A thorough, detailed history should permit the physician to make a presumptive diagnosis that needs to be confirmed or disproved by a thorough physical examination, which should include inspection, palpation, and percussion of various structures that might be involved with lesions producing pain in the neck, shoulders, and upper extremities (28). Palpation and percussion of the neck and movements in various directions indicate if the lesion is in the vertebral or paravertebral region. If these findings are negative, the shoulder should be examined thoroughly. In lesions of the shoulder girdle the pain is aggravated by palpation, percussion, and motion involving joints of the shoulder. The rest of the extremities are then examined thoroughly. In all cases a neurologic examination, including sensory, motor, and reflex tests, should be done (27). Special examinations should include imaging, electrodiagnostic studies, and sympathetic function tests. The rest of this section presents the most important points of the examination for pain in the neck, shoulders, and various parts of the upper limbs. The physical examination of the neck, shoulders, and upper limbs is described in more detail in three subsequent chapters.

Physical Examination

The physical examination should include the following features.

Neck

- Inspection of posture and gait, position of the head, curve of the neck, symmetry, and swelling
- Palpation of the hyoid bone, thyroid cartilage, thyroid gland, first cricoid ring, carotid pulses, lateral and posterior neck, supraclavicular fossa
- Palpation and percussion (to determine effects on pain, tenderness, paresthesia, and so forth) of the spinous processes, transverse processes, scaleni muscles, sternocleidomastoid muscle
- Range of motion (active, passive, against resistance): (a) anterior flexion; (b) lateral flexion (R); (c) lateral flexion (L); (d) extension; (e) rotation (R); (f) rotation (L)
- Effect of head compression test (Spurling's test), head or neck traction

Shoulder and Arm

- Blood pressure
- Position
- Shape
- Atrophy
- Palpation for pain, tenderness, radiation, paresthesia, dysesthesia, trigger points in muscles
- Range of motion at shoulder (active, passive, against resistance): (a) abduction; (b) adduction; (c) internal rotation; (d) external rotation; (e) flexion (at shoulder); (f) extension (at shoulder)
- Effect of each motion on pain and tenderness

Elbow and Forearm

- Inspection of position, shape, atrophy, swelling
- Palpation for pain, tenderness, paresthesia, trigger points
- Range of motion at forearm: (a) flexion; (b) extension; (c) supination; (d) pronation
- Range of motion at wrist: (a) dorsal flexion; (b) palmar flexion; (c) ulnar flexion; (d) radial flexion
- Effect of each motion on pain

Wrist and Hand

- Inspection of skin (color, temperature), pulse, shape, atrophy, swelling
- Palpation for pain, tenderness, paresthesia, trigger points
- Range of motion of fingers: (a) flexion; (b) extension; (c) adduction; (d) abduction; (e) opponens; (f) grip
- Effect of each movement on pain

Neurologic and Special Examinations

All tests involving the limbs should be done bilaterally.

- Sensory tests (determine and record presence of allodynia, hyperalgesia, hyperesthesia, hyperpathia, anesthesia, hypesthesia, hypalgesia): pinprick, pinch, temperature (hot and cold), touch, vibration, pressure
- Reflex tests (determine and record if normal, hyperactive, hypoactive, or absent): normal–biceps, triceps, brachioradialis, wrist jerk, finger jerk; pathologic–invert radial reflex, Hoffmann's reflex, Babinski's sign
- Sympathetic function tests: oscillometry, skin temperature (arm, forearm, hand, fingers), psychogalvanic reflex
- Muscle girth measurements (indicate specific site of measurement in centimeters from elbow for muscles of the limb): neck, arm, elbow, forearm, wrist, hand
- Special tests: head compression (Spurling's), head and neck traction, Adson's test, Allen's test, claviculocostal compression test, Valsalva's maneuver

Laboratory Examinations

A number of laboratory tests for the determination of the etiology of pain can be performed. These elucidate the presence or absence of anatomic and physiologic pathology, but do not determine the presence or absence of pain or its magnitude (see Chapter 14).

Imaging Studies

Radiography of cervical spine: anteroposterior, lateral, and oblique views of right and left sides; lateral views in flexion and extension can reveal recent and old trauma, congenital abnormalities, abnormal movement, neoplasm, infection. Radiography of the extremities can reveal bone and joint changes; they are not effective for soft tissue pathology.

Computed tomography scan of spine and of soft tissues can reveal much greater detail than radiography, particularly of osseous structures.

Magnetic resonance imaging scan is particularly useful in delineating soft tissues such as spinal cord, nerves, and muscles. It is useful in the extremities as well as neck.

Myelography is often combined with computed tomographic scan. It reveals subarachnoid space and any encroachment on dura by disk protrusion, degenerative changes in spine.

Diskography, injection of contrast medium into disk, reveals integrity of the annulus and nucleus and demonstrates presence of effects or damage to either structure; it has limited value because abnormal disks can be found in asymptomatic persons, especially those in the older age group.

Diskometry, injection of saline solution into normal disks, permits only a small amount of fluid to be injected before resistance is met; degenerated disk allows much more fluid to enter and ultimately causes pain and other symptoms; it has limitations because the test is technically difficult, produces discomfort, is clinically difficult to determine which disk to inject, can cause damage to the structure, and does not provide unequivocal information.

Electrodiagnostic Studies

Electromyography is used to determine pathology of formed cervical nerves of brachial plexus, components of the plexus, and dorsal and ventral roots (see Chapter 13 for details and Table 8-3 for nerve supply to various muscles).

Somatosensory-evoked potentials are capable of delineating peripheral nerve as well as spinal cord abnormalities of nerve conduction.

Laboratory Tests

- Routine tests: urinalysis, complete blood count
- Blood studies: calcium, alkaline phosphatase, acid phosphatase, blood glucose, serum uric acid, total cholesterol, triglycerides and high-density proteins, serum glutamic-oxaloacetic transaminase, aldolase, creatinine phosphokinase, creatine to creatinine ratio
- Immunologic studies: rheumatoid factors, complement, antinuclear antibodies, cell measurements, human leukocyte antigen typing, quantitative immunoglobulins (IgG, IgA, IgM), cryoglobulins
- Body fluid analysis: spinal fluid, synovial fluid
- Tissue biopsy if mass lesion identified

DIFFERENTIAL DIAGNOSIS

Table 54-5 lists the most important disorders that produce pain in the neck, shoulders, or upper limbs, or in all these structures, together with a brief description of the characteristics of the pain and the associated symptoms and signs. Acute pain conditions are well described in Weiner's text (28). Table 54-5 is presented to help in making an effective differential diagnosis. Further information on painful conditions in the neck and upper extremity is presented in the next five chapters.

TABLE 54-5. Pain in the neck, shoulder, and upper limb: summary of differential diagnoses

* The segmental distribution of sympathetic fibers by the major nerves to the limbs and their short course in the vessel wall are why periarterial sympathectomy, as originally advocated by Leriche (21), denervates only a segment of the artery and not the entire vessel, which would be the case if the sympathetic fibers passed along the entire length of the vessel.

CHAPTER 55

Neck Pain

Saadi Ghatan and Robert Goodkin

This chapter provides an overview of the epidemiology, anatomy, clinical evaluation, specific disease states and syndromes, and treatment of acute and chronic neck pain. It is organized to focus primarily on the most relevant and common problems seen in clinical practice, but at the same time provide a comprehensive survey of the etiologies and management of this troublesome complaint and at times perplexing clinical disorder. Neck pain is a nearly ubiquitous clinical problem seen by clinicians ranging from primary care physicians, to medical subspecialists, to surgical subspecialists, and, ultimately, to specialists in pain management. Although a detailed analysis of neck pain is beyond the scope of this chapter, it is written as a starting point for the treating practitioner, no matter what the area of his or her expertise.

EPIDEMIOLOGY

Although neck pain presents a formidable challenge in clinical practice, it has received little attention in the literature in comparison with low back pain. The majority of epidemiologic data on spinal-associated pain focuses on low back pain, and neck pain is included as an adjunct (1). Another challenge in the epidemiology of neck pain is its definition: For the purposes of this discussion, acute neck pain is defined as an episode lasting between 2 weeks and 6 months (2), and chronic neck pain is defined as an episode of greater than 6 months' duration (3). Everyone, to some extent, experiences at least transient neck pain that is self-limited and never comes to clinical attention, and the majority of painful episodes resolve spontaneously (4,5). Little is known about the precise prevalence of neck pain in general, but the most frequently quoted figures list its point prevalence at approximately 10% to 35% (3,6,7,8,9 and 10), with a lifetime prevalence between 35% and 50% (6,7 and 8,11,12). The most recent population-based data on chronic neck pain list a lifetime prevalence at around 13% to 14% (3,9).

One of the most common types of neck pain encountered in clinical practice is posttraumatic, or pain associated with *whiplash*- type movements, describing a hyperextension-hyperflexion neck injury. The subject of the whiplash syndrome and controversy surrounding its nosology are discussed later (see Mechanical Pain), but its common use in clinical practice and the mechanism of occurrence in automobile accidents warrant a discussion of its incidence and prevalence (13). Barnsley and colleagues (14) have calculated the derived annual incidence of symptoms from whiplash at 1.0 to 3.8 per 1,000 population based on numbers of rear- end motor vehicle accidents and the suggestion that 20% of those exposed to rear-end motor vehicle accidents develop neck pain (14,15). They go on to estimate a prevalence between 0.5% and 1.0% of the population having chronic neck pain after whiplash, and 0.2% to 0.4% with severe pain, underscoring its significance as a clinical problem (14). Still, one must approach such data with caution, because other epidemiologic studies have shown a prevalence of whiplash-associated neck pain that equals the population-based estimates of neck pain in the absence of trauma (3,15). Studies generated through insurance databases show conflicting figures, with an incidence of 1 per 1,000 among Australian claimants, with only 0.1 per 1,000 among New Zealanders (16), reflecting complexities of a combination of factors, including motivation, enabling circumstances, perceived benefits, perceived costs, social norms, peer and family pressure, and fear of recurrent pain and disability (14). Litigation also clouds the statistical picture as numerous studies have shown the effect of monetary gain on symptomatic improvement in neck pain (17,18,19 and 20). Treatment outcome with regard to surgery for cervical radiculopathy secondary to soft or hard disk protrusions does not appear to be affected to such a degree by compensation or liability issues (21,22 and 23).

Occupationally related neck pain is also well recognized, and the initial epidemiologic data on neck pain were generated from workplace-based studies. Hult noted that 80% of a population of male industrial and forest workers in a Swedish province reported a history of stiff neck and arm pain, and later studies by the same author showed a 51% prevalence in nearly 1,200 male workers, increasing with age without a difference between patients doing light or heavy work (11,24,25). In another Scandinavian study, Tola and colleagues (26) reported a neck pain prevalence of 81% for machinists, 73% for carpenters, and 57% for those involved in sedentary work. In general, work involving repetitive and forceful movements, as well as awkward postures of the head and neck, particularly when found in combination, is associated with the development of a musculoskeletal neck disorder, with odds ratios ranging from 1.5 to 5.7 (27).

In conclusion, the epidemiology of neck pain is difficult to document accurately given the variability in its observation and reporting and the complexities of pain behavior that influence both. In general terms it can be said that the vast majority of neck pain seen in clinical practice surrounds trauma or an aggravation of a predisposing degenerative spondylotic problem in the cervical spine (3). Still, the practitioner must concern herself or himself with other painful conditions that represent perhaps less than 10% of all pathologic processes affecting the neck. These include inflammatory conditions, infections, tumors, neurovascular conditions, congenital abnormalities, endocrinologic, neurologic, and rare and poorly understood chronic pain conditions.

RELEVANT ANATOMY AND PAIN SOURCES

Understanding neck pain and its myriad sources necessitates a thorough knowledge of the relevant anatomy of the cervical spine; its surrounding ligaments and musculature; the organs, vessels, and nerves contained within its confines; as well as the surrounding structures that may act as a source of referred pain (see Chapter 54). A baseline description of the neck's anatomy provides the framework from which to direct the history, physical examination, and further diagnostic tests that are discussed in the following sections. For the purposes of this discussion, the sources of neck pain and their anatomic correlates are divided into somatic (superficial, as well as deep), radicular, neurogenic, and referred visceral.

Superficial somatic pain rarely presents a diagnostic challenge, because the surface area of the neck is limited, and inspection of the skin and underlying superficial tissues usually provides the source of neck pain (e.g., infection, neoplasia). Herpes zoster (shingles) can occasionally cause a diagnostic challenge before the appearance of vesicles, but a dermatomal distribution of the pain and the ensuing vesicular eruption usually confirms the diagnosis (see Chapter 22).

Historically, sources of deep somatic or spondylogenic pain have been more problematic in their characterization. During the 1990s significant advances were made in the understanding of neck pain through its anatomic bases, particularly in the realm of spondylogenic or deep somatic pain (4,5,28). Most of the work has centered on the most epidemiologically common forms of neck pain, which are mechanical. Although any innervated structure in the neck is a potential source of pain, it comes as no surprise that the key pain generators associated with the most common types of neck pain are found in the cervical spine. Following the epidemiology of neck pain, the spine has been the focus of attention in studies concerning the etiology of neck pain.

The cervical spine is unique in its structural and functional complexity. It is made up of seven vertebrae, two of which have a superspecialized structure (atlas and axis), 14 zygapophyseal (facet) joints, 5 intervertebral disks (excluding C-7 to T-1), and a complex system of ligaments that allow strength and protection while at the same time maximizing flexibility. Disruption, injury, or inflammation involving any of these elements could produce neck pain.

Anatomic studies using cadaveric specimens (4,29,30,31 and 32) and functional studies (33,34,35,36,37 and 38) have provided the foundation for our understanding of neck pain related to the cervical spine. The zygapophyseal or facet joints receive a substantial innervation from the medial branches of the dorsal rami of the cervical nerve roots (30). Dwyer and Aprill, and later Fukui and colleagues, carefully studied pain patterns generated through stimulation of the occipitoatlantal, atlantoaxial, and subaxial facet joints in normal volunteers and patients with neck pain (30,33,36). These studies have laid the foundation for therapeutic maneuvers aimed at treating this now commonly recognized source of neck pain (37).

The atlantooccipital joint represents the articulation between the head and neck and is responsible for approximately 15 degrees of flexion and extension (39). The articulation between the occipital condyles and articular processes of C-1 is a facet joint with a large surface area. Dreyfuss and colleagues and Fukui and colleagues have convincingly demonstrated referred pain to the occipital and upper posterolateral cervical regions via injection of contrast media into and electrical stimulation of this joint (40,36). However, only anecdotal evidence exists to implicate this joint in chronic neck pain and cervicogenic headache (35).

Almost 50% of the head's axial rotation is facilitated by the atlantoaxial junction, with the remaining one-half provided by the subaxial cervical spine (39). The axis articulates with the atlas at three points, with two facet joints laterally and another joint posterior to the odontoid process. Here a synovial bursa separates the dens from the transverse band of the cruciate ligament. Neck pain is the most common presenting symptom in rheumatoid arthritis (RA), which frequently affects these joints. The odontoid process is susceptible to fracture, as well, and although rare, this condition may elude diagnosis and go undetected for some time. The clinician must have a high index of suspicion in the setting of recent and even remote trauma. The pain is centered in the occiput and posterolateral cervical regions; and this has been confirmed with functional studies (36).

Coupled with their involvement in whiplash injury described previously, the zygapophyseal joints also play an important role in radiculopathic neck pain. Neck pain secondary to nerve root irritation is possible in the subaxial cervical spine and is usually accompanied by pain shooting down the arm, known as brachialgia. The dorsal wall of the neural foramen is bordered by the facet joint and capsule; facet joint hypertrophy, a normal consequence of aging, can cause radiculopathy secondary to nerve root impingement (41).

In addition to the 12 other facet joints that exist between C-2 and C-3 and C-7 and T-1, the subaxial cervical spine has another 12 uncovertebral joints that are important clinically in neck pain from a radiculopathic source. Uncinate processes are the bony protrusions on the upper, posterolateral end-plates of the cervical vertebrae C-3 to C-7, that articulate with the neighboring vertebral body in the so-called joint of Luschka, or uncovertebral joint. Bland (4), in a study of 171 cadaveric specimens (42), points to the fact that these are not true synovial joints and are not innervated Therefore, they are not considered susceptible to the same disorders that cause zygapophyseal joint pain, such as systemic synovitis of RA or traumatic inflammation. Nonetheless, their hypertrophy and osteophytic degeneration can lead to progressive neural impingement and pain.

The concept of somatic myofascial or muscular pain has been controversial for over 30 years. Such pain syndromes have been ascribed to myriad pathophysiologic theories. They may be amenable to treatment through identification and therapeutic targeting of trigger points (43). Myofascial pain syndromes are discussed in detail in Chapter 28, Chapter 29, and Chapter 31; the long list of neck extensors, flexors, rotators, and lateral flexors are capable of producing pain caused by prolonged or excessive muscular activity as well as a response to neuropathic processes or primary muscle dysfunction. The pathophysiology of neck muscles is less understood than that of the other structures in the neck (44).

The most common source of radiculopathic neck pain is the degenerated cervical intervertebral disk, but many other etiologies are possible (Table 55-1). The annulus fibrosus of the intervertebral disk is endowed with nociceptive nerve endings (32). Along with its fibers to the facet joints, anterior and posterior longitudinal ligaments, and dura, the sinuvertebral nerve and posterior primary ramus innervate the disk capsule. Disruption of the disk by herniation can irritate these nerve endings, producing neck pain in early protrusion secondary to distortion of the posterior longitudinal ligament, followed by progressive brachialgia caused by nerve root compromise in the foramen (5,45).

Cranial neuralgias
Glossopharyngeal neuralgia
Superior laryngeal neuralgia
Upper cervical (C-2 to C-4) neuropathies
Diseases of the spinal cord and meninges
Intrinsic spinal cord lesions
Extramedullary intradural lesions
Extradural spinal cord lesions
Diseases of spinal nerve roots
Herniated intervertebral disk
Vertebral fracture or dislocation
Arthritis
Herpes zoster
Postherpetic neuralgia
Lesions of formed spinal nerves
Compression by vertebral tumors, arthritis
Compression by paravertebral lesions, abscess, Hodgkin's disease, or other tumors
Inflammation of the nerves
Lesions of the cervical plexus
Acute inflammatory lesions
Compression from tumors in the neck
Compression by aneurysm

TABLE 55-1. Most common causes of cervical neuralgia

It has long been known that simple mechanical compression or traction on a normal nerve root does not induce pain, yet slight manipulation of an inflamed nerve root produces the lancinating, burning pain of radiculopathy (46). The source of nerve root inflammation is not completely defined, but evidence points to an autoimmune phenomenon. The nucleus pulposus is an immunologically privileged site that is exposed after disk rupture, and evidence exists that the autogenous disk material elicits a cell-mediated immune response in the spinal canal. Furthermore, disk material contains inflammatory mediators that have been shown on a molecular biological level (47,48 and 49) to effect nerve root dysfunction electrophysiologically in the absence of mechanical compression (47). Other possible causes of inflammation that deserve mention are ischemia secondary to compressive microvascular occlusion or a mechanical alteration in axonal transport. The effectiveness of antiinflammatory medications in the treatment of neck pain from a radicular source lends further credence to the inflammatory provocation by cervical disk herniation.

Finally, the clinician must be aware of the nature of true radicular pain to distinguish it from a radicularlike pain that can occur in the absence of a true radiculopathy. Pseudoradicular pain can occur in relation to facet joint or disk disease, without nerve root involvement. A dull, aching pain that radiates from the neck into the arm, in contrast to the sharp, lancinating brachialgia or true radicular pain, results from referred pain that appears in mesenchymal structures of the same embryonic sclerotome in the injured tissue of the joint (5). Cervicobrachial neuralgia is discussed in Chapter 56.

Neurogenic pain, described as gnawing, burning, or tingling pain, can result from injury to the central nervous sytem. An unusual example of this is seen in the setting of posttraumatic syringomyelia, wherein a spinal cord injury has led to derangement in flow dynamics of the cerebrospinal fluid. In the area of spinal cord injury, a cystic dilatation of the cord is produced years after the initial trauma. The most common heralding complaint of posttraumatic syringomyelia is pain, localized to the level of the injury and its associated nerve roots. The presumed abnormality in such neurogenic pain is the loss of inhibitory input, allowing an excess of nociceptive information reaching the sensory areas of the cerebral cortex (5).

Pain from viscera that share the same embryologic segmental derivation of the cervical spine can present as neck pain. The submandibular glands, lymph nodes, thyroid, esophagus, heart, lungs, stomach, gallbladder, pancreas, and diaphragm are all capable of eliciting some component of neck pain, although this is rarely the only symptom of disease in these organs. The carotid body is another organ associated with neck pain in carotidynia, or swelling of the carotid bifurcation, although this pain is thought to be analogous to migraine and not visceral referred in nature (4).

HISTORY, PHYSICAL EXAMINATION, AND DIAGNOSTIC STUDIES

Although knowledge of anatomic pain generators is essential in considering the broad differential diagnosis of neck pain, the foundation of accurate diagnosis and treatment of neck pain remains in the history and physical examination. Nowhere are the principles of a detailed and complete history, taking into account the patient's present illness, its relation to concomitant illnesses, social and occupational history, and a thorough physical examination, more important. Neck pain is a common symptom that can arise from a multitude of structures in and outside of the neck and arise from both serious and trivial diseases. The clinician must be able to

distinguish between the two and rely on clinical skills, both to lead to useful diagnostic studies, and ultimately to the correct diagnosis.

The initial considerations in the diagnosis of neck pain are the severity of the problem, whether the neck pain is from a life- threatening source, and whether emergency surgical intervention is necessary to avoid a catastrophic neurologic event. Neck pain accompanied by a rapidly progressive motor or sensory deficit, urinary or fecal incontinence, or progressive gait disturbance should be recognized and promptly evaluated. Compromise of the upper cervical spinal cord segments with loss of phrenic nerve function caused by instability in the setting of trauma, inflammatory spondyloarthropathy, tumor, or infection can lead to respiratory failure and death if untreated. Rarely, neck infection in the form of an abscess leads to a rapidly fatal mediastinitis secondary to dissection of the infection through tissue planes.

Once a life- or spinal cord–threatening illness is ruled out, the characteristics of the patient's neck pain must be understood, including onset, duration, precise localization, radiation, quality (burning, lancinating, dull, shooting, aching), present status, and relation to current and past medical history. Cohen provides a diagnostic framework for the analysis of spinal pain, dividing it into mechanical and nonmechanical sources (50). The former is seen in the vast majority of neck pain cases, in anatomically normal as well as spondylotic spines. Pain is usually poorly localized, exacerbated by movement, and occurs in an essentially well person. Nonmechanical or medical sources such as infection, neoplasm, inflammatory osteoarthritis, and metabolic disease are usually recognized in the patient who is systemically unwell, in whom it is obvious that the clinical condition is not simply localized to the neck. Pain is usually well localized, without diurnal variation or relief from rest.

Issues of age, sex, family, and occupational history help to identify patients in risk groups in which neck pain is more prevalent. Younger patients are more likely to be affected by spasmodic torticollis or trauma, whereas osteoarthritis is predominant in the elderly population. RA is more common in female subjects, whereas ankylosing spondylitis is predominantly a disease of male subjects. Familial predisposition to rheumatic illness is seen in patients harboring the HLA-B27 major histocompatibility complex antigen (ankylosing spondylitis, Reiter's syndrome, and psoriatic arthritis) (see Chapter 27). Finally, the widespread prevalence of occupationally associated neck pain warrants an understanding of any intense, repetitive, sustained, or awkward physical requirements in the patient's job. Jobs that require repetitive flexion, rotation, and extension of the neck, in addition to forceful, repetitive use of the hands, in which sustained neck muscle contraction is necessary, place the patient at a markedly increased risk of developing neck pain, with odds ratios of up to 7.5 times that of workers without these requirements (27).

Finally, Bland points out the pertinence of questioning a patient's use of bifocal glasses, which would place the neck under increased flexion strain, and the patient's pillow use at night. These are simple but often overlooked points that might allow the clinician to understand the source of the patient's pain, and a simple change might solve a great number of cervical spine problems (4).

Physical examination in the setting of neck pain should be divided into (a) inspection; (b) palpation of bony structures; (c) examination of the soft tissues; (d) evaluation of range of motion; followed by (e) special tests in the diagnosis of neck pain. This should supplement rather than replace a thorough general systemic physical examination (see Chapter 12).

Inspection can take place from the moment the patient enters the office or examination room. Observation of the patient's posture in the ambulatory, sitting, and supine positions can be made during the history, with special attention to how the neck is held in relation to the shoulders and upper extremities. Torticollis (wryneck) is usually self-limited and disappears within a few weeks, but long-standing torticollis is associated with facial asymmetry and changes in the sternocleidomastoid muscle. Moreover, Bland cautions the clinician to consider the spine as a single functional unit, rather than divide it into cervical, thoracic, and lumbar segments during the examination, because the neck may be symptomatic because of positional changes arising from a problem in the thoracic or lumbar segments (4). An examination of the neck, with special attention to bony landmarks and skin should follow. The hyoid bone, thyroid cartilage, thyroid gland, and first cricoid ring should be recognized, and skin abnormalities can give important information regarding systemic or localized diseases.

Palpation of bony structures is best done with the patient supine to relax overlying muscles (4). In palpating the anterior neck, the examiner stands at the patient's side and supports the neck from behind with one hand while palpating with the other. The horseshoe- shaped hyoid bone is located at the level of the lower part of C-3 or at the intervertebral disk between C-3 and C-4. The thyroid cartilage is below the hyoid bone at the level of C-4 to C-5 and can be easily palpated, particularly at the prominent Adam's apple. The first cricoid ring is at the level of the C-6 vertebra and is the upper border of the trachea. Approximately 3 cm lateral to the first cricoid ring, the carotid tubercle can be palpated; this is the anterior tubercle of the transverse process of C-6, often called *Chassaignac's tubercle*. The carotid arteries are anterior to the transverse processes and can be palpated easily. They should be examined separately, because the carotid reflex and a syncopal event could be triggered if they are palpated together.

The posterior landmarks of the cervical spine include the inion (external occipital protuberance) in the midline, which marks the center point of the superior nuchal line. This is felt as a transverse ridge extending out on both sides of the inion. The spinous process of C-2 can be palpated, particularly in slender female subjects with the neck held slightly in flexion. The spinous processes of C-3 to C-6 are difficult to palpate, but the spinous process of C-7 (vertebra prominens) is readily palpable low in the neck. Provided the muscles are completely relaxed, the zygapophyseal joints can be palpated as small rounded domes deep in the transverse muscle and approximately 2.5 cm lateral to the spinous process. Each can be identified fairly accurately by remembering that the joint between C-3 and C-4 is at the level of the hyoid bone, the joint between C-4 and C-5 is at the level of the upper edge of the thyroid cartilage, the joint between C-5 and C-6 is at the level of the lower part of the thyroid cartilage, and the joint between C-6 and C-7 is at the level of the cricoid ring. Trauma, infection, malignancy, and osteoarthritis can all produce exquisite tenderness and pain on palpation of these joints. In general, if deep tissue examination is not possible, the examiner must make note as to whether the tenderness is occurring in the midline, often indicating a structural spinal problem, or in the paraspinous soft tissues.

Soft tissue examination is divided into anterior and posterior areas. The anterior neck, bordered laterally by the sternocleidomastoid muscles, superiorly by the mandible, and inferiorly by the suprasternal notch, represents an inverted triangle. The posterior neck includes the remainder of the neck. Again, the soft tissue examination is easier in a relaxed, supine patient.

The thyroid gland, an H-shaped structure, can be palpated in the midline below the thyroid cartilage. Diffuse enlargement, nodules, cysts, tenderness, or pain can be revealed. The sternocleidomastoid muscle is examined by asking the patient to turn the head to the opposite side; this muscle should be examined from origin to insertion. Palpation of the medial border for lymphadenopathy is necessary; if nodes are enlarged and tender, they suggest infection or metastatic disease related to the head and neck.

Examination of the posterior neck is best done with the patient in the sitting position, from the top downward. The occipital arteries are palpable approximately 3 cm lateral to the midline and run near the greater occipital nerves. Palpation that elicits pain or tenderness is seen in the setting of occipital neuralgia. Examination of the origin, insertion, and course of the trapezius muscle, from the C-2 to T-1 spinous processes to the scapular spines, is necessary to evaluate neck pain secondary to muscle trauma. As with the lymph nodes in the anterior neck, another chain of nodes lies along the anterolateral border of the trapezius, and enlargement and tenderness of these suggest infection or metastatic disease.

Range of motion is assessed by having the patient voluntarily flex and extend the neck through all ranges of motion (Fig. 55-1). The normal patient should be able to touch his or her chin to the chest and look to the ceiling without difficulty. Lateral bending should proceed smoothly through 45 degrees, and on rotation the patient should be able to turn the head in line with the shoulder. The authors do not recommend testing passive range of motion, for fear of causing neurologic injury in the setting of spinal instability. The patient protects the neck through tonic contraction of the paravertebral muscles, and overcoming this could have devastating consequences. Strength may be evaluated by testing movements against resistance (Fig. 55-2).

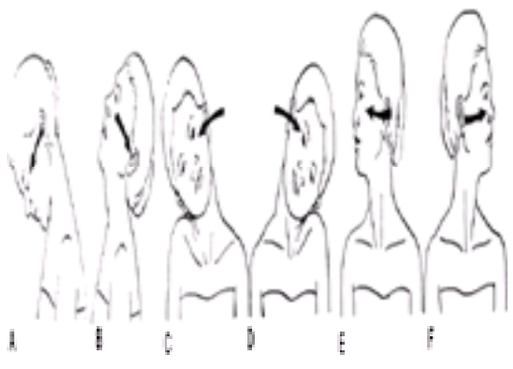

Figure 55-1. Active movement for testing the range of motion of cervical spine and neck muscles. **A:** Full flexion, which should permit touching the chin to the sternum. **B:** In maximum extension the occiput touches the spinous process of T-1. Lateral flexion in the absence of pathology permits the individual to flex 45 degrees to both the right **(C)** and left **(D)** sides. Right **(E)** and left **(F)** rotation. In normal individuals the chin should be in alignment with the shoulder.

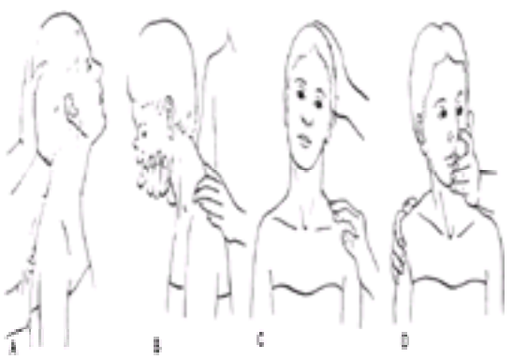

Figure 55-2. Method of testing muscles of the neck against resistance. **A:** Extension. **B:** Flexion. **C:** Technique for testing right lateral flexion against resistance; testing left lateral flexion is carried out by placing the left hand against the patient's head and by holding the shoulder with the right hand. **D:** Technique for testing rotation against resistance. To test right rotation, the examiner's hands are changed accordingly.

The neurologic examination is described in detail in Chapter 12. Muscle strength; sensory modalities including light touch, proprioception, and pinprick; and reflexes should be assessed in detail throughout the upper and lower extremities. Muscle, sensory, and reflex changes should be identified and correlated with the history, bony, and soft tissue portions of the examination to direct further diagnostic evaluation.

Special testing in the neck allows the identification of neurologic and mechanical abnormalities arising in the cervical spine. The distraction test is carried out by having the examiner stand behind the seated patient, lifting the head from the chin and occiput, and removing the weight of the head from the neck. Relief of symptoms during this test might point to foraminal encroachment on a nerve root as the etiology of the patient's neck pain. It also relieves pressure on the zygapophyseal joints. Spurling's maneuver (Fig. 55-3) is essentially a reverse of the distraction test and was classically described to assess nerve root compression or irritation. The head is tilted toward the painful side and pressure is applied to the top of the head. The radicular pain should be reproduced on such a maneuver (51). Valsalva's test is designed to increase intrathecal pressure and exacerbate compression within the cervical canal, either from tumor, infection, disk, or osteophytic change. The patient is asked to bear down as though having a bowel movement, and to describe any painful or sensory changes. Shoulder depression and abduction tests are designed to test nerve root compression and irritation by increasing and decreasing traction on the spinal nerve roots, respectively. Adson's test is used to assess vascular compromise in the arm secondary to subclavian impingement in thoracic outlet syndrome (Fig. 55-4). Here, the radial pulse is palpated and auscultation performed over the subclavian artery. The patient holds a deep breath with the neck extended and the chin turned toward the affected side to assess changes in the intensity of the radial pulse and to listen for a bruit over the subclavian artery (52). Other maneuvers to evaluate neurovascular compression are the costoclavicular (Fig. 55-5) and hyperabduction (52).

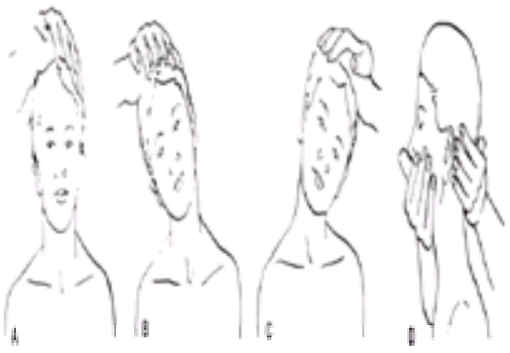

Figure 55-3. Spurling's test for determining the effect of compression of the cervical spine. **A:** The examiner first applies pressure directly downward, with gradual increase and maintenance of constant pressure for 30 to 60 seconds. The same procedure is repeated in right **(B)** and left **(C)** lateral flexion, which tends to close the intervertebral foramina on the side of the flexion even more than normal because of the pressure exerted, thus producing spontaneous pain or paresthesia or aggravation of the pain or paresthesia. **D:** Technique for applying upward traction; the pressure is gradually increased and held for 30 to 60 seconds. This opens the intervertebral foramina and decreases or eliminates pain from foraminal pressure on the cervical nerves.

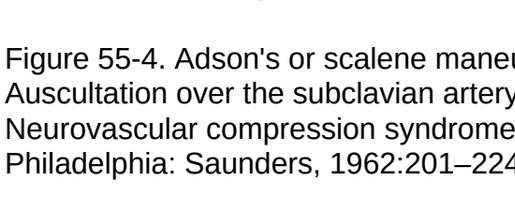

Figure 55-4. Adson's or scalene maneuver. This test is used in both the scalenus anticus syndrome and in patients with a cervical or abnormal thoracic rib. Auscultation over the subclavian artery being tested may reveal a bruit when the artery is partially compressed. (Modified from Allen EV, Barker NW, Hines EA Jr. Neurovascular compression syndromes of the thoracic outlet and shoulder girdle. In: Allen EV, Barker NW, Hines EA Jr, eds. *Peripheral vascular diseases*, 3rd ed. Philadelphia: Saunders, 1962:201–224.)

Figure 55-5. Costoclavicular maneuver. Auscultation over the subclavian artery, above or below the midportion of the clavicle, may reveal a systolic bruit as the artery is being compressed. The radial pulse and the bruit over the subclavian artery disappear when complete compression of the subclavian artery occurs. (Modified from Allen EV, Barker NW, Hines EA Jr. Neurovascular compression syndromes of the thoracic outlet and shoulder girdle. In: Allen EV, Barker NW, Hines EA Jr, eds. *Peripheral vascular diseases*, 3rd ed. Philadelphia: Saunders, 1962:201–224.)

Laboratory Evaluation

Leukocytosis is seen in the setting of infection and even some forms of malignancy, but rarely in mechanical neck pain. The erythrocyte sedimentation rate (ESR) is a more useful laboratory study in differentiating mechanical from nonmechanical and medical neck pain and measures the systemic response to injury. It is a general reflection of inflammation in the body and is usually normal in the setting of mechanical neck pain caused by osteoarthritis or whiplash. Hayes and Stinson (53) reported the normal ranges of ESR according to sex and age: Using the standard Westergren method, the upper limit of normal is 25 mm per hour for women and 15 mm per hour for men younger than 50 years of age, 30 mm per hour for women and 20 mm per hour for men older than 50 years, and can be more than 50 mm per hour over the age of 70 years. The trend in ESR over several weeks is more useful to follow than an absolute value from a single test. However, an ESR over 100 mm per hour usually signifies malignancy or infection. Its shortcoming as a test after surgery is that the ESR can remain elevated for up to 2 weeks (54) in the absence of a postoperative infection. Here, the C-reactive protein may be helpful, because it is an acute-phase reactant that returns to normal shortly after surgery in the absence of infection (54,55).

Blood chemistry tests that are useful in the setting of neck pain include serum calcium and phosphorus. Malignancy is associated with hypercalcemia, whereas calcium levels are normal in the setting of osteoarthritis and most mechanical causes of neck pain. Serum alkaline phosphatase is produced by osteoblasts, and elevations are seen in metastatic spine tumors and Paget's disease of bone.

Radiographic Studies

The clinician's armamentarium of diagnostic radiographic studies is vast and includes plain films, myelography, computed tomography (CT), and magnetic resonance imaging (MRI) (see Chapter 14). A basic description of the indications for each and their strengths and weaknesses in specific diagnoses is presented in this chapter. The clinician must select these studies carefully, balancing the demands of a litigious society with the financial limitations faced in the health care climate, to efficiently and effectively arrive at a diagnosis. Advances in this technology in the 1990s have revolutionized the diagnosis and therapy of neck pain.

Controversy exists surrounding the utility of plain radiography as the initial diagnostic study for neck pain. The lateral, anteroposterior, open mouth odontoid, oblique, and flexion-extension plain films can show the presence of fracture, subluxation, osteophytic changes, ligamentous calcification, and soft tissue swelling or bony destruction in the setting of infectious or neoplastic disease. However, several studies have shown that degenerative changes have a linear relationship with age, and their nearly ubiquitous presence in elderly patients is not significantly different in severity between asymptomatic and symptomatic individuals (56,57). These results are called into question by more recent data by Marchiori and colleagues (58), who found that increasing levels of spinal degeneration are related to increasing chronicity of patient complaints. Although radiography is readily available at a reasonable cost, debate continues over their usefulness in mechanical spinal pain (50).

The most sensitive imaging technique in cases of suspicion of neoplastic or infectious disease is the radionuclide bone scan. Technetium 99m is the radiopharmaceutical used to image osteoblastic activity and provides a general measure of bony inflammatory disease. Its limitation is in its low resolution and lower specificity than other imaging modalities in the cervical spine. Furthermore, a false-positive rate as high as 30% has been found in elderly patients in whom the diagnoses of infection or metastasis are frequently sought (59).

Myelography provides anatomic detail in the relationship between neural and bony structures. A nonionic water-based contrast agent is instilled into the subarachnoid space either through a C-1 to C-2 or lumbar puncture, and radiographs are obtained in the anteroposterior, lateral, and oblique planes. A defect in the dye column points to the area of neural compression; given its invasive nature and common complication of postprocedural headache [seen in up to 68% of postmyelography patients (5)], myelography is usually reserved for preoperative planning or in cases in which MRI scanning is contraindicated (see following discussion).

CT can be used as an adjunct to myelography, or it can be used alone to delineate in detail the bony anatomy of the cervical spine. When combined with myelography after the installation of intrathecal contrast, precise anatomic detail relating bony anatomy to neural elements is obtained. In the setting of trauma, small fractures not evident on plain radiographs can be seen on CT, and degenerative facet enlargement, canal stenosis, and early bony destruction by infection or tumor are readily evident, with spatial relation to the nerve roots and spinal cord.

Although bony detail is the main advantage of CT scanning, its major disadvantage is in the relative lack of soft tissue resolution. This deficiency is overcome in MRI scanning. Here, small differences in tissue density are formed into a computer-generated image with unsurpassed anatomic detail. It is the diagnostic method of choice in the setting of disk herniations, tumors (intramedullary and extramedullary, extradural), infection, intrinsic cord pathology (infarction, atrophy, multiple sclerosis), and osteophytic narrowing of the spinal canal. Recent advances in MRI technology have allowed the detection of nerve roots involved in radiculopathy (60). Patients harboring pacemakers and ferromagnetic aneurysm clips are precluded from undergoing MRI scans, and it is here that myelography may be a useful substitute. However, as with plain radiography, studies have shown that asymptomatic subjects commonly display the same imaging findings on MRI as those who are symptomatic with neck pain (61,62). Thus, although it provides the most sensitive detection of bony and soft tissue abnormalities, MRI scanning's high cost and lack of specificity necessitate caution on the part of the practitioner selecting it as a diagnostic study. As with myelography and CT scanning, it must be sought only in the confirmation of a clinical diagnosis suspected on historical and physical examination findings.

Finally, provocation diskography, although arguably highly sensitive and specific in the lumbar spine, has limited utility in the cervical region. Injection of the lumbar disk with contrast material should reproduce the patient's pain complaint in the setting of lumbar diskogenic pain. This should be relieved on injection with local anesthetic. A false-positive rate up to 40% has been documented in the cervical spine by Bogduk and colleagues in patients undergoing both diskography and zygapophyseal joint blocks, and numerous authors have questioned its validity as a diagnostic test (5,34).

SPECIFIC DISEASES AND DIFFERENTIAL DIAGNOSIS

This section is devoted to introducing specific diseases and syndromes that involve neck pain as their predominant symptom. It is divided into six portions, to cover mechanical pain, pain associated with inflammatory disease, neoplastic pain, pain of infectious etiology, and finally, miscellaneous diagnoses. Each portion should serve as an introductory guide to the most common disease states that affect the neck, as seen in a general clinical practice. Reviews are referenced for each disease state being discussed, to provide an entry point for further investigation by the reader.

Mechanical Pain

Included in this section are the most common pathologic entities that involve the cervical spine and produce neck pain: cervical spondylosis, fractures, subluxations, dislocations, disk herniations, neck strain, whiplash injury, in addition to congenital abnormalities that predispose the patient to neck pain (Klippel-Feil syndrome, os

odontoideum, basilar impression), and finally, rheumatologic disorders (including RA, psoriatic arthritis, and ankylosing spondylitis).

Cervical spondylosis represents a common cause of neck pain and is defined by the development of osteophytic or degenerative change in the disks of the cervical spine, as seen on radiologic studies and cadaveric specimens. It is a nearly ubiquitous disorder of the adult population that increases in severity with age and is probably related to the mobility of the cervical spine (5) and an accumulation of microtrauma. As discussed previously, these changes do not necessarily correlate with findings on plain films or MRI scans (56,57,61,62). The patient is usually older than 40 years of age, and the chief complaints are headache and occasionally neck ache and can be accompanied by radiculopathic or myelopathic symptoms and signs or both. Plain radiography is the diagnostic tool of choice, whereas more detailed images, such as MRI scans, are reserved for those patients with accompanying neurologic deficits, or for those in whom the pain is medically intractable. Treatment usually involves nonsteroidal antiinflammatory drugs (NSAIDs) and physiotherapy, with the use of a neck brace for acute exacerbations. Occasionally, facet joint injections may be helpful (33), but no clinical trials in the setting of spondylosis have been done. Surgery should be considered in those patients with intractable pain or a neurologic deficit.

Acute herniated nucleus pulposus (HNP) or herniated disk of the cervical spine is a more common source of brachialgia than neck pain, but the patient describes pain that seems to begin in the neck and radiates down the arm to the hand. This disorder was first characterized in the early 1940s, but is still incompletely understood (51,63,64). The cervical nerve roots are protected from lateral disk herniation by the laterally placed uncovertebral joints. By the age of 40, Bland maintains that the nucleus pulposus no longer exists because of desiccation and transformation to fibrocartilage (41,42). In fact, he goes so far as to say that “after age 40 years, it is impossible to clinically herniate the nucleus pulposus, as none exists at this point” (41,42). Thus, cervical HNP usually occurs posterolaterally, around the fourth decade of life, and usually gives rise to radiculopathic complaints, affecting the nerve root numbered below the given disk level (e.g., a C-6 to C-7 disk would give rise to a C-7 radiculopathy). The most common cervical HNP occurs at C-6 to C-7, approximately 50% of the time (65), followed by C-5 to C-6 in approximately 30% of cases.

The disk is innervated by the sinuvertebral nerve, which also supplies the periosteum of the surrounding vertebra, dura, and veins (31). Historically, the arm pain exceeds the neck pain and can be exacerbated by tilting the neck and head to the affected side, with axial loading (Spurling's sign) (51). Electromyography is useful in delineating radiculopathy, whereas plain radiography is of little clinical utility. The best radiologic studies in the detection of cervical HNP are CT myelography and conventional MRI. MR neurography may be useful in defining the affected nerve root in multilevel cervical spine disease when the clinical symptoms and findings do not localize the level (66). Most patients with acute HNP respond well to medical management, which includes collar immobilization, NSAIDs, and occasionally traction. In those patients whose pain or radicular complaint is refractory to medical therapy, anterior cervical diskectomy with or without fusion (67), and posterior foraminotomy with or without disk removal are both highly effective (22,68).

Neck strain, neck sprain, and *whiplash* are terms often used interchangeably, but should be considered along a continuum of severity (4). The most common form of neck injury and neck pain, neck strain, refers to nonradiating pain associated with a repetitive mechanical stress or a prolonged malposition of the cervical spine (5). The pathogenesis of the disorder is presumably related to muscular, ligamentous, joint capsular, or disk annular damage (44), and the muscular contraction and tension that are frequent adjuncts to this injury can produce a cycle of pain and spasm that prolongs and exacerbates symptoms produced from relatively insignificant events (5). Neck pain is often accompanied by occipital headache, exacerbated by movement, and eased with immobilization. Physical signs include a decreased range of motion, localized paraspinous muscle tenderness, and occasionally torticollis. Plain radiography may reveal a loss of the normal cervical lordosis caused by tonic muscular contraction and should be obtained to rule out fracture or congenital abnormality in the differential diagnosis. Prognosis for complete resolution of the pain is excellent. Most cases can be successfully treated with immobilization in a soft collar, NSAIDs, and physiotherapy.

Neck sprain can be considered as a traumatic neck injury of severity intermediate between whiplash (see following discussion) and neck strain. Here, minor ligamentous, capsular, or tendinous tears as well as muscular tears, contusions, or both result in symptoms, signs, and radiologic studies similar to those seen in neck strain, and treatment is much the same. Bland emphasizes the need for patient education, because prognosis in this disorder is highly influenced by extraanatomic factors. He associates four factors associated with increased duration of symptoms (greater than 9 months), including strong emotional factors, extensive medical history, prolonged and frequent treatment, and litigation (4).

In some instances the patient sustains a disruption of the supporting spinal ligamentous apparatus, facet joint capsules, and disk secondary to a hyperflexion or hyperextension injury (Fig. 55-6). The patient experiences neck pain without or with neurologic deficit. Imaging studies do not show evidence of a fracture of the vertebra, and there are no jumped facets. In the case of a hyperflexion sprain there is rupture of the posterior ligaments and joint capsules. Plain cervical spine radiography shows evidence of a kyphotic angulation with separation of the spinous processes without jumped facets. Hyperextension sprains may also be diagnosed on plain cervical spine radiography. There is disk space widening anteriorly with tearing of the anterior longitudinal ligament. There may be some retrolisthesis of the cephalad-vertebral body. An associated herniated disk should be ruled out in both conditions. MRI should be obtained to help define the extent of injury and is useful in planning treatment. We favor early operative stabilization, as it has been the authors' experience that prolonged immobilization even in a halo vest may not heal these injuries.

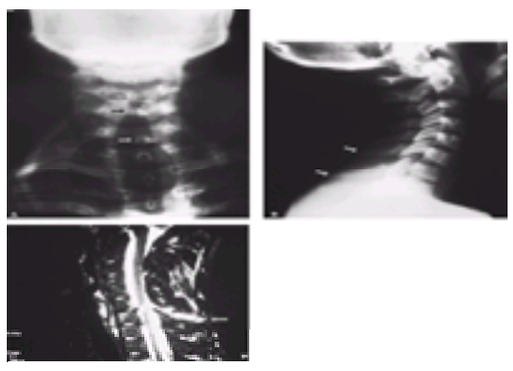

Figure 55-6. Hyperflexion sprain. **A:** Cervical spine radiograph, anteroposterior view, evidences widening between the spinous processes of C-6 and C-7 (*arrows*). **B:** Cervical spine radiograph, lateral view, evidences widening between the spinous processes of C-6 and C-7 (*arrows*), slight anterolisthesis of C-6 on C-7 with kyphotic angulation of C-6 relative to C-7. **C:** Magnetic resonance imaging, sagittal short-time inversion recovery images, evidences high signal of C-6 to C-7 interspinous process ligament (*arrow*) secondary to disruption of the interspinous process ligament and ventral dural indentation at C-6 to C-7 and C-7 to T-1 caused by disk protrusion, epidural hemorrhage, or both. There is increased signal in the spinal cord at the C-6 to C-7 consistent with a spinal cord contusion.

Whiplash injury, introduced in the epidemiology section, most commonly describes a hyperextension injury of the neck, but can also be seen with sudden movement of the cervical spine in hyperflexion and lateral bending (14). It is usually related to a sudden acceleration or deceleration motion that causes bony, ligamentous, muscular, or tendinous injury (Fig. 55-7). Compelling evidence exists for involvement of the zygapophyseal joints in the pathogenesis of whiplash-associated neck pain, from diagnostic studies, surgical intraoperative observations, postmortem examinations, and therapeutic interventions (69). Lord and colleagues (37) found cervical zygapophyseal joint pain in approximately 60% of patients with chronic pain after whiplash injury, using placebo-controlled diagnostic blocks of the joint capsules. Symptoms are often delayed for up to 24 hours after the time of injury and include neck pain, headache, dysphagia, paresthesia, weakness, visual and auditory symptoms, and dizziness, in descending order (70). Neurologic examination is usually normal, but neck range of motion is most commonly limited. Two studies (71,72), however, add to the ongoing controversy surrounding the whiplash injury syndrome. Schrader and colleagues (71) retrospectively studied the natural history of head and neck symptoms 1 to 3 years after rear-end collisions, outside the medicolegal context. They reported that no one had disability or persistent symptoms, and that there was no relation between the severity of the impact and the degree of pain. In attempting to determine whether“‘whiplash injuries' occur in low-speed rear impacts,” Castro and colleagues (72) subjected 19 volunteers to rear-end collisions. They concluded that the“limit of harmlessness” is between a velocity change of 10 to 15 km per hour (6.25 to 9.38 miles per hour) with regard to stresses arising from rear-end impacts.

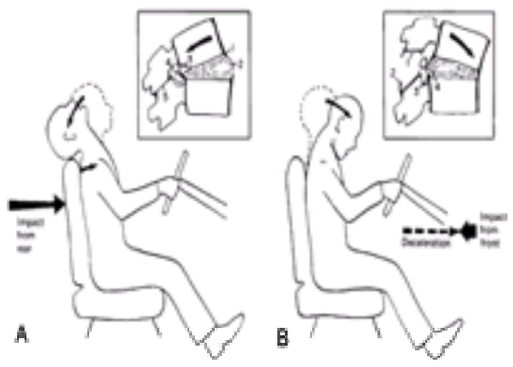

Figure 55-7. Schematic depiction of the mechanism of injury sustained from vehicular accidents. **A:** When the car is at a standstill the impact from the rear causes an acute hyperextension movement of the neck from acceleration. *Insert*: Sites of possible injuries: **1:** Anterior longitudinal tear. **2:** Anterior herniation of intervertebral disk. **3:** Chip fracture of the vertebral body. **4:** Joint encroachment into the intervertebral foramen. **5:** Acute facet impingement. **B:** Hyperflexion is caused by a deceleration injury from a front-end collision, which causes the body to stop suddenly but the head to continue to move forward because of momentum. *Insert*: Possible injuries. **1:** Acute synovitis caused by subluxation of the articular facets. **2:** Capsule tear articulation. **3:** Posterior nuclear herniation. **4:** Posterior longitudinal ligamentous tear. All these can cause injury to the nerve root. The flexion phase of injury can be isolated, can follow as a rebound or an extension injury, or can be followed by a hyperextension phase. (Modified from Cailliet R. *Neck and arm pain*, 2nd ed. Philadelphia: FA Davis, 1981.)

Whiplash injuries have been classified according to their severity in the Quebec Task Force on Whiplash Associated Disorders monograph (70). Briefly, whiplash injury is graded between I and IV according to association of neck pain (grade I) with musculoskeletal (grade II), neurologic (grade III), or bony injury (grade IV), and classified based on duration of symptoms into acute (4 to 21 days), subacute (22 to 180 days), and chronic (greater than 180 days). The Quebec Task Force recommends plain radiography in all patients with grades II, III, and IV whiplash, and CT and MRI scanning are warranted in patients with neurologic or bony injury.

As with neck strain and sprain, most whiplash injuries respond well to medical treatment involving temporary immobilization to allow healing of damaged tissues, coupled with NSAIDs. Prolonged immobilization, which would weaken cervical musculature, is not recommended (70), and as with neck strain and sprain, physiotherapy programs coupled with the practitioner's attention to emotional and psychological factors influencing their pain are critical in the management of whiplash pain.

