE DISTRIBUTION

Figure 8-1 and Figure 8-2 are included as reference points with regard to the derivation of peripheral nerves from the spinal cord and brainstem. Figure 8-1 depicts the gross anatomy of the spinal cord and the attachment of rootlets of the posterior (dorsal) roots and anterior (ventral) roots. Figure 8-2 depicts the relationship of the segments of the spinal cord to the vertebral canal and column. The anatomy of the cranial nerves involved in nociception and their derivation from the brainstem are discussed in Chapter 46.

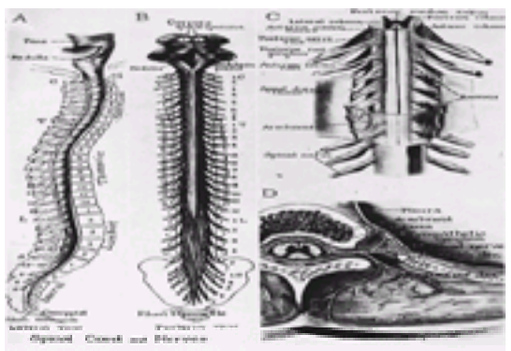

Figure 8-1. The spinal cord and the proximal portions of the spinal nerves. **A:** Lateral view of the spinal cord showing attachment of the nerves to the cord by their anterior and posterior roots. **B:** Posterior view of the spinal cord made possible by removal of the spinous processes and laminae. Note the relationship of the spinal cord segments and nerves to the vertebrae. In most individuals, the conus medullaris terminates at the lower border of the first lumbar vertebra. Caudal to the conus medullaris is the cauda equina, made up of rootlets that join together to form the anterior and posterior roots, near the point at which the latter join to create the formed nerve within the intervertebral foramina. **C:** Anterior view of the spinal cord with the dura-arachnoid removed from the upper portion of the specimen. The smaller anterior root fans out and divides into four to six rootlets, which form irregular rows attached to the cord in the anterolateral sulcus. The larger posterior root is composed of 6 to 10 rootlets attached to the spinal cord in a linear series along the posterolateral sulcus. These rootlets (fila radicularia) converge peripherally into two bundles, the fasciculi radiculi, which in turn unite near the dorsal root ganglion to form the posterior root. Within the intervertebral foramen the anterior and posterior roots join to make the formed spinal nerve. **D:** Cross section of the thoracic region showing the course and relation of a typical spinal nerve. Note its connection with the sympathetic ganglion. (div., division.)

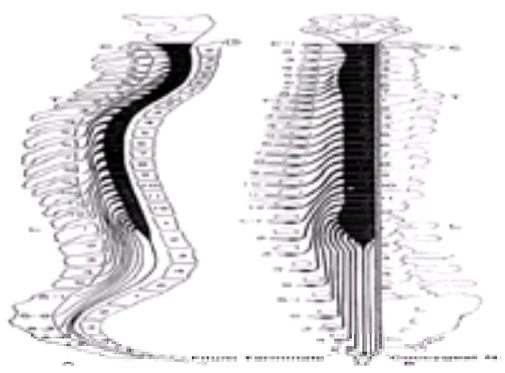

Figure 8-2. Schematic representation to show the relation of spinal column and the spinal cord, nerve roots, and the formed nerves. **A:** Lateral view. **B:** Posterior view. Note the direction of the spinal rootlets/roots in the various segments. The size of the spinal cord in relation to the spinal canal is exaggerated in **B** for the sake of clarity of the numbers of spinal cord segments and their relationship to the vertebrae. (C, cervical; L, lumbar; N, nerve; S, sacral; T, thoracic.)

Segmental Distribution of Sensory Nerves

The distribution of sensory fibers, which, of course, contain nociceptive axons, is more or less segmental throughout the body. This is the result of the preservation by the sensory levels of the nervous system of the original embryologic division of the body into metameres. The spinal segments that provide sensory and motor innervation to one embryologic division constitute a *metamere.* The cutaneous area supplied by a single pair of sensory roots and their ganglia is known as a *dermatome,* and the area of bones supplied by a similar unit is known as a *sclerotome.* The ventral roots also innervate the dermatomes and sclerotomes, supplying them with sudomotor, pilomotor, and vasomotor fibers, but the distributions of the two classes of fibers, the sensory (afferent) and the motor (efferent), never exactly coincide. Furthermore, the ventral root supplies motor fibers to skeletal muscles, and the area supplied by each segment is often referred to as the *myotome.*

This distribution is particularly segmental for the ectodermal structures—the skin and subcutaneous tissue. The nerves supplying the viscera are also segmentally distributed; as mentioned in Chapter 3, however, visceral afferent fibers are few in number in comparison with the number of somatic primary afferents. It has been estimated that visceral afferents constitute only 10% of the total number of afferents in dorsal roots. This paucity of visceral afferents is compensated in part by the

much larger area supplied by the visceral fibers in one root, the peripheral processes of which ramify widely. This is discussed later in this chapter in the section on segmental innervation of the viscera. Knowledge of the segmental distribution of sensory fibers is of critical importance in managing patients with acute and chronic pain.

Dermatomes

There are as many dermatomes as there are spinal segments, with the single exception of the first cervical segment, which in most individuals has no cutaneous distribution. Many investigators using various methods have mapped out the boundaries of the dermatomes. Although there were several investigations of the areas of skin supplied by dorsal roots during the nineteenth century, the first satisfactory delineation of the dermatomes came from the work of Sherrington in the 1890s (5,6). Sherrington's technique, known as the method of *residual sensibility*, was carried out in monkeys and consisted of sectioning several (usually three) dorsal (sensory) roots rostrad and three roots caudad to the root under consideration, which was allowed to remain intact. The area of sensation that remained in the otherwise unanesthetized area that resulted was the dermatome. Maps were drawn of the different dermatomes, and it was assumed that each dermatome resulted from the sensory axons that remain in the intact root.

Subsequently, the method of remaining sensibility was used extensively in humans by Foerster (7), who in the course of long experience with posterior root section (rhizotomy) for the management of intractable pain had the opportunity of determining every dermatome in the lower limbs and one dermatome in the upper limbs in humans. To fill the gap and to define other cervical and the thoracic dermatomes, he used what he called the *constructive method*, which consisted of dividing a series of contiguous posterior roots and testing sensitivity in the areas they supplied. Thus the superior border of the resulting anesthesia represented the inferior border of the dermatome supplied by the next higher intact root, and the inferior border of anesthesia marked the upper border of the next lower dermatome. The third method Foerster used was based on the antidromic response, in which the vasodilation that followed stimulation of the distal cut end of a dorsal root was mapped out. Foerster reported not only that great overlap existed among contiguous dermatomes, but also that significant variations existed in the cutaneous distribution of specific sensory roots, especially in the limbs, of different patients he studied. Figure 8-3 is based on reconstructions of Foerster's data by Haymaker and Woodhall (3) and by Lewis (8).

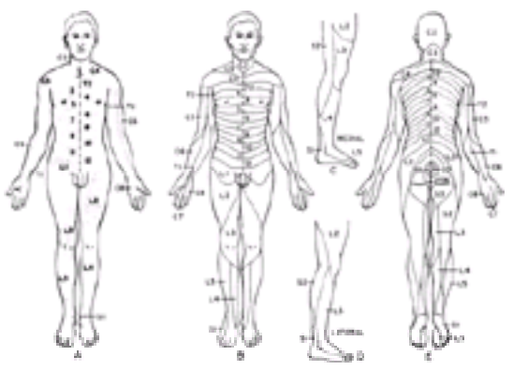

Figure 8-3. The dermatomes in humans according to the studies of Foerster. **A:** Overlap of the dermatomes in the upper and lower limbs not depicted in **B** to **E**. (**A** modified from Lewis T. *Pain*. New York: Macmillan, 1946; **B** to **E** from Haymaker W, Woodhall B. *Peripheral nerve injuries: principles of diagnosis*. Philadelphia: WB Saunders, 1945.)

At the same time as Sherrington's studies, Head (9), believing that herpes zoster was a disease of the posterior roots, closely observed and recorded the cutaneous eruptions of this affliction in the hope that it might accurately disclose the distribution of the posterior roots to the skin. Maps provided by a large number of cases of herpes zoster were examined and correlated with the borders of sensory loss arising from cord lesions at certain levels. Figure 8-4 is based on Head's preliminary data on cutaneous areas published in 1893 (9) and additional observations published in 1900 (10). It is important to note that there is little overlap in the trunk but some overlap in the lower limb. The patterns of Head's dermatomes in the lower limbs are similar to those reported by Foerster, but there are significant differences between the two patterns in the distribution of the upper limbs.

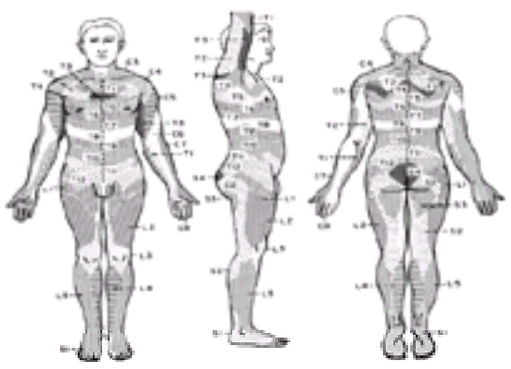

Figure 8-4. The dermatomes developed by Head, from observation of patients with herpes zoster lesions. There is no overlap of the dermatomes in the trunk, but there is some overlap of the dermatomes in the lower limbs. (Modified from Head H. On disturbance of sensation with special reference to the pain of visceral disease. *Brain* 1893;16:1; and Head H, Campbell AW. The pathology of herpes zoster and its bearing on sensory localization. *Brain* 1900;23:353.)

Many other investigators used Sherrington's technique of residual sensibility to produce dermatomal maps for many species. The major conclusions of these studies were that (a) the dermatomes overlap, and thus the area of the body wall supplied by the axons of a single dorsal root is greater than one segment; (b) because of this overlap, it is usually not possible to render an area of the body anesthetic by cutting only one dorsal root; (c) although the dermatomes overlap, the threshold for various stimuli is lowest in the central part of the dermatomal field; and (d) most of the dermatomes for the limbs do not extend to the midline of the body, so that dorsal and ventral axial lines are found in the extremities and result when the dermatomes from continuous spinal levels abut. Thus, the C-4 dermatome lies next to the T-2 dermatome and L-2 is next to S-2. This nonsegmental pattern of dermatomes in the limbs, published by Sherrington and Foerster, was based on the concept of dermatomic development proposed by Sherrington (5) and refined by others during the early part of the twentieth century. This concept suggests that whereas during embryonic life the spinal portion of the embryo is divided into metameres, this arrangement loses its uniformity when certain groups of metameres migrate into the limb buds, and as these extend more and more distally, the corresponding dermatomes also migrate. The dermatomes that have migrated become grouped parallel to the long axis of the future limb except at the distal part of the limb, at which they are arranged in loops over the expanding limb buds. Consequently, the dermatomes of the higher (rostral) segments are grouped along the preaxial border of the limb, and those of the lower (caudal) segments along the postaxial border, the two divided by ventral and dorsal axial lines.

In the 1940s, Keegan (11) carried out a series of studies of the dermatomes using three different techniques. One detailed careful charting of the area of pain and hypalgesia associated with compression of a single nerve root due to herniation of an intervertebral disk. By careful preoperative examinations, with particular emphasis on the distribution of the pain (obtained by asking the patient to indicate precisely where the pain was located) and skin testing by a light scratch method with a safety pin, he was able to map out the dermatomes in a large group of patients. The diagnosis of single root compression by a posterolateral (unilateral) disk was verified at surgery. He also studied hypalgesia produced by (a) paravertebral injection of procaine on individual cervical nerves that supply the upper extremity, carried out under radiographic control in 10 human volunteers, and (b) posterior rhizotomy of a single nerve root in the lower extremity. Figure 8-5 shows dermatomal charts of the upper and lower limbs, and Figure 8-6 is a complete dermatomal chart, published by Keegan. As shown in these figures, the dermatomes to the limbs consist of a series of continuous bands extending from the distal part of the limb to the midline, and there is no dorsal axial line. Moreover, these dermatomal areas do not overlap, but Keegan pointed out that his outlines were areas of detectable hypalgesia from loss of a single nerve root and represent the *primary* innervation, not the entire distribution of each nerve root. He agreed there must be considerable secondary overlap innervation for each nerve root, otherwise analgesia (rather than

hypalgesia) in the primary area would be found with loss of a single nerve root. He mentioned that at times he found a faint parallel strip of hypalgesia on each side of the primary dermatome that was half the width of the primary zone.

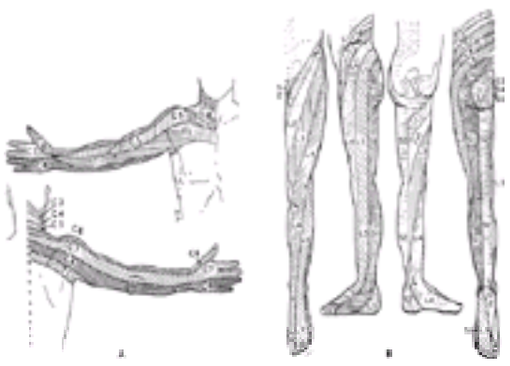

Figure 8-5. **A:** Dermatome chart of the upper extremity. **B:** Dermatome chart of the lower extremity. Dermatomes determined by pattern of hypalgesia from loss of a single nerve root. (**A** from Keegan JJ. Dermatome hypalgesia with posterolateral herniation of lower cervical intervertebral disc. *J Neurosurg* 1947;4:115; **B** from Keegan JJ. Neurosurgical interpretation of dermatome hypalgesia with herniation of the lumbar intervertebral disc. *J Bone Joint Surg* 1944;26:238.)

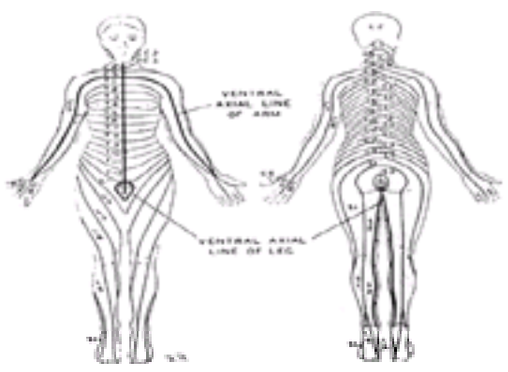

Figure 8-6. Composite dermatome chart of the human body developed by Keegan, from studies of the dermatomes in the upper and lower limbs and from a classical pattern of the dermatomes in the trunk. (From Keegan JJ. Dermatome hypalgesia with posterolateral herniation of lower cervical intervertebral disc. *J Neurosurg* 1947;4:115.)

Keegan, in collaboration with Garrett (12), suggested that the primary zone, containing more dense distribution of fibers from the dorsal root, represented the true primitive dermatome and that the secondary zone, containing fewer fibers, represented the area of overlap. In support of Keegan's finding and their explanation, they presented a different conception of the development of the dermatome in the limb bud. They postulated that the sensory branches of the limb nerve grew with the development of the limb bud along its dorsal surface and wound themselves around the preaxial and postaxial borders to the ventral surface, meeting along the axial line. Figure 8-7 depicts the concept they proposed and the one proposed earlier.

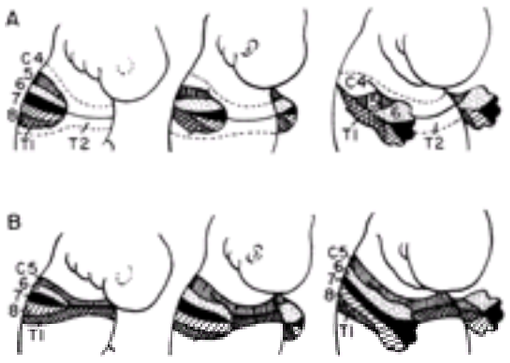

Figure 8-7. **A:** The classic concept of the development of the dermatomes in the limb bud at three stages of development, following the scheme suggested by Sherrington and refined by Bolk. **B:** The concept proposed by Keegan and Garrett. In **A**, certain groups of metameres migrate into the limb buds, and as they extend distally the corresponding dermatomes also migrate and become grouped parallel to the long axis of the future limb bud, except at the distal part of the limb, where they are arranged in a semicircle. As a result, the rostral segments are grouped along the preaxial border of the limb and the caudal segments along the postaxial border, with the two divided by the ventral and dorsal axial line. In **B**, the sensory branches of limb nerve grow with development of the limb bud along its dorsal surface and wind around the preaxial and postaxial borders of the ventral surface, meeting along the axial line. As a result, neighboring dermatomes across this line are noncontiguous with respect to number and overlap across the axial line is minimal.

More recently, studies of the dermatomes have been carried out by a number of other clinical investigators, including Hansen and Schliack (13), who, like Head, used the distributions of herpetic lesions and the zone of hyperalgesia associated with visceral disease and also used the pattern of hyperalgesia produced by a herniated intervertebral disk. Patterns published by these investigators are similar to those of Head for the trunk and somewhat similar to those of Keegan and Garrett (11,12) and Inman and Saunders (14) for the limbs. Bonica made observations of the pattern of dermatomes after paravertebral somatic nerve blocks, identifying the nerve by (a) the distribution of paresthesia upon contact with the needle point, (b) radiographic control of the precise location of the vertebral level of the bevel of the needle, and (c) injection of 2 mL of contrast medium and again verifying the location of the needle point. The nerve was then injected with a small volume (2 mL) of a local anesthetic (to avoid diffusion to adjacent segments), and the pattern of hypalgesia that developed was carefully ascertained. In the course of four decades, he used this technique experimentally in a group of human volunteers and as a diagnostic/prognostic procedure in evaluating more than 400 patients with segmental pain that was suspected to be due to herniation of an intervertebral disk, osteophyte, or other pathologic process that was subsequently proven at surgery. Bonica also used the technique to study the dermatomal pattern in surgical patients requiring an operation to a limited part of the trunk or the upper or lower limb. In these cases, each segment was injected with small amounts of fast-acting local anesthetic, observations were made as soon as hypalgesia developed, and the next segment was then injected. The procedure was also used to study the nociceptive pathways to the uterus in parturients (see Chapter 71).

Figure 8-8 has been developed on the basis of the dermatomal pattern published by Hansen and Schliack (13) and modified according to Bonica's observations. The dermatomal distribution to the anterior part of the lower limb is somewhat similar to that of Keegan, except that the first toe is predominantly supplied by L-5 and not L-4. It is difficult to rationalize the discrepant findings between Keegan and others with regard to the dermatomal pattern in the upper limb, particularly in regard to distribution of the dermatome to the midline anteriorly and posteriorly. Bonica was not able to demonstrate these patterns. Regional analgesia for operation on the neck, carried out with paravertebral block of C-2, C-3, and C-4 (deep cervical plexus block), invariably produces analgesia that extends anteriorly to the second, and often the third, thoracic dermatome on the trunk. In such patients, intense, noxious stimulation of the skin overlying the clavicle and just below that structure, which according to Keegan are supplied by C-5 and T-1, produced no sensation of pain. Similarly, deep cervical plexus block has been used to produce analgesia of the skin overlying the spinous process of the first, second, and third thoracic vertebrae and the skin of the adjacent paravertebral region. Perhaps the most important part of Keegan's pattern to rationalize is the difference in the distribution of the dermatomes in the back, discussed in the next paragraph.

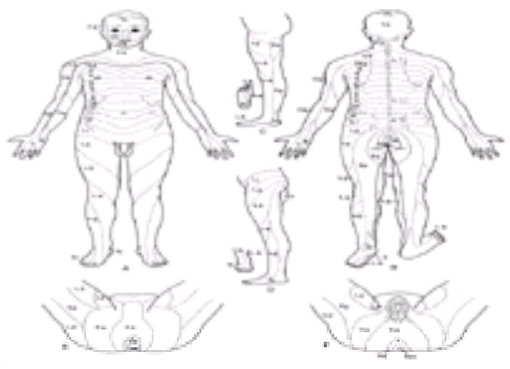

Figure 8-8. The dermatomes developed by Bonica on basis of personal observation and data published by others. See text for description.

Two clinically important features of the posterior part of the dermatomes need comment in relation to the distribution of the posterior primary divisions of the spinal nerves. One is the fact that the first cervical nerve does not supply any area of the skin, but the posterior primary division of the second and third cervical nerves not only compensates for this but also innervates the back of the scalp as far forward as the vertex and abut the first division of the trigeminal nerve. Moreover, the posterior primary rami of the sixth, seventh, and eighth cervical nerves, and of the fourth and fifth lumbar nerves, do not supply the skin. The second extremely important point is that beginning at approximately T-4 or T-5, the posterior division of each spinal nerve migrates within muscles caudally for a progressively greater distance before emerging from the muscles to supply the skin and subcutaneous tissue overlying the spinous processes, vertebrae, and the adjacent paravertebral region (Fig. 8-9, Table 8-1). These points are critically important when evaluating patients with back pain and attempting to identify the cutaneous nerve supply.

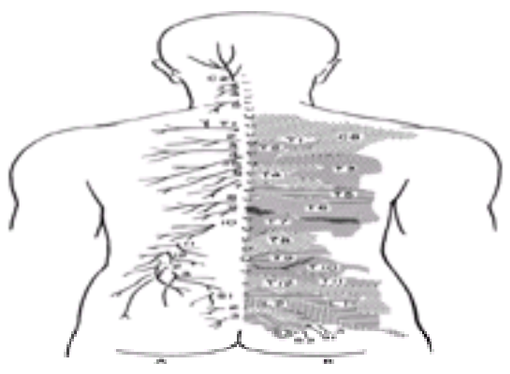

Figure 8-9. **A:** Caudad migration of the posterior primary division of the thoracic and lumbar spinal nerves. **B:** Distribution of these cutaneous nerves to the skin of the back.

Nerve of origin of cutaneous branch	Area of distribution*
T-2	T-4-5
T-3	T-5-6
T-4	T-6-7
T-5	T-8-9
T-6	T-9-10
T-7	T-10–12
T-8	T-12–L-1
T-9	L-1–2
T-10	L-2-3

TABLE 8-1. Distribution of cutaneous branches of posterior division of spinal nerves

The differences of pattern of dermatomes suggest that these are not simple sensory patterns that are the result of anatomic distribution of sensory axons of each particular dorsal root. Instead, the interaction of primary afferent fibers from various segments with neurons whose axons are in Lissauer's tract probably determine not only the size of the dermatome but the quality of the sensation as well (15). This is suggested by the monkey study carried out by Denny-Brown and associates (15,16) with section of roots distal to the dorsal root ganglion rather than proximal (as all other investigators before them had done). These studies showed that the size of each dermatome was enlarged. Strychnine also greatly enlarged the size of each dermatome, as did section of the lateral part of Lissauer's tract. The size of the dermatome was decreased by cutting the medial part of the tract of Lissauer or by cutting six roots on each side of the intact isolated root. This form of neuronal plasticity was also described in patients who had had dorsal rhizotomies for the relief of pain; the area of sensory loss and pain relief was modified by orally administered drugs (17).

Notwithstanding these issues, careful mapping of the dermatome to help pinpoint the site of a lesion that involves the formed nerve (or nerves) before it divides as it makes its exit through the intervertebral foramen is an important clinical tool. Similarly, as will be noted, elicitation of the area of segmental hyperalgesia present in patients with painful diseases involving various thoracic and abdominal viscera helps in differential diagnosis.

Sclerotomes

The segmental nerve roots that supply bones (sclerotomes) are illustrated in Figure 8-10. Comparison of this figure with those showing the dermatomes makes it obvious that they do not agree in spatial relationship, particularly in the limbs. It is only occasionally that a dermatome overlies a portion of the corresponding sclerotome. Whereas dermatomes are arranged along preaxial and postaxial borders of the limb, sclerotomes extend distally for almost the entire length of a limb. In some instances, the sclerotome is continuous, and in others it is interrupted. The skull is innervated by the trigeminal nerve in its anterior two-thirds and by the second and third cervical nerves in its posterior third. Each vertebra is supplied by the recurrent nerve derived from the posterior division of spinal nerves, whereas the ribs are supplied by the posterior and anterior primary divisions of their respective spinal nerves.

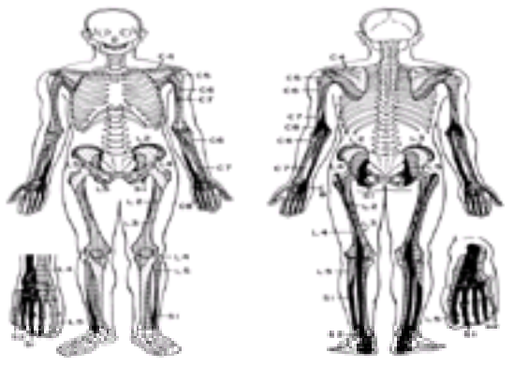

Figure 8-10. The sclerotomes in humans. Various patterns indicate the field of supply of each spinal segment. The skull is innervated by the trigeminal nerve in the anterior two-thirds and by C-2 and C-3 in the posterior third; the vertebrae are supplied by the posterior divisions of the spinal nerves, whereas the ribs are supplied by both posterior and anterior primary divisions of the spinal nerves. The inserts show the sclerotomes of the bones of the feet. (Modified from Déjerine J. *Sémiologie du système nerveux*. Paris: Masson, 1914.)

Myotomes

The segmental nerve supply of various muscles in the body is listed in Table 8-2 and is discussed in Chapter 13 in the section on evaluation of painful conditions by the use of electromyography.

TABLE 8-2. Nerve supply of muscles

Segmental Innervation of the Viscera

The viscera are supplied by sensory fibers, which are constituent fibers of the spinal and cranial nerves because they have their cell bodies in the posterior root ganglia of spinal nerves or the sensory ganglia of cranial nerves. The sensory fibers' central processes pass via the dorsal (and occasionally ventral) roots, whereas their distal processes accompany the sympathetic or parasympathetic nerves to end in the viscera. Usually, each viscus is supplied by dorsal roots of a number of spinal nerves.

Study of the segments that supply various thoracic and abdominal viscera was also initiated in the latter part of the nineteenth century when physiologists used the visceromotor reflex in animals. This method involves applying noxious stimuli to the stomach, for example, then determining the segmental reflex response of the abdominal muscles by systematically carrying out surgical dorsal rhizotomy until response is eliminated. At approximately the same time Head (9) also studied the segments supplying each viscus by carefully determining the extent of cutaneous hyperalgesia in patients with various visceral diseases. As is discussed in Chapter 9, nociceptive stimulation produces reflex responses, which include cutaneous hyperalgesia in the same segments that supply the viscera. After a long and very comprehensive study, Head developed the map of cutaneous hyperalgesia. In the 1920s, the knowledge he acquired in humans (10) and by experimental work in animals was confirmed in humans by various clinical investigators who used paravertebral somatic nerve block, discussed in Chapter 102 in patients with pain caused by disease of various viscera (18, 19). Subsequently, the data were also confirmed by using rhizotomy or sympathectomy for permanent relief of various painful conditions such as cardiac pain (20).

Because the segmental sensory supply of the various viscera is via the sympathetic and parasympathetic nerves, it is presented after discussion of the ANS. It is also repeated in each chapter containing discussion of pain due to each specific type of visceral disease, together with depiction of the gross anatomy of the nerve supply to the particular viscus.

Peripheral Nerve Supply

With a few exceptions, each peripheral nerve contains fibers from two or more adjacent dorsal roots, as depicted in Figure 8-11. As with dermatomes, some overlap exists among peripheral nerves, but less than with dorsal roots: Interruption of the nerve produces an area of complete sensory loss surrounded by a field of altered or diminished sensibility. Both of these zones are smaller than the area of skin that the nerve supplies. Such an area is revealed only if the nerve is left intact and all of the adjacent nerves are cut. Figure 8-12 shows the peripheral nerve supply of the skin, and Figure 8-13 depicts the peripheral nerve supply of bones. It is important to note that the peripheral nerve supply of the skeleton is closely linked with the muscle innervation. Most of the bones receive their innervation from nerve twigs that have penetrated from the attached muscles. For example, the nerve to the quadratus femoris muscle sends twigs to that part of the bony pelvis to which this muscle is attached. Moreover, joints are usually supplied by two types of nerves: articular branches derived directly from major nerves that supply the joint exclusively, and “accessory” nerves that are short branches derived from nerves supplying the muscles near or surrounding the joint.

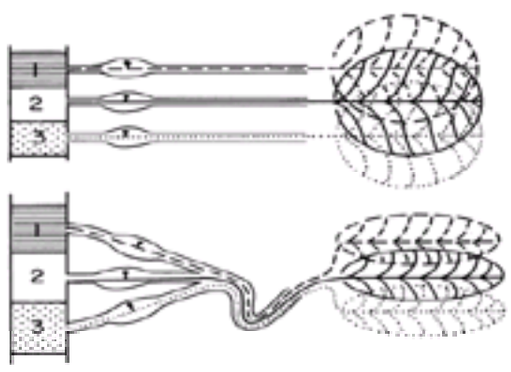

Figure 8-11. Simple diagrams to illustrate the overlap of cutaneous fields of segmental and peripheral nerves. In the upper figure three intercostal (segmental) nerves extending from the periphery to the spinal cord are represented. The lower figure illustrates a somewhat analogous but less extensive overlap in the peripheral nerves.

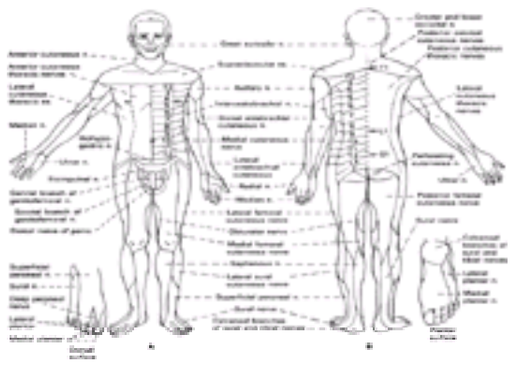

Figure 8-12. The cutaneous fields of peripheral nerves (n.). **A:** Anterior view. **B:** Posterior view. In both figures, the numbers on the trunk refer to the intercostal nerves. (Modified from Haymaker W, Woodhall B. *Peripheral nerve injuries: principles of diagnosis*. Philadelphia: WB Saunders, 1945.)

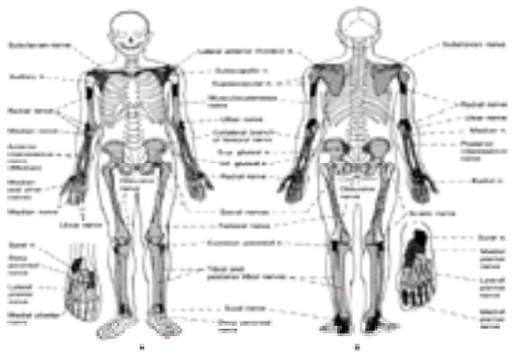

Figure 8-13. Peripheral nerve supply of the skeleton. **A:**Anterior view. **B:** Posterior view. The various peripheral nerve fields are indicated by different patterns. (Modified from Déjerine J. *Sémiologie du système nerveux*. Paris: Masson, 1914.)

Pain Sensibility of Tissues and Structures

This section contains a brief summary of the pain sensibilities of various body tissues and organs. Although mention of these is made throughout Chapter 3, here they are presented in a unified fashion to obviate the need for the reader to search for the information in various parts of that chapter.

Skin and Other Ectodermal Structures. The skin and mucous membranes in their entirety are pain sensitive to mechanical, thermal, or chemical injury, or a combination of these, and the pain is sharp, well localized, and often composed of two temporal parts: first pain and second pain. Other tissues of ectodermal origin, such as the *cornea* and the *dentin*, and the deeper structures of the *teeth* are also sensitive to noxious stimuli. The *conjunctivae* and the *glans penis,* like other mucous surfaces, are extremely sensitive to noxious mechanical and thermal stimuli. The subcutaneous tissues such as areolar tissue and fat are less pain sensitive because of the lesser number of nociceptive nerve endings. In contrast, deep fascia is very pain sensitive, mechanical or thermal injury causing moderately severe pain.

Musculoskeletal Structures. Skeletal muscles are sensitive to a variety of noxious stimuli, including injection of hypertonic saline or other algogenic substances, strong pressure, stretching, ischemia, and unduly forceful or sustained contraction during exercise. The severe pain and intermittent claudication caused by peripheral vascular disease are undoubtedly due to ischemia of the exercising muscle. Backaches, myalgias, and certain types of headaches are probably due to unduly prolonged contraction of the involved muscles. The tendons of muscles are sensitive to noxious stimuli, so strong pressure, injection of hypertonic saline, or squeezing causes pain.

Most *joints* are heavily supplied by nociceptors, including group IV and some group III afferents, which are markedly sensitized by chemical substances that are products of acute or chronic inflammation (see Chapter 3).

The *periosteum* is very sensitive to mechanical stimulation. Scraping with a periosteal elevator or stimulation of any kind results in moderately sharp pain. The cancellous portion of the bone is also pain sensitive, but the cortex is not.

Cranial Structures. Much of the *dura mater* can be incised, scratched, or cauterized painlessly in many patients. However, parts of the dura at the base of the brain and the dural arteries (particularly the middle meningeal and the great venous sinuses and their various tributaries from the surface of the brain) are uniformly pain sensitive. When these structures are pinched or stimulated electrically or stretched, pain is produced. The *cortex* of the brain and its pia-rachnoid covering can be stimulated electrically, burned, or incised without producing pain, but the *cerebral arteries* at the base of the brain, particularly the middle cerebral, vertebral, basilar, and posterior cerebral arteries, are sensitive, and noxious stimulation such as pinching, cutting, or electrical stimulation produces pain. Stimulation of the fifth, ninth, and tenth cranial nerves also produces pain. The *inner portion* of the brain, including its white matter, the ependymal lining of the ventricles, and the choroid plexus, is not sensitive to nociceptive stimuli. The *meninges* of the spinal cord have the same relative sensitivity as those that cover the brain.

Thoracic Viscera. The *visceral pleura* and the lung parenchyma are insensitive to nociceptive stimuli, but the *parietal pleura*, being richly supplied with somatic nerve endings derived from the intercostal and phrenic nerves, is very sensitive to painful stimuli. The *pericardium*, with the exception of its lower portion, which is supplied with nociceptive fibers from the phrenic nerve, is insensitive to noxious stimuli but produces pain in the presence of inflammation. The *heart* is insensitive to touching or manipulation of the ventricular walls or aortic ring or any other mechanical stimulation, but myocardial ischemia, endocarditis, vascular insufficiency, and certain other pathologic processes give rise to pain.

The *esophagus* is pain sensitive to chemicals applied to its mucosa, and abnormal motor function produces pain.

Abdominal Viscera. The *parietal peritoneum* is richly supplied with nerve endings derived from the intercostals and other spinal nerves and is sensitive to stretch and to chemicals. The visceral peritoneum and mesentery are insensitive to cut, burn, or scratch, but traction on the mesentery or rapid distension of the visceral peritoneum covering the spleen and liver results in pain.

The *stomach* and the rest of the *gastrointestinal tract* are also insensitive to cut, crush, or burns, but traction, rapid distention, and strong contraction under isometric conditions produce pain. Similarly, the normal mucosa is relatively insensitive to touch or pressure, but when inflamed, it is extremely sensitive to touch and chemical stimuli.

The *parenchyma* of the liver is insensitive to ordinary stimuli because it can be cut, burned, or torn without pain, but rapid enlargement of this organ, such as occurs in cases of cardiac decompensation or rapidly growing tumors, gives rise to pain, probably due to stretching of the hepatic capsule. The *gallbladder* is insensitive to cutting or clamping, but traction or distension causes pain that is especially severe when the gallbladder is inflamed. The *pancreas* is insensitive to stimuli that produce pain when applied to the skin, but inflammatory lesions or necrosis of this organ gives rise to excruciating pain. The *spleen* is also insensitive to cutting or mechanical stimuli, but inflammation of its serosa can give rise to pain, probably due to involvement of the parietal peritoneum. Rapid enlargement of the spleen is usually accompanied by pain caused by distension of its covering.

The *renal parenchyma*, like other solid viscera, can be cut, torn, or cauterized without pain, but traction on the kidney gives rise to pain due to the pull on the renal

blood vessels and the parietal peritoneum. Rapid distension of the *kidney, pelvis, ureters, bladder*, and *urethra* causes pain, especially in the presence of inflammation. *Kidney stones* are the most common cause of ureteral colic, one of the most painful disorders that can be experienced by humans.

The *body* of the uterus is insensitive to such mechanical stimuli as incision or gentle manipulation, but, as is well known, uterine contractions are invariably associated with pain. Stimulation of the *fallopian tubes* and *ovaries* gives rise to no sensations unless there is traction on the parietal peritoneum and the ligaments of the uterus. Faradic stimulation or rapid distension of the cervix causes pain referred to the lower abdominal wall, although this structure can be pinched with a forceps in conscious patients without invoking pain. The normal *vaginal mucosa* is insensitive to mechanical noxious stimuli. The *female external genitalia* have been found to be moderately pain sensitive to faradic stimulation; pain is felt at the site of stimulation. Pressure on the *testicle* causes excruciating pain, as does noxious heat.

AUTONOMIC NERVOUS SYSTEM

Because the ANS, especially sympathetic afferents and efferents, is frequently involved in various painful states, this is one of the most important portions of the nervous system to the physician involved in managing patients with acute and chronic pain. To properly manage the pain of angina pectoris, complex regional pain syndromes types I and II, pancreatitis, various peripheral vascular diseases, and other conditions, it is essential for the clinician to have thorough knowledge of the anatomy, physiology, and pharmacology of this system. For the anesthesiologist or other physician using nerve block therapy, it is also essential to have thorough knowledge and experience in techniques of blocking various portions of this system. These are discussed in Chapter 102. In this chapter, we discuss the general anatomic arrangement of the ANS and summarize the physiologic and pharmacologic considerations. As previously mentioned in Part IV, the sympathetic or parasympathetic nerves and the associated afferent nerves supplying various parts of the body are discussed in detail at the beginning of each section and also mentioned in some of the chapters contained in each section.

Anatomic Considerations

The ANS is composed of central and peripheral portions, as shown in Figure 8-14. The central portion consists of centers located in the cortex, hypothalamus, midbrain, and medulla and pathways located in the brainstem and spinal cord. The peripheral portion consists of afferent and efferent neurons, the axons of which are located outside of the central nervous system. The autonomic centers are discussed first, and then the peripheral parts of the system are considered. More detailed description can be found in the books by Hovelacque (21), Kuntz (22), Mitchell (23), and Pick (24) and the more recent paper by Janes et al. (25).

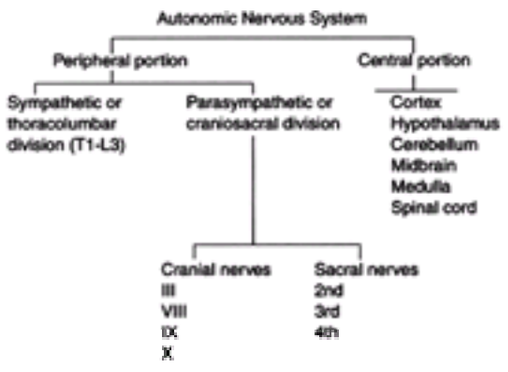

Figure 8-14. Autonomic nervous system.

Autonomic Centers

In the central nervous system, aggregates of neurons are functionally connected with the ANS by extensive ramifications that influence and coordinate all autonomic functions and, among other things, particularly integrate the control of respiration, blood pressure, body temperature, carbohydrate and fat metabolism, water balance, and sexual behavior.

The *cortex* provides integration of somatic and vegetative functions, including the correlation of conditioned reflexes, visceral processes, and pain with mental states. Experimental and clinical data (26) indicate that the major portion of the cortical influence on autonomic function emanates from the motor, premotor, and orbital regions of the frontal lobes. The cortical regulation of a given visceral function emanates from areas that are closely related to the cortical areas that influence the corresponding somatic function. In addition, fibers originating in the cortex pass to the autonomic centers in the hypothalamus and brainstem.

In the *hypothalamus* the anatomic centers of the ANS are most distinct and consist of 16 nuclei, depicted in Figure 5-11 and Figure 8-15. These include the supraoptic, paraventricular, suprachiasmatic, ventromedial hypothalamic, and dorsomedial hypothalamic nuclei, which are concerned with sympathetic function; the preoptic nucleus, which is concerned with parasympathetic function; and the mammillary nuclei, the actions of which are uncertain. In addition to these nuclei, autonomic nerve tracts in the hypothalamus integrate autonomic function among the various hypothalamic nuclei and between these and the limbic system, cerebral cortex, thalamus, and the reticular formation. A detailed discussion of the anatomy and physiology of the hypothalamus is given in Chapter 5.

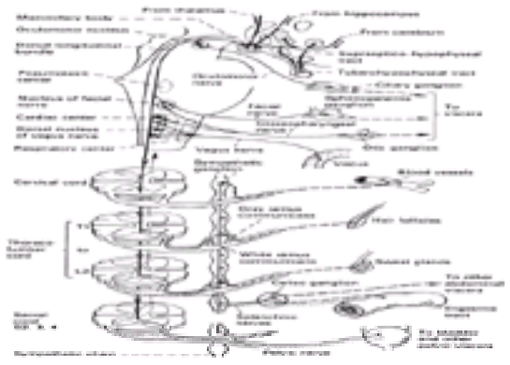

Figure 8-15. Schematic representation of autonomic pathways in the neuraxis and the efferent peripheral pathways. Note the connection among the various hypothalamic nuclei and between these structures and the nuclei and important autonomic centers in the brainstem and spinal cord. The dorsal longitudinal fasciculus (DLF) passes from the hypothalamus caudad through the central and tegmental portion of the mesencephalon and the tegmental portion of the pons to terminate in the reticular formation, the autonomic centers and cranial nerve nuclei in the brainstem, and in the intermediolateral cell column of the spinal cord. The DLF is composed of both crossed and uncrossed fibers, including some long ones and an extensive system of short fibers, which are arranged in the gray matter in frequent relays. Note also that the cell bodies of preganglionic sympathetic neurons are located only in spinal cord segments T-1 through L-2, whereas the parasympathetic neurons are located in cranial nerves and in S-2, S-3, and S-4. The solid lines represent preganglionic fibers, the dashed lines represent postganglionic fibers, and the dotted lines are afferent (sensory) fibers. Not shown are the sensory fibers contained in the facial, glossopharyngeal, and vagus nerves, which transmit nociceptive and other somatosensory information from the head.

The *cerebellum* plays a part in certain autonomic regulation, the anterior lobe being involved in the functions of respiration, circulation, and thermal regulation (27).

In the *midbrain*, *pons*, and *medulla* are located distinct autonomic centers that have been physiologically delineated. These include the nuclei, which give rise to the parasympathetic visceral efferent fibers of the cranial nerves, and special centers that regulate respiration and circulation.

The *thoracic* and *upper lumbar segments* of the spinal cord contain autonomic centers that regulate vasomotor activity, piloerection, and perspiration of the entire body as well as sympathetic and parasympathetic function of the viscera. The locations of the cell bodies of preganglionic sympathetic and parasympathetic neurons, which mediate their function in various parts of the body, are listed in Table 8-3. Some autonomic functions, such as vasomotor control, are bilaterally represented, whereas others, such as pupillary dilation, are unilateral. With bilateral representation, visceral nerve conduction takes place more effectively on the ipsilateral than on the contralateral side. Figure 8-15 depicts the autonomic pathways that connect the preganglionic neurons in the intermediolateral horn of the spinal cord with the hypothalamus and other brainstem structures.

Structure	Location of AC in spinal cord
Head and neck	T-1–4
Upper limb	T-2–8/9
Upper trunk	T-2–8
Lower trunk	T-9–L-2
Lower limb	T-10–L-2
Viscera	
Thoracic (sympathetic)	T-1–5 (8)
Abdominal (sympathetic)	T-5–L-2
Pelvic (parasympathetic)	S-2–4

TABLE 8-3. Autonomic centers (AC) in spinal cord

Peripheral Autonomic Nervous System

The peripheral portion of the ANS consists of pre- and postganglionic efferent fibers and afferent fibers from various body structures (22,23,28). These fibers are concerned with transmission of visceral sensation such as nociception, nausea, and fullness; with circulatory, respiratory, and visceral motor reflexes; and with the integration of visceral activities. Although many writers have followed the suggestion by Gaskell (29) and Langley (30) to restrict the term “autonomic nervous system” to efferent (motor) pathways, Mitchell (23), among others (28,31), points out the irrationality of this concept. If the role of the ANS is to regulate visceral function through reflex activity, it cannot do so without afferent and intercalary (connector) neurons as well as efferent (motor) neurons. In this book, the afferents associated with the ANS are referred to as “sympathetic afferents” and “parasympathetic afferents.”

The peripheral efferent pathways consist of a two-neuron chain, a primary presynaptic or preganglionic neuron, and a secondary postsynaptic or postganglionic neuron. The cell bodies of the primary preganglionic neurons are located in the central nervous system, either in the intermediolateral cell column of the spinal cord or in the visceral efferent nuclei in the brainstem. The axons of these cell bodies travel toward the periphery either by way of the anterior roots of the spinal nerves or through the cranial nerves, to reach outlying autonomic ganglia, in which they affect synaptic connection with the postganglionic neurons. The cell bodies of the postganglionic neurons are located within these outlying autonomic ganglia, and their axons pass to their terminal distribution in the wall of the viscera or in the wall of the blood vessels and to sweat glands and other target organs. On the basis of anatomic, physiologic, and pharmacologic characteristics, the peripheral portion of the ANS is divided into two parts: the parasympathetic or craniosacral division and the sympathetic or thoracolumbar division.

The cell bodies of the postganglionic neurons are arranged in aggregates known as *ganglia*, wherein the synapses between pre- and postganglionic neurons take place. As shown in Figure 8-16, there are four general groups of these ganglia, two with the sympathetic division and two with the parasympathetic division.

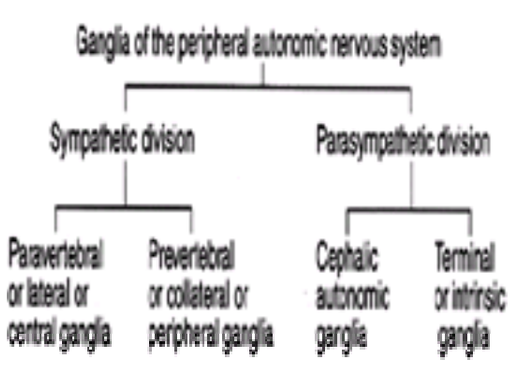

Figure 8-16. Ganglia of the peripheral autonomic nervous system.

Parasympathetic Division

Cranial Parasympathetics. The central portion of the parasympathetic division of the ANS consists of preganglionic fibers, which have their cell bodies in the gray matter of the brainstem, and their axons, which pass as component parts of the oculomotor, facial, glossopharyngeal, and vagus nerves (see Fig. 8-15). Those in the first three nerves synapse with short postganglionic fibers in the ciliary, sphenopalatine, otic, and submaxillary ganglia. The very long preganglionic parasympathetic fibers in the vagus terminate in intramural ganglia contained in the walls of the gastrointestinal tract, heart, and lungs, wherein they synapse with short postganglionic fibers that innervate the smooth muscles and glands in these organs.

Somatic afferent fibers are component parts of the facial, glossopharyngeal, and vagus nerves and transmit nociceptive and other somatosensory information from the ear, throat, back of the tongue, larynx, and tracheobronchial tree. Visceral afferents associated with the vagus nerve supply viscera in the chest and abdomen; transmit sensation of distension, fullness, and nausea; and constitute the afferent limb of reflex control of these structures.

Sacral Parasympathetics. The sacral portion of the parasympathetic division consists of preganglionic neurons, which have their cell bodies in the intermediolateral column of the gray matter of the second, third, and fourth sacral segments (see Fig. 8-15 and Fig 8-17). Their axons leave the spinal cord via the anterior roots of the nerves and run directly as the pelvic splanchnic nerves (nervi erigentes) to the pelvic plexuses. They pass through the plexus without interruption and finally reach and terminate in the terminal ganglia in the pelvic plexus and vesical plexus, and some in intramural ganglia of the urinary bladder, the descending colon, the sigmoid colon and rectum, and the genital organs. Afferent fibers associated with sacral parasympathetics transmit nociceptive information from the urinary bladder, lower part of the ureter, the descending colon, and the sigmoid colon and rectum. Other afferent fibers are involved in autonomic reflexes relevant to the functions of these structures.

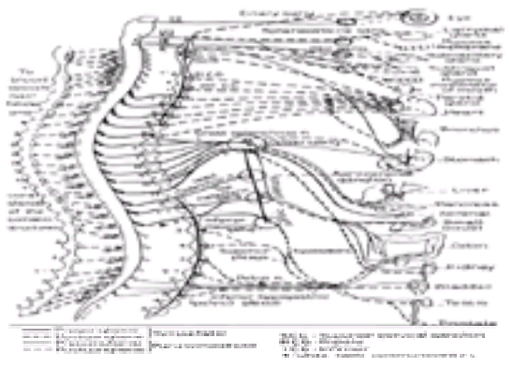

Figure 8-17. Distribution of peripheral autonomic nervous system to various structures of the body. On the reader's right are shown (from above downward) the four cranial nerves, which contain preganglionic parasympathetic fibers, the axons of preganglionic sympathetic fibers (which pass from the anterior root to the paravertebral sympathetic chain), and the parasympathetic preganglionic axons in S-2, S-3, and S-4. Note that the axons of all of the preganglionic sympathetic neurons pass via the white rami communicantes into the paravertebral chain, in which some synapse with postganglionic neurons, whereas others pass to the prevertebral sympathetic ganglia, in which they synapse with postganglionic fibers. On the reader's left are depicted the gray rami communicantes, containing postganglionic sympathetic fibers, which originate in the paravertebral chain and then pass to each of the spinal nerves to innervate blood vessels, hair follicles, and sweat glands in various parts of the body.

Sympathetic (Thoracolumbar) Division

The efferent portion of the sympathetic division of the ANS consists of preganglionic neurons, the two paravertebral (lateral) sympathetic chains, prevertebral and terminal ganglia, and postganglionic neurons (21,22,23 and 24) (see Fig. 8-15 and Fig 8-17).

Preganglionic Neurons. The cell bodies of the preganglionic neurons are located primarily in the first thoracic to second lumbar spinal cord segments, inclusive. Most of the cell bodies of preganglionic neurons are located in the intermediolateral (lateral) column of the spinal cord, but some become aggregated and form a second, less definite column on the medial side of the intermediolateral gray matter, which has been termed the *intermediomedial (medial) column* (22,23). Evidence also exists that some cell bodies of preganglionic neurons exist in the eighth cervical and third lumbar segments, and in some instances the seventh cervical and fourth lumbar spinal segments (32,33). In some instances, the axons of preganglionic neurons in the cervical cord descend, whereas those in the third and fourth lumbar segments ascend within the spinal cord and emerge through the first thoracic and second lumbar segments, respectively. Others pass via the eighth cervical or third (and perhaps fourth) lumbar anterior root and the homologous white rami communicantes.

The axons of these preganglionic neurons are carried in the anterior nerve root of the spinal nerve of the same segments and then via the white rami communicantes to synapse with postganglionic neurons in the sympathetic ganglia outside the neuraxis (see Fig. 8-17). The paravertebral ganglia and interganglionic fibers make up the lateral sympathetic chain, to which axons of preganglionic neurons first pass. On entering the sympathetic chain or trunk, some preganglionic axons end in the first ganglion they reach; some pass cephalad or caudad for varying distances within the sympathetic trunk before they synapse in the trunk; others pass through the chain without interruption to terminate and synapse within one of the prevertebral ganglia. Preganglionic fibers pass to and through the adrenal medulla and synapse within chromaffin cells, which are homologous to postganglionic neurons.

Preganglionic fibers from the upper five thoracic segments either terminate in the first sympathetic ganglion they reach or turn upward within the sympathetic trunk to synapse in a ganglion at a higher level, particularly the inferior or stellate ganglion and the intermediate, middle, and superior cervical ganglia. Some preganglionic fibers from the fifth to the tenth thoracic segments terminate in the first ganglion they reach; some ascend or descend; others pass through the paravertebral ganglia without interruption to become the superior thoracic (greater) splanchnic nerves, which terminate within the celiac ganglia (see Fig. 8-17). Some of the preganglionic fibers from the tenth to the twelfth thoracic segments and first and second lumbar segments terminate in the first ganglion they reach; some pass caudad; and others pass through the ganglia uninterrupted to become the middle thoracic (lesser) splanchnic nerves and the inferior thoracic (least) splanchnic nerves. The middle thoracic splanchnic nerves enter the celiac plexus and synapse in the aorticorenal ganglion, and the inferior thoracic splanchnic nerves pass directly to the renal ganglion, in which each synapses with postganglionic fibers.

Many preganglionic axons converge on each postganglionic neuron, whereas the collaterals of each preganglionic axon diverge into many postganglionic neurons. An extraordinary variability exists among ganglia and the quantitative degree of convergence and divergence. The number of postganglionic neurons in a ganglion is usually considerably higher than the number of preganglionic axons innervating it. The divergent and convergent synaptic connections guarantee a high safety factor for the transmission of excitation in the ganglia.

Postganglionic Neurons. The axons of some of the postganglionic neurons, which have their cell bodies in the paravertebral chain, become gray rami communicantes and join the spinal nerves and thus are distributed to the skin and various other somatic structures. The axons of other postganglionic neurons, which have their cell bodies in the paravertebral chain, pass to the thoracic and pelvic viscera, whereas the postganglionic neurons, which have their cell bodies in the prevertebral ganglia, become part of the prevertebral plexuses and thus are distributed to various viscera in the abdomen.

In addition to this classic distribution, some synapses take place in spinal nerves and thus bypass the sympathetic trunks (22,23) (Fig. 8-18). Moreover, some intermediary ganglia are located on the white rami communicantes or anterior spinal nerve roots and are thus located outside of the lateral sympathetic trunk (22,23). These anomalous sympathetic pathways are most frequent in the lower cervical and upper thoracic sympathetic trunk and in the lower thoracic and upper lumbar sympathetic trunk. As a result of these anomalies, the usual technique of surgical sympathectomy does not include them and may be responsible for incomplete sympathectomy of the limbs. In contrast, these anomalous pathways are invariably involved by sympathetic blocks because the local anesthetic solution diffuses to these various anomalous structures. The clinical implication of this is important: Even though a prognostic sympathetic block with local anesthetic produces complete sympathetic interruption (and pain relief), the sympathectomy might not. In such cases, the incomplete resection can be proven by a postsurgical sympathetic block, which invariably produces evidence of complete interruption and pain relief in sympathetically dependent pain syndromes.

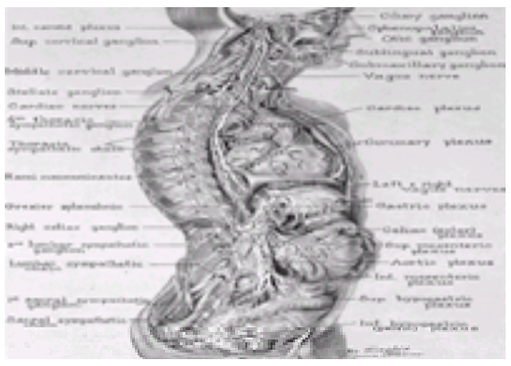

Figure 8-18. Gross anatomy of the peripheral autonomic nervous system. (After Hirschfeld L. *Traite et iconographie du système nerveux*, 2nd ed. Paris: Masson, 1865.)

Lateral Sympathetic Trunk. The paravertebral ganglia are segmentally arranged in two vertical rows, each ganglion being connected to the adjacent ganglia by longitudinal ascending and descending nerve fibers, thus forming what are commonly called the *two sympathetic trunks* (Fig. 8-19). These two trunks extend along the ventrolateral aspect of the vertebral column from the second cervical vertebra to the coccyx. The cervical ganglia lie ventral to the base of the transverse processes;

the thoracic ganglia lie over the heads of the ribs; the lumbar ganglia lie on the anterolateral surface of the lumbar vertebrae; and the sacral ganglia lie on the anterior surface of the sacrum medial to the anterior sacral foramina (see Chapter 102 for illustrations). The cephalic end of each of the two trunks is continued upward as the internal carotid nerve, branches of which eventually become distributed to the head. The caudal end of the trunks converges and terminates in front of the coccyx as the ganglion impar.

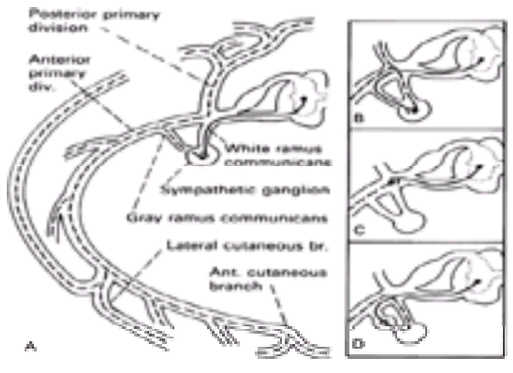

Figure 8-19. **A:** The course of sympathetic fibers in thoracic spinal nerves. Note particularly the course of the preganglionic fibers in the rami communicantes. Preganglionic fibers are shown as solid lines and postganglionic fibers as dashed lines. **B**, **C**, and **D** show unusual sites of synapse between preganglionic and postganglionic fibers. Section of the sympathetic ganglion in **C** would not produce interruption of the sympathetic pathways. (Ant., anterior; br., branch; div., division.)

In the cervical region, a condensation of the segmental ganglia has occurred, there being only four: the superior, middle, intermediate, and inferior ganglia. In 80% of subjects, the inferior cervical ganglion is fused with the first thoracic ganglion, forming the stellate ganglion (21,23). Below this level the paravertebral ganglia are segmentally arranged, there being 10 to 12 thoracic, three to five lumbar, four or five sacral, and one coccygeal.

Macroscopically, the lumbar sympathetic chain is the most variable portion of the peripheral sympathetic system, particularly with regard to the number of ganglia and the general forms of the two chains, which are extremely inconstant not only among different individuals but also on each side of the same person. According to Hovelacque (21), it is almost exceptional to find five ganglia, as classically described in most textbooks; it is more common to find only four or three, and not uncommonly a fusion of the first lumbar and twelfth thoracic ganglia. In addition, one rarely finds a chain on one side that is the same shape and size and in a similar position as the one on the other side. The location of the lumbar ganglia is also inconstant. In some instances they are segmentally located, whereas in other cases they are closely grouped and lie over particular segments, the most common location being between the second and fourth lumbar vertebrae. The ganglia may be situated on the body of the vertebra immediately in front of the aponeurotic arcades giving origin to the psoas muscles, or they may lie anterolateral to an intervertebral disk, the upper portion of the ganglion being in front of the vertebra above and the lower portion in front of the vertebra below.

Connections between Sympathetic Trunks and Spinal Nerves. The sympathetic trunks are connected to the spinal cord and spinal nerves by one or more rami communicantes and with visceral and somatic afferent fibers.

White Rami Communicantes. The white rami communicantes consist of myelinated preganglionic neurons and visceral afferent fibers. These are limited in their distribution and are present only in the thoracic and upper two or three lumbar segments, but usually not in the cervical, lower lumbar, or sacrococcygeal segments (see Fig. 8-17). These 14 or 15 pairs of white rami communicantes carry the only preganglionic fibers of the sympathetic outflow and are therefore the only connections between the central nervous system and the peripheral sympathetic system. All sympathetic motor impulses to the body and visceral sensory impulses to the central nervous system are conveyed through these anatomic bridges.

Gray Rami Communicantes. The gray rami communicantes consist of unmyelinated postganglionic sympathetic fibers, which pass from the sympathetic trunks to each of the spinal nerves to become distributed as vasomotor, sudomotor, and pilomotor fibers in the somatic areas. The vasoconstrictor fibers consist of unmyelinated postganglionic neurons, the cells of which arise in the ganglia of the sympathetic trunk, and the axons of which pass by way of the gray rami communicantes to all spinal nerves. By coursing peripherally through these nerves, they finally reach the blood vessels of the trunk and limbs. The pilomotor and sudomotor fibers have a similar course.

In addition to the gray rami communicantes, the sympathetic trunks give off rami that supply the viscera. The most important of these are the carotid nerve; the superior, middle, and inferior cardiac nerves; the superior, middle, and inferior thoracic splanchnic nerves; and the lumbar and sacral splanchnic nerves. They supply sympathetic fibers to the viscera of the head, chest, and abdomen. These are discussed in greater detail in various chapters of Part IV.

Sympathetic Afferents. Many sympathetic afferents mediate visceral pain from the heart and from the abdominal viscera, except some pelvic organs that are supplied by parasympathetic afferents. Although these fibers do not establish direct connections with the peripheral autonomic neurons, they pass through the ganglia of the sympathetic trunk, at which point they can be surgically or chemically interrupted. As previously mentioned, the cell bodies of visceral (and somatic) afferent fibers are located in the dorsal root ganglia of spinal nerves. Their short central processes pass to the spinal dorsal horn, where they make synaptic connection with dorsal horn interneurons and also with the cell bodies of neurons, the axons of which make up ascending pathways. Some dorsal horn neurons onto which primary afferents synapse pass anteriorly to connect with somatic motor neurons, and some make synaptic connection with preganglionic neurons in the intermediolateral cell column. Through these spinal segmental circuits, visceral afferents affect reflex connections, which are involved in increased skeletal muscle tension and increased sympathetic activity, and which in turn alter the function of the viscera (see Fig. 8-16).

The long peripheral processes of sympathetic afferents pass through the distal part of the posterior root, the formed spinal nerve, the white rami communicantes, and then through the ganglia of the sympathetic trunk without interruption to reach the viscera by one of two ways. One is by passing through one of the cardiac or splanchnic nerves and through the corresponding prevertebral plexus. The other is by passing through one of the nerves that passes from the sympathetic trunk directly to the viscera without traversing any of the prevertebral plexuses.

Ganglia and Plexuses of the Peripheral Autonomic Nervous System

Cephalic Ganglia. Autonomic ganglia include the ciliary, sphenopalatine, otic, and submaxillary ganglia, which are situated in relation to the third, fifth, and ninth cranial nerves. Each of these ganglia receives sympathetic postganglionic fibers, parasympathetic preganglionic fibers, and sensory fibers. The anatomy of these ganglia, as well as the sympathetic plexuses to the head, are discussed in Chapter 46, concerned with the anatomic and physiologic bases of pain in the head.

Autonomic Plexuses in the Chest. Three great prevertebral plexuses exist, consisting of aggregates of ganglia and interconnecting sympathetic, parasympathetic, and afferent fibers. These include the cardiac plexuses, the pulmonary plexuses, and the esophageal plexuses and are discussed in Chapter 60 in connection with the anatomic and physiologic bases of pain in the chest.

Abdominal Prevertebral Ganglia/Plexuses. As in the chest, three large prevertebral plexuses exist, which include prevertebral sympathetic ganglia as well as parasympathetic fibers from the vagus or the sacral parasympathetics and afferent fibers. These include (a) the celiac (solar) plexus, which breaks into approximately 10 important subsidiary plexuses that supply the abdominal viscera above the pelvis; (b) the superior hypogastric plexus; and (c) the inferior hypogastric or pelvic plexus, which supplies the pelvic viscera. These are discussed in Chapter 65, concerned with the anatomic and physiologic bases of abdominal pain, and Chapter 70, concerned with the anatomic and physiologic bases of pelvic pain.

Sympathetics to the Limbs and Trunk. The sympathetic nerve supply to the limbs is discussed in Chapter 54, dealing with the anatomic and physiologic bases of pain in the upper limb, and in Chapter 75, concerned with the anatomic and physiologic bases of pain in the lower limbs.

Summary of Sympathetic and Nociceptive Supply to Body Structures

Table 8-4 summarizes the sympathetic and nociceptive pathways to various body structures. It is based on information contained in the first edition of this book and subsequent comprehensive reviews (28,34) and information published by Mitchell (23), Pick (24), Pick and Sheehan (35), Netter (4), and Meyer (36). The parasympathetic supply to these various structures is not included for the sake of clarity and also because the origins of preganglionic parasympathetic fibers, their routes, and the locations of postganglionic fibers have previously been mentioned and are discussed in detail in Chapter 46, Chapter 54, Chapter 60, Chapter 65, Chapter 70, and Chapter 75.

TABLE 8-4. Summary of sympathetic and nociceptive nerve supply to more important body structures

Pharmacology and Physiology of the Autonomic Nervous System

This section on the pharmacology and physiology of the ANS is included for the sake of completeness and is *not* intended to be all inclusive. A few pharmacologic principles and the physiologic action of sympathetic and parasympathetic nervous systems are considered. Detailed discussions can be found elsewhere (21,23,29,35).

Pharmacology

Neurohumeral transmission in the peripheral ANS occurs in principle by the same mechanism as that at the neuromuscular endplate and at central synapses (Fig. 8-20). In contrast to the endplate, however, the pre- and postsynaptic structures in the ANS are extremely variable (myocardial cells, smooth muscle cells, gland cells, and neurons). Moreover, the density of innervation varies greatly among different smooth muscles.

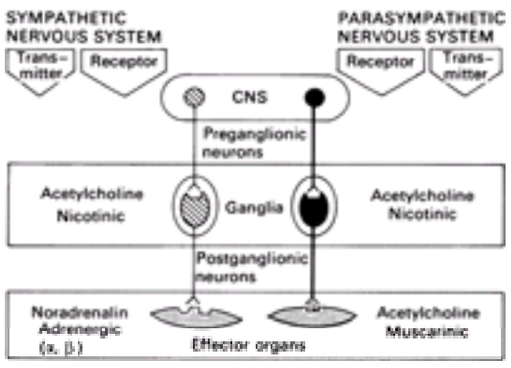

Figure 8-20. Transmitter substances in the peripheral autonomic nervous system. (Modified from Jänig W. The autonomic nervous system. In: Schmidt RF, Thews G, eds. *Human physiology*. Berlin: Springer-Verlag, 1983:111.)

Acetylcholine. Acetylcholine is released at all preganglionic autonomic nerve endings, both sympathetic and parasympathetic, and also by most postganglionic parasympathetic neurons—so-called cholinergic neurotransmitters. Some sympathetic postganglionic neurons are also cholinergic—those to the sweat glands and perhaps the vasodilator neurons to the resistance vessels in the skeletal muscles. The action of acetylcholine on the postsynaptic membranes of the postganglionic neurons can be simulated by nicotine and its action on the effector cells by muscarine. This suggests there are two kinds of receptors to which acetylcholine reacts: nicotinic and muscarinic, respectively (37,38). It has long been known that there are drugs that selectively block one or the other action. The nicotinic action of acetylcholine on the postganglionic neurons can be blocked by quaternary ammonium bases, which are thus called *ganglionic blocking agents*. The muscarinic action of acetylcholine can be selectively blocked by atropine (see Fig. 8-20).

Norepinephrine. Norepinephrine (noradrenalin) is the transmitter substance in sympathetic postganglionic nerve endings, and these cells are called *adrenergic neurons*. The cells in the adrenal medulla, which are homologues of the postganglionic neurons, mainly release epinephrine (adrenaline) into the bloodstream (80% adrenaline and 20% noradrenaline). The response of organs to catecholamines is mediated by two types of receptors: a-adrenergic and b-adrenergic receptors. As is well known, a variety of pharmacologic agents can either enhance or block the a-adrenergic and b-adrenergic action of the catecholamines.

Physiology

The ANS regulates activities that are normally not under voluntary or conscious control, including such important physiologic processes as metabolism, circulation, respiration, body temperature, digestion, sweating, and endocrine secretion. The integrating action that is exerted over these and other physiologic processes helps to maintain the constancy of the internal environment. This integration of function, termed *homeostasis* by Cannon (39), frees the individual from having to pay constant attention to the management of bare existence. It thus obviates the necessity of always being alert to the constant danger to which a changing environment subjects the individual.

All portions of the ANS take part in homeostasis, and the function of some of these parts is relevant to pain. The part played by the central portions has been alluded to in connection with the anatomy. The functions of the hypothalamus and the limbic system in pain are discussed in some detail in Chapter 5. The part played by the peripheral portion of the ANS in the regulation of autonomic function and homeostasis deserves emphasis because of the significant role its dysfunction plays in some painful states.

The sympathetic and parasympathetic divisions of the ANS have mutually coordinated actions that are often antagonistic, thus maintaining a functional balance. This balance is made possible by the dual autonomic supply of almost all of the viscera and of the other parts of the body. The effects of stimulating either portion of the ANS and its impact on various organs, visceral structures, and effector cells are summarized in Table 8-5. It deserves strong emphasis that in most situations the two systems act in an exquisitely synergistic fashion. For example, a reduction in arterial blood pressure produces a reflex response on the part of the cardiovascular system that consists of an increase in the rate and contractility of the heart and an increase in peripheral vascular resistance. This increase in heart and peripheral vascular resistance is brought about by an increase in the activity of the sympathetic nervous system and a concomitant and exquisitely coordinated decrease in the activity of the parasympathetic system (functional synergy).

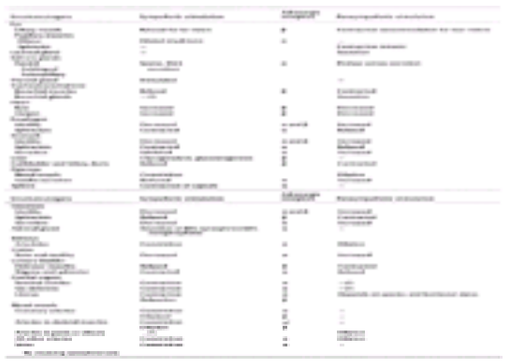

TABLE 8-5. Physiologic responses to autonomic stimulation

Close study of Table 8-5 makes it obvious that the sympathetic outflow is catabolic in function, a fact that is duly emphasized in discussing the pathophysiology of acute pain in Chapter 9. Although the sympathetic system is considered not absolutely essential to life, because in its absence one can survive in a very sheltered existence, it does have the important function of protecting the organism against adverse conditions by immediately and simultaneously activating all organs through rapid diffuse action. This prepares the individual for “fight” or “flight” by increasing cardiac output, through chronotropic and inotropic action and increase in peripheral resistance with consequent rise in blood pressure; an increase in blood sugar; contraction of the spleen with an increase in circulating red blood cells; constriction of all blood vessels (except those of the brain, heart, and skeletal muscles), resulting in redistribution of the blood to where it is needed most (the high-priority organs); and dilation of the bronchi and inhibition of the gastrointestinal and urinary functions. This rapid and diffuse action is made possible by the aforementioned vast synaptic connection of pre- and postganglionic fibers, a characteristic that is not common to the parasympathetic division, in which there is a one-to-one relationship between pre- and postganglionic neurons.

In contrast to the catabolic function of the sympathetic system, stimulation of which often gives rise to an extraordinary liberation of energy, the parasympathetic function is anabolic and most essential for life. It is concerned with conserving and storing energy, by slowing the heart rate, by enhancing digestion and absorption of food through stimulating the gastrointestinal tract, and by emptying the hollow organs, including the lower colon and urinary bladder, thus aiding in the elimination of waste products.

The functional balance that is normally maintained by the two systems is disturbed in certain disease states, either by the hyperactivity of one or hypoactivity of the other, or a combination of these. The resultant disturbance in autonomic function, if persistent, can prove deleterious to the entire organism. Linkages exist between the autonomic and immune systems that may be important in the production of disease states and the response to neoplasia and other chronic disease that may lead to pain (40). Pain itself may alter the immune response and thereby alter the progression of a disease (41). Animal and human physiologic and pharmacologic studies of visceral as well as somatic pain have demonstrated both plasticity and functional characteristics that are far more complex than the basic anatomy described in this chapter; entire books have been written, for example, on visceral pain (42). Some of these issues are discussed in Chapter 3, Chapter 4 and Chapter 5.

CHAPTER 9

General Considerations of Acute Pain

Barbara A. Coda and John J. Bonica

Acute pain consists of a complex constellation of unpleasant sensory, perceptual, and emotional experiences and certain associated autonomic, cognitive, emotional, and behavioral responses. Invariably, acute pain and these associated responses are provoked by noxious stimulation produced by injury or disease of skin, deep somatic structures, or viscera or abnormal function of muscle or viscera. The pathophysiology of acute pain is fairly well understood; its diagnosis is usually not difficult, and with important notable exceptions mentioned in the following chapter, therapy is effective. As a result of effective treatment, the self-limiting nature of the disease or injury, or both, and the pain and associated responses usually disappear within days or weeks. Improper therapy, however, can cause the acute pain to persist and the pathophysiology to progress to a chronic condition.

The purpose of this chapter is to give a historical perspective and to discuss fundamental aspects of acute pain that are applicable to various painful conditions considered in detail in other parts of the book. These include general characteristics, mechanisms, and the autonomic reflex responses associated with the various types of acute pain. The chapter is presented in six sections: Basic Considerations, including classification and general comments on etiology and epidemiology; Superficial (Cutaneous) Pain; Deep Somatic Pain; Visceral Pain; Referred Pain; and Biology and Pathophysiology of Acute Pain.

BASIC CONSIDERATIONS

That acute pain of peripheral origin is usually caused by injury or disease of the skin, subcutaneous tissue, or deep somatic structures, spasm of skeletal muscles or smooth muscles of the hollow viscera, or disease or abnormal function of the viscera is well known. Acute pain involving peripheral-central mechanisms is caused by injury, disease, or inflammation of the peripheral nervous system, whereas acute pain of central origin is caused by disease of the neuraxis. Because acute pain caused by diseases of the nervous system presents specific issues, it is omitted from this chapter but is considered in Parts III and IV.

The division of pain of peripheral origin into superficial and deep pain is based on the quality of pain and the structure from which nociception is initiated. In his classic book, Lewis (1) emphasized the importance of distinguishing superficial and deep types of pain by stating that “the difference in the qualities of skin pain and of deep pain is so clear and each belongs so exclusively to the corresponding structures that it would perhaps seem unsafe to class both together under the one unqualified term 'pain.'” He suggested that the differences might be caused not only by the involvement of “two corresponding systems of peripheral nerves,” but also by the embryologic origin of each structure: Skin pain arises from ectodermal structures and deep pain is derived from mesodermal structures, whereas “the endodermal structures are either devoid of pain fibers or contain very few.” Lewis insisted that no differences exist between deep somatic pain and visceral pain. Cervero (2,3) also used an embryologic approach to classify pain within the perspective of current knowledge, but supported the differentiation between pain from visceral structures and pain from somatic structures. He noted that pain of ectodermal origin (skin and mucous membrane) is characterized by its good localization and *brightness*; a pain of mesodermal origin corresponds to the present concept of deep pain, and pain of endodermal origin is represented by visceral pain: “The degree of ill-localization and dullness would be greater in pain of endodermal origin than that of mesodermal origin.” Peripheral mechanisms that contribute to these differences have been reviewed previously (4) and are considered in detail in Chapter 3.

Magnitude of the Problem

Acute pain problems are the most frequent reasons why patients seek the help of family practitioners and various other specialists; they are routinely encountered in emergency room care, the postoperative setting, obstetric practice, sports medicine, and the care of trauma and burn patients. In family practice, acute headache, minor injuries, and many other disorders routinely result in patients' requests for pain relief. This is also true in the practice of orthopedic surgery, dermatology, and virtually all other specialties of medicine and in dentistry and osteopathy as well as other, less orthodox, types of practices, such as chiropractic and acupuncture. Nurses spend a significant portion of their professional time providing relief of acute pain.

The incidence of acute pain problems for which health care is sought or for which medication is taken is vast, but precise data derived from comprehensive national epidemiologic surveys are not available. The following are general comments on the incidence of acute pain in various injuries, diseases, and disorders. Results of a national survey published in 1984 indicate that in a 1- year time period, more than 40 million visits were made to office-based physicians in the United States because of new pain (5). These were self-referred visits in which pain was the chief complaint, and the physician had not previously seen the patient for the condition associated with the pain. The pain complaints were diverse and included earache, headache, chest pain, back pain, gastrointestinal pain, and pain in other parts of the body. The largest proportion (41%) presented with musculoskeletal pain, particularly that localized to the lower and upper back. This figure represents the initial visit for the condition; the cumulative number was probably significantly higher because many of these patients made return visits. Although more recent data regarding physician visits for a chief complaint of new pain are not available, information about the number of physician visits for painful conditions suggests that the problem is not decreasing. In 1995 and 1996, musculoskeletal problems remained one of the most frequent principal reasons for visits and accounted for approximately 90 million visits each year (6,7). In addition, large numbers of visits were estimated for the following pain-related visits: ear and throat symptoms, 35 million; stomach and abdominal pain, spasms or cramps, 18 million; chest pain, 13 million; and headache, 11 million. In 6 of 10 visits, medication was prescribed, and the most common type of medication was for pain relief (approximately 14% of all medications in 1995 and 1996) (6,7).

Data published by the National Center for Health Statistics suggest that, in 1996, 129 million visits were related to acute injuries. Americans sustained 9.8 million fractures and dislocations, 19.4 million sprains and strains, 12.7 million open lacerations and wounds, 12.1 million contusions and other superficial injuries, and approximately 8.6 million “other concurrent injuries” (7). Because most of these injuries involved skin, subcutaneous tissue, bone, and other pain-sensitive structures, more than 80% of these persons experienced acute pain either at the time of injury or a few hours later (see Chapter 41 and Chapter 43). In addition, each year more than 1.5 million burns are experienced; burns and associated surgeries cause pain that may last for a few days to weeks and months, and many patients require prolonged hospitalization (see Chapter 42).

In 1996, nearly 25 million “surgical procedures” were performed on ambulatory patients and inpatients (8). Included in this total are nearly 1 million cardiac, thoracic, and major vascular surgeries; more than 7 million musculoskeletal surgeries; approximately 3 million abdominal surgeries; 1 million nose, throat, and dental surgeries; 3 million obstetric and gynecologic surgeries; more than one-half million debridements, skin grafts, and mastectomies; and 1 million renal and genitourinary tract surgeries. These totals do not include minor procedures and those expected to cause minimal pain, such as biopsies, lens and cataract surgeries, and nonorthopedic laparoscopic procedures. Based on available information, a large proportion of these surgical patients is likely to have experienced moderate to severe pain, lasting from 1 to 7 days (see Chapter 41). Moreover, a majority of the nearly 3 million women who experience labor and vaginal delivery each year are likely to have suffered

moderate to severe pain during childbirth (see Chapter 71).

A comprehensive and most revealing source of information on the incidence and prevalence of various types of pain is the Nuprin Pain Report (9). This publication contains data derived from the first nationwide survey on the prevalence of pain, which was carried out in 1985 by Lou Harris Associates under the sponsorship of Bristol-Myers Company. The survey was limited to adults and provided detailed information on the demographic characteristics of pain sufferers; the effect of pain on the work and lives of Americans; how people cope with pain; the relationship between pain, stress, and a number of environmental factors; use of physicians and other health professionals in the treatment of pain; and the relationship between pain and different lifestyles and behavior patterns. An abbreviated summary is given in Table 9-1. Most of the data have a sampling error of approximately 3% to 6% and therefore are likely to be representative of the pain experienced by adult Americans. The survey indicated that most Americans experience three or four different types of pain every year. Approximately one-half of those with pain have only an occasional problem 1 day to 5 days in duration, and in the majority the pain is mild to moderate. On the other hand, pain duration was 31 days or more in 32% of those with joint pain, in 27% of those with bacand in 7% to 10% of those with other types of pain. Moreover, the pain was severe or excruciating in more than one-third of the persons with pain in six of the seven categories.

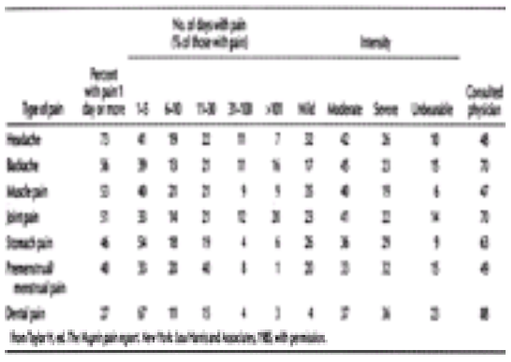

TABLE 9-1. Prevalence of pain

The Nuprin report also showed that physicians were consulted by 39% of those with mild pain, 51% with moderate pain, 74% with severe pain, and 82% with unbearable pain. Dentists were consulted by 12% of those with headache and 88% of those with dental pain; among the latter, 12% had mild pain, 18% moderate pain, 31% severe pain, and 48% excruciating pain. Clinical pain specialists were consulted by only 4% of those with headache, 7% of those with backache, and 5% of those with stomach pain, and, as expected, most of these were patients with severe or excruciating pain. These data suggest that surveys based on visits to physicians and other health professionals seriously understate the prevalence of pain. The survey also revealed that more than 4 billion workdays were lost by all adults, including 550 million by those employed full-time. Adding workdays lost by teenagers 17 years or younger and adults employed part-time gives a total loss of more than 650 million workdays by Americans in 1985. Using the mean income per day for that year, the data suggest that pain cost the American people more than $65 billion per year in loss of work productivity.

SUPERFICIAL (CUTANEOUS) PAIN

Superficial pain includes pain derived from the skin, subcutaneous tissue, and mucous membrane (see Chapter 3, Chapter 4 and Chapter 5). Noxious stimuli that are moderate and brief do not produce significant tissue damage and consequently have the purpose of alerting the individual and protecting him or her from external threat of injury. Throughout this text such stimuli are labeled *transient pain*. They rarely lead to health care consumption. Actual tissue damage that produces acute pain is caused by external or iatrogenic trauma, by burns or chemical agents applied to the skin, or by dermatologic disorders. The noxious stimuli associated with these conditions activate nociceptors that transduce the stimuli into nociceptive impulses that are transmitted to the neuraxis via A- d and C fibers. In addition, the tissue injury causes liberation of intracellular substances that produce sensitization characterized by (a) decrease in threshold; (b) increase in responsiveness to suprathreshold stimuli, manifested by decreased latency or greater number of impulses, or both; (c) the development of low-frequency spontaneous discharges; and (d) afterdischarge. These mechanisms are responsible for the pain, tenderness, certain associated sensations, and segmental and suprasegmental reflex responses.

Characteristics of Superficial Pain

The characteristics of superficial pain that distinguish it from deep somatic and deep visceral pain are its quality and localization. In 1937, Lewis described the two-phase response evoked by a single noxious stimulus applied to the skin, superficial tissue, or mucous membrane (10). These phases, called *first* and *second pain*, have been studied by Price and colleagues (11,12). Nociceptive mechanisms subserving these sensations, as well as their modulation, are described in Chapter 3 and Chapter 4. First pain, which is mediated by A-d nociceptors, is brief and localized, and has a sharp, pricking, or stabbing quality. This is followed 1.0 to 1.5 seconds later by a second burning, throbbing, or aching sensation of longer duration, which is mediated by C-nociceptive afferents (12). These qualities of pain are influenced by the extent of the injury and the time required for healing. In approximately one-third of the patients with acute injuries, an initial phase of no pain also exists. This phenomenon is discussed in the last section of this chapter, because it also applies to injuries to the deep somatic structures.

Sensation Associated with Cutaneous Pain

Superficial pain is usually associated with cutaneous tenderness, hyperalgesia, and hyperesthesia; in certain conditions, allodynia also occurs.

Cutaneous Tenderness

Cutaneous tenderness is said to be present when pain and discomfort are elicited by moderate pressure on the skin. This is related to, but is somewhat different from, hyperalgesia and allodynia. Pain may or may not be present concomitantly. The tenderness may occur with inflammation of the skin or after trauma to the skin, subcutaneous tissue, or deeper muscular tissue, and is likely caused by sensitization of nociceptors. Cutaneous tenderness can be elicited by pinching or pressing on the skin, and any area with cutaneous tenderness should always be compared with the symmetrically identical area on the opposite side.

Hyperalgesia and Allodynia

As noted in Chapter 2, *hyperalgesia* is increased sensitivity to noxious stimulation, whereas *allodynia* is pain caused by a stimulus that does not normally provoke pain. Among his early observations, Lewis (13) identified two distinct types of hyperalgesia: primary and secondary hyperalgesia. Sensitization at the site of injury to the skin, subcutaneous tissue, or mucous membrane is called *primary hyperalgesia*. Cutaneous hyperalgesia occurs after sustained exposure to ultraviolet radiation (sunburn), thermal or chemical burns, and laceration, contusions, or cuts of the skin. Primary hyperalgesia is characterized by a lowered pain threshold, increased response to suprathreshold stimuli, and spontaneous pain. *Secondary hyperalgesia* refers to changes that occur in a much larger area that surrounds the site of injury. It is characterized by hyperalgesia as well as allodynia. Within this diffuse region of secondary hyperalgesia, a smaller erythemic area of vasodilatation occurs called the *flare*, presumably caused by increased blood flow, and some edema caused by increased vascular permeability (14).

Cutaneous hyperalgesia also may occur with acute diseases of the peripheral nerves such as herpes zoster, and cutaneous hyperalgesia and allodynia also frequently develop after peripheral nerve injuries (complex regional pain syndrome type II) and central pain states. As discussed later in this chapter (see Cutaneous Hyperalgesia, Hyperesthesia, and Tenderness), cutaneous hyperalgesia also can be associated with deep somatic pain and can be a referred phenomenon of visceral pain.

Mechanisms of Cutaneous Hyperalgesia and Allodynia

The mechanisms of hyperalgesia and allodynia have been the subject of intense study for three-fourths of the twentieth century, and many speculations and hypotheses have been proposed to explain these phenomena. An extensive review of the older literature can be found on pages 94 through 101 of the first edition of this book. The most accepted hypotheses regarding the mechanism of cutaneous hyperalgesia include (a) sensitization of nociceptors by the endogenous chemicals

liberated from damaged tissue, (b) the axon reflex, and (c) increased sensitivity of dorsal horn neurons. Studies reviewed in the following sections suggest that sensitization of nociceptors is the basis for primary hyperalgesia, whereas secondary hyperalgesia involves neural elements, with axon reflex, changes in dorsal horn neurons, or both.

Sensitization of Nociceptors. LaMotte and associates (15) and Meyer and Campbell (16), among others, have studied the sensitization of different types of nociceptors in primary hyperalgesia by comparing the altered response of monkey nociceptors with human psychophysical responses to tissue injury caused by noxious heat. The results of these studies have been summarized by Meyer and colleagues (17). The marked primary hyperalgesia to heat after a burn to the glabrous skin is the result of sensitization of high-threshold mechanical nociceptors [Meyer and colleagues (17) labeled these *AMHs* (A-d nociceptors sensitive to intense mechanical and heat stimuli)]. Glabrous skin C-fiber polymodal nociceptors (CPNs) do not sensitize regardless of the intensity of the heat injury. However, sensitization appears to vary with skin type. Thus, in contrast to CPNs in glabrous skin, the hyperalgesia to heat after a minor burn to the hairy skin appears to be signaled by sensitization of CPNs [Meyer and colleagues (17) labeled these *CMHs* (C nociceptors sensitive to intense mechanical and heat stimuli)]. More substantial injuries to hairy skin lead to sensitization of high-threshold mechanical nociceptors and CPNs. Meyer and colleagues (14,17) emphasized that the characteristics of primary hyperalgesia differ from those of secondary hyperalgesia: Whereas in primary hyperalgesia an increased sensitivity to both mechanical and heat stimuli occurs, in the secondary region hyperalgesia only occurs with mechanical stimuli. Thus, light touch and light brushing cause considerable pain in the areas of secondary hyperalgesia and primary hyperalgesia. The mechanism of secondary hyperalgesia appears to involve changes in the peripheral and central nervous systems. Experimental evidence suggests that it may be caused by an axon reflex mechanism and central sensitization of dorsal horn neurons.

Axon Reflex. Some studies have suggested that the axon reflex is the basis for production of secondary hyperalgesia (18). This hypothesis is a modification of Lewis' conceptualization, which he first published in 1936 (13). Lewis proposed that secondary hyperalgesia was caused by spread of sensitization to adjoining pain receptors by activity of a distinct nervous channel, which he called *nocifensor nerves*, composed of a finely branching and rich end plexus in the skin, independent of sensory afferents and sympathetic fibers. Activation of nociceptors triggered a response reflexively (the axon reflex) in the nocifensor system that branched into adjoining tissue. Activation of these nocifensor branches led to release from their terminals of substances that in turn (a) increased blood flow and thereby produced a flare; (b) caused vascular permeability and thus produced edema; and (c) caused sensitization and activation of nociceptors that innervated the adjoining area, thus leading to secondary hyperalgesia. An important observation in Lewis' proposal was that electrical stimulation of a nerve trunk led to hyperalgesia to mechanical stimuli in the distribution of that nerve, even if the proximal end of the nerve was blocked with a local anesthetic during the stimulation period. Although the existence of a nocifensor system has been disproved, the axon reflex is now well established.

Fitzgerald (19) reported similar observations. She noted that antidromic stimulation of a population of CPNs in the hairy skin of rabbits resulted in heat thresholds that were significantly lower than those of CPNs of a control population. She showed that if a local anesthetic was injected into the injured area, there was no sensitization of C-polymodal nociceptors. Moreover, a population of CPNs that had a cut beside the receptive field before heat testing had a lower heat threshold than that of the control population. Fitzgerald did not report on the effects of antidromic stimulation or the cut on mechanical sensitivity. On the basis of these observations, it has been concluded that the effects are local (i.e., nerve impulses are involved locally in the spread of sensitivity from the damaged area to the undamaged part; secondary hyperalgesia). Others have been unable to replicate these results in other species.

Thalhammer and LaMotte (20) sought to determine whether an injury to one-half of the receptive field of a nociceptor might lead to spread of sensitization to the other half by applying a 56°C 7-second burn to one-half of the receptive fields of high-threshold mechanical nociceptors and CPNs located in the hairy skin. Sensitization to heat resulted in the half of the receptive field that was burned, but not in the other half, and no significant change in mechanical threshold was observed in either half. Similar results were reported by Meyer and colleagues (17) with a more substantial injury: 53°C 30-second burn. Meyer and colleagues also found that the response to heat of CPNs before and after scalpel cuts surrounding the three sides of its receptive field (no cut on proximal side) did not differ. Scalpel cuts on the volar forearm of human subjects resulted in hyperalgesia to heat stimuli within, but not adjacent to, the area of injury (17).

Cervero and Laird (21) demonstrated central interactions between low-threshold mechanoreceptors and nociceptors in human volunteers with experimentally induced secondary hyperalgesia. They found that tactile stimulation in an area of allodynia evoked axon reflexes (measured as increased cutaneous blood flow) concomitant with touch-evoked pain, whereas stimulation of normal skin did not. Furthermore, they showed that cooling the area of primary hyperalgesia or A-fiber blockade in the distribution of the area of allodynia abolished axon reflexes and allodynia. Thus, their studies suggest that pain sensations of allodynia and axon reflexes are produced by the same mechanism.

Sensitivity of Dorsal Horn Neurons. Meyer and colleagues (17) hypothesized that secondary hyperalgesia is caused either by a decrease in central inhibition of the mechanically induced nociceptive input or by excitation of low-threshold mechanoreceptors by central nociceptors. A similar concept had been proposed by Hardy and associates (22) three decades earlier, in 1952. After extensive experiments, they concluded that secondary hyperalgesia associated with deep or superficial injury caused increased excitability in the network of *internuncial neurons*, which received convergent noxious impulses from cutaneous and deep somatic tissue or cutaneous and visceral structures. They postulated that injury to the skin produced primary hyperalgesia and that as a result, the nerve endings became hyperexcitable, consequently barraging the dorsal horn with noxious impulses that sensitized the dorsal horn neurons to such an extent that they would be excited by *subliminal stimuli*. Evidence suggests that secondary hyperalgesia (more properly called *allodynia*, pain caused by nonnoxious stimulus to normal skin) is caused by sensitization of wide dynamic range neurons in dorsal horn. This has been discussed in Chapter 4.

DEEP SOMATIC PAIN

Previous chapters have included descriptions of the ample supply of nociceptors to muscles, tendons, joints, and bones. Under normal conditions, the order of sensitivity of these structures is as follows: The periosteum has the lowest threshold, followed by the ligaments, fibrous structures of joints, tendons, fasciae, and muscles (23). Inflammation causes significant lowering of pain threshold in these structures, especially joints and bones, including not only the periosteum but also the cancellous portion. Acute ischemia of muscle does not produce pain while the muscle is at rest, but pain becomes progressively more intense during exercise.

Clinical Characteristics

Deep somatic pain has a dull, aching quality, and although it is less localizable than cutaneous pain, it is sufficiently well circumscribed for avoidance of further damage to joint, muscle, bones, or all three. This is typically accomplished by immobilization of the involved structure, rather than escape. The extent and distribution of pain are significantly influenced by the intensity and duration of the noxious stimuli and the depth of the structure stimulated. Injury or disease of these deep somatic structures produces the same reflex responses as does injury to skin or viscera.

Pain in deep somatic structures has been experimentally induced in humans by pain-producing substances and by methods intended to reproduce spontaneous painful conditions: ischemia of a limb, experimental inflammation, injection of hypertonic saline, and other techniques (23). Measurements of deep somatic pain have been performed to determine the threshold of the sensation. Other studies have investigated phenomena frequently accompanying deep pain: radiation of pain, cutaneous hyperalgesia, and provocation of autonomic reflexes. The study of these phenomena in experimentally provoked deep somatic pain is fundamental for the interpretation of similar phenomena associated with spontaneous clinical pain. These studies have demonstrated the influence of the intensity and duration of the stimulus and the depth of the structure subjected to noxious stimuli on the spread of the pain and other characteristics.

Among the earliest human studies of the characteristics of deep somatic pain and the associated responses were those carried out by Kellgren and Lewis, who did most of the studies on themselves and their colleagues (24,25 and 26). They passed a needle through skin that had been locally anesthetized and then injected 0.1 to 0.3 mL of 6% saline as a form of noxious stimulus of deeper tissues. Kellgren (24,24) systematically studied the distribution of pain from stimulation of various skeletal muscles, interspinous ligaments, periosteum, deep fasciae, and tendon sheaths. Using these techniques, Kellgren (25) noted that stimulation of deeply situated periosteum with the point of a needle caused brief pain that the subject could localize at one, two, or three points, whereas prolonged stimulus from injected saline produced a more diffuse pain. Moreover, he noted that the intensity of the stimulus also affected the spread of the pain (Fig. 9-1).

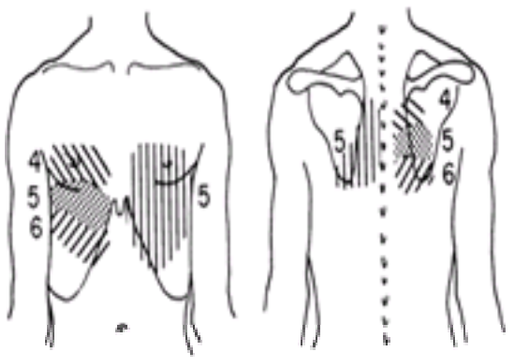

Figure 9-1. Distribution of pain caused by injection of intercostal muscles that shows effect of intensity of the stimulus on the spread of the pain. The right side of the figure shows pain produced by mild stimulation of the fourth (*cross-hatched*), fifth (*stippled*), and sixth (*cross-hatched*) intercostal spaces, depicting a segmental distribution. Following this, a more intense stimulus was provoked by injection of the left fifth intercostal muscle, which provoked pain that spread over the three segments, probably because of spread within the dorsal horn. (Modified from Kellgren JH. On the distribution of pain arising from muscle. *Clin Sci* 1937–1938;3:175–190.)

The influence of the duration of stimulus on the spread of pain was observed by Wolff (27). These investigators noted that brief stimulation of the mucosa about the ostium of the maxillary sinus produced a localizable intranasal sensation of pain, whereas prolonged stimulation of the same area caused the pain to spread over the homolateral portion of the nose, cheek, along the zygoma, into the temporal region, and into the upper teeth (Fig. 9-2). When the noxious stimulation was continued for 10 minutes, the area of pain spread over most of the area of the distribution of the second division of the fifth cranial nerve and ultimately spread to involve adjacent portions supplied by the first and third divisions. As noted in a later section (see Visceral Pain), a similar spread occurs with prolonged stimulation of viscera.

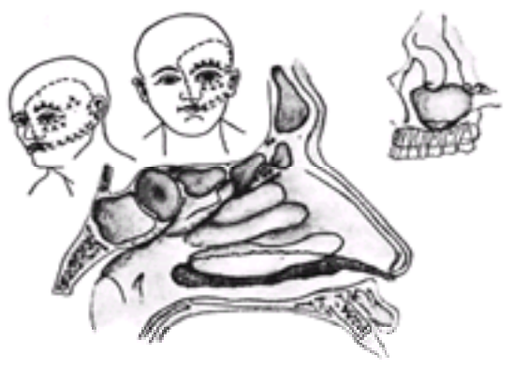

Figure 9-2. The influence of stimulation duration on the spread of pain. Brief repeated stimulations of the ostium of the maxillary sinus produced pain in the areas marked with an *X*, whereas when the stimulation was continued for 10 minutes, the area of pain spread over most of the area of the distribution of the maxillary nerve and ultimately spread to involve adjacent portions supplied by the ophthalmic and mandibular nerves (disorder indicated by *dashed line*). (From Dalessio DJ, Silberstein SD, eds. *Wolff's headache and other head pain*, 6th ed. New York: Oxford University Press, 1993:299, with permission.)

This phenomenon of spread caused by a prolonged stimulus is also seen clinically. If a localized pain caused by a minor injury is unrelieved, it can become diffuse, poorly localizable, and referred to a part that is remote from the original site of injury. Thus, the duration factor affecting spread of pain is of great clinical importance and must be seriously considered; early relief of clinical pain can preclude its spread.

Another important factor that affects the localization and spread of deep somatic pain is the depth at which the involved tissue is situated. Kellgren (24) found that pain elicited by stimulation of such subcutaneous tissue as superficial fascia; superficial tendons; superficial joints, ligaments, or periosteum; or superficial bone could be fairly well localized by the subject. Pain from the same structures, when deeply situated or from the belly of the muscle, was diffuse and was often referred to a distant area of the skin surface (Fig. 9-3).

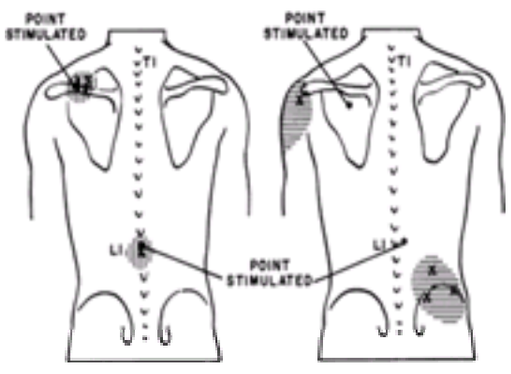

Figure 9-3. Diagram showing distribution of pain produced by injecting saline into subcutaneous periosteum (*vertical hatching*) and deeply situated periosteum (*horizontal hatching*). Points stimulated are top of spine and lamina of first lumbar vertebra and the spine and infraspinatus fossa of the scapula. The crosses indicate where the pain was experienced when the periosteum at the site of injection was scratched with a needle point. (Redrawn from Kellgren JH. On the distribution of pain arising from deep somatic structures with charts of segmental pain areas. *Clin Sci* 1939;4:35–46.)

Kellgren (24) also noted that the deep portion of the interspinous ligaments produced pain that followed a segmental pattern. Although the segmental pattern is best noted in the trunk (Fig. 9-4), it also is found in the limbs (Fig. 9-5 and Fig. 9-6).

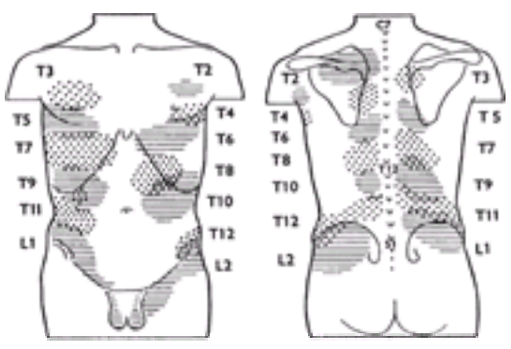

Figure 9-4. The areas of referred pain provoked by injection of saline into the interspinous ligaments of T-2–L-2 inclusive. Alternate areas have been hatched and

stippled for the sake of clarity. **A:** Anterior view. **B:** Posterior view. Note the overlap between areas of references, which, in the anterior part of the trunk **(A)**, are located in the skin supplied by the intercostal nerves and appear to follow a somewhat dermatomal pattern, depicted in Figure 8-8. In contrast, in the posterior paravertebral region the areas of referred pain are situated significantly more caudally than the vertebral levels and the intravertebral foramina through which the spinal nerves exit. Thus, it is noted that the area of referred pain from stimulation of the fourth thoracic interspinal ligament (i.e., ligament between T-4 and T-5) produces pain in the paravertebral region, which is opposite the spinous processes of T-6 and T-7; the area of referred pain from stimulation of the tenth thoracic interspinous ligament is opposite T-12 and L-2, and from stimulation of the first lumbar interspinous ligament the area of referred pain is opposite the spinous processes of L-4, L-5, and S-1. This is because of the progressively greater caudad migration of the posterior division of each spinal nerve. (From Kellgren JH. On the distribution of pain arising from deep somatic structures with charts of segmental pain areas. *Clin Sci* 1939;4:35–46. Copyright Biochemical Society and the Medical Research Society, with permission.)

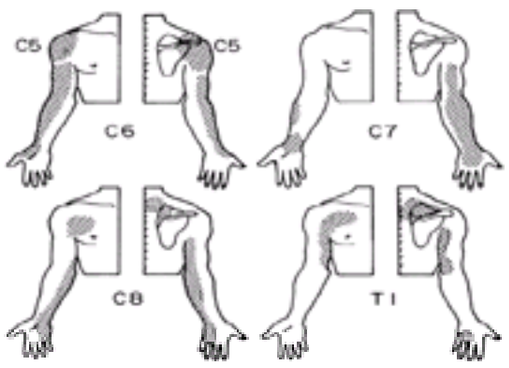

Figure 9-5. The area of referred pain provoked by injection of hypertonic saline into the interspinous ligaments C-5–T-1 inclusive on the anterior half of the body (on the reader's left in each of the four figures) and on the posterior part of the body. Note the segmental pattern of the area of referred pain similar to the dermatomes. (Modified from Kellgren JH. On the distribution of pain arising from deep somatic structures with charts of segmental pain areas. *Clin Sci* 1939;4:35–46.)

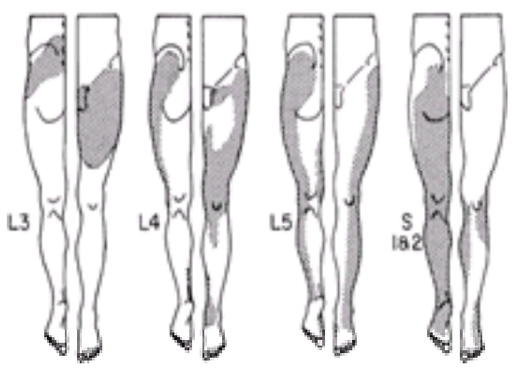

Figure 9-6. Diagram depicting the area of referred pain from injecting hypertonic saline into the interspinous ligaments L-3–S-2 inclusive. (Modified from Kellgren JH. On the distribution of pain arising from deep somatic structures with charts of segmental pain areas. *Clin Sci* 1939; 4:35– 46.)

Kellgren (25) also studied the reference of pain from injection of hypertonic saline into various muscles. Figure 9-7 shows the segmental distribution of pain produced by injection of various muscles in the upper limb and the first intercostal space, and Figure 9-8 shows distribution of pain from injection of muscles in the lower limbs. These observations also led Kellgren to observe that the injection of a given muscle is felt over a definitive area, seemingly following a segmental pattern, and that distribution for a given muscle is similar in different individuals. He concluded that the segmental areas displayed were determined by the nerve roots involved in supplying the corresponding muscles, so that different muscles supplied from a common root source yielded a common general field of pain distribution (Fig. 9-9) (25). Figure 9-10 is a map showing the reference of pain resulting from stimulation of various muscles by injecting hypertonic saline, which was developed from the data published by Kellgren (25).

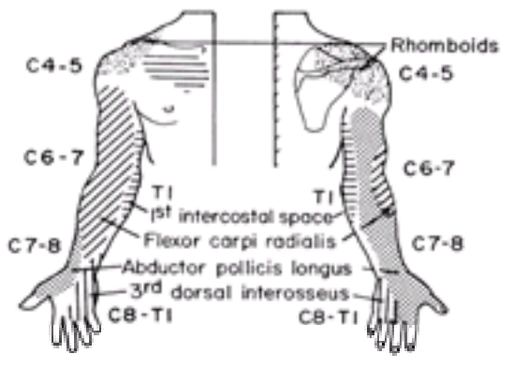

Figure 9-7. Distribution of pain provoked by injection of hypertonic saline into various muscles of the upper limb. (Modified from Kellgren JH. Observations on referred pain arising from muscle. *Clin Sci* 1937–1938;3:175–190.)

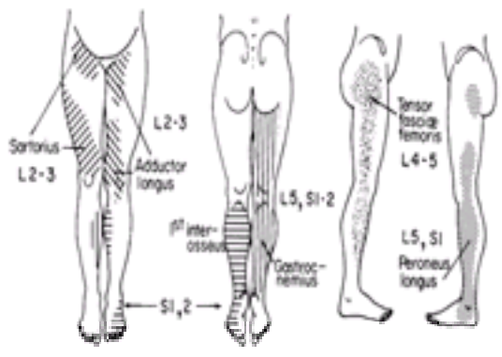

Figure 9-8. Distribution of pain provoked by injection of hypertonic saline into various muscles of the lower limbs. **A:** Anterior view showing pain (*oblique hatching*) from injection of the sartorius on the right side of the subject and injection of the adductor longus on the left side. **B:** Posterior view showing pain reference from injection of the first interosseous on the left side of the subject and gastrocnemius on the right side. **C:** Pain distribution from injection of the tensor fasciae femoris (*fine stipple*) and injection of the peroneus longus (*coarse stipple*). The numbers indicate the segmental nerve supply. (Modified from Kellgren JH. Observations on referred pain arising from muscle. *Clin Sci* 1937–1938;3:175–190.)

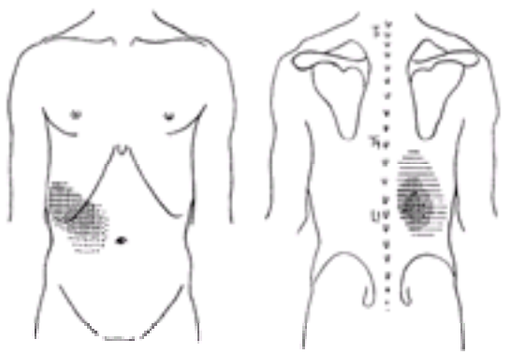

Figure 9-9. Distribution of the referred pain provoked by injecting hypertonic saline into different muscles supplied by the ninth thoracic nerve. Horizontal hatching shows areas of pain provoked by injection of multifidus muscle opposite the ninth spinous process; vertical hatching shows pain caused by injection of the ninth intercostal nerve in the midaxillary line; and stippled area shows area of pain caused by injection of rectus abdominus 3 cm above the umbilicus. (From Kellgren JH. Observations on referred pain arising from muscle. *Clin Sci* 1937–1938;3:175–190. Copyright Biochemical Society and the Medical Research Society, with permission.)

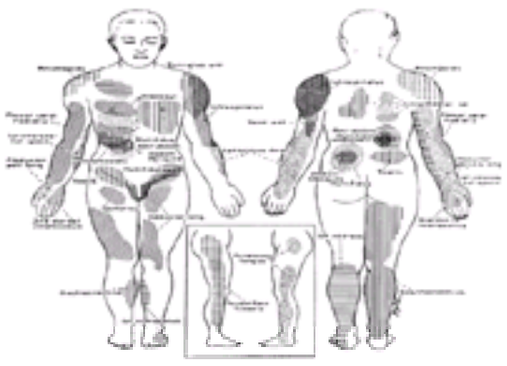

Figure 9-10. Composite map showing the reference of pain resulting from noxious stimulation of various muscles by injecting hypertonic saline. (From data by Kellgren JH. Observations on referred pain arising from muscle. *Clin Sc*ı 1937–1938;3:175–190.)

After his extensive investigations, Kellgren concluded that beneath the skin a second sensitive layer exists in which pain is localized with fair accuracy. This layer consists of the deep fascia encasing the limbs and trunk and any periosteum, ligament, or tendon sheath that is situated subcutaneously. On the other hand, all the structures deep to this layer give rise to diffuse pain of more or less segmental distribution. The pain is fully segmental in distribution when arising from the interspinous ligaments, intercostal spaces, and other structures situated deeply in the trunk and limbs, whereas the pain is more localized when arising from less deeply placed structures.

The work of Kellgren has been confirmed by several groups of investigators. The experimental human studies of Inman and Saunders (28) demonstrated the segmental pattern of deep somatic pain and noted that this pattern did not correspond to the dermatomes, but rather to the segmental distribution of muscles (myotomes) and bones (sclerotomes). They concluded that a deep somatic lesion, such as injury to muscle tendon or periosteum, can give rise to pain that radiates along the pathway corresponding to the approximate segmental innervation of the deep somatic tissues. Similar data derived from noxious stimulation of various skeletal structures were obtained by Travell and Simons (29). These investigators also found that the referred pain was experienced either within the reference area attributed to one segment, within a different portion of one segment, or within different fragments of several segments. These patterns were especially clear in myofascial pain syndromes with trigger areas in which the pattern of the referred pain and the associated phenomena are relatively constant and predictable. These findings suggest that impulses concerned in the unfamiliar reference of somatic pain, like those of visceral pain and cutaneous pain, follow fixed neural pathways.

Other Manifestations of Deep Somatic Pain

Like visceral and superficial pain, deep somatic pain is associated with cutaneous hyperalgesia, tenderness, reflex muscle spasm, and, not infrequently, sympathetic hyperactivity. Although these associated responses have long been known to occur with the pain of visceral disease, it was not until Lewis and Kellgren (26) demonstrated that these responses also occur with stimulation of deep somatic structures that they were fully appreciated. In one of these studies, they stimulated the first lumbar interspinous ligament because of the known likeness of the pain distribution to that of renal colic (Fig. 9-11). After injecting this ligament, they looked for retraction of the testicle on the same side because this is a phenomenon associated with attacks of renal colic. They noted that the retraction occurred unmistakably and repeatedly, became maximal as the pain increased to its maximum, and gradually disappeared as the pain subsided during the next 3 to 5 minutes. They also noted palpable rigidity and deep tenderness of the lower part of the abdominal wall of the corresponding side, which also disappeared with the passing of the pain.

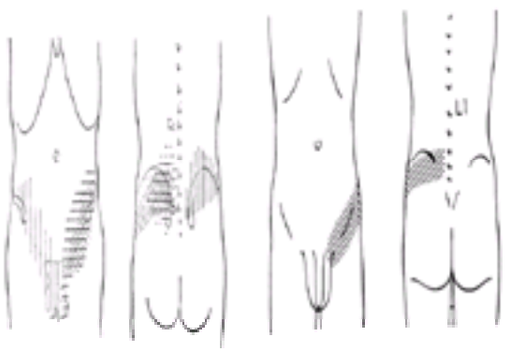

Figure 9-11. **A:** Distribution of pain in the first lumbar segment when provoked from stimulation of the testes (*vertical hatching*); from abdominal oblique (*horizontal hatching*); and from multifidus (*stippling*). **B:** Distribution of pain from stimulation of the first lumbar interspinous ligament. Note similarity in distributions of pain from stimulation of visceral and somatic structures. (Modified from Lewis T, Kellgren JH. Observations relating to referred pain, visceromotor reflexes and other associated phenomena. *Clin Sci* 1939;4:47–71.)

Similar observations have been made by many others. Procacci and colleagues (23) noted that on inducing pain in different muscles of the upper limb or chest with hypertonic saline injection, they were able to produce pain, hyperalgesia, alteration of cutaneous impedance, and an abnormal dermographic response (white dermographia) that had a segmental distribution corresponding to the injected muscle. They noted that injection of the somatic nerves with local anesthetic eliminated the cutaneous hyperalgesia and the variation of skin impedance and dermographia.

VISCERAL PAIN

Two main types of pain are associated with visceral disease, particularly disease of the abdominal organs: pain arising from the diseased viscus itself and thus called true visceral pain, and pain arising from the parietal peritoneum or pleura. Each of these may be felt in or near the diseased structure or in a remote area. On the basis of these considerations, Lewis (1) suggested four types of pain associated with disease of the viscera: true or localized visceral pain, referred visceral pain, localized parietal pain, and referred parietal pain.

True visceral pain occurs early in the disease and is characterized by a vague, diffuse, dull, aching pain, which is poorly localized and tends to radiate. It can be accompanied by a feeling of malaise, and, when severe, it induces strong autonomic phenomena such as sweating, vasomotor responses, bradycardia, nausea and vomiting, and sometimes an alarm reaction. It is usually felt in the midline and deep in the body. Thus, visceral pain caused by disease of the stomach and duodenum early on is felt around the midline area above the umbilicus, pain from appendicitis is felt in the periumbilical region, and pain caused by disease of the colon is felt in the lower abdomen (30) (Fig. 9-12). Some authorities call this type of pain *true visceral pain*, and others call it *splanchnic pain* [see Lewis (1) for references]. Another example of true visceral pain is the first manifestation of myocardial infarction; the pain is usually deep and poorly localized, and most often in the midline substernal or epigastric region (sometimes also in the interscapular region). Rather than pain, other unpleasant sensations such as gastric fullness, heaviness, pressure, squeezing, or choking may be experienced. As the intensity and duration of visceral pain increase, the pain may radiate and seem to originate from a wider area. For example, substernal pain or pressure, the sensations typically associated with early myocardial infarction, may spread to include diffuse chest pain as well as radiate down the arm or up into the neck and jaw. In some instances, the pain arising from viscera is referred to the skin and other somatic structures at considerable distance from the diseased viscus and has a segmental dermatomal pattern. One example of this type of referred pain is that felt in the inguinal region and testicle caused by ureteral stones.

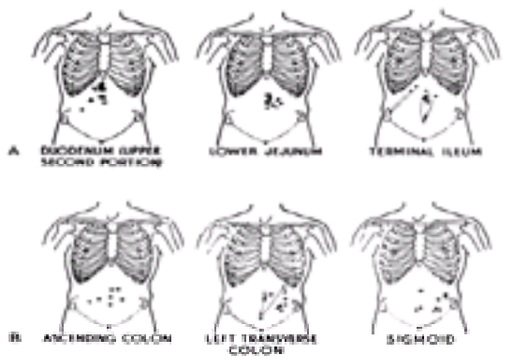

Figure 9-12. Areas of referred pain provoked by distension of various parts of the small intestine **(A)** and large intestine **(B)** by inflating a balloon sufficiently to provoke pain. (Modified from Jones CM. *Digestive tract pain*. New York: Macmillan, 1939.)

Parietal pain occurring with a disease process involves the parietal pleura or parietal peritoneum. This type of pain, which is usually described as sharp and occasionally stabbing, may be localized or referred to a distant site. When the disease process comes to involve the anterior abdominal wall or the parietal pleura in the chest, the pain is felt close to the diseased viscus. Parietal pain associated with the diaphragm presents a complex pattern. If the disease process involves the parietal pleura or parietal peritoneum covering the peripheral portion of the diaphragm, the pain is referred to the lower chest and abdominal wall on the ipsilateral side, reflecting the nerve supply to this region by the lower six intercostal nerves. On the other hand, if the disease process involves the central part of the diaphragm, whether the thoracic surface, as in diaphragmatic pleurisy or pericarditis, or the inferior peritoneal surface, as in subdiaphragmatic abscess, the pain is felt in the neck. It is usually sharp, lancinating, accurately localized, and referred to the skin and superficial structures overlying the trapezius muscles. This area of reference is explained by the embryonic origin of the organ. The diaphragm has its origin as a cervical muscle that has migrated caudally, carrying with it a cervical nerve supply (i.e., the phrenic nerves).