In some cases of pain refractory to medical therapy, a more invasive interventional approach may be warranted. Lord and colleagues (73) demonstrated the long-lasting efficacy of percutaneous radiofrequency neurotomy in the treatment of chronic cervical zygapophyseal joint pain after whiplash injury. Given the fact that over one-half of all whiplash injuries involve these joints, such treatment may have a significant effect on those patients suffering chronic pain.

Cervical Spine Fractures, Subluxations, and Dislocations

A detailed discussion of cervical spine fractures, subluxations, and dislocations is beyond the scope of this chapter. Trauma is the most common cause, but other causes, such as infection, primary and metastatic cancers, congenital abnormalities, and amyloidosis associated with long-term hemodialysis, are underlying conditions that can cause fractures or olisthesis. The reader is referred to Table 55-2 for a list of the many types of fractures and luxations that occur in the cervical spine.

TABLE 55-2. Traumatic injuries of the cervical spine

Neck pain is the primary complaint offered by the patient without or with neurologic deficit. After trauma in which the patient complains of neck pain, a cervical spine injury must be ruled out with appropriate imaging studies. Patients who have persistent neck pain after imaging studies that have failed to show evidence of a cervical spine injury should have repeat imaging studies and a review of the initial studies to rule out a missed fracture or delayed instability of the cervical spine.

Rheumatologic Disease

Inflammatory joint disease, when it involves the cervical spine, is a common source of neck pain. In the United States, RA is said to occur with an incidence approximating 3% (74), and although the majority of these patients develop joint pain, swelling, and tenderness affecting the joints of the extremities, the most commonly affected component of the axial skeleton is the cervical spine (5). Patients with cervical spine involvement are thought to generally have more severe rheumatoid disease and their prognosis is generally worse (4). Although RA is covered in detail in Chapter 27, its involvement in the cervical spine is discussed here.

Three main types of cervical spine involvement are recognized in RA: atlantoaxial subluxation (usually anterior displacement of C-1 on C-2), cranial settling (vertical migration of the odontoid), and subaxial subluxation (between C-3 and C-7). The presumed autoimmune inflammatory changes that affect the synovial joints and bursae or the appendicular skeleton target the structures lined with synovial membrane in the cervical spine. These include the atlantoaxial, zygapophyseal, and uncovertebral joints, as well as the disks, ligaments, and bursae in the neck. Chronic inflammatory damage of these structures results in laxity and subsequently instability, which threaten the lower brainstem, cervical spinal cord, and nerve roots. Inflammatory pannus behind the odontoid can cause lethal upper cervical cord compression, and vertebral artery compression as well as hydrocephalus and syringomyelia are other well-recognized complications of spinal deformity in RA.

Patients with cervical RA develop neck pain exacerbated by movement, with atlantoaxial disease producing pain in the upper cervical spine, and subaxial involvement producing pain in the lower neck and clavicular areas. Neurologic involvement is seen in more advanced cases of spinal cord or nerve root compromise related to deformity and soft tissue hypertrophy. Plain radiography is useful in showing structural abnormalities, and dynamic studies including flexion-extension, oblique, and open-mouth frontal projections should be obtained. Anterior subluxation at the atlantoaxial joint is the most common form of cervical spine derangement (5), followed by subaxial subluxation, lateral subluxation, cranial settling (vertical subluxation), and posterior subluxation. Therapy for cervical spine–associated RA involves patient education, collar or brace immobilization, particularly in cases of instability, physiotherapy, and medical management with NSAIDs for symptomatic relief, remititive agents such as hydroxychloroquine, d-penicillamine, and methotrexate, and systemic corticosteroids. Although surgery is reserved for patients with intractable pain and threatened or progressive neurologic damage, it can often be overlooked because of the slowly progressive course of cervical RA, the patient's debility caused by systemic RA, the poor correlation of radiologic with physical findings, and the often stoic personality of the RA patient (75). Surgery typically involves traction initially, for realignment, followed by fusion with or without decompression, depending on the extent of neural compromise.

Psoriatic arthritis is a less common form of rheumatologic joint disease, but over one-half of all patients with psoriatic arthritis develop neck pain (76) (see Chapter 27). The majority of these patients present with psoriasis before arthritis, making the diagnosis straightforward. The disease has two types of clinical manifestations in

the cervical spine: (a) disease characterized by erosions and subluxations resembling RA, and (b) disease involving ankylosis and calcification seen in ankylosing spondylitis.

Ankylosing spondylitis is a chronic inflammatory arthritis characterized by enthesopathy, defined as inflammation at the site of ligamentous insertion onto bone, which leads to new bone formation and vertebral fusion. Bony and cartilaginous inflammation causes granulation at these sites followed by ankylosis (joint immobilization) and ossification. Immobilization leads to osteoporosis and risk of fracture.

There is a strong genetic basis for this disease, as 95% of patients have HLA-B27 major histocompatibility complex, a cell surface marker associated with control of the immune response. However, the mechanism by which HLA-B27 antigen results in ankylosing spondylitis is unclear but most likely related to a genetically determined host response to an environmental factor (possibly intestinal flora [77]) in genetically susceptible individuals (5). Involvement of the lumbosacral spine is more common than the cervical spine, and neck pain appears late in the course of the disease. The classic ankylosing spondylitis patient with neck pain is a man in his 30s or 40s with neck stiffness and generalized pain. The posture is stooped because fusion of the cervical spine causes the head to protrude forward, making it difficult to look straight ahead. A resultant focal kyphosis occurs at the cervicothoracic junction (78), which is also the most frequent site of fracture (79) of the brittle, osteoporotic bone. Radiographic evaluation can reveal the characteristic *bamboo spine* in which syndesmophytes (calcification of the disk annulus and anterior and posterior longitudinal ligaments) encase the spine. Laboratory results show an elevated ESR and an absence of rheumatoid factor and antinuclear antibody. Treatment involves patient education, pain control with antiinflammatory medications, physiotherapy, and spinal stabilization and surgical or orthotic correction or both of spinal deformity when necessary.

Tumors

Mechanical neck pain and rheumatologic diseases are much more common sources of neck pain than neoplastic involvement, but overlooking this etiology for severe neck pain can lead to unnecessary morbidity and mortality. Tumors affecting the spine can be divided into metastatic lesions, primary bone tumors, and, less commonly, tumors associated with the nervous system. Neck pain is usually an early symptom of disease, worsening at night and with recumbency, and frequently initiated by a trivial traumatic injury.

Metastases to the cervical spine dramatically outnumber primary bone tumors, and increase in prevalence with age, although the cervical spine is less commonly affected than other areas of the axial skeleton. Each primary tumor has a different propensity to metastasize to the cervical spine, but the most frequently occurring are breast cancer in women and prostate cancer in men, with an incidence as high as 85% (80). Pulmonary, thyroid, renal, and rectal cancers are the second most common, nearing 60% incidence (80). The pathogenesis of vertebral involvement in these forms of cancer is related to the proximity of Batson's venous plexus to the spine and the primary organs involved with the cancer. This valveless venous system is thought to allow embolic cancer cells to metastasize to adjacent regions of the spine when pressure in the vena caval system increases, thereby creating back flow through these paraspinous venous channels.

Patients typically present with neck pain and occasionally torticollis, with tenderness on palpation. When metastasis involves the upper cervical spine (atlantoaxial region), pain predominates, because the cancer usually involves the anterior elements of the spine and neurologic compromise is rare given the wider capacity of the spinal canal at that level. Neural impingement is more likely in the subaxial spine, and pain and tenderness are proportional to destructive instability. A thorough clinical and radiographic examination, including plain films, bone scans, CT, myelography, and MRI scanning may be necessary to define neoplastic involvement. Plain films may be inadequate because 30% to 50% of bone density must be lost before becoming radiologically evident (81). Radionuclide imaging is the diagnostic study of choice, although it is nonspecific for inflammation and also positive in one-third of older patients who are at highest risk for metastasis but also have a high incidence of osteoarthritis (59,82). CT scanning is usually reserved for those patients in whom a positive bone scan is not confirmed by plain radiographic abnormalities, or in patients requiring preoperative planning. Myelography should be reserved for patients with neurologic compromise. MRI, although less accessible and more expensive, is the most sensitive and specific of the diagnostic studies in its ability to define the extent of the lesion, associated spinal involvement, bony infiltration in cases in which bone scans are nondiagnostic, and distinguish osteoporotic fracture from metastatic pathologic fracture. Indeed, in an age of ever-increasing diagnostic accuracy, the most common error in misdiagnosis of metastatic disease is inadequate diagnostic workup (4,43). Medical (hormonal), radiation, and surgical therapies are mostly palliative and are used to prevent catastrophic neurologic damage and to control pain.

Primary bone tumors must not be overlooked, particularly in the patient less than 50 years of age in whom metastatic disease is less likely. Malignant processes in this category include multiple myeloma, chondrosarcoma, chordoma, and lymphoma. Multiple myeloma is the most common primary bone malignancy in adults and represents a tumor of plasma cells, which reside in the bone marrow of the vertebral bodies. Bone pain and pathologic fractures are seen, accompanied by increases in serum calcium. Pain is the most common presenting complaint, although the cervical spine is the least commonly affected portion of the spine. In addition to hypercalcemia, multiple myeloma patients have elevations of Bence-Jones protein (excess immunoglobulin light chain) in the urine. Radiographic investigations are the same for metastatic disease with the exception of bone scans, which have no utility in multiple myeloma because of an absence of osteoblastic activity. Treatment involves chemotherapy with melphalan and prednisone, and bisphosphonates to control hypercalcemia by inhibition of osteoclastic activity. Pain management routinely uses NSAIDs and opiates.

Benign tumors, such as osteoblastoma, aneurysmal bone cyst, giant cell tumors, and osteoid osteoma are rare bony tumors and an even rarer cause of neck pain. Pain is usually insidious in onset and develops over months to years. The degree of neurologic involvement varies with the site of vertebral involvement, and most patients have a benign course. Although diagnostic studies such as CT and MRI are useful in diagnosis, tissue diagnosis and surgical extirpation remain the mainstays of diagnosis and treatment.

Infection

The rarity of tumor-associated neck pain is mirrored in neck pain of infectious etiology: Although it is an uncommon source of neck pain, its misdiagnosis can lead to catastrophic consequences, and the clinician must maintain a high index of suspicion to establish early diagnosis and initiate effective treatment. Vertebral osteomyelitis, diskitis, extradural abscess, and meningitis make up the vast majority of infectious diseases affecting the cervical spine.

Pyogenic osteomyelitis of the cervical spine is uncommon, affecting 1 in 250,000 in the general population, with an increased incidence among intravenous drug users and immunocompromised patients (83). Hematogenous spread via Batson's paravertebral venous plexus or nutrient arteries to the vertebral body are the common routes of infection; contiguous spread from soft tissue, lung, dental, and endocarditic infections is also seen. Local pain at the site of infection is the most common presenting complaint, usually insidious in onset and nonmechanical in nature. Local tenderness and decreased range of motion are found on examination. Neurologic deficits may be seen when the osteomyelitis is accompanied by a spinal epidural abscess (84). The ESR and blood cultures are the two most useful laboratory tests to obtain. The ESR, although nonspecific, can be used to monitor response to treatment, and blood cultures may be abnormal in up to 50% of patients with acute osteomyelitis, thereby negating the need for bone biopsy (5). As with metastatic disease, the bone scan remains the screening radiographic test of choice in the setting of infection, as it can demonstrate infection within the first few days, whereas plain radiography demonstrates changes approximately 1 month after the onset of infection (4,85). MRI carries the greatest sensitivity and specificity of the radiologic tests and can be used to assess adjacent soft tissue and disk space involvement, as well as neurovascular compromise.

As with tumors, histologic diagnosis is most important in predicting course and directing treatment. CT-guided biopsy of the spine is the usual diagnostic method when blood cultures fail to show an infective agent, but this is not always effective (Ghatan, Goodkin, and colleagues, *unpublished results*), and open biopsy may be necessary. Certainly, when bony destruction leads to spinal deformity or neurologic compromise is present necessitating surgical involvement, antibiotics should be withheld until definitive cultures have been taken. The organism most commonly seen in pyogenic osteomyelitis remains *Staphylococcus aureus*, although gram-negative organisms such as *Escherichia coli* and other Enterobacteriaceae are seen in osteomyelitis associated with urinary tract infections, and *Pseudomonas* predominates in intravenous drug use–associated disease (86). Treatment involves broad-spectrum antibiotics that include gram-positive, gram-negative, and anaerobic organisms initially, that are later tailored to culture results. Orthotic immobilization, NSAIDs, and opioid analgesics are the most effective means of pain management. Surgical decompression and stabilization are necessary in patients who have neurologic compromise and advanced bony destruction with deformity.

Infective diskitis can occasionally accompany vertebral osteomyelitis, but on its own it is a rare cause of spinal infection. Insidious and often long-standing neck pain is the common presenting complaint, and in the absence of osteomyelitis, the diagnosis must be considered in the patient who has had recent iatrogenic exposure, either through disk surgery or diagnostic diskography.

Spinal epidural abscess must be quickly recognized and effectively treated given its rapid and morbid course, whether it accompanies or is separate from vertebral osteomyelitis. Patients at risk are the immunocompromised, diabetics, alcoholics, and intravenous drug users. *S. aureus* is the most common infective organism. The

patient typically presents with neck pain that can rapidly progress to radicular symptoms and quadriplegia if untreated (87). The mechanism for neurologic damage is either mass effect from the abscess or thrombotic ischemia within subarachnoid vessels. Treatment involves surgical evacuation and appropriate antibiotic management.

Acute neck pain accompanied by generalized stiffness (meningismus), fever, and mental status changes are pathognomonic for meningitis. Viral or aseptic meningitis rarely has a defined etiology, but is occasionally caused by an enterovirus, and most commonly has a self-limited course. The more common bacterial meningitis is caused by *Streptococcus pneumoniae, Neisseria meningitidis,* and *Haemophilus influenza* in more than 80% of normal adult cases (88), whereas tuberculous, fungal, cryptococcal, and protozoan (toxoplasma) meningitides are seen in the immunocompromised patient. Prognosis is dependent on the general health and immune status of the patient, the infective organism, and the speed with which antimicrobial therapy is initiated.

Extracranial internal carotid artery dissection usually presents with headache and facial pain, neck pain, or both and is a recognized cause of stroke, especially in young persons (89). Unilateral, severe persistent neck pain of sudden onset may be the only symptom of extracranial internal carotid artery dissection (89,90). Patients may also present with a painful Horner's syndrome, pulsatile tinnitus, amaurosis fugax, and cerebral infarction without pain. There may be a history of minor trauma occurring a few hours to days preceding the onset of symptoms. Useful diagnostic studies include carotid duplex, transcranial Doppler, MRI, magnetic resonance angiography, CT angiography, and cerebral angiography. Treatment involves anticoagulation, starting with heparin.

Spontaneous cervical epidural hematoma presents with acute neck pain that may be accompanied by intrascapular pain or radiation of pain to the shoulders or upper extremities. Within hours the patient manifests neurologic symptoms, signs, or both. The patient may give a history of minor antecedent trauma or manipulation (91). One patient gave a history of a“bearlike hug” after which the patient developed acute excruciating neck pain. The patient was seen an emergency room and sent home with analgesic medication, only to return the following day with progressive neurologic deficit (personal case). MRI of the cervical spine and in some instances a CT of the cervical spine are diagnostic in most cases. Urgent neurosurgical intervention is usually performed (92,93), although in some cases patients have been treated without surgical intervention with resolution of the epidural hematoma and improvement in their neurologic deficits (94,95 and 96).

Postoperative Neck Pain

Postoperative neck pain is expected and usually subsides within a few days to a week. Prolong neck pain should alert the physician to possible complications. When seen after spinal surgery, it may be indicative of infection, spinal instability, postlaminectomy kyphosis, bone graft fusion failure or pseudoarthrosis, or may be just failure to relieve the patient's preoperative neck pain. In the latter situation the surgeon should consider whether the surgery accomplished its goal or whether further surgery may be warranted to further decompress the spinal canal or foramen or to remove, for example, a retained or missed extruded disk fragment.

Neck positioning and tracheal tube irritation during surgery can cause postoperative neck pain. Singer (97) reported on neck complaints after tonsillectomy or adenoidectomy. The differential diagnosis includes muscle spasm, cervical adenitis, retropharyngeal abscess, parapharyngeal abscess, peritonsillar abscess, cervical osteomyelitis, bacterial meningitis, and atlantoaxial subluxation. In the latter condition torticollis is present and may be present in cases of muscle spasm, retropharyngeal abscess, parapharyngeal abscess, or peritonsillar abscess. Evaluation includes physical examination, cervical radiographs, CT, MRI, or both CT and MRI, and, in some circumstances, radioisotope-imaging studies. Obviously, treatment is dependent on the diagnosis. Subarachnoid hemorrhage secondary to a ruptured cerebral artery aneurysm has been reported to present as postoperative neck pain (98).

“An unusual cause of ‘pain in the neck’” after flexible sigmoidoscopy and neodymium:yttrium-aluminum-garnet laser treatment for a sessile tubulovillous adenoma of the rectum was reported by Manjunath and Trash (99). A 76-year-old woman developed pain in her throat and neck after this procedure. She had diffuse swelling of her neck with crepitus. Radiographic studies evidence retropneumoperitoneum, pneumomediastinum, and surgical emphysema. The patient had sustained a perforation of the rectum at the time of the procedure.

Hosono and colleagues (100), in a retrospective study of surgery for cervical spondylotic myelopathy, reported a concerning incidence of postoperative neck and shoulder pain, and shoulder muscle spasms, 26% and 29%, and 42%, respectively, in patients who had undergone laminoplasty. The nuchal pain developed an average of 5.5 months postoperatively and decreased in the majority of patients within 1.0 to 1.5 years, although in four patients the pain persisted for more than 2 years. Shoulder pain developed an average of 1.5 years postoperatively and usually resolved within 1 year, although it persisted for more than 2 years in four patients. The most common postoperative axial symptom was shoulder muscle spasm. It presented an average of 6.4 months postoperatively and persisted for more than 1 year in 25 patients and more than 2 years in 10 of 30 patients who complained of postoperative muscle spasms.

Dysesthetic neck pain with syncope after surgery for neck tumors is a relatively recently reported syndrome (101). The patients complained of a burning or throbbing pain in the neck developing at varying times postoperatively up to 4 years later. This syndrome is distinguished from glossopharyngeal neuralgia without or with syncope. Spinal cord stimulation was reported to be successful in the treatment of two of the four patients.

Miscellaneous Diagnoses

This section covers several rare diagnoses of neck pain that deserve mention because of their difficulty in diagnosis as a source of chronic and refractory pain. Some studies have shed new light on their etiology and pathogenesis, making them more recognizable and perhaps more treatable.

The neck-tongue syndrome is characterized by pain in the neck and altered sensation in the ipsilateral half of the tongue, which is exacerbated by neck movements. Bogduk (29) has shown that the anatomic basis for the syndrome involves compression of the C-2 nerve root by subluxation of the lateral atlantoaxial joint. The afferent (proprioceptive) fibers of the lingual nerve travel via the hypoglossal nerve to the second cervical nerve root, and are compressed, resulting in a *proprioceptive* numbness, similar to that seen in Bell's palsy. Treatment involves a local nerve block at C-2, spinal manipulation, and orthotic immobilization. Atlantoaxial fusion has been effective in the treatment of medically refractory symptoms (102).

Eagle's syndrome, or neck pain related to an elongated styloid process, is characterized by recurrent throat pain, foreign body sensation, dysphagia, or facial pain, with occasional radiation to the ipsilateral ear (103). The clinical condition is exacerbated by palpation of the styloid process in the tonsillar fossa, and the etiology for the disorder is thought to be related to stretching of the fifth, seventh, ninth, and tenth cranial nerves in the peritonsillar tissue during fibrosis and scarring after tonsillectomy (104). Surgical treatment involving reduction of the elongated styloid process has been reported to be effective (105).

A variant of the syndrome is thought to be related to carotidynia, a painful nonspecific inflammatory disorder affecting the carotid artery or body. Symptoms include unilateral neck pain, and occasionally bilateral, radiating to the face, jaw ear, or scalp. There is tenderness over the cervical carotid artery, usually at the region of the carotid bifurcation. The pain may subside in a few hours or last days or even weeks. The pain may be acute and self-limiting. This acute form has been attributed to viral infections of the carotid sheath or other carotid lesions, such as carotid body tumors, arteritis, atheroma, occlusion, fibromuscular dysplasia, and aneurysms (90). Extracranial internal carotid artery dissection should be considered in the differential diagnosis (see previous discussion). A recurrent chronic syndrome is also described, and current opinion suggests that it is a migraine equivalent (4,90,103), triggered on examination by gentle palpation of the carotid body, and worsened by head and neck movement. It responds well to antimigraine medications (103). This condition must be differentiated from extracranial internal carotid artery dissection (see following discussion).

The hyoid bone syndrome is considered to be an insertional tendonitis or enthesopathy and is defined by pain and tenderness at the site of the greater cornu of the hyoid bone. Symptoms include discomfort, aching, or both on one or both sides of the neck at the level of the hyoid bone. Other complaints may be hoarseness or dysphagia on initiating swallowing. The syndrome is reported to have been first described in 1954. Medical management includes use of NSAIDs, injection of a local anesthetic, and corticosteroids. Surgical intervention with excision of the greater cornu of the hyoid bone has been reported to relieve the pain in 90% of patients operated who failed medical management (106).

The Barré-Liéou syndrome (posterior cervical sympathetic syndrome) involves a group of cranial symptoms including headache, vertigo, tinnitus, and ocular complaints that arise after whiplash injury (107). Variable and seemingly unrelated secondary symptoms such as restlessness, irritability, and lack of concentration develop. The syndrome is thought to arise because of injury to the cervical sympathetic chain, with resultant chronic neurovascular changes. Indeed, the wide-range subjective complaints in the absence of signs make the diagnosis extremely difficult, and the patients are often confused with malingerers (see Role of Psychosocial Factors in Neck Pain, later in this chapter). Radiographic characteristics, however, show cervical osteoarthritis; when the vertebral artery is compressed by osteophytes in the foramen transversarium, neck movement can exacerbate the symptoms, supporting a neurovascular etiology for the disorder (4). Cervical

sympathetic blocks are effective in the treatment of the disorder, and correction of mechanical compressive deformity has shown good results (107).

Calcific retropharyngeal tendonitis is an infrequently mentioned cause of neck pain. There is increasing anterior neck and throat pain aggravated by head and neck movement, and dysphagia. On examination there is neck tenderness and limited range of motion. Occasional mild fever, leukocytosis, and elevation of the ESR are present (108,109). It is diagnosed by findings of amorphous calcification anterior to C-1 to C-2 and asymmetric soft tissue swelling evidenced on CT, and diffuse swelling of the longus colli muscles causing a high signal in the prevertebral region on T2-weighted MRI (108,110). The symptoms usually subside in 1 to 2 weeks. Treatment is supportive. Retropharyngeal abscess and osteomyelitis and infectious spondylitis are among other conditions included in the differential diagnosis (43).

Other reported syndromes included in the differential diagnosis of cervical pain, albeit rare, are the thyroid cartilage syndrome and mastoid process syndrome in which there is“impressive tenderness” over the thyroid cartilage or mastoid process. The pain was improved with oral or topical NSAIDs (111). Neck pain as a presenting symptom of malignant hypertension was reported by Stockwell and George (112). They suggested that the neck pain is caused by cerebellar tonsillar herniation caused by increased intracranial pressure.

Role of Psychosocial Factors in Neck Pain

Up to this point, the epidemiologic, anatomic, and clinical discussions have focused mostly on objective symptoms, signs, diagnostic studies, and treatment protocols. To overlook the psychology of neck pain would ignore a vital aspect of the diagnosis and management of the disease. According to Bland, more than 30% of patients who consult their primary care physicians have significant psychological problems (4). Considering the ubiquitous nature of neck pain and its often-debilitating course, psychological factors are likely to play a prominent role in the presentation of these patients. Discrepancy between the level of pain and the person's general well-being, no identifiable organic cause for neck pain, vague complaints, exaggerated symptoms, gait or posture abnormalities, a defensive and aggressive attitude, nonanatomic neurologic deficits, the existence of litigation and compensation issues, and resistance to rehabilitation and therapy are some of the factors that should alert the physician to the possible role of psychological factors (4,5,113,114). Psychological assessment strategies and treatment concepts are discussed elsewhere in this text (see Chapter 16 and Chapter 24, Chapter 25 and Chapter 26).

CHAPTER 56

Cervicobrachial Neuralgia

John D. Loeser

Cervicobrachial neuralgia, often referred to as *brachial neuralgia*, is a broad descriptive term used to denote pain in the distribution of the lower four cervical and first thoracic nerves. It is caused by pathologic processes involving the spinal cord, nerve roots that make up the brachial plexus, the plexus itself, or its major branches (1,2 and 3). Neurologic evaluation supplemented by electrodiagnostic and imaging studies is the basis of differential diagnosis.

GENERAL CONSIDERATIONS

Etiology

In most instances brachial neuralgia is a symptom secondary to disease involving the roots, trunks, cords, or peripheral branches of the brachial plexus. The most common causative factor, particularly as the population ages, is cervical spondylosis; other common diagnoses include herniated nucleus pulposus, brachial plexopathy, trauma to the neck and shoulder with root stretching or avulsion, variants of the thoracic outlet syndrome, and peripheral neuropathies resulting from compression or trauma. Most neck and shoulder pains are musculoskeletal in origin, as discussed in Chapter 57, Chapter 58 and Chapter 59.

Brachial neuralgias can be categorized on the basis of the site of pathology: lesions of the spinal cord and dura; lesions of the spinal nerve roots; lesions of the formed spinal nerves; lesions of the brachial plexus; and lesions of one or more of the peripheral nerves derived from the plexus (e.g., median neuralgia).

Epidemiology

The precise incidence of cervicobrachial neuralgia is not known because of the lack of population-based studies. Several investigators have studied this problem and obtained reasonable data. Lawrence (4), in a study of approximately 2,100 men and 1,850 women in England, found that 9% of the men and 12% of the women had cervicobrachial pain. An apparent correlation with radiologic changes in the cervical spine and increasing prevalence with advancing age was found. History or findings of radicular or spinal cord disease were noted in less than 3% of the subjects.

Hult (5), in a study of Swedish forest and industrial workers, again found an age-related prevalence of cervicobrachial pain, which appeared to correlate with roentgenologic signs of cervical spondylosis. Almost 80% of those in the study group had a history of cervicobrachial pain. In another study, Hult (6) determined the frequency of symptoms among men in different professions who could be segregated into two major groups, those doing light work and those doing heavy work. The 471 men in the light work group were employed in retail trade, light industry, or a sedentary occupation, whereas the 660 men in the heavy work group included stevedores and those employed in construction, heavy industry, and the food industry. The findings are shown in Figure 56-1. The incidence of neuralgia among light workers plateaued to around 10% to 12% in those between the ages of 25 and 44 years, but increased to approximately 40% in those aged 45 to 49, after which it remained above 30%. The incidence of cervicobrachial neuralgia for heavy workers aged 25 to 29 was approximately the same as for light workers, but rose steadily with age. Between the ages of 30 and 44, the incidence for heavy workers was approximately 20%, after which it climbed steadily to an incidence of approximately 40% in those aged 55 to 59.

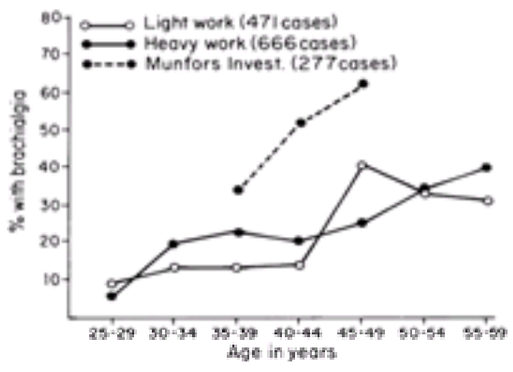

Figure 56-1. Incidence of brachialgia in three groups of subjects doing different types of work, showing the differences among the three groups and according to age groups. [Modified from Hult L. Cervical, dorsal and lumbar spinal syndromes. *Acta Orthop Scand* 1954; 17(Suppl):1–102.]

From these and the results of similar studies, it can be deduced that cervicobrachial pain is relatively common, is frequently associated with degenerative radiographic changes, and is usually a self-limiting symptom. Recurrent episodes of pain are common and increase in incidence with advancing age. Occupational stressors can lead to cervicobrachial pain (7). It is also well recognized that imaging studies may correlate better with age than with symptoms or signs (8).

Symptoms and Signs

The chief complaint of cervicobrachial neuropathy is usually pain, which is distributed according to the site of the lesion. Spinal cord or dorsal root lesions usually present with a radicular pain pattern that follows a dermatomal distribution. Lesions of the brachial plexus present with pain both in the root of the neck and in a peripheral nerve pattern. Lesions of the peripheral nerves distal to the plexus usually present with pain in the distribution of the affected peripheral nerve. The pain can be described as mild to severe, constant or intermittent, and lancinating or burning. A local dull, deep pain can also be present at the site of the lesion. Movements that stretch the involved nerves usually accentuate the pain.

It is common to have sensory disturbances accompany the pain of cervicobrachial neuralgia. All forms of sensory aberrations can be seen, including anesthesia, hypesthesia, paresthesia, hyperesthesia, hyperalgesia, and dysesthesia. If the offending lesion is primarily intrinsic to the spinal cord, pain and temperature sensation can be lost over several segments of the body, with preservation of light touch (girdle sensory loss).

Motor abnormalities are also common. Upper extremity myotatic reflexes can be depressed or absent. Muscle strength and bulk can be reduced. If the ventral roots or their axons are significantly compromised, fasciculations can be observed. Abnormalities in sympathetic nerve function are sometimes encountered and can include the loss of sweating and piloerection and a cool extremity, Horner's syndrome, and a diffuse forequarter deep pain. The dominance of the pain, sensory changes, and motor findings vary as a function of the site of the lesion and its causes.

Local tenderness is commonly noted at the lesion site. When the pathology involves the osseous structures of the neck, movements of the head and neck often exacerbate the pain. Lesions in the mixed nerves or brachial plexus result in pain to palpation in the supraclavicular region. Peripheral nerve lesions are often painful at the site of the lesion. If the lesion has been present for more than a month, and if axons have been damaged, a neuroma sign is often noted at the site of the lesion. Percussion at this area produces paresthesiae in the distribution of the involved nerve. If the lesion has been present long enough for regeneration to occur in the involved nerve, Tinel's sign can be elicited: Percussion of the nerve distal to the site of injury results in paresthesiae perceived in the distribution of the involved nerve. Tinel's sign indicates that some regeneration of the axons has occurred.

Diagnosis

The diagnosis of the cause of cervicobrachial neuralgia is based primarily on history; careful physical examination is also essential. Modern neurodiagnostic studies can be of great value in establishing a final diagnosis, but must be based on the history and physical findings if they are to be used efficiently. The general strategies for obtaining a history and performing a physical examination, as described in Chapter 12, should be used.

After a careful history has been obtained, the examiner should focus on the location and radiation of the pain. The neck should be inspected for loss of normal contours, atrophy of muscles, or other deformities. Localization in the neck without radiation into the arm usually implies musculoskeletal dysfunction. Radiation to the shoulder or distal arm is most often seen with root or plexus lesions; localized pain in the arm suggests a peripheral neuropathy.

The effects of motion of the neck and all the major joints should be ascertained next. Limitation of motion and pain locally suggests disease of the tendons, ligaments, joint capsule, or the joint itself (see Chapter 27, Chapter 28, Chapter 29, Chapter 30 and Chapter 31 and Chapter 55). Palpation of the painful region often increases the patient's pain. Relief of pain following infiltration of local anesthetics into the painful area confirms the presence of a localized musculoskeletal process. Myofascial pain syndromes of the neck and upper dorsal region are common (see Chapter 28, Chapter 29 and Chapter 30).

A thorough examination of the neck requires considerable skill. First, the patient should be asked to flex, extend, rotate, and laterally flex the head voluntarily as far as possible. Next, the effect of gentle traction on the head and of compression of the head should be noted. If significant reductions in the range of movement are seen, and if compression aggravates the pain while traction alleviates it, it is likely that cervical spondylosis or a herniated cervical disk is a causative factor. In such a patient, coughing, sneezing, and straining commonly cause an increase in pain. Other intraspinal lesions, although less common, can also be present.

The examination must include an assessment of the adequacy of the thoracic outlet, because congenital or acquired lesions can cause pain and neurovascular dysfunction by compressing the subclavian artery and lower brachial plexus. The radial pulse should be palpated with the arm dependent and with the arm externally rotated and extended while the neck is rotated toward and away from the arm. Obliteration of the pulse is common, even in a patient without any symptoms, and cannot be taken as indicative of a surgically treatable cause of the pain.

The course of the major nerves from the plexus distally should be palpated, looking both for local tenderness and for a possible neuroma sign or Tinel's sign. The skin should be inspected and palpated to ascertain temperature and sweating changes. Subtle autonomic changes can be present, indicating an occult neuropathologic process. The neurologic examination should be carried out with particular attention to the brachial plexus segments (Table 56-1). Knowledge of the cervical dermatomes is essential (9) (see Fig. 54-19). Spinal cord function should also be assessed by testing the lower extremities. The presence of Lhermitte's sign (electrical shocks radiating into the arms and legs when the neck is flexed) usually indicates an intradural spinal cord lesion. It is not pathognomonic for multiple sclerosis or any other disease state.

Ancillary diagnostic studies can include thermography; this does not indicate the presence of pain but does indicate an alteration in skin temperature, which suggests either vascular or neurologic dysfunction. Electromyography, nerve conduction velocities, and somatosensory-evoked potentials can be exquisitely localizing and can confirm the findings on physical examination (see Chapter 13).

Roentgenologic examination always starts with plain radiographs of the suspect area. Following these, tomography, computed tomographic (CT) scanning, or magnetic resonance imaging (MRI) can be ordered. If an intraspinal or radicular lesion is suspected, myelography is usually indicated (see Chapter 14).

Disk	Nerve root compressed	Finding
C4 to C5	C5	Pain radiates from midline neck to shoulder, often to medial scapula, anterior chest, and lateral aspect of upper arm; weakness in deltoids, supraspinatus, biceps, and brachioradialis; hyporeflexia at biceps and brachioradialis; numbness over deltoid and upper lateral arm
C5 to C6	C6	Pain radiates from midline of neck to shoulder, lateral upper arm, and radial forearm, sometimes to medial scapula and anterior chest; weakness in biceps and extensor carpi radialis; hyporeflexia at biceps; numbness over radial forearm, thumb, and first finger
C6 to C7	C7	Pain radiates from midline neck to shoulder, lateral upper arm, occasionally into index finger, and sometimes into anterior shoulder and medial scapula; weakness in triceps; numbness in index and middle fingers, often into palm
C7 to T1	C8	Pain radiates from midline neck to medial aspect of arm and ulnar side of forearm, and sometimes into medial scapula or anterior shoulder; weakness of triceps, wrist, and finger extensors except for flexor and extensor carpi ulnaris, all intrinsic hand muscles; hyporeflexia at triceps; numbness over fourth and fifth fingers and ulnar aspects of hand, forearm

TABLE 56-1. Findings with cervical nerve root compression

When the examination and diagnostic study results have failed to reveal a cause for cervicobrachial neuralgia, it is essential to remember that visceral pain can be referred to the neck and upper extremities. Lesions of the heart, mediastinum, lungs, diaphragm, and abdominal viscera can lead to pain in this region.

Local anesthesia can be used to establish a diagnosis when the findings are not clear-cut. Blocks of the spinal nerves, plexus, or peripheral nerves can help to localize the site of the causative lesion (see Chapter 102). Infiltration or dry needling of myofascial trigger points can often lead to dramatic relief and to the prompt establishment of a diagnosis in an otherwise puzzling patient.

LESIONS OF THE SPINAL CORD

Intrinsic Spinal Cord Lesions (IX-3)

Neoplasms or cysts of the cervical spinal cord can produce pain in the neck and arm. Significant neurologic deficits are almost always found in association with the pain. Vague and poorly localized pains over the trunk and arms can be seen, but the most common type of pain occurs in a segmental distribution at the level of the mass lesion, probably caused by stretching or compression of the intradural dorsal rootlets. This type of pain is usually aggravated by movements of the neck. Intrinsic lesions often lead to the loss of pain and temperature sensation in a girdle region a few segments below the level of the lesion, in this case usually over the upper thorax. This is because the decussating fibers of the spinothalamic tract are compromised (see Chapter 4). Neoplasms of the spinal cord, syringomyelia, herniated nucleus pulposus, or posttraumatic cysts are the common pathologic findings with lesions of this area. Infections are rare.

Neurodiagnostic studies are required to establish the diagnosis. Initial treatment is usually surgical, sometimes followed by radiation, chemotherapy, or both.

Extramedullary Intradural Lesions

Lesions within the dura but extrinsic to the spinal cord itself are not common, but they do occur and produce characteristic signs and symptoms. The two most common causes of this type of pathology are neurofibroma or meningioma; other tumors or congenital lesions occur rarely (10). The neurofibroma usually grows from a ventral root but can start on a dorsal root. The lesion typically presents with radicular pain and segmental motor and sensory changes. As its size increases, spinal cord dysfunction can occur, manifested by upper motor neuron findings in the lower extremities. A dumbbell neurofibroma can have a palpable mass in the neck and an intradural component, causing cord and nerve root compression.

Meningiomas usually originate dorsal or ventral to the spinal cord and do not have early radicular pain or signs; spinal cord dysfunction is usually the presenting complaint. Nonetheless, local neck pain can occur and, rarely, radicular pain and loss of function. Diagnosis is established by imaging studies. Treatment is exclusively surgical; these benign lesions should, whenever possible, be totally excised. Neurofibromas can grow both intradurally and in the spinal nerve, constricted by the bony foramen. Such a dumbbell tumor often requires a two-stage operation for excision.

Meningeal Carcinomatosis

Leptomeningeal metastases from solid tumors elsewhere in the nervous system or even in another organ can produce severe radicular pain (11,12) (See Chapter 35, Chapter 36 and Chapter 37). Patients with meningeal carcinomatosis have no significant mass lesions at the site of their painful neuropathy; the pain and nerve root dysfunction are caused by direct invasion of the nerve roots rather than by extrinsic compression. The pain-producing lesions can be too small to be seen by neuroimaging studies such as myelography, CT scanning, or MRI, although they may be visible on enhanced studies.

Carcinoma of the breast or lung, malignant melanoma, lymphoma, and leukemia are the most common primary tumors. Both children and adults can be afflicted with meningeal carcinomatosis, and radicular pain can be the first sign of this complication of the underlying disease. In children, leukemia is a frequent cause (13). Headache and pain along the entire spinal axis are also common. Many patients have sensory and motor deficits in multiple nerve roots, because meningeal carcinomatosis is usually a diffuse disease process.

The diagnosis is confirmed by identifying malignant cells in the cerebrospinal fluid by lumbar puncture. Radiotherapy or chemotherapy, depending on the primary lesion, is the appropriate treatment. The pain produced by this disease is relieved by narcotics to a varying degree. It has some of the characteristics of a deafferentation pain and is not exclusively nociceptive. Thus, anticonvulsants can sometimes be helpful (14).

Extradural Spinal Lesions

Extradural spinal lesions are more frequent than both types of intradural lesions. The most common diagnosis is herniated nucleus pulposus or cervical spondylosis (see Cervical Spondylosis, later in this chapter). Other causes of cervicobrachial pain that originates in the extradural space include metastatic tumor and abscess. Unusual lesions such as aberrant arteries can also compress nerve roots (15). Neoplasms that metastasize by way of the bloodstream frequently grow in the epidural space; carcinoma of the lung, especially apical (Pancoast's tumor), and breast, prostate, and thyroid tumors are the most likely primary lesions. The patient can have an epidural metastasis as the first sign of neoplasia, or the tumor might have long been recognized and treated before epidural metastasis.

The patient usually complains of severe pain in the region of the lesion and develops both radicular and spinal cord dysfunction. Diagnosis is established by myelography, CT scanning, or MRI. Chemotherapy, radiation therapy, and decompressive laminectomy can all be used. Treatment depends both on the biological properties of the tumor and on the patient's overall condition. If bone destruction is severe, a fusion may be indicated both to protect spinal cord function and to restore stability so that pain is reduced.

Epidural Abscess (IX-5)

An epidural abscess is usually painful; it is a surgical emergency and must be promptly treated by laminectomy and decompression as well as by appropriate antibiotics (16). The infection is usually blood borne from another region of the body, but cases with no known antecedent infection have been reported. The patient presents with severe pain in the midline overlying the region of the abscess, with tenderness to palpation of the involved area. Radicular pain can be present, especially on movement of the involved region. The patient usually has a fever and appears quite ill.

Tabes Dorsalis (IX-9)

Tabes dorsalis (tabetic neurosyphilis), characterized by demyelinization of the posterior column, dorsal roots, and dorsal root ganglion, can produce lancinating pain in a radicular pattern involving the cervical, thoracic, lumbar, or sacral roots (17). The usual patient is middle-aged, because it takes 10 to 20 years for this form of syphilis to develop its painful signature. The disease is much less common since the development of effective treatment for the destruction of the spirochete that causes the infection.

Symptoms and Signs

The patient describes shooting, stabbing, or lightning pains, much like those seen in tic douloureux in the face. The pains can shift from one region of the body to another; individual pains last only moments, but repeated episodes of pain can last for hours or days.

Sensory aberrations are uniformly present, including both hypersensitivity and hypesthesia. Paresthesia and dysesthesia of the distal extremities are common. Both the posterior columns of the spinal cord and the dorsal roots are involved in this syndrome; thus, long tract signs such as decreased vibration and position sense are often noted. Charcot joints and trophic skin changes caused by lack of protective sensation can be seen. Alterations in bowel and bladder function are common.

Treatment

Although the myelopathy or radiculopathy has no effective treatment, the lightning pains can often be ameliorated by anticonvulsants such as carbamazepine or phenytoin (14) (see Chapter 23). When medications do not control the pain, cordotomy is usually effective (18). This disease became rare in developed countries but has recrudesced as part of the acquired immunodeficiency syndrome epidemic (19). Scant data about the newer treatment options, either medical or surgical, are available (20).

LESIONS OF THE NERVE ROOTS (RADICULOPATHY)

Cervical Spondylosis

Etiology and Pathophysiology

The most common cause of pain in the cervicobrachial area is cervical spondylosis (cervical osteoarthritis) (1). The exact mechanism of the pain is not completely understood because innervated structures such as the ligaments, facet joints, and periosteum can produce radiating pain when they are mechanically distorted (21). Nevertheless, mechanical pressure on a dorsal root or dorsal root ganglion can lead to radicular pain. The details of this degenerative bone disease are discussed in Chapter 27 and Chapter 55. Compression of dorsal roots and ganglia can be the result of bony spurs and loss of foraminal height (Fig. 56-2). It is also possible that a subtle neuropathic process is responsible for myofascial and radicular pains (22,23). Degenerative processes in the cervical spine are related to age and to trauma but symptoms are not directly correlated with the magnitude of imaged changes (24).

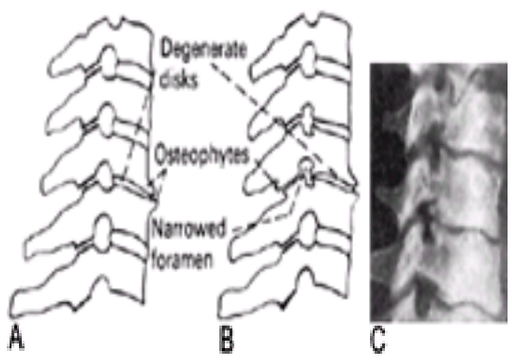

Figure 56-2. Osteoarthritis of the cervical spine, showing development of cervical spondylosis. **A:** Initially simple degeneration causes narrowing of the intervertebral disk, with formation of osteophytes anteriorly. **B:** Later the posterior or facet joints are affected, the articular cartilage is worn away, and marginal osteophytes encroach on the intervertebral foramen. **C:** Oblique view of the cervical roentgenogram shows severe encroachment of osteophyte, most pronounced at C-6 and C-7. Note the normal foramen below. (Modified from Adams JC. *Outline of orthopaedics,* 10th ed. London: Churchill Livingstone, 1956.)

Symptoms and Signs

Patients with cervical spondylosis can present either with spinal cord or nerve root dysfunction or both. The radicular signs are often multifocal (25). Pain can also be referred to the base of the skull or into the lower neck, chest, and shoulders.

Treatment

The initial treatment is aimed at alleviating the mechanical cause, reducing the inflammatory changes that occur in the nerve root secondary to repeated trauma (1), and providing symptomatic relief. Some patients respond well to a cervical collar and nonopioid analgesics; others might respond to cervical halter traction, muscle relaxants, analgesics, and antiinflammatory agents. Patients who do not achieve adequate pain relief with medications and physical therapies require surgical decompression of the bone spurs that impinge on the nerve roots and, sometimes, on the spinal cord (26). Myelopathy is an indication for urgent surgical treatment; radiculopathy can be managed conservatively with less risk of a major, sudden, irreversible increase in neurologic defect.

Herniated Nucleus Pulposus (IX-1)

Symptoms and Signs

Herniated nucleus pulposus in the cervical region is much less common than in the lumbar area (4,5 and 6). The typical patient has a history of intermittent neck pain with the sudden onset of severe radicular pain (radiculalgia), which usually follows trauma. Radicular pain is aggravated by coughing, sneezing, movement of the neck, especially extension, and Spurling's test, and is reduced by head traction (see Chapter 55). Significant radicular sensory and motor loss is often present; if the herniated fragment of the disk is large, spinal cord compression can also occur.

Most herniated disk fragments occur at the C-4 to C-5, C-5 to C-6, and C-6 to C-7 levels (Fig. 56-3). The pain pattern usually identifies the compromised nerve root; in some patients the pain is not localized and does not pinpoint the involved level. Some patients report diffuse pain in the suboccipital or lower cervical and upper chest regions, which can simulate the pain of myocardial infarction (see Chapter 61). Motor loss and the pattern of sensory changes can also help to localize the lesion (3). The cervical roots exit the spinal canal above the vertebral body of the same segment (the C-6 root is compromised by a C-5 to C-6 disk fragment). Typical radicular patterns in the cervical area are described in Table 56-1.

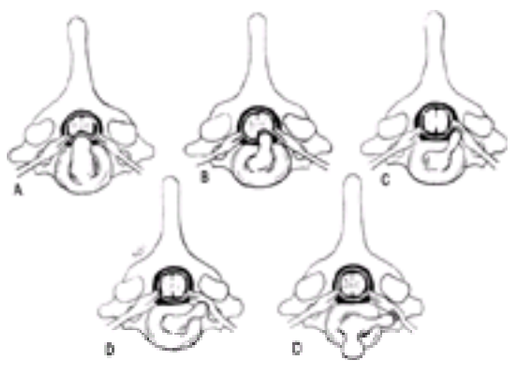

Figure 56-3. Various types of protrusions (herniations) of cervical intervertebral disks. **A:** Dorsomedial, which can produce bilateral cord compression (Stookey group I). **B:** Paramedian, which can produce unilateral cord compression (Stookey group II). **C:** Dorsolateral, which can compress the nerve roots intraspinally against the lateral part of the vertebral lamina (Stookey group III). **D:** Intraforaminal, which can compress the radicular nerve against the articular processes. **E:** Lateral and ventral protrusions. The lateral type can compress the vertebral artery and vertebral nerve.

Diagnosis and Treatment

Myelography and CT scanning reveal a discrete epidural defect; electromyography reveals a radicular pattern of denervation (see Chapter 13). If prompt symptomatic relief does not occur with cervical immobilization, traction, muscle relaxants, and analgesics, surgical removal of the herniated fragment is usually the optimal treatment. The surgical procedure can be performed either with an anterior interbody approach or with a posterior laminotomy and foraminotomy.

Fractures of the Cervical Spine (IX-4)

Spinal roots can be injured at the time of a cervical fracture or dislocation. Usually the acute neck pain is caused by the osseous and ligamentous injury; if a root has been compressed by the injury the patient also has radicular pain. Diagnosis is established by anterior posterior and lateral cervical spine roentgenography, CT, and MRI scanning.

Acute management obviously requires immobilization and realignment of the cervical spine, which can alleviate the root compression. When it does not, surgery for

decompression of the involved root must be considered, both to alleviate the pain and to maximize the opportunity for return of function.

In the chronic phase, a patient who develops radicular pain associated with neck movements should be thought to have an unstable neck until proven otherwise. Careful imaging studies to delineate abnormal motion are essential. Stabilization or surgical decompression of the compromised root, or both, usually relieve(s) the radicular pain and can restore lost nerve root function.

Brachial Plexus Avulsion (IX-11)

Avulsion of the brachial plexus is a misnomer: It is usually the dorsal and ventral roots that are torn from their entry zones into the spinal cord. Of course, a component of stretch of the roots or of the plexus with such an injury can be present. The entire syndrome is discussed here, recognizing that portions of the pain picture can result from pathology that exists in addition to the avulsion of the roots, such as a spinal cord or brachial plexus injury.

Etiology

In the adult the most common mechanism of avulsion of the roots is lateral flexion of the neck and downward thrust of the shoulder, putting maximal pressure on the upper roots of the plexus (C-5 to C-7). Motorcycle accidents are the common cause, and young men are most often injured. The resulting palsy can be partial or complete; some or all of the roots can be avulsed, some just stretched, and others not involved at all. Other mechanisms for injury occur in infants and children who rarely, if ever, develop a pain syndrome, no matter how profound the injury (27).

Symptoms and Signs

The pain can begin at the time of injury or can develop days to months later (28). It is usually described as burning or aching and is so intense as to disrupt totally the patient's life. The pain is perceived in the entire upper extremity but is usually maximal in the hand. It can be triggered by cutaneous stimulation over the chest or neck and is often aggravated by cold, anxiety, or stress. Often, tenderness is felt over the traumatized plexus; a neuroma sign can develop if the root is intact but the plexus is disrupted.

Diagnosis

The severity and extent of a brachial plexus avulsion injury should first be ascertained. Electrodiagnostic studies are essential. Myelography or MRI is important, because the root avulsions can actually be seen in many patients (29,30). Obviously, an avulsed root has no opportunity for regeneration. Careful documentation of the motor and sensory changes establishes a baseline that can be used to plot return of function. The presence of Horner's syndrome, paralysis of the serratus anterior, levator scapulae, rhomboids, or diaphragm all indicate root damage and probable avulsion. All these indicate injury central to the trunks of the brachial plexus. The likelihood of developing a severe pain syndrome is increased when many roots are avulsed.

Treatment

Local neck pain at the time of injury can be transient and can be a result of the trauma itself. In this phase the usual methods of treating musculoskeletal pain are effective. When the pain is referred into the anesthetic arm, brachial plexus avulsion pain can be diagnosed. This is not a pain caused by nociception; rather, it is a deafferentation pain. Management strategies must be based on the nature of the injury, the interval since injury, and the severity of the pain. Because the limb is often totally paralyzed and useless, the patient and uninformed physicians might advocate early amputation. Although this would eliminate an extremity that actually does impede the patient's activities, it never alleviates the pain.

Ablative and hazardous procedures should not be offered until the likelihood of regeneration has been considered; if significant regeneration can occur, the pain syndrome can abate without intervention. Hence, the interval since injury needs to be considered in assessing motor and sensory function to determine if any regeneration has been noted in the appropriate time frame. If regeneration is occurring, it is necessary to wait until the nerve has had the opportunity to regrow its connections before embarking on ablative surgical procedures to treat the pain.

Opiate analgesics are not often effective in the management of brachial plexus avulsion pain. If oral opiates fail, spinal opiates can be tried. Few studies support the effectiveness of any other medication, but most clinicians who have had experience with this syndrome recognize patients who seem to respond to anticonvulsant or antidepressant medications (14,31). Phenytoin, 300 mg per day; gabapentin (Neurontin), up to 1,200 mg four times a day; carbamazepine, 200 mg four times a day; and doxepin, 150 mg at bedtime, are often prescribed; dosages often require adjustment, and other medications can also be useful. Nerve blocks do not appear to have either a diagnostic or a therapeutic role.

When it is reasonably certain that regeneration is not going to occur, a surgical procedure can be contemplated. As stated previously, amputation does nothing to relieve the pain. Surgical repair of the brachial plexus can reduce pain as well as restore functions (32). When repair is not feasible, evidence suggests that dorsal root entry zone (DREZ) lesions are the most likely surgical procedures to stop this type of pain (33) (see Chapter 106). Cordotomy, myelotomy, and ablative brain lesions do not seem efficacious. Some patients have achieved relief with thalamic stimulation (34) (see Chapter 101). Spinal cord stimulation has been reported to be efficacious, but this has not been my experience (35).

The outcome from any treatment is difficult to assess, because many patients with brachial plexus avulsion pain gradually lose their complaints over a few years (28). Whether this reflects neural changes at the injury site or simply patients' recognition that no treatment works, and thus they stop complaining and searching for a cure, is unclear at this time.

The problem of brachial plexus injury was eloquently reviewed by Wynn-Parry (28), who commented on the importance of an accurate diagnosis: If the roots are not avulsed, repair of the plexus may be warranted. He found that comprehensive medical and rehabilitative care optimized pain relief. Some patients did respond to transcutaneous stimulation, but only if some innervation of the arm was intact. Our experience is similar to that of Wynn-Parry's: In the early stages of avulsion and stretch pain, patients require education and training in the use of relaxation, tensing, distraction, and physical therapy. Patients must know that spontaneous improvement over several years is common. Anticonvulsant and antidepressant medications can be helpful, whereas sedative-hypnotics are not. Transcutaneous electrical stimulation helps some patients, but there must be sensation in the region stimulated to achieve pain relief (see Chapter 98). Early return to normal social activities and gainful employment is also an essential component of a treatment program.