In a manner analogous to cutaneous dermatomes, which are arranged according to the embryologic anatomy of these tissues, viscerotomes are arranged according to the embryologic location of the viscera and involve both mesodermal and endodermal tissues. Ness and Gebhart (31) published an extensive review of the clinical and experimental studies that have led to our current understanding of the anatomy and physiology of visceral pain (Fig. 9-13). Figure 9-13A illustrates how the human viscerotomes correspond to the embryologic origins of the viscera. Because of the migration and rotation of viscera during embryologic development, somatotopic progress of the viscerotomes is not always obvious. One example is the complex formation of the diaphragm as described previously. Another example is the development of the gut, which forms loops and rotates in such a way that structures originally in the lower abdomen are finally located in the upper abdomen.

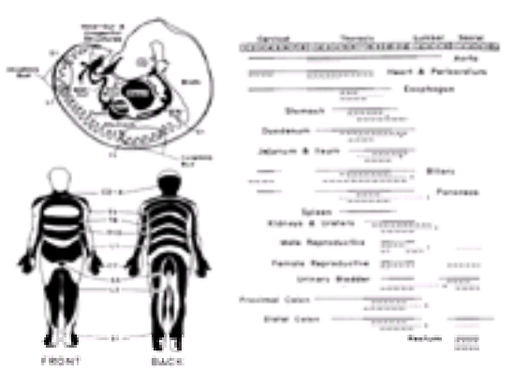

Figure 9-13. Human viscerotomes. **A:** Cross-sectional illustration of human embryo shows the original relation between location of the viscera and developing spinal nerves. **B:** Examples of dermatomes with corresponding spinal segments. **C:** Schematic representation of human viscerotomes (*solid, dashed,* and *dotted lines*) and their relation to dermatomes (segments indicated in grid above). The type of line indicates how the viscerotomes were determined, and the thickness of each line relates to the frequency of occurrence of referral site. Solid lines indicate sites of referred pathologic pain, dashed lines indicate sites of cutaneous hyperalgesia associated with visceral disease, and dotted lines indicate sites where nerve blocks or ablation of dorsal roots relieve pain related to visceral pathology. (From Ness TJ, Gebhart GF. Visceral pain: a review of experimental studies. *Pain* 1990;41:167–234, with permission.)

Visceral pain and parietal pain are usually associated with reflex skeletal muscle spasm, tenderness, hyperalgesia, and sympathetic hyperactivity and may evoke stronger emotional responses than superficial pains. These phenomena are discussed in connection with Referred Pain, later in this chapter.

Mechanisms of Visceral Pain

Effective (Adequate) Stimuli

Visceral pain cannot be provoked by stimuli that usually provoke cutaneous or deep somatic pain, such as pressure, cutting, or burning. In the early 1900s, Lewis (1) summarized work done by Lennander in 1900, a series of extensive observations of patients being operated on for intraabdominal surgery under local anesthesia and demonstrated that the intestine could be cut, crushed, burned, or stretched without causing sensation. These findings led him to advance the hypothesis that all of the internal organs that are innervated solely through autonomic nerves are devoid of pain sensation. Similar findings by Mackenzie (32) led many investigators to deny the possibility of painful sensations arising from stimulation of the viscera unless the stimulation is such that it will spread beyond the area innervated solely by visceral nerves and affect afferent components of spinal nerves (33). In 1911, Hurst showed that stretching of the intestine gave rise to considerable pain, and many subsequent studies (1) have established that pain does arise from viscera, but that cutting, burning, and crushing as described in early reports may not have been adequate stimuli.* Subsequently, Holmes (34) expressed his views on this matter thus: “This insensitivity of viscera to such somatic stimuli as burning and cutting is

not surprising, for as the viscera are not normally exposed to such traumas, it cannot be expected that they would be endowed with a nervous apparatus to respond to them."

Adequate stimuli that provoke visceral pain include (a) spasm of smooth muscles of hollow viscera; (b) contraction of gastrointestinal or genitourinary tracts under isometric conditions (i.e., contraction against obstruction); (c) sudden abnormal distension, stretching, or tearing of these structures; (d) rapid abnormal stretching of the capsule of solid viscera such as liver and spleen; (e) rapidly developing ischemia; (f) inflammation of the lining of the hollow viscera; (g) chemical or mechanical stimuli applied to the inflamed mucous membrane of these structures; (h) traction, compression, or twisting of the mesentery, ligaments, or blood vessels; and (i) necrosis of such viscera as the pancreas or myocardium (35). In clinical conditions, two or more of these causative factors may be concomitant and interact with each other. For example, a stone in the ureter or biliary tract usually provokes intense contraction and spasm of the smooth muscles and produces excruciating pain, which is promptly relieved by passage of the stone without causing tissue injury.

Visceral Nociceptors

Not all afferent innervation of the viscera is sensory. Stimulation of receptors such as the arterial baroreceptors and carotid body chemoreceptors activate autonomic functions that are not perceived, and thus are part of the afferent, but not sensory, innervation of the internal organs. Activation of other visceral receptors evokes sensations of fullness, discomfort, and even pain and are thus part of the sensory innervation of the viscera. The encoding mechanism for visceral nociceptive events remains a topic of controversy. One possible mechanism is that a single population of visceral receptors responds at an increased frequency to noxious stimuli. The other possible mechanism is that visceral pain is mediated by a population of specific nociceptors that responds only to noxious stimuli. Cervero (36) has presented experimental evidence for both specific nociceptors and nonspecific sensory receptors in the viscera. For example, some colonic receptors respond with increasing frequency to increasing magnitude of distension of the colon; this is paralleled by subjective feelings that progress from fullness to discomfort to pain. In other viscera, such as the ureter and biliary duct, pain seems to be the only sensation evoked, mediated by specific nociceptors (36,37).

Peripheral and Central Sensitization

Conscious perception of visceral pain, like cutaneous and deep somatic pain, depends on how afferent inflow is integrated in the central nervous system. Visceral input is subject to both peripheral and central modulation (37), but these processes differ in some ways from those observed in sensitization of cutaneous receptors (38).

One possible trigger for the sensation of visceral pain is peripheral sensitization of visceral nociceptors. Several investigators have demonstrated that ischemia lowers the response threshold for nociceptors in the colon and ureter (36). McMahon and colleagues (38) have described *silent* nociceptors, which are only activated in pathophysiologic states, such as inflammation. McMahon and colleagues have also presented evidence that this process may be mediated by nerve growth factor (38).

Unlike cutaneous nociception, spatial summation may reduce the effective threshold for pain in viscera (38). Spatial summation of visceral input may also help to explain the inability of localized mechanical stimuli to produce pain. Prolonged noxious visceral stimulation also increases the excitability of viscerosomatic neurons in the spinal cord. Cervero (37) has suggested that the increase in excitability may be mediated by positive feedback loops between spinal and supraspinal structures; these feedback loops may be responsible for enhanced motor and autonomic reflexes that frequently accompany visceral pain states. However, the postsynaptic actions of peptides such as *N*-methyl-d-aspartate can also contribute to enhanced visceral nociceptive neuronal activity (37). Nerve growth factor may also act indirectly to increase central nervous system excitability (38).

REFERRED PAIN

The term *referred pain* is generally used for pain localized not to the site of its cause but to an area that may be adjacent to or at a distance from such a site. Although Henry Head (39) is usually given the credit for first using the term in 1864, the phenomenon of referred pain had also been recognized by Sturge (40), Ross (41), and others. The mechanism of referred visceral pain has caused greater controversy than perhaps any other aspect of the general problem of visceral pain. As mentioned earlier in this chapter, referred pain is usually accompanied by hyperalgesia, reflex muscle spasm, deep tenderness, and autonomic hyperactivity.

Associated Clinical Manifestations

Cutaneous Hyperalgesia, Hyperesthesia, and Tenderness

Deep somatic, visceral, or both somatic and visceral diseases are frequently manifested by secondary hyperalgesia in the dermatomes supplied by the same spinal segments that supply the deep structure or viscera. Head (39) used cutaneous hyperalgesia to map out the dermatomes and thus study the nerve supply for various viscera. The hyperalgesia may involve the entire dermatome(s) or only part of a specific dermatome.

The presence of cutaneous hyperalgesia associated with deep somatic disorders or visceral disease had been recognized by Sturge (40) in 1883 and Ross (41) 4 years later. Since Head's classic publication (39), many investigators have studied various aspects of deep somatic or visceral pain (1,22,26,27). Properly carried out, the examination for hyperalgesia and hyperesthesia is used by the clinician to help in the diagnosis of the source of the pain.

Reflex Muscle Contraction

Muscular rigidity and contraction are important clinical manifestations of deep somatic or visceral disease. The muscles involved depend on the segments supplying the deep somatic structure or viscera as well as the intensity of the noxious stimuli. In diseases or disorders that produce mild referred pain, the reflex muscle spasm may be mild and limited to the spinal cord segments that supply the structure involved in the disease or the injured somatic tissue. An example of the correlation between the segments involved in the muscle spasm and the nerve supply is seen in the location of spasm in cholecystitis and appendicitis: In cholecystitis the spasm is in the upper abdominal muscle, and in appendicitis it is in the lower abdominal muscle. In renal colic, the contraction involves the cremasteric muscle, which is supplied by the first and second lumbar segments (which also supply much of the ureter).

Intense and prolonged noxious stimuli not only influence the extent of the referred pain, but also the extent and duration of muscle contraction. This point was well demonstrated by the experimental studies on genitourinary pain carried out by McLellan and Goodell (42). They noted that brief low-intensity electrical stimulation or overinflation of a balloon placed in the ureter caused localized pain and little or no muscle contraction, whereas prolonged or intense stimulation evoked a more complex phenomenon. The muscles of the abdominal wall on the stimulated side remained contracted, and after approximately half an hour the side began to ache. This ache became quite severe and lasted 6 hours, after which the pain subsided, but deep tenderness in the muscle continued until the following day (Fig. 9-14).

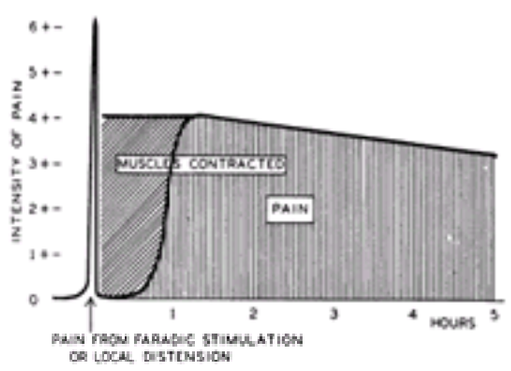

Figure 9-14. Schematic representation of a sudden pain arising from either faradic stimulation or local distension in the ureter or kidney pelvis. The severe transient pain was followed by contraction of skeletal muscles (erector spinae transversalis and internal and external oblique), which later developed an aching pain that lasted for several hours. (From MacLellan AM, Goodell H. Pain from the bladder, ureter and kidney pelvis. *Proc Assoc Res Nerv Ment Dis Am* 1943;23: 252–262, with permission.)

Clinically, muscular contraction associated with referred visceral pain may also be maintained for a long period of time and may even continue after the pain disappears. Moreover, in clinical conditions it is noted that extremely intense and prolonged noxious stimuli such as occur with acute pancreatitis not only produce more intense visceral and referred pain, but also may cause contraction of muscles above and below those spinal segments that supply the pancreas. In such circumstances there may be contraction of all of the thoracic muscles.

In addition, prolonged and sustained skeletal muscle spasm caused by intense noxious stimuli from the deeper structures can initiate new nociceptive impulses from the muscles, and thus sustain and aggravate the initial pain and discomfort. If the skeletal muscle spasm is not eliminated, it may lead to a vicious circle that tends to perpetuate the condition. The concept of intense contraction of skeletal muscles as a cause of new nociceptive impulses had been proposed by Lewis (1), Lewis and Kellgren (26), and Hardy and associates (22), and Bonica emphasized it repeatedly over three decades. This thesis was adopted by Zimmermann (43), who hypothesized that the positive feedback loop provokes new nociceptive impulses that not only aggravate acute pain, but also may contribute to the development of chronic pain.

Deep Hyperalgesia and Tenderness

In addition to cutaneous hyperalgesia, hyperesthesia, and tenderness, visceral disease and deep somatic disorders are frequently associated with deep hyperalgesia and tenderness. The tenderness is often felt by the patient deep to the skin and, in most instances, is closely associated with muscular contractions. It is felt in the affected muscles and usually outlasts the contractions and even the pain. The deep tenderness is not always of muscular origin, because the viscera themselves may be the site of the soreness. Thus, it is seen that patients with renal colic complain of deep tenderness in the testicle of the same side, which is presumably elicited from the deep tissues of the scrotal wall or from the tunics vaginalis.

Still other mechanisms can produce deep tenderness. In one study, Wolff (27) produced headache, deep tenderness, cutaneous hyperalgesia, and hyperesthesia in the temporal region of the head by prolonged stimulation of a tooth. Intracutaneous infiltration with procaine at the site of the most intense temporal headache, tenderness, and surface hyperalgesia resulted in reduction of the intensity of the headache, but the temporal muscles beneath the analgesic skin remained tender to palpation. When the local anesthetic was injected into the temporal muscle as well as intracutaneously, pain persisted although local tenderness was eliminated. It was only after infiltration of the tooth with procaine that there was complete relief of pain. They concluded that such tenderness resulted from a central (within the neuraxis) spread of hyperexcitatory effects induced by the sustained noxious stimulation.

Autonomic Manifestation

As mentioned previously, true visceral pain and referred pain associated with visceral disease or deep somatic disorders are often accompanied by sympathetic or parasympathetic hyperactivity. In most instances it is sympathetic hyperactivity manifested by increase in blood pressure, tachycardia, sweating, piloerection, and vasoconstriction associated with a neuroendocrine response (see Biology and Pathophysiology of Acute Pain, later in this chapter). In some patients, sudden intense noxious stimuli of the abdominal viscera produce parasympathetic hyperactivity, manifested by bradycardia, hypotension, and a feeling of severe general malaise.

Effects on Referred Pain of Anesthetizing the Area of Reference

One controversial and confusing problem of referred pain is the effect produced by infiltrating the area of reference with a local anesthetic. In 1928 Weiss and Davis (44) reported that local anesthesia of the abdominal wall in 25 patients with visceral disease produced pain relief. Subsequently, similar results were reported by Morley (45) on 13 patients with referred pain caused by visceral disease. Morley (45) also reported that the pain and hyperalgesia referred to the shoulder as a consequence of diaphragmatic irritation could be eliminated or diminished by infiltration of local anesthetic in that region.

Rose (46) noted that the pain of the first stage of labor could be relieved by anesthetization of the skin of the lower abdomen, an observation subsequently substantiated by others [see Bonica (47) for references]. Theobald (48) also reported the relief of pain in the reference zone resulting from dysmenorrhea or from electrical stimulation of the uterus. In his experimental studies of pain from the gastrointestinal tract using an inflatable balloon, Jones (49) reported that “it was possible to infiltrate with Novocain the skin area at which pain was experienced, for example, in the midepigastrium after distension of the first portion of the duodenum with resulting abolition of the local reference of pain.”

Notwithstanding these and other early reports on the efficacy of superficial analgesia in relieving the referred pain and hyperalgesia, negative results have also been reported. Woollard and colleagues (50) attempted to confirm Morley's findings by stimulating the phrenic nerve, which was exposed before avulsion. They noted that although stimulation produced pain in the distribution of the fourth cervical segment, it was not reduced by anesthetization of the skin of this area. Similar negative reports were made by Lewis (1), McLellan and Goodell (42), and many others [see Hardy (22) and Bonica (51) for references].

The obvious discrepancies reported have prompted several explanations. Theobald (52) suggested that the divergence between the results obtained by Morley (45) and those by Woollard and colleagues (50) could be attributed to the difference in the intensity of the stimulus they applied. In support of this hypothesis, he demonstrated that mild referred pain elicited by weak electrical stimulation of the cervix could be relieved by needling the affected cutaneous area. A further increase in the current caused pain that could not be relieved by needling, but frequently could be relieved by injecting 5 mL of saline solution intradermally. A still further increase in the current caused pain that could not be relieved by saline but could be eliminated by injection of 1% procaine. In nearly every patient studied, by raising the stimulus intensity, a point was ultimately reached when the pain persisted despite the injection of large amounts of local anesthetic and was usually referred to the same cutaneous area in which the latter was completely anesthetic. Bonica (47) observed that mild labor pain of the early first stage can be virtually eliminated by infiltrating the skin of the lower abdominal wall, whereas the severe pain of the late first stage is not affected appreciably. Wolff and coworkers (27) also reported that when the cutaneous hyperalgesia was more marked, the effect of procaine injection into the zone of hyperalgesia was more dramatic.

Hardy, Wolff, and colleagues have also explained the discrepancies and contradiction on the basis of whether the referred pain is associated with hyperalgesia (22,27). If hyperalgesia is not present, the referred pain depends only on the central effects of the spread of excitation of the original noxious impulses to the same and adjacent segments, and anesthetization of the region of referred pain does not reduce the intensity of pain. If hyperalgesia is present, injection of local anesthetic should abolish the element of the referred pain complex that depends on impulses from the zone of reference.

Hypotheses on the Mechanism of Referred Pain

In the 1880s and 1890s, Sturge (40), Ross (41), and Head (39) proposed similar concepts regarding the mechanism of referred pain. Sturge (40) suggested, in physiologic terms, that the pain in the left arm and fingers of patients with heart disease must be a conscious recognition of an “abnormal commotion” in the gray matter of the spinal cord. Four years after Sturge's hypothesis, Ross (41) proposed that in visceral disease two types of pain exist, a true splanchnic pain and a somatic pain, and that the somatic pain is caused by an irritable focus in the spinal cord. Head (39) seems to have accepted and somewhat elaborated the Sturge-Ross hypothesis. He did not deny the existence of pain of visceral origin and localization, but divided visceral pain into that localized vaguely inside the body (dull visceral pain) and that referred to the skin surface (aching referred pain). Head assumed that the reference was caused by convergence of visceral and skin nerves into the same spinal cord structures and a subsequent “physical error” of localization.

Mackenzie (32,53) incorporated Ross' concept of referred pain into his own theory of visceral pain, but he denied the existence of true splanchnic pain. For Mackenzie, only somaticlike structures (e.g., the skin, muscles, and peritoneum) were sources of painful stimulation. He believed that although sensory impulses can and do arise from viscera, none of these produces pain. He suggested that such impulses would, on entering the spinal cord, set up an *irritable focus* by constant bombardment of the same segments in which they entered (Fig. 9-15). In this way, they would diminish the threshold for somatic sensory impulses and produce cutaneous hyperalgesia and referred pain in the corresponding segments. Mackenzie labeled these phenomena, which he believed accounted for referred pain, as *viscerosensory reflexes*. Furthermore, he suggested that visceral afferent impulses activated the anterior horn cells in the same manner to produce skeletal muscle spasm and also activated anterolateral autonomic (sympathetic) cells, which produced piloerection, vasoconstriction, and other sympathetic phenomena. He referred to these somatic and autonomic motor reactions as *visceral motor reflexes*. Morley explained referred pain by using a modification of the *irritable focus* theory (45). He suggested that irritation of the spinal nerve endings in the mesentery or parietal peritoneum produced peritoneocutaneous and peritoneomuscular reflexes, provoked by inflammation of the disease. Shortcomings of this theory include, for example, its inability to explain the referred pain associated with conditions such as angina

pectoris, in which no inflammatory process exists and usually no direct contact with the overlying intercostal nerves exists.

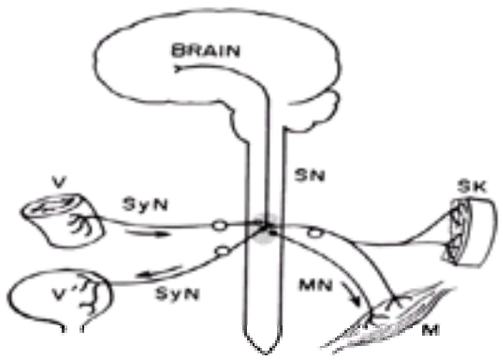

Figure 9-15. Diagram to depict Mackenzie's theory of mechanism of visceral referral of pain and related reflexes. An adequate stimulus from viscus (V) is conveyed to the spinal cord by afferents associated with sympathetic nerves (SyN) and stimulates spinal cord cells. If this stimulus produces activation of a pain pathway (SN), it results in pain being referred to the peripheral distribution of the somatic nerve from the skin (SK). The visceral stimulus also activates other neurons, which cause a reflex contraction of the skeletal muscle (M), supplied by motor nerves (MN), and also provokes a viscerovisceral reflex (V'). If the visceral stimulus is of sufficient intensity it may leave an *irritable focus* in the spinal cord (*stippled area*), resulting in cutaneous hyperalgesia, vasomotor and sudomotor changes in the skin, and persistent muscle contraction. (Modified from Mackenzie J. *Symptoms and their interpretation*. London: Shaw and Sons, 1912.)

Ruch (54) pointed out that Mackenzie's irritable focus theory, which is an extension of Sturge's and Ross' hypotheses, amounts to the suggestion that visceral impulses facilitate cutaneous impulses that originate in the skin, but that are insufficient in quantity to excite the spinothalamic tract fibers. Ruch (54) called this the *convergence-facilitation theory* to distinguish it from his own *convergence-projection theory*, which he first proposed in the early 1940s. Ruch's convergent-projection theory suggests that referred pain is brought about by the convergence of visceral afferent fibers with cutaneous nociceptive fibers on the same neuron at some point in the sensory pathways, at spinal, thalamic, and cortical levels, and that the system of fibers is organized topographically to provide the dermatomal reference (54). The first opportunity for this convergence is on the same spinothalamic tract neurons (Fig. 9-16). The resulting impulses, on reaching the brain, are misinterpreted as originating from somatic structures (such as the skin), because this had been the interpretation learned from previous experience in which the same tract fiber was stimulated by cutaneous afferents. The same explanation serves equally well for referred parietal pain, for example, as for that obtained by stimulation of the diaphragm. Although this theory accounts for the localization of referred pain, it does not address the issue of referred hyperalgesia.

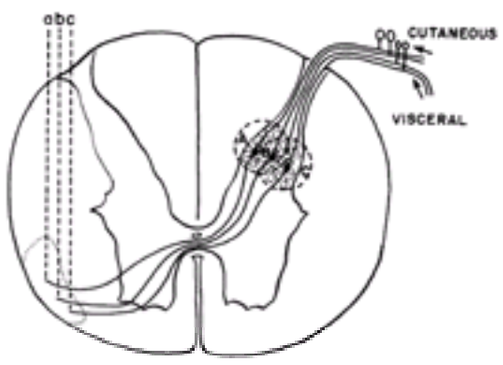

Figure 9-16. Diagram illustrating Ruch's theory on the mechanism of referred visceral and somatic pain. This theory is based on Sherrington's neuron pool concept. Because there are many more primary afferent fibers in the posterior roots than there are spinothalamic tract neurons, several primary afferent fibers converge on one spinothalamic tract neuron. *A*, *B*, and *C* represent a neuron pool consisting of all the spinothalamic tract neurons in one segment of the spinal cord. *A* is the field of neurons having connections only with afferent fibers from cutaneous sense organs. *B* is the field of overlap constituted by spinothalamic tract neurons that receive impulses from both visceral and cutaneous afferents, and impulses in *B* give rise to pain referred to the skin. *C* indicates those neurons of the pool that connect only with afferent fibers from the visceral cavities and give rise to unreferred or true splanchnic pain. Only one neuron in each category is represented; others are indicated by *ghost cells*. *a*, *b*, and *c* are fibers in the spinothalamic tract having cell bodies in fields *A*, *B*, and *C*, respectively. (From Ruch TC. Pathophysiology of pain. In: Ruch TC, Fulton JF, eds. *Medical physiology and biophysics*, 18th ed. Philadelphia: Saunders, 1960:350–368, with permission.)

In 1937, Morley (55) published an alternative explanation for referred pain based on the concept of the presence of efferent collaterals associated with afferent nerves. Stimulation of one of the afferent fibers could result in impulses that are conveyed antidromically by one or more of its efferent collaterals, and this causes liberation of chemical metabolites in the skin that stimulate nociceptive fibers. In 1948, Sinclair, Weddell, and Feindel (56) extended the hypothesis and proposed that “an essential factor in the production of referred pain is the existence of branching among the sensory pathways conveying the sensation of pain.” This theory suggests that the branched neurons innervate both somatic and visceral sites such that the source of afferent activity is obscured. Figure 9-17 summarizes the theories of referred pain. In the last three decades of the twentieth century, experimental evidence has been acquired to support both the visceral-somatic convergence theory and the peripheral nerve-branching theory.

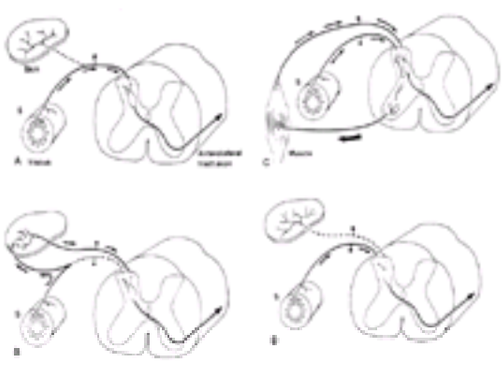

Figure 9-17. Summary of the most important theories of referred pain. **A:** A single primary afferent fiber, which branches to supply two structures, a viscus and the skin. Disease of the viscus causes stimulation (S) of the afferent fiber and thus produces impulses that reach the dorsal horn, where they are transmitted to cell bodies whose ascending axons transmit the message to the brain. Because the brain receives *pain* messages from the skin much more frequently than from the viscus, it misinterprets the location of the pain as being in the skin. **B:** Referred pain caused by antidromic activation of receptors at a distant secondary site. Disease of the viscus causes stimulation, which provokes impulses. Instead of passing to the dorsal horn, the impulses pass antidromically to the skin, where pain-producing substances are released and sensitize the terminals of cutaneous nociceptors so that innocuous stimuli can cause pain. In this case the brain correctly localizes the site of origin of the nociceptive messages, but not the site of the original pathologic process. **C:** Referred pain resulting from reflex phenomena. Stimulation of the diseased viscus provokes impulses that pass to the dorsal horn and then to the anterior horn. These cause powerful and sustained reflex muscle contractions and activation of muscle nociceptors. Impulses from these nociceptors are transmitted to the dorsal horn and thence to cells whose axons pass cranially via the anterolateral quadrant to the brain. As in the process described in **B**, the brain correctly localizes active muscle nociceptors but not the site of the original pathology. **D:** The convergence-projection hypothesis of referred pain, which suggests that visceral afferent nociceptors (S) converge on the same pain projection neurons as the afferents from the skin in which the pain is mistakenly perceived. (From Fields HL. *Pain*. New York: McGraw-Hill, 1987:90–91, with permission.)

Visceral-Somatic Convergence

Experimental data for the existence of convergence of visceral and cutaneous afferent fibers were first demonstrated in 1968 by Pomeranz and associates (57) in the thoracic spinal cord of cat, and a year later by Selzer and Spencer (58) in the lumbar cord of the same species. Both groups showed that many neurons within the gray matter of the spinal cord responded to electrical stimulation of skin nerves, and, in addition, could be driven by stimulation of the splanchnic nerves. Analysis of the visceral afferent fibers involved in the convergence showed that only small myelinated and unmyelinated fibers converged onto spinal cord neurons. These findings were confirmed by Fields and associates (59), and several years later they were confirmed by Guilbaud and associates (60). The latter group reported that only those spinal cord neurons that had a cutaneous noxious input could also be excited by injection of algogenic substances into the mesenteric artery. These and other older studies were cited in the report by Foreman and colleagues in 1981 (61), and Cervero (62) showed that visceral noxious input converged mainly onto those neurons having a noxious cutaneous input. Neurons in the spinal cord driven exclusively by innocuous stimulation of the skin were rarely driven by visceral input.

More recent work also has demonstrated that the neurons that have visceral and somatic convergence and that respond to visceral nociceptor stimulation have superficial receptive fields in the area expected for that viscus [see Foreman (63) and Willis (64) for references]. Thus, Foreman and Ohata (65) found that those neurons in the thoracic spinal cord of cat that had responded vigorously to coronary artery occlusion had superficial receptive fields in the left forelimb and shoulder of the animal. In his study of nociceptors of the gallbladder, Cervero (66) noted that those neurons activated by noxious intensities of biliary pressure had cutaneous receptive fields in the flank of the animal at the thoracoabdominal junction. These neurons could be activated by noxious and innocuous cutaneous stimulation of the receptive field as well as by stimulation of the muscle layers beneath the skin. Cervero (2,3) has pointed out that these types of cutaneous superficial inputs originate from the area to which the pain of biliary origin is usually referred in humans.

Finally, others have shown that nearly one-half of the neurons in the thalamic nuclei in which the spinothalamic tract terminates respond to noxious cutaneous inputs and to noxious stimulation of the abdominal viscera, and that visceral and somatic convergence has also been found in neurons in the somatosensory cortex of cat (3,64). Thus, findings in the experimental animal support Ruch's prediction.

Branching of Peripheral Nerves

Several investigators have found evidence of bifurcation in central and peripheral axons of dorsal ganglion cells (31). Perl and colleagues (67) have observed collateral projection of some mechanical nociceptors to receptive fields in skin and muscle. Bahr and associates (68) were able to activate dorsal root ganglion cells antidromically from the sympathetic chain (which contains visceral afferents) and a cutaneous nerve. Pierau and colleagues (69) have demonstrated that individual dorsal root ganglion cells can sometimes be activated by stimulation of two different peripheral nerves. Because these responses could be shown even after dorsal rhizotomy, they could not depend on spinal cord mechanisms. Double fluorescent dye transport studies (69,70 and 71) have provided additional evidence for branching of peripheral fibers, which supply both visceral and peripheral structures. Although it is possible that they may play a role in referred pain, the function of these dichotomizing fibers has not been conclusively demonstrated.

BIOLOGY AND PATHOPHYSIOLOGY OF ACUTE PAIN

The first edition of this book contains a detailed discussion on the long-standing controversy as to whether pain is a physiologic sensation with a protective function or a pathophysiologic phenomenon that is not protective but destructive. Biologists, physiologists, and other scientists have long adhered to the thesis that pain has the important biological function of signaling to the organism that it is in danger or of the existence of a noxious stimulus or agent, and that it is associated with immediate protective reflexes that tend to maintain homeostasis. Sherrington defined pain as “the psychological adjunct to an imperative protective reflex (72).” Other writers, especially clinicians who frequently treat patients with persistent or chronic pain, have opposed the biological protective concept. Leriche (73) wrote that “physicians too readily claim that pain is a reaction of defense, a fortunate warning which puts us on our guard against the risks of disease . . . I would oppose this extraordinary error, whose persistence I fail to understand, which has no shadow of justification.” These opposing views reflect a major difference between acute and chronic pain. With certain acute injuries or visceral disease, the pain and the associated reflexes have an important biological function that prevents further tissue damage. On the other hand, Leriche (73) and others, in taking the antiprotective function position, were speaking of the “pain associated with cancer, causalgia and neuralgia, which has become pathologic because of its mental and physical effects,” thus pointing out differences between acute and chronic pain. However, acute pain does not always have a beneficial biological function. The pathophysiologic effects of severe acute pain in the postoperative period, as well as with certain injuries, can be detrimental. Bonica (74,75) repeatedly emphasized these points, and they are reexamined here under the following headings: Biological Function, Relation of Pain and Injury, and Pathophysiology of Acute Pain.

Biological Function

Transient acute pain, as occurs when a person touches a hot stove or steps on a sharp object, promptly alerts the individual and causes him or her to immediately withdraw the limb and thus avoid further damage. Acute pain associated with more severe injuries involving deep somatic structures, such as fractures or sprains, imposes limitation of action and therefore tends to prevent further damage or aggravation of pathophysiology. The protective biological function of acute pain under these circumstances is widely accepted and appreciated. Similarly, acute pain of visceral disease has the biological function of warning the individual that something is wrong, it prompts him or her to consult a physician, and it is used by the physician as an aid in making the diagnosis. Moreover, as previously mentioned, acute pain associated with injury or disease is often associated with certain segmental and supersegmental reflex responses that help the organs maintain homeostasis. These autonomic reflex responses permit a person to *fight or run* and later enhance the healing process. In all of these and other circumstances, the pain and the associated reflex responses have an important biological function.

In some instances, the warning signal (pain) comes too late to avoid injury. Sunburn is a good example: We do not feel the pain until after the too-lengthy exposure to the sun has occurred. Similarly, in most visceral diseases, the pain is produced long after the beginning of the pathology, and therefore it is of no value as a protective reflex. Moreover, in many instances, injury to somatic structures occurs so rapidly that the associated pain does not help to prevent the injury. Indeed, some individuals who sustain an accidental injury experience no pain for minutes or even hours after the injury.

Relation of Pain and Injury

The phenomenon of a painless period after an injury has been reported by many writers. The most famous and widely quoted report was that of Beecher (76), who surveyed wounded soldiers admitted to the U.S. field hospital on the Anzio beachhead and noted that only one-third had sufficient pain to ask for medication. Similar findings of an initial painless period were reported by Carlen and associates (77), who studied Israeli soldiers who had suffered traumatic amputation during the Yom Kippur War. During World War II, Bonica also encountered wounded patients who, on questioning, stated they had felt no pain at the time of, and for some minutes after, an injury that subsequently required amputation of a limb. Although the incidence of a painless period after injury was significantly less than that reported by Beecher (76), it nevertheless was most impressive.

Injuries including fractures, severe sprain, and severe laceration that occur during contact sports are frequently painless for varying periods of time. Thus, the football player who sustains an injury may continue to play until he returns to the bench, or the boxer who sustains severe damage to his nose or face does not feel pain until the end of the contest. Such painless periods can be explained on the basis of stress-induced analgesia. However, painless periods are also experienced among persons who have incurred injuries in the home, at work, or in connection with vehicular accidents. This phenomenon was impressively demonstrated by Melzack and colleagues (78), who examined 138 consecutive accident victims admitted to the emergency department of a large city hospital. The injuries consisted of fractures (19%), sprains (18%), lacerations (17%), severe bruises (18%), and smaller percentages of amputations, stab wounds, burns, or crush injuries. Approximately 60% of the injuries were sustained at work or in the home, and the remainder occurred in the street or were sports related. Among this group, 37% of the patients reported a pain- free period, which varied in duration: 53% with injuries limited to the skin had a pain-free period, as had 28% of patients with deep tissue injury. The analgesia was specifically spatially limited to the region of injury, and all patients eventually developed pain.

On the basis of some of the aforementioned reports, his own experience of a painless period after a severe laceration of the scalp, and his observation of the behavior of two animals that had been injured, Wall (79) developed an innovative conceptualization of the relation between acute injury and pain. He proposed that after acute injury there are three periods of response: the immediate phase, a secondary phase, and a tertiary phase. He attributed the painless period to circumstances in which treatment of the injury does not have the highest biological priority: the three obvious high-priority behaviors are fighting, escaping, and obtaining aid. In humans,

escape includes calling for help or organizing help. In discussing the results of their study, Melzack and associates (78) state that the painless period “may have survival value.” They suggest that a limit on pain after injury prevents the organism from being overwhelmed by pain and therefore allows it to carry out adaptive behavior such as escape, hiding, “playing possum,” and other maneuvers that might prevent further injury in a dangerous situation. The secondary phase is characterized by the combination of tissue damage, pain, and anxiety and represents a transition period between coping with the cause of injury and preparing for recovery. During this phase, most individuals who incur tissue injury have moderate to severe pain. The tertiary phase is characterized by limited activity, prolonged sleep, poor appetite, limited attention span, and sometimes depression. Wall (79) suggested that these characteristics are “the optimal tactic to encourage cure and recovery of the damaged tissue.”

Pathophysiology of Acute Pain

Although it is universally accepted that acute pain has a biological function under certain circumstances, it is not generally realized or appreciated, even by some physicians, that persistent severe acute pain may prove deleterious to the organism. Thus, severe postoperative pain not only has no biological function but, if not adequately relieved, can also produce abnormal physiologic and psychological reactions that often cause complications. Similar deleterious effects result if the severe pain of injury or of such diseases as myocardial infarction and acute pancreatitis is not effectively relieved after it has served its biological function. Indeed, even severe pain associated with certain physiologic processes such as parturition, if allowed to persist, produce deleterious effects. These detrimental effects are consequent to progression of the segmental and suprasegmental reflex responses and cortical responses to an abnormal state. Because of the potential deleterious effects of severe postoperative and postinjury pain, clinicians have focused increasing effort on preemptive analgesia. Aggressive attention to prevention and treatment of postoperative pain, including the use of multimodal therapies, has been a topic of several reviews (37,80,81 and 82).

Responses to Tissue Injury

Tissue destruction, whether from crush injury, fracture, operation, or internal disease, results in local biochemical changes and autonomic reflex responses that are intended to maintain body integrity (see Chapter 3). The local biochemical changes produced by liberation of intracellular chemical substances into the extracellular fluids surrounding nerve endings to induce local pain, tenderness, and hyperalgesia have been discussed earlier. In addition to sensitizing the nerve endings, these algogenic substances also act indirectly by altering the microenvironment consisting of smooth muscles, capillaries, and efferent sympathetic fibers (43). The nociceptors, thus activated, transduce the noxious stimuli into impulses that are transmitted to the neuraxis. On reaching the spinal or medullary dorsal horn, these impulses are promptly subjected to peripheral, local, segmental, and supraspinal descending modulating influences, which, together with other factors, determine their further transmission. Some of the nociceptive impulses pass to the anterior and anterolateral horn of the same and adjacent segments of the spinal cord to stimulate somatomotor and sympathetic preganglion neurons, respectively, and thus provoke segmental autonomic (nocifensive) reflex responses. Other nociceptive impulses coming from the periphery stimulate dorsal horn neurons, the axons of which make up ascending afferent systems in the spinal cord and higher parts of the neuraxis, and transmit the nociceptive information to various parts of the brainstem and brain. Some of the impulses that reach the brainstem provoke suprasegmental reflex responses; others may activate the supraspinal descending modulating system, and still others reach the brain to provoke cortical responses.

Segmental (Spinal) Reflexes and Responses. Segmental (spinal) reflexes may enhance nociception and produce alteration of ventilation, circulation, and gastrointestinal and urinary function. Thus, stimulation of somatomotor cells may result in increased skeletal muscle tension or spasm, which initiates positive feedback loops that generate nociceptive impulses from the muscle (43) (Fig. 9-18). In their classic studies, Lewis and Kellgren (26) noted that when the pain provoked by injection of the ninth thoracic interspinous ligament was severe, the upper belly of the rectus abdominus muscle developed severe spasm, which stood out as an obvious *phantom tumor*. This usually caused the subject to “cease breathing owing to a sense of fixation of the chest,” and there was flattening of the lower ribs and diminished movement on the affected side. Although the reflex spasm and pain disappeared within minutes after the injection of the hypertonic saline, the skin tenderness remained for a considerable period.

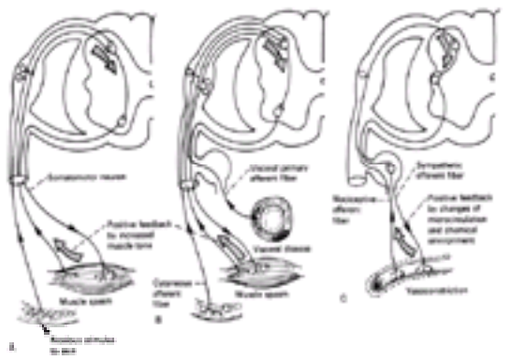

Figure 9-18. Diagram indicating possible mechanisms of self-excitation nociceptors by spinal reflexes. **A:** A somatomotor reflex induced by stimulation of cutaneous or muscle nociceptors causes skeletal muscle contraction, which in turn acts as a positive feedback to excite dorsal and ventral horn neurons (*arrows*) and produces an abnormal reflex mechanism, resulting in still further increase in muscle tension. **B:** A similar mechanism producing skeletal muscle spasm, initiated by a convergence of cutaneous and visceral primary afferents on viscerosomatic spinothalamic tract neurons. Stimulation of somatomotor neurons in the anterior horn produces reflex skeletal muscle spasm, which acts as positive feedback to produce and maintain a vicious cycle. **C:** Noxious stimulation of primary afferent fibers produces nociceptive input, some of which is transmitted to spinothalamic tract neurons. Other impulses travel to the anterolateral horn to stimulate sympathetic preganglionic (efferent) fibers, causing vasoconstriction, increased smooth muscle tone, and change in the chemical environment. The latter, in turn, acts as positive feedback to further increase nociceptive input.

Stimulation of sympathetic preganglionic neurons in the anterolateral horn of the spinal cord causes an increase in heart rate, stroke volume, and, consequently, cardiac work and myocardial oxygen consumption (38). In addition, sympathetic hyperactivity can decrease gastrointestinal tone that may progress to ileus and a decrease in urinary function that reduces urinary output. Because these responses to noxious stimuli occur in animals who have had vagotomy and C-1 spinal section, they are produced by truly spinal segmental reflexes.

It deserves emphasis that massive nociceptive stimulation not only sensitizes peripheral nociceptor afferents, but also can produce a nociceptive barrage that sensitizes dorsal horn neurons, interneurons, and anterior motor neurons. This is most likely to occur when C fibers from muscles, joints, and periosteum are stimulated and produce long-latency, long-duration facilitation that affects cells in lamina I and in deeper laminae and thus triggers prolonged increase in excitability of cells in lamina I and in deeper laminae (83). It produces a large expansion of receptive fields and can convert nociceptive-specific cells to cells that respond to light as well as intense stimulation (83). It also affects cells with receptive fields distant from the area served by the stimulated nerve. Although the facilitation is triggered by the arrival of impulses in C fibers from deep tissue, it is sustained by intrinsic spinal cord processes (84). This prolonged increase of excitability of central cells is probably the basis for widespread prolonged tenderness, hyperalgesia, that can persist for days or weeks after the injury (see Chapter 4).

Suprasegmental Reflex Responses. Suprasegmental reflex responses result from nociceptive-induced stimulation of medullary centers of ventilation and circulation, of hypothalamic (predominantly sympathetic) centers of neuroendocrine function, and of some limbic structures. These responses consist of hyperventilation, increased hypothalamic neural sympathetic tone, and increased secretion of catecholamines and other hormones. In 1929, it was shown that increased neural sympathetic tone and catecholamine secretion add to the effects of spinal reflexes and further increase cardiac output, peripheral resistance, blood pressure, cardiac workload, and myocardial oxygen consumption (85). In addition to catecholamine release, an increased secretion of cortisol, adrenocorticotropic hormone, glucagon, cyclic adenosine monophosphate, antidiuretic hormone, growth hormone, renin, and other catabolically acting hormones occurs, with a concomitant decrease in the anabolically acting hormones insulin and testosterone (85,86,87 and 88) (Table 9-2). This type of endocrine secretion, characteristic of the stress response, produces widespread metabolic effects, including increased blood glucose, free fatty acids, blood lactate, and ketones, as well as a generalized increased metabolism and oxygen consumption. The endocrine and metabolic changes result in substrate use from storage to central organs and injured tissue and lead to a catabolic state with a negative nitrogen balance. The degree and duration of these endocrine and metabolic changes are related to degree and duration of tissue damage, and many of these biochemical changes last for days (89). These and other findings have led to the development of the concept that inhibition of the stress response may improve outcome after surgery and trauma. To date, however, this hypothesis has not been adequately addressed in clinical studies (81).

TABLE 9-2. Neurophysiologic, endocrine, and metabolic response to injury

Psychophysiologic Responses

The intense anxiety and fear that develop in patients who experience severe acute pain consequent to an unexpected severe injury or acute myocardial infarction greatly enhance the hypothalamic responses characteristic of stress through cortical stimulation. Indeed, cortisol and catecholamine responses to anxiety may exceed the hypothalamic responses provoked directly by nociceptive impulses reaching the hypothalamus (90,91) (see Chapter 24). Moreover, anxiety and the related stress response can cause increased blood viscosity (92), clotting time (93), fibrinolysis (94), and platelet aggregation (95).

The deleterious effects of such reflex responses consequent to tissue injury and acute pain in producing complications have been reviewed (81) and are discussed in detail later in this book, but the following two examples illustrate some potential detrimental effects of acute pain. First, severe postoperative pain and the associated reflex responses are responsible for such pulmonary complications as hypoxemia, atelectasis, and even pneumonia. Moreover, as a result of powerful cutaneovisceral and viscerovisceral reflexes, patients develop ileus and decreased urinary output, as well as impairment of muscle metabolism, and are at increased risk of thrombus formation. That pain plays an important role is indicated by the fact that the excellent pain relief achieved with regional analgesic techniques can reduce complications (81) (see Chapter 41).

Studies of unpremedicated primaparas and multiparas have shown that the pain of uterine contractions causes a 5- to 20-fold increase in ventilation, with consequent severe respiratory alkalosis during contraction and alkalosis-induced hypoventilation between contractions (47). Moreover, the pain and anxiety produce a marked increase in sympathetic activity, resulting in increases of 50% to 200% in secretion of catecholamines and cortisol. These cause a significant increase in cardiac output and work of the heart and a marked increase in oxygen consumption, which is added to that inherent in the work of labor. This, together with loss of bicarbonate from the kidney (as compensation for pain-induced respiratory alkalosis and often reduced carbohydrate intake), can result in a progressive metabolic acidosis that is transferred to the fetus. The critical role of pain in these abnormal responses, which affect not only the mother but also the fetus and newborn, have been amply demonstrated by the use of regional analgesia, which eliminates the hyperventilation and markedly decreases the increase in cardiac output and other deleterious effects. These are discussed further in Chapter 71.

In conclusion, acute pain is commonly associated with injury or disease involving superficial and deep structures. Persisting acute pain stresses the injured or ill patient and can lead to deleterious physiologic and psychological effects. The relief of acute pain is an imperative for modern physicians.

---

*According to Sheehan (33), this concept was first suggested by Whyt in 1751, but his writing went unnoticed for 150 years until Hurst's investigations.

CHAPTER 10

General Considerations of Chronic Pain

Louis Jacobson and Anthony J. Mariano

> The world we have made as a result of the level of thinking we have done thus far creates problems we cannot solve at the same level of thinking at which we created them.
>
> —Albert Einstein

Chronic pain has customarily been defined as pain that persists for a specified time that is arbitrarily determined (e.g., 3 months or 6 months, or beyond the expected period of healing). A problem exists with this way of distinguishing chronic from acute pain. How would syndromes such as osteoarthritis be classified? Are they characterized by acute or chronic pain? In these cases, the syndromes may cause both acute and chronic pain. Acute pain may be initiated by ongoing stimulation of nociceptors, abnormal activity in inflamed tissue, or abnormal activity of sensitized neurons within the central nervous system (CNS), indicating tissue damage, but the pain extends over long periods. The fact that the pain may persist for years increases the likelihood that psychosocial and environmental factors will contribute to emotional distress and physical disability that are commonly observed with pain syndromes for which there is no ongoing physical pathology. Thus, two dimensions must be considered simultaneously, a time dimension and a pathology dimension. Pain that extends beyond the period of healing, in the absence of ongoing pathology, should be viewed as chronic pain. Pain of relatively short duration elicited by injury of body tissues and activation of nociceptive transducers at the site of local tissue damage should be viewed as acute pain. Pain, however, that extends over periods for which there is ongoing pathology might best be viewed as acute and chronic pain (see Chapter 2).

There has been a tradition within the literature to distinguish between chronic pain associated with cancer—"malignant pain"—and "nonmalignant pain," as from other syndromes unrelated to cancer. Little evidence exists to suggest that different neuronal elements are involved to warrant such a distinction. Moreover, given the discussion of acute and chronic pain, it is apparent that pain associated with a malignant disease may share features of both acute and chronic pain.

The term *chronic pain* as used in this chapter specifically excludes persistent pain that is associated with cancer. Although frequently confused in the literature, pain associated with malignant disease differs in several significant ways from the problems addressed in this chapter. First, pain associated with terminal cancer states is by definition time-limited. The problems and strategies outlined in this chapter are more appropriate for patients who are faced with the challenge of living with pain for many years. Second, pain associated with a malignant disease typically does not involve the conflict with the medical system and enmeshment in the legal-disability system that is characteristic of the population of chronic pain patients with pain not associated with neoplastic disease. Finally, pain associated with cancer is a symptom of a disease bearing a direct relationship predominantly with tissue pathology. In contrast, there is only a weak association between reported pain and objective findings of disease in chronic pain not associated with cancer (1,2,3 and 4). Of course, the treatment of pain associated with cancer can lead to new pain syndromes that are not directly owing to the neoplastic disease, such as radiation plexitis or painful neuropathy caused by chemotherapeutic agents. These pain syndromes are related to pathology in this case, iatrogenic and not neoplastic.

Thus, this chapter focuses on the large fraction of chronic pain patients for whom the cause of pain remains a mystery to biomedicine, because no associated lesion can be found or similar lesions exist in people who do not complain of pain. It should be noted, however, that many of the psychosocial and behavioral factor and related issues that we cover with regard to chronic pain not associated with cancer are relevant for consideration in treating patients with pain associated with cancer and for pain syndromes that share features of both chronic and acute pain.

Despite significant advances in medicine and the treatment of disease, chronic pain remains an enigma that health care professionals often manage poorly (5). Conventional understandings of disease fail to explain why some people are disabled by pain in the absence of an organic process that adequately accounts for the severity of their symptoms (1). Pharmacologic and somatic treatments fail to provide enduring pain relief. Patients who are overwhelmed by chronic pain fail to improve and are frequently intensely disliked by physicians (6,7). These patients are among the most debilitated, demanding, and dissatisfied of health care consumers (8,9).

The practitioners' challenge is how to help patients who attribute pervasive disability and dysfunction to persistent pain in spite of repeated failed treatment efforts and the absence of physical etiology. For the patient, intractable nonmalignant chronic pain is an overwhelming and all-consuming life experience. In a futile search for biomedical solutions, the patient develops a lifestyle that is centered around seeking diagnoses or treatment for pain, avoiding activities that are thought to cause pain, and attaining financial compensation for putative injuries or the inability to remain employed.

Recognition of the complexity of the problem is the initial challenge for the health care provider who wishes to help chronic pain patients. The report of the Commission on the Evaluation of Pain encourages an awareness by practitioners that chronic pain is best understood as a process that evolves over time (1). The chronic pain experience results from the entire progression of the patient's illness, the sociocultural context in which it occurs, and the interactions between health care professionals and patients (1). Iatrogenesis is a significant problem, and the health care professional who offers only biomedical "solutions" inadvertently risks becoming a large part of the problem. The challenge facing health care professionals is to learn new ways of thinking about chronic pain and disability.

The goals of this chapter are to provide an overview of chronic pain, outline key conceptual issues, and furnish broad clinical recommendations for the management of disabling chronic pain. Biological mechanisms of pain are reviewed briefly as a background for subsequent chapters in this book. More attention is focused on psychological and social factors that influence a patient's experience of pain, regardless of the presence or absence of a specific etiology.

The fundamental difficulties in treating disabling chronic pain lie in the philosophical and structural underpinnings of biomedicine. Cartesian dualism and notions of the "body as machine" permeate the culture of contemporary medicine and the medical-legal system of disability. Modern thinking about chronic pain emphasizes a more holistic approach that incorporates psychological, social, and cultural influences on pain and suffering (10,11). A general biopsychosocial systems approach to chronic pain is advocated (12,13), with special attention to the important role of the patient-provider interaction and self-care rehabilitation (14). From this perspective, practitioners frequently rely less on technical skills and more on interpersonal skills.

SIZE AND SCOPE OF THE PROBLEM

Disabling chronic pain is a major health care and social problem of epidemic proportions (15,16,17 and 18). Pain is the second most frequent complaint brought to the offices of providers in North America, after upper respiratory tract infections (1,18). Pain is also a common reason for hospital admissions (19). It is the most frequent cause of suffering and disability that seriously impairs quality of life (20).

A review of published information on chronic pain reveals both the magnitude and scope of the problem:

- Seventy million Americans report chronic pain, and many are permanently disabled (1).
- Approximately 10% of people in the United States have pain on more than 100 days per year (1).
- Chronic pain conditions, such as arthritis and migraine headaches, affect tens of millions of people.
- Low back pain (LBP) is the most common cause of workdays missed because of disability related to pain (14) and the condition that leads most often to workers' compensation claims (21).
- The annual incidence of LBP in the United States is estimated as 5% of the adult population (22), with a lifetime incidence or risk of 60% to 85% (23,24).
- The average sufferer has a long history of multiple episodes.
- Chronic, continuous back pain accounts for approximately one-fourth of the total prevalence (25,26). Seven million individuals experience LBP at any one time (1).
- Fourteen percent of the adult population in the United States have serious chronic back conditions, and approximately the same percentage experiences less severe back pain that is still significant enough to interfere with daily work or routine (27).

These findings also represent the experience of other Western countries, such as Sweden and Denmark (1).

The financial burden of chronic pain in the United States is astronomic. In 1987, the National Center for Health Statistics documented 70 million physician visits over a 3-year period in which pain was the primary complaint. These staggering numbers translate into more than 4 billion lost workdays for pain conditions (1). LBP alone costs at least $16 billion per year, with one-third allocated for medical costs and the remaining two-thirds for compensation (27).

Pathology alone does not account for the continued increase in disability and health care consumption related to chronic pain. The huge impact on the health care and social support systems of the inordinate amount of medical care expended on chronic pain is an important public health issue. Therefore, in addition to the suffering of individual patients, enormous medical and social resources are expended, and pain is costly in terms of compensation and loss of work (23).

Pain is especially challenging, because the more subjective the complaint, the more difficult and expensive it becomes to establish its relation to the inability to work (1). The award of disability for pain is growing rapidly (25). Conditions of the workplace are a better predictor of return to work than biomedical tests and measurements. Workers who do not recover from a back injury within several months have a high likelihood of progressing to long-term disability. Even among those who return to work after their injuries, the return to work is often unstable (28). Industrial injuries often have sequelae that persist beyond the time of the first return to work and may lead to recurring difficulties in the workplace. Therefore the recommendation is that the unit of analysis for the study of industrial LBP ought to be the individual who has the pain rather than an episode of back pain, and follow-up should continue for several years rather than for several months (29).

BIOLOGICAL MECHANISMS OF CHRONIC PAIN

The biological factors that contribute to chronic pain are considered under the following categories: peripheral, peripheral-central, and central. The following comments are intended to provide background material to chapters in Parts III and IV of this volume, in which detailed discussion of some of these hypotheses can be found. Chapter 6 discusses psychological aspects of pain in greater detail. Diagnostic issues are presented in Chapter 18, and treatment strategies are covered in Chapter 88, Chapter 89, Chapter 90, Chapter 91, Chapter 92, Chapter 93 and Chapter 94. Aspects of chronic pain are also covered in the chapters on regional pain in Part IV.

Peripheral Mechanisms

Peripheral mechanisms contribute to pain associated with chronic musculoskeletal, visceral, and vascular disorders. Peripheral pain conditions include arthritis, myofascial syndromes, chronic tendinitis, chronic ostalgia, headache, some forms of neoplasms, chronic pancreatitis, chronic peptic ulcer, coronary artery disease, and peripheral vascular disease. The pain may result from persistent noxious stimulation of nociceptors and their sensitizations (30). Alternatively, various reflex mechanisms and other factors may operate. These chronic pain syndromes are referred to as *nociceptive pain* because the pain is provoked by prolonged excitation of nociceptors. In addition, chronic pain produced by pathology limited to peripheral nerves without major irreversible change in the CNS is attributed to “peripheral mechanisms.”

The tissue damage of disease or injury causes liberation of endogenous chemicals, such as serotonin, histamine, bradykinin, and prostaglandins, which have excitatory effects on nociceptors. Many of these algogenic substances are both neuroactive and vasoactive. Excitation of nociceptors occurs either by direct action on the membrane of nociceptors or indirectly by altering their microenvironment. Depending on which substance predominates, there is impairment of the microcirculation with vasoconstriction or vasodilation. These agents promote a vicious cycle of nociception by increasing capillary permeability, enhancing the extravasation of additional algogenic substances, and perpetuating disturbances in the physiologic and biochemical microenvironment of nociceptors. Thereby, nociceptor excitation is increased.

Liberation of substance P from the peripheral nerve endings of nerve fibers, excited either orthodromically or antidromically, may exacerbate the peripheral nerve irritation. The role of algogenic substances in increasing the sensitivity of nociceptors to both noxious and nonnoxious stimuli is also discussed in detail in Chapter 4. Nociceptors are sensitized to nonnoxious stimuli, thus explaining the allodynia, hyperalgesia, and hyperpathia associated with chronic inflammatory disease.

Experimental studies show that chronic inflammation of the joint lowers the threshold to mechanical stimuli (30). A-d and C- nociceptor afferents are usually excited only by noxious stimuli. Nociceptive-specific neurons in lamina I of the spinal dorsal horn and neurons in the ventrobasal complex of the thalamus are also sensitized and are activated by light mechanical stimulation of the inflamed joint (31,32). The important role of peripheral mechanisms in chronic pain syndromes associated with chronic inflammation is suggested by the efficacy of aspirin and nonsteroidal antiinflammatory agents, whose action is predominantly peripheral (33).

Sensitization of nociceptors may occur after the administration of certain therapeutic agents and in various types of peripheral nerve injuries. The pain associated with peripheral neuropathies with no discernible nerve damage is also peripheral pain. Patients with neuritis (i.e., inflammatory reaction of the nerve without major permanent damage) experience relief with regression of the neuritis. The deep aching pain of brachial neuritis is alleviated by keeping the arm and shoulder motionless in the preferred position. The acute neuropathic disorders associated with leprosy are possibly caused by humoral antibody responses to systemically released antigen of *Mycobacterium leprae*. The nerve trunks are turgid with accumulated fluid, thereby resulting in tenderness and deep aching pain. That the symptoms may disappear with systemic corticosteroids strongly suggests peripheral mechanisms.

Persistent stimulation and consequent sensitization of nociceptors probably account for the pain of rapidly growing cancers of solid viscera associated with rapid distension of the investing fascia. A similar peripheral mechanism operates in tumor obstruction of large veins with consequent severe edema of the head or one of the limbs. Chronic obstruction of blood flow in arteries produces ischemia and consequent excitation or sensitization of nociceptors. Experimental data to support these speculations are meager, but clinical observation and experience suggest a peripheral mechanism.

Influence of Spinal Reflexes

Segmental spinal reflexes contribute to homeostasis. Acute disease or injury excites and sensitizes nociceptive afferents. This sensitization produces positive spinal reflex feedback loops that enhance nociceptor responses, induce excessive skeletal muscle tension, and increase sympathetic activity. Experimental studies suggest that tissue and nerve injury can cause prolonged increase in the excitability of cells in lamina I and deeper laminae of the spinal cord that can result in persistence of abnormal reflex muscle spasm and other reflex responses (34,35). These exaggerated responses may persist and contribute to the development and maintenance of

chronic pain states.

Clinical Implications

Pain due to ischemia from coronary artery disease recedes with bypass surgery and improved blood flow. Chronic pain due to persistent inflammation, such as arthritis, is relieved by drugs that decrease inflammation and prevent the synthesis of prostaglandins. Examples include aspirin and indomethacin. Local anesthetic injections into muscles (myofascial syndromes), tendons (tendinitis), and joints may relieve peripheral nociceptive pain. Pain attributable to joint degeneration is often relieved by removal of the affected joint and replacement with a prosthesis. These examples demonstrate the role of peripheral mechanisms in certain kinds of pain. Effective therapy may mitigate the long-term effects of persistent nociception on the CNS.

Peripheral-Central Mechanisms

Peripheral-central mechanisms are possibly relevant in chronic pain associated with partial or complete lesions of the peripheral nerves, dorsal roots, or dorsal ganglion cells that produce dysfunction in the neuraxis. Causalgia (complex regional pain, type 2), phantom limb pain, postherpetic neuralgia, and tumor invasion of peripheral nerves are clinical examples. The dysfunction involves both the central and peripheral nervous systems and is referred to as *deafferentation pain* (36).

A number of hypotheses, none fully inclusive, are proposed to account for these chronic pain states. These include the vicious circle mechanism, central summation theory (37), decreased peripheral inhibition theory (nerve dissociation theory, sensory interaction theory) (38,39), ectopic impulse generation or chronic nerve compression (40,41,42 and 43), deafferentation hypersensitivity (40,44,45,46,47 and 48), and the central biasing mechanism (49). They attempt to explain various clinical and experimental observations.

Patients with recent injury to a peripheral nerve may respond to targeted peripheral therapy. If early therapy is not available, the condition becomes refractory to treatment. It is as if the pathophysiologic process initially confined to the periphery becomes embedded in the neuraxis and is thereafter irreversible. Then, like central pain, it is intractable to therapy.

Central Pain Mechanisms

Disease or injury of the CNS may produce “central pain,” characterized by burning, aching, hyperalgesia, dysesthesia, hyperpathia, and other abnormal sensations. Central pain is associated with thalamic lesions (thalamic pain), spinal cord injury, surgical interruption of pain pathways, tabes dorsalis, syringomyelia, and multiple sclerosis. Integral to the genesis of central pain of spinal cord injury is the abnormal burst activity of deafferented neuron pools referred to as *pattern-generating mechanisms* (50). Diminished descending inhibition allows recruitment of extra neurons into the abnormally firing neuron pools, which intensify the pain and promote its spread. A detailed discussion of the mechanisms of central pain is presented by Tasker in Chapter 23.

CONCEPTUAL CONSIDERATIONS

Enigma of Chronic Pain

Patients present with the hope of a pain cure or a significant immediate symptom relief. Chronic pain puzzles patients because they are unable to comprehend why modern medicine cannot find a solution for their problem. Chronic pain frustrates providers because the etiology is usually unclear and satisfactory treatments are elusive (51,52,53,54 and 55). Complaints of incapacitating pain are reported either in a context of undiagnosable pathology or are grossly exaggerated in light of established physical findings. Little correlation exists between reported pain levels, physical findings, results of diagnostic tests, and observed disability (2,3 and 4). Carron's declaration that “minimal pathology with maximum dysfunction remains the enigma of chronic pain” epitomizes the challenge facing health care practitioners (56).

Over time, the course for many chronic pain patients is characterized by increasing disability in spite of multiple interventions. Brief periods of improvement often occur as new treatments are implemented, but these successes are typically short-lived, and the patient continues to decline functionally. Objective data suggest that the disease process is stable (or nonexistent) at a level that cannot account for the progression of subjective reports of distress and disability. The providers' enigma is that the patient's functioning is discrepant with the objective findings of pathology.

In the presence of this ambiguity, the relationship between the patient and the provider becomes strained and conflicted over time. To explain the discrepancy, the biomedically based provider, who relies solely on physical status to account for disability, typically concludes that the problems are psychological and either uninteresting or beyond his or her skills. Consequently, the patient is referred to a mental health practitioner, with either the explicit or implicit communication that his or her pain problems are “not real,” “in the head,” or psychogenic (57). Mutual frustration characterizes the relationship between “enigmatic” chronic pain patients and their providers. These emotions are fueled by failure of multiple treatments, distrust concerning the inadequacy of diagnoses, suspicion around the implications for disability determinations, tension over compliance with treatment recommendations, friction surrounding the voluntary control of symptoms, and conflict over rational surgical or pharmacologic treatment options.

“Overwhelming” Chronic Pain Syndrome

Despite the pain syndromes described earlier, many chronic pain patients do not present with a coherent, clearly defined constellation of symptoms and signs that denote a medical diagnosis. No common etiology, predictable natural history, defined course, or specific treatment exists for the multitude of painful conditions that suggests a basis for positing a single chronic pain condition (1). This void spawns a profusion of painful conditions with labels that masquerade as diagnoses but without a unifying rubric (10). Although the generic term *chronic pain syndrome* is widely used, it remains without official sanction. Like beauty, this syndrome is difficult to define, but one knows it when one sees it.

Much of the patients' and providers' frustration is traceable to this uncertain status of chronic pain within the scientific, clinical, and medical-legal communities. This lack of consensus among professionals and the conceptual tensions that emerge from different interpretations of related variables engender confusion and contradiction (1). What emerges is the designation of a “chronic pain syndrome” distinguished by behaviors and psychological characteristics that supersede the specific physical aspects of the painful condition (14). These characteristics are listed in Table 10-1.

An "enigmatic" presentation of pain to medical providers characterized by conflict and mutual dissatisfaction.
A lifestyle centered on seeking immediate relief from pain via repeated attempts to obtain medical or surgical treatment.
Repeated attempts to obtain pain-related financial compensation from social agencies such as Social Security, workers' compensation, and the Veterans Administration.
Significant disease conviction and excessive focus on somatic functioning.
Development of a variety of symptoms of psychosocial dysfunction that the patient maintains are secondary to pain. These include depression, alcohol abuse, illicit substance abuse for "pain relief," dependence on opioids or other medications with high potential for abuse, sleep disruption, excessive physical deactivation, severe family dysfunction, and significant disruption of vocational and familial roles.

TABLE 10-1. Characteristics of a patient with an overwhelmingly “chronic pain syndrome”

Even though the designation “chronic pain syndrome” implies a generic classification for an undefined ailment, it leads to confusion. We think it is a label born of desperation and used in the absence of anything more worthwhile. Chronic pain is common in the general population, but the full-blown chronic pain syndrome is relatively rare. With regard to chronic LBP, for example, only a small proportion of all individuals (5%) develop disabling chronic pain. They account, however, for a

disproportionately large proportion of the costs (85%) in terms of compensation and loss of work (22). The practitioner unaware of the distinction typically uses the same methods to address persistent pain in these qualitatively different problems. The iatrogenic process that begins as a well-meaning attempt to provide pain relief ends with the mutual frustration and conflict between provider and patient that is characteristic of chronic pain syndrome.

The term *chronic pain syndrome* causes misunderstanding relating to duration of illness and its implied benign nature, although one could argue that no pain is truly benign. The primary distinction for assigning pain as chronic is temporal. Chronic pain typically is defined as pain of longer than 3 months' duration. Patients with pain associated with a neoplastic disease, however, often have persistent pain for longer than 3 months and yet few manifest the chronic pain syndrome. The confusion between chronic pain associated with cancer and chronic pain not associated with neoplastic disease results in serious misunderstandings about their clinical management with regard to the long-term use of opioids (58,59). Providers inappropriately extrapolate management strategies for cancer patients to other types of chronic pain patients and advocate escalating opioid doses (60,61 and 62) without an appreciation for the differences in these populations (63,64). The chronic intractable benign pain syndrome (65,66) was proposed to differentiate these patients from those with malignant pain. The condition is, however, not benign and therefore it inaccurately represents the pain experience. Objections are raised about the use of terms such as *nonmalignant chronic pain syndrome*, with calls for more etiologically meaningful diagnosis (67). When specific, effective, targeted therapies are available, specific diagnoses are helpful because they profoundly influence the choice of treatment(s). With chronic pain, however, the presence or absence of an identifiable abnormality has little bearing on how a patient experiences pain, suffering, or disability (68).

Overwhelming chronic pain syndrome is a useful term because it accomplishes the hitherto elusive goals of creating a unifying rubric and overcoming the diagnostic conundrum. Regardless of the etiology of the painful condition and the presence or absence of a disease, enigmatic patients are universally both overwhelmed by pain and overwhelming to the medical and disability systems. Their distinguishing feature is that they repeatedly present to biomedical providers with pervasive disability and severe emotional distress that they attribute to pains that do not respond to conventional treatments.

Understanding overwhelming chronic pain syndrome begins with an examination of the process of help seeking. It is important to recognize that patienthood is a psychosocial, not a biological state (69). Many people with serious disease do not seek medical help. Conversely, in the case of chronic pain, many people without serious disease make use of medical services extensively. Rather than a disease, it is an experience in which psychosocial factors are better predictors of health care utilization than the number or severity of physical symptoms (70,71). Overwhelming chronic pain syndrome is fundamentally a psychosocial problem that is all too often managed in a biomedical culture and setting. It is a psychosocial condition with medical aspects, rather than a medical condition with psychosocial aspects (72).

Biomedicine underestimates the complexity of the pain experience. Understanding the process of medical help seeking by patients overwhelmed by chronic pain requires an appreciation of the distinction between disease and illness (73,74). Disease is a physical condition resulting from an organic process. Illness is the subjective experience and observed behaviors of an individual who believes that he or she is not well. Physicians diagnose and treat diseases and patients experience illnesses. It is pivotal to recognize that disease and illness do not stand in a one-to-one relationship and that the course of disease is distinct from the trajectory of the accompanying illness (69). Disease alone is neither necessary nor sufficient to account for the pain experience, and becoming well is not simply a matter of cure or pain relief.

Many contemporary health problems, of which chronic pain is a prime example, relate to illness rather than disease. Overwhelming chronic pain syndrome is an illness that has either no disease determinant or is discrepant with that accountable by disease alone (74). The incidence and prevalence of disease(s) are declining due to prevention and advances in early detection, elimination, and control of disease processes (75). Paradoxically, illness behavior, disability, health care utilization, and costs continue to increase. Chronic pain patients are overwhelmed by their subjective experience of illness, not by disease. It is this experience of illness, not the presence of disease, that motivates them to seek repeated medical treatment. The gap between disease as conceptualized by physicians and illness as experienced by patients requires bridging (69).

Social factors play a major role in the pain experience. The provider is an important source of social support through the medium of a healthy patient-provider partnership (76,77,78,79 and 80). However, the typical biomedical practitioner has neither the training nor the interest to address the many nonmedical issues that require consideration in treating people overwhelmed by subjective distress. Patients who stridently maintain that they have real physical disease in the absence of objective findings are difficult to manage because they do not respond positively to reassurances about their physical status. They vehemently object to suggestions that they have psychosocial problems other than those caused by pain. For the biomedical practitioner, such patients are overwhelming, both interpersonally and in terms of their demands for more and more service.

It is the mutual frustration and conflict among the patient, providers, and the medical-legal systems that distinguish the patient with overwhelming chronic pain syndrome from the more typical patient who has chronic pain but is easier to help. The addition of the designation “overwhelming” succinctly demarcates this distinction by identifying a unifying theme across many pain diagnoses. How practitioners attempt to help these patients is determined by their pain model.

MODELS OF CHRONIC PAIN

The chronic pain domain is inundated by a plethora of models. Eight prominent theoretical perspectives, categorized as either restrictive or comprehensive, have been posited to account for chronic pain (81). Restrictive models (mind-body dualism, psychological, radical operant-behavioral, and radical cognitive) ignore certain plausible facets of pain or potential interactions among them as either irrelevant or clearly secondary to the central facet of interest. Comprehensive models (International Association for the Study of Pain, gate control, nonradical operant-behavioral, cognitive-behavioral) take into account multiple facets and their reciprocal interactions. Colinearity among multiple and diverse facets of pain is clearly identifiable. The restrictive models are inconsistent with the empiric evidence. The evolution of thinking about chronic pain is characterized by progression from unicausal linear models to multicausal interactive models (82,83). It is repeatedly stressed in this textbook that only a comprehensive approach to chronic pain is plausible and capable of broad-based utility (81).

The choice of a particular model of pain is of paramount importance in determining the goals, methods, and desired outcomes of chronic pain treatment. Models are important because they determine the questions asked, the methods chosen, and the phenomena of interest to pain researchers. Models also dictate the behavior of health care practitioners in choosing diagnostic procedures, making therapeutic interventions, and making judgments about efficacy. Models determine how social institutions and agencies address the problem of pain (14). Therefore, the models profoundly influence the choice of which issues are relevant, the interpretation of clinical information, and the manner in which clinical and research questions are framed (84). In addition, the model has important implications for the expected behavior of both the provider and the patient during the therapeutic interaction. It virtually determines both the patients' and the providers' every clinical action and reaction.

One restrictive model, mind-body dualism (biomedical), requires further consideration because it has been the dominant perspective in Western medicine since the time of Descartes. It is also the ascendant lay model of chronic pain and the basis for the social health care structures that address the problem of chronic pain and disability. The biomedical restrictive model can be sharply contrasted with a comprehensive model, the biopsychosocial systems model, and both perspectives are examined in relation to the enigma of intractable chronic pain.

Biomedicine and Mind-Body Dualism

The biomedical model is enticing to providers trained in Western medicine because it offers the intricacies of diagnosis, therapeutic regimens that require sophisticated management, and the promise of exciting cures through the application of high technology. The clinical encounter is analytic, rationalistic, and scientifically oriented, with the putative painful disease process, and not the patient, as the main object of analysis. Pain is considered to be a sensory event, and the emphasis is on identifying the cause of nociception. Cure or pain relief is the desired outcome. It is assumed that once the pain is reduced, the observed disability will resolve.

Human beings are perceived in terms of their component parts and are fractionated into molecules, cells, organ systems, and body parts. Practitioners use sophisticated technical skills and resources in search of a diagnosis and a solution. They rely heavily on technology in the search for objective evidence of disease. Once the source of nociception is identified, treatments are initiated to fix the problem through surgical, physical, or pharmacologic interventions. Cure is contingent on precise diagnosis and rational treatment that is derived from pathophysiology and empiric research on clinical outcomes. Treatment is directed toward the underlying cause of the pain rather than its outward manifestations (the effects of the pain). Treatments considered most effective are those that eliminate or decrease the pain. It is usually assumed that the health care provider has the necessary expertise. The patient adopts a passive role while submitting to the expert recommendations of the physician (14). The patient's role is to follow the directions of the provider.

Reverence for objective information encourages a view of patients as repositories of disease rather than whole persons (85). The pain is separated from the person, who serves as its host. Cure-oriented physicians have no need to get to know pain patients, understand their individual values, or explore how illness affects their lives. When the goals are cure and pain relief, facts become differentiated from feelings, and the body becomes dissociated from the mind (85). Pain provides clues to diagnosis rather than existing as a phenomenon worthy of treatment in its own right. Patients are categorized as either diseased persons or as persons who erroneously believe themselves diseased. Becoming well involves either proper treatment or reassurance that “there is nothing wrong.” Patienthood is equated with pathology and interest is focused on the agents, the mechanisms, and the treatments of chronic pain (69).

Despite claims of biomedicine to a scientific basis that is both neutral and universal, social scientists point out the “hidden cultural scaffolding and social processes that shape practice and knowledge” (11). Some of these tenacious assumptions are so fundamentally linked to dominant Western philosophical traditions that they are taken for granted without awareness by the practitioner. Such background assumptions of Western biomedicine are exemplified by the belief that disease resides in the individual, independent of psychological and social influences, and the higher value placed on objective information rather than subjective patient reports. The result of such a world view is that the biomedical health care provider's attention is focused not on the patient but on the “it” of disease.

Chronic pain, however, challenges the central tenet of biomedical epistemology that there is objective knowledge, knowable apart from subjective experience (10). Pain is inseparable from psychological and social experiences, and there is no purely objective measure such as a “pain thermometer” (1,10). Without an objective measure of pathology that correlates with observed dysfunction, the biomedical practitioner is unable to form a rational treatment plan.

Despite growing dissatisfaction with health care, dualism is so entwined with the Western concept of the person that it remains the dominant model of health and disease in Western society. Most chronic pain patients adhere to this model as they cling tenaciously to their conviction that they have a “real, physical” disease. Patients respond poorly to traditional mental health services because they steadfastly insist that their primary problem is “physical, not mental pain.” The care of patients seeking medical treatment for symptoms related to psychosocial factors is difficult and costly. Multiple providers often treat one patient's pain from different perspectives with different goals. They exhaust all medical options, perform extensive diagnostic tests, and refer to numerous specialists for anesthetic and surgical procedures.

Rejected by biomedical practitioners who are no longer interested in their condition, patients search for other opinions, tests, and interventions. The health care system reinforces this notion and is unable to integrate the myriad of factors that influence a person's experience of pain and his or her search for pain relief. This often culminates in fragmented care, expensive and repetitive cycles of diagnostic tests, treatment failure, and a frustrating experience for both patients and providers. The medical-disability system insists on objective evidence of pathology before concluding that the patient is legitimately ill. Throughout this process, psychological and social factors are considered to be irrelevant in this restrictive model of pain.

The curative model fosters the clinical sciences that divide the care of patients among various subspecialties. The “soft” social sciences that examine intact human beings and their complex relationships are deemphasized. Subjective, immeasurable, unverifiable, and nonspecific phenomena that are not explicable by biological sciences are devalued. Psychological factors are ascribed a secondary role and regarded as trivial or spurious. Pain not conforming to current understanding of pathophysiology is disparagingly described as “all in the head.” The emphasis is on biological information as opposed to psychological or social data that are considered irrelevant to the disease process that is causing the pain. Biomedicine promotes the modernist belief that all things are potentially knowable (86). The implicit promise of modern medicine, based on the belief in inexorable progress, is that some day all disease will be conquered and, presumably, chronic pain, too. Although the concept of progress may be suitably applied to pure science, it creates problems for those in the health care professions because people are complex systems of whom complete understanding is unrealistic (86).

Biopsychosocial Systems Model of Pain

The enigma becomes decipherable with a shift from a biomedical to a biopsychosocial model, which views pain as an illness and an experience. The chronic pain experience is more comprehensible if viewed from a biopsychosocial perspective. This requires, however, that practitioners expand their skills beyond traditional biomedical methods, learn new conceptual models of chronic pain, acquire nontraditional skills, and become comfortable in different professional roles. The challenge is to create roles that use providers' expertise and skills while simultaneously providing services within a model that recognizes the complexity of chronic pain.

The biopsychosocial model is an alternative model for understanding health and disease that subsumes biomedical concerns and incorporates psychological and social dimensions (12). It provides a template for managing an individual person's suffering that is central to the chronic pain experience and compatible with current conceptualizations. Hanson and Gerber (14) have elegantly applied this perspective to chronic pain by building on cognitive-behavioral (75) and systems models (13) to develop a self- management approach.

From this perspective, responsibility for the daily management of pain and quality of life resides with the patient. Greater attention is given to the person with the disease than to biological processes. The provider's task is not to become more expert in the newest medication, intervention, and high technology, but instead to acquire the skills necessary to function effectively in the role of educator, motivator, and physician-healer (10,87,88,89 and 90). The provider is not a caretaker responsible for providing immediate pain relief to a passive patient. The role is one of an educator who assists an active patient in developing life-management skills and learning new ways to think about pain and coping.

In contrast to the reductionism of a biomedical approach, a systems model maintains that the whole is more than the sum of its parts. People, as living systems, are viewed from multiple levels of analysis ranging from the cellular to the social (13). Phenomena are best understood by studying interactions among the levels. From the biopsychosocial systems perspective, with regard to chronic pain, all three dimensions (biological, psychological, social) are considered as equally important determinants of the person's experience. Rather than positing simple cause-effect relationships, all aspects of the pain experience are in a continuous reciprocal determinism. Because the fundamental process is interactive, it is fruitless to attempt to identify any one dimension of the pain experience as more important than any other.

The enigma is not solved but rather dissolved. A cure does not exist for the multidimensional experience that is the overwhelming chronic pain syndrome. Therefore, questions of whether pain is real—that is, associated with pathology—are irrelevant. Pain is defined as simultaneously a physical and psychological experience (91). Rather than fractionating pain into separate parts, the biopsychosocial systems perspective regards nociception as inextricably embedded within a complex web of physical, psychological (cognitive, emotional, behavioral), social, and cultural factors (12,14,92,93). The person experiences pain and related disability in a wholeness inseparable from subjective states and social influence. Pain is lived as a whole, with perception, experience, and coping blending into each other as a unified experience (10).

A major focus of therapy initially is to assist the patient in moving from a biomedical perspective to a biopsychosocial model of chronic pain. Such a shift is critical in redefining the goals, methods, and expected outcomes of treatment. The provider adopts the role of a teacher or guide as opposed to a medical expert skilled in surgery, nerve blocks, or medication management. The patient is an active participant in the treatment process rather than a passive recipient of medical expertise. Therapeutic goals are rehabilitative and restorative rather than curative. The aim is to assist patients to develop pain management skills, identify targets for change in various areas of their lives, and accept more responsibility for the outcomes of treatment (see Chapter 109).

It is important to recognize, however, that a biopsychosocial systems perspective uses most treatments offered in traditional biomedicine, such as medications, physical, and psychological treatments. Rather than being diametrically opposed to a biomedical perspective, this model subsumes it (84). The biopsychosocial model is inclusive and fully accommodates all biomedical aspects, placing them in a broad context and providing guidance in the advisability and timing of their use. The major difference is that pain relief *per se* is neither the major goal of treatment nor the predominant focus of the clinical encounter. The biopsychosocial approach offers a wider scope of inquiry and intervention because biological factors are only one of many complex influences on pain. Efforts are made to shift the focus away from symptoms and to concentrate on strategies that increase functional activity and wellness despite the persistence of pain. The primary methods are educational, motivational, and interpersonal rather than medical, pharmacologic, or technological.

The biopsychosocial systems approach is tolerant of incomplete medical knowledge and accommodates medicine's limitations. When complete understanding is abandoned as a goal, the traditional tasks of the health care provider—listening, witnessing, educating, motivating, and relieving suffering—are no longer relegated to the small corner of medicine, the “art of medicine,” but return to its core (86). The biopsychosocial systems approach to chronic pain accommodates efficient, effective, and low-technology chronic care for a population of patients whose complexities outstrip the resources of a single provider. It effectively manages patients

who make inappropriate or excessive demands for services within organizations striving for cost-effective management.

CLINICAL CONSIDERATIONS

Patient-Provider Interactions and Chronic Pain: The Treatment Imperative

In 1974, Sternbach drew attention to the central role of the patient-provider interaction in the treatment of patients with overwhelming chronic pain (94). Many chronic pain practitioners and their patients participate in the mutually frustrating interaction termed the *pain game*. Reduced to its simplest form, the initial interaction between patient and professional proceeds as follows:

Patient (in obvious distress): I hurt. Please fix me.
Provider (with obvious confidence): I'll fix you.

When, however, neither a cause is identified nor adequate pain relief provided, the provider has little choice but to invoke one of the three Rs of biomedical chronic pain management: repetition, rejection, or referral. The diagnostic-treatment ritual can be repeated, the patient can be referred to yet another specialist, or the caregiver or health care system can simply reject the patient as having mental health problems, not physical problems. Over time, a variety of treatments are tried that ultimately fail, multiple investigations are offered, and referrals are eventually made to specialists. This cycle of defeat and frustration continues, the conflict escalates, and the relationship is terminated. The final meeting concludes:

Patient (indignantly): Another incompetent quack.
Provider (defensively): Another crock.

At this point, the patient transfers to another provider, and the process is repeated. The provider concludes that the reason the patient failed to respond favorably to treatment was because the pain was not real and there was “something wrong with the patient who did not respond to my perfectly good treatments.” He or she therefore repeats the process with the next patient who presents with similar initial problems because this patient has real pain and is a “good patient.”

The basic problem lies in the nature of the traditional patient-provider relationship (94,95). Both patients and providers share a biomedical model of chronic pain that regards the patient as a helpless victim of a disease. The fundamental challenge is to modify this process, in which the patient is assumed to present with clearly defined disease, the provider is expected to diagnose and treat a single cause, and cure or significant symptom reduction is the only meaningful outcome. It is further assumed that the provider is responsible for treatment outcomes and that any hope for improvement lies in the medical expertise of the professional. It is the responsibility of the provider to respond with some change in treatment until the patient reports satisfactory reduction of symptoms.

Use of the term *pain game*, although appropriate in the language system of transactional analysis, suggests that the patient is engaged in some sort of factitious effort to get well. For the vast majority of patients this is not true. The complaint of pain is virtually always real; malingering is rare. Similarly, providers unfamiliar with this terminology do not describe the process of being overwhelmed by such patients as any form of entertainment.

We prefer the term *treatment imperative* to describe this process because it emphasizes the tremendous professional, social, and interpersonal pressures that health care providers experience in their efforts to help patients (84). Chronic pain treatment is fundamentally a psychosocial process, not a scientific or technical endeavor. Patients are active participants in the treatment process, not passive objects of study. Overwhelmed providers are not dispassionate scientists who remain objective in their efforts to help patients. Regardless of the specific intervention, pain treatment always occurs in a psychological and social context in which the mutual expectations of the patient and provider interact to determine the exchange that occurs in the office (96).

A major impediment to treating chronic pain patients is the lack of awareness on the part of professionals of the importance of their own behavior on the patient's experience of chronic pain. The patient-provider relationship (76,77,78,79 and 80,95,97) is critically important for patients with overwhelming chronic pain and chronic illness. It is through their relationship with health care providers that patients seek validation of their problems for themselves, family members, and the various legal and social agencies involved in disability payments. Patients define the appropriate methods, goals, and desired outcomes of treatment through their interactions with helping professionals. It is difficult for patients to change their behaviors outside the office unless providers first change their own behaviors toward patients.

Role of the Health Care Professional in Chronic Pain Treatment

The behavior of the professional toward a patient who is overwhelmed by chronic pain depends on the model of pain used. A biomedical provider who values objective information and is most comfortable examining data minimizes interpersonal aspects of care. The clinical interaction is primarily one of gathering a report of symptoms, assessing the efficacy of current treatment, prescribing new treatments, and ordering further evaluations if the symptoms have not resolved. Practitioners work through an algorithm (list) of plausible treatments directed at pain relief. Both patient and provider share a biomedical view that maintains that social and psychological information is irrelevant, and a premium is placed on diagnostic and therapeutic procedures that can identify and eliminate “real” pain. The goals of treatment are curative, and the expectations are that treatment will attempt to provide maximal pain relief in the minimum amount of time.

In contrast, the biopsychosocially oriented professional functions as an educator-healer (84). In the context of stable chronic illness, a provider working from a biopsychosocial perspective feels little pressure to order additional high-technology investigations. Just as important as it is to know how to treat, it is important to know when to stop because there is no end to the number of potential treatments and procedures. No need to identify a single physical cause of pain exists because pain is assumed to represent a complex interaction across multiple systems of influence. Psychological information and social information are equally relevant to the patient's experience of pain and distress and are considered legitimate areas of clinical inquiry. Because the purpose of the clinical interaction is not to treat disease but to provide care (98,99 and 100), successful management involves the formation of a cooperative partnership in which there is clear communication, mutual respect, and trust (76,77,78,79 and 80,95,101,102). It is explicitly recognized that there can be healing without cure when one is attempting to help patients change their lives and not just their pain. The appropriate goals for such treatment are rehabilitative and long-term changes in function rather than immediate pain relief. Care is oriented toward patients taking responsibility for their own well-being, health, and functioning.

The key therapeutic challenge is to assist the patient in reconceptualizing chronic pain (the fourth *R* of pain management). The most fundamental goal is to change the nature of the patient-provider interaction by redefining the goals, methods, and outcomes of treatment (84). The focus of care is not to reduce pain but to redefine the problem. Decreased disability (14,103), increased ability (improved overall quality of life, increased function, decreased suffering), and decreased health care utilization (14,84,104) are considered meaningful goals of treatment.

The purpose of treatment is not to solve the problem of chronic pain but rather to dissolve it (84). Immediate pain relief is not the goal in the life-long management of chronic pain (84). By relinquishing pain relief as a primary goal and placing responsibility for rehabilitation with the patient (self-care), physicians are liberated from the shackles of the treatment imperative. Biopsychosocial care proceeds unimpeded by the specter of pain relief and the enigma is decipherable. Biomedical treatments are placed in a broad context and used as adjuncts to facilitate achieving a better life (84).

The fundamental assumptions in managing chronic pain are that it is a life-long condition not amenable to cure, patient-provider relations are pivotal, and beliefs and expectations determine outcome (84,105,106 and 107). A self-care, rehabilitation approach is advocated, healthy patient-provider partnerships are encouraged, and education and motivation are the primary tools (84). The most powerful therapy is the provider's attention, concern, interest, and careful listening. The practitioner who ignores the person and focuses on the disease, especially in cases in which there is no straightforward relationship between physiology and dysfunction, is part of the problem rather than the solution. Sir William Osler (108) provided the pivotal clue to deciphering the enigma with his statement: “It is more important to know what sort of person has a disease than to know what disease a person has.”

Patient and provider beliefs (105,106), expectations, and the quality of their interactions are more important than specific treatments in determining treatment outcome (107). Physicians should establish meaningful, long-term relationships with chronic pain patients that include social and interpersonal interactions. The common idiom “compliance with treatment” is pejorative because it carries connotations of fault with the patient, stigmatizes the patient, and ignores the role of the provider or medical system in the problem. *Cooperation* is a preferable term because medical consultation is a process of negotiation between the perspectives of the provider and the patient to elicit mutual cooperation in working toward common objectives.

Effective management requires an educational approach, a wise presentation of choices, and motivation based on mutual respect and trust. The processes of

relationship formation, education, and motivation enable patients to improve by adjustment of their beliefs and expectations. Effective communication and relationship building are optimally nurtured in an environment that values humanistic qualities and interpersonal skills. Getting to know a patient takes time. Transient encounters are inappropriate in long-term chronic pain management. Therefore, chronic pain care is best delivered in circumstances that allow for lengthy encounters over a long period. Efficiency-driven and time-limited settings typical of many outpatient treatment settings and acute care hospitals are incompatible with a biopsychosocial, self-care rehabilitation approach and instead reinforce the curative model.

Demedicalization of Overwhelming Chronic Pain

Demedicalization (74) refers to the efforts by health care professionals to reeducate patients that their disability and life problems are influenced by many other factors in addition to pain. Demedicalization is not an effort to convince patients that their pain is caused by psychological factors. Demedicalization does not preclude the use of active medical interventions. Rather, demedicalization is a process of challenging the belief that pain is the patient's primary problem and that medical interventions are the only solution. The full range of medical interventions are used but in a context that emphasizes the far greater importance of the efforts the patient makes in his or her own rehabilitation.

Chronic pain patients are stuck in an unhealthy equilibrium that is self-perpetuating and self-restrictive (109). They are overwhelmed by life and seek medical solutions for psychosocial problems. The more the traditional medical system rejects them, the more vigorously they pursue additional medical treatment and confirmation that their pain is real. Patients have elaborate, convoluted explanations for why they are helpless to change their lives. They lament that doctors victimize them and social agencies refuse to recognize the extent of their disability. They believe that they require further evaluations. They continue to stridently advocate for interventions that their providers believe are not indicated. A major goal of treatment is to engage these patients in a manner that supports them as people but challenges their dysfunctional beliefs about pain, its treatment, and the nature of their multiple problems.

Health care providers in general and physicians in particular ought to assume roles radically different from the Western tradition. The physician plays a pivotal role in demedicalization that transcends token “white coat credibility” (74,84). It is an active and crucial role because the physician has the skills, credibility, and authority to deliver the pivotal initial messages that patients can be better and hurt does not mean harm. He or she does this either alone or, preferably, in the context of the “team as the provider” (84). It is important that psychosocial providers understand, facilitate, and augment demedicalization to avoid couching their more holistically oriented treatments in a biomedical context. In the early stages of management, demedicalization prepares the way for full patient participation in their rehabilitation. In established patients, demedicalization is important in responding appropriately to somatic concerns, maintaining the biopsychosocial focus, and effectively managing lapse and relapse.

The process of demedicalization begins with the first clinical encounter. Despite numerous failures, the patient comes to the health care professional looking for pain relief. Most patients with overwhelming chronic pain are firm adherents of a biomedical model and have experienced many negative interactions with previous providers. They are highly sensitized to suggestions that their pain is “in their head.” It is very important that providers address this issue openly with patients and give reassurances that endorse the pain as real. It is helpful during the evaluation process to explain the detailed inquiry into psychosocial information as an attempt to get to know the patient as a person. Pain is a “family affair” and therefore spouses or other family members should be invited to clinical sessions and actively participate in the formal group education, individual evaluation, and long-term management process. Patients usually respond favorably to these approaches and are reassured after experiencing many previous negative “treated-like-an-object” encounters with providers.

Demedicalization requires that greater attention be paid to the person than to somatic processes and symptoms. Evaluation is directed toward understanding factors other than chronic pain that contribute to the person's experience of being overwhelmed. It is important to inquire directly about patients' beliefs concerning their own problems, what they want the providers to do, and what they are willing to do for themselves. Clear statements of the practitioner's own model of pain, clinic policies, and expectations about the process of working together are also helpful in identifying potential areas of conflict early in the treatment relationship. The interpersonal aspects of clinical care involve a continual process of negotiation and consensus building with regard to the nature of the problems and the appropriate treatments. The worst outcome is when the provider assumes the role of expert, neglects to ascertain the patient's beliefs, recommends treatment that is disregarded, and then manipulates drugs and doses in a futile effort to arrest the symptoms.

It is essential that patients are provided initially with a multidimensional formulation of their problems and the impact pain has on their lives. Previous biomedical providers have focused primarily on diagnosis and treatment of disease. A formulation, by contrast, is a set of working hypotheses about the patient's experience of pain, including past frustrations with medical care. An effort is made to communicate to the patient an understanding of the widespread impact pain has on his or her life. Rather than focusing exclusively on causes of pain, attention is paid to psychosocial factors that exacerbate and maintain disability. Special attention is given to identifying psychosocial factors that independently contribute to the patient's sense of being overwhelmed. The stage is set for subsequent long-term management by identifying pain as only one of numerous problems that a patient has in his or her life. The patient's belief that the only avenue leading to a better life is less pain is diplomatically but directly challenged. Patients are taught that only after they learn how to live better lives will they be less overwhelmed by pain.

This self-management perspective is not a grim alternative to failed medical interventions. A biopsychosocial self-care rehabilitation approach is recommended for the management of overwhelming chronic pain (11). It represents a positive option and an opportunity to develop a personal sense of control over pain and its effects. It matches the contemporary emphasis on social values of fitness, contentment, autonomy, individualism, self-control, and responsibility for one's own health and lifestyle. Patients who acknowledge that some pain is inevitable and that pain does not always lead to disability and who give up unproductive efforts to control pain are less disabled physically and psychosocially (105,110,111). Patients respond favorably to the message that they can be better, they may heal even if they are not cured, hurt does not mean harm, and they can do most things they want to do whether they hurt. Therefore, in the context of a supportive relationship, patients acknowledge and expect that cure is not possible. After many failures, most patients recognize the limitations of medicine (86). They become embroiled, however, in a new series of well-meaning but impossible promises as they continue the cycle of “doctor shopping.” Patients who are overwhelmed by chronic pain are desperately seeking help. The social-cultural-medical cure imperative drives them to follow the mirage of miracle treatments. Reformulation of the problem provides patients with the insight to switch their search to better care, not better treatment.

Patients should be offered a full range of medical, pharmacologic, and somatic interventions in the context of a self-management approach. Rather than promising pain relief, patients are informed at the outset that immediate and total pain relief is not an appropriate goal of treatment (84,111). Meaningful and prolonged change depends far more on patients' efforts in addressing their other problems. Patients who are physically deconditioned and lacking in essential social skills can expect to experience increased pain as they make efforts to change their lifestyle. In addition to somatic treatments, patients should be offered psychiatric or psychological care, counseling, family therapy, and drug and alcohol treatment, depending on the nature of their concomitant problems. It is important to realize that such treatment is not offered in place of medical treatment but rather as part of a treatment package for a “total person.”

Medications are offered as a means to “take the edge off pain” to facilitate physical, social, recreational, and vocational reactivation. Opioids are used rationally and are viewed as neither a panacea nor an ogre (medication to be avoided at all costs). The goal with opioids is to establish a stable, reasonable dose that does not escalate over time (58,59,63,64). The response to exacerbations in chronic pain is not to increase the medications. Rather, factors that potentially accentuate the patient's level of distress are explored. Exacerbations are more typically associated with life changes rather than biological changes.

Return visits emphasize the shift in focus away from pain symptoms to an emphasis on strategies that increase functional activity and wellness despite the persistence of pain (109). Emphasis in treatment is on helping the patient identify specific actions and facilitating the process of committing to change. In the context of patients making the cognitive reappraisal that they can get better and be well, they are asked to set specific behavioral goals for reactivation in areas such as recreation, socialization, and exercise. As long as cure is no longer promised, the emphasis is on what the patients are doing to help themselves have a better life. Failure to reach realistic goals that patients establish for themselves are recast as choices they make rather than treatment crises that demand changes in strategy and additional biomedical investigations and interventions.

From the provider's perspective, the actions of patients with overwhelming chronic pain seem self-defeating. They are, however, a way, albeit dysfunctional, for patients to maintain stability within their lives. Patients act in accord with their total experience of pain and any other way of behaving involves risk (109). Life in the “sick role” of a chronic pain patient may be safer, securer, and more predictable than life as a healthy, independently functioning adult (95,112). Although overt malingering is rare, the issue of secondary gain must be directly addressed. In addition to the frequently cited payoffs associated with disability compensation, access to opioids, or attention from spouses, the practitioner must be aware of the subtler reinforcement of the sick role. As long as the patient perceives himself or herself to be a “victim” of a disease (or an unfair medical or legal system), the patient is not responsible for the unsatisfactory circumstances of his or her life. A medical diagnosis endorses his or her disability. It enables the patient to reconcile personal failure and garner the privileges of the sick role. Overwhelming chronic pain legitimizes this role for overwhelmed patients unable to manage the demands placed on them. Demedicalization involves challenging this victim role and providing patients with access to the mental health or other services that enable them to learn more effective coping methods. The fundamental problem of these patients is not

that they cannot cope with pain but rather that they cannot cope without it. In these enigmatic patients, pain is often the solution, not the problem.

STRUCTURAL CONSIDERATIONS

The unsatisfactory results of treatment from both the patients' and providers' perspectives fomented demand for effective therapy. The complexity of overwhelming chronic pain requires an integrated multidisciplinary approach. Multidisciplinary treatment is essential in helping these patients (113,114). The structure of multidisciplinary care varies from inpatient programs affiliated with large teaching hospitals to time-limited day treatment programs, through to small outpatient clinics of cooperating professionals. Knowledge of the methods used by multidisciplinary programs is largely limited to the few that contribute to the published literature (115). Irrespective of the “local recipe” all formulae for multidisciplinary care require that the patient have access to medical and mental health providers who have a cooperative working relationship. Several broad issues are particularly relevant to the delivery of pain services by multidisciplinary teams operating from a biopsychosocial model of pain.

No single discipline has all of the skills and training necessary to address this multifaceted problem without consultation and participation from other professionals. Nevertheless, in the current health care environment, multidisciplinary programs struggle to survive. Fundamental systems-level changes are needed in the structure of pain programs, the models of service delivery, and the reimbursement for pain services (116,117). Several broad issues are relevant to the delivery of pain services by multidisciplinary teams using a biopsychosocial approach.

Beyond the identification of chronic pain as a clinical problem of interest, the term *pain clinic* implies nothing that is specific about the methods, models, or policies of a given program. Factors such as the reimbursement practices of insurance companies and the structure of the local health care delivery systems are important determinants of the types of services provided. Many “multidisciplinary” programs rely on invasive procedures and offer only lip service to a biopsychosocial approach (118). A multidisciplinary team working from a biopsychosocial perspective is more than a collection of specialists working independently. The defining characteristic of a multidisciplinary team is the integration and coordination among different disciplines in working toward shared goals. Effective teams do not simply treat the same patients, but rather work from a common biopsychosocial model of pain treatment. It is possible for a multidisciplinary team to inadvertently work within a biomedical model of pain if all participants simply treat the patient in parallel. A team composed of an anesthesiologist performing nerve blocks and a psychologist independently doing relaxation training foster the biomedical myth that immediate pain relief is the primary goal of treatment.

Multidisciplinary care is nurtured by interactive approaches to pain and disability. Traditional medicine is characterized by a hierarchical structuring of relationships among health care professionals. Physicians possess the most biomedical knowledge and consequently command the most authority. The hierarchy of rank determines to what degree other staff members can question decisions. Interdisciplinary teamwork, not an authoritarian hierarchy, best accommodates the needs of chronic pain patients. Effective teams recognize that biological, psychological, and social factors interact in determining the patient's experience. No single dimension is given primacy because it is explicitly recognized that it is impossible to separate out the various components of chronic pain. This recognition that “real” pain is not the sole province of physicians has important implications for the structure of the team. Traditional multidisciplinary structures, in which physicians are the team leaders by virtue of the primacy of their skills in a curative treatment model, are less relevant.

In addition to the prototypic multidisciplinary pain clinic described in Chapter 11, Chapter 18, and Chapter 109, other less complex approaches may be successfully used. Models of collaboration that emphasize an equal partnership between biomedical and psychosocial providers have been described (119). The codisciplinary approach (84,96,120,121) introduces the notion of the “provider as a team” (119,122,123) to those with overwhelming chronic pain. Patients and their families are seen jointly by a medical and a psychosocial provider for all clinic visits. This change in structure effectively communicates a biopsychosocial model to patients, facilitates the resolution of difficult patient interactions, changes patient expectations of physician behavior, and legitimizes the role of a mental health practitioner in chronic pain treatment. Codisciplinary care blends participating disciplines, incorporates the biopsychosocial system's ideal, and accommodates generic health care and ecosystemic approaches (74,119,122,123).

A biopsychosocial model requires that all involved providers, irrespective of discipline, function primarily as educators and motivators. Education and motivation are integral aspects of all clinical encounters, not the sole responsibility of nurses or psychologists in time-limited classes that teach coping skills. Initial extensive formal group education around key beliefs and expectations facilitates the initiation of cognitive reappraisal required for patients to shift the goals, methods, and outcomes of treatment (84). Although initial group education is helpful before individual treatment, the education process is ongoing. Patients may learn as much from their providers' own behavior (questions asked, treatments offered, explanations provided) in clinics as they do from more formal classes about pain.

Ultimately, it is all too often the structure of reimbursement systems and not the preponderance of scientific evidence that determines the nature of chronic pain services (124). Changes in health care delivery and reimbursement shifted the emphasis from inpatient to outpatient services (125). Attention has turned to managed care organizations (117,126). The cost-containment emphasis and the predominance of the biomedical model in reimbursement decisions has created tension between pain programs and the payers. In the interest of greater efficiency and improved outcomes, more effective screening procedures for pain programs have been suggested to select only “motivated” patients for treatment. The implementation of screening policies is understandable for structured pain programs to ensure “optimal return on their investment.” They do, however, beg a much more fundamental issue. What is the primary care provider to do with the vast majority of patients who do not meet such stringent eligibility criteria? Rejected by pain programs, such “unmotivated” patients return to their health care system and once more resume the process of searching for biomedical miracles.

Radical structural changes in reimbursement are needed to address the long-term care and management of difficult, high-utilizing patients. In pain programs that service capitated integrated network systems, such as the Veterans Administration medical system, health maintenance organizations, and national health care programs, patients rejected for pain treatment do not simply disappear but continue to demand more services. In fee-for-service settings, they simply fall by the wayside. Outside of a few specialized rehabilitation programs, screening criteria weed out those most in need of care. Consequently, we recommend no routine screening criteria despite many patients' active engagement in the pursuit of compensation for pain, significant psychiatric disorders, and many referrals because of provider discomfort with patient demands for escalating opioids (84,96,120). The key to success with such “unmotivated” patients lies in a focus on the patient-provider interaction and the formation of long-term relationships (see Chapter 94). Integrated network systems permit the formation of long-term treatment relationships rather than time-limited pain services. The Veterans Administration, in contrast to many health maintenance organizations, provides access to mental health service that patients receive concurrently with pain treatment. It also allows close coordination between pain specialists and primary care providers in long-term care.

Reimbursement practices based on biomedical curative models have not supported the delivery of systems-oriented biopsychosocial services. Acceptance of the biopsychosocial model seems impossible in a biomedically oriented reimbursement system. Changes in compensation are necessary before widespread access to integrated multidisciplinary care becomes routinely available. Ultimately, for wide acceptance, the structure of health care and the attitudes of caregivers need to change. Although change is slow, the reality of the exponentially escalating costs of treatment has led to the consideration of alternatives and experimentation (74,84,119,122,123). As the failure of models based on a no-cost denial of services becomes apparent, health care systems may consider low-cost alternatives (124).

CONCLUSIONS

Overwhelming chronic pain is a complex experience and not simply a biological event. Difficulties in pain management arise from the dominance of a dualistic model in medical training and clinical practice, the structure of health care and disability systems, and in lay knowledge. However, a biomedical model of pain dominates the delivery of services to chronic pain patients despite recommendations to the contrary by experts in the field (124).

Health care providers, insurance companies, and attorneys contribute to the problems of overwhelming chronic pain (109). To address the issues of overwhelming chronic pain, health care providers are required to scrutinize themselves and their own contributions to the problem. Patients who are overwhelmed by chronic pain are stuck in a “pain rut,” in which short-term strategies that reduce pain create long-term problems. Well-intentioned providers participate in this process by focusing on immediate pain relief as the primary goal of treatment. The inevitable failure of such efforts and the rejection of patients as not having real pain further intensify their search for biomedical solutions and documentation of disease. No villains exist in this mutually frustrating experience of the patient and provider. Pain patients are victims of providers trying their best to help them.

An important purpose of this chapter is to outline different ways of thinking about how to be helpful. The focus on interpersonal processes within a self-management model is not merely a poor alternative to biomedical treatment. It is the indicated treatment for those patients overwhelmed by problems of living, for which there are no rational medical options available. If one wants to help such people one has to learn new ways to think about the problem.

A major challenge to the health care system is the issue of severe disability that does not correlate with objective physical findings (see Chapter 17). In these enigmatic patients, pain is often the solution, not the problem (84). A medical diagnosis endorses their disability. It enables them to reconcile personal failure and garner the privileges of the sick role. Chronic pain legitimizes this role for overwhelmed patients unable to manage the demands placed on them. If patients are required to constantly prove that they are ill, it is impossible for them to get well. Acceptance of the complexity of chronic pain implies a rejection of the need to have objective evidence of pain to validate the patient's report of distress. The enigma of overwhelming pain is best understood and dissolved by never asking the initial inappropriate question(s). Chronic pain is a common idiom for communication, personal, and interpersonal problems (10). Patients with overwhelming chronic pain need better care, not more effective treatment. Care is an interpersonal process that occurs between a provider and a patient (98,99 and 100). Treatment is a technological process that occurs between a provider and a disease.

The chronic pain experience is a psychosocial problem with medical aspects rather than a medical problem with psychosocial aspects (72). Overwhelming chronic pain syndrome results from well-intentioned providers and health care systems trying to help patients but instead inadvertently reinforcing their illness conviction and more deeply entrenching their pain problem. No pill can cure and no surgery can excise the need to be sick (127). Patients' symptoms arise from cognitive, situational, psychological, social, and cultural factors that biomedical interventions fuel by their failure to abate. Pain patients are victims of a system that augments their need to be sick.

Disabling chronic pain is conceptualized as a marker of overwhelming distress, a dysfunction engendered by failure to cope with the demands of industrialized society. Chronic pain patients have a vulnerability to being overwhelmed by problems of living. Western medicine fuels the “chronic pain epidemic” by assigning medical diagnostic labels to ambiguous conditions (128,129). The process of medicalization is pervasive in biomedicine. Is degenerative disc disease, a natural continuous aging process observed in most people, best viewed as a disease process? What distinguishes it from graying of the hair, wearing of the teeth, and changes in the skin? The aging process, a natural continuous phenomenon, is viewed in disease terms as though it is a dysfunction (74). The health care system is an accomplice in the chronic pain epidemic, which is fueled by the processes of medicalization, somatization, and iatrogenesis (5,127,128,129,130,131 and 132). From the lifelong perspective of reducing disability, efforts directed at immediate pain relief are iatrogenic. The fruitless search for medical diagnosis, cure, and symptom relief fosters excessive health care use, iatrogenesis, somatization, medicalization, invalidism, and disability.

The understanding of the pain experience and the discipline of pain medicine have evolved greatly from meager beginnings. In the 1950s, enlightened and visionary providers questioned the value of somatic treatments (133,134 and 135), epitomized by nerve blocks performed in pain relief clinics (136,137 and 138). This healthy skepticism spawned the intellectual effort, inquiry, and experimentation that led to the progress that supplanted nerve blocks with more enlightened treatments. Pivotal contributions and milestones include multidisciplinary clinics (139), the gate control theory (140), behavioral techniques (141), the International Association for the Study of Pain and its journal *Pain* (139), analysis of interpersonal interactions (94), the biopsychosocial model (12), systems theory (13), the role of cognition, (75) and pain as a multidimensional experience (10,142).

The pioneering spirit and innovation that advanced the specialty of pain management ought to provide the impetus for the conceptual leap necessary to jump to the next level: a shift from coordinated to integrated care for chronic pain patients. To accomplish this change, it is essential that providers recognize the importance of relinquishing pain relief as a primary goal (84,106,111) and placing responsibility for rehabilitation with the patient (self-care) (14). It liberates patients from the stifling effects of the treatment imperative and enables biopsychosocial care to proceed unimpeded by the specter of pain relief. Another prerequisite for the shift is that multidisciplinary clinics and health care systems recognize the inextricable reciprocal relationships between the many facets that comprise the chronic pain experience (13). This serves as the springboard for the jump from coordinated to integrated care models. The integrated application of biological, psychological, social, and cultural factors in chronic pain management is essential to deciphering the enigma. A holistic view that unites mind and body and espouses an ecosystemic approach that blends the individual with his or her social contexts is crucial (74,84,122,123,142). An equal partnership between biomedical and psychosocial providers in generic health care teams is advocated (74,84,119,122,123). Thereby, the enigma is dissolved, and hitherto difficult and dissatisfied patients are managed satisfactorily. The major obstacle and challenge are that ecosystemic biopsychosocial care cannot be provided in a system that reimburses according to biomedical tenets.

CHAPTER 11

Multidisciplinary Pain Programs

John D. Loeser

In the introductory chapter, emphasis was placed on the need for a multidisciplinary/interdisciplinary (M/I) team approach to study the mechanisms of pain in general and many chronic pain syndromes in particular. Moreover, as mentioned there and emphasized in Chapter 10, the complex nature of these syndromes requires an M/I approach for evaluating patients and for developing and carrying out the most effective therapeutic strategies. Related to both issues are the needs of education and training in pain management. This chapter deals with all of these issues. The material is presented in three sections: evolution and current status of pain programs; description of the University of Washington (UW) Pain Center as one example of such a facility; and comments and conclusions regarding the development of such programs. More detailed discussion of the M/I approach to evaluation of patients with chronic pain syndromes is provided in Chapter 18. The implementation and results of this therapy are described in Chapter 109. This chapter is included at this juncture to serve as a bridge between the basic information contained in preceding chapters and the clinical aspects of the chapters that follow.

EVOLUTION OF MULTIDISCIPLINARY/INTERDISCIPLINARY PAIN PROGRAMS

Bonica first began to appreciate the need for a multidisciplinary approach to chronic pain during World War II after several months' experience in treating military personnel with a variety of pain problems at Madigan Army Hospital, Tacoma, WA. The writings of Leriche (1), Livingston (2), Mandl (3), and others (4,5 and 6) made neurologists, surgeons, and other physicians aware that blocking nerve pathways with local anesthetic was useful in managing patients with certain types of pain. As an anesthesiologist, he was referred many patients with major causalgia and reflex sympathetic dystrophy (now labeled *complex regional pain syndromes, types I and II*), painful phantom limb and other postamputation pain syndromes, myofascial pain syndromes, and obscure neurologic and musculoskeletal disorders. Not having had any experience with these procedures during his anesthesia training, Bonica read the available literature and proceeded with his assigned task.

In applying nerve blocks, he noted that patients with causalgia and other straightforward painful conditions responded to therapy, but patients with other complex chronic pain problems did not. Bonica realized that as a result of these factors, and because of lack of education in medical school and postgraduate training for specialization, he, like most other clinicians of his era, did not know the basic principles of managing patients with chronic pain. This realization prompted him to search the literature to acquire the necessary knowledge about the broad field of pain, especially chronic pain problems. He found that there was little information about the treatment of chronic pain, primarily because little research had been done, and that, other than the books by Leriche (1), Livingston (2), and Mandl (3), the available knowledge was scattered in numerous basic and clinical science journals and books, and thus inaccessible to the average physician.

Despite consulting the textbooks on medicine, neurology, and various other disciplines, Bonica continued to experience great frustration in trying to manage patients with complex pain problems by himself. Consequently, he sought the consultation of colleagues in neurology, neurosurgery, orthopedics, psychiatry, and other specialties in the usual manner inherent in traditional medical practice. Thus, if he wished to have a patient with a complex pain problem seen by an orthopedist, neurologist, and psychiatrist, each of these individuals would evaluate the patient in his or her office or in the patient's ward and then report the findings to Bonica by telephone, in writing on the patient's chart, or both. After the patient had been seen by all consultants, Bonica attempted to read the evaluation of each consultant and formulate a correct diagnosis and develop the best therapy. If questions arose he again contacted the consultant(s). It soon became apparent to him that to read and integrate the information of several consultations was slow and inefficient. This prompted Bonica to have frequent (two or three per week) face-to–face meetings in a conference room with all the specialists who had seen the patient, during which they reviewed each other's findings and discussed the case until they reached a consensus on the diagnosis and therapy. As far as is known from the literature and other sources of information, this was the first time that the M/I approach to pain was conceived and practiced.

These early experiences convinced Bonica that complex pain problems could be more effectively treated by an M/I team, each member of which would contribute his or her specialized knowledge and skills to the common goal of making a correct diagnosis and developing the most effective therapeutic strategy. These early experiences also led to the firm belief that much more research needed to be done on the basic mechanisms and pathophysiology of pain and that this also would require M/I efforts by groups of scientists and clinicians who could contribute their individualized expertise and skills to such studies.

By the end of his military duty in late 1946, Bonica had developed deep convictions about the need for (a) the widespread application of this multidisciplinary concept of pain management, (b) a better classification of pain syndromes, and (c) a textbook on the role, efficacy, and limitations of diagnostic, prognostic, and therapeutic nerve blocks.

First Multidisciplinary Pain Clinic

Immediately after World War II, Bonica put the concept of a multidisciplinary facility for the diagnosis and therapy of complex chronic pain problems into practice at Tacoma General Hospital, Tacoma, WA. The group consisted of an anesthesiologist, neurosurgeon, orthopedist, psychiatrist, internist, and radiation therapist, all of whom had special interest and some expertise in pain management. The group met every week or every 2 weeks and discussed complex problems. In addition to the members of the group, the conferences were attended by the patient's referring physician and others interested in the field, as well as by physicians in training (interns and residents).

At the beginning, a number of problems were encountered that were inherent in individual private practice. These included (a) the resistance by many physicians to accept the team approach and their reluctance to refer patients to the group, especially if the physician was in the same specialty as one of the members of the group; (b) difficulty in coordinating the time of conferences so that all of the key persons and the referring physician could attend; (c) difficulty in discussing the problem frankly, especially failure(s) of the referring physician and other specialists to make a correct diagnosis or to carry out effective therapy; and (d) the cost of the comprehensive evaluation, which was then considered too high. Despite these problems, for 13 years the group was modestly successful in its objectives and goals, and Bonica's conviction of the value of the multidisciplinary approach grew stronger.

Other Early Pain Clinics

After the war, Bonica had personal discussions with Dr. W. K. Livingston, who several years earlier had published his excellent book (2) and whose clinical research on pain and conceptualization of pain mechanisms made him one of this century's giants in this field. Bonica also communicated with a number of other anesthesiologists who were using diagnostic and therapeutic nerve blocks. In 1949, he met Dr. F. A. D. Alexander, who, unlike many other anesthesiologists, had a broad view of pain and its management (7). Alexander had independently developed the same concept, and in 1947 initiated a multidisciplinary pain diagnostic and therapeutic program at the Veterans Administration Hospital in McKinney, TX (8). During this early postwar period, a number of other anesthesiologists organized and ran *pain clinics*. Although some of these programs also involved other physicians as ad hoc consultants, the primary method of diagnosis and therapy consisted of various nerve block procedures, which at the time were the only nonsurgical treatment method besides drugs for pain control. These included programs in the United States developed by Woodbridge (4), Ruth (5), Rovenstine and Wertheim (6), Dittrick (9), Stubbs (9), Papper (10), Ruben (11), and Moore (12). In the United Kingdom, the first nerve block clinic was initiated in 1947 at the University College Hospital, London, by Dr. B. G. B. Lucas (13). The first multidisciplinary clinic was established in Oxford in 1964 by R. Richie Russell, who was a neurologist. Over the next decade, several other nerve block clinics were developed. The Intractable Pain Society was founded in Manchester in 1967 by Swerdlow; initially it had 17 members, but a decade later there were 59 members, 54 of whom were anesthesiologists. There were then 43 clinics, of which 23 had more than anesthesiologists on the active staff. From 1950 through 1970, similar clinics, usually based on anesthesiologic procedures, were started in most European countries, Canada, and Israel (14,15,16,17 and 18).