Postherpetic Neuralgia (IX-8)

Herpes zoster can affect the cervical dermatomes; postherpetic neuralgia of these segments can cause severe radicular pain. This syndrome is discussed in detail in Chapter 22; nothing is unique about its occurrence in the cervicobrachial area. The causative lesion does involve the dorsal roots, but the dorsal horn of the spinal cord and the peripheral nerve are also involved with the inflammatory and degenerative changes. This is a difficult pain syndrome to treat. It does not usually respond to opiate analgesics. DREZ lesions can be effective (see Chapter 106).

Diabetic Pseudotabes

Diabetes mellitus is associated with a plethora of myelopathies and neuropathies, many of which are difficult to diagnose conclusively (see Chapter 19 and Chapter 23). One form, known as *diabetic pseudotabes*, resembles tabes dorsalis with both radicular and dorsal column dysfunction and a radicular lancinating pain (20). This syndrome is distinguished from tabes by the negative serologic test results for syphilis and by the positive test results for abnormalities of sugar metabolism. Effective management of the diabetes seems to reduce the likelihood of this complication. Anticonvulsants are sometimes effective in the control of the lancinating pain.

LESIONS OF THE BRACHIAL PLEXUS

In all disorders of the brachial plexus pain can be increased by neck motion, use of the shoulder, or deep inspiration. Palpation or percussion of the supraclavicular fossa can lead both to the report of local pain and, often, to pain referred down the arm. Electrodiagnostic studies (see Chapter 13) are helpful in localizing the lesion. Reports on the frequency of the various lesions that can cause brachial plexus dysfunction and pain have been related to the patient referral system and to the

special interests of a particular author. Table 56-2 presents an approximation of the relative incidence of lesions of the brachial plexus.

Cause	Example(s)	Incidence (% of cases)
Trauma	Penetrating injuries (e.g., gunshot, knife); closed injuries—obstetric (newborn), mechanical distortion	70
Compression	Exogenous (knapsack paralysis); congenital abnormality; developmental abnormality	10
Vascular	Local disease of major vessels; generalized vasculopathy (lupus erythematosus, arteritis); secondary to radiation therapy	5
Infectious	Viral, bacterial (local sepsis, abscess, or cellulitis)	1
Neoplastic	Primary tumors of brachial plexus; secondary involvement of plexus by tumors of surrounding tissues (Pancoast's tumor)	10
Miscellaneous causes	Electric shock; parainfectious; following serum therapy; unknown	2

TABLE 56-2. Causes of brachial plexus lesions

Thoracic Outlet Syndromes (IX-13)

Numerous anatomic variations can be found at the cervicothoracic junction, some of which can compress either the vascular or neural structures, or both, that traverse the neck to enter the arm. The four major thoracic outlet syndromes are the scalenus anticus syndrome (Fig. 56-4), costoclavicular syndrome (Fig. 56-5), cervical syndrome (see Fig. 56-4), and hyperabduction syndrome (Fig. 56-6).

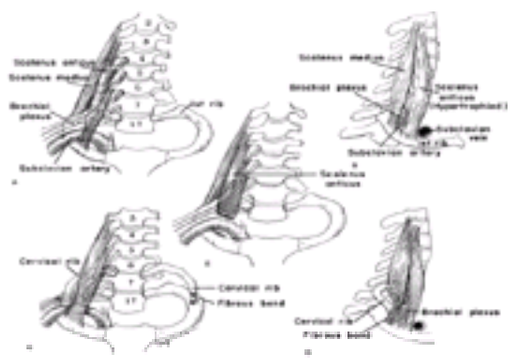

Figure 56-4. Mechanisms of the scalenus anticus syndrome with and without cervical rib. **A:** Normal anatomic relationship of the brachial plexus, subclavian artery, and scalenus anticus and medius muscles. **B:** Hypertrophied scalenus anticus muscle compressing the nerves and artery. **C,D:** Compression caused by cervical rib. **E:** Relief of compression by scalenotomy.

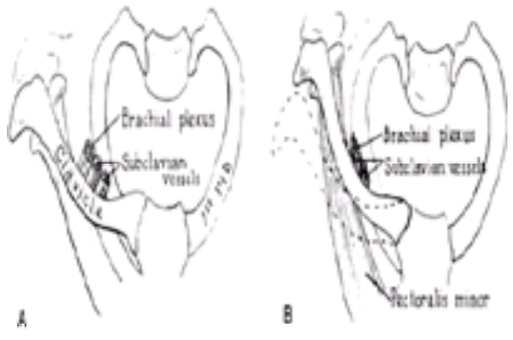

Figure 56-5. Mechanism of the costoclavicular syndrome. **A:** Normal relationship of the brachial plexus and the subclavian artery to the clavicle and first rib. **B:** Nerves and vessels are compressed with abnormal downward and backward bracing of the shoulders.

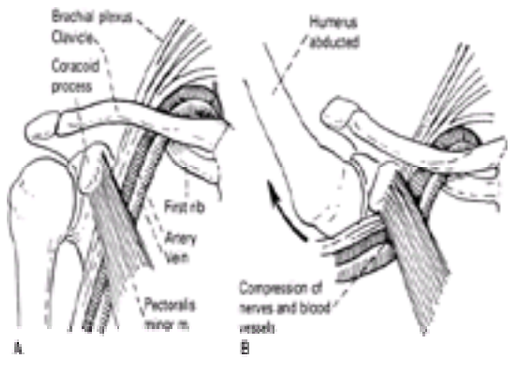

Figure 56-6. Mechanism of the hyperabduction or subcoracoid-pectoralis minor syndrome. **A:** Patient's right arm is represented as being dependent at the side of the body: The subclavian artery and vein and brachial plexus are not compressed in this position. **B:** With the arm laterally abducted to an elevated position, the brachial plexus and vessels are compressed by tension of the pectoralis minor muscle and to a lesser extent by the coracoid process.

Etiology

Thoracic outlet syndrome has been ascribed to such lesions as cervical rib, abnormal first thoracic rib, hypertrophy of the scalenus anticus, scalenus medius abnormal insertion, bands in Sibson's fascia, costoclavicular abnormalities, hyperabduction of the arm, and others. Most of these are known to occur without any symptoms in some people. Hence, their specificity should be questioned. Some of the structural abnormalities can impinge on various portions of the brachial plexus and produce neurologic deficits that are not typical of the lower trunk. Careful examination and diagnostic testing indicate the likelihood of such an atypical case. Some well-described variants of thoracic outlet syndrome have been seen, however, with consistent relationships between the patient's complaints and findings and an anatomic variation.

A well-characterized example is the cervical rib that impinges on the lower trunk and leads to atrophy and weakness in the hand and forearm, pain in the ulnar aspect of the forearm, and paresthesiae in the ulnar arm and forearm. Surgical treatment of this congenital anomaly usually relieves symptoms (36). Some are related to abnormal positioning of otherwise normal structures, whereas others can be caused by abnormal ribs or cartilage or abnormal muscle attachments and insertions (see

Fig. 56-5 and Fig. 56-6). Sunderland (37) has described the anatomic variations and how they might lead to compression of the relevant structures. Unfortunately, many authors have made unsubstantiated claims for various surgical procedures that are purported to relieve nonspecific complaints of shoulder, neck, arm, and hand pain. Others have questioned the actual existence of many of the alleged syndromes. Currently, physicians seem to find fewer patients with variants of the thoracic outlet syndromes than did physicians of earlier generations (38,39).

Symptoms and Signs

The usual syndrome involves the subclavian vessels and the lower trunk of the brachial plexus (C-8 and T-1). Varying degrees of vascular or neurologic compromise or both can be found, possibly with local supraclavicular pain. The pain and sensory changes are usually aggravated by any activity that puts tension on the plexus, including carrying heavy objects, working with the arms over the head, or performing repetitive movements of the arm. Pain is often in a radicular pattern, suggesting involvement of the C-8 and T-1 roots. Some patients report a deep ache within the arm without much localization. Cold weather often exacerbates the symptoms. The complaint of pain can precede by months or years the development of any other neurologic symptoms or signs.

Motor deficits are most common in the intrinsic muscles of the hand. Vasomotor changes are seen and are not necessarily associated with signs of vascular insufficiency, leading many to believe that the sympathetic fibers that accompany the subclavian artery are the cause of this phenomenon.

Diagnosis

Inspection and palpation often reveal a fullness of the supraclavicular fossa. The neural structures can be tender to palpation. Obliteration of the radial pulse with arm extension or abduction or traction can be present (Adson's or Allen's test), but this is often seen in asymptomatic people and does not reliably lead to any diagnosis or treatment success. Roentgenography of the neck can reveal a cervical rib or abnormality of the first thoracic rib. CT or MRI scanning is helpful in delineating soft tissue abnormalities (40). The differential diagnosis must include cervical spondylosis with radicular compression, myofascial pain syndrome, tumor of the brachial plexus, and almost any other cause of chronic pain in the neck.

Treatment

Conservative management is called for in patients thought to have a thoracic outlet syndrome. If frank vascular or major neurologic impairment is present, surgical decompression is a reasonable consideration (Fig. 56-7), but only a small proportion of patients fall into this category. The specific surgical procedure must be tailored to the findings at the time of surgery. The goal must be to provide adequate room for both the vascular and neural structures. A high cervical nerve root lesion, usually at C-4 to C-5, can cause spasm of the scalenus anticus, which can compress the lower trunk of the plexus. Such a patient has both a C-5 radiculopathy and signs of C-8 and T-1 dysfunction. Treating the cervical spondylosis or disk at C-4 to C-5 might obviate the need for scalenotomy.

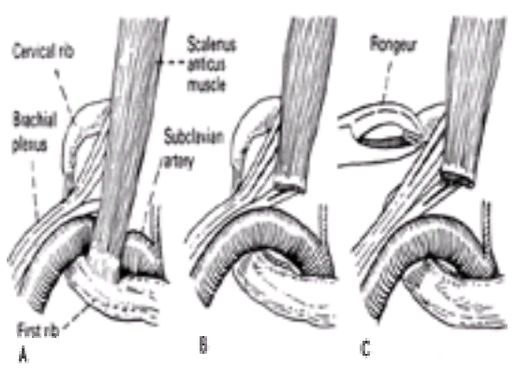

Figure 56-7. **A:** Pressure is exerted on the subclavian artery and the brachial plexus by the anterior scalenus muscle and by a tendinous band extending from the tip of a cervical rib to the first thoracic rib. **B:** Pressure on the subclavian artery is relieved by section of the anterior scalenus muscle but the tendinous band extending from the rib still compresses the brachial plexus. **C:** Pressure on the brachial plexus is relieved by removal of the tendinous band and the tip of the cervical rib.

Those on the staff of pain clinics see too many patients with severe neurologic deficits following surgical procedures for thoracic outlet syndrome. Many of these unfortunate sufferers did not have either vascular or nerve compression but were operated on for vague pains. Major vascular and nerve injuries occur too frequently to warrant exploratory surgery in this area (41).

Neoplasms (X-1)

Intrinsic Tumors

Tumors of the brachial plexus can present with pain and neurologic dysfunction. These are almost always benign schwannomas or neurofibromas, which can occur in isolation or can be part of a systemic disorder, such as multiple neurofibromatosis.

Symptoms and Signs. The involved plexus is usually tender to palpation and the mass can sometimes be felt or seen through the skin. Local and referred pain in the distribution of the involved segments is usually present. Sensory and motor loss are generally progressive. CT or MRI scanning is helpful in establishing a diagnosis; electrodiagnostic studies help to localize the lesion within the plexus.

Treatment. Treatment involves excision of the involved segments and repair of the plexus with cable grafts. This is often difficult if the neoplasm is in the middle of the plexus; only an expert in the management of peripheral nerve lesions should attempt this type of surgery. Malignant degeneration of these lesions can also occur, in which case surgery is then only palliative. Narcotic analgesics are often helpful in managing the pain of an intrinsic neoplasm, but some patients also have pain caused by deafferentation. Anticonvulsants or tricyclic antidepressants can be helpful for such patients.

Pancoast's Tumor (IX-12)

A tumor of the apex of the lung often involves the brachial plexus and is commonly called *Pancoast's tumor* (42). Pain is a common problem with such a lesion, and many patients are treated for diseases of the shoulder and neck for months or years before the true nature of the pathologic process becomes apparent (see Chapter 64 for more detailed discussion of Pancoast's tumor). These tumors are rare, accounting for only 5% of lung cancers (43). The initial pain syndrome usually involves the lower cervical roots or trunks.

Symptoms and Signs. Most patients with Pancoast's tumor have pain as their initial complaint (42). Although it was originally described as part of this syndrome by Pancoast, more recent studies indicate that Horner's syndrome is found in a minority of patients. CT scanning or MRI through the suspected region reveals a mass lesion that might be missed on plain roentgenography.

Treatment. The most common source of the neoplasm is the lung; the tumor is often radioresistant and might not respond to chemotherapy. When narcotics do not control the patient's pain adequately, a surgical or neurolytic procedure must be considered. Dorsal rhizotomy can be undertaken if the arm is already functionless secondary to tumor invasion of the plexus, but high cervical cordotomy is probably a wiser choice. Intracranial procedures have also been used, with varying results (44). Intrathecal or epidural narcotics can control this pain effectively in some patients.

Some patients develop severe pain following radiation therapy and chemotherapy, as well as surgery, for Pancoast's tumor. It is often impossible to determine the cause of the pain in such a patient. Nerve injury is often a major part of this patient's pain syndrome; the response to treatments designed to eliminate the pain of tissue damage is often poor. For example, such a patient, when treated by deep brain stimulation, may require an electrode both in the periaqueductal gray and in the

lateral thalamus to obtain complete pain relief (see Chapter 101).

Brachial Plexitis (X-2)

Brachial plexitis is an acute disorder that almost always begins with unilateral diffuse pain in the shoulder area and is soon followed by weakness, which is usually more pronounced in the proximal muscles than in the arm or hand. Sensory changes are usually less pronounced than the motor deficit, but varying amounts of paresthesia, dysesthesia, and hypesthesia have been noted. The pain usually subsides after the acute phase, and return of function generally occurs. Electrodiagnostic studies can help to establish this diagnosis (45).

The pathogenesis is not clear, but most believe that this is a viral illness or an autoimmune phenomenon (46). A rare, familial, recurrent brachial plexus neuropathy has also been described (47). Inflammatory lesions in the brachial plexus can also be caused by local hemorrhage or bacterial infection. The patient who develops profound paresis of the shoulder muscles can develop chronic shoulder pain because of the weight of the arm distracting the humeral head from the glenoid fossa. An arm sling alleviates this problem until return of function occurs.

Postradiation Plexopathy (X-4)

Lesions of the brachial plexus can follow radiation therapy for cancer (2,46,48). The differential diagnosis among tumor recurrence, scarring around the plexus secondary to surgery, and radiation-induced plexopathy is not easy. It is unusual for radiation plexopathy to develop less than 1 year after the termination of radiation therapy, unless high doses of radiation have been administered. The shortest latency seen is approximately 6 months, but latency periods of several years have also been reported. If the patient develops a brachial plexus lesion in less than 6 months or in more than 3 years following radiation therapy, however, tumor recurrence is more likely than radiation plexopathy. Chemotherapy, given in addition to radiation therapy increases the risk of plexitis (49). It is common that upper roots and trunks are initially involved in radiation plexopathy.

Symptoms and Signs. Alterations in sensation are the usual presenting symptoms in radiation-induced plexopathy. Chronic pain in the shoulder and arm is also found early in the course. Alterations in deep tendon reflexes appear at the same time as paresthesiae and definite hypesthesia. Motor deficits are the last to appear and usually follow the pain and sensory changes by several months. In some patients, pain and reflex changes can be the only findings.

Almost all patients with radiation plexopathy have skin changes caused by radiation and also might have changes in the deeper structures. Horner's syndrome is not found in radiation plexopathy; if present, the more likely diagnosis is tumor recurrence. The earlier that plexopathy follows the end of radiation therapy, the more likely is the disease to progress to complete loss of brachial plexus function. Lymphedema caused by radiation usually occurs within the first year after treatment; if it develops several years later, it is more likely that tumor is to be found. Palpation of the supraclavicular region does not discriminate between tumor recurrence and radiation-induced fibrosis unless a large mass of tumor has developed.

Diagnosis. When a patient develops brachial plexopathy after carcinoma, surgery, and radiation therapy, it is important to establish an accurate diagnosis. Roentgenography and CT or MRI scanning can be helpful (50). Often, needle biopsy or open exploration of the brachial plexus must be done. If tumor can be positively identified, a further course of radiation therapy can be warranted and might provide pain relief.

Treatment. Radiation-induced plexopathy is exceedingly difficult to treat. Physiotherapy can help to maintain range of motion and tissue health. The efficacy of neurolysis is debatable, although some favorable reports about pain relief have been published (48,51). Symptomatic therapy with narcotics helps some patients. Ablative neurosurgical procedures such as cordotomy or DREZ lesions are sometimes effective (52). Good results have also been reported with deep brain stimulation in the lateral thalamus (34).

Contusion or Stretching

Etiology and Pathophysiology. Much of the discussion of brachial plexus avulsion injuries is relevant to stretching or contusion of the plexus. Of course with avulsion, no potential for regeneration exists, but with stretch or contusion, regeneration is a possibility if the nerves have not been damaged so badly that fibrosis prevents regeneration. The mechanisms of stretching injury are the same as those of avulsion; clinically, it is often hard to discriminate between the two, and most injuries represent a combination of avulsed and stretched roots. Contusion is usually a result of blunt trauma to the lateral neck. The severity of the injury to the plexus is difficult to determine on initial examination. The brachial plexus can be injured during cardiac procedures, either by excessive retraction after a median sternotomy or by trauma to the lower cord during jugular venous catheterization (53).

Symptoms and Signs. Both contusion and stretching are associated with acute pain; the difficult management problem is, however, the development of chronic pain. Usually, the chronic pain is proportional to the severity of the injury and the pain diminishes as restoration of sensory function occurs. Exploration of the brachial plexus can be warranted in the acute phase for determining the extent of the injury and, if appropriate, when microsurgical repair of the disrupted plexus is contemplated. A successful repair not only maximizes the return of function but also reduces the likelihood of the development of a chronic pain syndrome.

Treatment. The development of chronic pain after contusion or stretching of a nerve or plexus mandates careful management. Obviously, an ablative procedure of any type is not warranted while the potential for nerve regeneration remains. Clinical examination and electrodiagnostic studies can indicate the degree and rate of return of function and can help in management decisions. When the pain has a component of electric shock–like jabs it is often helpful to prescribe an anticonvulsant for some patients, such as phenytoin or carbamazepine, whereas other patients have found tricyclic antidepressants to be helpful (see Chapter 85 and Chapter 86). Narcotics are not often useful because this is a form of deafferentation pain.

When the residuals of the injury appear to be fixed, a surgical approach should be considered. Exploration and repair of the plexus can help to restore nerve function, but often are not effective for the pain itself. If major functional deficits are present so that the arm is useless, DREZ (see Chapter 106) seems to be effective. Dorsal rhizotomies are not reliably useful, nor is cordotomy. No surgical or medical treatment has a consistently high chance of success.

Penetrating Trauma

Penetrating injuries of the brachial plexus can lead to severe pain. Complex regional pain syndrome type II can be an outcome (see Chapter 20), or other neuropathic pain syndromes can develop. Primary repair of the plexus, when carried out properly, is the best means of preventing a chronic pain syndrome. If a causalgic pain syndrome develops, prompt sympathetic blockade is indicated. If the plexus has been repaired, ablative lesions should not be undertaken until time for regeneration has elapsed. The likelihood of the development of a chronic pain syndrome following penetrating trauma decreases as nerve regeneration and return of function occur.

LESIONS OF THE PERIPHERAL NERVES

Acute Trauma

Symptoms and Signs

Any nerves of the shoulder girdle and arm can be injured by blunt or penetrating acute trauma. The injury is itself painful and neuropraxia occurs immediately; the development either of permanent neurologic deficits or of a chronic pain state depends on the severity of the injury. Obviously, penetrating injuries need to be explored acutely, and the nerve examined and the ends tagged for future repair, if possible. It is usually best to delay nerve suture until the extent of damage is demarcated in approximately 3 weeks after injury. When a major injury to a nerve has occurred, chronic pain can be a result of neuroma formation or entrapment in scar at the injury site; alternatively, it could be caused by central changes secondary to deafferentation. The pain is usually at the region of injury, but can also be referred distally in the sensory distribution of the nerve.

Treatment

Neurolysis or neurorrhaphy often alleviates the pain and restores neurologic function (54,55). Every attempt should be made to repair the nerve, because this greatly

reduces the likelihood of the formation of a painful neuroma (54). Minor nerves that are trapped in a scar can sometimes be rendered less painful by local injection of corticosteroids and local anesthetics. Medications are not helpful. Searching for small nerves in scarred tissue is rarely a successful surgical procedure in spite of the fact that local anesthesia can arrest the pain. Entrapment of a nerve in scar can lead to local pain and tenderness that may be alleviated by scar excision and pedicle or free flaps (56).

Entrapment Syndromes

Symptoms and Signs

Chronic trauma to the nerves in the arm occurs in various entrapment syndromes; at least one has been described for every nerve in the upper extremity (57) (Fig. 56-8 and Fig. 56-9). Entrapment syndromes usually present with local pain at the site of compression. The pain can radiate both proximally and distally. Depending on the nerve involved, sensory, motor, or sympathetic changes can occur in the distal territory of the nerve. Pain can also occur in the sensory field of the nerve. The various entrapment syndromes for the cervicobrachial region are contained in Table 56-3. The possibility of entrapment at more than one site must be kept in mind (58).

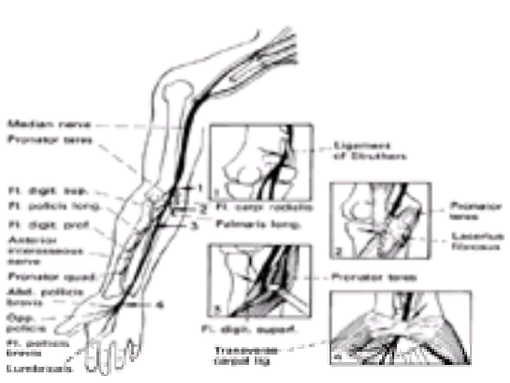

Figure 56-8. Entrapment syndromes involving the median nerve. **1:** Entrapment of the nerve above the elbow as it passes behind the supracondylar process and through the opening created by the ligament of Struthers. **2:** Entrapment by the lacertus fibrosus (bicipital aponeurosis) through its passage between or under the pronator teres. **3:** Entrapment of the anterior interosseous branch of the median nerve deep to the pronator teres and in relation with the flexor digitorum superficialis, flexor digitorum profundus, and flexor pollicis longus. Hypertrophy of any of these can entrap the anterior interosseous nerve. **4:** Carpal tunnel syndrome. Each of these syndromes produces local pain, radiating pain, or both, sensory changes, and weakness or loss of function of the muscles supplied by the nerve distal to the entrapment. See Chapter 59 for more details. (Developed by Bonica JJ, Domenowske M, from information in Dawson DM, Hallett M, Millender LH. *Entrapment neuropathy*. Boston: Little, Brown, 1983.)

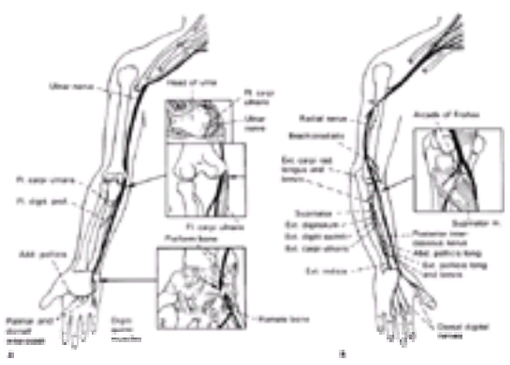

Figure 56-9. **A:** Entrapment syndromes of the ulnar nerve. **1:** Entrapment in the cubital fossa at the elbow either as a result of injury (fracture, subluxation) or through hypertrophy of the flexor carpi ulnaris. **2:** Entrapment of the ulnar nerve in Guyon's canal at the wrist. **B:** Entrapment syndromes of the radial nerve. This can occur high near the axilla to produce *Saturday night palsy* or can involve the posterior interosseous nerve after it enters the supinator muscle under the arcade of Frohse, where it can be compressed by hypertrophied muscle or tumors, ganglia, or synovitis. See Chapter 59 for more details. (Developed by Bonica JJ, Domenowske M, from information in Dawson DM, Hallett M, Millender LH. *Entrapment neuropathy*. Boston: Little, Brown and Company, 1983.)

TABLE 56-3. Upper extremity entrapment syndromes

Treatment

The management of entrapment syndromes involves attempting to decompress the nerve at its point of constriction. Sometimes this can be accomplished by physical means, such as a sling or wrist splint. Some patients have reported relief from perineural injection of corticosteroid solutions. Nerve blocks can help to localize the lesion, but they are rarely therapeutic. Often, however, surgical decompression is the most effective means of relieving the symptoms and of preventing further damage to the nerve.

Neoplasms

Tumors of the peripheral nerves in the upper extremity can present with pain, both locally and referred into the sensory distribution of the nerve (59). Varying amounts of motor and sensory loss can be found; the findings are usually gradually progressive. These are most often slowly growing benign lesions. Treatment entails surgical excision of the mass with repair of the nerve as required. Benign tumors can also arise adjacent to a nerve and can lead to a compression neuropathy.

CHAPTER 57

Musculoskeletal Upper Limb Pains

Barry Goldstein

Musculoskeletal disorders of the upper limb constitute the most frequent cause of pain and disability involving this region of the body. These disorders represent a continuum from a rotator cuff tear, which has both relatively clear diagnostic criteria and pathophysiology, to peritendinitis of the forearm, which is defined primarily by the specific location of pain and has a pathophysiology that is less well defined. From a clinical and epidemiologic perspective, some of these upper limb disorders present challenges similar to those of low back pain.

This chapter contains two sections. First, the anatomy, physiology, and biomechanics of the upper limb are described. This section is presented in a regional manner with a particular focus on musculoskeletal and nervous structures. Regions of the limb are organized into joints (e.g., sternoclavicular, glenohumeral, elbow, wrist) or limb segments (arm, forearm, and hand). There is a particular emphasis on function and clinically relevant topics. Second, there is a section on the clinical application of this material. General principles are provided rather than a comprehensive regional approach to upper limb problems. A detailed discussion of shoulder, arm, and elbow pain follows in Chapter 58 and forearm, wrist, and hand pain in Chapter 59.

ANATOMY

Shoulder

Pectoral Girdle

All vertebrates have limbs that are connected to the axial skeleton by way of a limb girdle. The human pelvic and pectoral girdles are designed in a way that reflects the overall function of the respective limb. In contrast with the lower limb, with its weight- bearing and locomotive functions, the pectoral girdle is built for mobility and does not have a bony junction with the vertebral column at all. Rather, the girdle articulates with the thoracic cage at the sternoclavicular joint, thereby permitting a wide range of motion for placement of the hand.

The pectoral girdle consists of two bones (scapula and clavicle), two synovial joints (sternoclavicular and acromioclavicular), and two movement interfaces (scapulothoracic and humeroacromial). The humeroacromial interface is discussed with the glenohumeral joint.

Clavicle. The S-shaped clavicle is a long bone, superficial and horizontal throughout most of its course. The medial two- thirds is rounded and convex forward to clear the neurovascular bundle of the upper limb at the apex of the axilla. Its sternal end is expanded and fits into the notch on the manubrium at the sternoclavicular joint. The lateral one-third is flat and its sternal end is expanded as it curves back to meet the scapula at the acromioclavicular joint (Fig. 57-1).

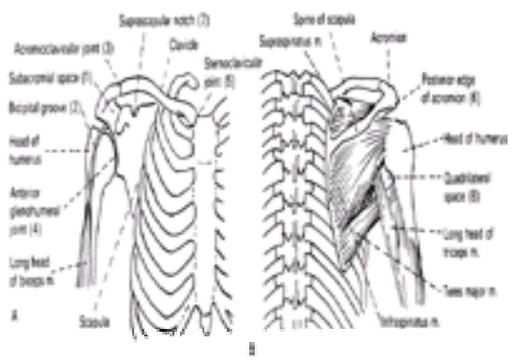

Figure 57-1. Anterior **(A)** and posterior **(B)** views of the shoulder identifying the various bones and joints and also the sites of pathologic processes that produce pain and tenderness. (1) Subacromial space, which can be involved with calcific tendinitis, rotator cuff tendinitis and impingement syndrome, and rotator cuff tear; (2) bicipital groove, which can be involved in bicipital tendinitis and biceps tendon subluxation and tear; (3) acromioclavicular joint, which can be involved with degenerative and infectious processes; (4) anterior glenohumeral joint, which can be the site of glenohumeral arthritis, osteonecrosis, glenoid labial tears, and adhesive capsulitis; (5) sternoclavicular joint, which can be the site of pain caused by infection, degenerative changes, or trauma; (6) posterior edge of the acromion, which can contribute to rotator cuff tendinitis, calcific tendinitis, and rotator cuff tear; (7) suprascapular notch, which can be the site of suprascapular nerve entrapment; and (8) quadrilateral space, which can be the site of axillary nerve entrapment.

Scapula. The scapula, or shoulder blade, is a remarkably thin, triangular bone that is attached to the thorax via muscular attachments and to the clavicle by way of the acromioclavicular joint (see Fig. 57-1). It possesses three borders and three angles. The three borders are the superior, medial (vertebral), and lateral (axillary). The three angles are the superior, inferior, and lateral. The scapula has costal (anterior) and posterior surfaces with its anterior surface in contact with the thoracic cage. From the upper part of the posterior surface, the spine of the scapula projects laterally, terminating in the acromion, which forms the lateralmost tip of the shoulder.

The lateral angle of the scapula is thick and strong, with an expanded large, shallow glenoid fossa, facing slightly forward and upward, ready to receive the head of the humerus. Just medial to the glenoid fossa is the coracoid process as it projects upward from the neck of the scapula. The coracoid process serves as an attachment site for several important ligaments and muscles.

Sternoclavicular Joint. The only bony articulation between the upper limb and axial skeleton occurs between the clavicle and the manubrium at the sternoclavicular joint. The entire pectoral girdle moves about the clavicle braced on the thorax at this saddle- shaped joint. The medial end of the clavicle is concave and fits over the convexity of the much larger sternocostal surface (Fig. 57-2). An articular disk between the sternum and clavicle divides the joint into two spaces and provides a greater congruence of surfaces than the bony articulation alone.

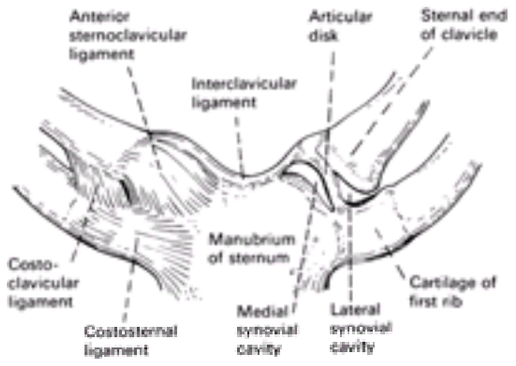

Figure 57-2. Anatomy of the sternoclavicular joints viewed from the front. (Adapted from Clement CD. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:366–367.)

Stability of the joint is provided by a strong, lax capsule and is enhanced by ligaments superiorly (interclavicular ligament) and posteriorly (posterior sternoclavicular ligament). The major stabilizing factor of the sternoclavicular joint is the strong costoclavicular ligament, attached from the first rib to the undersurface of the clavicle (see Fig. 57-2). This ligament limits elevation and rotation of the clavicle. It also serves as the fulcrum of movements at the sternoclavicular joint. The joint is weakest anteriorly where dislocation tends to occur (although dislocation is rare) and an effusion (e.g., infection) tends to point.

Acromioclavicular Joint. The overriding lateral end of the clavicle meets the medial border of the acromion at the acromioclavicular joint, a small, flat joint of the plane variety. The *step-off* between the two bones is often appreciated on physical examination. The joint capsule is lax and not very strong. It is strengthened superiorly by the acromioclavicular ligament, a quadrilateral band of parallel fibers extending between the acromial end of the clavicle and the adjoining part of the acromion. The major stabilizing structure at this joint is the unyielding coracoclavicular ligament (Fig. 57-3). The conoid portion of this ligament is fan- shaped, with its apex lying inferiorly, and lies in the frontal plane. It is attached from the *elbow* of the coracoid process to the apex of the posterior arc of the distal clavicle and serves as a vertical axis for scapular rotation. The trapezoid portion inserts into the medial border of the upper surface of the coracoid process and runs superiorly and laterally. It has a more horizontal course and attaches from the upper aspect of the coracoid to the clavicle. The trapezoid ligament serves as a hinge for scapular motion about a horizontal axis. A fall on the point of the shoulder may cause partial or complete disruption of the coracoclavicular ligament, resulting in separation of the acromioclavicular joint.

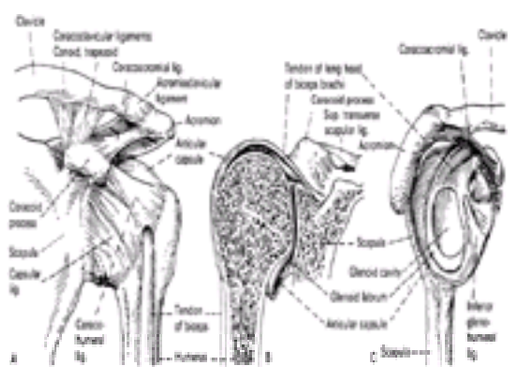

Figure 57-3. Anatomy of the shoulder joint. **A:** Anterior view of ligaments of the left shoulder. **B:** Coronal section through the head of the left humerus and shoulder joint, anterior half viewed from behind. **C:** Interior of the right shoulder viewed from its lateral aspect. (Adapted from Clement CD. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:368–372.)

Scapulothoracic Interface. Scapulothoracic movements are of a gliding nature and occur at an interface between the ventral surface of the scapula and the rib cage. The contacting surfaces involve the subscapularis and bare areas of the scapula with the serratus anterior overlying the second through the seventh ribs. Although the scapula is without bony or ligamentous connections with the thorax, numerous muscles hold the scapula in close opposition to the chest wall (e.g., serratus anterior, trapezius, rhomboids). Normally, the scapula is set obliquely on the thorax at an angle of 30 degrees, open anterolaterally, and moves along a curved thoracic surface during protraction and retraction (Fig. 57-4).

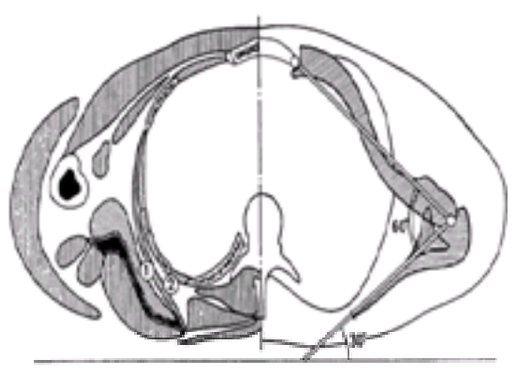

Figure 57-4. In the left half of this horizontal section through the thorax, the space between the scapula and serratus anterior is seen at (1). The space between the thoracic wall and serratus anterior is seen at (2). The right half of the section shows that the scapula runs obliquely, forming an angle of 30 degrees with the frontal plane. The clavicle also runs obliquely, forming an angle of 60 degrees with the scapula. (Reprinted from Kapandji IA. *The physiology of the joints*, 5th ed. Vol 1: Upper limb. Edinburgh, UK: Churchill Livingstone, 1982:39, with permission.)

Movements. Movements of the pectoral girdle include elevation-depression, protraction-retraction, and upward-downward rotation (Fig. 57-5 and Table 57-1). The fulcrum of movements is through the costoclavicular ligament. As the lateral end of the clavicle moves, the medial end moves in the opposite direction. During elevation, for example, the scapula and lateral extremity of the clavicle are raised, while the medial aspect of the clavicle slides inferiorly. During depression, the scapula and lateral aspect of the clavicle are depressed and the medial part of the clavicle is raised. Crutch walking is a good example of an activity in which active depression of the pectoral girdle occurs. Protraction, a movement that occurs during pushing activities, involves forward movement of the scapula and lateral clavicle and is accompanied by retraction of the medial clavicle.

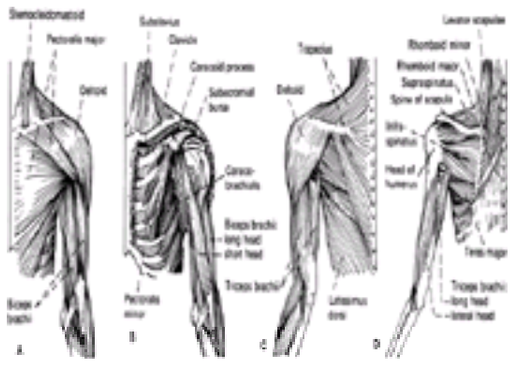

Figure 57-5. The muscles of the shoulder girdle and arm. Anterior views showing the superficial muscles **(A)** and deep muscles **(B)**. Posterior views showing the superficial muscles **(C)** and deep muscles **(D)**.

Elevation	Trapezius (upper fibers)
	Rhomboids
	Levator scapulae
Depression	Latissimus dorsi
	Pectoralis major (costal fibers)
	Trapezius (lower fibers)
Protraction	Serratus anterior
	Pectoralis minor
	Pectoralis major
Retraction	Trapezius
	Rhomboids
Upward rotation	Trapezius
	Serratus anterior
Downward rotation	Rhomboids

TABLE 57-1. Prime movers of the pectoral girdle

Rotation of the pectoral girdle occurs with movements of the shoulder above the horizontal plane. Both the clavicle and scapula rotate. Upward rotation of the scapula (the glenoid cavity moves superiorly) is required for full abduction and forward flexion of the shoulder (Fig. 57-6). The prime movers are the trapezius (upper and lower fibers) and serratus anterior. Axial rotation of the clavicle follows this movement passively once the capsule and ligaments of the acromioclavicular joint are put on tension. Downward rotation of the pectoral girdle is usually passive and assisted by gravity.

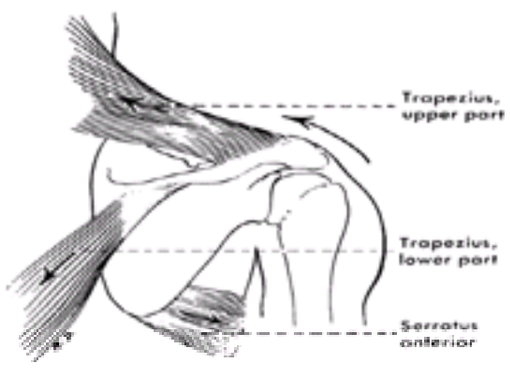

Figure 57-6. The muscles that rotate the scapula upward during abduction of the arm. Note that the upper part of the trapezius, which is attached to the outer part of the scapular spine, pulls upward, and that the lower part of the serratus anterior, attached to the lower part of the scapula, pulls the inferior angle laterally, while the lower portion of the trapezius, attached to the medial part of the scapular spine, pulls downward. (From Rosse C, Gaddum- Rosse P. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:235, with permission.)

Glenohumeral Joint

The glenohumeral joint is a synovial joint of the ball-and-socket type, linking the free limb through the ball (head of the humerus) to the socket of the pectoral girdle (glenoid cavity of the scapula). The head of the humerus is approximately one-third of a sphere, and it is much larger than the socket on the scapula by approximately four times. In anatomic position, the head faces superiorly, medially, and posteriorly with the lesser tuberosity in front and the greater tuberosity pointing laterally (Fig. 57-7). The rotator cuff muscles attach to the tuberosities.

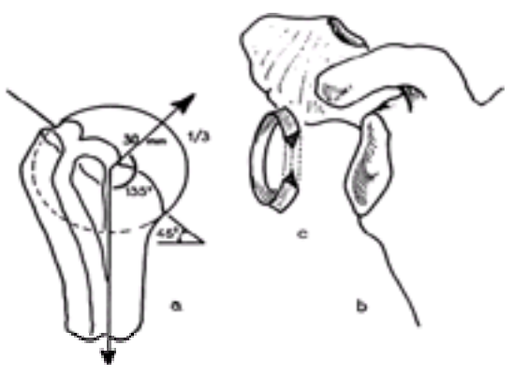

Figure 57-7. **A:** Head of humerus. **B:** Glenoid cavity of scapula. **C:** Glenoid labrum. The articular surfaces of the glenohumeral joint are typical of a ball- and-socket joint, which has three axes and three degrees of freedom. The head of the humerus faces superiorly, medially, and posteriorly. It corresponds to a third of a sphere 3 cm in radius. Its axis forms with the axis of the shaft an angle of 135 degrees and with the frontal plane an angle of 30 degrees. It is separated from the rest of the superior epiphysis of the humerus by the anatomic neck, which makes an angle of 45 degrees with the horizontal plane. The glenoid cavity of the scapula lies at the superolateral angle of the scapula and points laterally, anteriorly, and slightly superiorly. The glenoid cavity is much smaller than the head of the humerus but is deepened by a ring of fibrocartilage, the glenoid labrum. This is attached to the margin of the glenoid cavity and deepens it appreciably so as to make the articular surfaces more congruent. (From Kapandji IA. *The physiology of the joints*, 5th ed. Vol 1: Upper limb. Edinburgh, UK: Churchill Livingstone, 1982:23, with permission.)

The margin of the shallow, pear-shaped glenoid cavity is slightly raised and attaches to a ring of fibrocartilage, the glenoid labrum (see Fig. 57-7). The labrum deepens the socket significantly and is an important factor in the overall stability of the joint. Two small tubercles above and below the cavity (supraglenoid and

infraglenoid) serve as attachments for the long head of the biceps and triceps, respectively.

The capsule of the joint is thick and strong but lax, especially inferiorly, to allow great range of movement (see Fig. 57-3). It is attached to the humerus around the articular margins of the head except inferiorly, where its attachment is to the surgical neck, thus enclosing a portion of the epiphyseal line. The capsule then encompasses the joint completely and is attached to the scapula just beyond the glenoid labrum. With the arm hanging loosely at the side, there is a loose recess inferiorly, sometimes called the axillary fold, to allow space for the head of the humerus during full abduction (see Fig. 57-3). Conditions in which there are contractures or fibrosis of the capsule result in restriction of glenohumeral motion.

Thickenings of the anterior capsule are specified (superior, middle, and inferior glenohumeral ligaments) and strengthen the anterior and inferior capsule. The coracohumeral ligament attaches from the coracoid process to both of the tuberosities (anterior band to the lesser and posterior band to the greater tuberosity). These bands are quite strong and limit extension and flexion, respectively. The capsule and ligaments are a significant stabilizing factor at the end ranges of motion. Deficiencies in these ligaments are important in the development of instability.

The coracoacromial ligament extends from the undersurface of the acromion to the coracoid process (see Fig. 57-3). Along with the acromion and the coracoid process, it acts as a large articulating surface for the head of the humerus. The subacromial and subdeltoid bursae lie between the rotator cuff tendons and the arch. This structure has been implicated in shoulder impingement.

The synovial membrane lines the capsule and is in continuity (through the foramen of Weitbrecht in the anterior aspect of the capsule) with the subscapularis bursa. Synovium also invests the long head of the biceps as it courses beneath the transverse ligament, the latter being a thickened part of the capsule that bridges the gap from the greater to lesser tuberosity (e.g., over the upper end of the bicipital groove). The synovial cavity does not normally communicate with the subacromial bursa.

Humeroacromial Interface. The humeroacromial or subdeltoid interface is between the coracoacromial arch and the head of the humerus. The significance of this interface in the healthy shoulder is uncertain and its physiologic role during normal shoulder motion is still debated. There has been speculation that abduction of the internally rotated shoulder may result in mechanical impingement between the humeral head and overhanging arch.

The humerus is in contact with the coracoacromial arch when there is upward displacement of the humeral head (e.g., rotator cuff weakness, tears, or both) (Fig. 57-8). Compression of the supraspinatus tendon and bursa results in progressive injury of the rotator cuff. Furthermore, in the setting of large rotator cuff tears, the coracoacromial arch provides superior stability to the humeral head. Acromioplasty may result in superior instability during abduction activities.

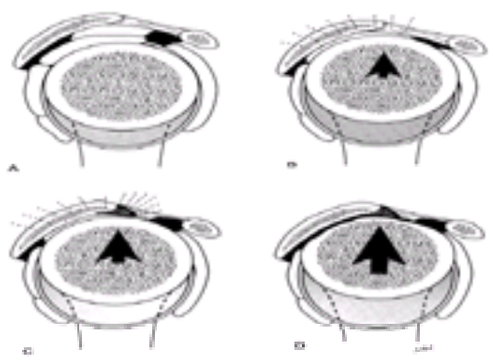

Figure 57-8. With progressive cuff fiber failure, the head moves upward against the coracoacromial arch. **A:** Normal relationships of the cuff and the coracoacromial arch. **B:** Upward displacement of the head, squeezing the cuff against the acromion and the coracoacromial ligament. **C:** Greater contact and abrasion, giving rise to a traction spur in the coracoacromial ligament. **D:** Still greater upward displacement, resulting in abrasion of the humeral articular cartilage and cuff tear arthropathy. (From Matsen FA. *Practical evaluation and management of the shoulder*. Philadelphia: Saunders, 1994:123, with permission.)

Mobility versus Stability. Full range of shoulder movement includes motion of both the glenohumeral joint and the pectoral girdle. At the glenohumeral joint, the ball and socket configuration allows relatively free movements of flexion -extension, abduction-adduction, and medial-lateral rotation. The prime movers are listed in Table 57-2 (Fig. 57-9).

Flexion	Pectoralis major (clavicular head)
	Deltoid (anterior fibers)
Extension	Latissimus dorsi
	Deltoid (posterior fibers)
Internal rotation	Pectoralis major
	Latissimus dorsi
	Teres major
	Subscapularis
External rotation	Infraspinatus
	Teres minor
	Deltoid (posterior fibers)
Abduction	Deltoid
	Supraspinatus
Adduction	Pectoralis major
	Latissimus dorsi
	Teres major
	Subscapularis

TABLE 57-2. Prime movers of the glenohumeral joint

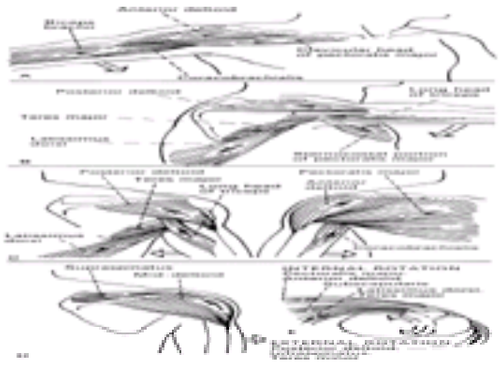

Figure 57-9. Muscles that move the shoulder and arm: flexors **(A)**, extensors **(B)**, adductors **(C)**, abductors **(D)**, and rotators **(E)**. (Adapted from Hollinshead WH. *Anatomy for surgeons*, 3rd ed. Vol 3: The back and limbs. New York: Harper & Row, 1982:325–330.)

Raising the arm above the head into flexion or abduction is brought about by a combined action at the glenohumeral joint and of the pectoral girdle. Abduction without any girdle movement is limited to approximately 90 degrees. This is because there is no further articular surface on the humeral head. Further abduction is made possible by way of external rotation of the humerus, thus providing further articulating surface.

There is also further abduction provided by upward rotation of the pectoral girdle. Of every 15 degrees of abduction of the arm, 10 degrees occurs at the glenohumeral joint and 5 degrees from upward rotation of the girdle. This 2:1 ratio of humerus to scapula exists throughout the entire range in a smooth, rhythmic pattern. The abduction or elevation of the arm overhead (180 degrees) requires 60 degrees of scapular rotation to alter the angle of the glenoid fossa on which the humerus articulates (Fig. 57-10).

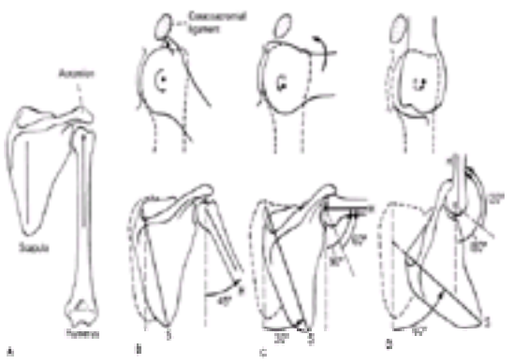

Figure 57-10. Biomechanics of the glenohumeral movements of arm abduction. **A:** Normal position of the head and shaft of the humerus (H). The circle in the head of the humerus indicates the center of rotation. **B:** Humerus abducted 45 degrees and the scapula (S) beginning upward rotation. The upper panel shows that the incongruity of the articulating surface of the head of the humerus, and the surface of the glenoid cavity causes the greater tuberosity of the humerus to impinge on the coracoacromial ligament. The upper panel in **C** shows that to allow the greater tuberosity to pass under the coracoacromial hood during arm abduction, the humeral head is depressed (depicted by downward movement of the center of rotation) and the humeral head rotated (*thin arrow*). The abduction movement of the arm is accomplished in a smooth coordinated movement during which for each 15 degrees of arm abduction, 10 degrees of motion occurs at the glenohumeral joint and 5 degrees occurs because of scapular rotation on the thorax. Thus, as noted in **C**, abduction of the arm to 90 degrees is accomplished by 60 degrees' rotation of the humerus and 30 degrees' rotation of the scapula. Full abduction of the arm, as shown in **D**, is accomplished by 120 degrees of rotation at the glenohumeral joint and 60 degrees rotation of the scapula. (Modified from Cailliet R. *Shoulder pain*, 2nd ed. Philadelphia: FA Davis, 1981.)

As compared with the hip, the shoulder is seen as a remarkably mobile but inherently unstable structure. Although this is undoubtedly true, stability of the shoulder is often underrated. Many individuals with a spinal cord injury live for several decades (some World War II veterans are now in their 80s and have been living with a spinal cord injury for more than 50 years), using their upper extremities for support, reaching, and wheelchair mobility without stability problems.

End-range stability is quite different than midrange stability. Three factors are important in end-range stability: bony, ligamentous, and muscular. Although not the major factor, bony factors at the shoulder are significant; the size and shape of the glenoid fossa is especially important. Furthermore, the integrity of the glenoid labrum is essential in enhancing bony surface congruity. Ligamentous factors, including the articular capsule, are critically important for end-range stability (see Fig. 57-3). These dense connective tissues act as check reins at the limits of motion. Muscles that connect to the humerus also limit motion and provide end-range stability.

Different mechanisms provide midrange stability, principally coaptation of the articular surfaces and glenohumeral balance. Coaptation of the articular surfaces keeps the head of the humerus pressed against the glenoid cavity. The rotator cuff muscles are important in this role and act as dynamic ligaments, shortening and compressing the glenohumeral joint regardless of the position of the shoulder (Fig. 57-11).

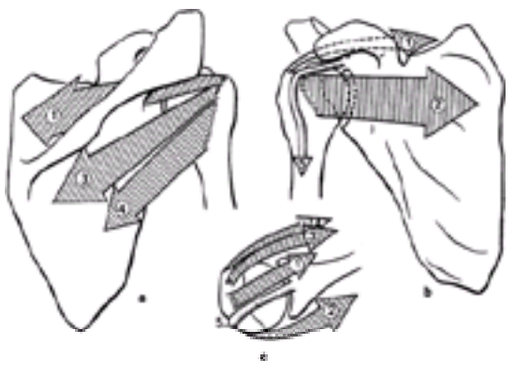

Figure 57-11. Scapula as seen from behind **(A)**, front **(B)**, and above **(C)**. Short, periarticular muscles run transversely across the joint, providing dynamic stability to the joint in all positions by pressing the humeral head against the glenoid cavity. Five muscles are illustrated in these figures as follows: supraspinatus (1), subscapularis (2), infraspinatus (3), teres minor (4), and the long head of the biceps (5). (Reprinted with permission from Kapandji IA. *The physiology of the joints*, 5th ed. Vol 1: Upper limb. Edinburgh, UK: Churchill Livingstone, 1982:35.)

Glenohumeral balance is the process in which the glenohumeral joint is positioned in space for maximal stability. This primarily involves positioning the scapula so the net humeral joint reaction force is aligned with the center of the glenoid cavity (Fig. 57-12). Both of these processes are dynamic and can be fortified by strengthening the rotator cuff muscles in the first case and scapular muscles in the second. A rotator cuff tear illustrates the importance of this mechanism. The rotator cuff muscles consist of the supraspinatus, infraspinatus, teres minor, and subscapularis. Tendons of the first three muscles insert onto the greater tuberosity, whereas the subscapularis tendon inserts on the lesser tuberosity (see Fig. 57-5). The tendons are broad and insert into the capsule of the glenohumeral joint, thus providing a strong conjoined tendon-capsule. Although the rotator cuff muscles are not as strong as many of the shoulder muscles (e.g., deltoid, pectoralis major, latissimus dorsi), their insertion into a continuous cuff around the humeral head permits stabilization of the glenohumeral joint in almost any position. Tears of the rotator cuff result in weakness of the shoulder because the shoulder joint cannot be stabilized for other stronger prime movers.