In New Zealand, the first nerve block clinic was started by Dr. Robert Boas in Auckland in 1971; it became multidisciplinary in 1972. Boas had received a year of training in Seattle and was strongly influenced by Dr. Bonica. The first pain clinic in Australia was founded by a multidisciplinary group of physicians at St. Vincent's Hospital in Sydney in 1962. This group published an article describing its early experiences in 1965 (19).

The first pain clinic in Japan was established in 1962 by Dr. H. Yamamura in Tokyo. Many other clinics developed in the subsequent decade throughout that country. Pain clinics did not develop in other Asian countries until the 1970s. Reviewing what is written about these earliest clinics suggests that there were physicians scattered throughout the world who recognized the failure of modern medicine to deal effectively with patients who suffered from chronic pain. Bonica's influence on the formation of multidisciplinary clinics and pain societies throughout the world started in the early 1970s when there were pain treatment facilities in most of the developed countries. The impetus for these clinics was clearly from individual health care providers, for little evidence exists that either governments or organized medicine had an interest in pain management.

Further Developments

By 1950, Bonica had records of more than 2,000 military and civilian patients he had treated alone and in collaboration with others, and he began to write a book on diagnostic and therapeutic nerve blocks. After formulating an outline, he undertook an exhaustive review of the literature and communicated with or visited many individuals working in nerve block clinics. From these various sources and personal observations he noted that (a) many anesthesiologists working in the field believed that nerve blocks were the primary diagnostic and therapeutic tools for most patients with pain; (b) many did not have the knowledge then available on pain mechanisms and had only a vague idea of the symptoms and signs of various pain syndromes and therapeutic methods available at the time; and (c) many were satisfied to act as mere technicians from whom the referring physician expected nothing more than a technical procedure. These experiences prompted Bonica to drastically alter the original format of the book and include large sections containing information about the anatomic, physiologic, pathophysiologic, and psychological bases of pain, general principles and guidelines for pain management, a classification and comprehensive discussion of the most important pain syndromes, and, of course, descriptions of the nerve block techniques as well as other therapeutic methods.

In this classic textbook, published in 1953 (18), Bonica emphasized the need for more research on pain, described the multidisciplinary approach to pain diagnosis and therapy, and emphasized the difference between acute pain and chronic pain. He proposed a new physician specialist, a *dolorologist*, as the leader of such a team. Although he realized that this was a hybrid term of Latin (*dolor*) and Greek (*logos*), he thought that the term would be more widely used than the term *algologist*, because at the time the term *dolorimeter* was widely used in pain research. In the late 1960s, Bonica began to use the term *algologist*. By the 1990s, the terms *pain management specialist* and *pain physician* were most commonly used, and neither *dolorologist* nor *algologist* had been widely accepted.

Although, as previously mentioned, during the early 1950s there were many pain clinics, only three were really multidisciplinary facilities. In addition to the one in Tacoma and the one directed by Alexander in Texas, there was one at the University of Oregon in Portland, directed by W. K. Livingston, who was then Chairman of Surgery. That program, which included the collaboration of Dr. Frederick Haugen, Chairman of Anesthesiology, and a number of other clinicians and researchers, was not only concerned with pain diagnosis and therapy, but was the first multidisciplinary pain research program supported by the National Institutes of Health of the United States.

His favorable experiences with these types of programs prompted Bonica, in the early 1950s, to begin espousing the multidisciplinary concept in numerous lectures and published papers, first in various parts of the United States and, beginning in 1954, in other parts of the world (20,21 and 22). During this period, Alexander also promulgated the multidisciplinary concept, but because of personal illness, he discontinued these efforts by the mid–1950s.

Start of University of Washington Pain Clinic

Promptly after his appointment as Chairman of the then new Department of Anesthesiology at the UW in 1960, Bonica enlisted the help of Dr. Lowell White, a neurosurgeon, and Dr. Dorothy Crowley, a member of the faculty of the School of Nursing, to develop a multidisciplinary pain clinic at the University. Because of his conviction about the multidimensional character of pain and of the importance of an M/I program, other specialists were recruited soon thereafter. Over the course of the next few years, the chairmen of the Departments of Psychiatry and Orthopedics and senior faculty in Rehabilitation Medicine, Clinical Psychology, Oral Surgery, General Surgery, and Radiation Therapy joined the pain clinic group. The program that Bonica started gradually evolved in complexity and the acquisition of support staff and space. By the late 1960s, he delegated leadership responsibility to other anesthesiology faculty.

Emergence of Pain Research and Therapy

Despite several hundred lectures and the publication of numerous articles in various parts of the world, the M/I concept was largely ignored by the medical profession for two decades. In the late 1960s and early 1970s, a number of factors converged to cause an increasing number of clinicians to put the concept into practice. These included the gradual development of additional M/ I clinics (23,24), the publication of the Melzack–Wall gate hypothesis (25), and the immense worldwide curiosity about the mechanism and efficacy of acupuncture as a method of pain therapy and for surgical anesthesia (26,27). Bonica planned and obtained funding from governmental and commercial sources for the First International Pain Meeting in Issaquah, WA, in June 1974. This gathering of scientists and clinicians led directly to the founding of the International Association for the Study of Pain (IASP) in 1974, and the publication of its journal, *Pain*, a year later. The willingness, indeed even eagerness, of the members of this multidisciplinary group to devote a significant amount of their time to the launching of IASP fulfilled Bonica's dream of making pain research and patient care an important scientific and medical activity throughout the world. The development of IASP, an international and truly interdisciplinary organization, was Bonica's most enduring contribution and the primary mechanism for the dissemination of the pain movement throughout the world. That organization has been extremely fortunate to have had Louisa Jones, who was originally a secretary for Dr. Bonica, as its Executive Director since its founding.

As also discussed in Chapter 1, these developments provoked an impressive surge in pain research, not only by neuroscientists, but also by behavioral scientists, and this work has added new dimension to the understanding of chronic pain and its M/I treatment. Other factors that nurtured this trend included (a) the training in the UW pain programs of a significant number of physicians from various parts of North America, Europe, Latin America, and Asia who subsequently returned to their homes and developed similar programs; (b) worldwide publicity given the UW facility in the lay press, several national television documentaries, and numerous articles in medical news media and scientific journals; and (c) during the period between 1969 and 1975, Bonica was invited by the ministers of health of a number of European and Latin American countries and Japan as a consultant to provide advice and direction for the organization and function of such pain management facilities. Key members of the UW Pain Center faculty also traveled through the United States and foreign countries carrying Bonica's message. Furthermore, those clinicians who had received training at the UW Multidisciplinary Pain Center returned to their home countries carrying both information and motivation inspired by Dr. Bonica and his UW colleagues.

Period of Growth of Pain Programs

From 1970 through 1990, the number of pain management facilities continued to increase. The proliferation of such facilities was so rapid as to prompt one medical

writer to refer to it as "medicine's new growth industry" (28). Because most of these facilities were directed by anesthesiologists, the American Society of Anesthesiologists, through its Committee on Pain Therapy, chaired by J. Modell, carried out a survey on such facilities in collaboration with the IASP and subsequently published the *Directory of Pain Clinics* in 1977 (29). Soon after it was published, as members of the committee, Bonica and Butler undertook the task of analyzing the report, which listed a total of 327 pain clinics. After studying the characteristics of each clinic, including the different number of specialties involved, the number and varieties of diagnostic and therapeutic methods used, and the number of pain syndromes treated, they arbitrarily classified them into the following categories: major comprehensive pain centers, comprehensive pain centers, monodisciplinary pain clinics, syndrome–oriented pain programs, and single–modality pain clinics. Of the entire group, 60% were located in the United States, 20% in Europe, 7% in Asia, an equal percentage in Canada, and the remainder in Australia and New Zealand. They also analyzed the distribution of these various categories in different countries and the specialty of the person in charge of each program.

Subsequently, Bonica recommended to the American Society of Anesthesiologists Committee on Pain Therapy that they adopt the aforementioned classifications and also suggested that the term *clinic* be used for outpatient facilities and the term *center* for programs with inpatient and outpatient facilities and educational programs. In 1979, the American Society of Anesthesiologists Committee, chaired by H. Carron, carried out a second survey and subsequently published the *International Directory of Pain Centers/Clinics* (30), which included the following classifications.

Major Comprehensive Pain Center. A major comprehensive pain center is an organized facility with space and personnel committed to the evaluation of the interaction of the physical, emotional, and sociological aspects of chronic pain problems, possessing the capability of developing a multidisciplinary approach to pain management. The following prerequisites are necessary to be identified as a major comprehensive pain center: space and beds assigned solely to the pain center; a professional staff representing five or more disciplines; full–time support staff (secretaries, nurses, therapists, and so forth); organized evaluative process for screening and selecting of patients; review and maintenance of records; participation of consultants of multiple disciplines; routine psychological assessment; ongoing research activities; organized training programs; availability of therapy appropriate for the physical and psychosocial problems found; and periodic evaluation of treatment results.

Comprehensive Pain Center. A comprehensive pain center is an organized facility with individuals or groups managing a great variety of chronic pain syndromes but unable to fulfill all the prerequisites for a major comprehensive pain center. The center should have the personnel and facilities for evaluation of the psychosocial as well as the physical aspects of chronic pain behavior and for administration of therapy appropriate to the problem found. To be identified as a comprehensive pain center, at least two– thirds of the criteria listed under major comprehensive pain center should be met.

Syndrome–Oriented Pain Center. A syndrome–oriented pain center is an organized facility that provides an in–depth study of all aspects of a particular pain syndrome and offers an acceptable treatment program for that syndrome. Examples of syndrome–oriented pain centers are low–back pain clinics and centers, headache or facial pain clinics and centers, cancer pain centers, and spinal cord injury centers.

Modality–Oriented Pain Center. The modality–oriented pain center is a facility that offers the chronic pain patient the appropriate therapy as defined by the specialty of the center. Other therapies may be used as adjuncts on a referral basis. Such a center may or may not provide extensive evaluative processes. Examples of such a center include nerve block clinics, transcutaneous electrical nerve stimulation clinics, acupuncture clinics, biofeedback clinics, and mental health centers.

Brena (31) analyzed the data in the 1979 directory and noted that of the 428 facilities, 278 (65%) were in the United States, 27 (6%) in Canada, 20 (5%) in Japan, 18 (4%) in Britain, between 8 and 12 facilities in each of the following countries: France, West Germany, Israel, Italy and Sweden; and the 21 other countries had one to five facilities. He also analyzed the density of pain clinics per 1 million population, and this ranged from 1.28 in the United States to 0.01 for Brazil. He also analyzed the distribution of clinical models among the pain control facilities and was also able to determine the medical specialty that directed the program in 335 of the facilities. The data presented in Table 11-1 are similar to those developed by Bonica and Butler from the 1977 directory (i.e., type of program and specialty primarily responsible for its direction).

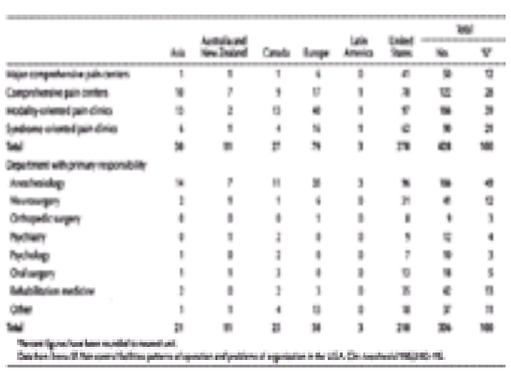

TABLE 11-1. Distribution of clinical models and medical specialties in pain control facilities

On the basis of various sources of information, it is estimated that in 1988 there were between 1,800 and 2,000 pain facilities in some 36 countries. Of these, 1,000 to 1,200 were in the United States, 200 to 225 in Britain, an equal number in Western Europe, 75 in Canada, 80 in Asia and Australasia, and the remaining countries had between 2 and 20 facilities. Making the uncertain assumption that the evolution of these centers has been similar to that before 1979, it could be roughly estimated that there were 150 to 200 major comprehensive pain centers, 500 to 550 comprehensive pain centers, 800 to 850 modality–oriented pain programs, and 350 to 400 syndrome-oriented programs. It is likely that these numbers will have doubled by the year 2000. Multidisciplinary pain centers have become a mature, recognized method of providing care to those who suffer from chronic pain. Texts have been written describing all aspects of their operation and discussing their efficacy (32,33,34 and 35). Diagnosis in a multidisciplinary pain center is discussed in Chapter 18, and treatment strategies and outcomes in Chapter 109.

Current Status of Pain Programs

Pain treatment facilities have now been created in almost every academic medical center and in hospitals of large and small size throughout the United States and Canada. Programs exist in most of the major cities of Central and South America and in every European country and most of its large cities. Pain treatment facilities are common in Japan and most of the Asian countries and are rapidly developing in China and India. New Zealand and Australia are also well supplied in the major cities. The only pain programs in Africa can be found in Egypt and South Africa; all of the Middle Eastern countries have some pain treatment facilities, led by Israel and Turkey. The qualifications of the personnel who staff these treatment facilities are variable, and no uniform standards for training or determination of competence exist. Only in the United States are there certifying organizations for individual providers and pain treatment facilities.

Sources of Concern

The impressive increase in the number of individuals who devote their time and effort to pain diagnosis and therapy and the large number of pain centers and clinics are gratifying, but they are also a source of serious concern. First, some of these facilities have been staffed by physicians and other health professionals who have had little or no training or experience in managing patients with chronic pain. Some of these well–intentioned clinicians have been attracted to the field because it is the fashionable thing to do; in other words, pain is the *in thing* of modern medicine. Of even greater concern is that some of these facilities are run by unscrupulous physicians and nonphysicians who use the current surge of interest in pain to exploit patients, as occurred with acupuncture clinics during the height of the public's interest in acupuncture during the early 1970s. These facilities run by dilettantes will surely be detrimental to the general cause of pain research and treatment and to the current international movement in the field, and, most important, will do more harm than good to individual patients.

Another concern is the implication that chronic pain is purely a psychological phenomenon. This has resulted from the involvement of psychologists and psychiatrists in the study of chronic pain, which has shown that the medical model is not sufficient to explain the abnormal illness behavior manifested by some patients and that the behavioral model of pain is required. This emphasis on chronic pain behavior resulting primarily from reinforcing environmental influences or so–called operant mechanisms is long overdue and has had a favorable effect on the management of many patients with chronic pain. Because these investigators have studied mostly patients with intractable pain caused by behavioral, psychological, and sociologic factors, they have come to believe that most, if not all, patients' chronic pain has

developed as a result of operant mechanisms or psychological factors. In view of the fact that in the United States only approximately 3% to 4% of all patients with pain are seen in pain centers and clinics (36), this is obviously a skewed view and does not include the more than 70 million Americans with chronic arthritis, cancer, complex regional pain syndrome, neuropathic pain, myofascial syndromes, and a host of other chronic pain syndromes in which the chronic pain is not caused primarily by affective and environmental factors, but rather to persistent dysfunction of the nociceptive system (tissue pathology, nervous system dysfunction, or both). Obviously, many of these patients are effectively managed by rheumatologists, orthopedists, neurologists, anesthesiologists, neurosurgeons, physiatrists, dentists, and other health professionals and need not be referred to a multidisciplinary pain program. On the other hand, as emphasized in Chapter 10, many other chronic pain patients are not effectively managed because of improper application of available knowledge and therapies. Such patients frequently develop physiologic, psychological, behavioral, and emotional problems and could benefit from a comprehensive M/I evaluation and rehabilitation program (see Chapter 18 and Chapter 109).

Another concern is the exploitation of a single modality to treat all patients, ignoring the unique needs of each. This is commonly seen in the pursuit of anesthesiologic procedures to treat chronic pain: Patients may have multiple blocks (until funding ceases) that do not lead to long–term improvement in the patient's functional status. Another example could be excessive physical therapy treatments, especially those that are *passive*, in the absence of functional gains. Finally, the fascination with alternative therapies is likely to deprive some patients who need comprehensive evaluation and treatment of an opportunity to obtain optimal outcomes.

Accreditation of Pain Programs and Certification of Specialists

Bonica repeatedly expressed concern for the proper training of clinicians involved in pain clinics, and soon after the founding of IASP he suggested that this organization, through its national chapters and perhaps with other professional societies, develop guidelines or criteria that could be used by facilities organized for the treatment of patients with chronic pain problems. It is now clearly recognized that accreditation of treatment facilities and certification of individuals must be a national or regional activity because of differing training and health care delivery systems. Within the United States, efforts were initiated in the late 1970s to establish guidelines and criteria for pain programs through the American Pain Society. During the course of several years, a committee of the American Pain Society, under the chairmanship of G. Aronoff, developed the criteria that were eventually accepted by the Board of Directors of the Commission on Accreditation of Rehabilitation Facilities (CARF). CARF, a nonprofit organization supported by the Joint Commission on Accreditation of Hospitals and a number of other national sponsoring organizations, has been surveying and accrediting rehabilitation facilities since the late 1960s. In 1981 the Board of Directors of CARF accepted the tasks of setting up criteria and surveying pain clinics and centers in the United States and in 1982 convened 13 regionally distributed full–time pain center directors to form the National Advisory Committee on Chronic Pain Management Programs. This group developed criteria and guidelines that were subsequently approved by the American Pain Society and CARF, and surveying of pain management facilities was begun in July 1983. Within 5 years, approximately 100 pain centers and clinics had been certified. By 1998, 204 programs had achieved certification. A summary of the evolution and function of CARF in evaluating pain programs has been published by Morse (37). CARF accredits pain treatment facilities, not individuals .

In the early 1980s, a group of physicians in the American Pain Society embarked on a program to establish certification for individual medical providers. They established an organization, initially called the American Academy of Algology, whose name was soon changed to the American Academy of Pain Medicine. The primary purpose of this group was to obtain recognition from the American Medical Association as a bona fide specialty and to offer a certifying examination for physicians. In 1998, the Academy had 1,200 physician members. It had been partially successful in obtaining AMA recognition and had established the American Board of Pain Medicine that had 827 diplomates who had passed their certifying examination. Pain medicine was still not a recognized specialty by the American Board of Medical Specialties. Similar programs both to certify individuals and accredit pain treatment facilities were being considered in many countries.

The American Society of Anesthesiology began to encourage training in pain management as part of anesthesiology residency training in the late 1980s. Fellowship training in pain management for anesthesiologists was not an official part of anesthesiology, however, and many individuals, as a response to community demand, claimed to be pain specialists with limited training. The American Board of Anesthesiology and the Accreditation Council for Graduate Medical Education held a series of meetings that led to approval of guidelines for pain education both in the anesthesiology residencies and in anesthesiology–sponsored pain fellowships. Training programs for pain fellowships were certified and a written examination was established to provide Advanced Qualification in Pain Medicine for anesthesiologists only. The first examination was offered in 1993 and it has been available in alternate years since that date; 1,541 anesthesiologists have been certified by 1998. There are 97 accredited pain management training programs as of this date. Only anesthesiology board–certified or board–eligible physicians may sit for this examination; those who have not trained in the United States are ineligible. The qualification is now known as Fellowship in Pain Medicine. No other specialty of American medicine offers a similar training program.

UNIVERSITY OF WASHINGTON PAIN CENTER

In the first decade after its founding, the multidisciplinary pain clinic program at the UW evolved into a group of 20 persons from 14 different medical specialties and other health care disciplines who participated in the activities of the program to varying degrees and devoted variable time and effort (20,21). Initially, the collaborative efforts of the pain clinic group were devoted exclusively to patient care and teaching, although certain members were doing independent research in their own laboratories. In 1971, Bonica recruited C. R. Chapman, an experimental psychologist who later became qualified in clinical psychology. Soon thereafter, a clinical and experimental pharmacologist joined the program, and we have subsequently recruited other basic scientists and clinical investigators with interests in pain research. The interaction, conceptual cross–fertilization, and scientific interchange made possible by these individuals and their efforts culminated in extensive collaborative research programs. As a result of the progressive growth of the program, especially research, in 1980 the Board of Regents of the UW designated the organization as the UW Multidisciplinary Pain Center. In 1983, Bonica resigned as Director of the Center and a major reorganization occurred under the leadership of J. D. Loeser. At that time, the Behavioral Medicine Division of the Department of Rehabilitation Medicine, led by Wilbert Fordyce, merged with the Anesthesiology Pain Service to create a unified patient care organization for those who suffered from either acute or chronic pain. This organization had inpatient and outpatient resources at the University of Washington Medical Center (UWMC). Faculty who worked at the affiliated hospitals (Seattle Veterans Administration Medical Center, Harborview Medical Center, Fred Hutchinson Cancer Research Center, and Children's Hospital and Medical Center) developed pain management services that were conceptually similar but totally independent of the Multidisciplinary Pain Center. Shortly thereafter, L. B. Ready began the relatively autonomous Acute Pain Service at the UWMC. This was designed to provide for the pain management of postoperative and posttrauma patients.

The separate inpatient and outpatient facilities were merged onto one ward of the UWMC in 1989, creating a wonderfully efficient base of operations for all of our pain management services. This also facilitated research and teaching programs. This ideal facility was dismantled in 1994, when the Multidisciplinary Pain Center was transferred to a primary care satellite clinic approximately 1 mile from the UWMC. At that time, a separate, hospital–based anesthesiology pain service was created to provide pain management services to all inpatients; only outpatients were to be cared for by the Multidisciplinary Pain Center. The fractionation of the Multidisciplinary Pain Center into separate sites and programs created many issues that interfered with the goals, finances, and training programs of the Multidisciplinary Pain Center.

Objectives and Goals

The primary objective of the Center has been to develop and maintain a broad M/I program for research, education, training, and patient care in pain and related areas. The specific missions of the Center are listed here:

- To enhance the quality of the care of patients with chronic pain referred to the UWMC and affiliated hospitals and to have the Clinical Pain Service serve as a model of an M/I facility for the diagnosis and therapy of complex pain problems
- To contribute to the education in pain management of graduate students of medicine, dentistry, clinical psychology, and other health professions
- To encourage the study of the basic mechanisms and the anatomic, physiologic, psychological, behavioral, and psychosocial aspects of acute and chronic pain, through individual research projects, program projects, and demonstration projects
- To encourage the development of research teams composed of critical masses of scientists and clinical specialists from appropriate disciplines to study some of the most important clinical pain syndromes, to evaluate current therapeutic modalities, and to develop new and better procedures for diagnosis and treatment of such syndromes
- To enhance interaction and communication among all pain investigators at the UW and to encourage cross–fertilization of ideas on pain research and therapy
- To educate and train biomedical scientists who will pursue careers in pain research
- To enhance the transmission of new knowledge about the diagnosis and therapy of pain to all practitioners of the health professions

The ultimate goal of these efforts is to contribute to the improvement of the quality of life for millions of persons who currently suffer needlessly from acute or chronic pain.

General Organization

To achieve its objectives, the Center was organized into two sections, the Clinical Pain Service and the Pain Research Center. The Center includes a staff of more than 50 scientists, physicians, and other health professionals who are members of or are affiliated with the following disciplines (in alphabetical order): anesthesiology, biological structure (anatomy), general dentistry, internal medicine, neurology, neurophysiology, neurosurgery, nursing, oncology, oral medicine, oral and maxillofacial surgery, orthodontics, orthopedics, clinical and experimental pharmacology, psychiatry and behavioral sciences, clinical and experimental psychology, rehabilitation medicine, sociology, and social work. Although some of the basic scientists' activities are limited to research and teaching, most of the persons are also involved in patient care. Their efforts are supported by more than 30 technical and clinical personnel and administrative and secretarial staff. The keys to such complex multidisciplinary efforts are effective organization of personnel and ample physical facilities, equipment, and financial resources.

Clinical Pain Service

The Clinical Pain Service includes outpatient and inpatient facilities for the diagnosis and therapy of all types of pain patients and for providing effective teaching and training programs for students of medicine, dentistry, and other health professions, for physicians in specialty training, for pain management fellows, and for practicing health professionals. The clinical pain services exist at each of the hospitals affiliated with the UW Medical School, as mentioned previously. At each hospital, clinical and support personnel are allocated to provide acute and chronic pain management services. At the UWMC, the Multidisciplinary Pain Center currently is located in a free– standing primary care clinic that manages outpatients and a separate service provides acute pain services as well as consultation and management for inpatients with chronic pain and for cancer patients who attend the Cancer Center at the UWMC.

Multidisciplinary Pain Center Personnel

Personnel include faculty and staff; almost all are full–time employees of the UW; many of the faculty spend only a portion of their professional time within the Pain Center. The following staff are required to operate the clinic:

Patient care coordinator: The patient care coordinator is responsible for (a) the initial review of referral letters and making telephone contact with the referring physician, patient, and sponsoring agency; (b) coordinating and processing all inpatient and outpatient admissions and patient consultations; and (c) obtaining authorization for care from the sponsoring agencies.

Patient services representatives: Patient services representatives answer and triage telephone calls, staff the reception desk, schedule patients, and process paperwork as needed.

Medical assistants: Medical assistants assist with patient flow in the clinic, process medical records, assist in procedures, and process billing records.

Nurses: Nurses assist in patient care and procedures, answer telephone calls, process prescription refills, educate patients, and process paperwork.

Physical therapists: Physical therapists participate in the assessment and treatment of patients.

Occupational therapists: Occupational therapists assist in the evaluation of new patients and provide patient care services.

Vocational counselors: Vocational counselors participate in patient assessment and the placement of patients into a job or job simulation activities.

Administrative assistani: The administrative assistant supports the programs of the Pain Service and works with the director to implement and maintain programs.

Secretaries: Secretaries provide direct support to the director and to the faculty who work on the Pain Services.

The faculty who work on the Clinical Pain Service are drawn from departments of the School of Medicine including Anesthesiology, Family Medicine, Physical Medicine and Rehabilitation, Psychiatry and Behavioral Sciences, Neurology, and Neurological Surgery. They include physicians and psychologists. A few private practitioners who are on the Clinical Faculty also regularly attend the Pain Center and assist in patient care. Faculty may participate in the structured program and its associated screening process or may see consultations and manage individual patients, or may do both.

Trainees: Resident physicians who rotate through the pain clinic, the pain fellows, and other health professionals assigned to the Clinical Pain Service as part of their training, constitute an important group of personnel who help with the evaluation and day– to–day care of patients.

Physical Facilities

The physical facilities of the Clinical Pain Service have changed dramatically in the 37 years since the Pain Clinic was established. At present, the Multidisciplinary Pain Center has superb clinical space in a new outpatient clinic approximately 1 mile from the UWMC. The clinic has a large waiting area, eight patient examination rooms, three counseling rooms, three conference areas, a patient lunch room area, a nerve block room equipped with an operating room table, an anesthesia machine and a C–arm fluoroscope, and three monitored recovery room beds. It is adjacent to a physical therapy/occupational therapy area known as the *exercise training center*. The clinic has underground parking and in–house laboratory and radiology facilities. The director and some faculty and staff have offices.

Patient Care

The operation of the Clinical Pain Service in evaluating and providing care for patients is discussed in Chapter 18 and Chapter 109. In general, (a) only patients referred by physicians or other health professionals are considered for treatment, and preference is given to patients with complex pain problems requiring M/I evaluation and those having such emergency pain problems as cancer or complex regional pain syndromes; (b) once the decision is made to accept the patient, the referring physician and the patient are requested to provide all available medical information, including a comprehensive summary of the pain problem and therapies used, imaging studies, and laboratory data; (c) patients are triaged to either an initial consultation with one physician or to a screening evaluation by a physician, psychologist, and vocational counselor (see Chapter 18).

An important aspect of patient care has been the development of an Acute Pain Service under the direction of Dr. Brian Ready. This was prompted by Bonica's personal experience and observation of patients as well as numerous reports (cited in Chapter 41) of the past and current inadequacy of providing effective relief to patients with acute postoperative and posttraumatic pain. Pain management anesthesiology specialists rotate through the service and provide relief using epidural analgesia achieved with narcotics, local anesthetics, or both and with patient–controlled analgesia, as well as regional anesthesia and analgesia. This service has been highly successful and has demonstrated the superiority of these techniques over the standard method of intramuscularly administering narcotics in relieving moderate to severe acute pain. This topic is discussed further in Chapter 41, Chapter 102, and Chapter 103. Loeser and Egan (35) have published a book on the Clinical Pain Service, describing its patient care activities in detail as they were in 1990.

When the Multidisciplinary Pain Center moved to the primary care clinic building in 1994, a new chronic pain service was created to provide services to inpatients at the UWMC. This was closely linked to the Acute Pain Service and was directed by Dr. Ready. Its faculty worked closely with the members of the Cancer Center to develop appropriate pain management services for this group of patients who were cared for at the UWMC. In 1997, new hospice care activities were under development at the UWMC that will also change the need for pain management services.

Educational Programs

The Clinical Pain Service provides teaching programs for medical students, residents (registrars) from various medical specialties and disciplines who are interested in pain, pain management fellows, and practicing physicians and psychologists who have special interest in pain.

Medical Students

The medical student teaching program includes (a) a preceptorship that provides first– and second–year students the opportunity to observe patient care activities; (b) a 4–week clerkship for students who have completed their basic clerkships and are in their third or fourth year of medical school; and (c) programs for students to work with Pain Center faculty in fulfilling the independent study requirements of the medical sciences program, which include the completion of a research project and a thesis. In addition, the faculty of the Pain Center participates in conjoint medical student lectures related to the anatomic, physiologic, and psychological substrates of nociception and pain.

Residents (Registrars)

In the past, residents from the Departments of Anesthesiology, Rehabilitation Medicine, Neurosurgery, Neurology, Psychiatry, Dentistry, and Oral Medicine have rotated through the Clinical Pain Service. Anesthesiology residents currently are required to have a 2– month rotation covering both acute and chronic pain; they may elect additional exposure in their final year of training.

Psychology Interns

The UW sponsors a psychology internship program, which allows its clinical psychology trainees to elect a rotation on the pain service for a period of 4 months. In addition, clinical psychology fellows from the geriatric training program have spent 3 to 6 months on the Clinical Pain Service.

Pain Management Fellows

The Pain Center has four 1–year fellowships available only to anesthesiologists. Fellows rotate through the Multidisciplinary Pain Center, the UWMC, Harborview Medical Center, and the Seattle Veterans Administration Medical Center. They may also elect to spend a month at Children's Hospital and Medical Center or in a private practice environment. This program is accredited by the American Board of Anesthesiology. The goal of this training program is to present the fellows with the broadest possible array of pain patients and to have them learn all aspects of the treatment of chronic and acute pain.

Other Health Professionals

During the 1990s, 20 to 25 physicians, called *short–term visitors*, have attended the Clinical Pain Service annually for periods ranging from a few days to a week. During this period they are given a formal presentation that describes the activities of the Clinical Pain Service and the Pain Center as a whole, and they are permitted to observe the management of patients with a variety of chronic pain problems.

In addition, during each year 7 to 10 physicians visit the Clinical Pain Service for periods of 1 to 12 months, and these are called *long–term visitors*. Most of these individuals are from countries in Western Europe, Latin America, and Asia. Whenever possible, these individuals are encouraged to obtain a temporary license so that they can participate in the care of patients and have a more extensive learning experience. Those who are not eligible for a Washington State license can only observe the clinical activities. Although these long-term visitors are an increased teaching and administrative burden on the resources of the Center, they represent a worthwhile expenditure of the energies of the Pain Center staff.

Pain Research Center

The Pain Research Center is intended to achieve its mission by (a) encouraging the integration of existing and new research projects into major areas of pain research; (b) developing a milieu that will attract young scientists to undertake pain research training and established pain scientists to contribute to the UW Pain Research Center as funds, space, and other resources become available; (c) encouraging collaboration with other research and clinical programs related to pain within the UW, and with other pain research programs in other institutions; (d) developing an active schedule of informal and formal research meetings of scientists and clinicians at appropriate intervals; (e) organizing and sponsoring or cosponsoring visits of outstanding pain scientists and clinicians to the Pain Research Center and the Clinical Pain Service; and (f) organizing and sponsoring an annual regional or national symposium on various aspects of pain research.

The scientific staff of the Pain Research Center carries out a large number of individual research projects on various aspects of pain and also has several program projects that include two or more research projects focused on such special problems as orofacial pain, cancer-related pain, spinal opioids, and nonmalignant chronic pain. Links to many other research and training programs exist within the UW and its affiliated institutions.

Research Training

The Pain Research Center provides laboratory, clinical research training, or both at the postdoctoral level for Ph.D. scientists and physicians, dentists, and other health science professionals who have a long–range interest in, and commitment to, the field of pain research. This effort has been supported by a research training grant awarded to the Pain Center with C. R. Chapman as program director. Since this program was initiated, a total of 17 research trainees have completed 1 to 3 years of training in pain research. These included Ph.D. and M.D. trainees from the United States and eight other countries. Although most of these trainees have returned to their home universities, several have accepted faculty posts at the UW and continue to remain as members of the Pain Research Center. The Pain Research Center also has had a successful predoctorate training program that has accommodated a number of individuals who have obtained their doctorates in the center. The program has also attracted qualified basic and clinical scientists who spent varying periods of time collaborating with Pain Research Center investigators.

Emma and John Bonica Endowed Chair for Research on Pain and Analgesia/Anesthesia

At the time of Dr. Bonica's retirement from the faculty of the Department of Anesthesiology in 1983, his colleagues, trainees, and friends embarked on a fund–raising campaign to create an endowed chair in pain research. Capably led by Dr. Thomas Hornbein, Dr. Bonica's successor as Chair, this group raised sufficient funds to create the first endowed chair in pain research. The initial occupant of this unique faculty position, Dr. Dennis C. Turk, assumed his duties in 1996. The existence of this key faculty position should lead to continued strength of the research activities of the Pain Center and helps to keep pain research alive within the Department of Anesthesiology.

COMMENTS AND CONCLUSIONS

With progressively greater experience with the multidisciplinary team approach in treating patients with complex chronic pain problems acquired since the late 1940s, we have become increasingly more convinced that the concept is sound and is one of the most efficient, if not the best, method of managing such patients. The same opinion was expressed by all of the participants of the symposium and workshop on multidisciplinary pain clinics sponsored by the National Institutes of Health (38). The IASP endorsed these concepts when it published, in 1989, its “Guidelines for Desirable Characteristics for Pain Treatment Facilities” (39). Review of our data at intervals has revealed the following conclusions.

1. Development of such a comprehensive facility was a slow process, especially at the beginning, when the American medical profession tended to discourage group efforts. One internationally known orthopedic surgeon (who knew nothing about our facility) referred to this concept as “treatment by committee.”
2. The emphasis of the group has changed from time to time as new members, representing disciplines previously not represented in the group, joined the team.
3. Unfortunately, patients are usually referred to the facility after too many ineffective therapies have been applied and failed and the patient has been subjected to prolonged needless suffering. Unrelieved chronic pain is a personally devastating experience that wreaks havoc with the patient and his or her family and work.
4. Many physicians believe that *pain clinic* is a synonym for *garbage pail* and demand that all their treatment failures be immediately transferred to pain clinic specialists. The treatment strategies used in a pain clinic are not universally applicable; patients must be selected for treatment just as they are for any other type of health care.
5. The success rate in the pain center varies with each of the different pain syndromes. The team does *not* make a correct diagnosis 100% of the time, nor do we always eliminate pain permanently. Nevertheless, the rate of success is better than that obtained by practitioners working alone, by members of a specialty group, or by members of general medical or surgical clinics. Although many of the physicians who have treated patients that were eventually referred to our facility have the same expertise in their particular fields as their counterparts in the pain center, they were unsuccessful because they worked in the isolation of

their offices with their available therapeutic facilities and did not have the benefit of an M/I input. Because most of the patients seen in our facility have not responded to traditional health care, the pain center would have to be considered successful even if only a small percentage were enabled to return to productive lives. Indeed, of the treated patients for whom return to work was a practical option, 65% were working at time of follow–up 6 to 12 months or longer after completion of treatment. Detailed data on this type of program are presented in Chapter 109.

6. One of the most important benefits from the M/I team effort is the *esprit de corps* generated among and enhanced by its members. Equally important is the continuous exchange of information. This broadens the knowledge and perspective of each member so that he or she can better use his or her professional talents during diagnostic workups or consultations as well as in teaching and research.
7. The facility has gradually attracted more and more scientists interested in pain research and has been highly effective in integrating clinical efforts and scientific investigation. These individuals have come to appreciate the problems encountered by the clinician in dealing with patients with chronic pain, which are quite different from the problems encountered in the experimental laboratory. By the same token, the presence of scientific research allows clinicians to appreciate the problems of the investigator, improves the quality of patient care, and helps keep clinicians abreast of recent progress in relevant fields. As a result, the pain center has developed several critical masses of basic scientists, clinical scientists, and practitioners who are doing individual and collaborative research, most of which has direct clinical relevance and that, one hopes, will eventually have therapeutic applications.

Problems and Disadvantages

During the evolution of the Pain Center we have encountered a number of problems. We have noted certain disadvantages of such a broad–based M/I effort.

1. During the early years, the hospital administration and health agencies provided a level of support that did not permit expansion of the program to meet the progressively increasing needs in patient care, education, and training. In recent years, financial issues have also retarded the development of the Pain Center. Furthermore, the unique aspects of M/I care are still not understood by many physicians and medical administrators.
2. An inadequate amount of time has been devoted in the curriculum of medical and dental students to permit an effective teaching program on pain. Moreover, funds have not been available to train pain management specialists. As indicated in the section Educational Programs, in more recent years we have been able to get more time for some students and to generate funds to train a number of clinical and research pain specialists.
3. Solving and treating complex problems requires a great amount of time and effort, and the team approach is costly, a fact that has created a number of problems. Thus, the cost of a comprehensive evaluation and the 3–week behavioral/medical/rehabilitation program totals approximately $17,000, a figure that uninformed insurance carriers, who refuse to reimburse for the services of the psychologist and other nonphysician personnel, find difficult to accept. On the other hand, the benefits of such programs outweigh even these costs. Low back pain patients at the UW Pain Center, for example, have not worked for an average of 3.4 years and have had an average of 2.6 major surgical operations for their pain (one had 42 operations for low back pain). On the basis of compensation payments for lost work days paid by the State of Washington and the cost of major operations, it can be conservatively estimated that the total cost for the average patient has been in excess of $75,000. Because, as previously mentioned, 65% of our patients are able to return to work after treatment, it is obvious that the program is cost–effective. The cost of efforts of numerous multidisciplinary teams is worth it, and in the long run will save society billions of dollars. This issue is discussed in Chapter 109.
4. Another disadvantage of the team approach is the risk of fragmenting the care of the patient among several people. In such a situation, if no single person is responsible for overall care, the patient is deprived of the important patient–physician relationship. This result can and must be obviated by having one member of the team serve as managing physician.

Advantages

Our experience has convinced us that these disadvantages are more than offset by the advantages of the team approach used for patient care, teaching, and research. The advantages are presented here.

1. The team approach provides a broad–based source of knowledge and expertise for the care of patients. Long experience has confirmed the deep conviction that the close interaction among various members of the team and the face–to–face group discussions during the conferences are much more effective and productive in making a correct diagnosis and formulating the most appropriate therapeutic strategy than communication by letter or telephone or through fragmented independent efforts inherent in traditional medical practice. In addition to providing a highly specialized consultant service to the referring physician and the patient, these conferences serve as an excellent forum for the exchange of ideas and information and thus constitute an effective teaching mechanism.
2. The M/I collaborative research efforts are likely to generate more information and more comprehensive perspectives on the problems of pain than could be generated by individual investigators working alone. The grouping of investigators fosters interaction among basic scientists and a variety of clinicians, and it helps to encourage other basic and clinical scientists to devote their efforts to pain research. Equally important, this interaction creates stronger bridges among the basic sciences and clinical disciplines of the institution. These bridges help to eliminate the chasm between basic scientists and clinicians that has heretofore precluded this type of collaborative research program and has unduly delayed the application of new knowledge to the scientific care of patients. All of the previously mentioned factors should result in a much more productive program of research, teaching, and patient care.
3. The multidisciplinary pain center is an ideal method of applying the biopsychosocial model of illness to patient care. This concept is particularly important for patients who suffer from chronic pain, as the more common biomedical model does not suffice to lead to optimal outcomes.

Requisites for Optimal Results

To achieve these objectives and accrue the aforementioned benefits, it is necessary to fulfill the following requisites and conditions:

1. The director of the program should have the capability of providing vigorous medical, scientific, and administrative leadership to the entire group. Because the team is composed of individuals who have appointments (and consequently allegiance) to their parent departments, it is essential that the director possess those qualities necessary to bring a heterogeneous group together and have it function as a single, efficient unit. He or she must possess a superior knowledge and skills in a special area of pain, and his or her performance in patient care, teaching, and research must be such as to win the respect of all his or her colleagues. In large programs of the type developed at the UW, the director must have an associate director for research and one for the clinical pain service. These associates must have the knowledge, expertise, and skills to provide the same type of vigorous leadership in their respective areas.
2. Each other member of the group must have special interest in pain and must be willing and able to devote sufficient time to the activities of the program. Moreover, each member must have the ability to interact frequently and productively with other members of the program and be willing to respect the opinions of others—in other words, each must be a real team player. Moreover, each member must possess thorough knowledge, experience, and skills in a particular area to contribute to a vigorous collective team effort and also must acquire broad knowledge of the basic and clinical aspects of pain beyond that of his or her specific discipline.
3. Each member of the team dealing with patient care, teaching, or research must work in an exquisitely coordinated manner, and all members of the team must meet frequently to discuss their findings on each patient and on specific research projects.
4. The program must have sufficient space and equipment as well as personnel and other resources, including a strong financial base, to carry out its program efficiently and effectively.
5. An M/I pain center must have highly effective teaching programs for students and practitioners and must develop a productive research program on various aspects of pain.
6. The multidisciplinary pain center must develop an intensive program to inform and educate the public and the staff of various governmental agencies to recognize and appreciate the importance and magnitude of pain as a serious national and world health problem that requires and deserves ample financial support.

SUMMARY

Pain has long been, and continues to be, an important subject for study by scientists and a phenomenon that still taxes the diagnostic acumen and therapeutic skills of physicians and other health professionals. In this chapter, the evolution of the various types of pain clinics and centers in the United States and other parts of the world has been summarized. It is apparent that the marked increase in pain research has not only greatly enhanced our knowledge of sensory coding and sensory modulation, but also has brought about a significant change in our conceptualization of clinical pain and pain therapy, particularly with regard to chronic pain syndromes. This, in turn, has encouraged many physicians and other health professionals to become involved in managing patients with pain within the context of multidisciplinary pain diagnostic and therapeutic facilities. The UW Multidisciplinary Pain Center has been described as an example of a university–based facility that has productive programs for the management of patients with complex chronic pain problems and for education and training and for research on pain. The problems, disadvantages, advantages, and requisites for success have been summarized.

CHAPTER 12

Medical Evaluation of the Patient with Pain

John D. Loeser

The general principles of the medical evaluation of patients with pain with special emphasis on patients with complex pain problems are discussed in this chapter. This chapter describes the initial medical evaluation in the physician's office, in which the patient with pain is seen for the first time. It also includes discussion of the objectives of the medical evaluation, general method of approach, characteristics of the pain, eliciting a detailed history, performing a comprehensive physical examination, including neurologic and musculoskeletal studies, and a presentation of the types of laboratory, radiographic, and other data that assist in the establishment of a correct diagnosis and developing the most appropriate and effective therapeutic strategies. This section is intended for physicians working either individually or within multidisciplinary programs.

The medical evaluation of patients with complex chronic pain problems is time consuming and often psychologically and physiologically taxing to the physician and patient. In addition to the medical evaluation, a psychological evaluation, preferably by a clinical psychologist, is often essential for the establishment of a diagnosis and the development of a therapeutically beneficial treatment plan. These tasks may be most efficiently achieved within the setting of a multidisciplinary/interdisciplinary pain program, particularly for the patient who has already consumed large amounts of health care resources.

The diagnostic processes carried out for specific pain syndromes are presented in Parts III and IV of this book. The reader is referred to the text by Weiner on the differential diagnosis of acute pain syndromes (1).

PRELIMINARY CONSIDERATIONS

Objective of the Medical Evaluation

Medical evaluation of the patient's pain involves making a correct diagnosis that permits the development of optimal therapeutic strategies. A primary objective is determination of whether the patient is having acute or chronic pain and, if the pain is chronic, whether it is a result of cancer or of a nonmalignant disease process. As emphasized frequently in this book, management strategies for acute pain and cancer pain often are dramatically different from those used for nonmalignant chronic pain. It is also important to determine whether organic disease was actually overlooked or arose during the course of the patient's pain complaint.

Another objective of the evaluation and treatment process is avoiding the fragmentation of care. Because patients with chronic pain have already had multiple interactions with health care systems through various, often simultaneous, physician contacts, it could be erroneously assumed that the patient has been and is receiving coordinated and monitored comprehensive care, thorough physical examination, coordinated medication management, and the necessary psychological assessment and treatment. This is often not the case, not only among pain patients but also among patients with other disorders who receive fragmented care from multiple physicians.

Another important objective of the medical evaluation is development of sufficient rapport with patients to be able to convince them that a psychological and psychosocial evaluation is essential. Without adequate information and psychological preparation, many patients reject the recommendation that they be evaluated by a clinical psychologist, social worker, vocational counselor, or other health professionals.

Initial Interview

During the initial visit between the patient with pain and the physician, several things should be accomplished, the most important of which is the physician's obtaining the confidence of the patient. The necessity of establishing a rapport between the physician and patient to gain full cooperation of the patient and to achieve optimal results cannot be overemphasized. As a result of previous therapy failures, many patients with chronic pain come to the consulting physician discouraged and pessimistic. Others are angry, bitter, and resentful. Many have been told that “your pain is in the head” and that “nothing can be done for the pain.” The difficult task of cultivating the confidence and faith of the patient can be accomplished in several ways. First, the referring physician should convince the patient that the consultant is a specialist in the management of pain and has special attributes that can help to solve the pain problem. During the initial visit, the pain specialist should strengthen the patient's belief in this by using and exploiting to the fullest extent those intangible attributes called the *art of medicine*. The physician should bring to the pain patient a quiet, considerate humanity and a confidence and security based on the conviction that all that can be done will be done to help. All patients must be made to feel that their individuality is recognized and that their problem is not meaningful only to them but is the most important phase of the physician's practice. A sympathetic attitude, consideration, affectionate care, and a deep interest in the patient's problem greatly enhance the cooperation of the patient during the evaluation procedure and also help to convince the patient that he or she can be helped with this pain problem.

The next objective is to inform the patient about the various steps and procedures to be followed during the evaluation process. Even if this has been done by others, the physician should describe the entire plan of assessment and management. The evaluation process and treatment could require a great deal of time and either repeated visits or a stay in the hospital. The patient's cooperation is essential; without it, favorable results cannot be guaranteed. The patient should agree to follow through either verbally or, as Sternbach (2) suggested, by signing a *management contract*. As mentioned, such cooperation is usually obtained without difficulty, provided that the physician discusses the problem fully with the patient, explaining the entire management plan in language that can be understood. At least 2 hours should be reserved for the initial visit to achieve all these objectives and to take the history and perform a comprehensive physical examination. It might take less time, but generally it takes longer. In the current health care environment, several visits may need to be scheduled to obtain adequate information.

Several points should be made in regard to the diagnosis. First, it is necessary to confirm or reject the diagnosis if one has already been made by the referring physician. In some cases the prior diagnosis, when critically examined, is found to be inappropriate or outdated, or to be a mere description of an initiating disease entity that might have little or no relation to the patient's present chronic pain problem. Even if the diagnosis was made correctly by a respected physician who has referred the patient to the clinical pain specialist for management, it is essential to investigate the problem fully. Often, additional information can be obtained that aids in the treatment plan. A detailed history and a comprehensive physical examination are therefore essential. Generally, the medical evaluation of the patient's chronic pain is based to a major degree on the history and to a lesser degree on the physical examination, and least on the laboratory data and imaging studies. Indeed, in many patients with chronic pain, it is essential to await the results of the psychological and psychosocial evaluation as well as those of consultation with other specialists and diagnostic studies before a definitive diagnosis can be reached.

Taking the History

Taking a detailed history is the most important part of the evaluation of the pain patient. Experienced clinicians rely heavily on a history in arriving at a diagnosis, because, when it is carefully and meticulously elicited, skillfully interpreted, and carefully analyzed, it provides important information not only about the possible mechanisms and pathophysiology of the chronic pain syndrome, but also about the emotional and psychological status of the patient (3). The history often affords the physician such a clear picture that diagnosis can be largely established from the symptoms alone, even before physical, neurologic, and laboratory examinations have been carried out. In other cases, the history might not be so decisive but can so limit the diagnostic possibilities that a logical program of investigation is suggested.

Finally, and equally important, the history affords the physician an unequaled opportunity to establish rapport with the patient by being friendly, understanding, and courteous; by being visibly interested in the problem and anxious to help; and by centering all attention on the patient. These actions are the cornerstone for a successful patient–physician relationship.

Guidelines

A comprehensive history consists of a history of the pain problem, a past medical history, a general psychological and psychosocial history, and a family history. These are elicited as for any other medical condition and need no elaboration here except in regard to matters that are of special concern in patients with chronic pain syndromes. The patient with chronic pain is frequently fatigued, irritable, and nervous, so the history is best taken in privacy with the patient as comfortable as possible. (The issue of having the spouse or some other involved family member or significant other present as part of the psychosocial evaluation is mentioned later and discussed in detail in Chapter 16 by Turner and Romano.)

During the process of history taking, the physician should avoid appearing hasty and should meet the patient on a common ground of language and vocabulary, resorting to the vernacular if necessary. Although a regular sequence is valuable in obtaining and recording the history, both for ensuring completeness and facilitating future reference, the history should never be obtained by following a stereotyped form or repeating a memorized list of questions. Patients may become resentful of losing their individuality when coerced into the physician's evaluation format.

The history should be recorded clearly and concisely in a logical, well–organized manner. Each statement must be considered in its relationship to the whole. It is important to stress the more significant manifestations and to keep irrelevancies to a minimum; essential factual material must be separated from extraneous information. Diagnosis involves the careful sifting of evidence and the art of selecting and emphasizing relevant data to enable a correct conclusion to be reached. It might be advantageous to record negative as well as positive statements, so that later examiners understand that the historian inquired into and did not overlook certain aspects of the disease.

The initial step of the history is to let patients tell their stories in their own words. The importance of this part of the examination of patients with pain was stressed by Leriche (4), who stated that the physician “who really wishes to investigate pain and find some means of abolishing it, ought to give great attention to his patient's complaints. He ought to listen to the story of their sufferings, however long and tedious it may be.” Although some patients do appear to exaggerate subjective sensations, they should be given an opportunity to express their feelings, because this can reveal important information. While the patient is talking, the physician should intervene as little as possible, and only to lead the story into directions in which useful information can be obtained, to exclude obviously irrelevant material, or to obtain amplification of statements that seem to be vague or incomplete. The use of open–ended questions is essential; closed questions might distort the patient's history and obscure diagnosis.

Whereas the patient's spontaneous narrative affords the examiner valuable information that aids in orientation to the patient's problem, rarely is it complete. Only exceptional patients recall all particulars of their illness and repeat them in accurate and chronologic order without confusing symptoms and their interpretation of symptoms (3). Furthermore, if the patient's mind is focused on a particular manifestation, he or she might not mention others of equal importance. Thus, it is usually necessary to augment the patient's account by asking leading questions that are tactfully presented. It is often necessary to go into detail regarding specific factors, many of which patients might not relate to their present condition, but whose presence or absence could be significant. The importance of an accurate, detailed record of events in cases that involve compensation for medical or legal problems deserves special emphasis.

Patients should be allowed to use their own words, and any suggestion of symptoms or diagnosis should be avoided. This is particularly important in obtaining the history from overly suggestive and somatically preoccupied patients (3). Special consideration must be given in taking the history of certain types of individuals. The garrulous person might have to be stopped from getting lost in a mass of irrelevant detail, whereas the timid, inarticulate, or worried patient might have to be helped by sympathetic questions or reassuring comments. The fearful, antagonistic, or paranoid patient should be questioned carefully so as not to arouse fears or suspicions; the patient with multiple vague complaints must be kept to specifics, and the evasive or undependable patient should be questioned more searchingly. This wide range of individual variations is important to consider in taking the history of any illness, but it is especially important when appraising the pain patient's complaints.

During the taking of the history, the physician has an unequaled opportunity to study the patient as a whole (i.e., manner, attitude, behavior, and emotional reactions). The tone of voice, bearing, facial expressions, any gesticulations, restlessness, delay or hesitancy of speech, and emotional responses to description of certain events or facts about marital or work history constitute important information in evaluating the character, personality, and emotional state of the patient and should be recorded in detail.

With these considerations regarding the taking of the history, we can now consider the general outline of the history and the specific aspects that must be elicited to make a correct diagnosis. Before doing so, however, the characteristics of pain on which taking the history of the pain and the physical examination are based are briefly reviewed.

Characteristics of the Pain

In eliciting the history of the pain and in examining the painful part, it is essential to obtain a detailed description of the location and distribution of the pain, quality of the pain, severity or intensity of the pain, and periodicity and duration of the pain and the affective concomitants of pain, best labeled as *suffering*.

Location and Distribution. The value of localizing the site and distribution of the pain in diagnosing its cause is universally recognized, but it should be remembered that the accuracy for such localization begins to diminish from the moment the pain ceases, and it is therefore best to obtain this information while the pain is actually present. Moreover, as elaborated in Chapter 9, pain arising from the skin or mucous membranes, and from the nervous apparatus that supplies these structures, is localized with almost negligible error, but pain arising from deep somatic or visceral structures can be referred remotely or localized with difficulty. Such referred pain might be accompanied by hyperalgesia, hyperesthesia, and deep tenderness. Pain with a segmental distribution can arise from dysfunction of the nerve roots or formed spinal nerves. Pain can be classified as localized, projected (transmitted or transferred), referred, or of reflex (sympathetic) distribution and as what some call *psychogenic pain* (see Chapter 26). Pain of any etiology also may be influenced by environmental and affective factors.

Localized Pain. Localized pain remains confined to its site of origin without radiation. Cutaneous hyperalgesia and hyperesthesia and deep tenderness can be present, but are also confined to the site of the disease. Examples of these are bursitis, tendinitis, and arthritis.

Projected (Transmitted or Transferred) Pain. Projected pain is perceived to be transmitted along the course of a nerve either with a segmental (dermatomal and sclerotomal) or a peripheral distribution, depending on the site of the lesion. Examples of projected pain with segmental distribution are the pain of radiculopathy caused by herpes zoster or other diseases involving the nerve root or nerve trunk before it divides into its major peripheral branches. Examples of projected pain with peripheral distribution include trigeminal neuralgia, brachial plexus neuralgia, and meralgia paresthetica.

Referred Pain. Referred pain is referred from a deep somatic or visceral structure to a distant region within the same segment, with or without hyperalgesia and hyperesthesia, deep tenderness, muscle spasm, and autonomic disturbances (see Chapter 9). No changes are seen, however, in the reflexes, and no muscle weakness or atrophy is present. This type of pain, the mechanisms of which are discussed in Chapter 9, is found in visceral disease and deep somatic disorders. In patients with this type of pain the segments involved are identified, and all somatic and visceral structures innervated by these segments are carefully examined for a pathologic process. Shoulder pain seen with a subphrenic abscess is an example of referred pain.

Reflex Sympathetic Pain. Reflex sympathetic pain does not conform to any segmental or peripheral nerve distribution or to any other recognizable pattern and is associated with hyperalgesia, hyperesthesia, and vasomotor and trophic changes. It is best exemplified by causalgia and other reflex sympathetic dystrophies. This type of pain has been relabeled *complex regional pain types I and II* to emphasize that the involvement of the sympathetic nervous system is neither required nor sufficient to explain the clinical syndromes (5).

Psychogenic Pain. The location and distribution of pain caused primarily by psychological or psychiatric disorders usually does not fit the normal neuroanatomic patterns. Examples include pain with glove or stocking distribution, pain involving the entire body, or various pains scattered all over the body. Although this is a commonly used label for pain without observable pathology, it certainly is not malingering or caused entirely by mysterious processes in the mind of the patient. Most often, this is pain behavior engendered by environmental factors. Other patients have myofascial pain syndromes that have been overlooked by their physicians. The

proper use of this diagnostic term requires positive findings that suggest that mental processes are the sole cause of the patient's complaints. It should not be a diagnosis of exclusion when no clear–cut physical findings explain the patient's symptoms. We have found that the label *psychogenic pain* is usually a sign that the physician does not like or believe the patient. Criteria such as those used in *Diagnostic and Statistical Manual* , fourth edition, are not well suited for the identification of patients who fit in this category. The reader should consult Chapter 26 for more discussion of this topic.

Quality. The quality of pain, as emphasized in Chapter 8 and Chapter 9, is a most important distinguishing characteristic because it indicates whether the causative factor is superficial or deep. Pain associated with a superficial lesion is usually sharp, burning, and well localized, whereas pain caused by deep somatic or visceral disease is dull, diffuse, and poorly localizable. Such assessment instruments as the McGill Pain Questionnaire can provide useful information about the qualities and intensity of the patient's pain.

Severity or Intensity. The severity or intensity of pain is another important characteristic. It is perhaps the most difficult aspect of pain to evaluate because it cannot be measured precisely (refer to Chapter 15 for a detailed discussion of the subject). Evaluation of the intensity of pain must rely on the patient's statements and on the examiner's ability to appraise the patient's personality and physical status. In the usual clinical setting, the patient is asked to rate the pain intensity on a 0 to 10 scale, 0 being no pain and 10 being the most severe or intolerable pain imaginable. As discussed in Chapter 15, others use descriptors such as *mild, moderate, severe, very severe* , and *excruciating* . A variety of psychometric tests have been developed to assess pain intensity and the sensory as well as affective components of pain (6).