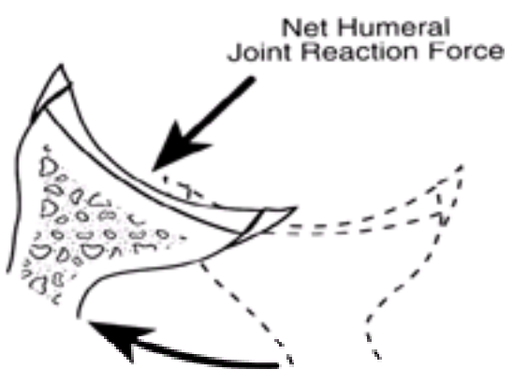

Figure 57-12. Glenohumeral balance is a stabilizing mechanism in which the glenoid is positioned so that the net humeral joint reaction force passes through the glenoid fossa. (From Matsen FA. *Practical evaluation and management of the shoulder.* Philadelphia: Saunders, 1994:62, with permission.)

Arm and Elbow

Arm

The arm consists of flexor and extensor compartments. The flexor compartment consists of the neurovascular bundle from the axilla and three muscles that are innervated by the musculocutaneous nerve (branch of the lateral cord; major segments are C-5 and C-6).

Flexor Compartment. As in the thigh, part of the flexor compartment is occupied by adductor musculature. The coracobrachialis, a muscle that is functionally and clinically unimportant, is the last vestige of adductors in the upper limb. The other powerful adductor muscles have migrated to the thorax, thereby providing great strength yet allowing substantial freedom of movement at the shoulder. Biceps brachii and brachialis are powerful flexors of the elbow (Fig. 57-13). In addition, the biceps is the major supinator of the forearm.

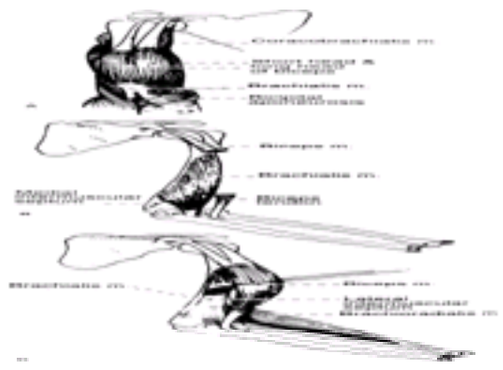

Figure 57-13. Flexor muscles of the elbow from **(A)** an anterior view; **(B)** with the bulk of the biceps resected; and **(C)** with the bulk of the brachialis resected. (From Rosse C, Gaddum-Rosse P. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:252, with permission.)

The biceps is a common source of pain. The long head of this muscle arises as a rounded tendon from the supraglenoid tubercle and passes through the shoulder joint capsule. It invaginates into the synovium until a sleeve of synovial membrane surrounds it. Thus, the tendon is intracapsular yet remains extrasynovial. On leaving the joint, the biceps tendon exits the capsule at the level of the transverse ligament between the humeral tuberosities and descends in the intertubercular groove. The short head of the biceps arises from the coracoid process. Each tendon expands into fleshy bellies that lie side by side in the arm and then converge into a flattened tendon that crosses the elbow joint to its insertion into the posterior lip of the bicipital tuberosity of the radius. There is a small bursa (bicipitoradial) between the distal tendon and its insertion.

Extensor Compartment. The extensor compartment of the arm consists of the triceps muscle, a strong extensor of the elbow and weak extensor of the shoulder. This muscle arises by three heads, one from the infraglenoid tubercle of the scapula and two from the humerus. The triceps inserts into the upper surface of the olecranon, the tendon of insertion separated from the olecranon by the subtendinous bursa. Innervation of the triceps is the radial nerve (branch of posterior cord; C-7 and C-8 are the major cord segments).

There is also a bursa between the olecranon and the overlying skin, termed the *olecranon bursa*. It allows the skin to glide freely over the olecranon process. Bursal inflammation around the elbow principally affects this bursa.

Neurovascular Bundle. There is a major neurovascular bundle that passes from the neck into the upper limb in a similar manner as the bundle that passes from the pelvis into the lower limb. The subclavian artery becomes the axillary artery as it passes the first rib and then changes name to the brachial artery at the lower border of the teres major. Rich anastomoses surround the scapula and the proximal humerus, making the upper extremity relatively unaffected by trauma and peripheral vascular disease as compared with the lower. The profunda brachii branch provides the extensor compartment with arterial blood; the brachial artery supplies the flexor compartment. Infrequently, there is a small fibrous band in the distal arm, attached from an anomalous supratrochlear spur to the medial epicondyle (ligament of Struthers), under which the brachial artery and median nerve may pass. Compression of the artery, nerve, or both might result.

Several major nerves enter the arm. Their origins are discussed in Nerve Supply of the Upper Extremity, later in this chapter. The radial nerve is the continuation of the posterior cord of the brachial plexus. As it leaves the axilla, the nerve enters the posterior compartment of the arm and lies on the proximal fibers of the medial head of the triceps in the radial groove. After innervating the triceps, it continues down through the arm and emerges through the lateral intermuscular septum in the distal arm. Here it lies between the brachialis and brachioradialis; its superficial branch is sensory and continues down the forearm as the superficial radial nerve. Its deep branch pierces supinator and becomes the posterior interosseous nerve.

The musculocutaneous nerve enters the arm by piercing the coracobrachialis and then supplies all three muscles of the flexor compartment. It emerges at the distal lateral arm and continues as the lateral antebrachial cutaneous nerve. A large branch from the medial cord and lateral cords of the brachial plexus join together to form the median nerve. It passes through the arm providing no branches until the elbow and forearm and is described in the following section. Similarly, the ulnar nerve does not innervate any structures in the arm. In the middle of the arm, the ulnar nerve pierces the medial intermuscular septum and descends in front of the medial head of the triceps. A thin aponeurotic band, the arcade of Struthers, extends from the medial head of the triceps to the medial intermuscular septum. The ulnar nerve passes under the arcade of Struthers and is occasionally entrapped at this site. In the distal arm, the ulnar nerve enters the cubital tunnel from the posterior compartment. Two cutaneous nerves traverse the arm. The medial cutaneous nerve of the arm (also known as *medial brachial cutaneous*) is subcutaneous and supplies the skin of the medial arm. The medial cutaneous nerve of the forearm (also known as medial antebrachial cutaneous) crosses the elbow anteriorly and enters the forearm to supply sensory innervation to the medial forearm as far distal as the wrist.

In crossing the elbow, each of the three major nerves of the forearm passes through two heads of a muscle as follows: median nerve through pronator teres, ulnar nerve through flexor carpi ulnaris, and radial nerve through supinator.

These sites are potential entrapment points of the nerve and are discussed in Localized Nerve Lesions, later in this chapter.

Elbow

The elbow is the joint of the upper limb that constitutes the mechanical link between the arm and forearm. As the shoulder positions the limb in space, the elbow allows the forearm to place the hand at any distance from the body. The elbow joint is of the hinge variety, between the humerus above with radius and ulna below, allowing 160-degree flexion-extension of the forearm. The articulating surfaces provide great stability to the joint. The distal end of the humerus has two articular surfaces, the pulley-shaped trochlea and the spherical capitulum (Fig. 57-14). The proximal ends of the two forearm bones have surfaces corresponding in shape to those of the humerus. Medially, the trochlear notch of the ulna articulates with the trochlea. It consists of a curved surface and ridge between two projections, the coronoid process anteriorly and the olecranon posteriorly. Laterally, the proximal end of the radius is shaped like a cup with a concavity that fits into the capitulum. Above the articular surfaces there are two humeral concavities. The anterior coronoid fossa receives the coronoid process of the ulna in full flexion and the posterior olecranon fossa receives the olecranon during extension (Fig. 57-15).

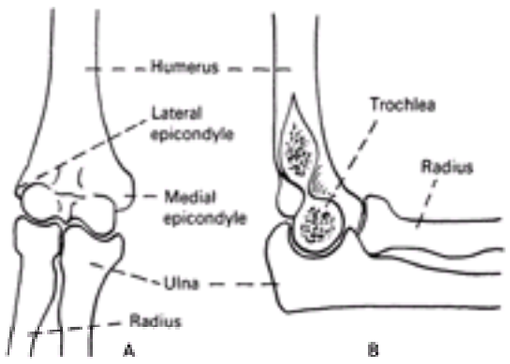

Figure 57-14. **A,B:** The bones of the elbow joint. (Modified from Matsen FA III. Biomechanics of the elbow. In: Frankel VH, Nordin M, eds. *Basic biomechanics of the skeletal system*. Philadelphia: Lea & Febiger, 1980:243–253.)

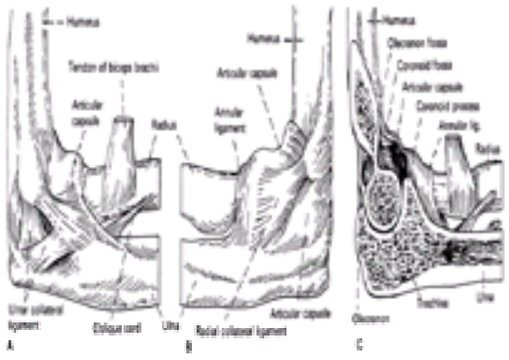

Figure 57-15. **A,B,C:** The ligaments of the elbow joints. (Modified from Clement CD. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:375–382.)

The capsule of the joint is relatively thin, enclosing both the elbow joint and the superior radioulnar joints. Attachments of the capsule surround the anterior and posterior fossae, but do not enclose the humeral epicondyles. Strong collateral ligaments act as stays located on the medial and lateral side of the joint and are named correspondingly, the medial (ulnar) and lateral (radial) collateral ligaments (see Fig. 57-15).

Synovium lines the capsule and is attached to the articular margins of all three bones. The membrane is reflected over the inner surface of the capsule and covers the fat pads within the anterior and olecranon fossae. Synovium also lines the gap between the proximal ulna and radius.

Movements

The range of active flexion is approximately 145 degrees, limited by apposition of the soft tissues. Extension is limited first by soft tissues (anterior capsule and flexor muscles) followed by the impact of the olecranon process on the olecranon fossa. The prime movers for flexion are brachialis, biceps brachii, and brachioradialis, although biceps is used when power is required. Accessory flexors include those muscles that arise from the medial epicondyle. The flexor muscles are at their optimal length and power when the elbow is at 90 degrees. The prime mover for extension is the triceps. Because the only prime mover is a biarticular muscle (unlike the flexors), the efficiency of the triceps depends in part on the position of the shoulder. Flexion of the shoulder lengthens the long head of the triceps and enhances its power. Weak accessory muscles arise from the lateral epicondyle (anconeus and supinator and the muscles that arise from the lateral epicondyle) but are thought to be functionally insignificant.

Nerve Supply

The musculocutaneous, median, ulnar, and radial nerves innervate the joint.

Forearm and Wrist

Forearm

The forearm consists of 20 muscles, found within a flexor and extensor compartment, which act across several joints (e.g., elbow, superior radioulnar, inferior radioulnar, wrist, and small joints of the hand). As with the arm, the major neurovascular bundles are found within the flexor compartment.

Flexor Compartment. There are eight muscles in the anterior compartment of the forearm. An easy memory scheme to remember the muscles is 2-2-2-2:

- Two muscles flex the wrist (flexor carpi radialis and ulnaris).
- Two muscles flex the fingers (flexor digitorum superficialis and profundus).
- Two muscles pronate the forearm (pronator teres and quadratus).
- Two muscles are *long* (flexor pollicis *longus* and palmaris *longus*).
- Most of these muscles are innervated by the median nerve except the ulnar nerve innervates flexor carpi ulnaris and the ulnar half of the flexor digitorum profundus (muscle bellies to the ring and little fingers).

The flexor compartment has a superficial, intermediate, and deep layer. In the superficial group, all of the muscles attach to the medial epicondyle and arise from a common flexor tendon. The muscles include pronator teres, flexor carpi radialis, palmaris longus, and flexor carpi ulnaris (Fig. 57-16). Irritation of the common flexor tendon (also known as medial epicondylitis) results from repetitive wrist flexion or pronation activities related to sports, occupation, and performing arts.

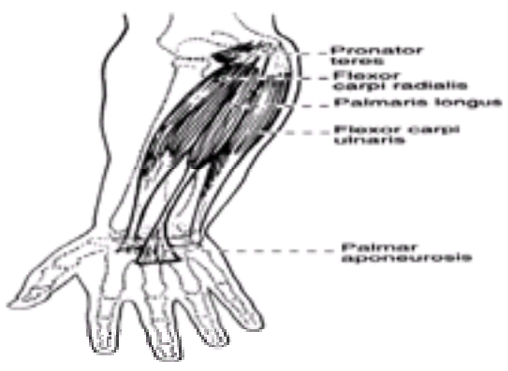

Figure 57-16. The superficial forearm muscles of the flexor compartment consist of pronator teres (cut in this figure), flexor carpi radialis (FCR), palmaris longus, and flexor carpi ulnaris (FCU). With the heel of the hand placed over the opposite medial epicondyle, palm lying on the forearm, the fingers point down along the four superficial and one intermediate muscles: thumb for pronator teres, index for FCR, middle finger tucked beneath the other fingers as the flexor digitorum superficialis, ring finger for palmaris longus, and little finger for FCU. (From Rosse C, Gaddum- Rosse P. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia:

Lippincott–Raven, 1997:260–261, with permission.)

The intermediate layer consists of the flexor digitorum superficialis (Fig. 57-17). Its origin is from the common flexor origin, proximal ulna (coronoid process), and proximal radius. There is a fibrous arch that stretches from the ulna to the radius. The median nerve passes behind this fibrous arch and is sometimes entrapped. In the distal third of the forearm, the muscle gives rise to four tendons; two are superficial (middle and ring fingers) and two are deep. A synovial sleeve, termed the *common synovial tendon sheath*, invests all of the long finger flexors (both flexor digitorum superficialis and profundus) as they pass beneath the flexor retinaculum in the carpal tunnel (Fig. 57-18). The tendons then emerge from the common sheath into the palm of the hand and each tendon enters an individual digital synovial sheath. The individual superficialis tendons finally split into two halves and insert onto the middle phalanx (Fig. 57-19).

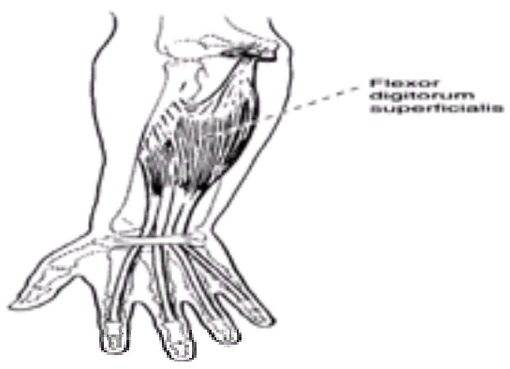

Figure 57-17. The flexor digitorum superficialis arises from the common flexor origin and deeper structures as well (proximal ulna and radius). The muscle gives rise to four tendons that insert onto the middle phalanges. (From Rosse C, Gaddum-Rosse P. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:260–261, with permission.)

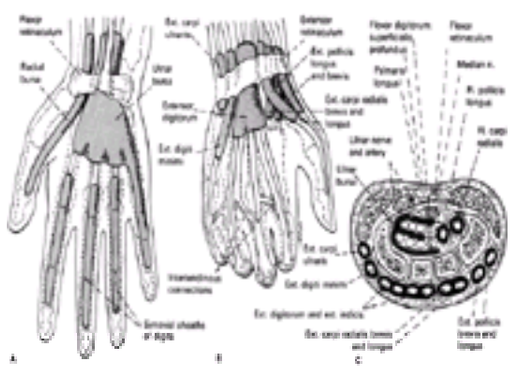

Figure 57-18. **A:** Palmar view of the wrist and hand showing the synovial sheaths of the flexor tendons in the carpal tunnel of the hand. Note the proximal extent of the radial and ulnar bursae in relation to the flexor retinaculum. **B:** Extensor retinaculum with the tendons and their synovial sheaths on the dorsum of the wrist. **C:** Transverse section of the wrist across the carpal tunnel, showing the relationship of the median nerve deep to the flexor retinaculum and superficial to the synovial membranes of the flexors to the wrist and hand. All eight flexor tendons of the fingers share a common sheath (ulnar bursa) **(A,C)**, as do the four tendons of the extensor digitorum on the back of the wrist **(B,C)**. (Adapted from Rosse C, Clawson DK, eds. *The musculoskeletal system in health and disease*. New York: Harper & Row, 1980.)

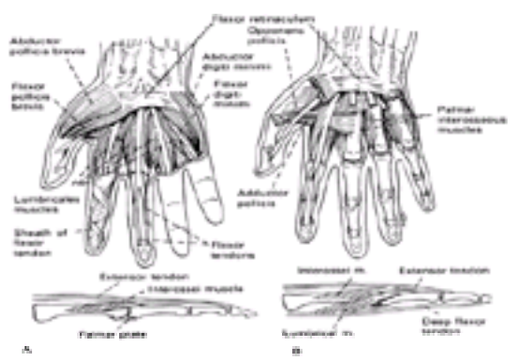

Figure 57-19. **A:** Palmar view of the intrinsic (thenar and hypothenar) muscles of the hand: superficial muscles. The palmar aponeurosis has been removed, and the synovial sheaths of the tendons of extrinsic plexus are not shown. **B:** The deeper intrinsic muscles with the tendons of the extrinsic plexus cut and removed. The lower panels show side view of finger to show the attachments of the interossei **(A,B)** and lumbrical **(B)**. (Modified from Rosse C. The hand. In: Rosse C, Clawson DK, eds. *The musculoskeletal system in health and disease*. New York: Harper & Row, 1980:227–251.)

The deep layer contains three muscles, flexor digitorum profundus, flexor pollicis longus, and pronator quadratus (Fig. 57-20). Flexor digitorum profundus arises from the proximal ulna and interosseous membrane. The muscle gives rise to four tendons, which lie side by side beneath the superficialis tendons. Each tendon passes into the digital synovial sheath immediately beneath its superficialis counterpart. The profundus tendon goes through the split in the superficialis tendon and continues to its insertion on the distal phalanx (see Fig. 57-19). Flexor pollicis longus arises from the radius. The muscle gives rise to a tendon that passes through the carpal tunnel and inserts on the distal phalanx of the thumb. A separate synovial sheath invests the tendon throughout the course from the distal forearm to its insertion (see Fig. 57-18).

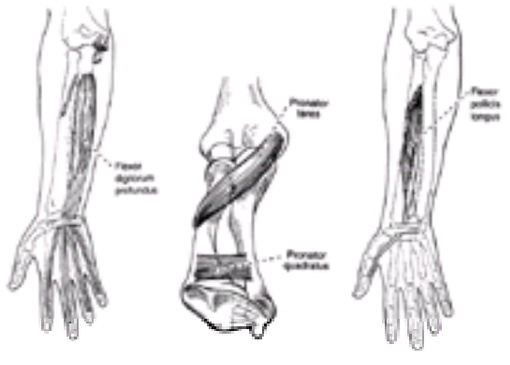

Figure 57-20. The deep layer of the flexor compartment consists of flexor digitorum profundus, flexor pollicis longus, and pronator quadratus. All of these muscles are

innervated by the anterior interosseous nerve. (From Rosse C, Gaddum-Rosse P. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:260–261, with permission.)

Extensor Compartment. There are 12 muscles in the posterior compartment of the forearm. These muscles are best remembered by the scheme 3-3-3-3:

- Three muscles extend the wrist (extensor carpi ulnaris, radialis brevis, and radialis longus).
- Three muscles extend the fingers (extensor digitorum communis, indicis, and digiti minimi).
- Three muscles act on the thumb (abductor pollicis longus, extensor pollicis brevis and longus).
- Three muscles cross the elbow and spell B-A-S (brachioradialis, anconeus, and supinator).

The radial nerve innervates all 12 of the muscles in the extensor compartment. The extensor compartment has a superficial and a deep layer. In the superficial group, the muscles arise from the supracondylar ridge (brachioradialis and extensor carpi radialis longus) and the lateral epicondyle (common extensor tendon) of the humerus (Fig. 57-21). The muscles attaching to the common extensor origin include extensor carpi radialis brevis, extensor digitorum, extensor digiti minimi, and extensor carpi ulnaris. Irritation of the common extensor tendon (also known as lateral epicondylitis) results from repetitive wrist and finger extension.

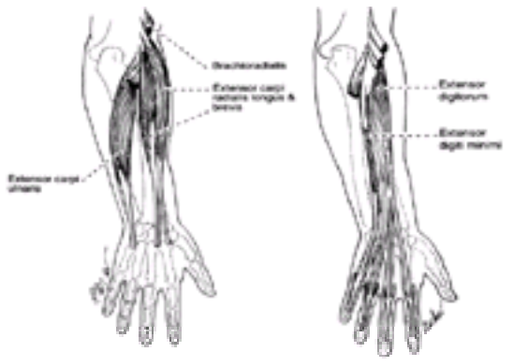

Figure 57-21. The superficial group of extensor muscles of the forearm consist of muscles that arise from the supracondylar ridge (brachioradialis and extensor carpi radialis longus) and the common extensor origin (extensor carpi radialis brevis, extensor digitorum, extensor digiti minimi, and extensor carpi ulnaris). (From Rosse C, Gaddum-Rosse P. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:260–261, with permission.)

Tendons crossing the dorsal wrist are enclosed for part of their course in tenosynovial sheaths (see Fig. 57-18). The extensor tendons pass through six fibroosseous, tenosynovial tunnels beneath the extensor retinaculum. The abductor pollicis longus and extensor pollicis brevis are usually in a single sheath and involved in DeQuervain's stenosing tenosynovitis.

Neurovascular Considerations. Two nerves share in the supply of the flexor compartment: median and ulnar. The median nerve passes through the two heads of pronator teres (also known as pronator passage), supplies all of the superficial and intermediate muscles (except flexor carpi ulnaris), and then passes down the forearm between the long finger flexors. Just distal to the pronator passage, the anterior interosseous nerve branches and enters the deep compartment of the flexor compartment. It innervates all of the deep muscles except the ulnar half of flexor digitorum profundus. Sensory fibers innervate the inferior radioulnar and wrist joints. The ulnar nerve enters the forearm by passing into a space, sometimes called the cubital tunnel, bordered by the olecranon and medial epicondyle and a fibrous sheath between them. It then passes through the two heads of flexor carpi ulnaris and down the forearm between that muscle and the underlying flexor digitorum profundus. It innervates both muscles, although only the ring and little fingers of the latter. Sensory fibers innervate the inferior radioulnar and wrist joints. Unlike the median nerve, the ulnar nerve does not enter the carpal tunnel; it crosses superficial to the flexor retinaculum with the ulnar artery.

While still in the arm, the radial nerve innervates the brachioradialis and extensor carpi radialis longus because both muscles arise from the supracondylar ridge on the humerus. The radial nerve then divides into superficial radial and posterior interosseous nerve in the distal arm. The latter passes through the two heads of supinator and supplies all of the remaining forearm extensors. The superficial radial nerve is entirely sensory at this point and supplies a small area of skin on the dorsum of the hand.

Radioulnar Joints. The radius and ulna are joined by an interosseous membrane and by two synovial joints (superior and inferior radioulnar joint). Supination and pronation, also known as rotation of the forearm, occur between these two bones. Supination-pronation is one of the most important movements in the upper limb because it is essential for the control of hand orientation during work, grasping an object, and activities of daily living (e.g., toileting, grooming, and feeding). In supination-pronation, the radius is the moving bone around a relatively stationary ulna.

Superior Radioulnar Joint. The superior radioulnar joint is of the pivot variety and has one degree of freedom (i.e., rotation between the radius and ulna). The head of the radius and its cylindrical rim are covered by articular cartilage and join with three structures: the capitulum of the humerus, the radial notch of the ulna, and the annular ligament (Fig. 57-22). The superior radioulnar joint communicates with the elbow joint and is included in the same articular capsule. Inferiorly, the quadrate ligament stretches between the neck of the radius and the inferior border of the radial notch on the ulna. Its fibers reinforce the inferior aspect of the elbow joint capsule. The major stabilizing factor of the superior radioulnar joint is the annular ligament, attached to the anterior and posterior margins of the radial notch of the ulna. It surrounds the head of the radius and binds it to the radial notch and also serves as an articular surface in contact with the head of the radius as it rotates during supination and pronation (Fig. 57-23).

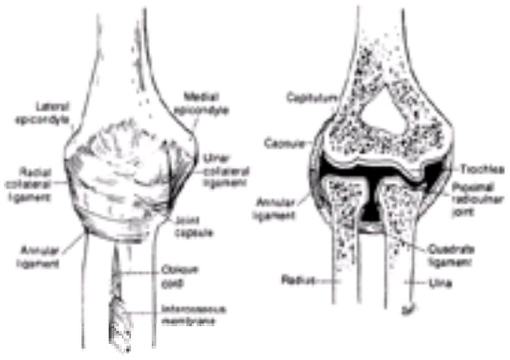

Figure 57-22. The elbow joint: On the left, the joint capsule is shown with its associated ligaments. The coronal section of the joint on the right shows the relation of the proximal radioulnar joint to the elbow. Articular cartilage is shown as an *even white line;* synovial membrane as a *ruffled white line;* synovial fluid is *black.* (From Rosse C, Gaddum-Rosse P. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:297, with permission.)

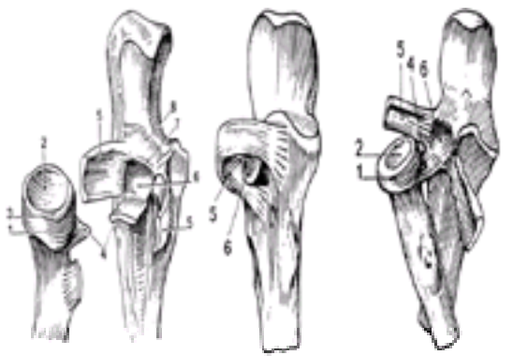

Figure 57-23. The superior radioulnar joint has 1 degree of freedom, rotation between the head of the radius and the radial notch of the ulna. The annular ligament (5) consists of a strong fibrous band attached by its ends to the anterior and posterior margins of the radial notch of the ulna. It surrounds the head of the radius and binds it to the radial notch. The quadrate ligament (4) consists of a fibrous band attached to the inferior border of the radial notch and to the neck of the radius. It reinforces the inferior aspect of the capsule and prevents distraction of the radial head away from the radial notch. Other anatomic features of interest include the following labeled structures: the head of the radius covered by articular cartilage (1); the cupped head of the radius articulating with the capitulum (2); and the radial notch of the ulna (6). (From Kapandji IA. *The physiology of the joints*, 5th ed. Vol 1: Upper limb. Edinburgh, UK: Churchill Livingstone, 1982:107, with permission.)

NERVE SUPPLY. The musculocutaneous, median, ulnar, and radial nerves innervate the joint.

Inferior Radioulnar Joint. The inferior radioulnar joint is also of the pivot variety and lies between the distal ends of the radius and ulna. Three-fourths of the cylindrical portion of the ulnar head articulates with the concave ulnar notch of the radius (Fig. 57-24). An articular disk lies in a horizontal plane at the distal edge of the joint and binds together the distal edge of the radius and the lateral aspect of the ulnar styloid process while allowing rotational displacement of the radius about the stationary ulna (see Fig. 57-24). The disk also separates the inferior radioulnar joint from the wrist joint, although the two joints are enclosed within the same capsule. Its proximal surface is in contact with the distal surface of the ulnar head. Its distal surface faces the carpal bones and is compressed during full adduction of the wrist. The synovial membrane lines the articular disk and the distal ends of the ulna and radius; between the bones, there is a redundant pouch of synovium called the sacciform recess (see Fig. 57-24).

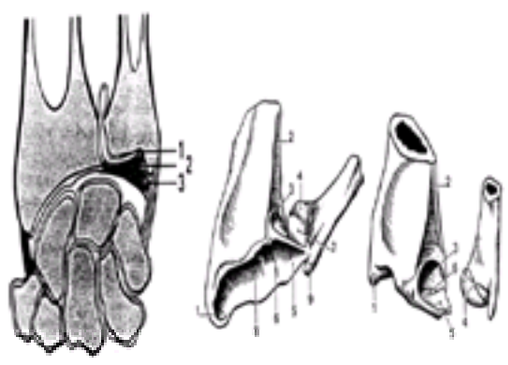

Figure 57-24. Figure at left: The articular disk separates the radio-ulnar joint from the radio-carpal joint. Figures at right and middle: The ulnar notch of the radius (3) faces medially and is concave. It articulates with the cylindrical portion of the ulnar head (4). At its distal edge is inserted the articular disk (5), which lies in a horizontal plane. It fills the gap between the ulnar head, the triquetrum, and acts as an elastic cushion, which is compressed during adduction of the wrist. The articular disk also separates the radioulnar joint from the radiocarpal joint. Other anatomic features of interest in the middle and right figures include the following labeled structures: radial styloid process (1), distal surface of the ulnar head (7), and carpal surface of the radius (8). (From Kapandji IA. *The physiology of the joints*, 5th ed. Vol 1: Upper limb. Edinburgh, UK: Churchill Livingstone, 1982:111, with permission.)

NERVE SUPPLY. The anterior and posterior interosseous nerves innervate the joint.

Wrist

The wrist is the distal joint of the upper limb and allows the hand to assume an optimal position to grasp an object. It is an ellipsoid joint between the distal surface of the radius and the proximal row of carpal bones that allows flexion-extension and adduction-abduction (Fig. 57-25). For most activities, the major articulation is between the radius proximally and the scaphoid and lunate distally. During full adduction of the wrist, the articular disk covering the head of the ulna and the ulnar styloid process articulate with the triquetral and pisiform bones. With flexion and extension some movement also occurs at the midcarpal joint (see Carpal Bones and Intercarpal Joints, later in this chapter).

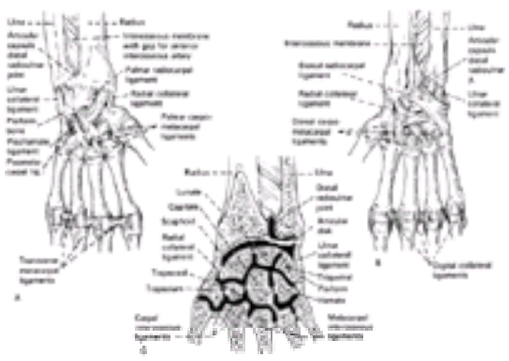

Figure 57-25. The bones and ligaments of the lower part of the forearm and the wrist: palmar view **(A)**, dorsal view **(B)**, and vertical section **(C)** to show the joints and ligaments (see text for details). (Adapted from Clement CD. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:382–383.)

Several ligaments strengthen the capsule of the wrist joint. Strong palmar and dorsal ligaments attach from radius and ulna to corresponding carpal bones (e.g., scaphoid, lunate, and triquetrum) (see Fig. 57-25). The palmar ligaments are particularly important during extension, counteracting the tendency for the carpal bones to be displaced proximally and anteriorly. Synovium lines the joint capsule but does not communicate with the inferior radioulnar joint.

Movements. The range of flexion is 80 degrees and does not quite reach a right angle. The prime movers for flexion include flexor carpi ulnaris, flexor carpi radialis, and palmaris longus. Extension range is slightly less at approximately 75 degrees because of tighter palmar than dorsal ligaments, and performed by extensor carpi ulnaris and extensors carpi radialis longus and brevis. When the wrist is fully flexed or extended, little movement into adduction or abduction is possible. In the neutral position, the range of adduction (45 degrees) is approximately three times that of abduction (15 degrees). The two ulnaris muscles adduct the wrist (flexor and extensor carpi ulnaris), whereas the abductors include the radialis muscles (flexor and extensor carpi radialis longus and brevis), abductor pollicis longus, and

extensor pollicis longus and brevis. True rotation does not occur at the wrist, but circumduction can occur as a combination of the movements described previously.

The position of maximal efficiency and strength for prehension is at 40- to 45-degree wrist extension and slight wrist ulnar deviation (15 degrees). This is the position in which the finger flexors are at their optimal length for a powerful grip. It is also important to observe that the wrist does not move in a direct anatomic plane. Many activities of daily living (e.g., eating) and work-related activities (e.g., hammering) illustrate that movement occurs along an oblique plane from extension combined with radial abduction to flexion combined with ulnar adduction.

Nerve Supply. The ulnar, anterior, and posterior interosseous nerves innervate the joint.

Hand

The human hand is remarkable in that powerful prehension is combined with finely controlled accuracy and sensitive tactile abilities. Free mobility of the thumb and a wide range of opposition, the ability to bring the thumb into contact with each finger, provide the hand with versatile abilities in positioning, grasping, and exploring.

Overall Organization. The skin of the dorsum and palm is quite different. On the dorsum the skin is loose and freely mobile, thus allowing free movement during prehension. In contrast, fibrous bands anchor and stabilize the skin of the palm with the underlying palmar aponeurosis. The soft tissues of the palm are organized into the same four layers as the foot. Beneath the palmar aponeurosis lie the short muscles of the thumb (thenar) and little finger (hypothenar). The next layer consists of the long flexors of the fingers (flexor digitorum superficialis and profundus) and the lumbricals. More deeply is the adductor muscle of the thumb, which comprises the third layer. Finally, the interosseous muscles lie between the metacarpal bones on the palmar and dorsal surfaces. Two neurovascular bundles lie on either side of the long flexor tendons.

Fibrous sheaths attach to the fingers and form fibroosseous tunnels along the concave palmar surfaces of the phalanges (Fig. 57-26). Synovial sheaths then surround the long flexor tendons and glide within the fibrous sheaths. The middle fingers each have a synovial sheath that is discontinuous with the common synovial tendon sheath (see description in Forearm and Wrist). The little finger has a synovial sheath that is continuous with the common synovial sheath (see Fig. 57-18). Finally, the thumb has a separate synovial sheath that does not connect with the common synovial sheath but is continuous through the carpal tunnel.

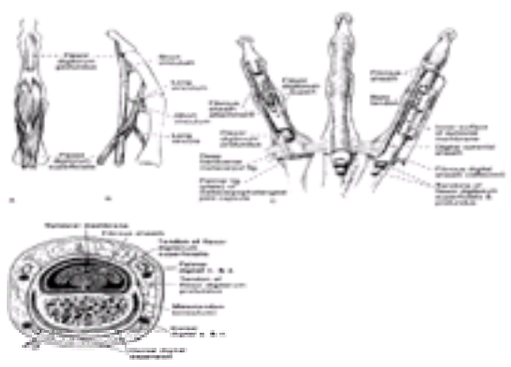

Figure 57-26. The arrangement of **(A,B)** the flexor tendons and **(C)** digital synovial sheaths and fibrous digital sheaths in the fingers. **D:** A transverse section across the proximal phalanx of a finger to show the arrangement of flexor tendons and their synovial sheaths within the fibrous flexor sheaths. (From Rosse C, Gaddum-Rosse P. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:278–279, with permission.)

The dorsum of the hand has little in the way of soft tissue layers. Skin and fascia slide freely over extensor tendons and bone. Digital nerves and vessels run in the subcutaneous fat. Beneath the deep fascia, the long extensor tendons terminate in the extensor hood known as the dorsal digital expansion.

When the long extensor tendons (extensor communis, indicis, and digiti minimi) reach the metacarpal heads, they are joined by the tendons of the interossei and lumbricals, thus forming the dorsal digital expansion on the dorsum of each finger (Fig. 57-27). The expansion divides over the dorsum of the proximal phalanx into a central slip and two lateral bands. The central slip is inserted principally into the base of the middle phalanx. The two lateral bands pass on either side of the proximal interphalangeal joint, fuse with each other beyond it, and insert into the base of the distal phalanx. Changes in the position of these parts of the extensor hood from trauma or disease produce common finger deformities (e.g., swan neck deformity and boutonnière deformity).

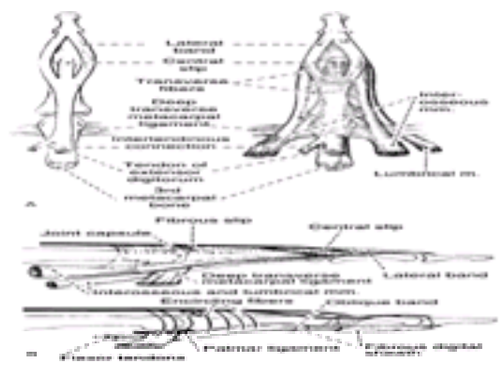

Figure 57-27. **A:** Components of the dorsal digital expansion seen from the dorsal aspect. **B:** The dorsal digital expansion seen from the side and some of its components illustrated schematically. (From Rosse C, Gaddum-Rosse P. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:295, with permission.)

Many small bones and joints provide the anatomic foundation of the hand. Carpal, metacarpal, and phalangeal bones join at the intercarpal, carpometacarpal, metacarpophalangeal, and interphalangeal joints.

Carpal Bones and Intercarpal Joints. Eight wrist bones are arranged in two horizontal rows of four and assemble a semicircle, the convexity of which is proximal and articulates with the forearm bones at the wrist (Fig. 57-28). The carpal bones form a gutter that is concave on the palmar side to accommodate the flexor tendons (see Fig. 57-18). The gutter is transformed into the carpal tunnel by the flexor retinaculum (also known as volar carpal ligament), attached to carpal bones that make up the anterior borders of the gutter (e.g., scaphoid and trapezium laterally, pisiform and hamate medially) (Fig. 57-29). The ulnar tunnel (Guyon's canal) transmits the ulnar nerve at the wrist. It is bounded on the sides by the hook of the hamate and the pisiform bone. The floor and roof of the tunnel are the transverse carpal ligaments and volar carpal ligaments, respectively.

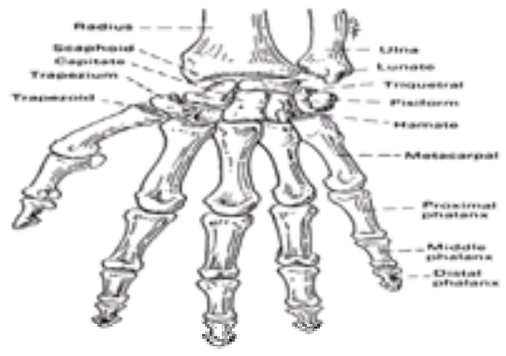

Figure 57-28. The bones of the lower forearm, wrist, and hand.

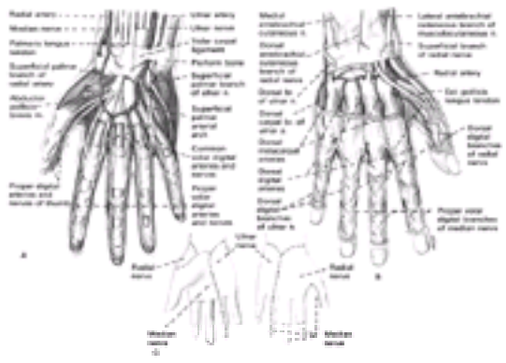

Figure 57-29. The nerves and arteries of the hand. **A:** Palmar view. **B:** Dorsal view. **C:** The cutaneous nerve supply of hand. Developed from numerous sources.

Functionally, the carpal bones and metacarpals consist of three vertical columns (Fig. 57-30). The lateral column of the thumb is made up of the scaphoid, trapezium, and first metacarpal. The intermediate column is important as the axis of the hand and is composed of the lunate, capitate, and third metacarpal. The medial column is the least important functionally and consists of the triquetrum, hamate, and medial two metacarpals (fourth and fifth).

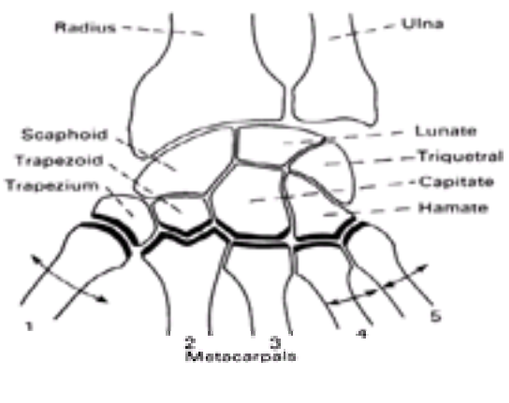

Figure 57-30. Articulations of the carpus with the radius and ulna and the metacarpals. Note that five metacarpal bones articulate with four carpal bones. The articulations of the second and third metacarpals are such that they immobilize this segment, whereas the articulations of the first, fourth, and fifth metacarpals permit mobility about the fixed central segments. (Adapted from Cailliet R. *Hand pain and impairment*, 3rd ed. Philadelphia: FA Davis, 1982:14.)

The carpal bones form synovial joints with one another. Palmar and dorsal capsular ligaments strengthen the intercarpal capsules (see Fig. 57-25). Joints between the proximal row of carpal bones communicate with the midcarpal joint, a large synovial joint between the proximal and distal row of bones that allows flexion-extension at the wrist. Distally, there is a large synovial cavity between the distal carpal bones, the carpometacarpal joints, and the intercarpal joints.

Nerve Supply. The ulnar, median, anterior, and posterior interosseous nerves innervate these joints.

Carpometacarpal Joints. Four carpal bones articulate with five metacarpal bones (see Fig. 57-30). The metacarpals have expanded bases by which they articulate with the carpal bones and each other. Carpometacarpal joints are of the plane variety and some movements of flexion-extension occur. The second and third metacarpal heads articulate with the trapezoid and capitate; as a unit they comprise a central, immobile segment. They are relatively fixed so that, as the hand is cupped, the first carpometacarpal moves on the radial side and the ulnar carpometacarpal joints (ring and little fingers) move on the ulnar side of this segment. The joint between the hamate and fifth metacarpal is particularly mobile and aids in this cupping motion. There is a single large capsule and joint space that communicates with all of the carpometacarpal joints (except for the first), intermetacarpal joints, and intercarpal joints of the distal row.

The first carpometacarpal joint is different from the rest and fundamental to the function of the thumb (Fig. 57-31). The thumb metacarpal is shorter and thicker; its base articulates with the saddle-shaped trapezoid. The shaft is set at nearly 90 degrees with the palm so that its flexor surface faces across the palm. The capsule of the joint is lax but strong; it does not communicate with the carpometacarpal joint. Several strong ligaments attach from the trapezoid to the base of the first metacarpal (e.g., anteromedial ligament and posteromedial ligament). Movements at this joint include flexion-extension (although most of this occurs at the metacarpophalangeal and interphalangeal joints), abduction-adduction, and opposition.

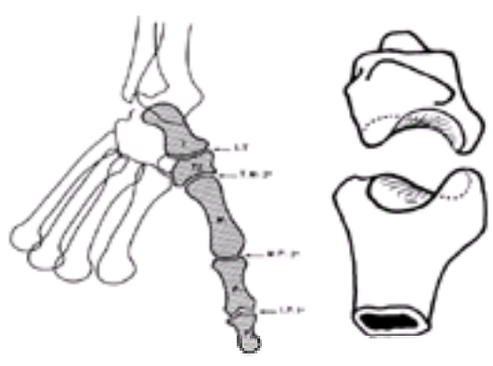

Figure 57-31. The carpometacarpal joint of the thumb is between the trapezoid and thumb metacarpal. It is a saddle joint with two saddle-shaped surfaces concave in one direction and convex in the other. (From Kapandji IA. *The physiology of the joints*, 5th ed. Vol 1: Upper limb. Edinburgh, UK: Churchill Livingstone, 1982:209, with permission.)

Nerve Supply. The ulnar, median, anterior, and posterior interosseous nerves innervate these joints.

Metacarpophalangeal Joints. The heads of the metacarpals are large and rounded with an articular surface that extends further on the palmar than extensor surface (Fig. 57-32). The bases of the proximal phalanges have a much smaller biconcave articular surface, thus forming an ellipsoid joint. The joint capsule is loose with recesses found anteriorly and posteriorly to permit freedom of movement. Indeed, free passive range of movement, including rotation, may be elicited in the relaxed hand. Only flexion-extension and abduction-adduction are possible actively. The joint capsule is thickened anteriorly by a stiff fibrocartilaginous pad called the palmar ligament or palmar plate (Fig. 57-33). These plates allow maximal contact between the bony surfaces and are flexible enough that flexion is not limited. Three types of ligaments attach to the palmar plate: collateral ligaments, deep transverse metacarpal, and the fibrous digital sheaths. Collateral ligaments are found on either side of the joint and are attached posterior to the center of curvature of the joint. Therefore, the ligaments are slack in extension and taut in flexion. Clinically, metacarpophalangeal joints must never be immobilized in extension in view of the risk of development of contractures of the collateral ligaments.

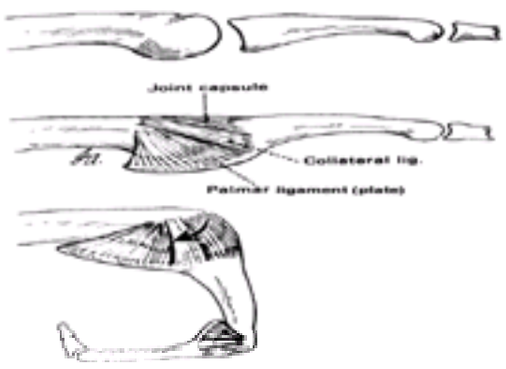

Figure 57-32. The metacarpophalangeal and interphalangeal joints: The attachment of the deep transverse metacarpal ligament to the palmar plate of the metacarpophalangeal joint is not shown. (From Rosse C, Gaddum-Rosse P. *Hollinshead's textbook of anatomy*, 5th ed. Philadelphia: Lippincott–Raven, 1997:304, with permission.)

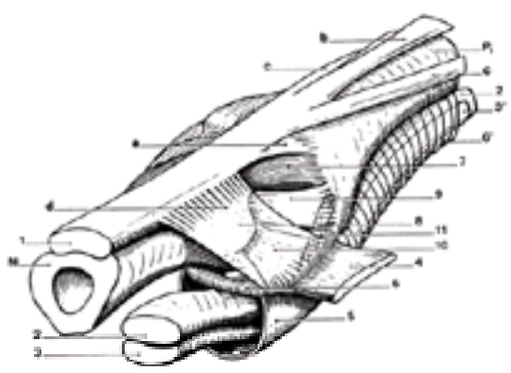

Figure 57-33. The ligaments of the metacarpophalangeal (MP) joints are viewed in this view from behind and above a joint. The insertion of the extensor digitorum communis is dorsal to the capsule of the MP joint and divides into a medial slip (b) and lateral slips (c). The joint capsule is thickened anteriorly by the palmar ligament (4). Collateral ligaments attach to the lateral tubercles (8) and also reinforce the capsule. Other anatomic features of interest include the following labeled structures: extensor digitorum communis tendon (1), flexor digitorum profundus tendon (2), flexor digitorum superficialis tendon (3), metacarpal pulley (5), and fibrocartilaginous plate (6). (From Kapandji IA. *The physiology of the joints*, 5th ed. Vol 1: Upper limb. Edinburgh, UK: Churchill Livingstone, 1982:181, with permission.)

The palmar plates are held together by way of the deep transverse metacarpal ligament of the palm so that its fibers span the entire width of the hand. It prevents separation of the metacarpal heads and contributes to the formation of the fibrous tunnels for the interossei.

Dense collagenous tissue forms a rigid tunnel for the flexor tendons of each finger. These fibrous digital sheaths attach to either side of the phalanges (palmar surface) and to the deep transverse metacarpal ligament.

Movements. Flexion has a range of approximately 90 degrees, whereas active extension is only approximately 30 degrees. Adduction and abduction are more limited to 20 to 30 degrees. Flexors of the metacarpophalangeal joints include flexor digitorum superficialis and profundus, the lumbricals, and the interossei. The major extensors are extensor digitorum communis, extensor indicis, and extensor digiti minimi. Abduction and adduction are performed by the interossei; the palmar interossei adduct (PAD) while the dorsal interossei (DAB) abduct the metacarpophalangeals.

The first metacarpophalangeal joint permits up to 70 degrees' palmar flexion and 25 degrees' extension. Flexor pollicis brevis and longus flex the first metacarpophalangeal. Extensor pollicis brevis and longus extend the joint.

NERVE SUPPLY. The deep branch of the ulnar nerve and the digital branches from the ulnar and median nerves innervate these joints.

Interphalangeal Joints. These are hinge joints with only flexion and extension movements (see Fig. 57-32). The head of each proximal and middle phalanx is pulley shaped with a central groove. The base of the immediately distal phalanx has a reciprocal surface with a crest that fits into the central groove. The capsule and ligaments are similar in structure to the metacarpophalangeal joints except there is no similar structure to the deep transverse metacarpal ligament.

Movements. The range of flexion at the proximal interphalangeal joints is slightly greater than 90 degrees. At the distal interphalangeal joints, maximum flexion is less than 90 degrees. At both the proximal interphalangeal and distal interphalangeal joints, range increases from the second to the fifth finger. Prime movers for flexion at the interphalangeal joints are both flexor digitorum superficialis and profundus at the proximal interphalangeal and only the latter at the distal interphalangeal. There is little, if any, active extension beyond the neutral position. The prime extensors of the proximal interphalangeal and distal interphalangeal joints are the lumbricals and interossei.

The interphalangeal joint of the thumb allows 90 degrees' palmar flexion and up to 35 degrees' extension. The flexor pollicis longus flexes the interphalangeal joint of the thumb and the extensor pollicis longus extends the joint.

NERVE SUPPLY. The digital branches from the ulnar and median nerves innervate these joints.

Nerve Supply of the Upper Extremity

Sympathetic Supply of the Upper Limb

A postganglionic (gray ramus) sympathetic nerve joins each root of the brachial plexus after exit from the intervertebral foramina and these sympathetic fibers hitchhike through the plexus and its nerves. Thus, each dermatome of the upper limb is supplied via the cutaneous nerves by sympathetic fibers to innervate blood vessels, sweat glands, and arrector pili muscles. The postganglionic nerve arises from cell bodies in the appropriate sympathetic ganglion from the lower cervical and

first thoracic sympathetic chain (see Chapter 8).

The preganglionic fibers for the upper limb originate within the spinal cord (preganglionic fibers arise from the thoracolumbar outflow) from the upper segments (T-2 to T-6). The cell bodies are located in the lateral horn and the axons exit via the ventral roots. They ascend in the sympathetic chain to synapse in the ganglion mentioned previously.

Brachial Plexus. In all vertebrates, each limb is organized into compartments. Limb plexuses supply the skin and muscles of these compartments. In the plexus, spinal nerves interchange fibers so that the major nerve branches distal to the plexus receive contributions from two or more segmental spinal nerves. The evolution of plexuses was an important adaptive structural and functional advancement, allowing further complex neuromusculoskeletal behavior and protection from injury.

All of the vertebrates, including humans, have a similar organization of limb plexuses. From fish to reptiles to humans, each limb plexus has the following features in common: (a) several spinal nerves (connected to spinal cord enlargements) contribute nerve fibers to the plexus, intermingle, and regroup; (b) each spinal nerve divides into a dorsal ramus and ventral ramus, however, only the ventral ramus contributes nerve fibers to the limb plexus; (c) each plexus divides into anterior divisions to supply flexor muscles and the overlying surface of the limb and posterior divisions to supply extensor muscles and the surface; and (d) each plexus is an organized meshwork of sensory, motor, and sympathetic fibers that innervates most of the extremity.

The brachial plexus, approximately 15 cm long and comprised of approximately 150,000 axons in the adult, is an extremely durable and load-tolerant structure. The roughly diamond-shaped plexus is strong and lax, features that make the plexus resistant to mechanical stresses within the normal physiologic ranges of motion. Additional strength is provided proximally, where the spinal nerves are bound down to the transverse processes with dense connective tissues. However, the connective tissue binding down the upper spinal nerves (C- 5, 6, 7) is denser than that of C-8 and Th-1, thereby protecting the upper roots from avulsion injuries. The plexus is further reinforced by the connective tissues of the nerves themselves (epineurium, perineurium, endoneurium), which makes them further resistant to tensile forces. All of these protective features are particularly important in mammals with mobile shoulders capable of full abduction (swimming, burrowing, climbing, and flying mammals) such as moles, birds, primates, and humans. For in these animals, the plexus is fixed at one end to a mobile neck and affixed at the other to an upper extremity built for free movement. The plexus is at additional risk of injury because it runs in close proximity to the shoulder joint, a remarkably mobile structure composed of bones that are sometimes dislocated and fractured.

General Survey of Upper Limb Innervation. The brachial plexus supplies most of the sensory, motor, and sympathetic innervation to the upper extremity including the pectoral girdle musculature and joints. There are exceptions to this rule. For example, branches of the cervical plexus supply part of the levator scapulae, and the spinal accessory nerve innervates the trapezius and sternocleidomastoid by way of a circuitous course that does not involve the brachial plexus. Sensory exceptions include skin overlying the pectoral girdle musculature (segmentally innervated by branches of the intercostal nerves) and the proximal, medial arm (innervated by the intercostobrachial nerve from Th-2).