Duration and Periodicity. The duration and other temporal characteristics of the pain are also determined because they suggest its mechanism, thus aiding the diagnosis. The patient should be asked whether the pain is continuous, intermittent, pulsatile, or characterized by a wavelike rise and fall in intensity because these factors are relevant. Determination of the length of the interval between painful episodes is important in aiding the diagnosis. In connection with these temporal factors, Lewis (7) suggested the use of a time– intensity curve (Fig. 12-1). The curve portrays the manner in which pain starts, the rapidity of its increase, the duration and smoothness at its height, and the manner of its decline. Pain can be experienced in various ways: as a brief flash, as in tic douloureux; in rhythmic pulses, as in inflammation of dental pulp or migraine; in longer and less rhythmic phases, as in intestinal colic; rising gradually or suddenly to a plateau that is maintained for a long period without any fluctuation before vanishing, as in angina pectoris or burns; and continuous but fluctuating in intensity, as in aches that arise from the musculature of the limbs. In addition to the time– intensity curve, the relations of the pain to the time of day, week, or season, weather conditions, and emotional stress or environmental cues also provide important information.

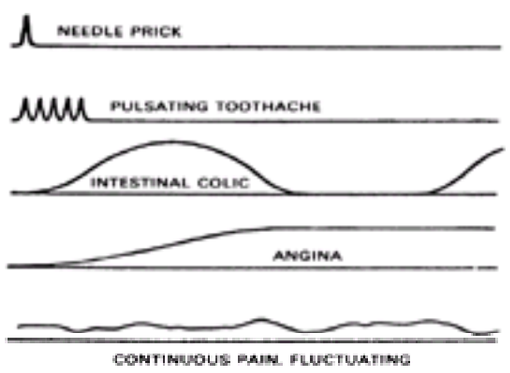

Figure 12-1. Time–intensity curve of various well–known pains. (From Lewis T. *Pain*. New York: Macmillan, 1942:176.)

General Outline of the History

The history of the pain, as for all clinical histories, usually begins with obtaining demographic data (if not already available), including the patient's name, address, sex, age, marital status, occupation, race, nationality, and religion. This demographic information may be collected by a written survey vehicle that the patient completes before the interview with the physician. A statement of the patient's major or presenting complaint is then obtained, which in this case is pain. This is followed by a description of the symptoms and course of the present illness, with a chronologic account of its development. This type of information gathering can be facilitated by using a standardized form that the patient completes before the physician interview, but such a form is never adequate for the full understanding of the patient's history.

History of the Pain

Pain at Onset. Detailed information should be obtained regarding the precise date of onset and the circumstances contributing to the causation of the pain. The location and distribution, quality, intensity or severity, and duration of the first pain should be ascertained. The type of onset, gradual or sudden, should be determined. If the pain was motion related, patients should be asked to demonstrate the position they were in and the action they were performing when the pain first occurred. For example, if the patient gives a history of onset of pain during a lifting maneuver, it should be ascertained whether the pain occurred during bending or raising of the trunk. Was the pain localized, or was it distributed along a limb? Was it shooting and sharp or dull and aching pain? How long did the pain last at the time of onset? Was the patient able to continue activities that day or was the pain immediately disabling? If the injury was job related, determining the interpersonal relations in the work setting at the time, as interpreted by the patient, is important. In addition, the patient should be questioned regarding any associated sensory (e.g., numbness), motor, or autonomic disturbances at the time the pain was first noticed. The patient should be questioned about the treatment received at the time of onset of pain and its effect.

Pain during the Interval. Detailed information about the course of the pain during the interval between the onset and time of evaluation is of great diagnostic value. Did the pain get better or worse with time? Did the location and spread change or remain the same? Were the quality, severity, and temporal characteristics of the pain and associated disturbance modified during the interval? It is essential to obtain detailed and precise data about the diagnostic and therapeutic procedures that have been carried out and the results achieved. It must be carefully and precisely determined whether the pain after surgery or any other therapy was the same as the pain before the procedures. Iatrogenic complications caused by inappropriate procedures add to the pain and suffering of many patients. For example, multiple abdominal surgeries, whether properly indicated for diagnosed organic disease or carried out under pressure of the patient's complaint of persistent pain, can lead to the formation of more adhesions and thus more pain. Every operation or diagnostic study carries with it a message that there may be a “broken part” causing the pain and may further increase the patient's somatic preoccupation and complaint of pain. In other cases, chronic use of medication over a long period can produce unwanted physical and psychological side effects.

Special care should be exercised early in the interview to determine whether the patient takes significant amounts of medication. Some chronic pain patients are confused and have impaired memories because of drug–induced cognitive defects. If such is the case, the patient should be placed on a detoxification program (see Chapter 16 and Chapter 18) before a diagnostic evaluation is continued and completed.

Present Pain. The patient should be asked to describe in detail the quality, site, distribution, intensity, and temporal characteristics of the pain at the time of evaluation and to indicate whether any of these factors has changed since the onset or during the interval. The patient is then asked what factors aggravate the pain, relieve the pain, and have no effect on the pain. Also, the patient should be asked what effect emotional disturbances, movement of the part, exercise, local pressure, heat or cold, coughing, sneezing, straining, and deep breathing have on the severity, quality, and distribution of the pain. The physician should be especially sensitive to the patient's description of the present pain and record it. If the patient describes the pain in unusually colorful terms that make no anatomic sense or implies some external and unusual causative factor, the likelihood of the pain resulting from a pathologic lesion decreases. Such phrases as “fishhooks in the mouth,” “red hot poker,” or pain “traveling down the leg and jumping to the opposite knee” should alert the physician to expect significant affective and environmental factors in the maintenance of the patient's pain. When the pain is constant and does not fluctuate with any physical or emotional activity, it is again more probable that a structural lesion is not the primary cause of the patient's complaint. Another clue that a specific lesion is unlikely to be found is when the patient states that the pain levels are always 10 out of 10.

Detailed information should be obtained about the effect of the pain on the patient's activities, the amount of time the patient is up and about (up time), and the amount of time the patient spends sitting or lying down (down time) while awake. This type of information is best elicited through the use of a 2–week diary in which

the patient records the physical activities, medication taken, and intensity of the pain during each waking hour. It is also important to obtain information on the effect of pain on sleep. Does the pain make it difficult to fall asleep? Does the pain awaken the patient from a sound sleep? (This subject is discussed in more detail in Chapter 16 and Chapter 18).

Elicitation of this part of the history, in which similar questions are asked repeatedly, can tax the patient as well as the physician. Patients should be impressed with the importance of providing detailed information and repeatedly encouraged to sustain their efforts during this long and tedious part of the evaluation. The physician must allow ample time for these patients because they present complex medical, psychological, and social problems, often associated with multiple areas of pathology.

Past Medical History. The past medical history is especially important in the evaluation of the patient with chronic pain in regard to developing the therapeutic strategy and predicting the outcome. The general health of the patient before the onset of the pain is elicited and recorded, followed by a history of past illnesses, operations, and accidents or injuries sustained, with the date and nature of each, period of disability, and sequelae (3). If the patient's health was normal before the onset of the pain problem, a return to normality can be expected with effective therapy. If, however, there have been many serious physical or psychological illnesses and the patient has been dependent on health care with a long history of health care–seeking behavior at times of stress, it is unrealistic to expect improvement beyond the previous best level of functioning.

In relating past illnesses and injuries, the patient might list only the serious or outstanding ones and fail to mention individual symptoms that could be of diagnostic significance (3). Consequently, detailed questioning is important to diagnose systemic and psychophysiologic illnesses. Symptoms referable to the various organs and systems can be investigated by inquiring about the function or dysfunction of the eyes, ears, nose, and throat, the cardiovascular and respiratory systems, the gastrointestinal and genitourinary systems, and other parts of the body that might be relevant to the present pain.

Family History. It is important to obtain information about the health of the parents and siblings and to determine whether they suffered frequent painful disorders and disability. Evidence exists that *modeling* is an important factor in the development of chronic pain behavior (8). Another relevant aspect of the family history is to ascertain tactfully and considerately whether the patient was the subject of childhood abuse. This factor also plays an important role in the development of chronic pain behavior (9).

Psychological and Psychosocial History. The psychological and psychosocial part of the history helps to determine the contribution of affective or environmental factors to the patient's pain complaint. Often, the factors generating pain at the onset of the disease are not those that are present when the patient is eventually seen by the pain specialist. Although this subject is discussed in detail in Chapter 16, some brief comments are made here for the sake of completeness.

A properly conducted psychological evaluation should delineate the contribution of environmental reinforcers to pain behaviors, the role of avoidance behaviors, and the presence of depression (10). A history of prior psychological disorders, substance abuse, vocational problems, family role models of chronic illness or pain, and recent stressors can enhance the understanding of the patient's current problem. Selection of the optimal treatment strategy also depends on this type of information.

The psychological assessment is based on a structured interview; the sequence of topics should be constructed so as to reduce the patient's restraints by first focusing on the pain problem (see previous discussion). Once this has been done, the physician can explore environmental and social issues and finally approach psychological, psychosocial, and marital or family problems.

The history of drug use is important from both the medical and psychological perspectives. It is best to start by questioning the use of prescription drugs, progressing to over-the–counter and alternative (e.g., herbal) medicines, and moving on to questions of smoking and alcohol use and illicit drugs. Physical dependence on drugs is relatively common in those in the chronic pain population, and alcohol dependence is a major problem.

The assessment of environmental reinforcers is a key part of the psychological assessment of the patient with a complex chronic pain syndrome. One must be cognizant of positive reinforcement (something good happens if the behavior is exhibited) and avoidance reinforcement (something bad is avoided by exhibiting the behavior). The latter is much more durable and less obvious to the patient and the observer. Areas to be assessed include activity changes, social reinforcers, avoidance behaviors, vocational factors, compensation–litigation issues, activation of recent stressors, family history, psychological dysfunction, and cognitive dysfunction.

One goal of psychological assessment is determination of the *cost* to the patient of the chronic pain problem. Not only should the economic factors be examined carefully, but also the social and personal costs of the patient's pain behavior. When the cost is high, the pain behavior is probably generated mainly by tissue damage or injury to the nervous system. Activity changes are an effective measure of the cost and reflect the probability that disuse and its secondary effects are contributing to the patient's pain. The conditioning of the heart and lungs reduces exercise tolerance and endurance, whereas decreased range of motion affects strength and speed in various body regions and can generate pain and prevent the patient from performing routine daily activities. Deactivation can also contribute to depression and isolation; social reinforcers can be lost because of decrease in activities.

Another area that requires scrutiny is clinical depression, a common condition in patients with chronic pain. It is necessary to do more than ask about the patient's mood. Other clues are persistent irritability, insomnia, chronic lassitude, weight gain or loss, and suicidal ideation. Depression is common in the elderly patient, but pain behavior also can be a cover–up for cognitive slippage in this age group (11).

Finally, it is important to carry out a vocational assessment, a topic discussed in detail in Chapter 17.

Physical Examination

Because pain is the most common symptom that causes the patient to seek medical counsel, physical examinations are most often performed to ascertain the cause of pain and its relation to an underlying disease. It might seem unnecessary, therefore, to emphasize the importance of such an examination, but those managing pain syndromes sometimes focus their whole attention on the pain without further inquiry. Because pain in general and chronic pain in particular have widespread effects (as emphasized in Chapter 10), an appraisal of the general physical, neurologic, musculoskeletal, and mental status of the patient must be done if a proper diagnosis is to be made. The physical examination is also important in establishing the physician's standing and competence in technical medical matters to the patient. In addition, it emphasizes that the physician has a high degree of concern for this particular patient and that the patient's complaints are taken seriously.

The physical examination of the chronic pain patient is often a demanding and lengthy process. It involves not only a general physical examination, but also more careful neurologic and musculoskeletal studies than are indicated for most other types of medical patients. Clinical assessment of the patient's functional abilities is also required, which is usually a tiring procedure for the patient and invariably involves maneuvers that exacerbate the pain. If the patient appears to be fatigued after obtaining the lengthy history it might be advisable to carry out a superficial preliminary examination and to postpone a more definitive study to a later date.

General Physical Examination

The general appearance of the patient is noted. The observations made during taking of the history are correlated with those made after the patient has disrobed. Any outward manifestations of pain should be noted in particular. The appearance and color of the skin, distribution of fat and hair, evidence of weight loss, emaciation, weakness, abnormal attitudes, contractions, contractures or deformities, atrophies or hypertrophies, enlarged glands, and presence of vasomotor or trophic changes are important points to observe and record. One should observe the posture of the patient and note the presence of lordosis, scoliosis, kyphosis, rounded shoulders, ptotic abdomen, flat feet, and if one shoulder or hip is lower than the other.

The facial expression and presence of flushing or paleness, sweating, pupillary dilatation, tears, tremors, muscular tension, or the appearance of anxiety, fear, or depression are important manifestations of pain, which should be noted. The gait is ascertained by having the (disrobed) patient walk in a straight line, backward, sideways, and on the toes and heels. The temperature, pulse, respiratory rate, blood pressure, height, and weight of the patient are recorded.

The skin and mucous membranes should be examined and their appearance, color, temperature, consistency, texture, elasticity, and any abnormalities noted. Nails of the patient whose history suggests a diagnosis of a complex regional pain syndrome, formerly called *reflex sympathetic dystrophy* , should be closely examined, with particular attention paid to texture, smoothness, and presence of fissures. The hair of such patients should also be examined in regard to amount, distribution, and

color and particularly to texture, because changes of this feature are a common manifestation of complex regional pain syndrome.

Examination of the Painful Region

After this general inspection, the specific region of the pain complaint is examined. This is done before proceeding with the rest of the physical examination because the patient expects the investigation to begin in the area in which the discomfort is located. Some patients feel resentful when the initial examination involves areas other than the painful region. The examination consists of inspection, palpation, and percussion, and sometimes auscultation of the region.

Inspection. Inspection of the area provides definitive data that can be correlated with the story given by the patient and with the information obtained by palpation, percussion, and special tests (3). The appearance and color of the skin overlying the painful area are observed closely and note is made of trophic manifestations, hypertrichosis, hyperhidrosis, cyanosis or flushing, cutis anserina (*goose flesh*), and visible evidence of muscle spasm. Gunn and Milbrandt (12) point out that presence of cutis anserina is a common manifestation of autonomic dysfunction caused by damage to nerve roots or to formed nerves during their exit through the intervertebral foramina, resulting in denervation supersensitivity (Fig. 12-2). Gunn and Milbrandt (12) emphasized that this manifestation is seen immediately when the patient undresses and cool air plays on the exposed skin, provoking the pilomotor effect in the dermatomes of the affected segmental level, and further stated that it is essential to watch the patient undress, examining the skin carefully because the reflex might be present only briefly. They believe that this pilomotor reflex can be reinforced or induced by firm digital pressure over any tender motor point within the affected segment (12).

Figure 12-2. A readily seen signal of neuropathy affecting the autonomic system is an isolated patch of *goose bumps* created by a super-sensitive pilomotor reflex responding to exposure while undressing. Here it appears locally at the shoulder and arm, indicating trouble related to segments C-5 and C-6.

Palpation. Palpation of the region provides further information about the pain. Deep tenderness is best elicited by digital palpation, using the middle finger to exert firm deep pressure on the painful site. The area of tenderness is mapped out, and the neural segments involved are ascertained. If any doubt regarding the existence of a pathologic basis for the pain patient's complaint is present, the findings can be confirmed or discounted by repeated palpation, approaching the region from a different direction each time. If this is done while the patient is distracted, evocation of pain in the same region is some indication of a pathologic process. During palpation of the region, these evocations of pain should be correlated with subjective (symptoms) and objective (signs) manifestations of the painful disorder, and a determination made of whether any discrepancy exists between them. Subjective pain behavior includes grimacing, groaning, shouting, writhing, and other verbal and nonverbal expressions. The degree of such subjective behavior expected for a particular condition varies greatly with the cultural and ethnic backgrounds of the patient; writhing and groaning on the part of an ordinarily stoic individual can signify a more noxious condition than the same behavior from a customarily flamboyant person. Likewise, such behavior can be more marked in an anxious or depressed person with a given condition than in someone without these emotional problems. Objective signs associated with some painful conditions are those that are not wholly under the voluntary control of the patient, and include manifestations of autonomic discharge such as sweating, flushing, tachycardia, elevated blood pressure, and muscle spasm.

In patients with a pathologic process, palpation provides not only a qualitative reaction but also quantitative data proportionate to the stimulus used. Therefore, the response of the patient to palpation of the opposite symmetric nonpainful side when it is palpated in exactly the same manner should be noted. This also provides important information regarding the sensitivity of the patient to noxious and nonnoxious stimuli, as well as information about the sensitivity of the painful region.

To determine whether the tenderness and pain provoked by palpation are caused wholly or in part by overlying skin allodynia, hyperalgesia, or hyperesthesia, the brush test, pinch test, pinprick test, and scratch test are used. The brush test consists of lightly stroking the skin with a cotton wisp or something similar; the report of pain indicates allodynia and is suggestive of spinal cord dysfunction. The pinch test consists simply of pinching the skin between the thumb and index finger, applying the pressure along close parallel lines beginning over the adjacent nonpainful area, and continuing over the painful part and then beyond to the farther asymptomatic area (Fig. 12-3). The pinprick and pin scratch tests are used similarly to examine superficial pain sensibility and are described in detail in connection with the neurologic examination (see following discussion). These procedures should also be carried out over the opposite and corresponding nonpainful areas as controls to obtain an index to the patient's response to stimuli, to show the patient what to expect, and to provide a subtle, subconscious basis of comparison when the affected side is examined. Response should be evaluated by noting any wincing, groaning, or voluntary complaint by the patient, or by the onset of reflex muscle spasm. The patient is asked only neutral and nonsuggestive questions. These tests should always be used as complementary procedures to maneuvers intended to elicit, reproduce, or evaluate pain and tenderness by percussion, jarring, or pounding, because such percussion tests are positive in the presence of cutaneous hyperesthesia, which contributes greatly to misdiagnosis if unrecognized. The presence of objective signs tends to suggest a significant organic or pathologic substrate underlying the patient's pain complaint, whereas excessive subjective signs in relation to objective signs tend to indicate a major psychological component to the patient's complaint but do not rule out underlying structural pathology.

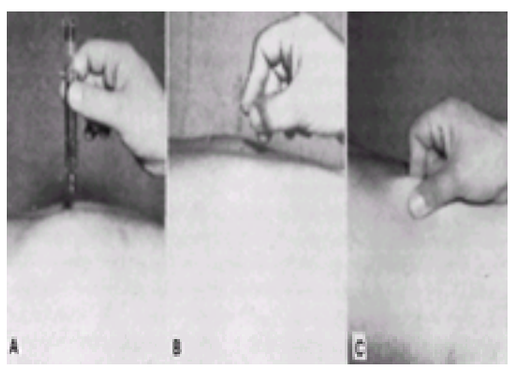

Figure 12-3. Techniques used for testing pain sensation. **A:** Pinprick test. **B:** Pin scratch test. **C:** Pinch test (see text).

Gunn and Milbrandt (12) mentioned two other objective signs that are manifestations of denervation sensitivity consequent to damage to spinal nerves that can be provoked by palpation. Both signs are manifestations of trophedema, in which a gradual thickening of subcutaneous tissue is seen and the overlying skin tends to be fissured and prone to heavy folds. This alteration in the quality of skin produces a *peau d'orange* effect similar to that described for malignant lumps of the female breast and is similarly accentuated when the skin is gently squeezed together or when the back is fully extended (Fig. 12-4). Trophedematous subcutaneous tissue has a boggy inelastic texture when rolled between the thumb and finger, distinguishable from subcutaneous fat. When a patch of skin and subcutaneous tissue a few centimeters in diameter is gently squeezed together it neatly forms a fold of flesh; in contrast, trophedematous tissue does not budge or finally yields altogether, with a sudden expanding movement similar to that of inflating a rubber raft. A second test that indicates trophedema is the matchstick test. Trophedema is nonpitting to digital pressure, but, when the end of a match is used, the indentation produced is clear–cut and persists for several minutes, distinctly longer than that seen over normal skin (Fig. 12-5). This test result may be positive and produce a deep indentation over an extensive area, or in milder cases it might only cause a slight

indentation over the skin overlying the tender motor points.

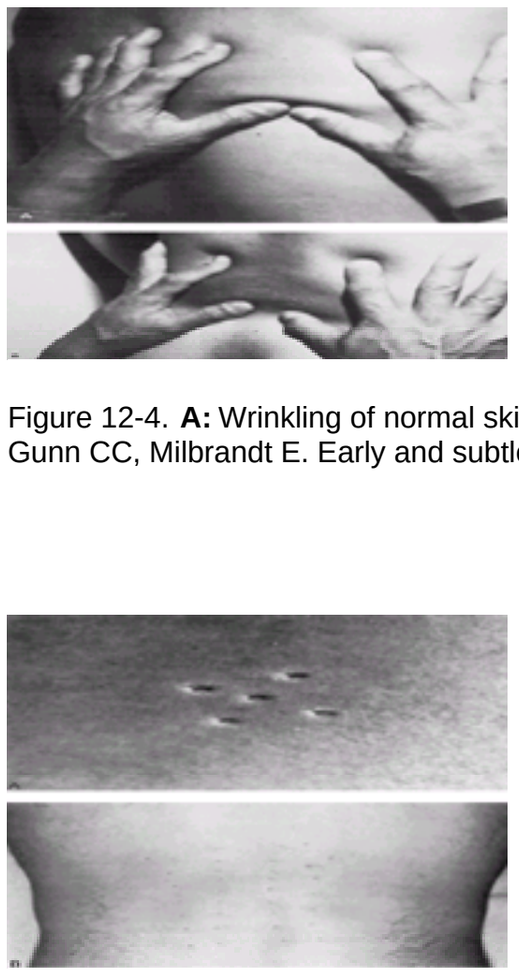

Figure 12-4. **A:** Wrinkling of normal skin when gently squeezed together. **B:** Trophedematous skin when gently squeezed together, the *peau d'orange* effect. (From Gunn CC, Milbrandt E. Early and subtle signs in low-back sprain. *Spine* 1978;3:267–281.)

Figure 12-5. **A:** The matchstick test. Trophedema may be found by pressing on the suspected area using the end of a matchstick. The deeper the indentations, and the longer they last (up to many minutes), the more severe the neuropathy. **B:** In low back pain, the matchstick test result is often positive over an area that is more widespread than the painful area. This patient had symptoms only in the low lumbar back, but indentations are seen at all lumbar levels, which indicates that even though pain is limited to one level the neuropathy is more extensive. (**A** from Gunn CC, Milbrandt E. Early and subtle signs in low–back sprain. *Spine* 1978;3:267–281.)

Other Procedures. In addition to these procedures, the pain is further evaluated by other methods. Factors or circumstances that reproduce, aggravate, or relieve the pain are determined, because they represent important and often conclusive evidence in making the diagnosis. One should particularly determine the effect on the part of pain of palpation, motion, application of heat and cold, exercise, walking up steps, deep breathing, coughing, sneezing, straining, digital pressure over the regional arteries, assumption of the prone, supine, and upright positions, and Valsalva's maneuver. In Bonica's experience, the intravenous administration of small amounts (100 mg) of thiopental sodium provided insight into the intensity of the noxious stimulus in body structures. Whereas this amount normally causes patients to manifest uninhibited overreaction in the presence of severe noxious stimuli, patients in whom the pain has little or no nociceptive basis manifest complete relief. This is not the case, however, in patients with central pain, in whom small amounts of intravenous barbiturate provide relief, whereas larger doses of narcotics do not. This is discussed in detail in Chapter 23.

Examination of Other Regions

Like many other clinicians, we believe that in any but the most obvious and simple cases the rest of the examination should be done because it frequently reveals pertinent data that cannot be obtained otherwise. The head, neck, chest, abdomen, back, and extremities are carefully examined and evaluated, but because these are discussed in detail in the introductory chapters on pain in various body regions, and because they are well known, they are not considered further here.

Neurologic Examination

After a complete history and general physical examination, which must be considered to comprise the cornerstone of the diagnostic evaluation of the patient with a pain complaint, a neurologic examination is carried out. In this section we present a screening neurologic examination that should be performed on all patients. A detailed examination of selected aspects of the nervous system relevant to specific regional pain syndromes is discussed in the introductory chapter to the various regional pain syndromes in Part IV of this book. A more detailed discussion of the examination of the nervous system can be found in works by De Jong (3) and by Wilkins and Rengachary (13). A discussion of the anatomy of the peripheral somatic and autonomic nervous systems is presented in Chapter 8, which contains illustrations of the dermatomes and sclerotomes.

Screening Neurologic Examination

A minimum neurologic examination should be performed on every new patient without regard to the region or type of pain. It takes only a few minutes to perform such a screening neurologic examination and is just as essential as auscultation of the heart and lungs and usually more valuable in the assessment of the patient with pain. It requires only the following simple instruments: clean safety pin, cotton applicator stick, tuning fork (128 or 256 cps), reflex hammer, and ophthalmoscope–otoscope. It is easiest for the examiner to have a clear-cut system and to follow the same routine whenever a patient is evaluated. The following procedure has worked effectively for us, but alternate schemes are certainly equally valid (Table 12-1). The patient should be comfortably seated on an examination table clad only in underwear or a loosely fitted gown.

Nerve or central nervous system location	Function tested
Cranial nerves	
II (optic)	Visual acuity and fields
III (oculomotor)	Extraocular muscles
IV (trochlear)	Pupillary constriction
VI (abducens)	Ocular movement
Cervical sympathetic	Pupillary dilatation
V (trigeminal)	Sensation in face and anterior two-thirds of the scalp; corneal reflexes; muscles of mastication
VII (facial)	Facial muscles
VIII (auditory)	Hearing, balance
IX (glossopharyngeal)	Gag and swallow
X (vagus)	Gag and swallow
XI (accessory)	Shoulder shrug, head rotation
XII (hypoglossal)	Tongue movement
Funduscopic examination	Retina, papilledema, vascular changes
Spinal nerves	
Sensation	Light touch, pinprick, vibration, position sense
Motor	Reflexes, strength, gross atrophy
Coordination	Gait, Romberg's test, rapid alternating movements, finger-to-nose testing
Cerebrum	Orientation, language, memory, mood

TABLE 12-1. Screening neurologic examination

Function of Cranial Nerves. The neurologic examination commences with the assessment of cranial nerve function. Visual acuity is easily tested by either a pocket

Snellen's chart or reading newsprint; visual fields can be evaluated by confrontation and contrasting the perimeters of the patient's fields to those of the examiner. This is a rather crude method, and significant visual field deficits can be missed unless formal perimetry is obtained (cranial nerve II). The functions of extraocular muscles and pupillary activity are then assessed. Conjugate gaze should be observed in the cardinal positions, nystagmus should be noted as present or absent, and the pupillary size, equality, and response to accommodation should be ascertained (cranial nerves III, IV, and VI).

The trigeminal nerve is quickly evaluated by checking corneal reflexes, facial light touch and pinprick sensation, and jaw deviation on opening (cranial nerve V). Facial muscles are assessed by observing facial tone and symmetry with grimace and eye closure (cranial nerve VII). Hearing is assessed by placing a watch adjacent to each ear or by rubbing the fingers together (cranial nerve VIII). The gag reflex is checked along with elevation of the uvula by placing an applicator stick lightly in each tonsillar region (cranial nerves IX and X). Strength in the trapezius and sternocleidomastoideus muscles is evaluated by shrugging the shoulders and by turning the head against resistance (cranial nerve XI). Tongue protrusion and lateral movements complete the screening examinations of the cranial nerves (cranial nerve XII). After the cranial nerves have been assessed, the ophthalmoscope is used to evaluate pupillary light reaction and the fundi. Every patient deserves funduscopic examination.

Function of Spinal Nerves and Neuraxis. Sensation over the trunk and extremities is rapidly screened; a tuning fork quickly tests vibration sense in each hand and foot. A cotton wisp is used to ascertain light touch in each extremity and over the chest and abdomen; a safety pin, discarded after use on each patient (or sterilized), is used to test pinprick sensation distally and proximally on each extremity and bilaterally over the chest and abdomen. The superficial abdominal and cremasteric reflexes are ascertained by stroking the abdominal and mesial thigh skin with the pin.

Screening motor evaluation is simple and rapid: gross strength in flexors and extensors at shoulders, elbows, wrists, finger abduction and adduction, and thumb opposition are determined, as is that of hips, knees, and ankles in flexion and extension. Myotactic reflexes at triceps, biceps, quadriceps (knee jerks), and gastrocnemius (ankle jerks) are readily tested with a reflex hammer (Fig. 12-6). Reflexes should be graded on a 0 to 4+ scale, and strength on a 0 to 5 scale. The presence or absence of Babinski's responses must be noted. (The innervation of specific muscles is presented in Table 8-2 in Chapter 8.)

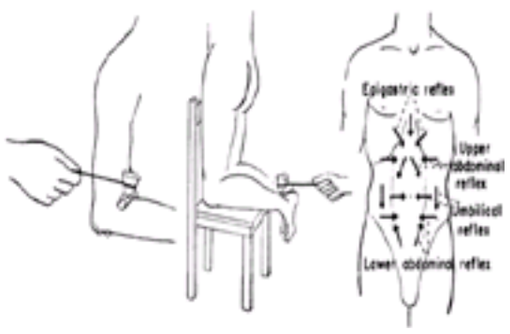

Figure 12-6. Methods for eliciting reflexes. **A:** Biceps reflex. **B:** Achilles tendon reflex. **C:** Sites for eliciting superficial abdominal reflexes.

Coordination can be assessed by observing sitting and standing balance, gait, finger-to–nose testing, and rapid alternating movements such as hand clapping or placing the thumb on the other fingertips. Romberg's test (standing with feet together and eyes closed) completes this segment of the examination.

Sympathetic Function. Sympathetic function is examined by measuring vasomotor, sudomotor, and pilomotor activities. Sudomotor function can be evaluated by observing the patient's sweating pattern in a warm room, by performing a formal sweat test, by means of an infrared skin temperature probe, or by measuring cutaneous resistance, because the major factor contributing to lowered skin resistance is the presence of sweat.

Pilomotor function can be examined by observing for the development of cutis anserina (goose flesh) on gentle stroking, tickling, or scratching of the skin. Vasomotor function can be evaluated by observing the flushing of the skin associated with vasodilatation and the pallor caused by vasoconstriction. The limb can be heated or cooled with the application of hot or cold towels and the skin inspected visually. Alternatively, one can measure skin temperature directly by application of a thermocouple to the skin and comparing temperature in one part of the body with that of the homologous region. Vasomotor activity also can be evaluated by more sophisticated technology, such as a laser Doppler device, which actually measures skin capillary blood flow. Measurement of skin temperature by ultraviolet photography or liquid crystal thermography devices are other highly sensitive methods of determining regional differences in skin blood flow. Thermography has no direct link to diagnosis or magnitude of pain.

Cerebral Function. The final portion of the screening examination is determination of cerebral function, which has already been evaluated to some degree during the history and physical examination. It is customary to assess orientation to time, place and person, recent and remote memory, parietal sensory function (e.g., right–left orientation, two–point discrimination, double simultaneous stimulation), language function, and purposeful coordinated movements. The assessment of mood is also essential (see Chapter 16).

The use of terms to describe sensory abnormalities is often confusing (6). *Hypesthesia* denotes decreased sensation or increased threshold for sensation, anesthesia denotes no sensation, hypalgesia means decreased response to a painful stimulus, and analgesia denotes absence of pain on noxious stimulation (see Chapter 2). *Paresthesia* means the report of an abnormal sensation, either spontaneous or evoked by stimulation; patients often use such terms as pins and needles. *Dysesthesia* denotes an unpleasant abnormal sensation. *Allodynia* is a term used for pain caused by a nonnoxious sensation, as in complex regional pain syndromes types I and II. It usually characterizes central hyperactivity after a nerve injury. *Hyperpathia* is a painful syndrome characterized by increased reaction to a stimulus, especially a repetitive stimulus, and an increased pain threshold. It is common to have paresthesia and dysesthesia after nerve injury; any combination of sensory aberrations can be found.

General Principles

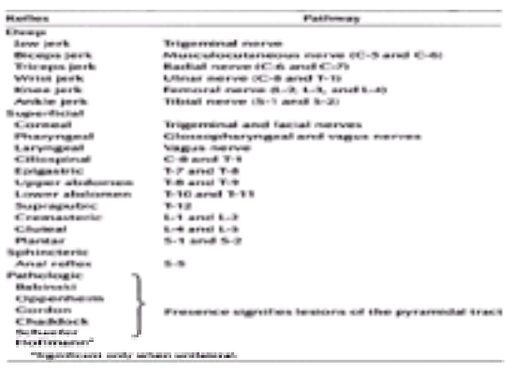
The question of what is normal or abnormal is often difficult for those who are not neurologists or neurosurgeons. A few general principles are helpful.

Except for strength, the right and left sides of the body should be identical on neurologic testing. Depending on occupation and physical condition, the dominant side of the body can be stronger (especially the grip) and the muscles have more bulk. Any asymmetry of sensation or reflex is abnormal.

A wide latitude of normal is seen on myotactic reflex testing (Table 12-2); absent reflexes are never normal, nor is clonus (4+ reflex). Table 12-3 lists the commonly tested superficial and deep reflexes and their segmental and peripheral nerve supplies.

Grade	Observation
0	Absent reflex
Trace	Reflex present only with facilitation
1+ to 3+	Normal range; asymmetry is significant
4+	Pathologically hyperactive; sustained clonus is present

TABLE 12-2. Grading of reflexes



Reflex	Pathway
Deep	
Jaw jerk	Trigeminal nerve
Biceps jerk	Musculocutaneous nerve (C-5 and C-6)
Triceps jerk	Radial nerve (C-6 and C-7)
Wrist jerk	Ulnar nerve (C-8 and T-1)
Knee jerk	Femoral nerve (L-2, L-3, and L-4)
Ankle jerk	Tibial nerve (S-1 and S-2)
Superficial	
Corneal	Trigeminal and facial nerves
Pharyngeal	Glossopharyngeal and vagus nerves
Laryngeal	Vagus nerve
Ciliospinal	C-8 and T-1
Epigastric	T-7 and T-8
Upper abdomen	T-8 and T-9
Lower abdomen	T-10 and T-11
Suprapubic	T-12
Cremasteric	L-1 and L-2
Gluteal	L-4 and L-5
Plantar	S-1 and S-2
Sphincteric	
Anal reflex	S-5
Pathologic	
Babinski	Presence signifies lesions of the pyramidal tract
Oppenheim

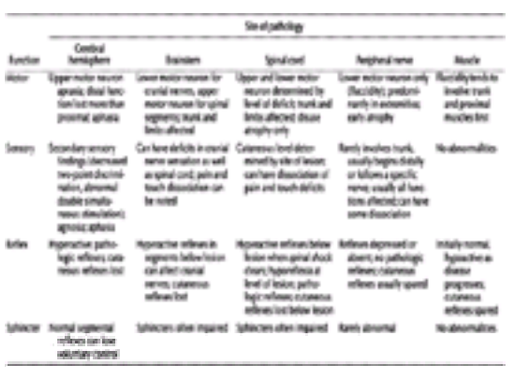
*Significant only when unilateral.

TABLE 12-3. Reflexes and their pathways

Neurologic deficits rarely end at the exact midline and tend to follow the territories of peripheral nerves, dermatomes, or hemibody. Deficits that are exactly horizontal are not likely to have a structural corollary: On the trunk, the dermatomes slope downward from the posterior midline. Somatically preoccupied patients often report profound sensory loss without apparent loss of function (e.g., the patient who claims to have an anesthetic hand can hold a pencil or grasp a key). Another sign of hysterical deficit is a sensory change that ends abruptly at the midline. Because nerves overlap somewhat from either side, such a finding is incompatible with a structural neurologic deficit. Similarly, the report that a vibrating tuning fork cannot be perceived on one side of the sternum or calvarium is a sign of hysterical sensory loss.

Patients with significant drug or alcohol intake often give bizarre neurologic examination results that revert to normal when drug effects abate. This is particularly true of the chronic pain patient receiving multiple narcotic and sedative-hypnotic drugs.

It is essential to describe the examination findings in writing before attempting to localize the lesion(s) and guess at the pathology. If the examiner has written down the findings, others can use the information to aid in establishing diagnosis and therapy. Variations in nerve territories and dermatomes occur. The patterns depicted in Chapter 8 are the most common, but by no means absolute, findings. Every physician should be able to characterize the findings on history and physical examination as suggesting a disease of muscle, peripheral nerve, spinal cord, brainstem, or cerebral hemispheres (Table 12-4).



Function	Site of pathology: Cerebral hemisphere	Brainstem	Spinal cord	Peripheral nerve	Muscle
Motor	Upper motor neuron signs; dorsal horn cell more than proximal aphasia	Lower motor neuron for cranial nerves, upper motor neuron for spinal segments; trunk and limbs affected	Upper and lower motor neuron determined by level of deficit; trunk and limbs affected; disuse atrophy only	Lower motor neuron only (flaccidity); predominantly in extremities; early atrophy	Fasciculity; tends to involve trunk and proximal muscles first
Sensory	Secondary sensory findings; observed two-point discrimination, abnormal double simultaneous stimulation; agnosia; aphasia	Can have deficits in cranial nerve sensation as well as spinal cord; pain and touch dissociation can be noted	Cutaneous level determined by site of lesion; can have dissociation of pain and touch deficits	Rarely involves trunk, usually begins distally or follows a specific nerve; usually all functions affected; can have some dissociation	No abnormalities
Reflex	Hyperactive pathologic reflexes; cutaneous reflexes lost	Hyperactive reflexes in segments below lesion can affect cranial nerves; cutaneous reflexes lost	Hyperactive reflexes below lesion when spinal shock clears; hyperreflexia at level of lesion; pathologic reflexes; cutaneous reflexes lost below lesion	Reflexes depressed or absent; no pathologic reflexes; cutaneous reflexes usually spared	Initially normal; hyporeactive as disease progresses; cutaneous reflexes spared
Sphincter	Normal segmental reflexes can lose voluntary control	Sphincters often impaired	Sphincters often impaired	Rarely abnormal	No abnormalities

TABLE 12-4. Clinical manifestations of neurologic pain

Common diseases are more likely than rare ones. Most patients do not harbor more than one active disease affecting the nervous system.

Sensory examination requires a high level of patient attention and cooperation if the results are to be meaningful. All sensory responses are subjective; it is only the recognition of a familiar pattern that causes the examiner to believe that some sensory findings are objective. It is wise to perform the sensory examination before the patient is fatigued. The patient must be alert, relaxed, and informed if the results are to be significant. Patients in severe pain often cannot give an accurate sensory examination.

Examination of the Musculoskeletal System

A screening examination of the musculoskeletal system indicates or excludes functional impairment of this system. If an abnormality is revealed, a more detailed examination of the region is indicated, as discussed in various chapters in Part IV. The occupation of the patient may be highly relevant to the complaint of pain (14). The following is the sequence recommended by Clawson and associates (15) and incorporates strategies described by Waddell and Turk (16).

The patient must disrobe with the exception of underwear. The patient is inspected from the front, side, and back. Attention is directed to body type and posture, abnormal spinal curvature, deviation from normal alignment of the limbs, and other deformities, such as abnormalities of the foot arches and toes. It is important to note the symmetry of the shoulders, the overall symmetry of the arms, elbows, forearms, and hands, and the symmetry of the pelvis, thighs, knees, legs, and feet.

Inspection of the patient from the side permits assessment of the degree of cervical lordosis, dorsal kyphosis, and lumbar lordosis, whereas inspection from behind the patient permits determination of lateral curvature if the spine is in balance. The term *balance* describes the patient with scoliosis whose head is in line over the middle of the pelvis. If the head is lateral to the middle of the pelvis, progressive deformity can be expected.

The patient is then asked to walk in the examining room or large area outside the examining room, and any abnormal forward or backward movements or other irregularities of gait are noted. In addition, the arm swing, stride length, and the push off and heel strike should be observed and recorded. As the patient walks toward the examiner, abnormal side–to–side movements of the trunk and other abnormal movements are looked for. The patient should next be asked to walk on the toes, holding the examiner's hand if necessary for stabilization to test the motor function of the S–1 nerve. The patient is then asked to walk on the heel (again holding the examiner's hand if necessary), a maneuver that assesses the innervation of the dorsal flexors of the ankle, which are innervated primarily by the L–5 nerve.

In examining the muscular system one should observe the strength and power, tone, volume, and contour of the muscle, noting any atrophies, hypertrophies, or signs of irritability such as fibrillary twitching (2,10,14). For proper evaluation of muscle strength it is necessary to know the normal function of each muscle or muscle group as well as the peripheral and segmental nerve supplies (see Table 8-2). The following brief outline can be used as a preliminary or screening appraisal of the strength and function of important muscle groups. These can be evaluated by observing their motions and comparing them with those of the opposite side, or by applying passive resistance to the movement or having the patient resist the examiner's active attempt to move fixed parts.

Neck Muscles

The range of motion of the neck is measured in full flexion, extension of the neck, and lateral and rotatory movement of the head. Normal function requires that in full

flexion the chin touch the chest and in extension the examiner's finger be trapped between the occiput and the C–7 spinous process, whereas rotation should be more than 70 degrees from the sagittal plane (Fig. 12-7; see also Chapter 55 and Fig. 55-1, Fig. 55-2, and Fig. 55-3).

Figure 12-7. Maneuvers for testing muscle function. **A:** Lateral flexors of the neck. **B:** Biceps brachii. **C:** Flexors of the thigh.

Upper Extremity

The function of the muscle of the upper extremity is evaluated by testing the hand grip, raising of the shoulder, abduction of the arms, flexion, extension, supination, and pronation of the forearm, flexion and extension of the wrist, abduction and adduction of the fingers, and touching the fifth finger with the thumb. The patient is asked to stretch out the arms horizontally in front of the body with the fingers spread to check symmetry. The function of the palmar intrinsic muscles is assessed by the examiner's attempt to press the fingers together against the patient's resistance to the movement.

The patient is asked to abduct the arms fully, placing the palms together above the head. Normally the arms touch the ears, with the head and cervical spine in the vertical position. This maneuver tests the functional range of the shoulder, acromioclavicular, and sternoclavicular joints as well as the functional range of lateral rotation of the humerus.

The patient is asked to bring the arms to the side, rotate the humerus medially, and move the forearm up to place the thumb on the back between the scapulae. Normally, the hand should reach the level of the inferior angle of the scapula. The range of movement of the elbow is also tested in this manner and painful affliction, deformities, and muscle weaknesses are thus revealed. The symmetry of the two sides should be ascertained.

The patient must grasp the index and long fingers of each of the examiner's hands. The examiner attempts to move the patient's arms in all directions (up, down, laterally, and medially) while maximum resistance is offered by the patient. This is an effective, although somewhat crude, method of assessing strength of the muscles of the hand, wrist, and elbow, and even of the shoulder. Pain in any of the joints in the upper limb can result in failure to offer resistance.

Trunk Muscles

The muscles of the trunk are evaluated by asking the patient to take a deep breath, get up from a recumbent to a sitting position with the arms folded on the chest, and to flex, extend, and rotate the trunk. The patient is asked to bend forward and attempt to touch the floor while keeping the knees extended. The presence or absence of scoliosis is best demonstrated in this position. The lumbar spine is further tested by having the patient extend as far back as possible, and the thoracic spine is tested by performing rotation movements. To test rotation of the spine effectively, the physician stabilizes the pelvis and asks the patient to rotate as far as possible. The greatest range of rotation occurs in the thoracic spine.

Lower Extremity

The function of the muscles of the lower extremity is evaluated by having the patient step up, raise the leg, and rise from a squat position; resistance abduction and adduction of each limb as well as flexion and extension of the leg, foot, and toes are tested also. Having the patient squat with the feet flat on the floor and the knees and hips fully flexed is an excellent way to assess the function of all major joints of the lower limbs. Watching the manner in which the patient gets down and up provides an accurate impression of the muscle power of the limbs.

The history and physical examination are the cornerstones of diagnosis for the patient with acute or chronic pain. Those who have not perfected the art of obtaining both of these are at peril in the management of the patient with pain.

CHAPTER 13

Electrodiagnostic Evaluation of Acute and Chronic Pain Syndromes

Walter C. Stolov

The common association of somatosensory and somatomotor systems involvement in acute and chronic pain syndromes requires a complete evaluation of these systems to establish an accurate diagnosis. Although the clinical history and the physical examination can suggest involvement, and structural radiologic examinations can imply damage to the central and peripheral somatic systems, only direct examination can confirm or deny that function has been lost or impaired.

This chapter reviews the reactions of nerve and muscle to injury and defines the terminology likely to be present in a report of an electrodiagnostic medicine examination. The subsequent discussion includes common entrapment syndromes, radicular syndromes, traumatic syndromes, systemic syndromes, and functional syndromes that are associated with pain and are electrodiagnostically analyzable. For more detailed discussions, several standard texts can be consulted (1,2,3,4 and 5).

BASIC CONSIDERATIONS

The reactions of nerve and muscle to injury are relatively small in number. Their detection and localization, however, can be elusive if the electrodiagnostic medicine examination is inappropriately designed. In electrocardiography or electroencephalography, in which electrode placements are standard, the test can be administered by a technician and the data later interpreted by the appropriate physician. Electrodiagnostic examinations, on the other hand, are highly individualized, and rarely are any two examinations alike. In electrodiagnosis, the plan of the examination is more important than the interpretation of the results. An incomplete study whose results are properly interpreted can lead to incorrect diagnoses, and subsequently inappropriate treatment.

For illustration, consider an electrodiagnostic study of a patient with hand pain and numbness in which the distal motor and sensory conduction of the median nerve from the wrist to the hand is found to be prolonged. A conclusion that a carpal tunnel syndrome is present would indeed be consistent with the data. It might be incorrect, however, because of the failure to include a more proximal examination of median nerve conduction and a study of other nerves to ensure that a peripheral neuropathy is not present. In the latter, distal segments of all the peripheral nerves are likely to show slowed conduction, no more or less so than the median nerve, making a carpal tunnel syndrome diagnosis highly unlikely.

The electrodiagnostician has a large number of muscles that can be studied and peripheral nerves and segments of peripheral nerves that can be examined. Also, many central evoked responses can be studied on peripheral stimulation to provide information on spinal cord and cerebral function. Central responses from stimulation of all the peripheral nerves can be examined.

In view of the number of available elements that can be tested, an effective electrodiagnostic examination must first begin with a plan of what should be examined, based on historic and examination data. Specifically, the initial plan is based on the following items:

- The differential diagnostic possibilities of concern to the referring physician
- The additional diagnostic possibilities suggested to the electrodiagnostician after review of the patient
- Knowledge of the anatomy and physiology of the neuromuscular and musculoskeletal systems
- The electrodiagnostic findings expected from the various reactions of nerve and muscle to injury and disease
- The effect that premorbid disease or trauma can have in modifying results
- The level of sophistication of equipment available

Furthermore, examination plans are not static. They can be modified as the examination evolves, for results initially obtained might suggest additional diagnostic possibilities not previously considered.

For the electrodiagnostic examination to contribute effectively to the analysis of acute and chronic pain syndromes, it must be done by a physician trained in electrodiagnostic medicine, not only for the interpretation but also for the actual performance of the examination, because of the on-the-spot judgments that need to be made.

A useful measure of competence is successful passage of the rigorous written, practical, and oral examinations of the American Board of Electrodiagnostic Medicine, admittance to which requires documented training.

The current terminology for an electrodiagnostic study is an *electrodiagnostic medicine examination (or consultation)*. *Electromyography* (EMG) has in part become a generic term inclusive of all the available studies, as has the term *electromyographer* to describe the examiner. Strictly speaking, electromyography refers exclusively to needle electrode evaluation of action potentials seen in skeletal muscles at rest and on volition, and hence parallels the definition of electrocardiography and electroencephalography. The terms *electrodiagnostic medicine* and *clinical neurophysiology* are mostly used to describe the laboratories in which electrodiagnostic medicine examinations are performed. The glossary prepared by the American Association of Electrodiagnostic Medicine, which is adhered to by many, has standardized the definition of many terms that are used (6). For the purposes of this review, the following definitions are used:

EMG refers to direct examination of skeletal muscle via needle electrodes.

Nerve conduction studies (NCS) refers to examination of conduction along peripheral motor and sensory nerves and plexuses.

Late responses refers to potentials evoked by peripheral stimulations that evaluate spinal cord or near spinal cord function.

Somatosensory-evoked potential (SEP) *responses* refers to potentials detected over the spinal cord, brain, or both on peripheral nerve stimulation, and on stimulation of the skin over dermatomal sites and over peripheral sensory nerve fields.

Reactions of Nerve and Muscle to Injury

Nerve

Peripheral motor, sensory, or mixed nerves contain myelinated and unmyelinated fibers. NCS largely focuses on the faster-conducting myelinated fiber, and of this group the larger diameter, fastest-conducting fibers are the ones most easily studied. Conduction in such fibers can be slowed or blocked through disease or injury to

the myelin, the axon, or both. The effect of disease or trauma can be local or diffuse, and in any given whole nerve it can affect some or all of the fibers.

A primary demyelinating process can include a denuding at the nodes of Ranvier, a diffuse or relatively localized thinning of the myelin with a resultant decrease in diameter, or a more general disorganization, again diffuse or segmental. An intussusception of the myelin at the nodes can occur also. Thinning and denuding result in a slowing of conduction and can progress to induce a reversible or irreversible conduction block. When remyelination occurs, the new myelin is thinner and the nodes of Ranvier end up closer together, resulting in slow conduction even if the causal factor has been removed.

In a reversible conduction block, a natural or electrically induced action potential (e.g., traveling wave of depolarization) fails to continue through the region of damage. In such a situation, stimulation of the nerve fiber on the distal side of the block results in conduction. The axon in this example remains relatively healthy, hence the myelinated fiber distal to the block remains unaffected. Such a block remains reversible if it is possible to remove the cause of demyelination or axolemma damage and permit the healing process to take place. If the primary demyelinating process progresses to cause axonal degeneration, the block becomes irreversible. On the distal side of such a lesion, wallerian degeneration occurs and the distal nerve segment can no longer conduct impulses until axonal regrowth occurs (Fig. 13-1).

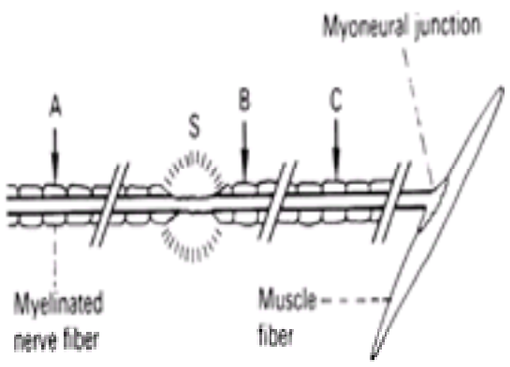

Figure 13-1. Schematic of nerve-muscle complex illustrating conduction block. In the normal situation, stimulation at point A elicits a response at points B and C and at the muscle. If a reversible block (neurapraxia) exists at site S, then stimulation at point A will not elicit a response at points B or C or at the muscle. Stimulation at point B, however, elicits a response at point C and at the muscle because the nerve segment distal to the block is still capable of conduction. If an irreversible block has developed at site S, stimulation at point B will not produce a response at point or at the muscle because the nerve segment distal to the block has undergone wallerian degeneration.

Primary axonal disease can also induce slowing of conduction through a reduction in fiber diameter. Slowing so induced is of a lesser magnitude than the slowing induced by a demyelinating process. Axonal disease is generally associated with metabolic disorders and diffusely affects the entire length of the axon (e.g., diabetes, uremia, folate deficiency). Primary axonal disease is not associated with reversible conduction blocks. The most distal segment of the axon, however, can progress to degeneration. The greater the distance from the nourishing cell body, the more likely degeneration and loss of conduction. Hence, the signs are more pronounced distally. Primary axonal disease can induce secondary demyelination. It is therefore not uncommon, in processes that are primarily demyelinating or primarily axonal, for the electrodiagnostic medicine examination to exhibit features of both.

Processes that affect nerve fibers, be they axonal or myelin in origin, and their associated slowing or conduction blocks can occur in the central and peripheral somatomotor and somatosensory systems and, hence, are potentially uncoverable through the electrodiagnostic medicine examination. Axon and myelin disease processes do not affect all nerve fibers equally. Because electrodiagnostic NCS or SEP studies involve examination of the responses from whole nerve stimulation, the results reflect the collective effect of all the nerve fibers in the group.

Muscle

The response of skeletal muscle to injury of primary importance in EMG and NCS is that which occurs secondary to denervation.

The muscle fibers in skeletal muscle are organized into motor units, the number of muscle fibers per unit ranging from approximately 10 in the extraocular muscles to 2,000 in the large muscles of the leg. A motor unit is made up of a single anterior horn cell, its axon, the terminal branches of the axon, and the muscle fibers that are attached to each terminal branch via the myoneural junction (Fig. 13-2). Thus, in a healthy motor unit, depolarization of an anterior horn cell on volition or of an axon through external stimulation results in an ultimate depolarization and contraction of all the muscle fibers of the motor unit to which it is connected. The wave of depolarization successfully travels in all the branches of the axon and induces, through acetyl choline release at the myoneural junction, a depolarization wave along the individual muscle fibers of the unit to initiate the excitation-contraction coupling process.

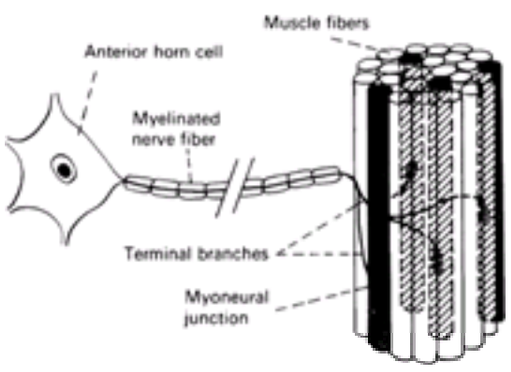

Figure 13-2. The components of a single motor unit. The muscle fibers of the unit (*shaded*) are interspersed among fibers of other units. The myoneural junctions are located approximately midway between the ends of the muscle fibers.

The muscle fibers of a single unit in the muscle are interspersed among muscle fibers of other units; in a large muscle a single unit can have a cross-sectional diameter of as much as a centimeter. Furthermore, the number of fibers per unit within a single whole muscle is variable and obeys the size principle. Smaller anterior horn cells have thinner axons, fewer terminal branches, and a smaller number of muscle fibers per unit, and they are more easily depolarized on volition. When externally stimulated, however, the thicker axons of the larger anterior horn cells have lower thresholds and are depolarizable at lower current strengths than are the thinner axons of the smaller anterior horn cells.

At rest, although nerve and muscle cell membranes are polarized, the positive charge densities on the outside and the negative charge densities on the inside contribute no net electric field externally. Hence, the environment of the cells is electrically silent at rest. Should a depolarization wave be induced, either on volition or by external stimulation, the uniformity of the charge densities is disrupted and measurable electric fields are induced. The resultant action potentials are detectable along the nerve or in the muscle.

When denervation occurs, the reaction of the muscle fibers is the same regardless of cause. The myoneural junction degenerates, and the entire muscle fiber membrane becomes sensitive to acetylcholine. The membrane potential becomes unstable and circulating acetylcholine can spontaneously depolarize the cell at any site along its membrane, inducing the excitation-contraction coupling process and causing the fiber to fibrillate. The time course from axon death to fibrillation varies. It depends on the distance from the site of axon death to the target muscle. The longer the nerve fiber, the more *nutrition* it contains and the longer it takes for

fibrillation to occur. In the case of damage to a nerve root, for example, the paraspinal muscles may begin to fibrillate 7 to 10 days after axonal death, whereas the distal muscles of the lower extremities may not fibrillate for 17 to 21 days.

Muscle fiber atrophy commences with denervation and degeneration of the denervated fibers may begin to occur within a year. Some fibers last a long time in an atrophic, denervated state.

In primary muscle disease (e.g., dystrophy, myositis), a relatively similar response occurs in diseased muscle fiber. Muscle fiber membranes become unstable and can spontaneously fibrillate. Furthermore, in primary muscle disease the number of muscle fibers per motor unit decreases as individual muscle fibers die. This occurs without damage to the nerve fiber, although in myositis the inflammatory process can also involve distal terminal nerve branches.

Nerve-Muscle Repair

If axon death occurs through, for example, compression, blunt trauma, or section, the distal segment of the nerve degenerates. Regeneration of this segment can occur as long as the cell body remains intact and connective tissue continuity is preserved or can be fashioned. In compression or blunt trauma, the endoneurial connective tissue sheath of the axon is preserved, providing a conduit for regrowth of the nerve fiber. In nerve rupture or clean sections, surgical approximation of the proximal and distal nerve ends or a nerve graft is required to permit reinnervation to occur.

After axon interruption, it takes approximately 1 month for the cell body to prepare itself for the regrowth process. The regrowth rate itself varies from 2.5 to 4.0 cm per month (7). Rules of thumb that can be used are a millimeter per day, a centimeter per week, or an inch per month. In motor nerves, an additional month may be required to establish new myoneural junctions once the regenerating nerve fiber has reached its muscle. Using these time frames for cell body preparation, linear growth, myoneural junction recovery, and the length of the nerve segment of interest, one can predict when reinnervation will occur if regeneration is possible. When muscle fibers are reinnervated, they cease to fibrillate and are subsequently restored to their more normal diameter.

Regenerating nerve is of small diameter and at first either nonmyelinated or only partially myelinated. It therefore conducts impulses more slowly than a normal fiber. Even when fully mature, a normal conduction velocity might not be achieved and the size of the new motor unit might not equal that of the preinjury state. Furthermore, the number of muscle fibers reinnervated depends in part on how far away the target muscle is from the initial site of axon interruption. Some muscle fiber degeneration may have occurred by the time regenerating nerve fibers reach the muscle. Reinnervated muscle fibers of a unit are more likely to be clumped together rather than dispersed and intermingled with fibers from other units.