Formation of the Brachial Plexus. Five spinal nerves, C-5, 6, 7, 8, and Th-1 emerge from their respective intervertebral foramina and course downward along the gutter-shaped transverse processes of the lower cervical vertebrae, immediately dividing into a small dorsal ramus and large ventral ramus. The brachial plexus is formed by the ventral rami of these five nerves after they have given segmental branches to the scalene muscles and a branch from C-5 to the phrenic nerve. More often than not, a slender branch from C-4 contributes fibers to the plexus (1). Also, there is often a small branch from Th-2, but this might be primarily composed of sympathetic fibers.

Distal to the roots the orderly junction and separation of nerve fibers can be identified (Fig. 57-34). (a) The formation of three trunks: Of the five major roots of the plexus, the upper two unite to form the upper trunk, the lower two unite to form the lower trunk, and the middle root continues as the middle trunk. Therefore, C-5 and 6 intermix in the upper trunk, the middle trunk carries only C-7 fibers, and the lower trunk is composed of C-8 and Th-1 fibers. (b) The separation into six divisions: The three trunks each divide into an anterior and posterior division behind the clavicle. (c) The formation of three cords: Just distal to the divisions, at the outer border of the first rib, all three posterior divisions unite to form the posterior cord whereas the anterior divisions form the lateral and medial cords. The anterior division from the lower trunk continues as the medial cord whereas those from the upper and middle trunks unite to form the lateral cord. Therefore, the posterior cord is composed of C-5, 6, 7, 8, and Th-1 fibers; the medial cord contains C-8 and Th-1; and the lateral cord has fibers from C-5, 6, and 7. The medial cord, ulnar nerve, or both frequently receive a communicating branch from the middle trunk and carry C-7 fibers.

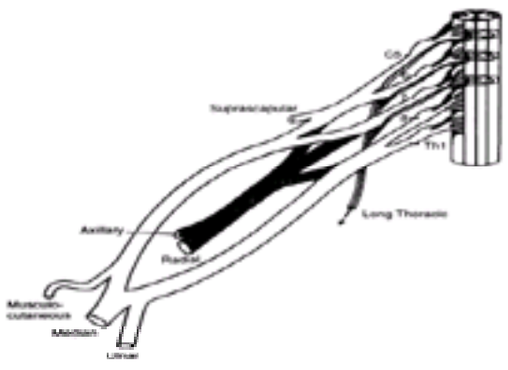

Figure 57-34. Diagram demonstrating the formation of the brachial plexus and the origin of major nerve branches. (From Goldstein B. Applied anatomy and electrodiagnosis of brachial plexopathies. *Phys Med Rehabil Clin North Am* 1994;5:479, with permission.)

Position of the Plexus and Surrounding Anatomy. After the spinal nerves travel a short distance they proceed downward and anterolaterally in the interval between the anterior and middle scalene muscles, where they unite to form the three trunks. At this point, the brachial plexus is beneath the floor of the posterior triangle, enclosed within the prevertebral fascia and at risk during operations in this area. The fascia envelops the brachial plexus in a *sleeve* or sheath, enclosing the neurovascular bundle as it courses down the neck and into the axilla. Therefore, there is a fascial-enclosed neurovascular compartment that extends from the cervical transverse processes, across the posterior triangle, beneath the clavicle, and well into the axilla. Extremely violent injuries often tear this fascia in conjunction with the scalene muscles and avulse the tubercles of the transverse processes from which the muscles and fascia attach.

The three trunks emerge from between the scalenes and converge toward the upper surface of the first rib, where they are arranged in a fairly vertical manner (i.e., upper, middle, and lower). The lower trunk is in contact with the first rib, a relationship that has been discussed in great detail in the thoracic outlet and postmedial sternotomy plexopathy literature. As the trunks cross the first rib they are in close proximity with the subclavian artery, anterior scalene muscle, and subclavian vein. Because of the slope of the first rib, the order is not only front to back but also rising upward; the vein being so low as to be hidden entirely by the clavicle. This permits a brachial plexus block (supraclavicular block) above and behind the vessels.

Each trunk then divides into anterior and posterior divisions, which pass inferior to the concavity of the medial two-thirds of the clavicle and accompany the axillary artery. Finally, the divisions reunite to form the cords within the axilla, named by their relationship with the second part of the axillary artery.

The brachial plexus can be palpated in the posterior triangle of the neck, in the angle between the clavicle and sternocleidomastoid. To map out the surface anatomy, the brachial plexus in the neck lies below a line from the posterior margin of the sternocleidomastoid at the level of the cricoid cartilage to the midpoint of the clavicle.

Branches of Spinal Nerves Before the Plexus Is Formed. The branches from the most proximal part of the spinal nerves are extremely important to the electromyographer. Although somewhat artificial and arbitrary, the early branches can be separated into four subdivisions. (a) Primary rami: Each spinal nerve divides into a dorsal and ventral ramus. The dorsal ramus innervates the dorsal dermatomes and myotomes—therefore, the skin, subcutaneous fat, deep fascia, and longitudinal extensor musculature of the spine. (b) Sympathetics: Each spinal nerve from Th-1 to L-2 (or L-3) has a branch that consists of myelinated, preganglionic fibers (white ramus communicantes) destined for the sympathetic chain. It is important to recall that there is great divergence in the sympathetic system. Therefore, from a relatively small area of preganglionic cells in the spinal cord (Th-1 to L-2) the axons diverge, stimulate the postganglionic cells within the sympathetic chain, and thereby innervate all of the glands and body wall. Because the Th-1 preganglionic fibers innervate the head and neck, avulsion of the Th-1 spinal nerve results in

the sympathetic-deficient clinical syndrome of Horner. (c) Segmental branches: Segmental nerves from the ventral rami innervate the scalene muscles (anterior, middle, and posterior), prevertebral muscles (longus capitis and longus colli), and sensation to the deep fascia of the neck (prevertebral fascia). (d) Contribution to the phrenic nerve: The communication with the phrenic nerve from C-5 arises from the proximal ventral ramus.

Branches from the Brachial Plexus. When the basic formation of the brachial plexus has been learned, it is a simple matter to put in the branches of the plexus if one remembers the odd number rule: 3-1-3-5-5. The rule states that three nerves branch from the roots, one from the upper trunk, and the remaining nerves branch from the cords (three from the lateral cord, five from the medial cord, and five from the posterior cord). Clinically, it is helpful to focus on those supraclavicular branches off the proximal aspects of the plexus (roots and trunks) and the infraclavicular branches from the cords.

SUPRACLAVICULAR BRANCHES (THREE NERVES BRANCH FROM THE ROOTS). The nerves from the roots together with the branches of spinal nerves before the plexus are of paramount importance because they all arise from the proximal aspect of the spinal nerves. Involvement of these nerves is evidence of nerve root avulsion in most cases.

The three branches from the roots arise from C-5 to C-7 in a successive manner: dorsal scapular nerve from C-5; nerve to subclavius from C-5, 6; and long thoracic nerve from C-5, 6, and 7 (Table 57-3). The branches from the roots might also be remembered as the *nerve to*'s—therefore, nerve to rhomboids, nerve to subclavius, and nerve to serratus anterior. The *dorsal scapular nerve* (C-5) is unusual in that a single segment innervates the target muscles, the rhomboids and part of levator scapulae. This is helpful in attempting to distinguish a proximal injury that only involves C-5 from one that involves caudal segments as well. The *nerve to subclavius* (C-5, 6) branches from the roots or might also arise from the superior trunk. The distinction is trivial and the nerve unimportant to the clinician except to help remember the odd number rule and its occasional contribution to the phrenic nerve. The *long thoracic nerve* (C-5, 6, 7) travels on the outer surface of the serratus anterior and supplies it in a segmental fashion (upper slips of the serratus anterior are innervated by C-5, middle muscle fibers by C-6, and the lowest by C-7).

TABLE 57-3. Supraclavicular branches

SUPRACLAVICULAR BRANCHES (ONE NERVE FROM THE UPPER TRUNK). The only nerve that branches from the trunks is the suprascapular nerve (C-5, 6) which innervates the supraspinatus and infraspinatus muscles (see Table 57-1). To differentiate a suprascapular mononeuropathy from an upper trunk injury, other C-5, 6 innervated muscles might be examined (deltoid and biceps).

INFRACLAVICULAR NERVES (3-5-5 FROM THE CORDS). The cords continue distally to form the principal nerves of the limb. Each cord terminates into two principal nerves as follows: lateral cord (lateral head of the median and musculocutaneous); medial cord (medial head of the median and ulnar); posterior cord (axillary and radial). The remaining branches are listed in Table 57-4.

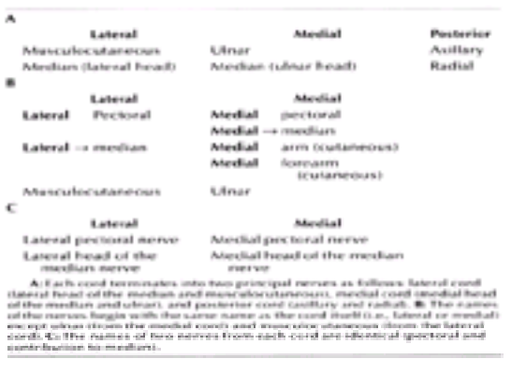

TABLE 57-4. Infraclavicular branches

Memorizing the brachial plexus is often a frustrating task, and one that is soon forgotten. There are many mnemonics and memory aids, as well as descriptions of the infraclavicular nerves. There is no need to repeat them here. However, it is appropriate to review some general facts and principles of the infraclavicular nerves.

The junction of the three posterior divisions from each trunk forms the posterior cord. Its five branches innervate the extensor muscles of the shoulder, elbow, wrist, and fingers. The radial nerve supplies all of the posterior muscles of the arm and forearm. The axillary nerve innervates the deltoid muscle (and teres minor). The remaining nerves supply the muscles of the posterior axillary fold (subscapularis, teres major, and latissimus dorsi). As a group, these latter muscles extend, medially rotate, and adduct the shoulder.

The lateral and medial cords innervate the flexor muscles of the upper extremity and are best remembered together. It is particularly easy to remember the names if two details are kept in mind. First, the names of the nerves from both of these cords begin with the same name as the cord itself (i.e., lateral or medial) except ulnar from the medial cord and musculocutaneous from the lateral cord (see Table 57-2). Second, the names of two nerves from *each* cord are identical (pectoral and head of the median). Finally, the cutaneous branches from the medial cord, annoying details when first studying the plexus, are extremely important in differentiating lower proximal plexus lesions (medial cord, lower trunk, and lower roots) from distal lesions (ulnar nerve). They are the medial cutaneous nerves of the arm and forearm.

The major nerves to the upper limb are discussed in greater detail within each anatomic section (e.g., arm, forearm, and hand). Common focal nerve lesions and palsies are then discussed in the clinical section on nerve compression syndromes.

APPLIED ANATOMY AND CLINICAL REFERENCES

There are many different classification schemes of painful upper limb musculoskeletal and neurologic disorders. Most of those that produce pain in the shoulder, arm, and elbow are in Chapter 58; those that afflict the forearm, wrist, and hand are discussed in Chapter 59. Cervicobrachial neuralgia is reviewed in Chapter 57. Causalgia is discussed in Chapter 20, myofascial pain syndromes in Chapter 29, and fibromyalgia in Chapter 30.

The following section is organized into three areas: joint and bone pain, overuse injuries and soft tissue pain, and nerve pain. Common painful conditions are presented to highlight anatomic principles and practical problems in the upper limb.

Joint and Bone Pain

Upper extremity joint and bone pain are frequent presenting complaints in many patients. Details about the mode of onset, number and localization of affected joints, and distribution of joint involvement assist in the diagnosis of arthropathies.

Acute Onset

The acute onset of joint pain is characteristic of infectious arthritis, although several other arthropathies may have an acute presentation. Examples of an acute onset also include crystal-related arthropathies, rheumatic fever, and palindromic rheumatism. Rheumatoid arthritis (RA) and psoriatic arthritis sometimes present with a sudden onset, although an insidious presentation is more common. Infectious arthritis is discussed as a typical example of an acute monoarthritis.

Infectious Arthritis. The annual incidence of bacterial arthritis is approximately 10 to 20 per 100,000. The higher incidence is related to a warm, humid climate and poorer socioeconomic conditions.

Several bacterial and nonbacterial agents have been found as the cause of infectious arthritis although *Neisseria gonorrhoeae* and *Staphylococcus aureus* are the most common causes. Most cases of infectious arthritis are the result of hematogenous spread; posttraumatic infection, direct inoculation, and spread from adjacent osteomyelitis also occur. Postoperative cases (e.g., postoperative diskitis) and infected prostheses are major causes as well, although antibiotic prophylaxis has resulted in a dramatic decrease in infection rate. In the immunosuppressed individual nongonococcal and nonbacterial arthritis occur more commonly. The incidence of tuberculosis continues to increase and may be the source of upper extremity infectious arthritis.

Bacterial arthritis usually presents with a single hot swollen joint, although a child may present with a high fever and other systemic signs. When the upper extremities are involved, acute bacterial and nonpyogenic arthritides most commonly affect the wrist joint. The sternoclavicular, elbow, and small joints of the hand are also sometimes involved. Pain is often present at rest and exacerbated by movement. The joint capsule is typically distended and warm and held in the neutral position to give maximum compliance and avoid higher intrasynovial pressure. The diagnosis requires analysis of joint fluid. Joint fluid should be completely drained as some agents (e.g., *S. aureus*, gram-negative bacilli) result in rapid cartilage and bone destruction. For example, a delay in treatment beyond 2 to 3 days may result in significant joint destruction in septic arthritis of the elbow. Treatment consists of early and aggressive drainage of the joint and administration of appropriate antibiotics.

Acute Osteomyelitis in the Upper Extremity. Acute osteomyelitis usually affects children or young adults and is often difficult to differentiate from an acute monoarthritis. Typically, the infection begins in the metaphysis of the radius or humerus, although the carpal bones and metacarpals are sometimes involved. In the young child, the cartilaginous growth plate is still vascular, and it is common for the infection to spread into the epiphysis. Involvement of the joint cavity is common in this younger age group. The older child and young adult have an avascular growth plate and spread to the joint is less common.

Chronic Joint and Bone Pain

Chronic pain, stiffness, and loss of function occur in a variety of rheumatologic diseases. Three common rheumatologic disorders are reviewed here: RA, osteoarthritis (OA), and gout.

Rheumatoid Arthritis. RA is a chronic, systemic, inflammatory disease that affects approximately 2.5 million people in the United States. Both genetic and environmental factors are involved in this autoimmune disease. A genetic influence is suggested by a fourfold increase in concordance in monozygotic compared with dizygotic twins. The mean age at onset is 35 to 55 years, and there is an insidious onset in 70%. More women than men develop RA by a ratio of 3:1.

Local symptoms and signs involve joint pain with three or more joint areas involved, morning stiffness, rheumatoid nodules, and warm, swollen joints. Constitutional symptoms include fatigue, anorexia, weight loss, depression, generalized weakness, malaise, lymphadenopathy, and low-grade fever. Morning stiffness usually lasts longer than 1 hour, along with extraarticular symptoms such as achiness. Pain occurs at rest and with movement, often disturbing sleep.

Early in the course of the disease, several changes in joint structure occur. Joint effusion, tenderness, and inflammation of the synovium occur, producing a soft tissue swelling that is easily detected during evaluation of the patient. Additionally, decalcification localized in or adjacent to the involved joints often occurs.

RA affects most of the joints in the upper limbs, and the associated disability is great. For example, 9 of 10 people with RA have significantly reduced function after 10 years, particularly related to impaired hand function. Fewer than 50% are able to continue to work after living with RA for 15 years (2).

In the upper limbs, RA has the greatest affinity for the small joints of the hands and usually starts in the metacarpophalangeal and proximal interphalangeal joints. These joints are typically symmetrically involved, boggy, swollen, and warm early in the disease. The surrounding skin is erythematous. Volar subluxation and ulnar drift of the metacarpophalangeals are characteristic deformities.

The wrists (radiocarpal joints) and distal radioulnar joints are usually involved in RA. The synovium is boggy and palpable on the dorsal surface of the wrist. Early changes also include loss of range of motion, particularly with wrist extension. Synovitis commonly affects the weakest support of the wrist on the ulnar side. Finally, clicking of the distal radioulnar joint may be present at the early stages of RA.

Tenosynovitis of the tendon sheaths is found in approximately two-thirds of rheumatoid hands. Pain, swelling, nodules, and eventual rupture of both long flexor and extensor tendons are commonly found in RA. A trigger finger is a frequent feature of flexor tenosynovitis.

Later manifestations of RA are well described. Pain and deformity result from intraarticular and extraarticular tissue injury. The boutonnière deformity develops as a result of thinning and destruction of the extensor mechanism at the proximal interphalangeal joint (see Fig. 59-23). The lateral bands move progressively in a volar direction, eventually generating a flexion movement at the proximal interphalangeal joint rather than one of extension. The digit then assumes a flexed posture at the proximal interphalangeal joint and extended position at the distal interphalangeal joint. The swan neck deformity develops as a result of joint destruction to the palmar ligament at the proximal interphalangeal joint (see Fig. 59-24). The palmar ligament normally limits extension; therefore, after its destruction, hyperextension occurs (typically at the proximal interphalangeal joint). This allows the lateral bands to bowstring on the dorsal aspect of the middle phalanx, resulting in a decreased extension movement at the distal interphalangeal joint. Flexor digitorum profundus then pulls the distal interphalangeal joint into a flexed position.

Rheumatoid nodules often develop in the upper extremities as later manifestations of RA. These nodules are subcutaneous and occur on extensor surfaces about the olecranon process and proximal bony prominence of the ulna and over the extensor surfaces of the metacarpophalangeal and proximal interphalangeal joints.

Radiographic changes of RA also include joint space narrowing. Bony erosion occurs in the joint itself and osteopenia, or diminished bone density, can be present in the periarticular region.

Osteoarthritis. OA is an age-related disorder that is the most common type of joint disorder in the world (3). The majority of people over 65 years of age have some form of OA, and approximately 16 million people have OA in the United States. Age, systemic factors (e.g., obesity), exposure, and genetic factors are all thought to play a role in the disease. OA is a disease confined to the joints and is characterized by destruction of the articular cartilage and subchondral bone. It is classified as primary and secondary. Secondary OA occurs in response to previous injury, prolonged heavy use, or damage by prior infection or inflammatory arthritis; primary OA has no known causes. Research indicates that the familial tendency of primary OA may be linked to a defect in a procollagen gene.

The patient with OA typically has slowly developing joint pain, inactivity stiffness, and enlargement of joints. Reduced joint function and severe disability often result from OA. Pain is usually described as use-related; however, rest pain and night pain occur in many individuals. Bone and muscular pain are also frequently reported.

Joint involvement is usually asymmetric, and in the upper extremities, the distal interphalangeal, proximal interphalangeal, and thumb base are most frequently involved. Early disease usually consists of aching in the affected joints. Inflammation occurs intermittently, and involved joints may present with warmth and tenderness. The hallmarks of hand involvement in OA are Heberden's (distal interphalangeal) and Bouchard's (proximal interphalangeal) nodes. These nodes are firm

swellings that are often tender and erythematous. Loss of motion and frank instability may develop. Trapeziometacarpal joint involvement occurs in approximately one-half of individuals with OA and commonly leads to loss of hand function. As the joint deformity develops, the base of the thumb enlarges giving a swollen or *squared* appearance. It is sometimes confused with wrist involvement because it may present with poorly localized pain at the base of the thumb and wrist joint. The patient often complains of pain during grasping types of activities (e.g., opening a jar) and pinch activities.

OA of the acromioclavicular joint is common. Pain, tenderness, and crepitus are well localized to the joint. Pain is worse with movements of the shoulder above 90 degrees because most movement of the AC joint occurs during full abduction and flexion activities. OA at this joint is frequently associated with inferior osteophytes and rotator cuff tears.

Radiographic changes in OA include joint space narrowing from the eroded cartilage, subchondral sclerosis and cysts, and osteophyte formation. There is relatively poor correlation between radiographic grading and reporting of pain.

Crystal-Related Arthropathies. The deposition in and around joints of crystals often leads to inflammation, deformity, loss of function, and pain. Monosodium urate monohydrate (gout), calcium pyrophosphate dihydrate (pseudogout), and basic calcium phosphates are the more common causes of crystal-related arthropathies. Acute and chronic forms of the disease may occur. The differential diagnosis of the rapid presentation of a hot, swollen joint is that of an acute monoarthropathy. In the chronic setting, the differential diagnosis includes RA, OA, and other destructive arthropathies. The diagnosis is established by analysis of joint fluid and radiography. Crystal identification under polarized light differentiates monosodium urate monohydrate (strong negative birefringence) from calcium pyrophosphate dihydrate (weak positive birefringence). Radiographic changes in gout usually demonstrate erosive changes in affected joints, yet calcification is usually absent. In pseudogout, radiography demonstrates chondrocalcinosis and degenerative joint changes.

Gout most commonly affects middle-aged men. Although the joints of the lower extremity are more commonly involved, the small joints of the hands or wrist might be involved in acute gouty arthritis. Virtually any joint may be involved in chronic gout. Tophi are characteristic firm nodular or fusiform swellings and histologically demonstrate a foreign body granuloma surrounding a core of monosodium urate monohydrate. Tophi develop over joints, in the subcutaneous tissue on the extensor surface of the forearm, on synovial sheaths and bursae, and in subchondral bone. Tophi are often confused with rheumatoid nodules.

Pseudogout is predominantly a disease of the elderly. Acute synovitis (usually termed *pseudogout*) and chronic arthritis (usually termed *chronic pyrophosphate arthropathy*) occur. As with gout, any joint may be involved, but the more commonly affected upper extremity joints include the wrist, glenohumeral, and elbow. Affected joints usually reveal signs of OA and varying degrees of synovitis.

Repetitive Motion Disorders of the Upper Extremity and Soft Tissue Pain

Repetitive motion disorders of the upper extremity are common. The United States Department of Labor Statistics showed that more than 60% of new occupational illnesses in 1992 were associated with repetitive motion and there has been an increase since then. The overall national rate increased from 5 cases per 10,000 workers in 1982 to 44 per 10,000 in 1992. A great proportion of these cases is upper extremity repetitive-related disorders such as rotator cuff dysfunction and peritendinitis about the wrist. Repetitive motion disorders are also common in avocational activities. It is estimated that approximately one-fourth of all sports participants develop overuse injuries, and many of these involve the soft tissues of the upper limbs (4).

These disorders have a diversity of terminologies (e.g., overuse injury, repetitive stress syndrome, activity-related musculoskeletal disorder) and have complex multifactorial etiologies. Further, they can involve many tissues such as muscle, nerve, ligament, and tendon. Although many of these terms imply that the pathophysiology is well understood, overuse injuries probably represent several different pathologic entities (e.g., in tendon tendinitis, tendinosis, peritendinitis) associated with distinct etiologies (repetition, cumulative trauma, sustained static loading). A useful operational definition is that an overuse injury is one in which there is a summation of biomechanical loads applied beyond the tolerance of the biological tissues.

The fundamental questions that arise in repetitive motion disorders are what is the relationship between biomechanical loads and tissue response, and why do some loads induce adaptive responses while others lead to pathologic changes? The tendons and ligaments of the upper extremity provide many different examples of both adaptive and pathologic changes. For example, where tendons change directions, traverse narrow tunnels, pass through a pulley, or are impinged by surrounding structures, the anatomy and composition of the tendon change from that of a regularly arranged dense connective tissue to that of fibrocartilage. This has been demonstrated in the region of the tendon that experiences compressive and frictional forces rather than the usual pure longitudinal forces. In other words, when a tendon experiences significant compression and friction, it undergoes adaptive changes from a primary fibrous tissue to one that is more fibrocartilaginous in nature. Although initially adaptive, fibrocartilage is less vascular and less capable of responding to repetitive microinjury compared with a typical tendon. Eventually, pathologic changes develop and chronic overuse injuries are the result. There are numerous clinical examples of this problem in both the lower and upper extremity (e.g., Achilles tendinitis in runners and dancers, supraspinatus tears in pitchers). Indeed, tendon injury within a zone of relatively hypovascular fibrocartilage is probably one of the most important unifying concepts of chronic, overuse injuries.

Other tissues experience injury after repetitive mechanical loading in addition to tendons and ligaments. Nerve compression syndromes are common and reviewed in a separate section below. Injuries to cartilage, bone, muscle, and skin are also known. Several common problems are discussed below.

Shoulder

Rotator Cuff Tendinopathy. Rotator cuff tendinopathy is the result of prolonged or repetitive use of the upper extremity, particularly in an abducted position. There is considerably less pathologic study of the early stages of rotator cuff disease by comparison with more accessible tendons (e.g., forearm flexors). Yet, there are similar findings in that the designation *rotator cuff tendinitis* might be a misnomer; *tendinosis* is perhaps a more suitable term. Pathologic findings range from degenerative necrosis without a cellular infiltrate to degenerative lesions with abundant neovascularization (5,6).

Rotator cuff tears are age-related and activity-related conditions, and eventually there is tearing of the cuff in middle age or older. In most cases, they are thought to start as small focal failures of the supraspinatus tendon and progress to larger tears. A relatively minor injury might or might not be noted. Rotator cuff tears occur in younger people as a result of trauma or repetitive forceful overhead activities (e.g., a major league pitcher).

Rotator cuff tears are either partial (incomplete) or full thickness (complete). Pain, weakness, and functional problems are typical after a rotator cuff tear. Pain is often progressive and may radiate down the lateral aspect of the arm or into the base of the neck. Weakness and functional deficits primarily relate to abduction activities. It is important to note that as progressive tearing occurs and weakness develops, there is worsening upward displacement of the humeral head (see Fig. 57-8). This results in further compression of the rotator cuff and the subacromial bursa.

Subacromial Bursitis. Inflammation of the subacromial bursa may present as acute or chronic shoulder pain. Pain is typically located in the lateral shoulder and worse with movement. The bursa may be compressed by a narrowed humeroacromial space (e.g., traction spur on the undersurface of the acromion and upward displacement of the humeral head in the case of rotator cuff weakness). In chronic cases the bursa may become thickened and fibrotic. Radiographic studies may be entirely normal, although a calcium deposit in the subdeltoid or subacromial bursa may be seen. It is sometimes difficult to distinguish between subacromial bursitis, acromioclavicular arthritis, bicipital tendinitis, and rotator cuff tendinopathy. Many of these disorders may coexist.

Bicipital Tendinitis. The course and angulation of the long head of the biceps make it susceptible to degenerative changes and tears. Pain is typically anterior in location, worse with use, and radiates down the anterior arm. Rupture of the transverse humeral ligament sometimes occurs with complaints of a catching or clicking sensation as the long head subluxes in and out of the bicipital groove. Examination is directed at reproducing the pain, subluxation, or both of the long head. Provocative tests include resisted flexion and supination of the forearm. After a tear, there is obvious asymmetry between the symptomatic and asymptomatic sides since the torn biceps bulges distally in the arm.

Elbow

Epicondylitis. Medial and lateral epicondylitis is a common cause of elbow and forearm pain. Epidemiologic studies have estimated that up to 3% of the population develop lateral epicondylitis (7). Age, systemic factors, and repetitive overuse have been implicated in the cause of epicondylitis. Commonly, the cause is related to the musculotendinous origin at the epicondyle. Nerve entrapments, infection, and periostitis occur less frequently.

Pathologic studies have not supported an inflammatory-mediated process. Rather, histopathologic examinations have demonstrated disorganized granulation tissue and necrotic areas. Epicondylosis and tendinosis have been proposed as more appropriate terminology by some authors (8). These studies have also questioned the local and systemic use of antiinflammatory medications as a treatment strategy in these conditions.

Medial and lateral epicondylitis typically present with an insidious onset. Pain is localized over the respective epicondyle with sporadic radiation into the forearm. Use of the forearm extensors (with lateral epicondylitis) and flexors (with medial epicondylitis) aggravates the pain. Resisted wrist extension typically reproduces the pain in lateral epicondylitis. Resisted wrist flexion and pronation reproduce symptoms in medial epicondylitis. Palpable tenderness over the respective epicondyle and common musculotendinous origin are also characteristic.

Investigative studies are used to rule out other conditions on the differential diagnosis such as nerve entrapment (electrodiagnostic studies) and arthritis (radiography).

Olecranon Bursitis. Olecranon bursitis is the result of overuse, trauma, inflammation, or infection. It is a common problem (approximately 3 in 1,000 outpatient visits), particularly in those who have recurrent elbow trauma at work or play. The affected elbow usually reveals a posterior elbow swelling that is warm, erythematous, and mildly tender. Systemic symptoms are unusual. Individuals with rheumatic disease (e.g., RA or gout) often have an acute aseptic inflammatory olecranon bursitis. Since the bursa is subcutaneous, direct inoculation from work-related activities is common. Septic olecranon bursitis is usually caused by *S. aureus*, group A b-hemolytic streptococcus, and *S. epidermidis*. Percutaneous aspiration of the bursa should be performed whenever inflammation or infection is suspected.

Wrist and Hand

Tenosynovitis and Peritendinitis. There have been many descriptive studies and case series of tenosynovitis and peritendinitis about the wrist. Most of the studies are related to work (9,10). Numerous studies have demonstrated that repetitiveness of work movements and the use of high forces were risk factors for the development of forearm tenosynovitis and peritendinitis. Local ache, pain during movement, weakness in gripping, and tenderness have been observed after repetitive activities such as assembly line and meat cutter's work. Both acute and chronic stages of the condition have been identified. The diagnosis of wrist tenosynovitis and peritendinitis is based on clinical findings since there are no diagnostic tests to establish the actuality of the diagnosis.

DeQuervain's Disease. DeQuervain's stenosing tenosynovitis is the prototype of a tendon entrapment syndrome. This disorder involves the synovial sheaths of the abductor pollicis longus and extensor pollicis brevis (see Fig. 57-18). Risk factors are related to vocational and avocational activities. Repetitive pinch activities while moving the wrist in radial and ulnar directions result in pain along the involved tendons. DeQuervain's tenosynovitis was also thought to be an inflammatory disorder. However, histopathology has demonstrated peritendinous fibrosis without inflammation and fibrocartilaginous metaplasia of tendon sheath tissue. Once again, the terminology is misleading, and DeQuervain's disease should probably be thought of as a degenerative disorder. Most patients report pain on the radial aspect of the wrist and at the thumb base during pinch grip and grasping activities. The tendon sheaths of abductor pollicis longus and extensor pollicis brevis are often tender and swollen. Crepitus may be palpable.

Trigger Finger or Thumb. Trigger or snapping finger is the most common repetitive motion disorder of the hand (11). Tenosynovitis of the long flexor tendons results in fibrosis and constriction of the fibrous sheath; a tendon nodule often develops at the same site. The nodule is able to slide through the tendon sheath when the finger is flexed but hangs up on the end of the sheath. The finger gets stuck in a flexed position. With increased force, the tendon snaps back into extension. Pain is local around the stenotic area and over the nodule. Individuals with trigger finger often have rheumatologic problems (e.g., RA) or diabetes mellitus.

Localized Nerve Lesions

Localized nerve lesions are a common source of pain in the upper extremity. There are several possible mechanisms that result in focal injury to a nerve, yet compression and trauma are the most common causes. Many compression lesions involve nerves that are otherwise normal. However, there are predisposing conditions that make nerves more susceptible to injury (e.g., diabetes mellitus, alcoholism, and Guillain-Barré syndrome).

The diagnosis of a focal nerve lesion depends on elucidating weakness and atrophy of the muscles supplied by the nerve distal to the lesion. Sensory findings, which usually appear earlier, provide less reliable localizing signs than motor deficits because sensory dermatomes overlap considerably. Electrodiagnostic tests can delineate the exact distribution of denervated muscles and localize a focal nerve lesion. MR neurography can also be useful.

Median Nerve

In the arm, compression of the median nerve is rare. Entrapments by the bicipital aponeurosis, by extreme flexion of the elbow, and by the ligament of Struthers have all been reported. Compression of the nerve beneath the ligament of Struthers occurs at a point proximal to the pronator teres (12).

In the cubital fossa, the median nerve passes between the two heads of the pronator teres muscle and under the origin of the flexor digitorum superficialis. The nerve can be entrapped by either structure. The pronator teres syndrome has been reported as a repetitive strain injury in athletes and in such workers as carpenters, mechanics, and writers.

The anterior interosseous nerve is entrapped or damaged in the forearm, resulting in the syndrome of Kiloh and Nevin (also known as anterior interosseous syndrome) (13). This may be the result of direct trauma, forearm fractures, phlebotomy from the cubital vein, or fibrous bands related to the flexor digitorum superficialis. Three muscles are weak as a result of injury to the anterior interosseous syndrome: flexor pollicis longus, the radial half of flexor digitorum profundus, and pronator quadratus. The pinch maneuver (ask the patient to make the *OK* sign) results in flattening of the distal aspect of the thumb and second digit; a triangle is formed rather than a circle. Symptoms include forearm pain and weakness of pinch, grip, or both.

Entrapment of the median nerve in the carpal tunnel is the most common entrapment neuropathy. Carpal tunnel syndrome is most common in persons working in jobs that require use of hand-held vibrating tools, repetitive wrist motion, forced hand movements, or all three, as performed by assembly workers, packers, bricklayers, and musicians.

The increase of pressure inside the carpal tunnel compresses the median nerve beneath the unyielding flexor retinaculum. Pain and paresthesias on the palmar-radial aspect of the hand characterize the syndrome in addition to symptoms that are often worse at night, exacerbated by repetitive, forceful use of the hand, or both. Patients often describe relief by shaking their wrist (flick sign). Careful neurologic examination and electrodiagnostic testing are important in establishing the diagnosis. In severe cases, weakness and atrophy of thenar muscles are present. Electrodiagnostic studies are used to confirm the diagnosis.

Ulnar Nerve

Ulnar nerve compression at the elbow is the second most common entrapment neuropathy. Elbow pain may extend to the forearm and is accentuated by repeated trauma (e.g., heavy labor), leaning on the nerve (e.g., individuals with paraplegia who frequently lean on the elbow or medial forearm), or repeated elbow flexion (e.g., painting, hammering). Hypertrophy of the flexor carpi ulnaris occurs in overhand athletes and may compress the nerve in the cubital tunnel.

Sensory symptoms and signs typically involve the medial hand (distribution of the ulnar nerve). Sensory loss of the medial forearm is not consistent with an ulnar nerve lesion at the elbow since this area is innervated by a separate nerve, the medial antebrachial cutaneous (medial cord; C-8 dermatome). Weakness may occur in any of the ulnar innervated muscles (flexor carpi ulnaris, fourth and fifth bellies of flexor digitorum profundus, hypothenar muscles, adductor pollicis, and the interossei), although it is much more common that the hand muscles are involved.

Ulnar nerve compression at the wrist occurs in the canal of Guyon. Repeated trauma at work or play such as stapling or bicycling is the usual cause. Extrinsic pressure from a synovial cyst, calcium deposits, and handcuffs has also been reported. The clinical features of this entrapment are variable, since the ulnar nerve separates into several end-branches within Guyon's canal. Both sensory (little finger and medial half of the ring finger) and weakness (hypothenar muscles, interossei, and adductor pollicis) effects are well described. Diagnostically, it is helpful to remember that the cutaneous branches to the proximal aspect of the medial hand (both palmar and dorsal nerves) separate from the ulnar nerve in the forearm, but the branches to the fingers come off the ulnar nerve distally in the canal.

Therefore, compression in Guyon's canal spares the ulnar aspect of the hand but not the fingers.

Radial Nerve

Radial nerve compression occasionally occurs in the proximal arm or region of the spiral groove. Although this usually is the result of fracture, compression by crutches or leaning against a hard object (*Saturday night palsy*) have also been described. Radial nerve palsy from axillary compression (*crutch palsy*) results in triceps weakness as well as all of the muscles in the extensor compartment of the forearm. Compression in the spiral groove spares the triceps. Clinically, the patient complains of arm and forearm pain with characteristic wristdrop (weakness of wrist and finger extensors).

The most common radial nerve compression palsies occur about the elbow. Pain at the lateral aspect of the elbow, sometimes with radiation to the dorsal forearm, is a common manifestation of radial nerve compression in this area. Exacerbation of pain during or after heavy work is typical, and a deep, aching sensation in the forearm extensors is often described. Radial nerve compression at the elbow is frequently confused with lateral epicondylitis since both often present with lateral elbow pain. Several structures might compress the nerve including the margin of extensor carpi radialis and the fibrous arch of supinator (arcade of Frohse). The posterior interosseous nerve syndrome is compression of the deep branch of the radial nerve at the arcade of Frohse. In this syndrome, brachioradialis and the radial wrist extensors are spared. Therefore, weakness of the wrist is not as pronounced as more proximal radial nerve lesions, and there is characteristic radial deviation of the wrist during extension. Entrapment of the posterior interosseous nerve is thought to result from forceful repetitive supination-pronation of the forearm or abrupt extension of the elbow (e.g., hammering, Frisbee throwing, and backhand tennis stroke). Direct pressure such as that produced by Canadian (forearm) crutches might also result in similar nerve palsy.

Brachial Plexopathies

Clinical Presentation. A lesion of the brachial plexus results in motor, sensory, sympathetic, or all three kinds of disturbances. Tragically, in many cases, there is a high proportion of intractable pain. Because of the changing arrangement of the brachial plexus as it is followed distally, injuries of it may result in many diverse paralyses, anesthesias, and paresthesias, depending on the exact level at which it is injured and the extent of injury to the various elements at that level. Sympathetic fibers might also be involved, resulting in decreased sweating with postganglionic lesions. If a Th-1 root avulsion occurs, preganglionic sympathetics might be interrupted and a Horner's syndrome may result. Finally, findings typical of a lower motor neuron process might occur—therefore, decreased tone, atrophy, and hyporeflexia.

Classification. The various classifications of brachial plexopathies are confusing. Anatomic, surgical, etiologic, pathophysiologic, and mechanistic classifications have all been used and are not repeated here. However, it is helpful to consider a few general organizational differentials since the implications for electrodiagnostic evaluation, treatment, and prognosis are considerable. These include the following: (a) mechanism of injury (traction, compression, vascular, ischemic); (b) type of injury (neurapraxia, axonotmesis, neurotmesis, root avulsion); (c) open versus closed injuries; and (d) preganglionic versus postganglionic lesions.

Etiology. The causes and incidence of brachial plexopathies may vary greatly, particularly when comparing wartime periods with those during civilian life. Undoubtedly, trauma accounts for a large proportion of brachial plexopathies during both periods. *Closed injuries* are much more common in civilian life, with vehicular injuries, industrial accidents, and sports-related trauma accounting for most of them in adults. Violent torsion of the upper extremity, either upward or downward, may damage the plexus. Injuries to the brachial plexus of the infant may occur during birth, as a result of the strain placed on the plexus by wide separation of the head and shoulder during a difficult delivery. The mechanism of traumatic injuries— therefore, the force, rate of deformation, and direction of injury—ultimately determine the extent and location of the injury. *Open injuries* are common during both wars and civilian life. Gunshot wounds and knife injuries to the neck or axilla, shrapnel, and blast injuries can all result in brachial plexus lesions. *Iatrogenic injuries* occur during surgery (particularly procedures in the posterior triangle of the neck and in the shoulder, and when the thorax is opened), regional anesthetic blocks, and by other procedures with needles and cannulas.

At other times the causes are not as obvious. Cervical ribs, fascial bands, tumors, and scar might all directly compress the brachial plexus. Aneurysms and thrombosed veins (i.e., subclavian) may press directly on the trunks of the plexus. Years after radiation therapy a slowly progressive brachial plexopathy might appear. Brachial plexopathies might follow a vaccination. And idiopathic brachial plexus lesions, of several anatomic varieties and scores of names (brachial plexus neuropathy, multiple neuritis of the shoulder girdle, neuralgic amyotrophy of Parsonage and Turner, localized nontraumatic neuropathy in military personnel, paralytic brachial neuritis, cryptogenic brachial plexus neuropathy) occur, yet the cause remains obscure.

Differential Diagnosis. Particularly with nontraumatic brachial plexopathies, a fairly broad differential must be considered when there is a presentation of pain, numbness, weakness of the upper extremity, or all three. The differential should include musculoskeletal problems including disorders of the shoulder and cervical spine, spinal cord injury, anterior horn cell disorders, syringomyelia, intraspinal neoplasms, myopathies, peripheral neuropathies, and psychogenic paralyses. Coexistent musculoskeletal and central nervous system injuries (e.g., spinal cord injury, traumatic brain injury) are common after violent trauma and present a challenging diagnostic evaluation. Up to 80% of severe traumatic brachial plexopathy cases sustained multiple trauma to the head and skeletal system.

CHAPTER 58

Shoulder, Arm, and Elbow Pain

Michael J. Moskal and Frederick A. Matsen III

Pain is a most common shoulder and elbow symptom. The causes of shoulder and elbow pain are many and varied, including injury, degeneration, inflammation, vascular disease, tumor, and referral from a distant site. Shoulder pain is exceeded in clinical frequency only by backache, neck pain, and headache (1). The reason for this high frequency is that the shoulder girdle is a complex articulation; its stability and smooth function depend on the integrated function of numerous ligaments, tendons, muscles, and five distinct articulations. The frequency of pain in the elbow region is less than shoulder pain. Nevertheless, painful conditions involving the elbow also significantly impair the function of the upper limb and deserve serious consideration.

SHOULDER AND UPPER ARM PAIN

The shoulder girdle consists of three cartilage-to-cartilage articulations—acromioclavicular (AC), sternoclavicular, and glenohumeral joints—as well as two atypical articulations—scapulothoracic interface and humeroscapular motion interface (HSMI). A painful shoulder may involve one or more of these structures. Motion, stability, strength, and smoothness characterize a well-functioning shoulder. Many etiologies of pain are mechanical and can be attributed to shoulder stiffness, instability, weakness, or roughness.

Patient Self-Assessment

We find that patient self-assessments of health status and shoulder function help characterize the patient's condition from his or her own perspective. We obtain these assessments at the time of initial presentation as part of the baseline before treatment, or the “ingo.” These patient self-assessment questionnaires are filled out periodically after treatment has been instituted to define the “outcome” of treatment. For these purposes, we use a general health assessment, the short form 36 (SF-36), and a shoulder-specific questionnaire, the simple shoulder test (SST) (2).

The SST is an inventory of 12 common shoulder activities that provides a basic characterization of the shoulder's function. The 12 yes or no questions were derived from the common complaints of patients presenting to the University of Washington Shoulder and Elbow Service for evaluation (Table 58-1). The SST has been shown to be (a) reproducible on test-retest (2,3), (b) practical in a busy practice setting (2,3), (c) sensitive to a wide variety of shoulder disorders (2,3 and 4), and (d) able to quantitate the change in shoulder function resulting from treatment and to permit the identification of treatment failures (5).

	Yes	No
1. Is your shoulder comfortable with your arm at rest by your side?		
2. Does your shoulder allow you to sleep comfortably?		
3. Can you reach the small of your back to tuck in your shirt with your hand?		
4. Can you place your hand behind your head with the elbow straight out to the side?		
5. Can you place a can on a shelf at the level of your shoulder without bending your elbow?		
6. Can you lift 1 lb (a full pint container) to the level of your shoulder without bending your elbow?		
7. Can you lift 10 lb (a full gallon container) to the level of the top of your head without bending your elbow?		
8. Can you carry 20 lb (a bag of potatoes) at your side with the affected extremity?		
9. Do you think you can toss a softball underhand 30 yards with the affected extremity?		
10. Do you think you can throw a softball overhand 20 yards with the affected extremity?		
11. Can you wash the back of your opposite shoulder with the affected extremity?		
12. Would your shoulder allow you to work full-time at your regular job?		

TABLE 58-1. The simple shoulder test (SST)

The SF-36 is a general health status questionnaire that has been widely used to demonstrate the health status of control populations and populations with well-defined medical and psychological conditions, including the effectiveness of orthopedic management (6,7,8,9,10,11,12,13,14,15 and 16). The form documents health status from the standpoint of the patient; it is practical and easy to complete, and it has been shown to be sensitive to musculoskeletal disease and to orthopedic treatment. The importance of factors such as the SF-36 scales of emotional role function, mental health, and social function is well demonstrated in the work of Summers et al., who found that the objective severity of the disease showed little relationship to patients' reports of pain (17). Psychological variables were much more closely correlated with measures of pain and functional impairment (18).

We use the information gained from the SST and SF-36 self-assessment questionnaires to monitor the effectiveness of our treatment. The efficacy of the treatment is the difference between the ingo scores (at presentation) and the outcome scores (after treatment). We find that monitoring treatment efficacy using self-assessment tools is often more meaningful than using traditional medical metrics, such as range-of-motion and strength testing. Interestingly, Bostrom et al. (19) found that standardized assessments of shoulder function were more reliable and reproducible than conventional range-of-motion measurements.

Evaluation of the Patient

In that our primary interest is the mechanical treatment of painful and dysfunctional shoulders, we seek a mechanical cause of the patient's problem. We attempt to define the problem in terms of the shoulder's four mechanical properties: motion, stability, strength, and smoothness (2). If a patient's problem can be understood in mechanical terms, mechanical treatment may be effective. Shoulder pain that is not mechanical in origin usually requires a nonmechanical solution. Symptoms from mechanical problems typically relate to certain activities or positions. They are reproducible and usually well localized. By contrast, nonmechanical problems are typically not related to shoulder activity or position and may be more difficult for the patient to localize. Nonmechanical pain is diffuse and may involve the entire extremity. Nonmechanical problems may be accompanied by heat, swelling, redness, and tenderness and are often most manifest at night. Shoulder pain may also have a neurologic pattern, with radiation from neck to locations distal to the deltoid tubercle, or be aggravated by certain neck positions rather than shoulder positions.

History

It is important to obtain a complete history of any painful condition from onset up to the time of presentation. Details about the characteristics of the pain, including

precipitating factors, location, intensity, quality, duration, and aggravating and relieving factors, should be obtained. The presenting complaint and associated symptoms can give valuable clues to the correct diagnosis. For example, a patient with cervical spondylosis may present with shoulder pain and weakness in addition to paresthesias in a radicular distribution. A large, full-thickness rotator cuff tear may produce shoulder pain and weakness without sensory changes. The pain of acute calcific tendinitis characteristically comes on suddenly and is of such severity that the shoulder often cannot be used. The pain of degenerative joint disease is often insidious in onset and unrelated to any particular inciting process, although it may be exacerbated by injury. Pain from subacromial roughness produces symptoms when the shoulder is used in midrange positions, such as drinking from a glass, but diminishes when rested. Pain unassociated with shoulder use should always make the physician consider the possibilities of infection, tumor, or referred pain.

The location of shoulder pain provides useful information. Cervical radiculopathy often produces pain in the upper part of the shoulder and at the base of the neck. AC joint disorders (e.g., inflammation or degenerative changes) often produce pain and other symptoms just anterior to that particular articulation. Pain over the lateral deltoid is frequently of rotator cuff origin, whereas pain over the posterior glenoid humeral area often is related to conditions of the glenohumeral joint articular surface. The activities and motions that produce shoulder pain provide additional information of diagnostic significance. For example, anterior glenohumeral subluxation usually produces pain when the shoulder is abducted, extended, and externally rotated such as in an overhead throwing motion. Subacromial roughness usually produces pain when the arm is used in intermediate positions of elevation. A frozen shoulder is painful and globally restricted in all motion planes. Extension and rotation of the neck commonly exacerbate shoulder pain from cervical spondylosis. The complete history should also note other medical conditions of possible relevance to the shoulder pain. Examples might include rheumatoid arthritis, epilepsy (may result in a shoulder dislocation), diabetes (often associated with a frozen shoulder), infection, and neoplasia. Previous evaluations, treatments, medication, physical therapy, and surgery should be noted. Patients having numerous steroid injections to treat “bursitis” not infrequently turn out to have rotator cuff tears. The relationship of the shoulder pain to a patient's occupation is critical to understanding the impact of the problem on the patient's life and may also suggest the possibility of secondary gain considerations. The patient's use of pain medication is important for gaining a complete understanding of the patient's problem. Finally, attention should be paid to the patient's age, habitus, occupation, body type, posture, and emotional and cognitive functions as well as physical state.

Physical Examination

A reproducible examination consisting of inspection, palpation, range of motion, and motor testing has proved useful in the examination of patients with shoulder pain. The examiner begins by viewing the anterior aspect of both shoulders simultaneously. One should look for generalized or focal swelling, atrophy, and skin changes, including scars. Postural abnormalities such as forward-rolled or drooped shoulders should be noted. Muscular atrophy is suggestive of chronic rotator cuff tears or denervation. Scapular winging may result from nerve dysfunction or glenohumeral abnormalities.

Determining the range of motion of the cervical spine should be part of the examination of all patients with shoulder pain (Fig. 58-1A). It is particularly important to note if neck extension and rotation to the painful side exacerbate the shoulder pain. These motions narrow the intervertebral foramina on the side to which the head is turned, accentuating cervical radiculopathy. Examination of the cervical spine should be accompanied by neurologic screening of the upper extremities, with the physician looking for hypesthesia, weakness, or reflex loss (see Chapter 55 for a detailed description of the examination of the cervical spine).

Figure 58-1. First four maneuvers in palpation of painful shoulder. **A:** Palpation of the cervical spine. **B:** Palpation of the biceps tendon. **C:** Location of the supraspinatus tendon. **D:** Palpation of the coracoid process.

Figure 58-1B shows the maneuver to locate and palpate the biceps tendon. This tendon is identified as the point on the proximal humerus that lies straight anterior when the arm is internally rotated 10 degrees. Tenderness at this point may suggest bicipital tendinitis; however, many normal individuals have tenderness here. Once the biceps tendon has been located, the supraspinatus tendon insertion is palpated at the greater tuberosity just lateral to the biceps tendon (Fig. 58-1C). This is the area of the rotator cuff most commonly affected by subacromial roughness and rotator cuff disease. The normal coracoid process is frequently tender if vigorously palpated; it is rarely the site of shoulder pathology (Fig. 58-1D). The next two steps are palpation of the AC and sternoclavicular joints. The AC joint is a relatively common site for inflammatory, degenerative, and traumatic disorders, whereas the sternoclavicular joint is much less commonly affected. These joints can be palpated easily just beneath the skin (Fig. 58-2). Crepitus at various sites is felt with passive or active range of motion. Subacromial roughness at the HSMI produces a sound and a feel somewhat like wadding up newspaper. The examiner places his or her hand over the superior aspect of the shoulder, stabilizing the scapula, while the abducted arm is passively internally and externally rotated (Fig. 58-3A). Glenohumeral crepitus results when there is loss of the articular cartilage over the glenohumeral joint, producing a harder grating sound like sandpaper on wood. The joint is best palpated posteriorly just beneath the angle of the acromion as the adducted arm is internally and externally rotated (Fig. 58-3B). Scapulothoracic crepitus can usually be palpated over the superior medial border of the scapula when the patient elevates or protracts the shoulder (Fig. 58-3C). The sound is similar to the noise produced when two sets of knuckles are rubbed against each other.

Figure 58-2. **A:** Palpation of both acromioclavicular joints. **B:** Palpation of both sternoclavicular joints.

Figure 58-3. Palpation of various regions for crepitus. **A:** Subacromial region. **B:** Glenohumeral region. **C:** Scapulothoracic region.

A patient's maximal range of motion can be characterized using six basic parameters: (a) Forward elevation is measured as the maximal angle of humeral elevation in relation to the thorax as viewed from the side (Fig. 58-4A). External rotation is measured (b) at the side and (c) with the arm at 90 degrees of abduction (Fig. 58-4B). Internal rotation is measured (d) with the arm at 90 degrees of abduction as well as (e) the highest segment of posterior midline anatomy that can be reached by the thumb (trochanteric, gluteal, sacral, lumbar, or thoracic segment) (Fig. 58-4C). (f) Maximal cross-body adduction is the distance between the antecubital fossa and the contralateral anterolateral corner of the acromion (Fig. 58-4D). In addition to documenting the maximal range of motion, the quality of movement (ease, smoothness, and associated pain) and the rhythm during movement should be recorded.

Figure 58-4. Evaluation of the passive range of motion of various parts of the upper limb. Measurement of the angle of range in forward elevation **(A)**, external rotation **(B)**, internal rotation **(C)**, and cross-body adduction **(D)**

The shoulder exam should include testing the strength of the rotator cuff and deltoid muscles. The supraspinatus can be evaluated by having the patient resist a downward force while his or her arm is elevated in the anterior scapular plane and internally rotated (thumb pointed to the floor). The infraspinatus is tested by assessing the power of external rotation at the side or with the arm abducted to 90 degrees. The subscapularis should be tested while the arm is internally rotated and the hand presses away from the posterior thorax while the examiner resists “lift off.” As the examination progresses, other muscle groups such as the scapular stabilizers (rhomboids, trapezius, serratus anterior) and power movers (deltoids, pectorals) of the shoulder may be included in the evaluation.

Radiographic and Other Studies

Imaging studies of the shoulder are costly and should be used with discretion. We obtain a standard series of shoulder radiographs on most new patients to exclude arthritis, calcification, dislocation, tumor, and old trauma (2,20,21,22 and 23). Other studies, such as ultrasound, magnetic resonance imaging (MRI), bone scans, cervical spine films, and electromyography/nerve conduction velocity, are reserved for conditions in which they are likely to alter the patient's management.