Denervated muscle fibers do not last indefinitely if not reinnervated. Some begin to disintegrate at 1 year, and most, if not all, are gone by 3 years and the muscle becomes fibrotic. Even if regrowing axons arrive, no muscle fibers exist to innervate.

A second healing process, collateral reinnervation, also exists; it occurs much more rapidly if not all of the motor nerve fibers to a given muscle are damaged. In collateral reinnervation, undamaged motor nerves are signaled, in an as yet unknown way, to grow new branches, which then seek to reinnervate the denervated muscle fibers. This process yields an increase in the number of motor fibers per motor unit and can be detected within 1 month of injury.

Electrodiagnostic Medicine Examination and Its Terminology

All of the reactions to injury of nerve and muscle and the healing processes described are detectable in an appropriately designed electrodiagnostic medicine examination. The electrical equivalents of these processes have a specific vocabulary. The data displayed in the electrodiagnostic report are described in specific ways. This section defines and clarifies how the EMG, NCS, late response studies, and SEP examinations reveal injuries to nerve and muscle. It must be remembered that the descriptions of the reactions of nerve and muscle to injury were expressed in terms of single nerve fibers, single muscle fibers, and motor units. In the electrodiagnostic medicine examination, whole nerves or whole muscles are studied and explored. The responses that are seen in these examinations can thus be a mix of normality and abnormality because disease or trauma affects individual nerve fibers, muscle fibers, motor units, and central nervous system elements in variable and incomplete ways.

Electromyography

In an EMG, individual skeletal muscles are explored with monopolar or concentric needle electrodes to detect membrane instability, alterations in the character of the individual motor units, and the number of motor units (i.e., volitionally active motor neurons) in the muscles. The examination begins with the skeletal muscle at rest.

Insertion activity refers to the responses obtained when the needle is moved in small increments through the muscle (Fig. 13-3A). The slicing of the needle through the muscle cells disturbs the uniform charge density distributions, producing local currents and recordable high-frequency short-lived potential changes. This activity is sustained during the movement and ends when needle movement ceases. If many muscle fibers have already degenerated, insertion activity is reduced because a reduced number of viable, excitable cells are present. If membrane instability is present, either from denervation, primary muscle disease, or, in some instances, upper motor neuron disease, two additional responses are seen after needle movement ceases: positive sharp waves and fibrillation potentials, representing abnormal spontaneous single muscle fiber discharges.

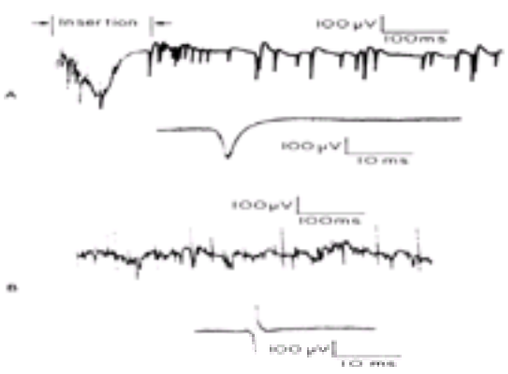

Figure 13-3. Involuntary needle electromyography action potentials at rest (negative values are above the baseline). **A:** Insertion potentials are seen in the first 250 ms of this record. They were produced as the needle sliced through muscle fibers. The insertion potentials are followed by a train of positive sharp waves. A single positive sharp wave is also illustrated. **B:** Fibrillation potentials. The sharp spikes are seen against a background of positive sharp waves. A single fibrillation potential is also illustrated.

Positive sharp waves are electrical potentials that persist following cessation of needle movement (see Fig. 13-3A). These potentials have characteristics that make them easily recognizable. They occur in muscle fibers whose membranes are partially unstable but usually not so unstable that they fibrillate spontaneously. Needle injury of these partially unstable fibers induces a regular frequency discharge, which generally progressively decreases in amplitude, slows in frequency, and ultimately ceases. Positive sharp waves in a progressive lesion are generally followed in several weeks by the second sign of membrane instability—namely, that associated with fibrillation.

Fibrillation potentials are seen in association with fully unstable muscle fiber membranes (Fig. 13-3B). These are single muscle fiber action potentials associated with spontaneous fibrillation. Fibrillation potentials are also easily recognizable and are distinguishable from positive sharp waves. They can also be triggered by needle movement as the local currents induced by movement depolarize nearby susceptible unstable fibers.

The amount of positive sharp wave and fibrillation potential activity is often graded from 1+ to 4+. This grading scale is nonlinear (e.g., 2+ does not mean there is twice as much damage when compared with a 1+ response). The amplitudes are also examined; if small (less than 100µV) they may reflect responses from atrophic fibers and suggest that the instability is chronic or at least of approximately 6 months' duration. Positive sharp waves and fibrillation potentials on recently diseased

muscle fibers are generally larger.

Fasciculation potentials are also examined for, with the patient at rest. They are involuntary discharges of whole motor units or parts of motor units and are neurogenic in origin. Discharge frequencies are irregular and range from approximately 3 to 20 per minute. Their size and shape resemble those of motor unit action potentials (MUAPs; described in this section). The site of the initial depolarization can be at the anterior horn cell (e.g., amyotrophic lateral sclerosis) or along the axon from an external irritation (e.g., compression, trauma).

Complex repetitive discharges can also be seen with the patient at rest. They are involuntary and highly localized. The action potentials associated with these discharges are of high frequency, and the discharges are continuous, usually of a collection of individual muscle fibers depolarized by ephaptic excitation. They start and stop abruptly and are nonspecific in that they can be seen in chronic or old neurogenic or myopathic disease.

After examining the muscle with the patient at rest, the examiner asks the patient to perform weak volitional activity and examines the action potentials produced. The MUAPs are the responses seen when all of the muscle fibers of a particular motor unit are depolarized in a relatively synchronous manner. These potentials are much larger in amplitude and longer in duration than positive sharp waves and fibrillation potentials (Fig. 13-4). With weak contraction, the motor units initially recruited are the type I motor units, which discharge at rates of 5 to 10 per second. Normal MUAPs are usually triphasic in character. In stronger contractions, type II motor units are recruited. These have larger amplitudes and longer durations. Maximum contractions in a normal muscle reveal a discharge of many MUAPs, which flood the screen. The development of this recruitment pattern is carefully examined. In abnormal states, a reduced recruitment pattern on maximum contraction can be caused by a loss of lower motor neurons or loss of upper motor neuron drive. Functional and pain inhibition also produces a reduced recruitment pattern. The patterns for each are different and easily recognizable by the experienced examiner.

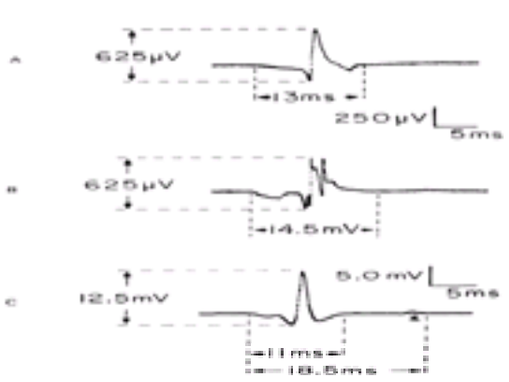

Figure 13-4. Samples of motor unit action potentials recorded by monopolar needle electrodes. **A:** Normal triphasic wave. **B:** Polyphasic (eight phases) wave of longer duration and of similar amplitude. **C:** Large amplitude potential with a triphasic basic component and a small late component, a satellite potential (*). Note amplitude calibration in **C** compared with that in **A** and **B**.

In disease states, individual MUAPs can show decreases in amplitude and duration (e.g., a reduced number of muscle fibers per motor unit) or an increase in amplitude and duration (e.g., a greater than normal number of muscle fibers per motor unit) and excessive polyphasicity (see Fig. 13-4B). Polyphasicity can be caused by a reduction in the number of muscle fibers in a motor unit, as is common in primary muscle disease, or loss of synchronous discharge of the muscle fibers because of increased variability in conduction velocities of terminal nerve branches. Polyphasic potentials are usually associated with a decrease in the amplitude and duration of the MUAP. Small-amplitude, short- or long-duration polyphasic MUAPs also occur after nerve fiber regeneration. Polyphasicity with normal or larger amplitude MUAPs is seen in association with collateral reinnervation processes. MUAP amplitude, duration, phasicity, and the recruitment pattern on volition can be measured quantitatively or qualitatively and assessed for increases or decreases with regard to normal expectations.

Single-fiber electromyography (SFEMG) is a specialized technique not usually useful in the analysis of pain syndromes. The response of a single muscle fiber from a single motor unit, discharging during a weak volitional contraction, is examined with a special needle. If the needle picks up a synchronous discharge from other individual muscle fibers of the same unit within the region of the needle, an increased density of fibers within the unit can be surmised and suggests a state of reinnervation (8).

Peripheral Nerve Conduction Studies

Motor Nerves. External stimulation of a mixed or pure motor nerve induces contraction of the target muscle it serves. If the electrical stimulus is supramaximal (e.g., all motor neurons stimulated), then all motor units within the target muscle are depolarized relatively synchronously. A biphasic potential (M wave) is usually recorded if the recording surface electrode is placed over the motor point of the muscle (Fig. 13-5).

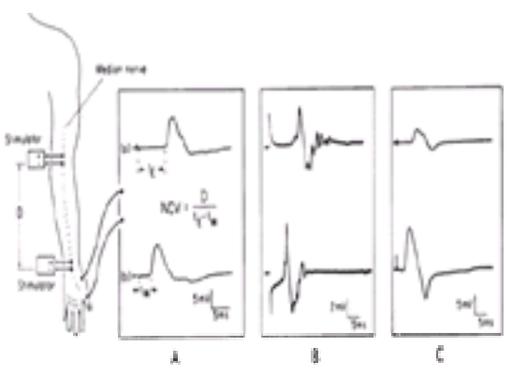

Figure 13-5. Schematic representation of the determination of median nerve motor conduction velocity (NCV) from the elbow to wrist, illustrating three different types of responses: t_E and t_W are the latencies from time of stimulation to time of onset of response of the muscle, from elbow and wrist stimulation, respectively. *D* is the distance between the two points of stimulation. **A:** A normal response. Note that the amplitude of the response from the elbow and wrist stimulations are essentially equal, as are the wave shapes. **B:** Temporal dispersion associated with segmental demyelination. Note the smaller amplitude of the response on elbow stimulation compared with stimulation at the wrist as well as distortion of the wave when the elbow response is compared with the wrist response. **C:** Partial neurapraxic block between the two points of stimulation. Note the much smaller response from elbow stimulation without distortion of wave form when compared with the response on wrist stimulation.

The *latency* of the response is the length of time from initiation of the stimulation to the beginning of the muscle response. It is a measure of the speed of the fastest conducting motor neurons in the nerve bundle. If the nerve can be accessed in at least two places, both proximal to the target muscle, the velocity of conduction of the fastest motor neurons in the nerve segment between the points of stimulation can be obtained. A subtraction of the distal latency from the proximal latency removes any need to consider neuromuscular transition time.

Conduction velocity is determined by dividing the distance between the two sites by the difference in the two latencies, because this difference reflects the time the depolarization wave, induced at the proximal site, took to reach the distal site of stimulation. The *amplitude* of the response is a measure of the number of motor units present within the target muscle. The *duration* of the response reflects the range of velocities of all the motor neurons in the nerve bundle to the muscle. The amplitude of the response from the more proximal stimulation is generally smaller than that obtained from the more distal stimulation, whereas the duration is generally longer. In a normal situation, an amplitude decrease of approximately 20% or a duration increase of approximately 15% occurs because of normal temporal

dispersion. The dispersion occurs because, as the distance traveled increases, the differential time of arrival of the fastest and the slowest nerve fibers at the muscle from the proximal stimulation is greater than that from the more distal stimulation.

An increase in temporal dispersion occurs when the range of values of the slowest to the fastest fiber has increased through segmental demyelination (see Fig. 13-5B). This increase is manifested by a larger decrease in amplitude, a longer duration, and a wave shape distortion when the response to proximal stimulation is compared with the response to distal stimulation. A large decrease in amplitude, when one is comparing the proximal with the distal stimulation without an associated increase in duration, usually means that at least a partial neurapraxia exists between the two points of stimulation (see Fig. 13-5C). Some of the fibers, stimulated proximally, are blocked, and the depolarization wave does not reach the muscle.

Sensory Nerves. The parameters of latency, amplitude, and conduction velocity and the possibility of neurapraxia pertain also to peripheral sensory nerve examination (Fig. 13-6). Action potential duration is usually not useful. Conduction velocity determination requires only a single stimulation because the evoked response is sampled at a point over the nerve itself. Velocity is determined by dividing the distance between the site of stimulation and the location of the sampling electrode by the latency of the response. Amplitudes reflect the number of viable sensory fibers capable of conducting impulses from the stimulating to the sampling electrode. Sensory nerves can be measured orthodromically (in the direction they physiologically conduct) or antidromically. The amplitudes of the sensory-evoked responses are on the order of magnitude of microvolts and are more difficult to measure than those evoked over muscle on motor nerve stimulation, which are usually on the order of magnitude of millivolts.

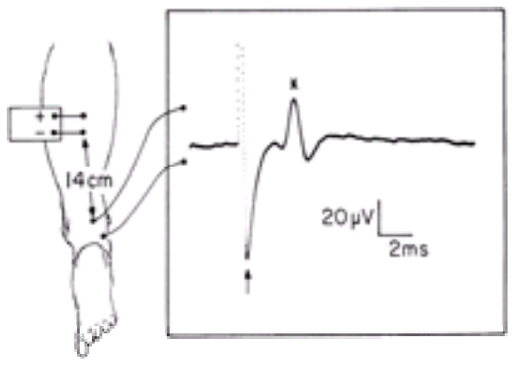

Figure 13-6. Sural nerve sensory conduction. The nerve was stimulated at the calf, and the antidromic response was sampled behind the lateral malleolus. The stimulus artifact is indicated by the arrow, and the sensory-evoked response by the asterisk. The distance between the cathode of the stimulator and the response electrode was 14 cm. The latency of the response measured to the peak of the negative deflection was 3.4 milliseconds, yielding a conduction velocity of 41 m/sec.

Late Responses. Peripheral stimulation also produces peripheral responses that are evoked after the action potential induced on peripheral stimulation has traveled to the spinal cord or brainstem and returned. Some are true reflexes (e.g., H wave, tibial sensory–tibial motor; blink reflex, cranial V–VII; bulbocavernosus reflex, pudendal sensory–pudendal motor), whereas others (F waves) are not.

The H-wave response is the electrical equivalent of the ankle deep tendon reflex, when the tibial nerve is stimulated. It is a monosynaptic reflex response. Stimulation is performed over the tibial nerve behind the knee via current selections that favor stimulation of the group 1A afferent fibers in the nerve. The synapse occurs in the spinal cord at approximately the level of the S-1 root entry zone. After the synapse, discharge of the anterior horn cells induces the motor response (Fig. 13-7A). The response is sampled via surface electrodes over the gastrocnemius-soleus group. The latency of the response, as modified by age, length, or both, and the amplitude are the parameters examined. Disease or injury anywhere along the pathway (tibial nerve, S-1 root, vertebral canal, spinal cord) induces abnormalities.

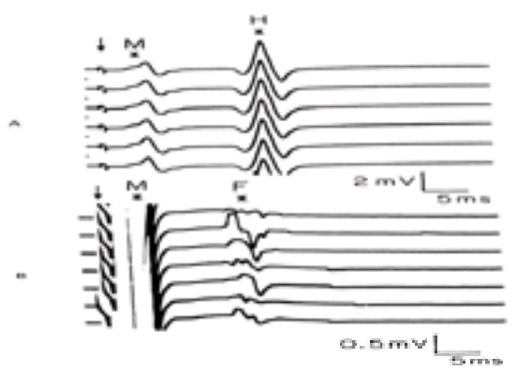

Figure 13-7. Late responses. **A:** H-wave response on tibial nerve stimulation in the popliteal fossa recording over the gastrocnemius-soleus. The M wave is the direct response. The H wave, which results from stimulation of sensory nerve fibers (i.e., group 1A) of the tibial nerve, represents the motor response after a single synapse in the spinal cord. **B:** Median nerve F-wave response on stimulation of the median nerve at the wrist. The M wave represents the direct response of the thenar muscle. The delayed F wave results from antidromic motor nerve fiber stimulation. No synapse occurs at the cord. The small F-wave response represents the small number of anterior horn cells that induced a rebound discharge.

Femoral nerve stimulation at the inguinal ligament can also elicit a monosynaptic reflex response over the quadriceps muscle. This response is the electrical equivalent of the patellar tendon reflex. No other H-wave responses are generally obtainable in the lower extremity and no consistently useful ones are obtainable in the upper extremity, except perhaps in infants.

The F wave is more universally obtainable (Fig. 13-7B). Although it requires adequate spinal cord function as well as peripheral nerve function, it is not a reflex. It is obtained on stimulation of motor nerves antidromically and supramaximally. Approximately 5% of the motor neuron fibers so stimulated *rebound*, and, as a result, a late second response is sampled over the target muscle of the nerve (2). The first response seen is the M wave. Rebound occurs because, for some of the anterior horn cells, the axon hillock refractory period ends before the local currents in the spinal cord have dissipated, and an orthodromic discharge down the motor nerve occurs. Each simulation usually induces the F-wave response in a different 5% of the motor neurons. As a result, latency and amplitude of the F-wave response vary (see Fig. 13-7B). Latency is also related to age and limb length. Usually, the shortest latency response in a set of stimulations is the parameter selected, although average latency, the range between the fastest and the slowest F-wave responses and the number of F waves elicited in a train of stimulus (penetrance) can also be useful.

F waves can be elicited from all mixed or motor nerve stimulations in the upper or lower extremity. When late responses are combined with peripheral studies, the most proximal portions of the nerve or its spinal roots can be evaluated. Appropriate combinations of F- and M-wave latency measurements are also capable of measuring the conduction velocity of fibers carrying the F- wave response (2). For the H and the F wave, the spinal cord *turnaround time* is estimated at 1 millisecond.

Somatosensory-Evoked Potentials

Measurement of SEPs permits analysis of syndromes that induce, in particular, proximal sensory nerve or root or spinal cord impairment. SEPs are evoked on peripheral stimulation of mixed or pure sensory nerves and on skin (dermatomal) stimulation (9,10,11 and 12). The responses evoked can be tracked to the somatosensory cortex. From periphery to brain, three synapses occur for the primary arrival short-latency response on sensory or mixed nerve stimulation: at the nucleus cuneatus and nucleus gracilis in the mid medulla, in the thalamus, and at the cortex. The predominant pathway in the spinal cord is in the posterior columns (13,14). The amplitude of the responses is small, on the order of magnitude of a few or even less than 1 μV. Single stimulations are not detectable at the regions

where responses are usually sampled because of biologic and electrical noise interference. Special averaging equipment is necessary to cancel out the noise and extract the signal. As many as 100 to 2,000 responses might need to be averaged. Supramaximal stimulation is not necessary, and most patients can be studied.

Responses to stimulation of lower extremity sensory or mixed nerves are sampled over the leg, the lumbar spine root entry zones, and at the scalp (Fig. 13-8) (15,16). In the upper extremity, Erb's point, the cervical spine, and the scalp areas are sampled (Fig. 13-9) (9,10,17,18). Dermatomal skin stimulation responses in the lower extremity or trunk are recorded at the scalp, and in the upper extremity they are also recordable as well at Erb's point and over the cervical spine (12,19).

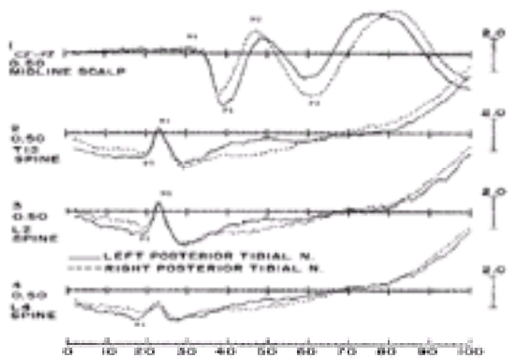

Figure 13-8. Normal somatosensory-evoked potential responses on tibial nerve (n.) stimulation at the ankle. The L-4, L-2, and T-12 responses were obtained with surface electrodes over the respective posterior spines with the reference electrode placed laterally. The scalp response occurred between the active surface electrode 2 cm behind the skull vertex (CZ') and a frontal reference (FZ). The amplitude calibrations on the right are in microvolts, and the time calibration is in milliseconds. The labels *N* and *P* refer to negative or positive peaks.

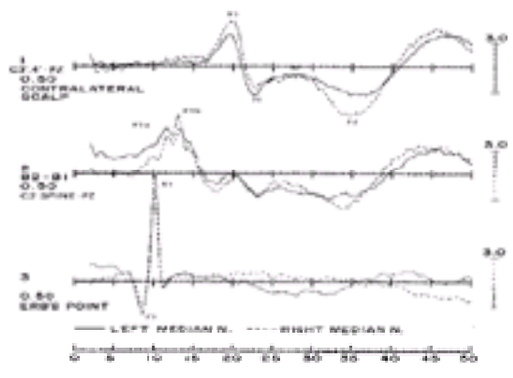

Figure 13-9. Normal somatosensory-evoked potential responses on stimulation of the median nerve at the wrist. The response at Erb's point is between a surface electrode at Erb's point on the ipsilateral side referred to the contralateral Erb's point. The second cervical spine response is between a surface electrode over the spinous process of C-2 and a reference electrode over the midfrontal area of the scalp (FZ). The contralateral scalp response is over the sensory cortex area of the parietal lobe (C_3 or C_4) referred to the frontal region (FZ).

The parameters measured include latencies and amplitudes, and, in particular, at the scalp, the configuration of the response. Sensory impairment in the periphery, in the plexuses, within the vertebral canal, in the spinal cord, and more proximally are detectable. Coupling of SEP results with those of peripheral studies and late-response examinations permits a more complete evaluation of the somatosensory system than peripheral studies alone.

Summary

The techniques described and the data they reveal permit a physiologic evaluation of the somatosensory and somatomotor systems. When abnormalities are seen on EMG, NCS, late responses, and SEP studies, the nature and location of the disease or injury process can be obtained. The results of the electrodiagnostic medicine examination alone, however, cannot reveal the cause of the damage to the system. Determination of the cause (e.g., tumor, trauma, degeneration, inflammation) requires the integration of the results of the electrodiagnostic medicine examination with the history, physical examination, and structural radiologic examinations, together with an understanding of the anatomy of the neuromusculoskeletal system and its variants.

CLINICAL SYNDROMES

The sections that follow indicate the electrodiagnostic abnormal groupings that permit the decision making necessary to suggest the presence or absence of entrapment, radiculopathy, trauma, systemic disease, and functional syndromes as possible causes of an acute or chronic pain complaint. Electrodiagnostic studies cannot, however, quantify pain, nor can they confirm that the neuromuscular abnormalities detected are causally related to the pain complaints. Therefore, it does not necessarily follow that elimination of the abnormalities eliminates the patients' complaints. At the end of each of the following sections, a case example is given to illustrate the application of the methods described.

Entrapment Syndromes

Entrapments involving mixed nerves are more likely to produce motor and sensory symptoms and physical examination signs, as well as motor and sensory electrodiagnostic abnormalities. For pure or relatively pure motor or sensory nerves, the abnormalities are likely to be respectively exclusive. In evaluating a patient for the possibility of entrapment, one must recognize that the sensory symptoms of pain or numbness do not occur exclusively in the referred territory of the sensory nerve. Entrapments can produce a vaguely described discomfort in areas more proximal to the exclusive distal distribution of the sensory innervation. Furthermore, because so- called pure motor nerves (e.g., no skin distributions) can carry muscle and joint afferents, entrapment of such nerves can also induce a deep diffuse discomfort.

Table 13-1 lists the more common nerve entrapments in the upper and lower extremities (20). The type of nerve (mixed, motor, or sensory) is included as well as the location of the entrapment.

Site	Nerve
Cervical rib	Lower trunk brachial plexus
Scalenus anticus	Lower trunk brachial plexus
Suprascapular notch	Suprascapular nerve
Quadrangular space (below glenohumeral joint)	Axillary nerve
Spiral groove of humerus	Radial nerve
Ligament of Struthers (above elbow)	Median nerve
Ulnar cubital tunnel (elbow)	Ulnar nerve
Pronator teres (forearm)	Median (anterior interosseus branch) nerve
Supinator (forearm)	Radial (posterior interosseus branch) nerve
Carpal tunnel (wrist)	Median nerve
Canal of Guyon (wrist)	Ulnar nerve
Hook of hamate (palm)	Ulnar (deep branch) nerve
Inguinal ligament	Lateral femoral cutaneous
Fibula head	Peroneal nerve
Above ankle	Superficial peroneal nerve
Tarsal tunnel (medial ankle)	Tibial nerve

TABLE 13-1. Sites of potential nerve entrapments

Entrapments that are chronic and not transient lend themselves best to electrodiagnostic approaches. Chronic entrapments can appear as relatively acute from a symptom point of view. Usually, a phase exists during which the entrapment is symptomatically silent. During the silent phase, fiber diameters can decrease as a result of the compression, without inducing a conduction block. Furthermore, even if conduction block occurs or axonal degeneration occurs, a certain magnitude of loss must occur before a patient's *ordinary activities* become impaired, be they motor or sensory, or before irritation of the nerve reaches a level sufficient to induce a noxious afferent stimulation from the site. In addition, the small fibers, particularly those carrying pain stimuli, are more resistant to compression.

Transient entrapments, in which a change in body position can relieve the pressure, are more difficult to detect electrodiagnostically. Testing in such cases can require that the study be performed when symptoms are occurring or can be induced.

The electrodiagnostic approach for evaluating entrapment is fairly similar from nerve to nerve. For motor nerves or motor components of mixed nerves, the following situations should be considered:

- If the nerve can be stimulated above and below the suspected site, and the evoked amplitude of its target muscle can be measured, a reduction in motor conduction velocity of the nerve segment containing the entrapment can be obtained. The reduced conduction velocity signifies fiber thinning through demyelination and remyelination. A reduced amplitude of the evoked response from the proximal stimulation, compared with the response obtained from the more distal stimulation, signifies a partial neurapraxia (see Fig. 13-5C). An increase in temporal dispersion can also occur.
- If the nerve can be stimulated above the suspected site but not distal to it, because of accessibility problems, then a latency measure from the time of stimulation to the time the motor-evoked response is obtained is compared with normal values or with the value obtained in the opposite extremity, in unilateral problems. A prolonged latency should result if the entrapment has been sufficient to result in fiber thinning. Again, amplitudes of the two sides can be compared.
- If the suspected site is too proximal to permit stimulation proximal to the site of entrapment, then examination of the F-wave response to the target muscle can be studied and compared with normal values or with that obtained with the opposite extremity, in unilateral problems.
- The target muscles of the suspected motor nerve must also be studied with needle EMG. If motor axon degeneration has occurred, membrane instability is seen, and on maximal volition, a reduced number of MUAPs is noted. Such a reduced recruitment also results from a partial neurapraxia, but if neurapraxia alone is present, no membrane instability is seen. If membrane instability is found, other muscles in the general region or area need to be studied, particularly when other underlying diseases might be present, to be certain that the membrane instability is unique to the nerve and to the entrapment in question. In addition, individual MUAPs can have abnormalities of amplitude, duration, and phasicity in chronic entrapment, secondary to collateral reinnervation.

For sensory nerves or sensory components of mixed nerves, similar stimulation techniques can be used:

- If antidromic stimulation can be delivered proximal to the site of the suspected entrapment and the sensory-evoked response can be sampled distal to the site, conduction velocities or latencies can be determined for evidence of conduction slowing. Amplitudes can be examined; if they are reduced, a conduction block or axonal degeneration is suggested. Orthodromic stimulation is also used.
- For entrapments involving sensory nerves that are too proximal to permit stimulation proximal to the site but can be stimulated orthodromically at a distal site, the SEP response can be examined and compared for latency to indicate slowing and for amplitude to indicate conduction block or axonal degeneration, with normal values or against contralateral responses in unilateral conditions.

Case Example

A 42-year-old woman with a 6-month history of progressive left arm and hand numbness was suspected of having either a C-7 radiculopathy or thoracic outlet syndrome. Numbness first appeared in the middle finger and subsequently ascended up the medial side to the axilla, with some sharp pain laterally. Symptoms at night made sleep difficult. Recently, the numbness was present during the day, and weakness in the left hand was increasing. Physical examination documented decreased grip strength. Strength was reduced in the biceps, triceps, and deltoid, probably from arm discomfort. Decreased light touch was present over the medial arm and forearm.

Needle EMG results of the muscles of the upper extremity, encompassing roots C-5 through T-1, including thenar and hypothenar intrinsics and cervical paraspinal muscles, were negative.

Conduction studies of the motor and sensory components of the median and ulnar nerves are shown in Table 13-2.

Nerve	Segment	Distal latency (ms)	Velocity (m/sec)	Amplitude (μV)
Left median motor	Elbow to wrist	4.2	52	8.5 M
Left median sensory	Wrist to digit 2	4.2	NA	46 D
Left median sensory	Wrist to digit 3	4.2	NA	36 D
Left ulnar sensory	Wrist to digit 5	3.2	NA	58 D
Left ulnar motor	Axilla to below elbow	NA	##	12.0 M
Left ulnar motor	Below elbow to wrist	2.8	45	12.5 M
Left ulnar F-wave	Wrist to spinal cord	26.8	##	NA
Left ulnar F-wave axillary loop	Axilla to spinal cord and back to axilla	11.8	NA	NA

NA, not applicable.

TABLE 13-2. Conduction studies of median and ulnar nerves

The normal needle EMG confirmed the absence of an active motor radiculopathy. The normal ulnar nerve motor conduction velocities, ulnar F-wave conduction velocity, axillary loop latency, and amplitude of the ulnar sensory-evoked response confirmed the absence of ulnar neuropathy, including at the thoracic outlet level. The prolonged median nerve sensory latency from the wrist to digits 2 and 3, compared with the normal ulnar sensory latency from the wrist to digit 5, all three of which were obtained over the same length (14 cm) of nerve, confirmed a left carpal tunnel syndrome. The median motor distal latency was also slightly prolonged, almost two standard deviations greater than normal. The smaller median sensory amplitudes, compared with that of the ulnar sensory amplitude, suggested median sensory axonal loss. Finally, the reduced conduction velocity of the median motor nerve, compared with the ulnar, suggested a retrograde distortion of the median motor nerves proximal to the carpal tunnel. The absence of membrane instability in the needle EMG examination of the thenar muscles confirmed that the carpal tunnel syndrome had not yet induced motor nerve axonal degeneration.

The patient had a surgical carpal tunnel release, and all symptoms cleared within 10 days (see Figure 13-10 for additional examples).

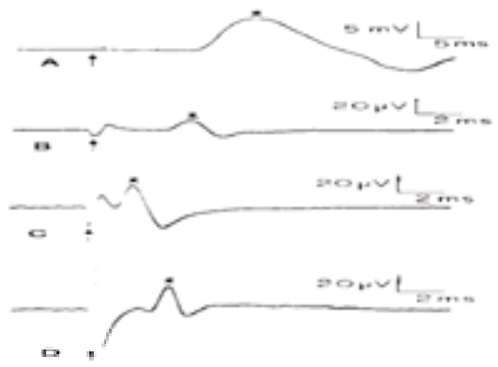

Figure 13-10. Carpal tunnel syndrome with sensory nerve neurapraxia. **A:** Thenar muscle evoked response (*asterisk*) on stimulation of the median nerve at the wrist proximal to the carpal tunnel at a standardized distance of 8 cm from the electrode over the thenar muscle. The latency of this response from the stimulus artifact (*arrow*) to the beginning of the response is 4.2 milliseconds (ms), which is on the slow side but within normal limits. **B:** Sensory response (*asterisk*) sampled at the index finger 14 cm distal to the point of stimulation of the median nerve proximal to the carpal tunnel. The latency of this response measured from the stimulus artifact (*arrow*) to the peak of the negative deflection (*asterisk*) is 4.2 milliseconds. The amplitude of the deflection measured from the negative peak to the subsequent positive peak is 30 μV. **C:** Sensory-evoked response over the index finger from stimulation of the median nerve in the midpalm distal to the carpal tunnel. The latency of this response is 1.9 milliseconds, and its amplitude is 50 μV. **D:** Sensory-evoked response (*asterisk*) over the fifth finger 14 cm distal to the point of stimulation of the ulnar nerve at the wrist. The latency of this response is 3.0 milliseconds, and its amplitude is 34 μV. The longer sensory latency on median nerve stimulation at the wrist compared with ulnar nerve stimulation at the wrist for the same 14 cm of nerve length implies slowing through the carpal tunnel. Similarly, the comparison of the 1.9 ms from midpalmar stimulation to the 4.2 milliseconds latency for wrist stimulation implies slowing in the region from the wrist to the midpalm in the median sensory nerve. The larger amplitude of the median sensory nerve response on midpalmar stimulation compared with wrist stimulation (50 versus 30 μV) indicates a sensory neurapraxia, because 20 μV of amplitude has been lost.

Radicular Syndromes

Damage to nerve roots at or proximal to the intervertebral foramen, where the sensory ganglia are located, encompasses the radicular syndromes. Included in this group are lesions affecting the cauda equina within the vertebral canal below the conus medullaris. An electrodiagnostic medicine examination that concludes a radiculopathy is present does not reveal the cause of the damage. A radiculopathy induced by an extruded disk, tumor, arteriovenous malformation, or even diabetes, for example, can all produce the same electrodiagnostic abnormalities.

Because there are only seven cervical vertebrae and eight cervical nerves, the cervical nerve roots, C-1–C-7, exit above the pedicles of the corresponding vertebrae, and the C-8 root exits above the pedicles of the T-1 vertebra. Beginning with the T-1 root and below, the roots exit below the pedicles of their corresponding vertebrae.

Immediately on exiting the intervertebral foramen, the spinal nerve divides into its anterior and posterior primary divisions. The posterior primary division turns dorsally, looping over the posterior facet joint formed by the articular processes of the vertebrae above and below. The motor branches innervate the paraspinal musculature, extending as much as two levels above and two levels below the immediate region. All spinal nerves from C-3–S-1 contain posterior primary divisions that are distributed in this way. The anterior primary division from C-5–T-1 forms the brachial plexus, and the anterior primary divisions from L-1–S-2 similarly form the lumbosacral plexus. Only in the thorax (T-2–T-12) do the anterior primary divisions remain isolated and distribute as thoracic nerves.

As a result of plexus formations and redistributions of spinal nerve fibers into the terminal peripheral nerves of the plexuses, all muscles of the upper and lower extremities are innervated by the fibers of more than one spinal nerve.

Root disease can be motor or sensory if the anterior and posterior roots are separately involved, or mixed if both are damaged. An injury, as in an entrapment syndrome, can induce only a conduction block, or, if severe or long-standing, axonal degeneration. In the case of the anterior root, distal axonal degeneration leads to denervation of some or all of the muscles supplied by the anterior primary division in the extremities and to denervation of the paraspinal musculature supplied by the posterior primary division. In sensory axonal degeneration that occurs proximal to the sensory root ganglia, the axon distal to the ganglia remains capable of supporting the conduction and does not degenerate.

Needle EMG and SEPs are the main electrodiagnostic aids for the determination of radiculopathy. Late responses and the examination of amplitudes of motor-evoked responses on peripheral nerve stimulation can also contribute. The flow diagrams in Figure 13-11 and Figure 13-12 suggest approaches based on how soon after an acute insult the different studies can be considered. It is useful to group the discussion of the electrodiagnostic approaches into cervical, thoracic, lumbosacral, and low sacral radiculopathies. The following discussion assumes that the examination is being performed on patients without prior back surgery.

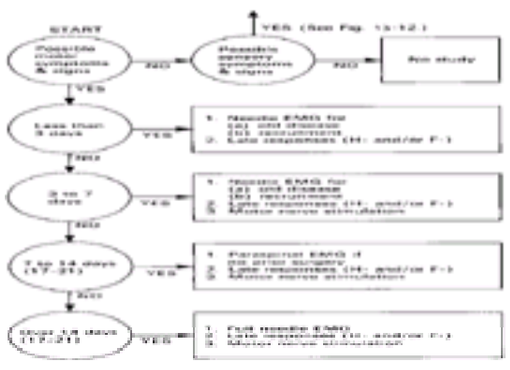

Figure 13-11. Flow diagram of appropriate electrodiagnostic studies in the evaluation of radiculopathy if signs or symptoms of weakness are present. The studies to consider are based on the duration of the symptoms and signs. See Figure 13-12 for appropriate approaches if only sensory symptoms and signs are present. (EMG, electromyography.)

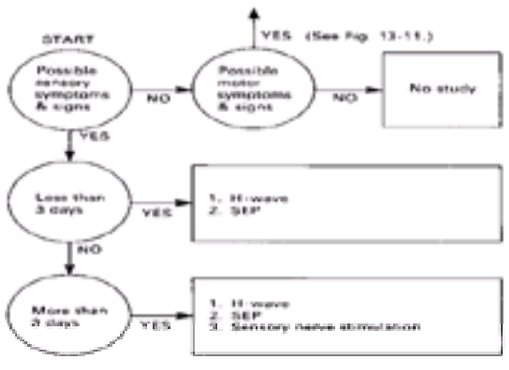

Figure 13-12. Flow diagram of appropriate electrodiagnostic examinations to consider for sensory symptoms and signs and in the evaluation for possible radiculopathies: See Figure 13-11 for appropriate approaches if motor symptoms and signs are present. (SEP, somatosensory-evoked potential.)

Cervical Radiculopathies (Roots C-5–T-1)

Even though only one specific root is suggested by the clinical examination, needle EMG of the upper extremity muscles should be carried out so that at least two muscles with innervation from each of the roots (Table 13-3) are sampled. From such an examination, a clear pattern can emerge. The presence of membrane instability in a muscle implies motor axon degeneration and generally is associated with a reduced recruitment pattern. A reduced recruitment pattern alone, without membrane instability, implies the existence of only a conduction block without axonal degeneration. Fasciculation can also appear, indicating an irritating focus. The membrane instability in peripheral muscles and in the paraspinal muscles is diagnostic for radiculopathies because it signifies involvement of both the anterior and posterior primary divisions and, hence, a lesion at or proximal to the intervertebral foramen.

Muscle	Spinal nerve roots
Deltoid	C-5, C-6
Biceps	C-5, C-6
Pronator teres	C-6, C-7
Extensor carpi radialis longus and brevis	C-6, C-7
Triceps	C-7, C-8
Extensor carpi ulnaris	C-7, C-8
Extensor digitorum communis	C-8, C-7
Flexor carpi ulnaris	C-8, C-7
Thenar group	T-1, C-8
Hypothenar group	T-1, C-8

TABLE 13-3. Dominant root innervations of some upper extremity muscles easily accessed by needle electromyography

Within 7 to 10 days after onset of axonal degeneration, paraspinal muscles show membrane instability, whereas 17 to 21 days may be necessary for the more distal muscles of the extremity.

Dermatomal SEPs provide information on the status of the sensory root. Skin stimulation of the lateral shoulder (C-5) and over the digital nerves of the thumb (C-6), middle finger (C-7), and little finger (C-8), and recording at Erb's point, at the cervical spine, and at the scalp, with contralateral comparisons, can reveal a conduction block or sensory axonal degeneration proximal to the dorsal root ganglia.

Abnormal F-wave responses (e.g., absent or of prolonged duration) at the thenar and hypothenar muscles elicited by median and ulnar nerve stimulation, respectively, suggest C-8, T-1, or both kinds of root involvement. F-wave responses for more proximal roots are not readily accessible.

A softer, but sometimes useful, sign is a reduction in amplitude of the motor-evoked responses on peripheral stimulation (e.g., thenar for C-8–T-1 on median stimulation, flexor carpi ulnaris for C-8 on ulnar stimulation, triceps for C-7 on Erb's point stimulation, extensor carpi radialis for C-6 on radial nerve stimulation, and biceps for C-5 on Erb's point stimulation). For the amplitudes to be reduced, motor axonal degeneration must have occurred; hence, needle EMG results should also be positive for membrane instability. Peripheral sensory-evoked amplitudes are normal and unaffected in lesions proximal to the dorsal root ganglia.

Thoracic Radiculopathy (T-2–T-12)

Needle EMG is limited to the paraspinal muscles and to the abdominals. The rectus abdominus, served by T-7–T-12, is easily accessed. Membrane instability is likely the only finding of interest because recruitment patterns are not useful. Fasciculations, however, can be helpful.

Careful SEP serial dermatomal stimulation with left-right comparisons of scalp recordings can permit detection of sensory root disease.

No F-wave or peripheral stimulation techniques are useful.

Lumbosacral Radiculopathy (L-1–S-1)

The approach of the needle EMG in these radiculopathies parallels that of the cervical area. All of the EMG abnormalities discussed also apply here. Muscles sampled should be broad enough to confirm a pattern obeying a root distribution (Table 13-4). Again, the finding of membrane instability in peripheral and paraspinal muscles confirms anterior and posterior primary division involvement and a lesion proximal to the intervertebral foramen.

Muscle	Spinal nerve roots
Vastus medialis	L-4, L-3
Rectus femoris	L-4, L-3
Adductor longus	L-4, L-3
Anterior tibialis	L-5, S-1
Extensor hallucis longus	L-5, S-1
Tensor fascia lata	L-5, S-1
Medial hamstrings	L-5, S-1
Lateral hamstrings	S-1, L-5
Medial gastrocnemius	S-1, L-5
Lateral gastrocnemius	S-1, L-5

TABLE 13-4. Dominant root innervations of some lower extremity muscles easily accessed by needle electromyography

The tibial H wave is a late response useful for S-1 root disease, particularly in the absence of clear-cut EMG findings. A prolonged H- wave latency or a markedly reduced amplitude of the response when compared with the uninvolved side can be caused by disease in the afferent or the efferent limb of the reflex. An abnormal H wave in the presence of a normal EMG would suggest sensory root involvement or motor root conduction block. Although less useful, a peroneal nerve F wave recorded at the extensor digitorum brevis muscle can be studied to assist in the diagnosis of L-5 lesions.

SEP studies of the response to posterior tibial nerve stimulation at the ankle (mostly S-1) and the peroneal nerve at the knee (mostly L-5), with recording over the back at the root entry zones and at the scalp, can be useful in detecting sensory root conduction block or slowing of conduction. In addition, scalp recordings of the response to dermatomal stimulation of L-5 and S-1 over the foot, L-4 below the knee, and L-3 above the knee focus more specifically on the individual roots.

Peripheral motor stimulation, with comparison of evoked amplitudes over the muscles of the involved and uninvolved sides for the detection of motor axon loss, are also considered. Peroneal nerve stimulation with the measurement of evoked amplitude at the extensor digitorum brevis, mostly for L-5 lesions, and tibial nerve stimulation with measurement of the evoked amplitude over the abductor hallucis, mostly for S-1 lesions, have been used.

Low Sacral Radiculopathies (S-2–S-4)

Limited, although useful, approaches exist for low sacral lesions. These lesions are further clarified by urodynamic studies.

Needle EMG for low sacral radiculopathies is restricted to the anal sphincter. Membrane instability, reduced tonicity at rest, and a reduced recruitment pattern on volition can all be detected.

The bulbocavernosis reflex can be electrically studied for abnormalities in the S-2–S-4 roots, the pudendal nerve, or both. This is a polysynaptic reflex response elicited by penile or clitoral skin stimulation with needle or surface recording in men over the bulbocavernosus muscle and in women in the urethral sphincter or over the surface of the perineum. It is more easily elicited in men simply because of the easier accessibility of the penis and the bulbocavernosus muscle. The afferent and efferent limbs of the reflex travel in the pudendal nerve served by the S-2–S-4 roots.

An SEP study of the scalp response to penis or clitoris skin stimulation can also be useful for deficits in the pudendal nerves.

Paraspinal Electromyography in Postsurgical Backs

The usefulness of paraspinal EMG is diminished in regions in which previous laminectomies have been performed (21). Paraspinal muscle stripping to access the lamina causes denervation of the paraspinal muscles because the procedure usually damages the posterior primary divisions. Approximately 2 or more years might be necessary for reinnervation to be completed or, if not completed, for the residual denervated fibers to degenerate. During this period, membrane instability on needle EMG is likely to be seen. A qualitative impression of old or newly denervated muscle fibers can sometimes be made when the amplitudes of the fibrillation potential and the positive sharp waves are closely examined. Old fibers are more atrophic, and their membrane and instability responses are of comparatively low amplitude.

Multiple Root Syndromes

The cauda equina syndromes of lumbar spinal stenosis and arachnoiditis deserve special mention because their electrodiagnostic findings are usually different.

Lumbar spinal stenosis is a slowly progressive process that, if compromising lumbar and sacral roots, does so at a rate that permits adaptation. Furthermore, when symptoms are produced, the patient is usually able to assume a position that causes the symptoms to fade, giving the involvement a transient character. A gradual diminution in diameter of the nerve fibers slows conduction through the region of impairment without necessarily inducing axonal degeneration. Even if axonal degeneration is induced, it occurs in insufficient numbers at any one time. As a result, needle EMG may not show membrane instability but may show decreased recruitment patterns, and the individual MUAPs may show increased amplitude and durations because of prior collateral reinnervation. SEP data, on the other hand, may be particularly abnormal because of the thinning of the fibers and attenuation of the incoming signal (Fig. 13-13). Dermatomal SEP abnormalities may show multiple root abnormalities, but in varying degrees and rarely with full left-right symmetry, as might be seen, for example, with a peripheral neuropathy. They also have a greater sensitivity than EMG for spinal stenosis (22,23,24).

Figure 13-13. Somatosensory-evoked potential responses at the scalp in a patient with spinal stenosis. The responses to skin stimulation of various dermatomes are shown. The response to L-2 dermatome stimulation is normal and shows left-right symmetry. No response is seen at the scalp to left and right L-3 and L-4 dermatome stimulation. Tibial nerve stimulation at the ankle and L-5 and S-1 dermatome stimulation also did not show a response at the scalp (not shown). Electromyographic examination in the patient documented active radiculopathy bilaterally only in the S-1 roots. Myelography documented vertebral canal narrowing from L-1 to L-5, with nerve root encroachment of the left L-5 and the right L-4 and L-5 roots. At surgery, severe stenosis was seen from L-3 to S-1. Decompressive laminectomy at L-4 and L-5, partial laminectomy at L-3, partial diskectomy at L-3–4 and L- 4–5, and nerve root decompression foramenotomies at L-3, L-4, and L-5 were performed. Symptoms improved after surgery.

In arachnoiditis, the lesion is more aggressive. Membrane instability on EMG is usually present bilaterally across many muscles and roots, and SEP responses similarly show more symmetry than in spinal stenosis. In both conditions, F- and H-wave responses are abnormal.

Case Example

A 56-year-old man complained of intermittent bilateral numbness over the first, second, and third digits of his left hand for 6 months. Recently, the numbness had spread to include the fourth and fifth digits and grip strength had decreased. Tinel's sign was elicited over the ulnar groove at the elbow, and atrophy and weakness of the left hand were present.

Needle EMG of the left deltoid (C-5), biceps (C-5), pronater teres (C-6), extensor carpi radialis (C-6), triceps (C-7), extensor carpi ulnaris (C-7), flexor carpi ulnaris (C-8), extensor digitorum communis (C-8), and the flexor digitorum superficialis (C-8) was normal. The thenar (C-8–T-1), first dorsal interosseous (C-8–T-1), and hypothenar muscles (C-8–T-1) all showed positive waves and fibrillation potentials and a decreased number of MUAPs. Needle EMG of the lower cervical paraspinal muscles also showed membrane instability.

Conduction studies of the ulnar nerve were done. These revealed conduction velocities of 60 m per second from Erb's point to the axilla, 56 m per second from the axilla to below the elbow, and 55 m per second from below the elbow to the wrist, all of which are normal. Stimulation of the ulnar nerve and recording of the evoked sensory response over the fifth digit revealed an amplitude of 3 µV, which was 14 and 20 times less, respectively, than the sensory-evoked responses obtained at the first and third digits on median nerve stimulation at the wrist. The ulnar nerve F-wave response recorded over the hypothenar muscles on stimulation of the ulnar nerve at the wrist revealed a normal (56 m/sec) conduction velocity of the F-wave response from the wrist to the spinal cord.

Normal ulnar nerve peripheral conduction and F-wave responses indicated no entrapment. The normal F-wave response, coupled with the positive needle EMG findings in the small muscles of the hand innervated by both the median and ulnar nerves, coupled with the positive paraspinal findings, implied C-8 or T-1 root disease. The reduced sensory-evoked response in the fifth digit favored C-8 root disease with involvement of the posterior root ganglion.

Radiography revealed marked degenerative joint disease at the C-5–C-6 level, and cervical myelography was inconclusive for root encroachment. An anterior diskectomy at C-5–C-6 and an exploration at C-7–T-1 on the left were performed. At the C-7–T-1 level, free disk material was found encroaching on the C-8 spinal nerve in the intervertebral foramen.

Traumatic Syndromes

Given the plethora of ways accidents and injuries take place, nerve and muscle damage can occur literally anywhere in the body. Frank nerve section can result from sharp objects or bullets or internally in association with fractures. Traction injuries are common in high-speed accidents. Blunt trauma or compression injuries can induce total nerve damage without separation. Muscle trauma and the associated inflammation can induce compartment syndromes and yield primary muscle destruction, as well as nerve damage to terminal branch elements or to nerves traversing the compartment.

The anatomy of the peripheral nervous system and the anatomic relationships between the peripheral nervous system and the musculoskeletal system suggest some specific regions of vulnerability where trauma can injure the nervous system and provide a source for pain complaints in need of evaluation. Table 13-5 lists these vulnerable sites, the type of trauma inducing the damage, and the nerve elements likely to be involved. All of these can be evaluated electrodiagnostically.

Trauma and site	Vulnerable nerve(s)
Acute lateral flexion of head and neck	Brachial plexus
Glenohumeral dislocation	Axillary nerve
Scapular fracture	Suprascapular
Humeral fracture	Radial
Elbow fracture or dislocation	Ulnar
Wrist fracture (distal radius)	Median
Forearm trauma and compartment syndromes	Median (anterior interosseus) and radial (posterior interosseus)
Pelvis (pubic rami) fractures	Obturator
Hip fracture and dislocations	Sciatic (peroneal, tibial)
Knee derangements	Peroneal
Below-knee anterior compartment syndromes	Peroneal (deep branch)
Ankle fractures	Tibial and peroneal

TABLE 13-5. Sites vulnerable for traumatic nerve injury

The electrodiagnostic approach to the evaluation of trauma depends on whether the examination is done in the acute phase or 3 to 4 weeks or more after onset. Examination in the acute phase is usually directed at determination of injury location, the presence or absence of muscle paralysis, and whether nerve continuity has been lost. A high index of suspicion for nerve damage must also be considered even when not particularly obvious, to ensure that reduced muscle function, surmised simply as pain inhibition, is not also actual nerve damage. An electrodiagnostic examination performed in the acute phase can lead to an earlier recognition of nerve damage than might be evident, leading to more appropriate treatment. In particular, if head injury is present or cognition is impaired, electrodiagnostic studies should be considered in the acute phase because the clinical examination might be incomplete.

In the chronic phase, some of the same questions can be addressed that were asked acutely but were unanswered because life-saving measures took precedence. In addition, after the effects of acute trauma have settled down, more definitive assessments of damage than those obtained acutely are possible and beginning assessments of prognosis can be made.

Acute Phase

Needle EMG of target muscles of motor nerves suspected of damage permits a determination if any nerve fibers are able to conduct impulses through the region of trauma. Volitional contraction is asked for, reflex responses via tendon taps are induced, and noxious stimulation is delivered to assess whether any MUAPs are detectable and to what degree. If any are detected, nerve continuity in some degree must exist. If no MUAPs are detected, clearly no conduction through the region is present. An absent response, however, is the same whether complete nerve separation, total crush injury without separation but with total axon destruction, or a complete physiologic conduction block (neurapraxia) exist.

No membrane instability is seen, even in total sections, in the acute phase, because an insufficient length of time has elapsed for wallerian degeneration to take place and for acetylcholine sensitivity to appear.

Motor nerve stimulation proximal to the site in question, with either a surface or needle electrode placed on the target muscle, further adds to the solution of the continuity question. Any response in the target muscle from the proximal stimulation concludes that at least some continuity exists. Proximal stimulations may be more useful than needle EMG with volitional effort because pain may inhibit the latter. An absent response on proximal stimulation is also compatible acutely with complete section or a complete reversible physiologic block. Motor nerve stimulation distal to the suspected region still yields a normal response because the distal segment of even a severed nerve remains capable of conduction until wallerian degeneration has occurred. It may take anywhere from 2 to 10 days, depending on the length of the distal segment, before distal stimulation fails to induce muscle contraction. Serial studies of latency and amplitude after a severing injury may suggest severance before complete conduction failure has occurred.

Peripheral sensory nerve stimulation is also useful, provided the nerve can be accessed on either side of the region of injury. If this can be done, then the same type of data results as in peripheral motor stimulation.

Late responses, in particular F waves, are useful if the region of injury is too proximal to permit stimulation of motor nerves proximal to the site. Stimulation of the motor nerves distal to the site and examination for the presence or absence of an F-wave response is performed. If a response is present, nerve continuity through the site is present. If the F-wave response is absent, again the same reasons for blocked conduction apply.

SEP responses permit assessment of a block at the site of injury for sensory signals. Distal stimulation of mixed nerves or pure sensory nerves or of skin dermatomes with an evoked response determination over the spine or scalp can determine if injury has produced an interruption of conduction. Again, the interruption of conduction would be the same for nerve section, nerve compression with complete axonal destruction, and nerve compression with a purely physiologic block.

Chronic Phase (after 3 to 4 weeks)

Needle EMG of target muscles now becomes quite useful. If nerve section or axon death at the site of injury has occurred, membrane instability on the needle EMG examination documents the loss. No voluntary MUAPs are seen if interruption is complete and membrane instability is present. If some MUAPs are present along with membrane instability, the loss is incomplete.

Peripheral NCS of motor nerve segments distal to the site of injury with sampling electrodes over the target muscles now permit differentiation between the physiologic conduction block and axon interruption. If complete axon interruption has occurred, the distal nerve segment is not excitable, and no target muscle response is seen. If only some of the axons have been interrupted, the amount of axon loss can be estimated from the amplitude of the evoked response on stimulation of the distal nerve segment. The estimate of amount of loss is best obtained by a comparison of the amplitude with that achieved on the contralateral uninvolved side. If only a physiologic block has occurred, the target muscle demonstrates a normal response. Stimulation proximal to the injury can document a healing conduction block if serial examinations demonstrate a progressively increasing amplitude in the target muscle response.

Similarly, peripheral sensory NCS, distal to the lesion site, can be used to document sensory nerve degeneration. A response seen immediately after injury that later disappears confirms axon death through nerve section or a major compression.

SEPs coupled with peripheral sensory NCS permits determination of whether an injury is proximal to the sensory root ganglia, particularly in brachial plexus injuries. For example, the persistence of a peripheral sensory-evoked response in the thumb, coupled with an absent SEP response over the brain on thumb stimulation, implies root avulsion rather than trauma to the upper trunk of the plexus. In the latter case, no peripheral response and no SEP response is seen.

Case Example

A 33-year-old man fell while mowing his lawn and landed on his right wrist in the volar-flexed position. He experienced immediate wrist pain. After the acute pain subsided, he noticed an inability to dorsiflex the wrist. The next day radiographic results were negative, and paralysis of voluntary wrist and finger extension was apparent. An electrodiagnostic examination was performed 10 days after injury.

Needle EMG revealed absent membrane instability in the triceps (all heads), brachioradialis, extensor carpi radialis longus and brevis, extensor carpi ulnaris, extensor digitorum communis, supinator, and extensor indicis. On volition, recruitment was normal in all three heads of the triceps; however, only a few scattered voluntary MUAPs were seen in the brachioradialis, extensor digitorum communis, supinator, and extensor indicis. No voluntary MUAPs were seen in the extensor carpi radialis longus or extensor carpi ulnaris.

Stimulation of the radial nerve at Erb's point, recording over the triceps, evoked a normal response with a latency of 4.6 milliseconds. No response was present over the extensor carpi ulnaris on Erb's point stimulation. Recording over the brachioradialis produced a normal latency of 6.2 milliseconds, but the evoked amplitude was only 600 µV. Stimulation of the radial nerve above the elbow produced a normal response in the brachioradialis and the extensor carpi ulnaris. Furthermore, tetanic stimulation of the radial nerve above the elbow produced excellent contraction of wrist and finger extensors.

The lack of a response at the extensor carpi ulnaris on Erb's point stimulation with an excellent response on stimulation above the elbow, coupled with the much greater response over the brachioradialis, on above-elbow stimulation compared with Erb's point stimulation, documented the presence of a conduction block (neurapraxia) of the radial nerve proximal to the branch of the nerve to the brachioradialis and distal to the radial nerve branches to the triceps. The block was deemed reversible, because, if it had destroyed axons, the radial nerve would no longer be stimulatable distally. The absence of membrane instability was expected because 10 days had elapsed since the injury.

The presence of some voluntary MUAPs in some of the muscles distal to the block led to the diagnosis of an incomplete neurapraxia of the radial nerve, proximal to the brachioradialis branches. The block was probably induced by a forceful contraction of the lateral head of the triceps when the patient hit the ground and a resultant compression of the radial nerve as it winds around the humerus. Retesting in 2 weeks was recommended to assess for the existence of a partial denervation component. It was estimated that significant recovery could be expected in 4 to 6 weeks.

One month later, the patient had normal wrist and finger extension function. No further needle EMG was performed, because it was presumed that the block had been completely reversible and that no axonal loss had occurred.

Case Example

A 24-year-old man, 7 weeks before electrodiagnostic examination, was hit with an axe in his left neck. Radiography documented C-4 and C-5 vertebral fractures on the left, and the neurologic examination confirmed a Brown-Séquard syndrome. The persistent flail character of the left upper extremity raised the question of whether the flaccidity was secondary to a brachial plexus lesion, which might suggest the need for surgery.