Specific Shoulder Conditions

Shoulder Stiffness

Shoulder stiffness can result from abnormalities of the joint surface, such as fracture or arthritis. These are considered later under the section on roughness. In this section we consider stiffness attributable to problems with humeroscapular soft tissues: frozen shoulder and posttraumatic or postsurgical stiff shoulder. The term *frozen shoulder* (or adhesive capsulitis) refers to an idiopathic limitation of humeroscapular motion due to contracture and loss of compliance of the glenohumeral joint capsule. By contrast, in a *posttraumatic* or *postsurgical stiff shoulder*, adhesions, scarring, and capsular contracture result from previous injuries or surgery to the soft tissues around the glenohumeral joint and the HSMI. A stiff shoulder may accompany or even mask other conditions, including cervical radiculopathy, rotator cuff disease, or neoplasm.

Evaluation. It is important to document the circumstances surrounding the onset of stiffness, the duration of the condition, and any tendency toward worsening or improvement. Possible risk factors, such as a period of immobilization, metabolic diseases (diabetes or hypothyroidism), or referred pain from the neck, chest, or abdomen, should be sought out. In posttraumatic stiff shoulders, the relationship of motion loss to previous surgery or injury becomes evident from the history. The age of patients with frozen shoulder is typically between 43 and 63 years. The history often reveals that patients have difficulty sleeping comfortably on the affected side, throwing overhand, washing the back of the opposite shoulder, and tucking in their shirts.

Physical examination may reveal loss of range of flexion, external rotation, internal rotation, cross-body adduction, or a combination of these. Pain often occurs at the limits of the range of motion, but the shoulder is often comfortable in the easily allowed range. Muscular function is typically unaffected in the allowed ranges of motion.

We typically obtain two radiographic views of a stiff shoulder: (a) an anteroposterior (AP) radiograph in the plane of the scapula, with the humerus in 35 degrees of external rotation, and (b) an axillary radiograph to evaluate the glenohumeral joint articular surface fracture or dislocation.

Diagnosis. Functionally significant restriction of shoulder motion and the absence of major previous shoulder injury or surgery support the diagnosis of frozen shoulder. Glenohumeral motion is typically limited in all directions. Radiographs may show osteopenia but not other pathologic abnormalities. The diagnosis of a posttraumatic or postsurgical stiff shoulder is based on functionally limited motion after trauma or surgery; the loss is often not symmetrical. Radiographic studies are important to rule out conditions associated with loss of articular cartilage or other problems limiting shoulder range and motion, such as an overlooked posterior dislocation of the shoulder. It is important to remember that a stiff shoulder may be associated with underlying conditions, such as cervical radiculopathy, metastatic tumor, shoulder tendinitis, and other disorders.

Treatment. Frozen shoulder is treated by gentle, frequent, patient-conducted stretching exercises and a general aerobic fitness program. These exercises are performed at least five times a day. Forceful passive stretching should be avoided because of the risk of fracture or damage to the articular surface, labrum, capsule, or rotator cuff. Pain should be controlled with nonnarcotic oral medications and assurance. Occasionally, pain may significantly inhibit patients' ability to perform their exercises. These patients may benefit from a steroid injection into the glenohumeral joint (24,25). Most, but not all, cases of idiopathic frozen shoulder improve substantially with nonoperative treatment (26,27). In the situation in which a well-motivated patient continues to have major functional limitations after 4 to 6 months of an exercise program, a more aggressive approach may be considered. For a classic frozen shoulder, a gentle examination performed under anesthesia (28) may be considered. Manipulation is not used in the posttraumatic or postsurgical stiff shoulder because of the risk of fracture or of cuff tearing. For refractory shoulder stiffness, an open surgical release (29,30), arthroscopic release (31,32), or a combination of the two may be considered. After manipulation or surgical release, an early motion program is implemented, ideally with continuous passive motion.

Summary. The evaluation and management of shoulder stiffness requires localizing the site of involvement and quantifying the severity of each limited motion. Equally important is identifying possible concomitant musculoskeletal and systemic disorders. Most cases of stiff shoulder respond to a patient-conducted home exercise and fitness program.

Shoulder Instability

For the upper extremity to carry out its many and varied functions, the shoulder must provide a stable link between the humerus and thorax. This requires that the

humeral head be held centered within the glenoid. The shoulder does not have the intrinsic stability provided by the deep socket of the hip. In contrast to other joints with shallow sockets (knee, elbow, or ankle), the shoulder is not stabilized by isometric ligaments. The primary mechanism for maintaining head centering is concavity compression (2). Instability may arise from a traumatic episode or from the decompensation of the mechanisms normally providing midrange stability.

The glenohumeral joint has static and dynamic stabilizers. Static stabilizers include the glenoid articular surface, the glenoid labrum, the capsule, and its ligaments. Dynamic stabilizers include the rotator cuff and deltoid and also the periscapular musculature. The rotator cuff and deltoid provide compression of the humeral head into the glenoid socket and control of the net joint reaction force. The periscapular muscles control the scapula, which orients the glenoid to support the humeral head. In the midrange of motion when the static restraints are lax, compression of the head into the glenoid concavity is the primary mechanism of shoulder stability. At the extremes of motion the capsule and ligaments tighten sharply to check motion and stabilize the joint.

The patient's answer to three questions may help the physician to synthesize a problem with instability:

1. “Did your problem start with a major injury, and if so, what was the position of your arm?”
2. “In what positions does your shoulder go out?”
3. “Can you make your shoulder go out for me?”

From these questions, one can infer the type of instability. Traumatic instability is anteceded by a significant forceful injury. The position of the arm at the time of injury will result in a typical direction of instability. A patient with problems of instability in the midrange of motion with significant antecedent injury may have multidirectional instability.

Traumatic Glenohumeral Instability. Traumatic instability arises from an injury of sufficient magnitude to tear the glenohumeral capsule, ligaments, and/or rotator cuff or fracture the humerus or glenoid. Avulsion of the anterior glenohumeral ligament mechanism deprives the joint of stability in positions in which they are major stabilizers—that is, maximal external rotation and extension of the arm. Midrange stability may also be compromised if the glenoid is damaged, reducing its surface area. The exact location and type of traumatic injury depend on the age of the patient and the magnitude, rate, and direction of force. Avulsions of the glenoid labrum or glenoid rim tend to occur in young people. For patients older than 35 years of age, traumatic instability tends to be associated with greater tuberosity fractures and rotator cuff tears. Although the humeral head may disassociate from the glenoid in any direction, the most common direction is anterior. In traumatic instability, intrinsic stabilizing mechanisms are altered: diminished angles of balance stability, loss of concavity compression, loss of adhesion-cohesion, loss of the glenohumeral suction cup, loss of finite joint volume, and loss of capsuloligamentous restraint (2,3,33).

Evaluation. In evaluating traumatic instability, the most important element is the definition of the original injury. Common injury mechanisms are a fall while skiing, an arm tackle in football, or a block in volleyball. Traumatic instability may occur without a complete dislocation. Shoulder instability may manifest as apprehension when the arm is placed near the position of injury. Characteristically, the shoulder is comfortable when troublesome positions are avoided. Patients who have recurrent dislocation are anxious and apprehensive that the shoulder may “go out” when it is placed in certain positions. There may be a history of increasing ease of dislocation or dislocation during sleep. The most consistent functional impairments tend to be the inability to throw overhand, to put the hand behind the head, and to lift 8 pounds to head level.

The goal of the physical examination is largely to confirm the impression obtained from the history: instability with a certain combination of arm position and force application. The most common direction of instability is anteroinferior. Stability in this position is challenged by externally rotating and extending the arm elevated in the coronal plane (Fig. 58-5A). Apprehension, the fear of uncontrollable glenohumeral translations, typically occurs if stability is compromised. Pain in this position is not specific for instability; such pain may also relate to stiffness or abutment of the glenoid against the posterior cuff insertion on the humeral head. The load and shift test (Fig. 58-5B) determines the integrity of the anterior glenoid labrum. The examiner compresses the humeral head into the glenoid fossa and attempts to translate the head anteriorly. If the labrum is intact, the humeral head will not translate anteriorly, and one can conclude that the labrum is not contributing to instability. In all patients, especially those older than 35, the strength of external rotation and internal rotation must be examined to evaluate the rotator cuff. Finally, a careful neurologic examination is in order to determine whether any nerve lesions are associated with the instability (34). Radiographs frequently help to confirm the diagnosis. The instability series of radiographs consists of an AP view in the plane of the scapula, with the humerus in 35 degrees of external rotation, an apical oblique view (35), and an axillary view. Findings may include an impaction fracture of the posterolateral humeral head (Hill-Sach's lesion) from contact with the anteroinferior corner of the glenoid, a periosteal reaction to the ligamentous avulsion at the glenoid lip (Bankart lesion), or occasionally a fracture of the glenoid rim (36). In the patient with suspected rotator cuff pathology (age older than 35 years and weakness), imaging, such as by expert ultrasound or MRI, is of value because (a) the best results are obtained with prompt repair of traumatic cuff tears, and (b) the approach for rotator cuff surgery is quite different from that for repair of an anteroinferior capsular lesion.

Figure 58-5. Maneuvers to evaluate stability of the glenohumeral joint. **A:** Apprehension test. **B:** Load and shift test.

Diagnosis. The diagnosis of traumatic instability is based on (a) a mechanism of injury sufficient to tear the glenohumeral ligaments, such as a major external rotation torque applied when the arm is elevated near the coronal plane, and (b) functionally significant recurrent episodes of apprehension or instability (2,36,37). In the evaluation of recurrent anterior instability, apprehension or instability should be present when the arm is externally rotated and abducted to 90 degrees. The diagnosis is supported when previous radiographs document a dislocation or current radiographs show the characteristic posterolateral humeral head fracture and/or a glenoid lip fracture or calcification.

Treatment. For some patients, appropriate management consists solely of education about the nature of the lesion and identification of the positions and activities that need to be avoided. Strengthening the shoulder musculature may help prevent the shoulder from being forced into positions of instability. We consider surgical treatment for informed patients who are unwilling to accept the functional limitations imposed by recurrent instability. The goal of surgical treatment of traumatic anterior glenohumeral instability is the safe, secure, and anatomic reattachment of the detached glenohumeral ligaments to the lip of the glenoid from which they were avulsed. No attempt is made to modify the normal laxity of the anterior capsule. The anatomic reattachment should reestablish not only the capsuloligamentous check rein but also the fossa-deepening effect of the glenoid labrum (38). A secure repair allows early controlled mobilization and protected activities of daily living, thereby minimizing the possibility of unwanted stiffness. Surgical treatment of traumatic anterior involuntary instability has a success rate of 95% to 98% (37,39,40,41,42,43 and 44).

Atraumatic Glenohumeral Instability. Atraumatic instability arises without major trauma, occurs in the midrange of motion, and is typically symptomatic in more than one direction. A shoulder that has been stable may become unstable after a minor injury or a period of disuse. Certain shoulders may be more susceptible to atraumatic instability. A flat or small glenoid fossa, a thin excessively compliant or redundant glenohumeral capsule, weak rotator cuff muscles, or poor neuromuscular control may, individually or in combination, contribute to instability of the glenohumeral joint.

Evaluation. Atraumatic instability presents most commonly in persons younger than 30 years of age. A relatively minor event such as an awkward lift or a sneeze may be all that is needed to launch a predisposed, but compensated, shoulder toward instability. The patient may notice that the shoulder is loose or that it slips out. The instability may be sufficiently subtle that the patient is aware only that the shoulder does something unnatural in certain positions. The patient may volunteer that the

shoulder can be popped out or that at times the shoulder feels as if it needs to be popped out. The positions of the shoulder, frequency of symptoms, and any associated atypical symptoms such as numbness or tingling should be documented. These patients typically have difficulty sleeping, lifting overhead, or throwing. Physical examination begins with the patient demonstrating the positions in which the shoulder feels unstable or different. The patient may demonstrate a spontaneous jerk test by bringing the elevated arm horizontally across the chest, causing the humeral head to subluxate posteriorly, and by returning the elevated humerus to the coronal plane, the joint reduces with a clunk. Patients may demonstrate that the joint subluxates inferiorly when they attempt to lift an object or tie their shoes. Finally, when they lie on the shoulder or elevate it in a posterior humerothoracic plane, they may produce anterior subluxation. As the patient is maneuvering his or her shoulder in space, faulty patterns of scapulohumeral mechanics such as the lateral scapular droop during lifting or retracting the scapula during anterior humeral elevation may become apparent.

The extent of laxity on manual testing is documented for all directions of translation; however, the magnitude of translation for shoulders with atraumatic instability may be the same as that of normal shoulders or those with traumatic instability (2,45). Therefore, we pay particular attention to the patient's response during laxity testing, seeking recognition of the provocative direction(s) of translation. We always make a point of examining the contralateral shoulder. Usually, but not always, the opposite shoulder yields similar translational distances as compared with the symptomatic shoulder. This provides a foundation to discuss with the patient and family the rationale for a rehabilitation program to regain dynamic control. Strength testing of the rotator cuff and deltoid and periscapular muscles is used to gauge muscle power and to infer its contribution, or the lack of it, to stability. Radiographic examination includes an AP view, with the humerus in 35 degrees of external rotation, an apical oblique view, and an axillary view. These views may show that the humeral head center is translated away from the glenoid center or a dysplastic glenoid. In most cases, however, the x-rays are normal.

Diagnosis. The diagnosis is predicated on demonstrating the patient's inability to keep the humeral head centered in the glenoid fossa, especially in the midrange of motion, along with the absence of an injury that could tear glenohumeral ligaments. The physical examination should reproduce symptomatic glenohumeral translations. Radiographs show an absence of any traumatic lesion.

Treatment. The hallmark of treatment is patient education and neuromuscular rehabilitation. Patients should avoid positions or activities of instability and specifically avoid voluntary subluxations, even if they feel that their shoulder “needs” to be popped out of joint. An exercise program is instituted that consists of rotator cuff strengthening (internal and external rotation), humeroscapular balance retraining, and muscular endurance (2,46). Good or excellent results can be expected in more than 80% of patients treated with rehabilitation (47).

In those patients who remain disabled, operative intervention may be considered. The patient must understand that capsulorrhaphy is not always curative and that the potential for recurrence is significant. He or she must also understand that surgery typically tightens the capsule, which may limit motion and may cause discomfort. Even after surgery, good strength and kinematics techniques remain the primary stabilizers of the joint.

Summary. Patients with atraumatic instability are usually young, perhaps with a family predisposition to “loose joints” and do not have a history of major trauma. The instability is most prevalent in the midrange positions commonly used in activities of daily living; the contralateral shoulder may be “loose.” Rehabilitation is the treatment of choice.

Patients with traumatic instability usually have a readily defined traumatic event; however, a complete dislocation of the glenohumeral joint is not necessary. The shoulder is unstable near the extreme of joint motion, and instability or apprehension can be reproduced by placing the arm in a position similar to injury. For the well-informed patient who does not wish to accept the positional instability, surgery usually corrects the definable defect in the capsulolabral complex.

Shoulder Weakness

Rotator Cuff Tears. The four muscles of the rotator cuff are uniquely adapted to contribute to muscle balance and make a major contribution to shoulder strength. Their insertion into a continuous cuff around the humeral head permits these muscles to provide an infinite variety of moments to oppose unwanted components of the stronger deltoid and pectoralis muscles. When the function of the cuff muscles is compromised, the shoulder loses both balance and strength due to the loss.

Full-thickness cuff lesions are unusual in those younger than age 40 because the young healthy rotator cuff is highly resistant to disruption or degeneration. When cuff lesions occur in the younger age group, they may be only partial thickness, or they may include the avulsion of bone from the tuberosity. Like the rest of the body's connective tissues, rotator cuff tendon fibers become weaker with disuse and age; as a result, less force is required to disrupt them. The symptoms from an acute cuff tear may resolve, leaving the shoulder asymptomatic, except for an increment in weakness. Thus, we not infrequently encounter patients with large cuff defects and minimal or no symptoms. If these shoulders remain stable, with the humeral head centered in the glenoid, they can demonstrate excellent function. Bilateral degenerative cuff defects are common. In one of our studies we found that 55% of patients presenting with a symptomatic cuff tear on one side also had a tear on the opposite side (48).

Cuff failure may progress as major episodes of tendon tearing or as creeping tears involving relatively few fibers at a time. Degenerative lesions of the cuff typically start at the deep surface of the anterior insertion of the supraspinatus near the long head of the biceps. It is difficult for these lesions to heal because of the compromised vascularity and large applied loads that the healing tissue must endure. When a tendon fiber fails, the attached muscle fibers contract and increase the gap needed to be closed; synovial fluid enzymes remove the fibrin clot necessary for healing of the cuff tear. In the absence of repair, the degenerative process tends to continue through the substance of the supraspinatus tendon to produce a full-thickness defect in the anterior supraspinatus tendon. A full- thickness defect tends to concentrate loads at its margin, facilitating additional fiber failure with smaller loads than those that produced the initial defect.

As the rotator cuff fibers fail, the humeral head is subjected to the unbalanced upward pull of the deltoid. As a result, the thinned cuff allows the humeral head to move superiorly toward the coracoacromial arch. The cuff is abraded with motion against the arch. The progression from partial-thickness tear toward massive cuff tears can take place as a subtle, subclinical degenerative process. It can also progress as a series of episodes interpreted as “tendinitis,” “bursitis,” or “impingement syndrome,” as sequential injuries produce acute extensions of the defect. It is important to note that cuff defects arising with minimal or no injury suggest that the cuff tissue is of poor quality and thus is more likely to fail again after surgical repair. By contrast, acute tears resulting from major injuries are more likely to involve robust tissue that is amenable to a durable repair.

The disuse of torn tendon leads to scarring and atrophy of tendon and muscle. Loss of cuff material from the degenerative process limits what is available for repair. Local injections of steroids may further compromise the healing potential of failed cuff fibers. As a result of these factors, the effectiveness of repair is limited by the quantity and quality of the tissue available at the time of surgery.

Evaluation. A tentative diagnosis of rotator cuff tear can be made by history and physical examination (49,50 and 51). A typical scenario for degenerative cuff fiber failure is an older individual who has an insidious onset of weakness of flexion and external rotation, perhaps punctuated by episodes of “bursitis” or “tendinitis.” Failure of weakened tendon tissue may not produce much in the way of pain, bleeding, or swelling. If the patient has pain, it is typically referred to the deltoid insertion. The shoulder may have been treated with steroid injections, with some relief of discomfort but without improvement in strength. More acute incremental losses of strength from tear propagation may follow lifting or falls. Patients with full-thickness rotator cuff tears are older than 30 and typically older than 40 years old. Patients with cuff tears typically have problems with such activities as sleeping on the affected side, placing the hand behind the head, lifting 8 pounds, and throwing overhand.

A greater injury is required to tear the cuff of individuals at the younger end of the age distribution. Younger patients with cuff tears commonly give a history of a sudden eccentric loading, such as trying to support a falling load or trying to cushion a fall with the arm; often, they complain of “tearing” and may hear a snapping sound as the tendon gives way. Traumatic glenohumeral dislocations in individuals older than the age of 40 years have a strong association with rotator cuff tears. These traumatic cuff tears may also involve the subscapularis, producing weakness in internal rotation.

Shoulder weakness may also result from neurologic lesions. Long thoracic nerve palsy causes posterior winging of the scapula on attempts to elevate the arm. Radiculopathy of the sixth cervical nerve results in pain on top of the shoulder with radiation down the arm below the deltoid tubercle, weakness of the cuff and biceps, diminished biceps reflex, and sensory changes on the lateral forearm. Suprascapular neuropathy from brachial neuritis typically has an acute onset of pain lasting several weeks, followed by weakness of external rotation and flexion.

On physical examination, atrophy of the spinatus muscles can be seen by casting a shadow from a light over the head of the patient. Rotator cuff defects may be palpable just posterior to the bicipital groove and just medial to the greater tuberosity. Crepitus upon rotation of the arm elevated to shoulder height may result from

the abrasion of torn tendon margins against the coracoacromial arch (a positive “abrasion sign”).

Many patients with substantial complete cuff tears retain the ability to elevate their shoulders, although this movement is often weak. Passive motion is typically greater than active. Isometric tests that challenge the strength of different components of the cuff demonstrate weakness, pain, or both, a positive “tendon sign.” The supraspinatus is challenged by isometric flexion of the internally rotated arm, which has been elevated 90 degrees in the plane of the scapula. The infraspinatus is challenged by isometric external rotation with the arm in neutral rotation at the side. The subscapularis is challenged by isometric internal rotation, pushing the hand away from the waist in the posterior midline.

Partial tears tend to demonstrate a minimal loss of strength with relatively more pain and stiffness. Passive forward elevation, internal rotation up the back and in abduction, and cross-body adduction are limited due to selective tightness of the posterior capsule. The shoulders will often be painful with elevation, due to stretching of the capsule as well as forced translation of the humeral head toward the acromion, compressing the rotator cuff. Large tears may involve both the infraspinatus and supraspinatus and compromise external rotation strength. Massive tears compromise the subscapularis and weaken internal rotation in addition to external rotation at the side and in abduction.

Standard radiographs may be helpful in evaluating shoulder weakness. We obtain an AP view, an axillary lateral view, and a 30-degree caudal AP view. On the AP view, chronic cuff disease may be accompanied by sclerosis of the undersurface of the acromion or cysts in the greater tuberosity and tuberosity avulsion fractures in younger patients with acute tears. Traction spurs in the coracoacromial ligament, from forced contact with the cuff and the humeral head, are best seen on the 30-degree caudal-tilted AP. In large cuff tears, the head of the humerus may be subluxated upward toward or against the undersurface of the acromion, narrowing the AC interval (Fig. 58-6). In cuff tear arthropathy, the humeral head may have lost the prominence of the tuberosities (become “femoralized”), and the coracoid, acromion, and glenoid may have formed a deep socket (become “acetabularized”). Incomplete-thickness rotator cuff lesions usually have normal radiographs.

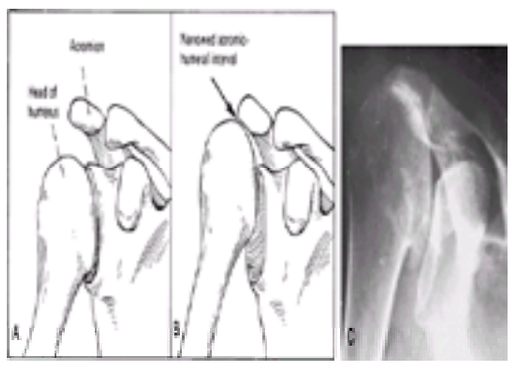

Figure 58-6. **A:** Diagram of the normal relationship of the acromion and head of the humerus, the so-called acromiohumeral interval. **B,C:** Diagram and radiograph of narrowed acromiohumeral interval, probably due to rotator cuff tear.

A number of different studies are available for imaging the rotator cuff. MRI can reveal information about the tendon and muscle. Dynamic ultrasonography (52) can reveal the thickness of the various components of the cuff and the extent of cuff defects. Each of these tests adds expense to the evaluation of the patient. Resources can be conserved by not ordering imaging tests unless it will change the management of the patient. Patients younger than age 40 years without a major injury are unlikely to have significant cuff defects; thus, cuff imaging is usually not helpful. At the other extreme, patients with weak external rotation and atrophy of the supra- and infraspinatus muscles whose plain radiographs show the head of the humerus in contact with the acromion do not need cuff imaging to establish the diagnosis of a rotator cuff defect. The management of patients with nonspecific shoulder symptoms and an unremarkable physical examination is unlikely to be changed by the results of any cuff-imaging test. The primary indication for cuff imaging is to establish the diagnosis in situations in which it would affect treatment, such as a 47-year-old patient with weakness of flexion and external rotation after a major fall on the outstretched arm and who has normal radiographs.

Diagnosis. Patients with incomplete-thickness rotator cuff lesions are typically 30 to 52 years of age at presentation, whereas patients with complete-thickness rotator cuff tear usually present between 48 to 75 years of age. Onset in younger patients is related to injury that unexpectedly applies a major eccentric load to an elevated humerus during work or sport, whereas in older patients, the onset may be insidious and apparently atraumatic. Patients with cuff tears typically complain of significant weakness, especially on elevation of the arm in anterior planes, and functional problems such as difficulty sleeping, difficulty lifting 8 pounds to shoulder level, and difficulty throwing.

On physical examination, patients with incomplete-thickness rotator cuff lesion usually have positive tendon signs, with pain as a significant component. An abrasion sign (crepitus on passive rotation of arm in elevated position) is often present if the tear involves the superior surface of tendon. Those patients with complete-thickness rotator cuff tear have positive tendon sign, with less pain. Atrophy of the supraspinatus and possibly infraspinatus is seen and often there is an abrasion sign.

Patients with cuff tears often have normal radiographs. With chronic full-thickness tears, radiographs may show superior displacement of the humeral head in relation to the acromion and a traction spur formation in the coracoacromial ligament. There may be cystic changes in the greater tuberosity and sclerosis of the undersurface of the acromion.

Treatment. Treatment of shoulder weakness caused by cuff failure is determined by the functional needs of the patient and the state of the cuff tendon. Substantial information concerning the reparability of a rotator cuff defect can be determined from the history. Acute tears in younger, healthy individuals without prior shoulder disease are likely to be repairable. Long-standing tears associated with major weakness in older patients probably offer tissue of insufficient quality and quantity to be repairable. The prognosis for a durable repair is further compromised if the history reveals prior treatment with local or systemic steroids, smoking, or difficulties in healing from previous injuries or surgeries. Critical determinants of the success of operative treatment are the quality of the residual tendon and muscle and the amount of cuff tendon tissue that has been lost. The expected strength of the cuff diminishes with age, disuse, and the duration of the cuff defect. With chronic tears, there is time to explore nonoperative management, including a general shoulder strengthening and stretching program. This nonoperative program may be the treatment of choice for patients who are not candidates for surgery or for those in whom achieving a durable repair seems unlikely. The goals of a nonoperative program are to optimize the strength and coordination of the muscles about the shoulder that remain intact. The rehabilitation program initially emphasizes stretching: supine forward elevation, cross-body adduction, internal rotation up the back, and external rotation. As the range of motion increases and pain decreases, strengthening exercises are added. It is important to avoid aggravating positions and activities.

Operative repair is considered when the shoulder demonstrates weakness from a cuff defect, and there appears to be a substantial chance of achieving a durable functional repair—that is, the quality and quantity of tendon are sufficient for repair. A prompt surgical repair of the rotator cuff is considered for physiologically young patients with acute tears and tears associated with instability. Repair should be carried out before tissue loss, retraction, and atrophy occur. If inspection of the cuff at surgery reveals good-quality tissue in sufficient quantity, the contractures are released, and the tendon is secured to the anatomic insertion site on the humerus under normal tension with the arm at the side. The repair is accomplished as a tongue in groove, with the cuff tendon drawn into a trough near the tuberosity, providing a smooth upper surface to glide beneath the acromion. Cuff repair is a shoulder-tightening operation; thus, it is not a treatment for the shoulder with functional limitation caused by tightness, even if a cuff defect is present. If the shoulder demonstrates stiffness, especially of the posterior capsule, a shoulder mobilization program is instituted before consideration of surgery.

Rotator cuff surgery (cuff repair or debridement) is considered for chronic or “atraumatic” tears with persistently substantial symptoms in spite of a nonoperative treatment trial. If there is major tissue loss and the residual tendon is of poor quality, a robust repair cannot be performed. Under these circumstances, the coracoacromial arch is preserved to provide the shoulder with its last vestige of superior stability. We smooth the torn cuff edges and excise the hypertrophic bursa and scar tissue in the subacromial area to allow unimpeded passage of the humeral head and residual cuff beneath. It is also helpful to smooth the uncovered tuberosities if they are prominent or irregular.

After rotator cuff surgery, the patient is returned to the recovery room with the affected arm in continuous passive motion. Immediate postoperative motion, facilitated if

the surgery is performed under a brachial plexus block, is valuable because there is a tendency for scarring between the undersurface of the acromion and the upper aspect of the rotator cuff or proximal humerus. The patient is expected to perform passive exercises in flexion and external rotation. Before discharge, the patient should be able to attain 140 degrees of passive flexion and 40 degrees of passive external rotation. A progress chart mounted on the patient's wall helps to document progress toward these discharge goals. The specific rehabilitation program depends on whether the cuff was repaired or debrided. Patients are usually pleased with the results of cuff surgery. However, it may be difficult to determine what aspect of the treatment program is responsible for the improvement. Many patients with deficient cuffs are surprisingly comfortable and functional and therefore never undergo surgery. It is also known that the tissue encountered at surgery is not infrequently insufficient to allow a durable repair, yet the patient is improved after debridement surgery.

We studied the integrity of the rotator cuff repair and patient satisfaction. The integrity of the rotator cuff at follow-up, not the size of the tear at the time of repair, was the major determinant of the function after surgical repair. Five years after surgery, the chances of the repair of a large tear remaining intact were not as good as those for a small tear. Older patients tended to have larger tears and a higher incidence of recurrent defects. Patients were generally satisfied with the results of surgery, even when expert sonography showed that the cuff was no longer intact at follow-up. Shoulders with intact repairs at follow-up had the greatest range of active flexion as compared with those with large recurrent defects, and the patients also had demonstrated the best function in activities of daily living. For patients without an intact cuff, the degree of functional loss was related to the size of the recurrent defect.

Surgical complications may worsen the function of a cuff-deficient shoulder. A serious complication is compromise of the deltoid muscle, the most important motor for shoulder elevation. Nerve injury or failure to achieve a strong reattachment of the anterior fibers to the acromion may compromise deltoid function. Scarring in the HSMI between the acromion and deltoid and the cuff and humerus can restrict humeroscapular motion, negating any benefit achieved from restoring cuff integrity. This complication results from immobilization of the cuff against the acromion and deltoid after surgery and the formation of adhesions or spot welds that inhibit motion. Loss of superior stability can result when the coracoacromial arch is sacrificed without reestablishing stability with a durable cuff repair. In this situation, deltoid contraction pulls the head of the humerus anterosuperiorly, rather than elevating it (Fig. 58-7A and Fig. 58-7B). The deltoid becomes stretched so that the humeral head seems to be just below the skin (Fig. 58-7C).

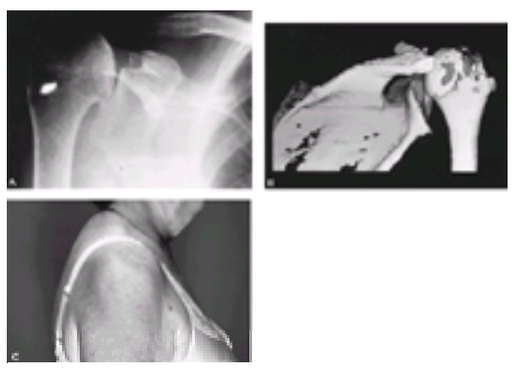

Figure 58-7. **A:** The humeral head is anterosuperiorly displaced upon the glenoid after surgical resection of the anterior acromion and coracoacromial ligament. **B:** A three-dimensional computed tomography reconstruction viewing the glenohumeral joint from a posterior aspect. **C:** The humeral head is anterior and superior and prominent below the skin.

Although cuff repair may increase the strength of the shoulder, our preference is to avoid having the patient return to heavy lifting, pushing, pulling, or overhead work after a major cuff repair. Thus, we attempt to initiate vocational rehabilitation as soon as the diagnosis is made, indicating that in spite of optimal treatment, there is a substantial risk of retearing if the cuff is subjected to major loads. It is important to remind both the patient and the employer that a cuff tear usually occurs through abnormal cuff tendon. Repairing the tear does not restore the quality of the tendon tissue; thus, the cuff remains vulnerable to sudden or large loads.

Summary. Rotator cuff tears increase in prevalence with increasing age and are common causes of shoulder weakness. With the exception of young patients with significant trauma, most rotator cuff tears occur in degenerated tissue, which makes the cuff susceptible to small, eccentrically applied loads. Many patients with torn rotator cuffs are surprisingly comfortable and functional and therefore never undergo treatment. For other patients, the mainstay of treatment may be education, stretching, and strengthening.

Rotator cuff repair is strongly considered in active patients who develop sudden weakness after an injury. Selected patients with chronic tears who are functionally disabled after a trial of nonoperative treatment may be candidates for rotator cuff surgery. The tissue encountered at surgery maybe insufficient to allow a durable repair.

Calcific Tendinitis

Acute calcific tendinitis is a common cause of shoulder pain and is often self-limited. The calcium deposits most frequently occur in the supraspinatus tendon (53). The etiology and pathophysiology of acute calcific tendinitis are not well understood. Some have attributed the calcium deposition to local microtrauma, whereas others have attributed it to local hypoxia (54,55). The pathogenesis of calcific tendinitis seems to be a degenerative process with secondary calcification within the tendon fibers (7,56,57). Cailliet (56) proposed that small particles, consisting primarily of calcium salt, are formed during degeneration of the tendon. The hyperemia associated with an acute episode causes coalescence of the calcium with formation of a liquid calcium mass, but as the vascularity subsides, this calcified mass returns to a dry state that can be seen radiographically. Uhthoff et al. (55) suggested that the primary stimulus is hypoxia, which results in transformation of a portion of the tendon into fibrocartilage. According to this view, calcification occurs in extracellular matrix vesicles located in the areas that have undergone fibrocartilaginous transformation and not associated with inflammation or scarring.

Evaluation. Calcific tendinitis often presents with the sudden onset of well-localized pain without a history of trauma (58). Calcific tendinitis typically occurs in patients approximately 40 years of age (59). The pain can be severe enough to limit shoulder motion and interfere with sleep. The rotator cuff is locally tender and strength testing reveals pain and mild weakness. Bursal hypertrophy and subacromial roughness are not uncommon. Radiographs show calcium deposits in the supraspinatus or one of the other tendons of the shoulder (Fig. 58-8). Usually a calcific deposit is seen on underpenetrated radiographs of the shoulder, particularly if the radiograph is taken so that the deposit is not superimposed on the humerus itself. Consequently, oblique angles are sometimes required to demonstrate the calcific deposit in profile.

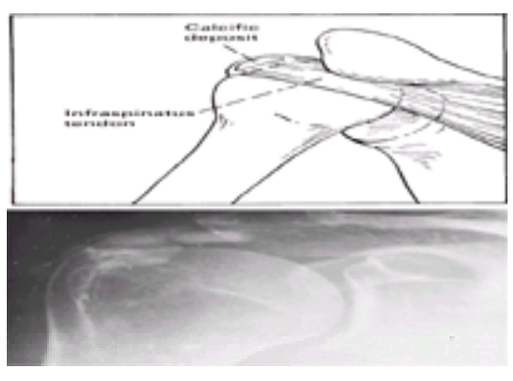

Figure 58-8. Diagram **(A)** and radiograph **(B)** of the infraspinatus tendon with a calcific deposit.

Diagnosis. Diagnosis of acute calcific tendinitis is based on its characteristic history, localized pain, and rotator cuff tenderness. Radiographs show calcification commonly in the supraspinatus tendon. It is important to differentiate this condition from chronic calcium deposition in the shoulder, which is frequently asymptomatic (53).

Treatment. Antiinflammatory medication, rest, and a single subacromial injection of local anesthetic and steroid are usually helpful. In the early phases of the condition, the calcium may be aspirated with a large-bore needle. Active assist and passive range-of-motion exercises help maintain shoulder motion. Functionally significant persistent symptoms can be treated by surgical removal of the calcium deposits followed by rotator cuff rehabilitation.

Summary. Acute calcific tendinitis is often self-limited; however, simple excision is typically curative for patients with prolonged symptoms and functional impairment.

Shoulder Roughness

There are five areas of the shoulder in which smoothness is required for optimum function. Two are atypical articulations known as the scapulothoracic interface and the nonarticular HSMI. The three cartilage-to-cartilage articulations are the AC, sternoclavicular, and glenohumeral joints. These articulations may be affected by trauma, autoimmune diseases, neuromuscular disorders, and aging. Roughness produces problems during active use of the shoulder. The positions and circumstances that elicit a problem should be carefully defined.

Subacromial Roughness. Subacromial roughness or abrasion involves the HSMI. The HSMI is a partially bursa-lined interface that lies between a deep group of structures (proximal humerus, rotator cuff, and biceps tendon sheath) and a superficial group of structures (deltoid, acromion, coracoacromial ligament, coracoid process, and tendons attaching to the coracoid). Excursions of up to 4 cm take place at this nonarticular interface (2). This motion interface includes what is often referred to as the subacromial “space.” However, empty spaces do not exist in the intact shoulder, and the area beneath the acromion and coracoacromial ligament is occupied by bursa and cuff in contact with each other. Normal humeroscapular motion requires smoothness at this interface just as much as it depends on smoothness at the glenohumeral articulation.

Subacromial roughness rarely results from the superficial aspect of the motion interface (the undersurface of the coracoacromial arch) as a consequence of developmental variances in the shape of the acromion or coracoid, or from secondary traction spurs in the coracoacromial ligament. More commonly, roughness of the deep aspect of the interface results from complete or partial- thickness cuff tears involving the upper surface of the tendon, bursal hypertrophy, sutures or lumpy tendon attachments after cuff repair, prominent tendon calcifications, or abnormal prominence of the tuberosities.

Alterations in the normal postural relationships of the humerus and scapula can result from capsular imbalance or cuff deficiency. Tightness of the posterior capsule can produce superior obligate translation of the humeral head on the glenoid on elevation of the humerus in anterior scapular planes, forcing abrasive contact between the cuff and the undersurface of the coracoacromial arch. Cuff deficiency may also allow superior translation of the humerus in relation to the scapula, creating localized abrasion of the proximal humerus beneath the unyielding acromion. Repeated forced contact of the cuff or proximal humerus with the undersurface of the anterior acromion can produce a traction spur extending out into the coracoacromial ligament. However, this intraligamentous spur does not compromise the smooth passage of the humerus and cuff beneath the arch. Continued subacromial abrasion may grind up the remaining interposed rotator cuff tissue. When the cuff is gone, this abrasive contact erodes the humeral articular cartilage, leading to cuff tear arthropathy.

Evaluation. The most common complaint of patients with subacromial roughness is limited function with the arm in intermediate positions of elevation. Patients may complain of grinding, catching, or snapping in addition to weakness. It is important to have the patient describe the onset of the problem, mechanism of injury, and nature and progression of functional difficulties as well as the specific maneuvers that reproduce the symptoms. The patient should be asked about the response of the shoulder to previous treatment, including exercise, injections, physical therapy, and surgery.

On physical examination, the examiner can distinguish the site of roughness by selectively restricting motion to one joint at a time. Roughness in the subacromial area of the HSMI is usually manifested on rotation of the arm near 90 degrees of humeroscapular elevation while stabilizing the clavicle, acromion, and scapular spine on the chest wall. Crepitus upon this maneuver, which reproduces the patient's complaint, constitutes a positive subacromial “abrasion sign.” The tenor of the crepitus is usually a higher-pitched sound, like the sound produced by wadding up a piece of paper. Strength testing of the rotator cuff tendons may elicit pain, weakness, or both. Stiffness, especially of the posterior capsule, is frequently present and is manifested as limited cross-body adduction and internal rotation.

Radiographic examination includes an AP view in the plane of the scapula, a 30-degree caudal-tilted AP view, an outlet view, and an axillary view. Primary or secondary changes of the undersurface of the coracoacromial arch, such as sclerosis or traction spurs of the coracoacromial ligament, may be seen.

Diagnosis. The diagnosis of subacromial roughness is characterized by limited function with the arm in intermediate positions of elevation. With the scapula stabilized, rotating the humerus in midrange elevation produces subacromial crepitus that reproduces the function-limiting symptoms, a positive abrasion sign. The coexistence of rotator cuff disease manifested as tendon signs and/or radiographic changes such as subacromial sclerosis or a traction spur of the coracoacromial ligament further supports the diagnosis of subacromial roughness.

Treatment. Unless the diagnostic evaluation dictates otherwise, the patient is reassured that crepitus and occasional catching do not necessitate surgical intervention. Crepitus on moving the humerus with respect to the deltoid and coracoacromial arch is very common and may be of little functional significance. For patients with functionally significant roughness of the nonarticular HSMI, the aim of nonoperative management is to restore normal kinematics: minimize stiffness, optimize shoulder mechanics, and increase strength and endurance. The first goal is flexibility, eliminating adhesions or posterior capsular tightness that may cause obligate anterosuperior humeral translation and subacromial abrasion. As flexibility is improved, attention is then directed at optimizing the normal stabilizing effect of the rotator cuff musculature by strengthening exercises, emphasizing internal and external rotation strength and endurance. Finally, the periscapular muscles are strengthened to improve posture and shoulder rhythm.

If a persistent and thorough rehabilitation effort fails to restore functional humeroscapular smoothness, consideration may be given to a surgical approach to the problem. Surgical smoothing is likely to be of functional benefit only if the patient's functional problem can be clearly localized to the subacromial region. Some patients demonstrate compromised smoothness of various aspects of the HSMI after injury or surgery—for example, roughness at the site of surgical reattachment of the subscapularis as it passes beneath the coracoid muscles on rotation. However, most functionally significant problems are in the subacromial zone and associated with some type of rotator cuff disorder. Subacromial surgery may not be beneficial for poorly defined pain or cuff strain; subacromial surgery may actually compound shoulder stiffness by creating additional sites for adhesion formation. We have found that surgical treatment of subacromial roughness is most likely to be successful in a well-motivated patient older than age 40 whose problem has been refractory to a good home program effort and whose symptoms are reproduced by the abrasion sign. The patient needs to understand what the procedure may or may not accomplish. The procedure is not expected to restore the shoulder to heavy work or to high-level athletics, but it should improve the shoulder's ability to perform activities of daily living, light work, and recreation. Workers injured on the job tend not to return to heavy, over-the-head labor (60,61). Maximal improvement after this procedure may take 6 to 12 months and will require home exercises identical to those before surgery. At time of surgery, other abnormalities may be encountered that need attention, such as a defect in the rotator cuff, bony abnormalities, or calcium deposits.

In the surgical management of subacromial roughness, it is essential to preserve the deltoid and the coracoacromial ligament to maintain the “roof” of the shoulder. The bursa on the deep surface of the deltoid muscle is entered. Thickened bursa is resected to help smooth the space and to allow inspection of the subjacent rotator cuff. The undersurface of the acromion is assessed and then bony and/or soft tissues are smoothed if indicated. An evaluation of the integrity of the cuff is made at this time. If a cuff defect is present, its reparability is assessed. When substantial roughness of the nonarticular HSMI exists in the presence of an irreparable cuff defect, emphasis is placed on smoothing the contacting surfaces rather than “decompression.” Rough edges of the acromion, hypertrophic bursal tissue, prominent tuberosities, and irregular edges of cuff tissue are removed to leave the smoothest possible HSMI. Smoothness of the motion between the anterior aspect of the subscapularis and the deep surface of the muscles originating from the coracoid process must be verified as well. If tightness is present, the approach may need to be modified to allow appropriate releases.

After surgery, the shoulder is placed in immediate passive motion. We hypothesize that immediate postoperative passive motion induces the undifferentiated cells in the surgical site to generate a smooth new motion interface, rather than irregular and adherent surfaces. We use immediate postoperative continuous passive motion until the patient can carry out his or her mobilization program without assistance. Again, the specifics of the postoperative rehabilitation program are tailored to the

patient and the nature of the operative procedure.

At present, “failed acromioplasty” is a very common condition among patients referred to our shoulder service. Postacromioplasty problems often include (a) no improvement, (b) increased pain, (c) loss of anterior deltoid strength, (d) increased stiffness, and (e) anterior-superior instability. These failed open or arthroscopic acromioplasties were usually performed for a preoperative diagnosis listed as “impingement syndrome.” However, a careful history often suggests other diagnoses, such as a stiff shoulder, cuff strain, partial-thickness cuff tears, and nonspecific shoulder pain. Poor results from subacromial surgery result when an excessive amount of acromion was removed, the acromion was transected, an irregular undersurface of the acromion resulted, or deltoid reattachment failed.

Summary. Roughness of the HSMI is frequently subacromial in location. Crepitus and occasional catching do not mandate surgical intervention unless they are associated with major refractory symptoms.

Glenohumeral Roughness. The humeral head and the glenoid normally articulate through smooth, congruent, and well-lubricated joint surfaces. Glenohumeral arthritis results when these joint surfaces are damaged by congenital, metabolic, traumatic, degenerative, vascular, septic, or inflammatory factors. The causes and pathophysiology of these conditions are identical to those of similar disorders affecting other joints. It is significant, however, that destruction of the glenohumeral joint surface can proceed from any of these causes in the absence of involvement of other joints (62). Especially in older populations, the prevalence of these conditions approaches 20% (63,64 and 65). In degenerative joint disease, the glenoid cartilage and subchondral bone are typically worn posteriorly, sometimes leaving intact articular cartilage anteriorly. The cartilage of the humeral head is eroded in a pattern of central baldness, often surrounded by a rim of remaining cartilage and osteophytes. In inflammatory arthritis, the cartilage is usually destroyed evenly across the humeral and glenoid joint surfaces. Cuff tear arthropathy occurs when a chronic large rotator cuff defect subjects the uncovered humeral articular cartilage to abrasion by the undersurface of the coracoacromial arch. The erosion of the humeral articular cartilage begins superiorly rather than centrally. Neurotrophic arthropathy arises in association with syringomyelia, diabetes, or other causes of joint denervation. The joint and subchondral bone are destroyed because of the loss of the trophic and protective effects of its nerve supply. In capsulorrhaphy arthropathy, prior surgery for glenohumeral instability leads to joint surface destruction. In this situation excessive anterior or posterior capsular tightening forces the head of the humerus out of its normal concentric relationship with the glenoid fossa. The eccentric glenohumeral contact increases contact pressures and joint surface wear. Most commonly, an overtightened anterior capsule produces obligate posterior translation, posterior glenoid wear, and central wear of the humeral articular cartilage.

Evaluation. The patient with significant glenohumeral arthritis usually presents with pain and loss of function that are refractory to rest, antiinflammatory medications, and exercises. The history should include a description of the onset of the problem, the mechanism of any injuries, and the nature and progression of functional difficulties. Systemic or polyarticular manifestations of sepsis, degenerative joint disease, or rheumatoid arthritis may provide helpful clues. A past history of steroid medication, fracture, or working at depths may suggest the diagnosis of avascular necrosis. Past injury or surgery suggests the possibility of secondary arthritis or capsulorrhaphy arthropathy. Often, the patient can describe motions that are problematic or specific maneuvers that are required to “unlock” to get past a certain sticking point. Occasionally, patients describe a sensation of apparent instability or unwanted shifting of the shoulder. Interestingly, the degree of functional compromise of the shoulder at the time of presentation for evaluation is comparable for the different diagnoses (2,66). Apparently, it is the level of functional impairment, irrespective of the diagnosis, that brings the patient in for evaluation. Matsen et al. reported the self-assessment of 103 patients with primary glenohumeral degenerative joint disease (2,67). More than half of the SF-36 pain and physical role function scores were more than one standard deviation below those of age- and sex-matched controls. These patients consistently reported the inability to perform standard shoulder functions, such as sleeping comfortably, lifting 8 pounds to shoulder height, washing the back of the opposite shoulder, throwing overhand, and tucking in a shirt behind. Self- assessment of shoulder function and health status was used to compare patients with those with rheumatoid arthritis and degenerative joint disease of the shoulder (17). Not all patients with glenohumeral roughness are the same; some patients are severely compromised due to the systemic nature of their disease, whereas others may have their problem well localized to the shoulder and be otherwise healthy. The self-assessed overall health status of individuals with glenohumeral arthritis is most compromised in the domains of physical role function and overall comfort. For patients with primary and secondary degenerative joint disease, other SF-36 parameters such as vitality and overall health were relatively close to population-based age- and gender-matched controls. The health status of patients with rheumatoid arthritis, capsulorrhaphy arthropathy, and avascular necrosis was poorer than controls of the same age and sex.

Physical examination often reveals mild or moderate muscle wasting about the shoulder due to disuse or muscle fiber failure. Isometric strength is documented in flexion, extension, abduction, and rotation. Individuals being considered for prosthetic arthroplasty should have good deltoid and rotator cuff strength. Limited range of motion commonly accompanies arthritis, which is related to adhesions and contractures of the glenohumeral capsule, rotator cuff muscles, and the HSMI. The limitation of glenohumeral motion is most easily identified if one of the examiner's hands is used to stabilize the scapula while the flexion/extension and internal/external rotations of the humerus relative to the scapula are documented with the other. Crepitus at the glenohumeral joint is often best palpated posteriorly just inferior to the angle of the acromion as the humerus is rotated at the patient's side.

In the evaluation of glenohumeral arthritis, standardized radiographic views are necessary to understand the disease process and its severity. Standard views include an AP view in the plane of the scapula and a true axillary view. These views indicate the thickness of the cartilage space between the humerus and glenoid, the relative positions of the humeral head and glenoid, the presence of osteophytes, the degree of osteopenia, and the extent of bony deformity and erosion (Fig. 58-9). Superior displacement of the humeral head relative to the scapula suggests major rotator cuff deficiency. If a humeral arthroplasty is being considered, a templating AP view of the humerus in 35 degrees of external rotation relative to the x-ray beam with a magnification marker and the arm in 45 degrees of abduction is obtained. This view places the humeral neck in maximal profile, allowing comparison of the proximal humeral anatomy with that of various humeral prostheses and places the middle of the humeral articular surface in the middle of the glenoid fossa. Thinning of the central aspect of the humeral articular cartilage typical of degenerative joint disease (the “Friar Tuck” pattern) is revealed, whereas radiographs with the arm in other positions may suggest the presence of a thicker layer of cartilage at the periphery of the head. Articular cartilage loss can be substantially underestimated even with appropriately taken radiographs.

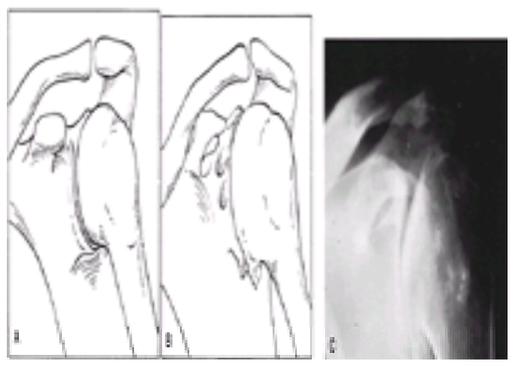

Figure 58-9. **A:** Diagram of normal glenohumeral joint in anteroposterior view. **B,C:** Diagram and radiograph of joint showing degenerative changes (sclerosis, osteophytes, cysts, and diminished joint space) associated with osteoarthritis.

Computed tomography (CT) scans are obtained if there is question about the amount or quality of bone available for reconstruction. Most often these questions can be answered from plain radiographs alone. Imaging of the rotator cuff by MRI or ultrasound is carried out only if it will affect management of the patient. Usually the status of the rotator cuff can be understood from evaluation of the history, the physical examination, and the plain radiographs.

Diagnosis. The diagnosis of glenohumeral roughness is based on the documentation of impaired motion resulting from disruption of the joint surface smoothness. Patients complain of limited function, and on physical examination, crepitus and limited glenohumeral motion are common. On radiographic examination, joint space narrowing, periarticular sclerosis, and varying degrees of osteophytes can be seen.

Treatment. In the early stages of glenohumeral roughness, the mechanics of the shoulder can be optimized by patient-conducted gentle range-of-motion and strengthening exercises, nonsteroidal antiinflammatory medications, and specific treatment for rheumatologic and septic involvement. It is important that vigorous torques and forces not be applied in an attempt to regain motion because of the concern for causing obligate translation and accelerated wear. Surgery is considered for well-informed, well-motivated, cooperative, healthy patients with functionally significant glenohumeral roughness that is not responsive to the home exercise program. Patients who are well informed and motivated before shoulder reconstruction are more likely to obtain an optimal result. The realistic goals of glenohumeral arthroplasty for a given shoulder should be discussed with the patient. Prosthetic arthroplasty is not recommended for patients who intend to return to occupational or

recreational activities that apply sudden impact or heavy loads to the joint. Such individuals should be counseled to delay the procedure, to consider an alternative reconstructive operation, or to alter their lifestyle to accommodate more appropriately a prosthetic arthroplasty.

Two approaches to glenohumeral roughness do not involve a prosthesis; they represent opposite extremes of surgical intervention. Glenohumeral arthrodesis is usually reserved for attempts at salvaging septic arthritis or complex deficiencies of the joint surface associated with permanent loss of the rotator cuff and deltoid. A nonprosthetic arthroplasty is considered for the uncommon young shoulder demonstrating early glenohumeral joint surface roughness and significant stiffness. The anterior capsule is typically tight and glenohumeral osteophytes are present. There is substantial remaining articular cartilage, with the shoulder in the “centered position” on both the AP radiograph in the plane of the scapula and the axillary view, and there is no posterior subluxation of the humeral head on the glenoid in the axillary view. In this circumstance, a capsular release and thorough osteophyte resection may help restore smoothness and motion.

Shoulder prosthetic arthroplasty is considered for patients who understand the risks and limitations of this procedure and who have sufficient bone stock, stability, and muscle control. Contraindications to arthroplasty include an active or recent shoulder infection and major loss of deltoid function. The chances of a good result are diminished by several factors. A history of smoking or narcotic use, unrealistic patient expectations, and poor patient motivation can compromise the postoperative course. Deltoid weakness, rotator cuff tears, tuberosity nonunion or malunion, and poor quality of tissues increase the technical difficulties during surgery and potentially compromise the final result. Finally, special preoperative and postoperative considerations need to be taken into account for patients who have had previous shoulder surgery, previous shoulder trauma, neurotrophic arthropathy, and a history of remote infection. The characteristic pathologies of the disease processes help guide the surgical approach.