Muscle strength testing revealed extremely weak musculature in the C-5 and T-1 innervated muscles and possible in C-8, with essentially no function through muscles innervated by C-6 and C-7. Light touch sensation only was present in the lateral shoulder (C-5). Sensation was absent in the thumb (C-6), middle finger (C-7), and little finger (C-8). Sensation was normal in the medial upper arm (T-1).

Needle EMG confirmed the presence of membrane instability (positive sharp waves and fibrillation potentials) in all muscles of the upper extremity innervated from C-5–T-1. The number of voluntary MUAPs was markedly decreased in muscles served by the C- 5 and T-1 roots, with essentially absent voluntary MUAPs in the muscles innervated by the C-6, C-7, and C-8 roots.

Motor nerve stimulation of the median and ulnar nerve at the elbow and at the wrist, recording over the thenar and hypothenar muscles of the hand, respectively, demonstrated normal conduction velocities with markedly reduced (50% of normal) amplitudes in the evoked responses. Stimulation of the radial nerve above the elbow produced no response in the wrist or finger extensors.

Sensory nerve stimulation of the median nerve at the wrist and the radial sensory nerve in the forearm, with recording of the evoked response in the thumb (C-6) using ring electrodes, produced normal responses of 60 and 14 µV, respectively. Sensory nerve stimulation of the median nerve at the wrist, recording over the middle finger (C-7), also produced a normal response of 60 µV, and sensory nerve stimulation of the ulnar nerve at the wrist, recording over the little finger (C-8), produced a normal response of 55 µV.

SEPs on median nerve stimulation at the wrist revealed normal responses at Erb's point, a weak to near absent response over the cervical spine, and no response at the scalp. SEPs on direct stimulation of the thumb, middle finger, and little finger revealed no responses at the scalp (Fig. 13-14).

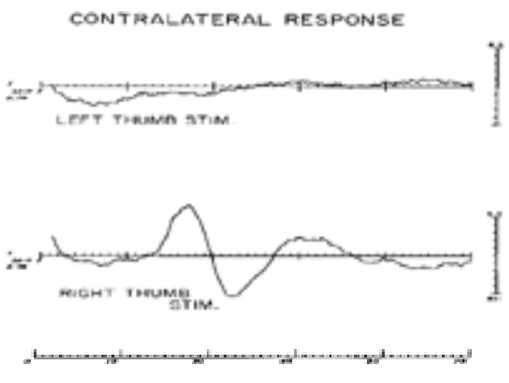

Figure 13-14. Somatosensory-evoked potential responses at the scalp to left (upper) and right (lower) stimulation of digital nerves of the thumb (C-6). Note absence of a response to left-sided stimulation and a normal response to right-sided stimulation. Amplitude calibration is in microvolts, and time calibration is in milliseconds. The lesion in this example was proximal to the C-6 posterior root ganglion, because peripheral sensory stimulation was normal (see text).

The excellent sensory responses, over digits 1, 3, and 5 on distal, radial, median, and ulnar nerve stimulation confirmed intactness of sensory axons up to and including posterior root ganglia in the intervertebral foramen of spinal nerve roots C-6, C-7, and C-8, as did the excellent Erb's point response on median nerve stimulation at the wrist. Absent scalp responses in the SEP studies confirmed the accuracy of the patient's assessment of absent sensation in his hand and led to the conclusion that the block in conduction of sensory signals was proximal to the dorsal root ganglia.

The median and ulnar motor nerve responses confirmed some T-1 motor function, and the absence of a response to radial nerve stimulation confirmed motor neuron loss through the C-6, C-7, and C-8 roots or cord centers.

The conclusion was drawn that the persistent flail weakness of the left upper extremity was not secondary to a brachial plexus lesion, but rather secondary to a lesion proximal to the intervertebral foramen, involving either or both nerve roots and the cervical cord centers for motor and sensory fibers.

Systemic Syndromes

In diffuse, relatively symmetric pain syndromes, electrodiagnostic examination may be necessary and should be considered to assist in the diagnosis. Polymyositis, for example, could be present with chronic, diffuse muscle pain and tenderness with varying amounts of weakness. A more acute symmetric pain presentation can

occur in Guillain-Barré syndrome.

In polymyositis, NCS, late responses, and SEPs are normal, but needle EMG shows abnormalities. Membrane instability is present if muscle destruction is occurring. In fact, needle EMG can be helpful in monitoring corticosteroid dosages. A well-controlled myositic patient is less likely to show membrane instability than one whose corticosteroid dosage is too low. In addition, MUAPs have characteristic features. The loss of individual muscle fibers within a motor unit shows MUAPs of decreased amplitude, decreased duration, and increased polyphasicity. Voluntary recruitment patterns are full, but maximum amplitudes are reduced.

In Guillain-Barré syndrome, the lesion is in the peripheral nerve. Segmental demyelination can be documented by motor NCS. Velocities are slowed, and temporal dispersion is increased. Abnormal F- and H-wave responses may be the earliest sign because disease can first attack the proximal segments of nerves and leave the distal segments undisturbed. Thus, normal peripheral NCS with delayed or absent F-wave responses indicates proximal slowing or a conduction block. A response of a target muscle on peripheral motor NCS in the presence of profound weakness signifies a conduction block secondary to demyelination proximal to the site of stimulation. Needle EMG of paralytic muscles can be used to determine whether demyelination has caused secondary axonal death by documenting muscle fiber membrane instability. A normal response on peripheral nerve stimulation is also produced if spinal cord or brain damage has affected the upper motor neurons to cause a profound weakness. For situations in which pain is suspected as secondary to ischemic neuropathy, electrodiagnostic examination can be helpful. In particular, the mononeuropathy or polyradiculopathy of diabetes is easily studied by the NCS and EMG techniques described. Furthermore, these particular syndromes are generally distinguishable from the diffuse distal axonal sensorimotor symmetric peripheral neuropathy of diabetes on which it is superimposed.

Case Example

A 63-year-old man was referred with the possible diagnosis of nerve root compromise secondary to spinal stenosis. Chronic low back pain was intermittent for several years, with a recent increase in discomfort aggravated by ambulation and associated with radiation into the buttocks and thighs. In addition, during ambulation, his legs felt “wooden” and he felt a “burning” in the soles of his feet. The burning was also frequently present without ambulation. Examination of the neuromuscular system was unremarkable except for reduced ankle deep tendon reflexes and bilaterally atrophic extensor digitorum brevis muscles. Position sense was normal, and no clear sensory impairment was present. The patient had an 8-year history of diabetes, which he indicated was well controlled by diet.

Needle EMG bilaterally in the vastus medialis, rectus femoris, anterior tibialis, extensor hallucis, medial and lateral hamstrings, medial and lateral gastrocnemii, and lumbar paraspinal musculature was unremarkable. Recruitment patterns were normal, and no membrane instability was seen.

Late response studies of tibial H waves, performed bilaterally, were symmetric with latencies of 35 milliseconds (2 milliseconds greater than expected values), and with a small amplitude of 0.2 mV. Motor and sensory nerve conduction studies were performed the next day to determine whether the delayed H wave was a sign of S-1 nerve root abnormalities or was associated with a diabetic peripheral neuropathy.

Conduction studies, all on the right side, are shown in Table 13-6.

Nerve	Distal latency (ms)	Conduction velocity (m/sec)	Amplitude (μV)
Median motor	3.6	51	6.3 K
Median sensory	4.4	43	18.0
Ulnar motor	3.2	58	7.0 K
Ulnar sensory	4.0	51	28.0
Peroneal motor	4.7	34	0.6 K
Peroneal sensory	Not applicable	34	1.5
Sural sensory	4.7	30	9.0
Tibial motor	4.8	39	5.5 K

TABLE 13-6. Results of motor and sensory nerve conduction studies

The negative needle EMG examination result confirmed the absence of an active radiculopathy. The motor and sensory conduction studies, however, confirmed a significant peripheral neuropathy, largely axonal. Specifically, sural nerve conduction was three standard deviations (SD) away from normal, evoked amplitude was 2 SD below normal; peroneal sensory velocity and amplitude were 2 SD below normal; peroneal motor conduction velocity was greater than 2 SD below normal, and the amplitude was greater than 3 SD below normal; and tibial motor velocity was 2 SD below normal. In the upper extremity, median motor velocity, median sensory latency and velocity, and ulnar sensory velocity were also abnormal. A systemic axonal, sensory, more than motor, and lower extremity, greater than upper extremity, peripheral neuropathy was concluded.

The patient was referred for endocrinologic studies, which revealed the diabetes to be poorly controlled. The patient was placed on chlorpropamide, and the back pain was treated conservatively, with good results.

Functional Syndromes

The physician who does not maintain a high degree of suspicion that the weakness or sensory loss seen in the chronic pain patient may be functional does so at his or her own peril and that of the patient as well. Too many operations have been performed on backs, necks, legs, and arms for weakness, paralysis, or sensory deficits that were presumed to be organic but were actually functional inhibitions or frank conversion reactions unassociated with malingering.

Weakness, paralysis, and sensory loss should be viewed, until proven otherwise, as part of the pain behavior complex discussed in Chapter 25 and Chapter 26. Humans have an amazing capacity to subconsciously inhibit motor function and sensory input in the presence of physiologically normal somatomotor and somatosensory systems. The electrodiagnostic examination can detect such functional inhibition by the responses seen in peripheral motor and sensory NCS, needle EMG, and SEPs.

If even the slightest suggestion occurs to a physician that the patient's behavior, weakness, and sensory complaints do not fit or make sense with the medical history and physical examination, electrodiagnostic examination might be the next thing to consider.

The most difficult of the functional patterns to detect are those that *grow out of* or are associated with an initially *legitimate* injury or disease process. For example, after an ankle sprain or even a fracture, in which ankle dorsiflexion was inhibited initially because of pain, the dorsiflexion weakness might persist long after healing of the acute process should have occurred. The documentation of functional inhibition in such a case is achieved by demonstration of a normal response on stimulation of the peroneal nerve at the knee and the ankle and the demonstration that no membrane instability is present on needle EMG of the *paralyzed* muscles.

Lower extremity functional inhibitions are more prevalent than those affecting the upper extremity. Both appear as inhibitions that affect performance of work-related activities of an inherently distasteful character to the patient or activities that produce stresses with which the patient has difficulty dealing.

Lower extremity functional problems are usually apparent on ambulation. Some gait patterns that suggest a functional origin and indicate a need for an electrodiagnostic examination are presented here:

- Full knee extension throughout the stance phase
- Knee buckling at the end of the stance phase just before heel strike of the swinging opposite limb
- A dropped foot during swing
- An absent heel strike at the beginning of stance
- Toe walking during stance

- Foot inversion during stance
- Use of the hand on the anterior aspect of the thigh during stance
- Use of the hand to help advance a leg during swing
- Continuous contact and dragging of the foot on the floor during swing in a position of hip and foot external rotation
- A decreased duration of stance phase of the involved leg
- Use of a cane or a crutch on the *same* side as the affected leg

The electrodiagnostic examination findings that suggest functional inhibition are listed here:

- Normal M-, F-, and H-wave responses on stimulation of peripheral motor nerves, serving muscles that appear to be weak or paralyzed on voluntary effort
- Normal peripheral sensory nerve-evoked responses and normal central SEP responses on peripheral sensory nerve stimulation in regions in which the patient reports absent or reduced sensation on direct examination.
- No membrane instability and normal MUAPs on needle EMG examination in patients with profound weakness presumed to be caused by a lower motor neuron problem. The needle EMG examination also detects irregular noncontinuous bursts of MUAP activity as the patient engages in largely ineffectual and *rachety* voluntary effort.

Case Example

A 43-year-old man suffered a displaced fracture of the tip of the medial malleolus of his right ankle 14 months before his electrodiagnostic examination. An open reduction with internal fixation was initially performed, and the ankle was immobilized in a plaster cast. The immediate postoperative period was complicated by a superficial *Pseudomonas* infection. Chronic pain and continued ambulation difficulty persisted after cast removal and even after metal screw removal. The persistent gait abnormality was manifested by toe-drag during the swing phase of the right leg. On clinical examination, no voluntary function was seen in the anterior tibialis, peroneal, or toe extensor muscles. In addition, leg edema and superficial dysesthesias were present.

Needle EMG of the anterior tibialis, extensor hallucis, peroneus longus, and extensor digitorum brevis revealed absent membrane instability (i.e., positive waves or fibrillation potentials). On voluntary effort, a marked reduction in the number of voluntary MUAPs was seen. Those that were present were of normal configuration. The recruitment effort was unsustained with occasional bursts of MUAPs, suggesting cerebral inhibition.

Conduction studies of the right peroneal nerve, stimulating at the fibula head and at the ankle and recording over the extensor digitorum brevis, produced a conduction velocity of 52 m per second (normal) and an evoked response at the extensor digitorum brevis of 12 mV (normal). In addition, a normal F-wave response was seen over the extensor digitorum brevis on stimulation of the deep branch of the peroneal nerve at the ankle. Comparison of the evoked responses at the extensor digitorum brevis on stimulation at the knee and at the ankle revealed normal temporal dispersion.

The excellent response on peroneal nerve stimulation revealed the nerve to be fully viable. The normal F-wave response indicated that the peroneal motor nerve fibers were intact clear into the spinal cord. The absence of membrane instability of the needle EMG confirmed no loss of motor axons to any of the muscles served by the peroneal nerve. The diagnosis of functional inhibition as the cause of the gait abnormality and the weakness was made.

Psychological and social review revealed much stress. The treatment program, directed at relieving the stresses, at reambulation, and at restoration of voluntary ankle dorsiflexion, eliminated the gait abnormality, resolved the edema, and caused the dysesthesias to fade.

CONCLUSIONS

The symptom of pain usually implies nervous system involvement. The complaint, as discussed in Chapter 9 and Chapter 10, is derived from myriad factors. Whereas a correctable lesion can be present, the more chronic the complaint, the less likely a localizable lesion is the cause. Before any therapeutic considerations, particularly a surgical approach to correct a suspected lesion that might involve the somatomotor or somatosensory system, careful and complete diagnostic evaluations are essential. The power of the electrodiagnostic examination for the detection of neuromuscular disease has been clearly established.

In this chapter, the essential ingredients of available electrodiagnostic studies have been reviewed. Specifically, the way in which needle EMG, peripheral motor and sensory NCS, late responses, and SEP analysis can be used to evaluate entrapment syndromes, radiculopathies, traumatic syndromes, systemic syndromes, and functional syndromes have been discussed.

All physicians faced with patients with pain complaints should establish a relationship with a physician skilled in electrodiagnostic medicine for assistance when somatomotor and somatosensory involvement is suspected, even if the history and the physical examination have obvious features. The likelihood of misdiagnosis and faulty treatment is therefore reduced.

CHAPTER 14

Imaging Pain Patients

Alexander B. Baxter and Kenneth R. Maravilla

Primary imaging studies for the patient with acute pain aim to confirm or exclude a diagnosis based on history and physical examination. For patients with recurrent or persistent pain whose diagnosis remains obscure, or for patients with pain that appears to be solely related to degenerative disease, the role of imaging is expanded. Specialized techniques can help detect subtle evidence of disease, direct therapy, and select patients for surgical or radiologic intervention.

A comprehensive discussion of computed tomography (CT), magnetic resonance imaging (MRI), ultrasound, and radionuclide examinations is beyond the scope of this chapter and can be found in most general radiology textbooks. Refinements in CT, MRI, and spinal interventional procedures have led to new applications in evaluating and treating patients with chronic pain syndromes. This chapter reviews the imaging approach to several regional pain syndromes as well as imaging techniques that can be used to select surgical candidates among patients with back pain, tic douloureux, and peripheral nerve entrapment syndromes. Techniques and indications for MRI of the cranial nerves and posterior fossa vasculature, diskography for nonradicular back and neck pain, and high-resolution MRI of the brachial plexus and peripheral nerves are discussed. The role of imaging in conjunction with diagnostic and therapeutic nerve blocks is also addressed.

HEADACHE

Headache is a common symptom, and choosing the patient who should have a cranial imaging study can be challenging (see Chapter 48). The diagnostic yield of neuroimaging examinations in patients with headaches and a normal neurologic examination, or in patients with typical migraine, is low (Table 14-1) (1). Certain clinical situations, however, should prompt cranial imaging: Acute onset of an extremely severe headache, worsening subacute headache, headache associated with focal neurologic signs or cognitive impairment (in patients without a history of migraine), new headache in patients older than age 50, and headache in immunocompromised patients or patients with known malignancy (2,3). Patients over the age of 65 with new onset of pathologic headache have a 15% incidence of serious intracranial disease, including temporal arteritis, tumor, and infarct. In contrast, patients younger than age 65 have only a 1.5% incidence of detectable underlying pathology (4).

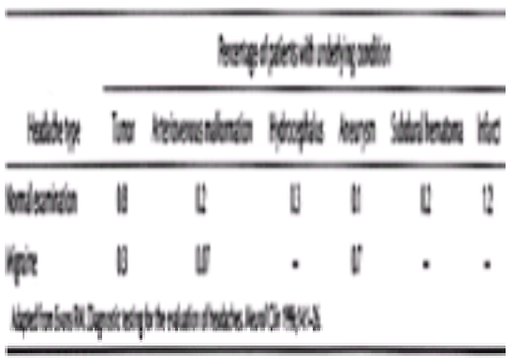

TABLE 14-1. Neuroimaging yield in headache

Acute Headache

Severe, acute headache, especially if associated with neurologic abnormality or depressed sensorium, suggests possible subarachnoid hemorrhage (SAH). The devastating consequences of untreated ruptured aneurysm require prompt exclusion of SAH in this setting. Diagnosis is best made by CT demonstration of hyperdense blood in the subarachnoid space or detection of xanthochromic cerebrospinal fluid (CSF) on lumbar puncture in patients with a negative CT examination (5). CT sensitivity for detection of SAH is reduced as the time interval from hemorrhage increases. Ninety-five percent of SAH are identified on CT in patients scanned within 24 hours of aneurysm rupture. At 3 weeks, only 30% of SAH are detected by CT (1). If SAH is present, subsequent imaging is directed at detecting an aneurysm (Fig. 14-1) or arteriovenous malformation (Fig. 14-2). Venous sinus thrombosis (Fig. 14-3 and Fig. 14-4) (6,7), benign perimesencephalic SAH (8), arterial dissection (9) (Fig. 14-5), migraine, and benign thunderclap headache can also present as acute, severe cephalgia.

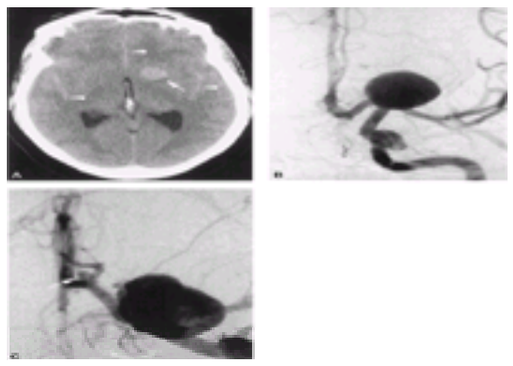

Figure 14-1. Subarachnoid hemorrhage caused by ruptured terminal internal carotid artery aneurysm. **A:** Nonenhanced computed tomography shows hyperdense aneurysm (*arrow*) and blood within interhemispheric and sylvian fissures (*arrowheads*). The ventricles are mildly enlarged and clot is present within the third ventricle. **B:** Left internal carotid artery arteriogram shows a 2-cm aneurysm arising from the termination of the internal carotid artery.

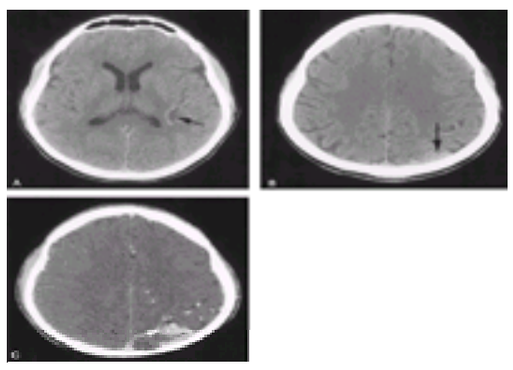

Figure 14-2. Arteriovenous malformation. A 39-year-old man with several days' headache. **A:** Noncontrast computed tomography shows enlarged, slightly hyperdense vessels in the sylvian fissure (*arrow*). **B:** Hyperdense, dilated veins at the varietal vertex (*arrow*). **C:** Computed tomographic angiography shows the arteriovenous malformation nidus as well as dilated feeding arteries and peripheral draining veins.

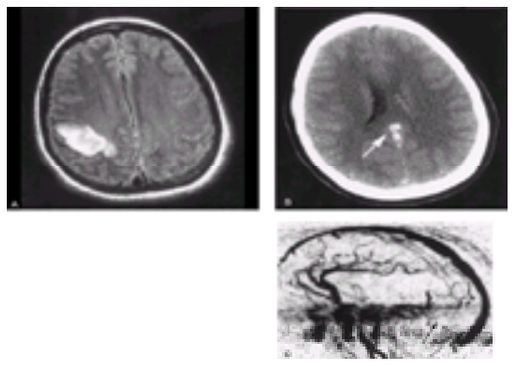

Figure 14-3. Venous sinus thrombosis with cortical infarct. A 26-year-old postpartum woman with headache and left hemiparesis. **A:** Axial FLAIR image at level of centrum semiovale shows increased signal in precentral gyrus, indicating cortical infarct. **B:** Nonenhanced computed tomography shows high attenuation in vein of Galen and straight sinus (*arrow*). **C:** Magnetic resonance venogram shows absence of flow through straight sinus with patent sagittal and transverse sinuses.

Figure 14-4. Venous sinus thrombosis with bilateral thalamic infarcts in a 24-year-old woman with 4 days of headache followed by several hours nausea and depressed consciousness. Nonenhanced computed tomography shows low attenuation changes in both thalami, with increased attenuation in the internal cerebral veins (*arrow*) and straight sinus (*arrowhead*).

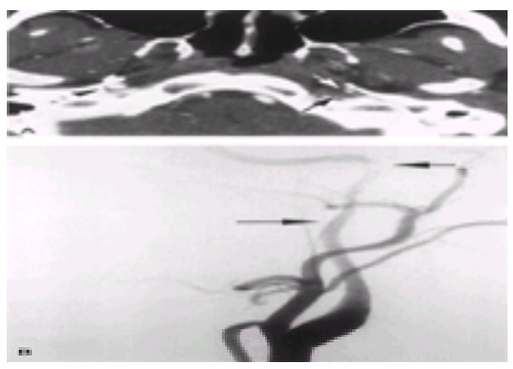

Figure 14-5. Internal carotid artery dissection in a 37-year-old man with headache and left pupillary constriction. **A:** Computed tomographic angiography at skull base shows decreased caliber of left internal carotid artery (*white arrow*) at the skull base. Intramural hematoma surrounds the narrowed lumen (*black arrow*). Normal right internal carotid artery (*arrowhead*). **B:** Left internal carotid arteriogram shows smooth narrowing of distal cervical internal carotid with near complete occlusion at the skull base (*arrows*).

Imaging the patient with suspected SAH should begin with nonenhanced CT. Cisterns and sulci must be carefully examined for hyperdense acute blood, which can be subtle if the amount of hemorrhage is small, or if the bleed occurred more than 24 hours before CT. Although nonenhanced CT has a sensitivity of 97.5% when obtained within 12 hours of symptom onset, lumbar puncture can detect xanthochromic CSF in patients with SAH but normal CT scan results. This is particularly important in patients who are evaluated 12 or more hours after headache onset (5,10). Red cells detected by lumbar puncture performed immediately after the onset of symptoms may not permit distinction between spontaneous hemorrhage into the CSF and traumatic lumbar puncture. In the absence of SAH, nonenhanced CT can detect signs of other pathologies, including increased density within a thrombosed dural venous sinus, venous infarction, and edema associated with intracranial mass lesions. If subtle abnormalities are found on nonenhanced CT, further imaging evaluation includes contrast-enhanced CT or MRI. In the absence of SAH, MRI is a more sensitive technique to evaluate the patient for other causes of headache, including dural venous sinus occlusion, venous infarct, and intracranial infection. If SAH is detected, cerebral arteriography is generally used to further evaluate the location and features of an aneurysm or arteriovenous malformation.

Magnetic resonance angiography (MRA) and CT angiography are useful for rapid, noninvasive diagnosis of intracranial vascular lesions. CT angiography is a dynamic, CT-based angiographic technique in which thin slice images are obtained rapidly and continuously during the first pass of the arterial phase of an intravenous contrast infusion. In this manner, axial images covering several centimeters of the cervical or cerebral vessels can be acquired in less than 1 minute. Using rapid computer processing, planar and three- dimensional reconstructions can be created to display the enhanced blood vessels in a manner analogous to the projection images from catheter arteriography. CT angiography or MRA can assist in the rapid diagnosis or exclusion of aneurysms and arteriovenous malformations in the acutely ill patient, or to clarify subtle findings in patients with questionable abnormalities on nonenhanced CT. Similarly, carotid dissection can be detected by imaging the upper cervical vasculature with either technique (see Fig. 14-5) (11,12).

Chronic Headache

Imaging findings are unrevealing in most cases of isolated chronic headache. Nonetheless, intracranial lesions sometimes present only with headache, although they are usually associated with other neurologic signs or symptoms (13). When headaches are caused by underlying pathologic disorders, the differential diagnosis is broad. Serious primary conditions include intraparenchymal, dural, or skull base tumors (14); unruptured aneurysms (15); abscesses; arterial dissection (16); venous sinus thrombosis; and arteriovenous malformations. CT or MRI without intravenous contrast excludes most intracranial masses, and if the results are normal, can reassure the clinician and justify continued clinical observation and symptomatic treatment. If the clinical evaluation points toward metastasis, abscess, or a vascular process, then contrast-enhanced CT or MRI is an appropriate study.

Acute sinusitis is a common cause of headache or facial pain and can be diagnosed by plain film or CT (see Chapter 52). Screening sinus CT is more sensitive than plain radiography and is now used routinely at our center. Designed as a rapid, limited CT examination targeted only at the paranasal sinuses, this study can be performed at only a modestly increased cost compared with plain films. CT has the additional advantages of evaluating the middle ear and mastoid air cells, as well as the subtle bony and mucosal changes reflecting chronic sinusitis. In the patient with recurrent sinusitis, thin section coronal CT assists in planning of endoscopic sinus surgery (Fig. 14-6) (17).

Figure 14-6. Chronic sinusitis. Coronal, nonenhanced screening sinus computed tomography through the face shows opacification of the left maxillary sinus caused by chronic inflammation (*long arrow*). The osteomeatal unit (*short arrow*) and uncinate process (*arrowhead*) are clearly demonstrated on the opposite side.

The syndrome of CSF hypotension is characterized by positional headache and variable symptoms of nausea and vomiting and visual, auditory, or vestibular disturbances. Normal CSF pressure in the recumbent position, and in the absence of prior lumbar puncture, is between 7 and 18 cm H_2O. CSF hypotension can be caused by spontaneous development of a CSF leak (18) or may result from diagnostic lumbar puncture, epidural anesthesia, myelography, head injury, or overdrainage of CSF shunts (19).

Spontaneous, posttraumatic, and postlumbar puncture CSF hypotension probably reflect chronic leakage of CSF through a dural defect (20). Cranial MRI with gadolinium demonstrates smooth, continuous enhanced dural thickening, subdural effusions, and downward vertical displacement of the brain. In some cases, the dural thickening may extend inferiorly to involve the spinal canal as well. These findings may disappear with resolution of CSF hypotension after successful treatment by blood patch, epidural saline injection, or surgical repair of the defect (21,22 and 23). Headache with MR findings of diffuse enhanced dural thickening, not explained by prior surgery or infection, should prompt a diligent search for occult spontaneous CSF leak. Such occult, spontaneous leaks may recur through the skull base, or, less frequently, via a spinal dural defect (Fig. 14-7).

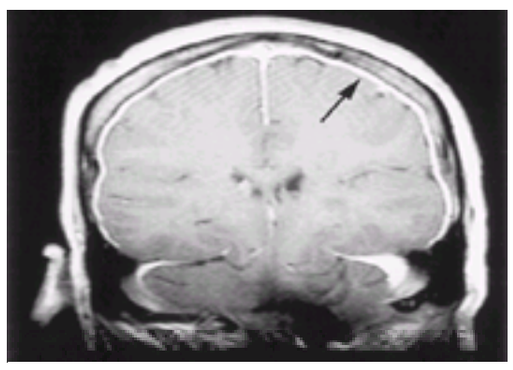

Figure 14-7. Cerebrospinal fluid hypotension caused by overshunting. A 54-year-old woman with ventriculoperitoneal shunt. Diffuse dural thickening and enhancement (*arrow*) caused by shunt valve with insufficient resistance. Similar findings may be seen in patients with postlumbar puncture, dural tears, or posttraumatic cerebrospinal fluid leaks.

FACIAL PAIN

Intractable trigeminal neuralgia (tic douloureux) can be related to a branch of the superior, anterior, or posterior inferior cerebellar artery that contacts the cisternal portion of the fifth cranial nerve (24) (see Chapter 47). Surgical intervention with placement of a prosthesis to separate the offending vessel from the root entry zone of the cranial nerve is often effective in relieving symptoms (25). Diagnosis of vascular loops in the prepontine cistern and cerebellopontine angle was difficult before the development of MRI. Thin section high-resolution MRI and MRA, using specialized, phased array radiofrequency receiver coils and multiplanar or three-dimensional reformatting can accurately demonstrate all relevant posterior fossa structures and aid in identification of surgical candidates (26,27 and 28).

The diagnosis of vascular loop syndrome is made by demonstration of a blood vessel contiguous with, or preferably distorting, a cranial nerve close to its origin from the brainstem at the root entry zone (Fig. 14-8). This portion of the nerve is sensitive to irritation from pulsations in the contacting artery. The diagnosis is based on appropriate clinical symptoms as well as definitive MRI/MRA findings, because a small number of asymptomatic patients show vascular loops contacting the cranial nerve origins. Imaging findings alone do not justify surgical treatment, which is based on symptom severity and failure of medical therapy. Other causes of trigeminal nerve dysfunction include meningioma, schwannoma, arachnoid cyst, chordoma, and chondrosarcoma. These can be diagnosed by conventional cranial MRI and CT.

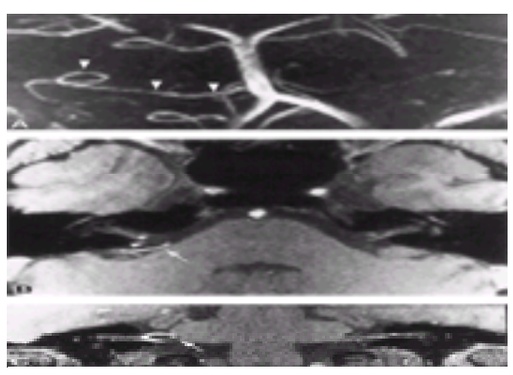

Figure 14-8. Vascular loop compression of the eighth nerve. **A:** Anteroposterior projection of a magnetic resonance arteriogram (MRA) of the vertebral basilar arterial system shows a good demonstration of a prominent right anterior inferior cerebellar artery (*arrowheads*). However, this standard MRA display does not allow one to determine the relationship of the looping portion of the vessel to the underlying neural structures. **B:** Axial source image of the MRA now shows a good demonstration of a vascular loop (*arrow*), which lies contiguous with the eighth nerve near its origin from the brainstem. **C:** Coronal reformatted image from the MRA data set confirms the contiguous position of the vascular loop with the eighth nerve near its root entry zone (*arrow*).

Vascular loops can compromise other cranial nerves in the basal cisterns. Chronic vertigo can be caused by posterior fossa vessels contacting the root entry zone of the eighth nerve (see Fig. 14-8) and compression of the intracisternal seventh nerve can result in hemifacial spasm. High-resolution MRI/MRA can be used to identify potential vascular loop syndromes causing these symptoms.

SPINAL PAIN

Technical advances in surgical fusion of lower lumbar vertebrae have resulted in safer, less invasive operations and have generated renewed interest in diagnostic tests that might predict a favorable surgical outcome for the back pain patient (29,30 and 31) (see Chapter 76). Conventional MRI, CT, and CT myelography can accurately evaluate spinal canal or neuroforaminal stenosis, lumbar disk protrusion, extrusion, or sequestration in the patient with pain and radiculopathy (32). Gadolinium-enhanced MRI can distinguish between postsurgical scar and recurrent disk herniation in the patient with prior back surgery and persistent or recurrent pain (33). Because of the prevalence of degenerative changes, annular tears, and herniated disks in asymptomatic patients, CT or MRI findings alone do not prove that a given disk is the cause of the individual patient's pain (34).

Before the advent of spinal CT and MRI, diskography was the only radiologic technique for directly assessing the anatomy and integrity of the intervertebral disk. From this anatomic standpoint, CT and MRI have replaced diskography (35). Indeed, its present role is as a provocative test, with the aim of selecting patients with a greater likelihood of improvement after spinal fusion procedures. Diskography involves injection of radiographic contrast material into an anatomically abnormal (suspect) disk and one or two normal (control) disks, and recording the patient's reported pain sensations during injection (Fig. 14-9) (36).

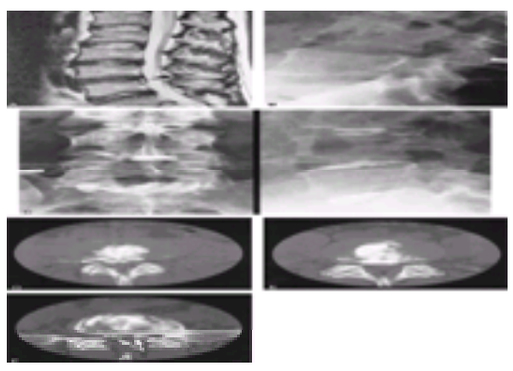

Figure 14-9. Diskogram. A 34-year-old man with chronic lower back pain with radiation to left leg. **A:** Sagittal T2-weighted lumbar magnetic resonance imaging examination demonstrates an annular tear at L-4–5 as well as mild disk dessication at L-3–4 and L-5–S-1. **B:** Lateral fluoroscopic spot film showing placement of 25-gauge Chiba needles within the intervertebral disks at L-3–4, L-4–5, and L-5–S-1.

C: Anteroposterior (*left*) and lateral (*right*) fluoroscopic images after injection of contrast material. During contrast injection, the patient reported no pain at L-3–4, mild (2/10) pain similar to clinical symptoms at L-4–5, and minimal (1/10) pain unlike clinical symptoms at L-5–S-1. **D:** Postdiskography axial computed tomography through L-3–4. Internal fissures and small central annular tear (*arrow*). **E:** Axial computed tomography through L-4–5. Internal fissures.

F: Axial computed tomography through L5–S1. Internal fissures and annular tear with focal herniation (*arrow*).

Diskography is performed with fluoroscopic guidance and meticulous sterile technique. The risks of the procedure, including nerve root injury, contrast media reaction, diskitis, osteomyelitis, and epidural abscess are reviewed with the patient (37,38 and 39). After sterile preparation of the skin over the flank and generous local anesthesia, 22- or 25-gauge needles are placed into the center of both suspect and control disks via an oblique coaxial approach. One milliliter to 2 mL of nonionic contrast material is injected into each disk, and the patient is questioned as to the severity of pain with contrast injection and whether it is similar, different, or exactly the same as their usual back pain. Fluoroscopic and CT images are obtained at each disk level to evaluate disk morphology and to confirm appropriate placement of contrast. A positive test result is indicated by reproduction of the patient's symptoms during injection of a morphologically abnormal disk, without similar discomfort on injection of control disk levels (40).

Diskography is a unique provocative test for diskogenic pain, but patients' reporting of symptoms during disk injection can be affected by psychological factors as well as interview technique (41,42). The diskographic identification of a painful disk also does not guarantee that the patient will respond to surgical fusion at that level (43). Because ongoing controversy exists as to its accuracy and value (44), diskography is probably best indicated before proposed surgical therapy in the setting of severe, intractable back pain without radiculopathy or CT or MRI evidence of disk herniation. In this setting, diskography may confirm the levels of symptomatic disks, or may be nondiagnostic, with pain at both suspect and control levels.

MAGNETIC RESONANCE NEUROGRAPHY

Neurogenic pain involving the neck, shoulder, and the upper extremity can result from cervical nerve root compression, brachial plexopathy, thoracic outlet syndrome (TOS), ulnar nerve entrapment at the elbow, or median nerve compression at the carpal tunnel (see Chapter 56). Precise definition of the level of nerve compression or injury can be difficult, even with electrodiagnostic studies. MRI of the cervical spine and brachial plexus and MR neurography permit direct visualization of the brachial plexus and peripheral nerves and can confirm the presence of neural irritation, edema, or compression (45,46 and 47). Pathologic states caused by variant anatomy, prior trauma, scar tissue or mass lesion, and musculoskeletal causes of pain can be excluded (Fig. 14-10, Fig. 14-11 and Fig. 14-12). MRI of distal musculature can provide evidence of denervation in the distribution of a given peripheral nerve (Fig. 14-13 and Fig. 14-14).

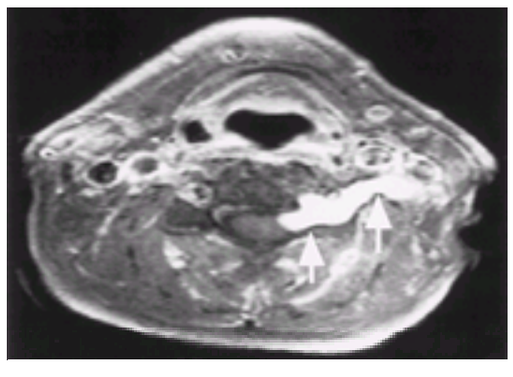

Figure 14-10. C-5 schwannoma. An 81-year-old man with 4 years of left upper extremity pain and dysesthesia. Axial and coronal short tau inversion recovery images

reveal a dumbbell-shaped high signal intensity extradural mass involving the left C-4/5 neural foramen (*arrows*).

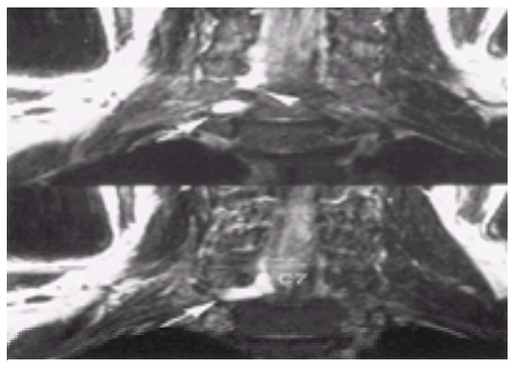

Figure 14-11. Nerve root avulsion. A 25-year-old man with traumatic injury to the right brachial plexus following a motorcycle accident that resulted in a flail upper extremity. After the accident he suffered from daily, intermittent, lancinating pain. Electromyography demonstrated absent cortical and brainstem response to stimulation of median and ulnar nerves and upper trunk of brachial plexus (C-6–8 roots). Coronal T1 and short tau inversion recovery images show proximal meningeal diverticuli at C-6, C-8, and T-1 (*arrow*) as well as abnormal signal in the right brachial plexus.

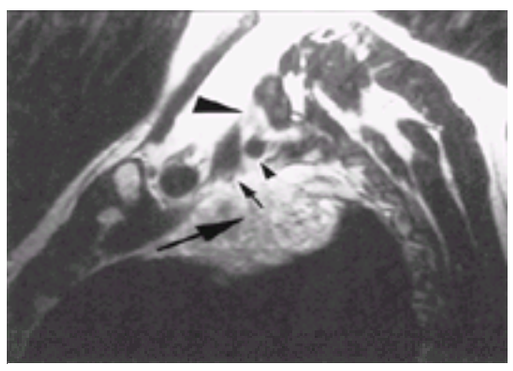

Figure 14-12. Pancoast's tumor. A 42-year-old man with mild cough. Posterior superior mediastinal mass was identified on plain radiograph. Sagittal T2 images demonstrate the pulmonary apex mass that abuts but does not surround the subclavian artery. At surgery, the mass was found to be a hemangioma. Magnetic resonance imaging is useful for evaluating the extent of chest wall tumors as well as brachial plexus and vascular invasion.

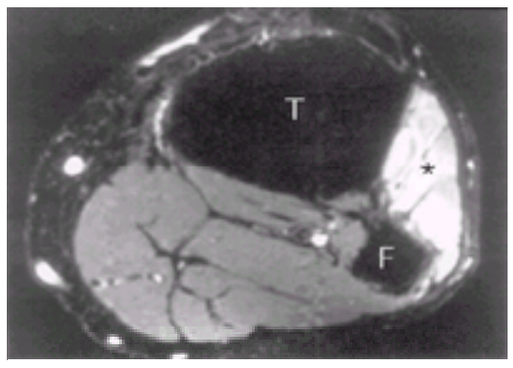

Figure 14-13. Subacute denervation in the distribution of the peroneal nerve. This axial short tau inversion recovery image of the proximal calf at the level of the fibular head (F) and the tibial metaphysis (T) demonstrates markedly hyperintense signal intensity within the anterior compartment muscles (*asterisk*). Note the muscles of the posterior calf for comparison, which show normal signal intensity. This illustrates the typical appearance of acute and subacute denervation that in this case followed severe injury to the left common perineal nerve.

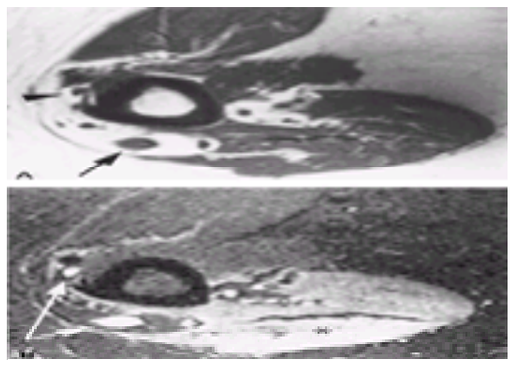

Figure 14-14. Ulnar and radial nerve injury. This patient suffered a severe left brachial plexus injury, with radial and ulnar neuropathy. **A:** T1-weighted axial image through the left upper arm showing location of the radial (*arrow*) and ulnar (*arrowhead*) nerves. T1 sequences generally demonstrate anatomic relationships better than corresponding short tau inversion recovery sequences. **B:** Short tau inversion recovery image showing increased signal in radial and ulnar nerves (*arrows*) as well as increased signal in triceps muscle (*asterisk*).

Brachial plexus, cervical root, or sacral MRI is optimally performed using a phased-array surface coil and large matrix size. Coronal and sagittal T1-weighted images provide superb anatomic definition. Fast spin echo T2 and short tau inversion recovery (STIR) sequences are sensitive to changes in normal signal intensity within the roots, trunks, and cords of the brachial plexus. STIR sequences suppress signal from fat, increasing the conspicuity of abnormal nerves. It is often helpful to image both sides of the patient simultaneously for comparison with the asymptomatic side (48). Optimal MR neurography at the elbow, wrist, or arm also requires high-resolution surface coils, a large matrix size, T1, fast spin echo T2, and STIR sequences. Imaging is conducted in the axial plane (perpendicular to the nerve) and either the coronal or sagittal plane. Acute and subacute denervation of muscles supplied by peripheral nerves is evident as increased signal on T2 and STIR sequences, loss of muscle volume, and sometimes enhancement after gadolinium administration. Chronic denervation results in marked loss of muscle mass together with fatty infiltration. The increased T2 changes seen in acute and subacute denervation are not seen. Axial T2 or STIR images of the musculature supplied by an injured peripheral nerve can identify denervation and are an indirect but effective means of determining the affected nerve and level of injury (see Fig. 14-13 and Fig. 14-14) (45).

Abnormal changes in peripheral nerves identified by MR neurography include focal or generalized enlargement of the nerve, increased signal on T2 and STIR

sequences, loss of fascicular architecture, enhancement after administration of gadolinium, and displacement or compression of the nerve by soft tissue or osseous masses. MR neurography requires specialized surface coils and high-resolution techniques for optimal imaging. It is particularly useful for patients with unexplained neuropathy, for whom surgical intervention is planned, or when the anatomic site of abnormality remains unclear after clinical examination and electrodiagnostic studies (49,50).

ENTRAPMENT SYNDROMES

Extremity pain, dysesthesia, and weakness can result from entrapment of nerve roots, compression, injury, or infiltration of the brachial, lumbar, or sacral plexi and compression of peripheral nerves at several sites (51,52). Anatomic diagnosis is not always clear and may require imaging of the spine or trunk as well as the affected extremity.

Cervical spine MRI, CT, or CT myelography demonstrate intervertebral disk herniation, spinal canal and neuroforaminal stenoses, and degenerative changes in evaluating radiculopathy. Contrast-enhanced MR can identify spinal cord and vertebral tumors in addition to postoperative scars. Brachial plexus and pelvic MRI, using high-resolution phased array coils, can define the course of nerve roots, trunks, divisions, and cords in the patient with plexopathy, as well as detecting masses, traumatic injuries, and inflammatory changes (48) (see Fig. 14-10 and Fig. 14-11). Direct imaging of peripheral nerves at common sites of entrapment can confirm the location of injury or tumor, and patients who might benefit from decompressive surgery can be identified (Fig. 14-15; see Fig. 14-14) (50).

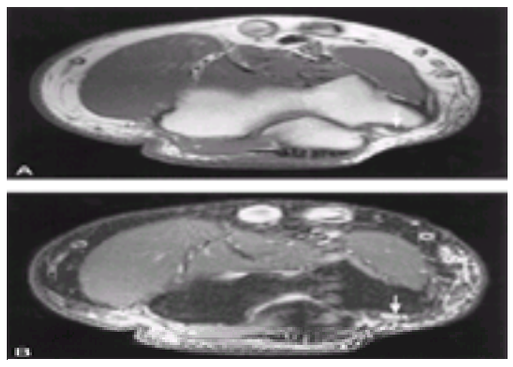

Figure 14-15. Ulnar entrapment. Axial T1 (**A**) and short tau inversion recovery (STIR) (**B**) images of the right elbow taken at the level in which the ulnar nerve passes through the cubital tunnel. **A:** On this T1-weighted image, a normal sized right ulnar nerve is nicely demonstrated surrounded by perineural fat (*arrow*). **B:** The STIR image, however, demonstrates abnormally increased hyperintensity within the nerve that is abnormal (*arrow*) and that, in the presence of appropriate symptoms, is an indication of ulnar nerve entrapment.

Brachial Plexus

The true TOS is a rare condition caused by compression of the lower trunk and or medial cord (C-8 and T-1 nerve roots) of the brachial plexus between the first rib, the anterior scalene, and the middle scalene muscles (see Chapter 55). Most patients have a controversial syndrome characterized by variable supraclavicular and upper extremity pain, dysesthesia, and weakness without the presence of an anomalous cervical rib or objective physical examination or electromyographic findings of nerve abnormality (53). A minority of patients have a predominately vascular form of TOS with symptoms resulting from subclavian artery compression or venous insufficiency and possible thrombosis (54). Because musculoskeletal inflammatory conditions, complex regional pain syndromes, and distal compressive neuropathies can have similar symptoms, the diagnosis of TOS can be extremely difficult. Although decompression of the inferior brachial plexus and subclavian vessels by transaxillary resection of the first rib has been successful in management of some patients with TOS, generally after a trial of physical therapy, the decision to operate is rarely straightforward.

The role of imaging in suspected TOS is not clearly established at present and is currently under evaluation. Panegyres and colleagues reported sensitivity of 79% and specificity of 87.5% for the detection of distortion or displacement of the brachial plexus or subclavian vessels in 20 patients with symptoms of TOS who underwent bilateral brachial plexus MRI examination. They also described soft tissue bands arising from the C-7 transverse process in 75% of symptomatic sides and 16% of control sides (55). In contrast, Poole and colleagues did not identify soft tissue bands in any of the 23 patients with clinical TOS who had MRI examinations. They believed history and physical examination were the most helpful predictors of good surgical outcome, and that imaging and electrodiagnostic studies were valuable primarily in identifying other sources of pain (56). Continuing improvements in high-resolution MR examination of the brachial plexus may help to identify surgical candidates on the basis of nerve signal abnormalities, but prospective studies have not yet been published.

Peripheral Nerve Entrapment Syndromes

Carpal tunnel syndrome is the result of median nerve compression at the carpal tunnel (see Chapter 59). Clinical features, usually sufficient for diagnosis, include paresthesia and hyperesthesia in the median nerve distribution, radiation of pain along the volar aspect of the forearm, nocturnal pain, exacerbation with repetitive movements, and atrophy of the thenar muscles. Carpal tunnel syndrome is most often caused by repetitive injury of the median nerve within a compromised carpal tunnel volume, but can also be caused by focal space-occupying lesions, local inflammatory processes, or metabolic derangements related to systemic illness (57,58). Proximal nerve entrapment in the cervical spine, thoracic outlet, and along the course of the median nerve can mimic carpal tunnel syndrome. The pronator syndrome, and the anterior interosseous syndrome are distal median nerve compression syndromes in which the nerve is compressed by the two heads of the pronator, or after the branching of the anterior osseous nerve, along the interosseous membrane, respectively. Both of these syndromes can produce symptoms identical to carpal tunnel syndrome (49).

Although ultrasound and CT have been used to evaluate anatomy of the carpal tunnel and visualize the median nerve (59), MR is superior to these technologies in confirming the diagnosis of carpal tunnel syndrome, by virtue of its greater contrast sensitivity and its ability to detect abnormal signal intensity changes within a compressed median nerve. A coronal T1 scout image allows selection of axial scan levels through the wrist. Axial T1 and STIR (or T2) images should be obtained at the distal radiocarpal joint, proximal carpal tunnel, distal carpal tunnel, and metacarpal bases. Dedicated phased-array coils are valuable in increasing image quality to better demonstrate these small structures (Fig. 14-16) (45).

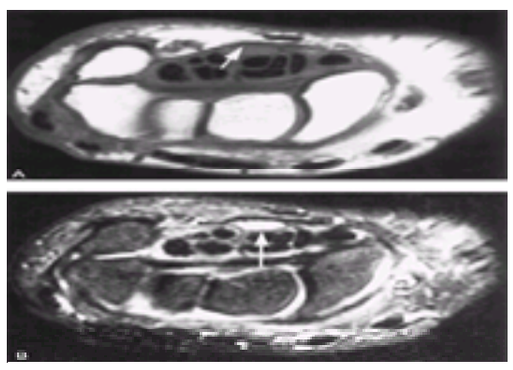

Figure 14-16. Carpal tunnel syndrome secondary to tenosynovitis. **A:** Axial T1 image through the carpal tunnel shows increased girth of the median nerve and bowing of the flexor retinaculum (*arrow*). **B:** Corresponding axial short tau inversion recovery image shows increased signal in the median nerve (*arrow*), as well as high signal fluid surrounding the tendon sheaths.

Findings in carpal tunnel syndrome include increased girth of the median nerve proximal to the carpal tunnel, flattening of the nerve within the tunnel, increased bowing of the flexor retinaculum, and increased signal intensity of the median nerve on T2 and STIR sequences. Ganglion cysts, lipomas, posttraumatic or degenerative bony deformities, and other soft tissue tumors are easily identified on MRI. Thickening or separation of tendons with increased signal changes on T2 or STIR sequences indicates tenosynovitis. Often idiopathic, it can also be caused by trauma, rheumatoid arthritis, and chronic infection. Amyloid, gout, acromegaly, hypothyroidism, and other systemic diseases associated with carpal tunnel syndrome are generally diagnosed on the basis of clinical, laboratory, and plain film findings (60,61,62 and 63).

Similar entrapment syndromes are also found in the ulnar canal at the elbow, peroneal nerve behind the knee, and at Guyon's canal, in which the distal ulnar nerve enters the wrist (64). High-resolution, surface coil MRI can be diagnostic, but its application requires careful attention to the anatomy of the particular nerve involved (45).

Imaging studies play an important role in the facilitation of diagnostic and therapeutic nerve blocks (see Chapter 102, Chapter 103 and Chapter 104). Accurate placement of needles for the injection of local anesthetic or neurolytic substances can be confirmed by radiographs, fluoroscopy, or CT scanning. These imaging techniques can prove the localization of a needle at a specific anatomic site and confirm the actual nerve or nerve root that is being blocked. The injection of a contrast agent with a local anesthetic solution can reveal the distribution of the agent used and confirm which nerves have been exposed to the anesthetic solution. This is particularly important when a surgical decision is based on the responses to nerve blocks. These techniques are particularly useful in patients whose anatomy has been distorted by disease processes or prior surgical procedures. The development of open magnet MR scanning may lead to an increase in the use of this imaging technology in the performance of nerve blocks.

Radiography is commonly used to confirm the placement of needles in the performance of facet joint blocks, paravertebral somatic nerve blocks, or transsacral blocks. Fluoroscopy is used in the placement of epidural electrodes or catheters. Surgical procedures such as gangliolysis of the trigeminal nerve or radiofrequency rhizolysis or spinal nerves are performed with fluoroscopy. CT scans are commonly used for celiac plexus block. Modern imaging techniques facilitate the use of nerve blocks by providing proof of the exact location of the needle or the spread of injectate.

CONCLUSIONS

Diagnostic imaging in patients with acute pain has a clearly defined role in establishing or confirming a pathologic diagnosis, and directing medical, surgical, or radiologic intervention. Patients suffering from chronic, recurrent, or intractable pain from degenerative disease, anatomic variations, chronic inflammatory conditions, neoplasm, and postoperative or posttraumatic scarring may benefit from specialized imaging examinations for the determination of etiology, treatment planning, and prediction of the outcome of directed therapy.

CHAPTER 15

Measurement of Pain

C. Richard Chapman and Karen L. Syrjala

This edition of this book, like its predecessors, emphasizes that pain is a complex perceptual experience. When pain is acute, it is often psychologically inseparable from fear and general distress. When it is chronic, it can become the focal element in a complex network of suffering that involves depression, somatic preoccupation, physical limitation, sleep disturbance, and hopelessness. Despite this complexity, meaningful evaluation of a patient with pain, and successful treatment, typically require quantification of the patient's pain.

Monitoring the severity and duration of pain can enhance patient care and improve the fit of the treatment to the patient. Such monitoring is essential for quality patient care in circumstances with fluctuating pain intensity: postoperative settings, intensive care environments, management of the cancer patient, and during the performance of invasive diagnostic procedures. The ability to quantify relevant dimensions of chronic pain also is critical for successful patient management because (a) chronic problems have a relatively stable baseline and permit rigorous assessment to determine outcomes of interventions; (b) evaluating treatment effects protects against the dangers of overmedication and repeated surgery; and (c) when a poor fit exists between demonstrable organic disease and pain behavior, treatment of chronic pain is often a process of rehabilitation that requires documentable increases in activity level and functional capability. Certain dimensions of pain, but not others, might indicate the success or failure of treatment. Furthermore, some patients or some types of problems are better suited for certain interventions than for others. Optimal matching of patient and treatment strategy depends on accurate and comprehensive assessment of the pain problem.

This chapter provides an introduction to the measurement of pain in clinical environments. We offer an overview of current methods for the assessment of acute and chronic pain and discuss basic issues to consider when measuring pain. Finally, we provide guidelines for measuring pain in different settings and maintaining a clinical database. For a comprehensive treatise on pain measurement, the reader can consult the *Handbook of Pain Assessment* by Turk and Melzack (1).

BASIC CONSIDERATIONS

Progress in Pain Measurement

Bonica published the first edition of this book in 1953. The ensuing decades have produced substantial progress in pain assessment, theory, and technology. Theorists and clinical researchers now agree that pain is a complex experience rather than a simple sensation. Simplistic concepts such as pain threshold have largely disappeared from contemporary parlance in the field of pain. Elegant methods of multidimensional assessment of pain have emerged to replace them. Many of these have attempted to exploit the words used to describe pain in the construction of rigorous test instruments. Increasingly, clinical investigators are assessing both sensory and affective dimensions of pain. Some have extended assessment to include the ways that pain interferes with daily living.

The importance of the cardinal distinction between acute and chronic pain, which Bonica emphasized in the first edition (2), has gained wide acceptance, and many care providers now understand that pain complaint can reflect complex psychological and even sociologic factors in addition to sensory and emotional experience. Many new tools for measuring pain in clinical settings have emerged in the 1990s. The most recent reveal an increasing tendency to measure syndrome-specific pain states. No single standard exists for quantifying pain in all circumstances.

Noteworthy progress has occurred in measuring pain associated with life-threatening diseases such as cancer and acquired immunodeficiency syndrome (AIDS). Also, both theoretical and technological advances have led to the development of tools for the assessment of functional impairment related to pain states. Increasingly, clinical investigators are finding that subjective measures of pain intensity, taken alone, are rarely adequate as indicators of patient well-being or as gauges of response to intervention. Pain causes fatigue, impairs concentration, prevents restorative sleep, and makes normal or productive behavior difficult. Accordingly, the newer pain measurement tools assess the subjective phenomenology of pain together with its effect on daily living (see Chapter 16).

The challenge of reliably quantifying pain still remains, but progress continues in this area. Enthusiasm for improving pain measurement has not waned within the scientific or clinical community. Thanks to the precedents of the pain guideline documents produced by various organizations, including the Agency for Health Care Policy and Research at the National Institutes of Health (3,4), recording pain has become standard practice in many hospital and other clinical settings.

Pain Assessment in Acute Versus Chronic Pain

As other sections of this book emphasize, acute pain is a transient, continuously changing state that differs radically from normal daily life (see Chapter 1). It relates intimately to intense emotional arousal, it typically has at least a rough association with tissue pathology, and it usually has clear, well-focused sensory location and characteristics. Acute pain states can be brief, lasting moments or hours, or they can persist, lasting weeks or months until the disease or injury heals. Chronic pain, in contrast, is an enduring condition that has become a component of the daily life of the patient. This definition excludes many forms of cancer pain or rheumatoid arthritis but includes pain associated with other persistent musculoskeletal, neuropathic, visceral, and degenerative disorders, and pain problems with behavioral components. Its sensory characteristics are more often, but not always, multifocal and vague, sometimes inappropriate for the organic pathology evident, and relatively similar across time. As with headaches or postherpetic neuralgia, the problem can become a chronic part of someone's daily life even while the pain itself may come and go. Although the same technology applies to the measurement of acute and chronic pain, the goals of assessment and the interpretation of the measures are usually different.