Capsular release, subscapularis lengthening, and freeing of the nonarticular HSMI are usually incorporated in every shoulder arthroplasty. The technical demands of these procedures are high because of the critical interplay between the pathoanatomy, the amount of bone resected, the soft tissue balancing, the size and positioning of the components, and the quality of the bone and soft tissues. In glenohumeral arthroplasty, the humeral head is replaced by a metal alloy, such as cobalt chrome, and the glenoid is resurfaced by ultrahigh-molecular-weight polyethylene.

Prosthetic humeral arthroplasty without a glenoid component is considered in four circumstances: (a) if the humeral joint surface is rough, but the cartilaginous surface of the glenoid is intact; (b) if there is insufficient bone to support a glenoid component (e.g., after severe medial erosion of the glenoid in rheumatoid arthritis); (c) if there is fixed upward displacement of the humeral head in relation to the glenoid in association with massive cuff deficiency; and (d) if extraordinary demands will be placed on the shoulder that would increase the risk of glenoid component complications (e.g., motion disorders or paralysis of the lower extremities). Prosthetic humeral hemiarthroplasty offers the opportunity to restore the normal smooth convexity of the proximal humeral articular surface with an essentially normal glenoid surface. The need for humeral head replacement most commonly arises in atraumatic avascular necrosis or in fractures involving the humeral head. When performing a hemiarthroplasty, the goal is to restore the humeral articular surface to its normal location and configuration. Because the glenoid is not replaced, the size, radius, and orientation of the prosthetic humeral joint surface must duplicate those of the original biological humeral head. Often the details of the patient's normal humeral anatomy can be best obtained from radiographs of the opposite shoulder.

In degenerative joint disease, the glenoid face is typically flattened and often eroded posteriorly from chronic posterior subluxation. The glenoid may be distorted by peripheral osteophytes, masking the location of the anatomic fossa. The humeral head may be flattened in a corresponding manner and effectively enlarged by the proliferation of “goat's beard” osteophytes from the anterior, inferior, and posterior articular rims. Intraarticular loose bodies may lie hidden in the subcoracoid or axillary recesses. Anterior capsular and subscapularis contractures are common in degenerative joint disease.

In the rheumatoid shoulder, the soft tissues and the osteopenic bone are often fragile and susceptible to disruption or fracture at and after surgery. Usually, the glenoid face has been concentrically eroded medially, occasionally to an extent that precludes placement of a glenoid component. The humeral head and glenoid are often small, with a corresponding reduction in joint volume. The rotator cuff may be torn or attenuated. In juvenile rheumatoid arthritis, the diminutive osseous morphology may require smaller or even custom- made components.

Shoulders affected by capsulorrhaphy arthropathy and posttraumatic arthritis present additional challenges. Previous surgery or trauma can cause significant scarring about neurovascular structures and alter their anatomic positions. Soft tissue contractures, bone deficiencies, and implants from previous surgery complicate surgical exposure and increase potential for glenohumeral instability after the arthroplasty. Malunions or nonunions of the humeral shaft, surgical neck, tuberosities, or glenoid substantially increase the difficulty of the bony reconstruction.

Because the primary goals of arthroplasty surgery are to provide motion and smoothness, immediate postoperative passive motion is important. The immediate postoperative program is essentially the same as that used after the release of a frozen shoulder. We use a simple motor-driven adjustable cam and pulley system that puts the shoulder through a 90-degree arc of flexion and a 45-degree arc of rotation for much of the first 48 postoperative hours. The patient is taught to use the opposite arm for assisted elevation and external rotation. A motivation chart is maintained on the wall of the patient's hospital room, displaying progress toward the discharge goals of 140 degrees of elevation and 40 degrees of rotation. Grip and external rotation isometrics are started immediately. Unless a rotator cuff repair has been performed, the patient is encouraged to use the shoulder as comfort permits for active elevation and activities of daily living. If rotator cuff repairs or osteotomies have been performed, active motion and isometric cuff strengthening are delayed until healing has occurred.

Summary. The management of glenohumeral roughness provides an opportunity to combine all available knowledge about the shoulder in formulating the best treatment plan for the patient. Ultimately, surgery offers the opportunity to optimize capsular laxity and muscle mechanics, as well as joint surface smoothness, size, shape, and orientation (68,69,70 and 71).

Acromioclavicular Joint Roughness. The AC joint is a diarthrodial joint composed of the distal clavicle, medial acromial facet, and interposed fibrocartilaginous disk. Stability of the AC joint is enhanced by the capsular ligaments as well as the coracoclavicular ligaments. Fractures, compression injuries, dislocations and/or instability, and osteolysis of the distal clavicle can precipitate articular surface roughness and subsequent pain. Articular cartilage degeneration (joint surface roughness), subchondral cysts, and metaplastic bone formation (spurs) are common findings. Spurs are found more commonly on the superior surface than the inferior surface. Radiographically, AC osteoarthritis is seen much more often than osteoarthritis of the glenohumeral joint (72).

Evaluation. Patients with AC arthritis may complain of pain in the anterolateral aspect of the shoulder. They may or may not give a history of trauma (73). Osteolysis (bone resorption) of the distal clavicle most commonly occurs without antecedent trauma (74,75). Weightlifters or patients engaged in repetitive weightlifting seem to be at an increased risk to develop osteolysis of the distal clavicle (76). The pain tends to be increased by overhead, across-the-chest arm movement or lying on the affected shoulder. The signs and symptoms share common features with rotator cuff disease and glenohumeral arthritis. On physical examination, passive cross-body adduction and/or forward elevation, especially greater than 90 degrees, produce pain in the area of the AC joint. Pain posteriorly or laterally is more suggestive of glenohumeral pathology. Shoulder motion typically is not appreciably decreased, but the local pain is exacerbated at the extremes of movement. An unduly prominent lateral end of the clavicle suggests AC joint separation. This prominence is due to the scapula sagging inferiorly rather than an upwardly displaced clavicle. The clavicle can be displaced posteriorly into the trapezius muscle or tent the skin in severe separations. Palpation (see Fig. 58-2A) can reveal an irregular bony thickening of the joint margins due to the osteophytes of arthritis; in contrast to septic arthritis, there is no soft tissue thickening and no increase of local skin temperature. Swelling at the AC joint may not be from primary AC joint pathology but rather from cyst formation due to a massive chronic rotator cuff tear (77,78).

Radiographic examination of the AC joint alone includes an AP view, a 15-degree cephalad-tilted AP view, and occasionally a coned-down view of the joint. A cephalad-tilted view places the AC joint on profile without the spine of the scapula obscuring the view. An AP of the shoulder can overpenetrate the AC area and thereby diminish radiographic details. Coning down the view of the joint enhances bony detail by allowing for appropriate penetration. An axillary view can be very helpful; although obscured by the humerus, the position of the joint and presence of an os acromiale can be determined. For example, an AC joint separation in which the clavicle is posteriorly displaced into the trapezius is best visualized on the axillary view. The use of weights to enhance subtle instability has been shown to be ineffective (79) and, acutely, can be painful.

Diagnosis. The diagnosis of AC roughness is based on an insidious onset of pain, which may or may not have been preceded by an injury. The pain should be relatively directed to the AC joint area. AC instability and separation are preceded by an injury, typically a direct blow to the shoulder. Joint space narrowing, bony hypertrophy, and subchondral cysts and sclerosis are common radiographic findings (Fig. 58-10). In osteolysis, osteopenia and cyst formation are more characteristic.

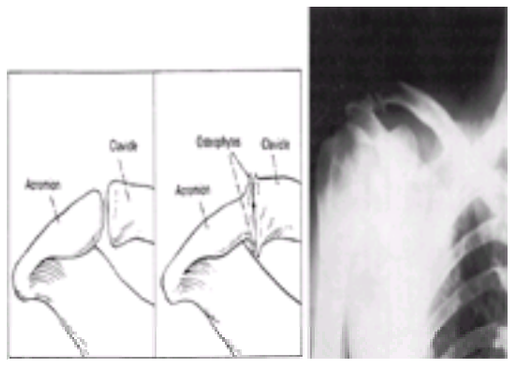

Figure 58-10. **A:** Diagram of a normal acromioclavicular joint. **B,C:** Diagram and radiograph showing degenerative changes associated with subluxation and osteoarthritis of the joint.

Treatment. If the patient has mild to moderate pain, nonsteroidal antiinflammatory drugs as well as avoiding overhead use of the arm can minimize symptoms. Acute mild AC subluxation can be managed by rest and a sling for a few days. Early shoulder motion diminishes the propensity for adhesion formation and decreased motion. Surgical intervention for AC joint arthritis should be considered only if severe pain and disability persist and can be localized specifically to the AC joint. Care must be taken to avoid excessive clavicular resection, heterotopic bone, and instability or weakening of the deltoid origin. Severe cases of AC separation such as posterior displacement of the clavicle into the trapezius muscle or skin tenting should be managed surgically by excision of the lateral end of the clavicle and stabilization of the clavicle, which may include reconstruction of the coracoclavicular (conoid and trapezoid) ligaments (80).

Summary. Roughness of the AC joint is often well tolerated with activity modification and antiinflammatory medications; failing nonoperative treatment, surgical resection of the distal end of the clavicle may result in symptomatic improvement. Mild instability of the AC joint is often well tolerated; acute operative intervention should be reserved for severe symptomatic separations.

Sternoclavicular Joint

Pain due to arthritis, instability, and trauma in the region of the sternoclavicular joint is uncommon. Like the AC joint, the sternoclavicular joint is a diarthrodial joint composed of the medial end of the clavicle, an interposed fibrous disk, and the sternum. The costoclavicular, interclavicular, and capsular ligaments provide stability.

Evaluation. The sternoclavicular joint is one of the least commonly dislocated joints in the body. Tremendous forces, direct or indirect, are usually required to produce a traumatic dislocation. Arm movement increases pain in a patient with an acute fracture or dislocation. Often there is prominence or retraction about the sternoclavicular joint in anterior or posterior dislocations, respectively. However, soft tissue swelling may accompany a posterior dislocation, giving the appearance of an anterior dislocation. In recurrent dislocation or subluxation, the clavicle can be felt to click out of joint when the shoulders are braced back and to go back into position when the shoulders are arched forward (72). Posterior dislocations can be accompanied by circulatory or respiratory compromise. Arthritis of the sternoclavicular joint is often associated with hypertrophy of the medial end of the clavicle without soft tissue swelling or erythema. Often the patient complains of crepitus, pain, or both associated with arm movement. Sternoclavicular joint tenderness is commonly present in arthritic conditions as well as acute dislocations.

Plain radiographs are useful to delineate gross anatomic alignment of the joint. A 40-degree cephalic-tilted AP view of both sternoclavicular joints will show an anterior displaced clavicle to be superior to a horizontal line at the level of the joint, whereas a posteriorly displaced clavicle will appear inferior. Computerized tomography is the best modality to evaluate the bony architecture of the sternoclavicular joint in acute and chronic disorders.

Diagnosis. The appearance of the sternoclavicular joint on plain x-rays can be difficult to interpret due to overlying structures. A CT scan will confirm the position of the clavicle relative to the sternum. Like other arthritic conditions, pain associated with sternoclavicular arthritis begins insidiously and is increased by arm movement.

Treatment. Anterior dislocations can be reduced but typically redislocate. Although prominent, a chronic anterior dislocation is often well tolerated (81). Acute posterior dislocations can be reduced by closed techniques and are usually stable after reduction. Should operative reduction be necessary, a thoracic surgeon should be available. The patient should be carefully evaluated, as concomitant vascular or pulmonary injuries are not uncommon. Antiinflammatory medications and rest usually reduce the pain of arthritis. For those patients with pain and functional limitations, surgical resection of the medial head of the clavicle with preservation of the costoclavicular ligament may be helpful (82).

Summary. Sternoclavicular disorders are uncommon. Most disorders are well tolerated. Posterior dislocations can be usually reduced closed. Concomitant injuries can be significant, and a thorough evaluation is required. Most commonly, arthritis responds favorably to nonoperative modalities.

Scapulothoracic Motion Interface

The scapulothoracic motion interface is the site of movement between the scapula and the chest wall. The deep aspect of this interface consists of the ribs and their covering musculature. The superficial aspect of the interface consists of the scapular border along with the serratus muscles. No muscle covers the anteriorly inclined superior medial corner of the scapula. This corner is a potential site of bony contact between the scapula and the thoracic wall, especially if the normal postural relationship between the scapula and the rib cage is altered. If injury or disuse allows the scapula to ride low on the chest, for example, the superior medial corner of the scapula may “washboard” over the ribs, producing a snapping scapula. Thinning of the interposed subscapularis and serratus muscles may yield a similar effect. Malunions of scapular or rib fractures can also present major irregularities at the scapulothoracic motion interface. Hypertrophy of the subscapular bursa or osteochondromata of the anterior surface of the scapula can also disrupt smooth gliding of the scapula on the chest wall.

Evaluation. Patients often complain of a popping or clicking in their shoulder with scapular movement. Scapular maltracking can accompany rotator cuff disorders as well as glenohumeral instability (83). Nerve palsies such as of the long thoracic or spinal accessory nerve can produce weakness and subsequent dysfunction. The examiner can help distinguish scapulothoracic roughness from glenohumeral problems or from problems at the humerothoracic motion interface by selectively restricting the motion at first one site and then the other. Shrugging, protracting, and retracting the scapula while the examiner disallows glenohumeral motion permits independent assessment of the smoothness of the scapulothoracic motion interface. Palpation of the site for roughness may localize the problem to the superior medial border of the spine of the scapula. Alternatively, rotating and elevating the arm while the examiner stabilizes the clavicle, acromion, and scapular spine on the chest wall allows independent evaluation of the glenohumeral joint and the HSMI.

Radiographic examination should include an AP and lateral views in the plane of the scapula; CT can help localize the sites of specific structural abnormalities but is of minimal value in evaluating a snapping scapula resulting from abnormal posture.

Diagnosis. Rarely, roughness in the scapulothoracic motion interface is caused by an anatomic abnormality such as a malunited fracture or an osteochondroma on the anterior undersurface of the scapula. These unusual causes can often be diagnosed on a lateral radiograph of the scapula. Scapulothoracic crepitus, or “snapping scapula,” is most commonly caused by altered scapulothoracic posture and mechanics.

Treatment. The primary treatment of this condition is reassurance; restoration of normal posture; and strengthening of the serratus anterior, subscapularis, trapezius, and rhomboids. It is essential that the patient avoid voluntary or habitual scapulothoracic snapping. More aggressive treatment is considered only in the rare patient who has functionally significant, involuntary, nonvocationally related scapulothoracic snapping that has failed to respond to a prolonged, nonoperative management program. Refractory cases of snapping scapula may respond to local injection, to bursal resection, or to resection of the superior medial angle of the scapula. Because these procedures do not treat the primary problem of altered scapulothoracic posture, failure to improve shoulder function is not infrequent unless postoperative rehabilitation reestablishes normal muscle positioning. Complications of surgery can be related to failure to reattach securely the muscles inserting on the superior medial angle of the scapula, to injury to the nerve to the lower trapezius, to leaving residual prominent edges of the scapula, and to scarring in the scapulothoracic motion interface.

Summary. Snapping scapula is usually secondary to abnormal scapular posture and tracking; structural abnormalities are uncommon. Scapular winging and maltracking can be associated with primary glenohumeral pathology or muscular weakness. Periscapular muscular strengthening exercises are helpful to improve postural relationships between the chest wall and scapula.

Neuropathy

Peripheral nerve entrapment about the shoulder is unusual. Suprascapular nerve compression, quadrilateral space syndrome, thoracic outlet compression, and acute brachial neuritis all can result in diffuse shoulder pain, weakness, or both.

Evaluation. Nerve lesions about the shoulder often cause vague shoulder pain, weakness, or both. Isolated infraspinatus involvement is suggestive of compression of the suprascapular nerve at the spinoglenoid notch, whereas involvement of both the supraspinatus and infraspinatus is characteristic of suprascapular notch compression. In long-standing cases, atrophy of the supraspinatus or infraspinatus fossae, or both, are present, and electrodiagnostic tests will show increased latency. External rotation at the side and abduction are often weak. Occasionally, space-occupying lesions such as ganglia arise from the glenohumeral joint and compress local nerves as in a spinoglenoid notch cyst compressing the nerve to the infraspinatus. Axillary nerve compression by fibrous bands in the quadrilateral space is uncommon. Malunited clavicle fractures can limit the space between the clavicle and first rib and compress the brachial plexus. Acute onset of pain without antecedent trauma followed by a reduction in pain with a variable persistence of weakness is suggestive of acute brachial neuritis (84).

Radiographic examination of the shoulder is typically negative. If a history of trauma exists, oblique views of the scapula may be helpful in delineating the bony morphology after fractures. For ganglia, MRI may be helpful to identify the ganglia as well as associated labral pathology. Magnetic resonance neurography may also delineate the site of nerve pathology for major nerves and the brachial plexus.

Diagnosis. A high index of clinical suspicion is needed. Often symptoms are vague and can be mistaken as primary rotator cuff, AC, or glenohumeral pathology. In severe cases, electrophysiological studies may be positive. Radiographic and angiographic studies can be supportive if structural abnormalities exist.

Treatment. In the absence of structural abnormalities, thoracic outlet syndrome (85) and suprascapular neuropathy (86) respond favorably to nonoperative therapy such as postural exercises, antiinflammatory medications, and physical therapy. In acute brachial neuritis, expectant management with or without pharmacologic therapy is appropriate. Pain typically resolves, whereas mild weakness can persist. Surgical decompression should be reserved for those patients with persistent significant pain and functional limitations that can be conclusively attributed to nerve compression.

Summary. Peripheral nerve lesions about the shoulder occur infrequently, signs and symptoms are vague, and ancillary studies are frequently nondiagnostic. Surgical decompression may be indicated when the lesion is defined and significant symptoms persist.

ELBOW AND LOWER ARM PAIN

The elbow consists of three distinct articulations. The ulnohumeral joint allows flexion and extension; the proximal radioulnar and radiocapitellar joints allow axial rotation. Pain in the elbow is caused by diseases and injuries similar to those affecting the shoulder. Like the shoulder, motion, stability, strength, and smoothness characterize a well-functioning elbow. A normal elbow enables the hand to be placed in various positions around the body. The etiologies of pain will be divided into stiffness, instability, weakness, and roughness; entities such as olecranon bursitis and neuropathy will be part of an additional category. Frequent extraarticular causes of pain in the elbow region are lateral (tennis elbow) and medial (golfer's elbow) epicondylitis, ulnar neuropathy, and olecranon bursitis. Intraarticular disorders such as arthritis, loose bodies, and osteochondritis dissecans occur less often. Elbow stiffness may be due to lesions that are intraarticular, extraarticular, or a combination of both etiologies.

Patient Self-Assessment

Patient self-assessments of health status and elbow function are useful tools to help characterize patients with elbow pain. They provide practical, standardized, and meaningful characteristics of the status of the patient at the time of presentation. According to Turchin et al., patient self-completed functional questionnaires can be valid and reliable assessment tools for the elbow and do not suffer from observer-based bias (87). We believe that the complete evaluation of patients with elbow problems requires both disease-specific and overall health status measurements. We use the information gained from the simple elbow test (SET) (Table 58-2) and SF-36 self-assessment questionnaires to monitor the effectiveness of our treatment. The SET is a binary (yes or no) patient self-completed inventory of activities that can be performed. Effectiveness is the change from ingo scores (at presentation) to outcome scores (after treatment). The results of treatment, both operative and nonoperative, are dependent on the physician, the procedure, and rehabilitation. Again, it is important to remember that the objective severity of the disease showed little relationship to patients' reports of pain, whereas psychological variables were much more closely correlated with measures of pain and functional impairment (18).

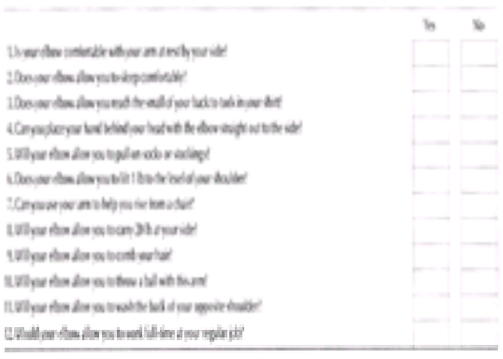

TABLE 58-2. The simple elbow test (SET)

Anatomic-based patient assessments have been used extensively to monitor the results of orthopedic treatment. Observer-based aggregate scoring systems seem to reliably assess the anatomic aspects of elbow impairment (87). However, Bostrom et al. found that standardized assessments of function are more reliable and reproducible than conventional range-of-motion measurements. Functional inventories provide useful information that is meaningful to both the treating physician and the patient.

Evaluation of the Patient

The diagnosis of elbow pain can be a challenging task and should be undertaken within the context of the patient's overall status. In the patient with elbow pain, we attempt to define the problem in terms of the elbow's four mechanical properties: motion, stability, strength, and smoothness. If a patient's problem can be understood in mechanical terms, effective treatment plans can be formulated. All elbow pain is not mechanical in origin and may be best managed by a multidisciplinary approach. Identifying the best management approach for each individual patient is the primary challenge a physician faces. Mechanical elbow problems are typically related to certain activities or positions and are reproducible. Although the patient recognizes them as mechanical in nature, the localization of pain may be due to secondarily affected structures as in ulnar nerve neuritis secondary to chronic valgus instability of the elbow. Nonmechanical problems are typically not related to activity or position and are more diffuse in nature. We will limit our discussion of mechanical etiologies of elbow pain.

History

Like the shoulder, elbow disorders do not exist in isolation, but rather in the context of the overall health of an individual. It is essential to obtain a complete history of

any painful condition at the onset, during the interval time between onset and presentation, and at the time of the physician interview. Details about various characteristics of the pain, including precipitating factors, location, intensity, quality, duration, and aggravating or relieving factors, should be obtained. Mechanical elbow pain can be fairly well localized to the joint. Pain radiating to the mid-arm, forearm, and hand may be due to nerve entrapment.

Physical Examination

During the physical examination, both arms must be uncovered so that the painful part of the affected limb can be compared with the opposite limb. As in the shoulder, an examination should include inspection, palpation, and determination of the active and passive range of motion. During inspection, special note should be made of the bony contours and alignment, muscle mass, and the presence of scars or other signs of injuries. Articular effusions are best appreciated in the lateral triangle created by the olecranon, lateral epicondyle, and radial head. Bursal effusions are seen posteriorly over the olecranon tip. Palpation should be systematic and include the flexor and extensor muscle tendinous insertions; radial capitellar joint; posterior ulnohumeral joint; collateral ligaments; and the areas of the posterior interosseous nerve (radial tunnel), ulnar nerve (cubital tunnel), and median nerve at the pronator teres muscle. Muscle power and stability testing may be painful and should be undertaken last.

Normal flexion and extension of the ulnohumeral joint have a range of approximately 0 to 140 degrees. Supination and pronation should be tested with the elbow flexed at a right angle and the arm adducted to the side to eliminate rotation of the shoulder. The normal range is approximately 80 degrees of supination (palm up) and 80 degrees of pronation (palm down). If the range of rotation is restricted, the possible causes may be in the forearm and wrist as well as in the elbow. Motion accompanied by crepitus can be due to articular incongruity such as in arthritis, loose bodies, or intraarticular adhesions. Flexion, extension, supination, and pronation power should be evaluated and compared with that of the same muscles on the opposite side. Wrist extension and flexion strength as well as any associated symptoms should be elicited. The integrity of the lateral and medial ligaments of the elbow, stability of ulnar nerve at the cubital tunnel, and the competence radiocapitellar joint should be documented. The neurologic examination consists of cervical spine range of motion, assessment of symptom exacerbation due to neck position, a functional evaluation of the cervical nerve roots, and sensory and reflex testing as indicated in each unique case.

Radiographic Examination

Radiographs may provide additional evidence to ascertain the diagnosis. The minimal examination includes AP views of the distal humerus and proximal forearm and lateral views in maximal flexion and extension. The AP view should be perpendicular to the elbow in complete extension. Elbows that do not extend fully should have separate perpendicular AP views of the distal humerus and proximal forearm. Accessory radiographs such as radiocapitellar, cubital tunnel, oblique, and stress views can be added as the clinical situation dictates. MRI, CT scans, and bone scans are occasionally needed in the workup of disorders such as osteochondritis dissecans, loose bodies, or fractures.

Elbow Stiffness

A flexion contracture, loss of elbow extension, may be caused by fractures, dislocations, arthritis, burns, head injury, and increased spasticity as, for example, from cerebral palsy (88,89,90,91,92 and 93), and the resulting loss of motion may cause significant morbidity. The specific components of posttraumatic elbow contracture vary according to the mechanism of injury (94,95 and 96). A useful way to classify elbow contractures is to identify the structures involved as to what severity. Contractures may be divided into intrinsic (intraarticular changes—fracture, loose bodies, synovitis) and extrinsic (capsular contracture and scarring, collateral ligaments, flexor-extensor musculature, heterotopic bone and skin) etiologies and combined intrinsic and extrinsic causes.

Evaluation

The nature of the initial injury, duration of time, previous treatment (operative and nonoperative), and associated injuries should be assessed. The duration of stiffness or the initial injury may have rendered the articular cartilage incompetent and limit functional return. Previous surgical procedures and extraarticular posttraumatic deformities may have altered the neurovascular anatomy around the elbow joint. The sequelae of a head injury should be stable and the patient should be able to cooperate with the requisite intensive rehabilitative effort if surgical treatment is considered. Active and passive pronation, supination, flexion, and extension should be recorded. Associated crepitus, catching, or popping is suggestive of intrinsic pathology. Muscle strength should be tested and any associated spasticity is noted. Finally, the patient should have realistic goals and realize that gains as well as pain relief may not be complete.

Radiographs of the elbow are essential. Elbows that do not extend fully should have separate perpendicular AP views of the distal humerus and proximal forearm taken. Lateral views of the elbow in maximum flexion and extension help to assess the role of bony abutment in stiffness. Occasionally, CT scans can better assess the bone contours and fracture healing that may influence treatment.

Treatment

Most activities of daily living are performed in an arc of motion of the elbow from 30 to 130 degrees of flexion (97), and therefore treatment is usually indicated for patients who have functional limitations due to contractures of greater than 30 degrees or flexion of less than 130 degrees, as well as those patients whose occupation or functional demands require more than the available range of motion. Those patients with a lesser degree of contracture who have pain, popping, or locking of the elbow suggesting some intraarticular derangement may also be candidates for management of their contracture.

For contractures of short duration and little evidence of intraarticular damage, conservative therapy for elbow flexion contractures may include early range-of-motion exercises and an aggressive active and passive physical therapy program coupled with dynamic or static splinting (98,99).

Surgical treatment is indicated for well-informed and motivated patients refractory to conservative treatment and patients in whom an increase in range of motion as well as decrease in roughness is beneficial. Many patients have combined intrinsic and extrinsic etiologies of elbow stiffness. Our surgical approach is sequential; the anterior soft tissues and bone are addressed first followed by the posterior structures. Intraarticular adhesions, osteophytes, the anterior radial capitellar joint, and the anterior capsule are addressed sequentially. As dictated by the resultant range of motion, attention is then directed to the posterior compartment. The triceps can be elevated and released off the humerus, adhesions and olecranon tip osteophytes are removed, and the olecranon fossa is dábrided and widened as necessary. Range-of-motion exercises are started immediately after surgery. Neural function, especially the ulnar nerve, is monitored postoperatively. Neural excursions may not be able to compensate for the postoperative increase in elbow joint motion.

Summary

Elbow stiffness can cause significant functional impairment and pain. In carefully selected patients, significant improvement in function and pain relief can be achieved by surgical debridement, soft tissue release, and aggressive postoperative range-of-motion rehabilitation.

Elbow Instability

The elbow joint is highly constrained due to its osseous configuration. The articular surfaces are closely approximated, and the radiocapitellar and ulnohumeral articulations provide bony buttresses against varus and valgus stresses. The medial collateral and lateral collateral ligamentous complexes provide additional restraint to valgus and varus stresses, respectively.

Valgus Instability

The anterior oblique bundle of the medial collateral ligament of the elbow is the primary stabilizer to valgus stress (100,101 and 102). The diagnosis of valgus instability is often difficult, requiring a combination of a careful history and physical examination.

Evaluation. Major trauma to the medial collateral ligament such as simple dislocations rarely result in symptomatic instability (103). Medial collateral ligament compromise may be disabling in the context of lateral collateral ligament or bony insufficiency. Nerve injuries, especially the ulnar nerve, are not uncommon after elbow dislocations. Stretch injuries or entrapment of a nerve may be a source of continuing pain and altered function. Minor degrees of valgus instability may be symptomatic in competitive overhead athletes such as tennis or baseball players. The patient often gives a history of repetitive overhead activities such as throwing.

An overhead athlete often complains of medial pain, increased ease of fatigue, pain, or a combination of these symptoms associated with an acute injury. Pitchers may complain of pain during acceleration as well as ulnar nerve symptoms (104). Valgus stress testing is performed by applying a valgus load to the elbow brought through an entire arc of motion. One hand applies the stress while the other hand palpates the medial side as the elbow is brought through an entire arc of motion. Pain, tenderness, or both; crepitation at the medial ulnohumeral, radiocapitellar, posterior olecranon-medial humerus; or laxity are suggestive of valgus instability. In most cases, the examination results are rather subtle, characterized by a mild increase in laxity with an ambiguous end point. Valgus stress testing can be performed with the patient sitting and the arm braced next to the body; alternatively, the patient can be placed prone on an examining table, the arm is stabilized against the table, and valgus stress is applied.

Radiographs for instability include an AP, lateral, and, if indicated, AP stress views. In chronic cases, bony hypertrophy of the medial aspect of the posterolateral humeral column with concomitant changes of the lateral olecranon and radiocapitellar chondromalacia is a common finding. Stress AP views show medial joint space widening with concomitant lateral widening between the olecranon and the distal humerus due to ligamentous incompetence. An avulsion fracture or cortical hypertrophy of the medial epicondyle are common findings as well.

Diagnosis. Medial collateral instability is characterized by a history of major trauma, such as an elbow dislocation or repetitive overhead throwing with increasing functional disability. A demonstration of instability by physical examination or imaging studies is important. Arthroscopy may play a role in the evaluation of valgus instability (105). Opening of the medial ulnohumeral joint to valgus stress as little as 1 to 2 mm indicates disruption of the anterior bundle of the medial collateral ligament.

Treatment. Patients with severe instability despite congruous articular reduction, the failure to achieve a congruous reduction after an elbow dislocation, or elbow dislocations associated with unreconstructable radial head fractures also should be stabilized surgically. Most patients with minimal instability respond to rest, antiinflammatory medications, and physical therapy stressing flexor- pronator strengthening. If symptoms persist and the patient desires to return to highly competitive sport or the elbow is grossly unstable after major trauma, a ligamentous repair or reconstruction can be offered to the patient. After surgery, the patient needs to resume a flexor-pronator and generalized muscular strengthening program.

Posterolateral Rotatory Instability

Lateral collateral ligament insufficiency is being recognized more commonly. According to O'Driscoll et al., rupture of the ulnar part of the radial (lateral) collateral ligament is the primary lesion in posterolateral rotatory instability of the elbow (106). The radial head and ulna abnormally subluxate posteriorly and laterally on the humerus. Patients may complain of lateral elbow symptoms, and these may have been previously misdiagnosed as lateral epicondylitis.

Evaluation. Incompetence of the lateral collateral ligament complex commonly occurs after a posterior elbow dislocation. Patients with lateral instability often give a history of elbow trauma or previous surgery on the lateral side of the elbow. For example, the patient may not be aware of the significance of a fall. An elbow “sprain” with persistent symptoms may have been either a dislocation with spontaneous reduction or a significant subluxation. Often, symptoms arise with axial loading such as rising from a chair with arm assist. Patients may complain of popping, catching, or grinding. Occasionally, patients will notice that the elbow slips out of place or locks in when the forearm is extended.

The relationship of the radial head and the humerus is the focus in provocative testing of the lateral elbow. The posterolateral rotatory instability test (pivot shift) (106) is a useful provocative maneuver. In this examination an axial and valgus load is applied to the elbow, with the forearm supinated. Palpation of the radiocapitellar joint may reveal that the radial head subluxates posterolaterally on the humerus. With greater degrees of instability, the subluxation of the radial head and ulna causes a prominence over the radial head. A dimple may appear with reduction of the ulna and radius at approximately 40 degrees of flexion.

Radiographic examination includes an AP view, a lateral view, and occasionally a lateral stress view. Stress views may demonstrate a radial head that is slightly inferior to the capitellum. CT or MRI scans with or without intraarticular contrast are occasionally helpful.

Treatment. As with medial instability, a course of nonoperative treatment, including rest, medication, behavioral modification, and functional strengthening, is instituted. However, nonoperative therapy is typically less successful for posterolateral instability than for valgus instability. Operative stabilization involves capsular plication, ligamentous repair, or reconstruction with a tendon graft.

Summary. Elbow instability is often subtle in its presentation and physical examination. A high index of suspicion, a thorough history, and a careful examination often confirm the diagnosis. Isolated valgus instability requiring operative intervention is uncommon except in athletes with high-demand overhead activity.

Elbow Weakness

Epicondylitis

Epicondylitis is one of the more common painful afflictions of the elbow. The etiology is thought to be a series of small tears in the origin of the extensors at the lateral epicondyle or the flexor-pronator mass at the medial epicondyle. Laterally, the extensor carpi radialis brevis and, medially, the pronator teres and flexor carpi radialis are most commonly affected. Although often referred to as an “- itis,” evidence of substantial local inflammation is usually lacking. Histologically, the pathologic tissue consists of a vascular fibroblastic proliferation that characteristically lacks inflammatory cells (65). Intraarticular changes such as synovitis or synovial thickening are occasional findings.

Evaluation

Medial epicondylitis is often called “golfer's elbow,” whereas lateral epicondylitis is referred to as “tennis elbow.” However, most patients with epicondylitis are neither golfers nor tennis players. Pain that interferes with activities of daily living is the most common presenting complaint. Morning stiffness and a generalized ache are not uncommon. The patient often localizes the pain to the medial epicondyle, distal to the medial aspect of the antecubital fossa, or just distal to the lateral epicondyle. The patient with lateral epicondylitis may complain that the pain is accentuated by grasping or lifting. Difficulty turning the key to start a car or to pick up objects with the palm up (wrist flexion) is commonly associated with medial epicondylitis.

On physical examination, palpation reveals tenderness localized just at the insertion of the forearm wrist flexors into the medial epicondyle or the wrist extensors into the lateral epicondyle (extensor carpi radialis brevis). Stretching or contracting the involved musculotendinous units against resistance should reproduce the patient's symptoms.

Posterior interosseous nerve compression may occur in approximately 5% of patients who seem to have lateral epicondylitis (107) and can be the cause of failed surgical treatment for refractory lateral epicondylitis (108). The posterior interosseous nerve can be palpated approximately 5 cm distal to the lateral epicondyle between the extensor digitorum longus and the brachioradialis (the radial tunnel). A history of burning pain and tenderness in the radial tunnel is suggestive but nonspecific. Likewise, the ulnar nerve should be evaluated as part of a medial epicondylitis workup. Ulnar nerve tenderness and paresthesias on the dorsum of the hand and ulnar two fingers with elbow hyperflexion are suggestive of an ulnar nerve neuritis. Posterolateral rotatory and valgus instabilities of the elbow, although completely different entities, can have symptoms similar to epicondylitis.

Although we often recommend an AP and lateral x-rays of the elbow, radiographic studies typically do not demonstrate abnormalities. Occasionally, calcifications of the soft tissues or bony changes of the epicondyle are encountered.

Diagnosis. The diagnosis of elbow epicondylitis is made by history of heavy elbow use and a characteristic physical examination. Tenderness just distal to the prominence of the epicondyles near the tendinous insertions, as well as pain with resisted wrist extension or flexion, is typical. Radiographs, bone scans, and electrodiagnostic tests are usually negative.

Treatment. Treatment of epicondylitis should include activity modification, rest, and antiinflammatory medication. Occasionally, enforced rest with a dorsiflexion wrist splint or a counter-force brace is helpful. Sometimes local steroid injections into the area of maximal pain are useful. After the acute symptoms have subsided, the extensor carpi radialis brevis is stretched by elbow extension, forearm pronation, and wrist flexion. In a similar fashion, the flexor-pronator mass can be stretched by elbow extension, forearm supination, and wrist extension. Postexercise cryotherapy is useful to diminish pain. When stretching is no longer painful, a progressive

strengthening program should be instituted to prevent recurrent episodes. These exercises must not be done to the extent that they produce pain; rather, the patient should strive for multiple repetitions of the exercise against light resistance to build endurance and strength.

For patients with continued functionally significant symptoms, a release of the extensor carpi radialis brevis from the lateral epicondyle (9,109,110 and 111), or the flexor-pronator mass from the medial epicondyle, may diminish symptoms.

Summary. Epicondylitis is a noninflammatory degeneration of the tendinous insertions at the medial or lateral epicondyles of the elbow. Most cases respond well to nonoperative therapy: a stretching and strengthening program. Refractory cases can be managed by dábriding the area of degenerative tendons and resuming postoperative stretching and progressive resistance exercises as part of functional rehabilitative program.

Distal Biceps Tendon

Rupture of the distal end of the biceps brachii tendon occurs infrequently compared with its proximal counterpart. According to Gilcrest and Albi, 97% of biceps tendon ruptures occur proximally, whereas only 3% occur distally (112).

Evaluation

The tendon typically avulses from the radial tuberosity (113), frequently tears the lacertus fibrosis, and thereby eliminates muscle function (114). Patients usually describe that they were attempting to lift a heavy object before rupture. Ecchymosis of the forearm, elbow, and arm is typical. Distal ruptures are associated with substantial loss of elbow flexion and supination strength and can cause major functional deficits. The distal biceps tendon avulses and migrates proximally; it can be palpated proximal to the antecubital fossa. Occasionally patients may present late after their initial injury. These patients complain of pain and weakness but do not have the signs of an acute injury. Radiographs should include an AP and a lateral of the elbow and are typically normal.

Diagnosis

Patients who sustain distal biceps tendon ruptures are typically middle-aged males involved with heavy lifting. They have loss of flexion and especially supination strength. The biceps tendon is often palpable proximally in the antecubital fossa.

Treatment

To avoid weakness and the associated functional disability, we recommend acute anatomic repair. Morrey et al. (113) compared results of immediate anatomic reattachment, delayed reattachment, attachment to the brachialis tendon, and nonoperative treatment of distal biceps ruptures. Immediate reattachment restored normal strength in flexion and supination at 1 year in comparison with conservative treatment, which resulted in a 40% loss of supination strength and 30% loss of flexion strength. Late reconstruction by inserting the tendon into the brachialis resulted in improved, but not to normal, supination and flexion power (115). Anatomic repair of the distal biceps tendon can performed by a two-incision technique similar to that described by Boyd and Anderson (116) or a one-incision technique through a modified Henry approach (117).

Patients who present with chronic distal biceps rupture require careful and thoughtful management. Anatomic repair is difficult, if not impossible, after chronic rupture due to prolonged musculotendinous unit contracture, tendon degeneration, and scarring around the radial tuberosity. There have been isolated case reports describing surgical management of chronic distal biceps rupture using fascia lata graft (118) or free semitendinosus graft (119) to bridge the gap between retracted tendon and the radial tuberosity. Since 1990, one of us (FAM) has offered reconstruction with an autogenous semitendinosus graft and has good results.

Summary

Early anatomic repair of acute distal biceps ruptures is the ideal treatment to restore strength and function. Late reinsertion can yield good results; however, these are usually inferior to acute repairs. A semitendinosus autograft can be considered for patients who have a chronic tear of the distal biceps tendon that has retracted so that it can no longer reach the radial tuberosity.

Elbow Arthritis

The most common types of arthritis affecting the elbow are osteoarthritic, posttraumatic, and rheumatoid. Classic findings in the osteoarthritic elbow include osteophytes from the coronoid and olecranon (120), loose bodies, and bony hypertrophy of the distal humerus (121).

Athletes who throw in their sport are particularly prone to lesions in the posterior compartment degenerative osseous changes due to valgus loads placed on the elbow (122). Posteromedial olecranon osteophytes corresponding with hypertrophy of the humerus (123), radiocapitellar chondromalacia, and loose bodies are common (124). Pain may result from repeated impaction during the late acceleration and follow-through phases of throwing (125).

The elbow is the second most common site of osteochondritis dissecans (72,126). This disorder is characterized by necrosis of part of the articular cartilage and of the underlying bone, with eventual separation of the fragments to form intraarticular loose bodies (Fig. 58-11). The precise cause of this condition is unknown (72,126), although injury may play a prominent role. The capitellum seems to be primarily affected, perhaps due to impairment of blood flow to the affected segments of bone and cartilage by thrombosis of the end artery (72) or due to the inherent mechanical properties of the capitellar articular surface. Increased strain on the capitellum during high valgus loads as in pitching may predispose the capitellum to injury. Topographically, significant differences exist in the mechanical properties and thickness of capitellar and radial head articular cartilage (127). The size of the necrotic segments of the articular surface as well as secondary radial head changes vary. A line of demarcation forms between the avascular segment and the surrounding normal bone and cartilage; after an interval of months, the avascular segment separates as a loose body.

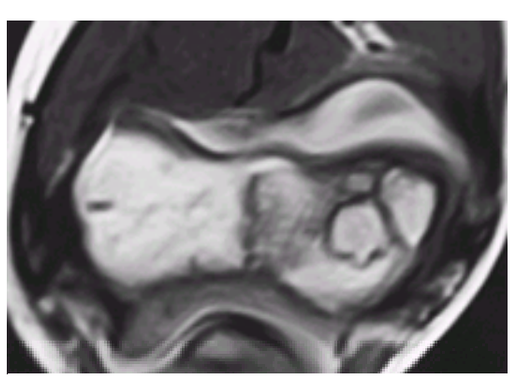

Figure 58-11. A magnetic resonance imaging scan of the distal humerus. Osteochondral fragments are readily seen in the capitellum.

Evaluation

Characteristics of a patient with osteoarthritis of the elbow are fairly consistent. Patients tend to be older males, except throwing athletes, who tend to present at younger ages. They have mechanical symptoms due to bony changes, including locking, grinding, and catching. Flexion contractures associated with posterior mechanical abutment are common. The patient complains of pain, which is aggravated by use of the elbow. The range of motion of the elbow is frequently limited, with extension greater than flexion. Palpation of the elbow elicits tenderness and effusions are occasionally present. Strength is typically diminished. Patients with inflammatory arthritis have a more variable presentation. Pain and mechanical symptoms are similar, although significant articular effusions are more common in

inflammatory arthridities, such as rheumatoid arthritis.

Radiographs may reveal loss of radiographic joint space, osteophytes, distal humeral hypertrophy, and loose bodies; posttraumatic deformities; and osteopenia and bony erosions in inflammatory arthritis. Conventional radiography, however, typically underestimates the number of loose bodies found at surgery (128,129,130,131 and 132); a patient with mechanical symptoms may have symptomatic loose bodies without radiographic evidence. Occasionally, CT scans and MRI may help in the evaluation of disorders such as early osteochondritis dissecans or significant posttraumatic deformities.

Diagnosis

An arthritic elbow is usually stiff, crepitant, and painful on joint motion. Loose bodies typically manifest as popping or catching with motion. Inflammatory elbow arthritis is usually accompanied by an elbow effusion, which is most often apparent in the area of the radiocapitellar joint. Aspiration of an elbow effusion is usually indicated to confirm inflammatory or septic etiologies. Radiographs may or may not be confirmatory.

Treatment

Gentle physical therapy and antiinflammatory medications along with activity modification may satisfactorily control the symptoms of elbow arthritis. Patients with osteochondritis dissecans without fragmentation may benefit from splinting until symptoms resolve.

Surgical debridement with osteophyte excision, loose body removal, and capsular release is an effective means of treatment in selected patients with mild arthritis. However, arthritic conditions tend not to improve by loose body removal alone (130,131,132,133,134 and 135). Loose bodies are commonly found in both anterior and posterior compartments in elbows with osteoarthritis and osteochondritis dissecans (136,137 and 138). Isolated loose body removal is effective in cases of osteochondritis in which the fragments of bone and cartilage are separated (72).

The goal of surgical debridement and smoothing is to improve elbow mechanics. Occasionally, isolated roughness of the radiocapitellar joint may exist, associated with pain on pronation and supination without substantial problems on elbow flexion or extension (139,140 and 141). Simple radial head resection in a stable elbow may provide dramatic relief.

In some cases of severe arthritic conditions, such as rheumatoid arthritis, an elbow arthroplasty usually produces excellent results (142,143). However, the patient must not place high demands on the elbow. Joint replacement for posttraumatic or osteoarthritis is not as successful as in rheumatoid arthritis. These patients tend to place higher stresses across the elbow, and the nature of the arthritic disorder tends to result in bony hypertrophy and diminished range of motion.

Summary

In carefully selected patients, surgical debridement and smoothing relieve pain, with some increase in motion. However, degenerative changes and subsequent symptoms may progress despite debridement. Total elbow arthroplasty reliably diminishes pain and improves function in low-demand patients, especially those with rheumatoid arthritis.

Olecranon Bursitis

The olecranon bursa normally allows for the smooth gliding of the skin over the prominence of the olecranon. Trauma, infection, and autoimmune disorders can produce a persistent bursal effusion.

Evaluation. Most disorders of the olecranon bursa are not painful, although septic olecranon bursitis may produce substantial discomfort. The primary symptom is a swollen area over the point of the elbow (Fig. 58-12). Patients may not like the appearance or have difficulty placing their elbow on a hard surface. Palpation over the olecranon bursa usually elicits tenderness. Infectious bursitis can be associated with erythema. Radiographic evaluation may demonstrate spurs on the olecranon.

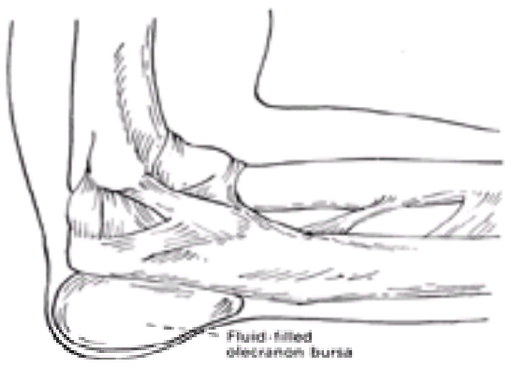

Figure 58-12. Diagram of bursa distended with fluid in olecranon bursitis.

Diagnosis. A swollen olecranon bursa is easily distinguished from an elbow effusion by its subcutaneous location. Whenever infection is suspected, aspiration of the bursa followed by Gram's stain and culture is indicated (144,145).

Treatment. Traumatic olecranon bursitis often subsides with rest of the arm, an elbow pad, and antiinflammatory medications. Occasionally, refractory cases require surgical excision. Septic olecranon bursitis may require incision and drainage if not responsive to systemic antibiotics.

Summary. Olecranon bursitis is usually self-limited and responds well to nonoperative treatment. If an infectious etiology is suspected, an aspiration is usually indicated; however, repeated aspirations are not recommended. Surgical excision, although usually successful, carries an increased risk for postoperative skin complications.

Neuropathy

The major nerves to the hand pass by the elbow, and each is associated with a specific entrapment syndrome. The median nerve can be trapped under the pronator teres muscle (146,147) or its anterior interosseous branches distal to the elbow (107,148); the radial nerve can be trapped in the radial tunnel (149); and the ulnar nerve, in the cubital tunnel (150,151). Inflammatory or idiopathic mononeuropathies such as posterior interosseous nerve palsy may occur without structural compression.

Evaluation

Pain in the proximal forearm and hand may be due to nerve entrapment. The distribution of pain often follows the anatomic distribution of the nerve but the pain is occasionally vague. For instance, posterior interosseous neuropathy produces vague proximal forearm pain yet this nerve does not provide cutaneous sensory innervation. Characteristic motor and sensory losses may occur and are perhaps most common for ulnar entrapment at the elbow. The anatomic location of the major nerves should be palpated in sequential fashion: the radial (posterior interosseous) nerve approximately 5 cm distal to the lateral epicondyle in the radial tunnel, the median nerve in the proximal forearm as it passes between the two heads of the pronator teres, and the ulnar nerve as it passes posterior to the medial epicondyle and into the flexor-pronator mass. Provocative maneuvers such as elbow hyperflexion (ulnar nerve), resisted pronation (median nerve), and resisted long finger extension (radial nerve) are helpful but not diagnostic. Strength and sensory testing should be part of the routine evaluation.

Radiographs are typically nondiagnostic except in the unusual cases of osseous deformity. Nerve conduction velocities and electromyography can demonstrate neural changes and may help guide treatment. Magnetic resonance neurography may be useful.

Diagnosis

Clinical history and physical examination supported by ancillary studies are often diagnostic of neuropathy. Exacerbation of the symptoms by compression, muscle contraction, or joint position that accentuates the entrapment is characteristic.

Treatment

Exercises, injections, antiinflammatory medications, and splinting can be effective for nerve entrapment syndromes. Activity modification is helpful but may not be realistic. If symptoms are substantial or progressive, surgical decompression may be required (107,146,147,149,150,151 and 152). The results of surgical decompression are usually good, provided a specific and accurate diagnosis has been made.

Summary

Neuritis may occur as an isolated phenomenon or as common sequelae of an elbow disorder such as chronic valgus instability. Failure to recognize neural pathology as primary or secondary elbow pathology can compromise the result of treatment.

CONCLUSIONS

Disorders of the shoulder and elbow can affect eight separate articulations. Each can be compromised by stiffness, weakness, instability, and roughness. Often, these basic characteristics do not exist in isolation but rather in combination. Identification of a mechanical problem may suggest a rational orthopedic treatment.

CHAPTER 59

Painful Conditions of the Forearm, Wrist, and Hand

Edward E. Almquist

The wrist and hand are the working unit of the upper extremity and are considered to constitute 90% of its function (1). The forearm, elbow, arm, and shoulder are primarily units for placing the functional device of the upper extremity, the hand, in an appropriate position. This predominant role of the wrist and hand and their complex anatomic functions make this region of the body susceptible to accidental injuries and inflammation caused by wear and tear, most of which usually produce pain. Moreover, because the hand and arm occupy a significant part of one's body image, they are considered an outward extension of one's personality. Injury, disfigurement, and pain cause important psychological disturbances in many patients. For example, a painful neuroma of the finger may cause embarrassment because of the inability to shake hands and greet people properly. This may, in effect, produce a more timid personality than would be normal for a particular patient. Therefore, it is important to recognize and treat not only the pathologic disorder but also its associated psychological reactions.

This chapter includes discussion of the most important painful conditions of the forearm, wrist, and hand. The material is presented in five major sections: basic considerations, which include epidemiology and evaluation of the patient; painful disorders of the forearm; painful disorders of the wrist; painful disorders of the hand; and neuropathic disorders of the wrist and hand. More detailed information can be found in various books on these subjecyts (2,3,4,5 and 6).

BASIC CONSIDERATIONS

Epidemiology

Injuries to the hand and wrist are the most common type of upper extremity trauma. In an epidemiologic study of industrial injuries in the state of Washington, upper extremity injuries, mostly of the hand and wrist, constituted the majority of industrial claims for musculoskeletal disorders (7). In addition to obvious trauma, including fractures and lacerations, there are even more frequent nonspecific painful conditions, such as tendinitis, ligamentous sprains, muscle strains, and compressed or irritated nerves. Arthritis is also enormously common in the upper extremity. Arthritic conditions of the distal joints of the fingers probably are the most common arthritic conditions in the body, followed closely by that of the basilar joint of the thumb. Rheumatoid arthritis can be a devastating incapacity to the upper extremity, with one-third of those affected being severely disabled or totally dependent (8,9 and 10).

In addition to injuries and arthritis, an estimated 5 million American workers had symptoms of synovitis, bursitis, or tenosynovitis of the upper extremity in 1980. These caused 37 million days of restricted activity, 5 million days of bed disability, and 2.2 million days of work lost. Approximately 40% of these cases involved the wrist and hand (11).

Evaluation of the Patient

The diagnosis of disorders of the forearm, wrist, and hand is made through a comprehensive history and a detailed and specific physical examination, frequently aided by roentgenography and other special tests. It is important to remember that pain in the forearm, wrist, and hand is often referred from disorders of the cervical spine, occasionally from shoulder disorders, and not infrequently from around the elbow.

History

The detailed history should alert the examiner to the diagnosis in approximately 70% of cases. It is imperative, however, that the examiner ask the appropriate questions, listen carefully to the responses, and determine what these responses mean to the patient. If the patient has pain, its location, intensity, quality, and temporal characteristics should be established. The examiner should ask the patient to point with one finger to the most painful area and show where the pain radiates. The patient should be asked what aggravates the pain, what relieves it, and how the pain is affected by cold, heat, rest, and activity. The patient should be asked if there is swelling present and under what circumstances, if there is crepitus or snapping, and if so, what makes these signs occur.

If a specific injury was involved in producing the disorder, the examiner must determine the forces involved in the accident or injury as accurately as possible from the patient's description. He or she should ask the patient to reconstruct in pantomime the sequence of events: which way the hand or arm was twisted, how it moved, what struck the hand, what type of force was involved. Was the wrist or hand in dorsiflexion or volar flexion? Was there a rotary force involved in producing the injury? As an example, when a 1.5-horsepower drill turning in wood strikes a nail and suddenly stops, it produces a sudden rotary force to the wrist of the drill operator. Such details of the injury should be determined by careful questioning of the patient (12).

Physical Examination

The key to the physical examination is a careful knowledge of the underlying anatomy. The forearm, wrist, and hand lend themselves well to anatomic examination. Most of their components are palpable and identifiable through surface evaluation, and they can be compared with the opposite side to reveal any visual or palpable differences.

Examination of the Forearm. Both forearms should be uncovered to above the elbow, with all jewelry removed, and the two sides compared. They should be observed for any deformity, engorgement, inflammation, change in color, or swelling, as well as skin damage, bruising, and masses (13). Rotation should be evaluated by placing both elbows firmly against the patient's trunk and having the patient turn the hands actively, palms up and palms down. Supination and pronation should be 70 to 90 degrees from the neutral plane, or that position of the forearm with the thumb pointed upward. The majority of people have a range of approximately 80 degrees. This can be checked with a goniometer by placing it across the flexion crease of the wrist in its maximum rotation and aligning the other end of the goniometer with the humerus. Tender areas in the forearm should be elicited initially by having the patient point to the tender area, which then should be carefully evaluated by the examiner. Next, the various extensor muscles should be palpated, the sulci between the muscles noted, and any masses or acute tenderness recorded. The flexor muscles are somewhat less distinct, but the general area can be identified. Masses should be described as to position and size, as well as tenderness and consistency. The examiner should ascertain whether tapping the mass elicits a tingling sensation farther distal (positive Tinel's sign).

Examination of the Wrist. Inspecting the wrist, the examiner should note swelling and where it is localized, venous engorgement, texture and quality of the skin, and visible masses. Range of motion of the wrist can be evaluated in dorsiflexion, volar flexion, ulnar deviation, and radial deviation, as outlined in Figure 59-1. As there is variation in motion among individuals, usually the motion of the wrist is compared with that of the opposite side. Gripping strength of the hand and wrist is next evaluated, preferably before specific tender areas are elicited and perhaps aggravated. Use the dynometer three separate times, alternating between the painful and the nonpainful side and checking for consistency of readings. The dynometer may also be set at varying squeeze-grip settings between wide and narrow. At the very wide and the very narrow settings, the grip should have less strength than at the intermediate, assuming a good range of motion of the fingers. The nondominant arm is usually 10% to 15% weaker. Inconsistent efforts, tremulousness, and cog wheeling are suggestive of anxiety, depression, inattention, or other reactions to the injury. Weakness inconsistent with the appearance of muscle bulk suggests conscious motivational problems.

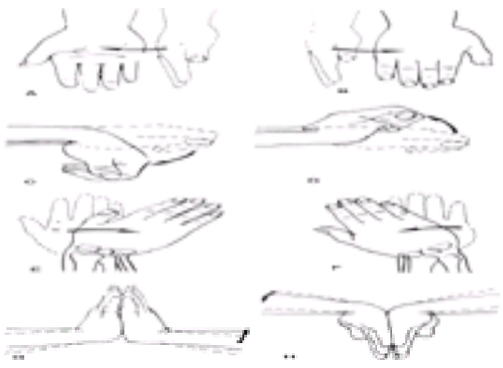

Figure 59-1. Movement of the wrist and hand. **A:** Supination. **B:** Pronation. **C:** Palmar flexion. **D:** Extension (dorsal flexion). **E:** Abduction (radial deviation). **F:** Adduction (ulnar deviation). To test the strength of the muscles responsible for these movements, the patient is asked to make each movement against resistance offered by the physician. **G,H:** Sample methods of measuring wrist flexion and extension. (Modified from Burton RE, ed. *The hand: examination and diagnosis*, 2nd ed. New York: Churchill Livingstone, 1983:8–9.)

The dorsiflexion of the wrist is measured by a goniometer along the flexor aspect of the wrist and then paralleling the third metacarpal. It should average 70 degrees. Volar flexion is likewise measured by placing the goniometer along the dorsum of the wrist and along the third metacarpal, and it averages 80 degrees. Ulnar deviation is measured by placing the goniometer along the midaxis of the forearm and then noting the angle of deviation of the third metacarpal, which is 30 to 40 degrees. Radial deviation using the same landmarks is 20 degrees (see Fig. 59-1).

The key to most unobvious diagnoses of the wrist is palpation. The most important aspect of that evaluation is knowing the underlying anatomy. That can be evaluated by examining one's own wrist and determining each anatomic point, starting at the skeletal prominence on the radial aspect of the wrist (Fig. 59-2). The most prominent radial structure is the styloid. One centimeter proximally, the sharp ridges dividing the first dorsal compartment of the adductor pollicis longus and the extensor pollicis brevis muscles may be felt running approximately 30 degrees obliquely from proximal and lateral to palmar and distal. Another centimeter dorsal to the radial styloid lies a prominent bony structure, Lister's tubercle, around which the extensor pollicis longus tendon angulates to approach the thumb. The flat area ulnar to Lister's tubercle is the fourth interosseous compartment, occupied by the common extensor and indicis proprius tendons. Just ulnar to the fourth canal is the head of the ulna, a smooth, rounded bone that can be felt moving independently of the radius. It is important to palpate that structure in pronation and supination and to check its stability in palmar and dorsal translocation and compare it with the opposite side.

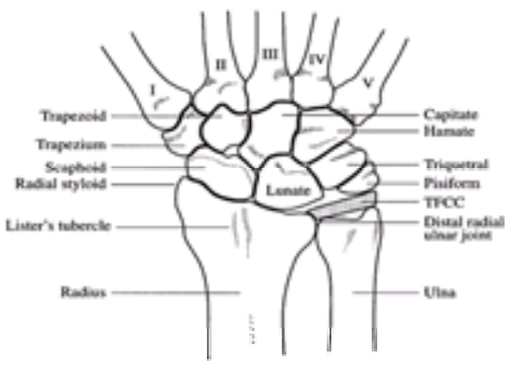

Figure 59-2. Bony anatomy of the wrist. (TFCC, triangular fibrocartilage complex.)

On the volar side of the wrist, the radial artery can be palpated just to the flexor side of the radial styloid, and it often can be visualized pulsating in thin individuals. The ulnar artery is deep to the head of the ulna and is difficult to palpate, as it lies beneath the flexor carpi ulnaris tendon.

The flexor carpi radialis, palmaris longus, and the flexor carpi ulnar tendon can be seen tensing the volar wrist skin. It is important to remember that approximately 15% of people do not have a palmaris tendon. The individual carpal bones and their attached ligaments can also be evaluated. The scaphoid lies in the anatomic snuffbox between the first and second dorsal compartments. These landmarks are readily visualized as one extends the thumb on the radial deviated wrist. A depression in the skin denotes the snuffbox, and deep to that lies the body of the scaphoid bone. The distal scaphoid can be evaluated by feeling the volar bony prominence just proximal to the base of the thumb. This rounded, firm mass, 1 cm in diameter, is the tuberosity scaphoid. By grasping between the bony firmness beneath the extensor tendon to the thumb, just distal to the radius, and the scaphoid tuberosity, the examiner can define the two poles of the scaphoid. Its stability can be tested by applying pressure to the tuberosity and noting the stability of the dorsal portion of the scaphoid. Also, Watson's test can be performed by pressing on the tuberosity of the scaphoid and moving the wrist from ulnar to radial deviation, noting a click or pain, which would indicate instability of the scaphoid, or scapholunate separation.

The scapholunate interval may be palpated between the scaphoid and the lunate with the wrist in ulnar deviation. The lunate is covered by the fourth dorsal compartment, comprising the common extensor and indicis proprius tendons. It is less clearly palpable than the scaphoid, but its dorsal surface can be evaluated, and it is important to observe whether any tenderness or mass is present. To the ulnar side of the lunate lies the triquetrum. The stability of that bony structure distal to the ulnar head can be readily evaluated. Its stability relative to the ulnar head and to the lunate should be noted. Also, tender areas in the triquetrum, or just on the proximal surface of it in the area of the triangular fibrocartilage complex (TFCC), should be noted. This is a common area for synovitis and ligamentous tears (see Fig. 59-2).

The stability of the midcarpal joint, that series of joints between the scaphoid, lunate, and triquetrum and the trapezium, capitate, and hamate, is next evaluated. Firmly grasp the wrist over the lunate and scaphoid and then dorsally and volarly translocate the remaining carpus. This often elicits a click and may be startling to the patient. In loose-jointed individuals this is not unusual and can be compared with the opposite side. The stability of this joint and any tenderness across it should be ascertained. Tenderness over the scaphotrapeziotrapezoid joint can be defined from either the more proximal scaphoradial or the more distal trapezial-first metacarpal joints, and this is not an uncommon site of specific pain and tenderness associated with arthritis. In radial and ulnar deviation of the wrist, the triquetral hamate joint glides obliquely, proximally dorsally, and distally volarly and can be evaluated for tenderness and stability.

The distal carpal joints where the carpi meet the metacarpals are next evaluated. In the thumb area, this is a very mobile joint. It is discerned by grasping the thumb and, with the opposite hand, the scaphoid and trapezium and rotating the thumb as well as translocating it in radial-ulnar and dorsal-volar positions. Stability, pain, and crepitus are easily ascertained. The second carpometacarpal joint should be stable and can be evaluated by running a finger along the dorsum of the second metacarpal and noting as a small sulcus appears at its proximal portion as it articulates with the capitate. The same procedure can be performed for the third metacarpal joint. The fourth and fifth metacarpal joints are mobile to 30 to 40 degrees and can be evaluated by grasping the third and fourth metacarpals and translocating that onto the hamate.

The pisiform, which is a sesamoid bone in the carpus, not a true component of the structural wrist segment, can be palpated just proximal to the proximal portion of the hypothenar eminence. With the wrist in a slightly flexed, ulnar-deviated position, this bony prominence can be palpated and then moved with pressure by the examiner's thumb. Tenderness and crepitus, if present, should be noted. One centimeter distal to that and slightly toward the midline is a barely palpable firmness, the hook of the hamate. This is the radial aspect of Guyon's canal.

Examination of the Hand. The hand lends itself readily to evaluation of its anatomic components (14). There is little soft tissue covering it, and its functional components are readily visualized and palpated. Inspection should include comparing with the opposite hand. The color of the hand, swelling, sweating, the presence or absence of calluses compared with the opposite hand, and in particular, the texture of the hand are invaluable observations. The patient may say that the hand is useless or too painful to allow any activity at all, yet if vigorous calluses are present, the validity of that statement may be questioned. The examiner should also note masses, swelling, or deformity across joints, the general nutrition of the skin, whether necrosis is present, clubbing of the fingernails, and tumorous changes in the skin.

Range of motion of the hand is evaluated by noting the full extension of the fingers and the thumb and the flexion of the fingers relative to the opposite side. The fingers should be able to touch the distal crease in the palm. Range of motion should be noted both actively, as the patient's ability to bend or extend, and passively, as the examiner's ability to bend or extend, each finger. That may be noted as the inability to touch the distal palmar crease by X cm or the lack of full extension by X cm. Also, the metacarpophalangeal (MCP), the proximal interphalangeal (PIP), and the distal interphalangeal (DIP) joints should be evaluated for range of motion individually. Range of motion of the MCP joints averages 0 to 90 degrees, with 0 being full extension. Occasionally, the index finger has a range 10 to 15 degrees less than 90 degrees. PIP joints should go from complete extension (0 degrees) to 110 degrees of flexion and DIP joints from 0 to 60 degrees of motion. Increased extension of the PIP joints beyond 0 degrees is called hyperextension. Some patients may have considerable hyperextendability or may even show a deformity called *swan neck*, in which the PIP joints hyperextend and the distal joints flex. This may be normal in loose-jointed people or abnormal following ligamentous tears or erosion of the ligaments from rheumatoid arthritis and so forth.

The MCP joints also abduct and adduct away from the third metacarpal as the fingers are spread apart and closed. The index finger should abduct approximately 20 degrees and the little finger approximately 30 degrees from the plane of the third finger. Thumb motion is checked for in full extension and full flexion. The thumb should be able to touch the fifth metacarpal head. The thumb should also be checked, in adduction, for how close it comes to the second metacarpal; in abduction, how far it moves away from the plane of the second metacarpal; and in opposition, how it rotates out and across the palm (Fig. 59-3 and Fig. 59-4).

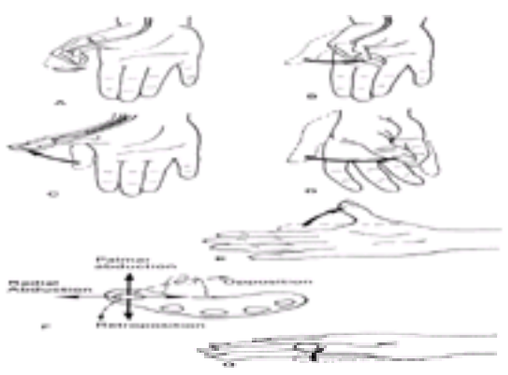

Figure 59-3. Movements of the thumb. When the thumb is in a neutral position, its palmar surface is oriented medially and its dorsal surface is directed laterally. **A:** Flexion of the distal phalanx is effected by the flexor pollicis longus. **B:** Flexion at the carpometacarpal joint is effected by the flexor pollicis brevis and opponens pollicis. **C:** Radial abduction is produced by the abductor pollicis longus and brevis. Not shown is adduction, achieved by the adductor pollicis. **D:** Opposition of the thumb to the fingers is achieved by the combined action of the flexor pollicis brevis, opponens pollicis, and the abductors. In this manner the metacarpal bone is rotated to a position in which the palmar surface of the thumb faces the palmar surface of the little finger. **E:** Palmar abduction is achieved by the abductor pollicis longus. **F:** Definition of thumb movements. **G:** Extension is effected by the extensor pollicis brevis and longus and the abductor pollicis longus. (Modified from Burton RE, ed. *The hand: examination and diagnosis*, 2nd ed. New York: Churchill Livingstone, 1983:9–26.)

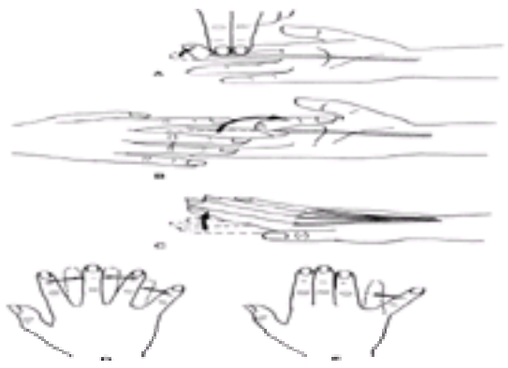

Figure 59-4. Movements of the second through fifth fingers. **A:** Action of the flexor digitorum profundus is tested by having the patient bend the tip of each finger while the examiner stabilizes in extension the proximal interphalangeal joint. As each muscle is examined, the muscle is tested against resistance. **B:** Function of the flexor digitorum superficialis for each finger is individually tested by having the patient bend the finger at the middle joint while the examiner stabilizes in extension the other fingers, so as to eliminate the action of the flexor digitorum profundus. The procedure is repeated for each finger to test passive and active motion against resistance. **C:** Function of the extensor digitorum communis is tested by having the patient place the hand flat on the table in a neutral position and then having the patient raise the fingers above the table as far as possible. **D:** Testing the function of the interosseous muscles. The dorsal interossei abduct the fingers from an imaginary line longitudinal through the axis of the middle finger. In addition to the dorsal interossei, the abductor pollicis longus and brevis abduct the thumb and the abductor digiti minimi abducts the little finger. The palmar interossei adduct the second, fourth, and fifth fingers toward the middle finger, whereas adduction of the thumb is achieved by the adductor pollicis. **E:** Testing the function of the abductor digiti minimi. (Modified from Burton RE, ed. *The hand: examination and diagnosis*, 2nd ed. New York: Churchill Livingstone, 1983:9–26.)

The various tendons and muscles that move and give strength to the fingers and thumb should next be evaluated. Each finger has two flexor tendons, except that 45% of individuals have only one flexor tendon in the little finger. Each finger has a series of extensor tendons (common extensors that extend the MCP and PIP joints) and a complex arrangement of the small muscles of the hand that extend the PIP and DIP joints. [These are well described in detailed anatomy texts such as Netter's *Atlas of Human Anatomy* (15).]

The examiner should check the function of the distal joint, where the profundus tendon inserts. Grasp the finger just proximal to the distal joint, ask the patient to flex the finger, and check for strength. The profundus tendons generally originate in one muscle mass, so individual distal joint motion is difficult. Specific function of the sublimus or superficialis tendon can be evaluated by grasping the fingers not to be examined, holding them in extension, and asking the patient to flex the examined finger. For example, to examine superficialis muscle function of the middle finger, extend the index, ring, and little fingers and then have the patient flex the middle finger; only the sublimus tendon will be able to move that finger. It may be of interest to check the little finger with that test to see if there is a sublimus tendon to the little finger. Frequently, that is congenitally absent. The thumb has one long flexor tendon, which can be evaluated by grasping the base of the thumb and having the patient flex the distal joint. It is important to check not only mobility, but also the strength of each tendon muscle unit that activates finger-thumb mobility.

The strength of the intrinsic muscles of the hand also can be evaluated. The first dorsal interosseus muscle radially deviates the index finger. Its strength and bulk can be readily palpated in the sulcus between the thumb and the index finger. Strength of abduction and adduction of the fingers quantitate ulnar nerve muscle function. Strength of the thumb in opposition and adduction evaluates the three thenar muscles. Two of them are usually supplied by the median nerve, and one, the deep, short flexor to the thumb, is generally innervated by the ulnar nerve. The strength and bulk of the muscle should be evaluated by having the patient oppose and abduct the thumb against the examiner's resistant finger and comparing it with the opposite side. Atrophy or weakness of that muscle may indicate median nerve dysfunction.

Evaluation of Circulation. The hand is usually liberally supplied with circulation by a series of vascular arcades running between the radial and ulnar arteries, and the hand can readily survive with only one major artery intact. Allen's test can verify both radial and ulnar artery patency. Have the patient elevate the hand above the head and make a firm grasp. The examiner should then firmly press over the ulnar and radial arteries on the volar side of the head of the ulna at the wrist level and at the volar side of the radial styloid. This should occur as the patient is holding the hand over the head and grasping. The hand may then be brought down and opened, and the examiner should note the paleness of the fingers and the palm. Release pressure on the radial styloid and note the usual flush of color coming into the fingers from the radial side. Absence of that flush indicates nonpatency of the radial artery. Repeat the test, releasing the ulnar artery from beneath the ulnar head and noting the flush of blood. The ulnar artery is located in Guyon's canal on the radial side of the hypothenar eminence, and tenderness or a thrill in that area may indicate vascular stenosis or an aneurysm, especially if Allen's test shows no blood flowing through the ulnar artery.

A digital Allen's test also can be performed by elevating the hand and compressing both sides of the finger on the flexor lateral margins while compressing the finger itself with the examiner's grasp. Then, the pressure on one side of the finger can be released and digital artery patency monitored by the flush of returning blood. The test is then repeated on the other side of the finger. A more accurate evaluation can be done using Doppler studies or, in critical situations, arteriography. Sudomotor stability of the hand may also be checked by immersing the hand in cold water and noting color and vascular changes.

Evaluation of Nerve Function. The three major nerves to the hand should be evaluated individually. The median nerve enters the forearm at the flexormedial aspect at the elbow. It goes deep to the flexor tendons in the midforearm and passes beneath and slightly to the radial side of the palmaris longus tendon, which is in the midline of the wrist. The palmaris longus tendon becomes prominent when the wrist is minimally flexed against resistance. This tendon is absent in approximately 15% of individuals. The median nerve supplies sensation to the thumb, index, and middle fingers and the radial half of the ring finger normally, although not infrequently this innervation pattern can shift one finger radially. Median nerve motor function supplies the thenar muscles and the index- and middle-finger lumbrical muscles. Therefore, checking thenar muscle function is an important aspect of strength testing for the median nerve, and strength should be compared with that of the opposite side. The median nerve in the forearm supplies the long flexors to the thumb, index, middle, and ring fingers. It also supplies the radial wrist flexor.

Sensory testing should include stroking the finger and asking the patient whether it feels the same as other fingers or the same finger on the opposite side. Sensibility also can be checked by stroking the finger with a soft object, such as cotton. It can best be quantitated by evaluating how well the patient can distinguish two points from one (Weber's discrimination test). To perform this test, place two paper clip ends lightly on the tip of the finger, just blanching the skin. Begin with the two ends widely separated, and if there is abnormal sensation start in a normal sensory area. Once the patient learns the test, progressively diminish the distance between the two points. Test each finger and thumb so that the patient cannot see what is happening. Two-point discrimination varies from 3 to 5 mm on the fingers and the flexor surface of the thumb. However, blind Braille readers can learn to discriminate points less than 2 mm apart. Other parts of the hand are much less acutely discriminating. On the back of the hand two-point discrimination is roughly 10 mm and on the palmar aspect of the hand 8 to 10 mm. Only the tongue has two-point discriminatory sensation as acutely sensitive as that of the fingertips.

Vibratory sensation should be tested under certain circumstances, and different frequencies are used in threshold testing. A tuning fork is placed lightly on the finger, and the patient's sensation thresholds are evaluated for different frequencies. A Semmes- Weinstein Fine-Hair Testing System can be used, particularly in research applications. This test is often performed by hand therapists and requires specific training to perform properly. Sensitivity to hot and cold may be important in specific proximal neurologic disorders.

The radial nerve supplies sensation to the back of the hand overlying the middle and index fingers and the dorsum of the thumb. Sensation in that area can be tested by light touch. The radial nerve innervates the long extensor muscle to all the fingers, thumb, and wrist. The distal portion of this nerve can be palpated, particularly on thin individuals; over the radial styloid, three or four nerve branches can be rolled under a gently moving finger just dorsal to the radial styloid. The muscle function of the radial nerve is tested by noting strength in the extensor tendons of the wrist and the extensor tendons of the fingers and comparing with the opposite side.

The ulnar nerve has both a major sensory and a motor component. It passes into the forearm dorsal to the medial epicondyle at the elbow, runs beneath the flexor carpi ulnaris muscle, and enters the hand through Guyon's canal, a small confined space just on the ulnar side of and superficial to the carpal canal. It cannot be readily palpated in any of these areas distal to the medial epicondyle area at the elbow. Function of this nerve is tested by examining the sensation of the little finger and the ulnar half of the ring finger. Occasionally, the ulnar nerve also goes to the ulnar half of the middle finger. Muscle strength is best tested by evaluating the first dorsal interosseous muscle: Have the patient radially deviate the index finger against resistance and note that strength, comparing it with the opposite side, and note

the bulk of the first dorsal interosseous muscle. The ulnar nerve also supplies function to the long flexor (profundus) to the little finger.

Abducting and adducting the fingers test the intrinsic muscles of the hand, which are ulnar innervated. Atrophy of the intrinsic muscles or atrophy between the metacarpal muscles is pathognomonic of ulnar nerve dysfunction at some level. Froment's sign is positive when ulnar nerve motor dysfunction is present. Froment's sign is tested by placing a piece of paper between the patient's index finger and the thumb and checking the position of the thumb as the examiner tries to pull the paper away from the patient. Normally, the distal joint of the thumb remains in extension, but if ulnar nerve dysfunction is present, the tip of the thumb flexes significantly to increase pressure and attempt to keep the paper from moving.

In checking sensation or lack of sensation, it is important to evaluate sudomotor activity. This is particularly important in children who often cannot cooperate fully in testing, particularly for pinprick sensation. If the patient says he or she has no feeling in the fingers yet is sweating vigorously over the finger, either there is a proximal neurologic lesion or there is false information. Lack of sweating in young children is often important in evaluating their nerve function because they may have difficulty cooperating with testing. Ninhydrin testing can be used to evaluate lack of sweating objectively. Ninhydrin stains the proteins in the sweat glands. After the hand is sprayed with ninhydrin and blotted on paper, absence of a fingerprint denotes lack of nerve function. Also, lack of wrinkling when the fingers are placed in water would indicate lack of pseudomotor activity and hence nerve function.

Radiography and Laboratory Tests

Radiography. Radiographs are almost always required for diagnosis and treatment of injuries and many other conditions of the forearm, hand, and wrist. Extraosseous calcification can substantiate a diagnosis of tendinitis, and fractures or suspected fractures, of course, require the use of radiography. Often spot, oblique, and additional views are necessary to establish the presence of a fracture. Stress fractures of the forearm, although not common, can be the source of pain, and radiographs reveal them. Some fractures are not evident on initial radiographs (e.g., fracture of the scaphoid often shows up only in later radiographs). Colles' fractures and radial fractures, particularly epiphyseal fractures in children in which only the epiphyseal plate is involved, may not show up until callus appears. Standard posteroanterior and lateral radiographs may need to be supplemented by other views.

The six-view series of radiographs for wrist instability includes the standard (posteroanterior) view of the wrist and the anteroposterior or supinated view of the wrist, with the hand in maximum ulnar and radial deviation, and also with the hand contracted into a fist. These views often show scapholunate separation that may not be visualized in static views. Cineroentgenography can show dynamic instability and is easily obtained.

Other Imaging Techniques. Magnetic resonance imaging (MRI) and computed tomography show good details of the forearm and confirm the diagnosis of ischemic necrosis of the lunate in Kienböck's disease before it is seen by radiography. These techniques also show soft tissue tumors in the forearm, wrist, and hand, as well as a deep ganglion. Newer MRI technology also has isolated the ligaments of the wrist and in particular the TFCC, the soft tissue articulating structure at the distal end of the ulna. General use of this technology is somewhat limited by expense.

Arthrography is useful for evaluating ligamentous continuity in the wrist. It can show disruptions, but must be read with some discretion in that very small tears in the ligaments between joints may be visible where they are not clinically significant. Arthrography is used almost exclusively at the wrist joint. The three component joints of the wrist are usually evaluated: the distal radioulnar joint, proximal carpal joint, and midcarpal joint. If dye is placed in the proximal carpal joint, it should not flow into the distal radioulnar joint. If it does so, it is an absolute sign for disruption of the TFCC. Dye flowing between the lunate and triquetrum would indicate disruption of the lunotriquetral ligaments. They may be subtle or partially disrupted and still show leakage. It may be necessary to define these leaking joints by placing the dye in the midcarpal joint and seeing if it flows retrograde into the proximal carpal joint.

Ultrasound has advanced to the point at which it can ascertain abnormal structures in the wrist, in particular the presence of occult ganglions. It is less expensive than MRI but requires skilled examiners.

Arthroscopy is another diagnostic tool for wrist evaluation. It involves surgical penetration of the wrist with at least a local anesthetic and considerable technical skill and imaging equipment. In complex cases and uncertain diagnoses this tool may be necessary. TFCC tears and ligament disruptions in localized areas of arthritis are readily evaluated in all three joints using this technique.

Laboratory Tests. Laboratory tests are not routine for evaluating the painful hand and wrist but can be useful in special circumstances. Lupus erythematosus, rheumatoid arthritis, gout, and septic arthritis, to name a few, are diagnoses whose confirmation is substantiated by laboratory tests. The reader is referred to Chapter 27 for further discussion of arthritides and diagnostic testing.

PAINFUL DISORDERS OF THE FOREARM

Table 59-1 lists the most important painful conditions of the forearm, wrist, and hand that are considered in this chapter. Once the diagnosis of a specific condition is made, the most effective therapeutic strategy can be developed and carried out.

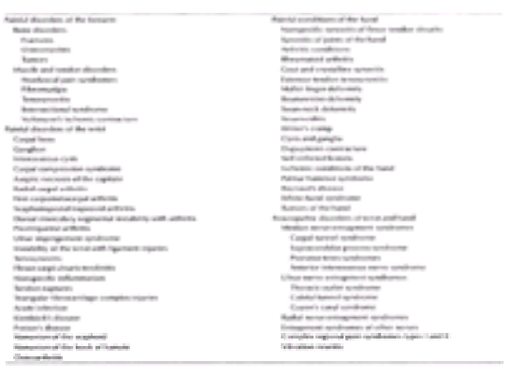

TABLE 59-1. Painful conditions of the forearm, wrist, and hand

Bone Disorders

Fracture and Dislocation

Among all age groups, fractures of the radius and the ulna are the third most frequent type involving the upper extremity, exceeded only by fractures of the phalanges of the hand and of the carpal bones (10,16). Because of the critical role the radius and ulna play in the function of the upper limb, fractures of these bones are also the third most frequent cause of restricted activity days and bed disability days, and the fourth most common cause of days lost from work (10).

Etiology. Fractures of the forearm are of three types: proximal, shaft, and distal. Proximal fractures are in or associated with the elbow and are discussed in Chapter 58. Midforearm or shaft fractures usually involve both bones of the forearm. They can be subtle, markedly deformed, or even open. Because of the multiple and complex rotatory forces of the muscles acting on the various segments of the forearm bones, open stabilization of shaft forearm fractures is almost always necessary in adults to maintain stability. Children have a thick periosteum that frequently adequately stabilizes forearm fractures to obviate the need for open stabilization. A direct blow to the ulna or radius may cause a one-bone forearm fracture. These are often stable, requiring only immobilization. Occasionally, a stress fracture is seen in these bones and may need bone scanning to define.

The third type of forearm fracture is distal, near the wrist joint, and represents 15% of fractures in adults. Usually these are caused by a wrist extension injury. On occasion, they may be subtle and difficult to recognize. Tenderness directly over the area associated with deformity or bruising should arouse a high degree of

suspicion. Radiographs are usually diagnostic. In children's fractures, a type 1 epiphyseal injury occurs only across the epiphyseal plate and may not be evident by radiography until new bone is forming. Torus fractures in children are a crinkling of the dorsum cortex of the radius, an effect of the deforming force on the softer, more resilient bone in children. The clinical deformity is minimal. Lateral radiographs are diagnostic. Cast immobilization only is the treatment.

Distal radial fractures are classified, like all fractures, as stable or unstable, open or closed, intraarticular or extraarticular. Stable fractures are those that, when reduced, remain in position. Most distal radial fractures are stable and extraarticular. If there is more than a little angulation at the fracture site, reduction is necessary; more than 10 degrees of dorsal angulation of the radial articular surface is not well tolerated by the adult patient.

Intraarticular radial fractures need to be well reduced. Articular fractures with displacement of greater than 1 mm almost universally lead to later arthritic changes in that joint. It is important to do what is necessary to reduce and stabilize these fractures. Sometimes closed reduction is sufficient, or external fixation traction or surgical stabilization with pins or plates may be necessary. There is often considerable crushing and shortening of the radius with distal fracture. Reduction of the shortening and stabilization to prevent resettling may be necessary. If a radial fracture heals with much deformity or misalignment, poor function results. This is of particular concern in the younger patient.

Most distal radial fractures involve the ulna, and usually only a small fragment is fractured from the styloid process. If, however, no ulnar fragment is present, it usually means the TFCC (a ligamentous-like structure on the ulnar side of the wrist) has been torn. This is treated by immobilization of the radial fracture. In significant wrist fractures sustained in hyperextension injuries, the proximal radial head at the elbow should be evaluated and probably radiography performed because radial head fractures are not uncommonly associated with this type of injury.

Osteomyelitis

Acute osteomyelitis is rather uncommon in the forearm bones, but when it develops, infection may be blood-borne (hematogenous) or may be introduced from without, usually as a result of a compound fracture. The hematogenous type occurs mainly in children and usually affects the radius more often than the ulna, and the lower metaphysis rather than the upper one (16,17). Because the upper metaphysis of both the radius and ulna is partly or wholly within the capsule of the elbow, infection of the metaphysis can spread directly to the joint to cause pyogenic arthritis. In contrast, at the wrist the metaphysis of the radius is wholly outside the capsule, and consequently direct spread of infection to the joint is unlikely.

Symptoms and Signs. The clinical features of osteomyelitis include a rapid onset of pain over the affected bone and general malaise. Physical examination reveals systemic illness with pyrexia and exquisite tenderness, which is clearly circumscribed over the affected bone. The overlying skin is warmer than normal, and often the soft tissues are indurated, but later a fluctuant abscess may be present.

Diagnosis. The diagnosis of acute osteomyelitis is made through the history, physical examination, radioisotope scanning with technetium 99m, and laboratory studies including white cell count, erythrocyte sedimentation rate, and blood cultures, which may be positive in the incipient stage but are not invariably so (16).

Treatment. Treatment includes bed rest, systemic antibiotic therapy for at least 6 weeks, and, if necessary, surgical incision to release pus to reduce the risk of ischemic bone necrosis. Chronic osteomyelitis of the radius and ulna usually follows an acute untreated infection. In addition to bed rest and antibacterial drugs given for nonsuppurative flares of infection, surgical intervention to effect a thorough drainage and sequestrectomy for persistent purulent discharge may be necessary. More detailed discussion of osteomyelitis is found in Chapter 95.

Tumors of the Forearm

Various types of benign tumors can develop in the bones of the forearms; these include osteoma, chondroma, osteochondroma, and giant cell tumor (18). Chondroma of the ulna or the radius may retard growth in the affected bone, whereas growth of the other bone proceeds normally. This may cause marked curvature of the affected bone and a severe deformity from uneven growth. This usually requires surgical correction by osteotomy.

Giant cell tumor frequently develops in the lower end of the radius, which is one of the favorite sites of this tumor in the upper limb. The lower end of the ulna is also susceptible. Treatment involves surgical excision. If the lower end of the ulna is the part affected, the bone should be excised up to a point well proximal to the tumor, whereas if the tumor is in the lower end of the radius, radical excision and replacement by a suitable bone graft are recommended (18).

Fibromatosis is a tumorlike condition, primarily of childhood and adolescence, which seems to follow trauma. Scarlike tissue becomes invasive and may enlarge, producing a firm mass; it may encompass the nerves with compression-type syndromes; or it may erode into the radius or ulna, producing not only pain but also fractures. Lytic lesions of the bone in the midforearm in adolescents are suspicious for this condition.

Neurofibroma is another tumor condition that affects the forearm, with large, tender masses associated with hyperpigmentation of the skin. The patient usually has other areas of involvement. MRI evaluation can define the mass.

Blood vessel tumors, hemangiomatosis and arterial venous malformations, are tender, sometimes painful conditions of the forearm associated with vascular changes. These tumors are more distal, often presenting with swelling and venous engorgement. They can be localized and possibly excised, but not infrequently are widespread and invasive.

Neurilemmoma is a benign tumor of the Schwann cell in a large or small nerve, ultimately affecting the nerve function. This may be quite significant when the tumor is in a major nerve. Most commonly, however, these tumors are in small nerves and can be diagnosed by the presence of Tinel's sign over the mass.

Benign lipomas are perhaps the most common tumors in the forearm and often are associated with multiple lipomas in the body, showing hereditary prevalence. They are usually quite superficial, but may be bothersome or become tender with persistent manipulation by the patient.

Malignant tumors, either primary or metastatic, rarely involve the radius and the ulna. When osteosarcoma does occur in the forearm, the lower end of the radius is the usual site. Malignant bone tumors invariably produce moderate to severe pain, which may be localized or felt through the entire forearm, hand, and even the arm. Therapy for the tumor and for pain control is discussed in detail in Chapter 35 and Chapter 95.

Disorders of the Muscles and Tendons

Myofascial Pain Syndromes and Fibromyalgia

These syndromes are defined by pain and tenderness developing in muscles and soft tissue areas, often associated with activity, in circumstances in which there is no other specific pathologic entity identified (see Chapter 30 for detailed discussion of this topic). There is a tender muscle not associated with nerve compression, with a tear in the tendon such as in tennis elbow, or frictional tenosynovitis. This type of condition has been an enigma to clinicians. It seems to respond favorably to local anesthetic injections, often with cortisone, when the condition is quite localized to *trigger points*. It is often associated with people who use their arms vigorously and has been a common complaint in the workforce. There is little objective evidence of its pathogenesis. The more generalized condition of fibromyalgia is being developed as a rheumatologic entity in the literature, and forearm problems are among the related complaints. It is important to rule out specific disorders that may mimic this condition. Appropriate treatment includes pain relief, job and activity changes, injections, antidepressant medication, and antiinflammatory medication. These are often coupled with physical therapy modalities. Diagnosis of these conditions is discussed in Chapter 29 and Chapter 30.

Tenosynovitis

Acute and chronic frictional tenosynovitis, also called *tendinitis*, is a common clinical condition, particularly in young adults whose occupations demand repetitive movements of the wrist and hand. The condition is attributed to friction between the tendons and the surrounding tendon sheath resulting from overuse of the hand. The tendons affected are those of the deep muscles of the back of the forearm, especially the extensors of the thumb and the radial extensors of the wrist. The pathophysiology consists of a mild inflammatory reaction of the tendon and paratendon with local swelling and edema. This condition is discussed in some detail in

the sections on the wrist and hand.

Intersectional Syndrome

Intersectional syndrome is tenosynovitis that affects the forearm where the adductor pollicis longus and pollicis brevis extensor tendons cross the radial wrist extensor tendons. It is diagnosed by a tender, often swollen area 8 to 10 cm proximal to the wrist joint along the radius. Crepitus is often heard or palpated when moving the thumb and wrist. This condition seems to be caused by unusual or strenuous use of the thumb. The treatment is rest by splinting the wrist and thumb, antiinflammatory medication, and local corticosteroid injection. Rarely, in chronic cases, surgical debridement of the inflamed bursa is necessary.

Volkmann's Ischemic Contracture

Volkmann's ischemic contracture is characterized by fixed contracture of the flexor muscles in the forearm and deformity of the wrist and fingers.

Etiology and Pathophysiology. The ischemia of the muscle can be brought about by injury to, or obstruction of, the brachial artery near the elbow or by tense edema of soft tissue of the forearm constrained within an unyielding fascial compartment (19). Any major fracture in the elbow region or upper forearm may lead to arterial occlusion. Especially important is a supracondylar fracture of the humerus with displacement causing severance or contusion of the brachial artery by the sharp lower end of the main shaft fragment. The rapidity and severity of the ischemia depend on the rapidity and degree of injury. Sudden, severe occlusion of the brachial artery may cause severe ischemia and gangrene of the fingers and hands. More often, the collateral circulation provides sufficient perfusion to the hand for it to remain viable, but not enough to nourish adequately the flexor muscles of the forearm or the main peripheral nerve trunks. Severe tense edema in the anterior fascial compartment of the forearm also can produce ischemia, a consequence of severe injury in the region. The ischemia causes necrosis of muscle fibers of the forearm flexor group, especially the flexor digitorum profundus and flexor pollicis longus, with subsequent fibrosis and shortening. In some cases the cause of the vascular obstruction is an overly tight plaster cast or bandage of the forearm or arm.

Symptoms and Signs. Soon after the injury, the patient experiences severe ischemic pain in the forearm, which may radiate to the hand. On examination in the incipient stage, the fingers are white or blue and cold, the radial pulse is absent, and active finger movements are weak and painful. Passive extension of the fingers is especially painful and restricted. At this stage, evidence of severe nerve impairment (e.g., anesthesia of the fingers and paralysis of the small muscles of the hand) sometimes is present but not always.

In the established stage of Volkmann's ischemic contracture, which develops gradually within a few weeks or a month of the injury, a striking flexion contracture of the wrist and fingers from shortening of the fibrotic forearm flexor muscles is present. Sensory and motor paralysis of the hand may persist as complicating factors, but they are not an essential feature of Volkmann's contracture (16, 20).

Diagnosis. Diagnosis is based on the history and physical examination. In the incipient stage, absence of the radial pulse associated with severe pain on forced extension of the fingers should suggest a diagnosis of Volkmann's contracture. The presence of anesthesia and paralysis of the hand confirms this diagnosis. In the established phase the diagnosis is confirmed by the history and the clinical findings.

Treatment. If the incipient stage of Volkmann's contracture is diagnosed soon after the injury based on the presenting clinical symptoms and signs, the condition should be handled as an emergency because the effects of occlusion become irreversible after approximately 6 hours (16, 19, 20). All splints, plaster, and bandages that might be obstructing the circulation should be promptly removed. In the case of fracture, gross displacement of the fragments is corrected by gentle manipulation, and a well-padded plaster splint is applied. These measures may be performed under regional analgesia achieved by blocking the brachial plexus in the axilla. This procedure not only promptly relieves the pain but also effects sympathetic interruption and consequent increase of the collateral circulation. If these measures fail to bring about a return of adequate perfusion within 60 to 90 minutes, the anterior fascia of the forearm should be exposed surgically and split longitudinally to permit exploration of the brachial artery; if severe damage is noted, it should be repaired. Continuous brachial plexus block analgesia is maintained in the postoperative period to control pain and produce vasodilation of the collateral vessels (see Chapter 102 for details of technique).

In the established stage of Volkmann's contracture, restoration to normal is impossible. In mild to moderate cases, acceptable function may be restored by intensive exercise under the close supervision of a hand therapist. In more severe cases, the muscle shortening may be counteracted by lengthening of the forearm muscles or by detachment and distal displacement of the flexor muscle origin (16).

Myofascial Pain Syndromes and Fibromyalgia

These have already been mentioned in reference to the forearm in this chapter. They are discussed in detail in Chapter 29 and Chapter 30. They are just as much of a mystery in the wrist as they are elsewhere in the body.

PAINFUL DISORDERS OF THE WRIST

Although sprains and tendinitis of the wrist are common diagnoses, they convey little specific pathologic meaning. They tend, in fact, to be *wastebasket* diagnoses. More specific diagnoses of disorders of the wrist are now possible because of our increased understanding of the biomechanical processes involved and the inflammation they produce. In addition, the modern diagnostic procedures mentioned in the introductory part of this chapter and discussed in Chapter 14 have enhanced our ability to make specific pathologic diagnoses.

Most nonacute wrist pain results from the effects of inflammation. Inflammation is either endogenous, such as that associated with collagen disease or infection, or secondary, resulting from mechanical injury such as nonunion of bones, loose bodies, and torn cartilage. Specific diagnosis of such conditions is possible and should be pursued. For example, generally the specific ligament injured and the specific area of the carpus affected by the loose body or the specific cartilaginous deficit can be identified. In other words, general diagnoses should be supplanted by specific ones, such as scapholunate ligament tear, torn triangular fibrocartilage, and chondromalacia of the lunate. Specific anatomic and pathologic entities causing wrist pain are discussed in the following sections.

Carpal Boss

Carpal boss is characterized by a specific tender area over the junction of the second, third, or both second and third carpometacarpal joint, often associated with osteophyte formation and sometimes associated with a ganglion (21). This condition is illustrated in Figure 59-5.

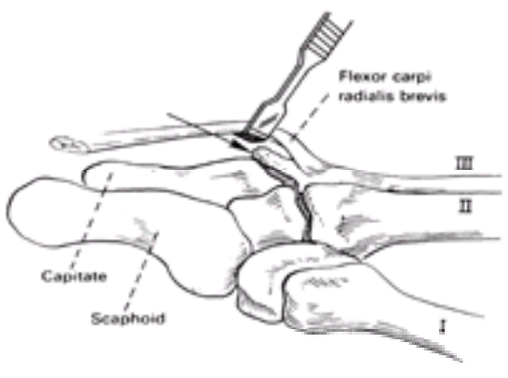

Figure 59-5. Carpal boss syndrome, which is caused by a painful dorsal exostosis (*arrow*) on the adjacent surface of the second and third carpometacarpal joints. Lateral radiograph may show a bony prominence or even an ossicle.

Etiology

The cause of a carpal boss is unclear. It may be associated with a chronic sprain. Excessive mobility of the second and perhaps the third metacarpal and the rocking movement of that joint, which was designed for little movement, could produce excessive wear (21).

Symptoms and Signs

A carpal boss is very tender directly over the joint. The pain is moderately sharp, locally radiating, aching, and often follows strenuous activity. For instance, if the hand is used extensively for gardening during the day, the pain may become quite severe that evening. The pain is not specifically localized to the joint but involves a generalized ache in the wrist and hand. The tender area on the wrist just at the second or third carpometacarpal joint, however, is specific.

Diagnosis

Lateral radiographs or tomograms may show an osteophyte or loose body. Triphasic bone scan shows increased technetium 99m pickup in the area of the second or third carpometacarpal joints (Fig. 59-6).

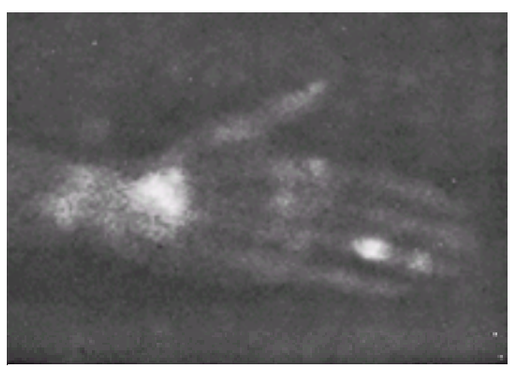

Figure 59-6. Technetium 99m triphasic scan of a hand shows a positive uptake in the second and third phase over the area of the carpal boss reflecting intense inflammatory reaction in this area.

Treatment

The majority of cases of carpal boss are mild and can be treated with splinting for rest, oral antiinflammatory medications, and injections directly into the joint of a long-acting corticosteroid such as triamcinolone, together with a local anesthetic agent. When such conservative treatment is not adequate, surgical treatment may be indicated. Many patients benefit from debridement of the joint by removal of the osteophytes and loose bodies. Fusion of the joint is sometimes required to afford relief. Surgical debridement alone without fusion is successful in approximately 90% of patients (22).

Ganglion

A ganglion is a fluid-filled mass located about tendons or joints (Fig. 59-7). It may be small or quite large. The fluid contains a high concentration of hyaluronic acid. The wrist is the most common area for ganglia, but they can occur in other parts of the body, most notably the fingers and the feet. Some have suggested that friction, related to excessive motion or a subtle injury, causes a ganglion (22). Another theory is that ganglia are outpocketings or herniations of synovial fluid, producing a pseudoepithelium and cyst (22).

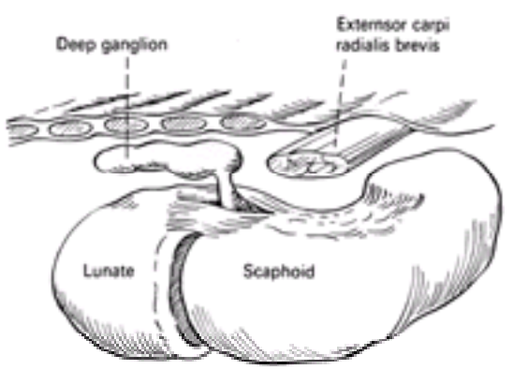

Figure 59-7. Deep ganglion, which usually presents as a painful tender area on the dorsum of the wrist usually just over the proximal scaphoid and lunate and deep to the extensor tendons. Ganglia are usually so deep and small that frequently it is difficult to palpate them.

Symptoms and Signs

Deep ganglia may or may not be painful. If not painful, they are usually ignored. Some patients complain of localized pain and marked tenderness, particularly in the area of the scapholunate joint where either no mass or a faintly palpable firmness is noted. Some large masses may not be tender at all. Others appear small but are painful in the period of expansion of the ganglion. Small intracapsular cysts may be very tender with localized general mechanical soreness that radiates from the wrist and a deep, aching pain usually related to activity.

Diagnosis

The typical ganglion presents as a large, soft mass on the dorsum of the wrist or, less commonly, on the volar aspect and radial side of the wrist. All are easily diagnosed. They are often painful, seemingly because they stretch the adjacent radial artery. Deep, small ganglia may not be palpable in the dorsum of the wrist. These can be a very slight mass but are associated with a tender area, usually localized between the junction of the scaphoid and lunate. Technetium 99m scans are usually minimally active. MRI or ultrasound can delineate these occult ganglia.

Treatment

Treatment of ganglia depends on the number of symptoms. Often, with a small mass that is not painful, simple aspiration just to establish a diagnosis, followed by observation, is sufficient. Repeated aspirations or aspirations with cortisone injection have been reported to be no more effective than observation, because ganglia often disappear spontaneously.

If a painful, tender mass persists, surgical removal may be necessary. Excision should be done under adequate operative conditions so that the cyst can be identified. The joint is usually entered and the cyst removed completely. Removal of a large ganglion sometimes requires grafting a small portion of the retinaculum over the

extensor tendons to close the joint (22).

Dorsal cysts almost always come from the area at the junction of the scaphoid, lunate, and capitate. Some patients, particularly women, have multiple areas of cysts in the dorsal capsule of the wrist. These tend to recur; if noted at the time of the initial surgery, a large excision with a graft may be necessary (22).

Interosseous Cysts

Cysts in the lunate or scaphoid or other carpal bones are often clinically undetectable and are noted only by radiography (Fig. 59-8). They appear as small lytic areas and are noted particularly on tomography.

Figure 59-8. Radiograph showing a carpal cyst (*arrow*). Most painful carpal cysts are in the scaphoid or lunate.

Etiology

The cause of carpal cysts is unclear. They seem to represent ganglia that are intruding into the bone. Some seem to be related to old injuries, and some may be caused by small fractures in the chondral plate with impulsion of synovial fluid. Once the cyst has begun to develop, a trap-door phenomenon can occur in which a small amount of fluid is pushed into the area and the cartilage acts as a hinge, not allowing the fluid to extrude and causing positive pressure, which expands the cyst within the bone.

Symptoms and Signs

Many of these cysts are minimally painful. Others, although small, produce a dull, aching, joint-type pain that is aggravated by activity, but often present as a constant ache with or without excessive use. The pain is deep in the wrist and is not well localized.

Diagnosis

Diagnostic blocks with a local anesthetic injected into the wrist do not relieve much or all of the pain. Triphasic bone scans are markedly positive. Tomography is particularly helpful in outlining the cyst and may even show its proximity to the joint surface. Some cysts are secondary to obvious arthritic changes within the wrist; loss of joint space and eburnation of the adjacent subchondral plate are typical osteoarthritic or rheumatoid arthritic changes.

Treatment

Treatment depends on the severity of the symptoms. Some asymptomatic cysts found only on radiographs need not be treated. Painful cysts, particularly those large enough to cause a small fracture and resulting in pain with activity, should be treated by curettage of the cyst, approaching it from a nonarticular area. The cyst should be packed with cancellous bone graft. Healing of the graft usually produces complete relief of symptoms.

Carpal Compression Syndrome

Carpal compression syndrome is the aftermath of acute or chronic extension injury to the wrist in which the scaphoid (at times the lunate) sustains cartilage damage, impinging beneath the lip of the radius (Fig. 59-9). It is often associated with carpal instability. The chief symptoms of carpal compression syndrome are localized tenderness in the dorsal margin of the proximal carpal row and pain, particularly on extension of the wrist and on direct compression over the scaphoid or lunate. Lateral tomograms may reveal small osteophyte formations, or even loose bodies, on the dorsal scaphoid or lunate. Triphasic bone scans are distinctly positive. The most effective treatment of this condition is limitation of activity and antiinflammation medication. Rarely, excision of osteophytes or drilling of the sclerotic bone margin is necessary, although this gives only partial relief.

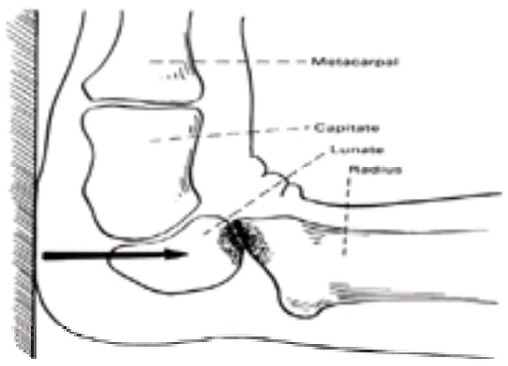

Figure 59-9. Carpal compression syndrome, which usually results from a hyperextension wrist injury. As a result, the adjacent surfaces of the dorsal radius and lunate or scaphoid are compressed enough to cause cartilage damage and loss (*arrow*). Eventually, osteophytes may even develop.

Aseptic Necrosis of the Capitate

Aseptic necrosis of the capitate is relatively uncommon, but not rare (Fig. 59-10). It is usually seen in men who do strenuous work. The exact pathologic process is unclear, but a stress fracture across the proximal neck of the capitate is the most likely explanation.

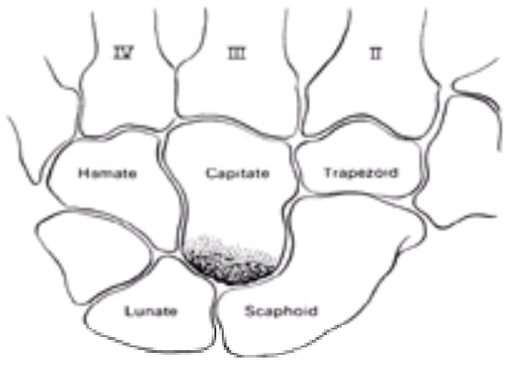

Figure 59-10. Aseptic necrosis of the capitate bone of the wrist.

Symptoms and Signs

Patients with this condition complain of progressive dorsal pain and tenderness. The tenderness is in the midcarpal area, particularly with compression, dorsiflexion, or marked volar flexion.

Diagnosis

In the early phases of aseptic necrosis of the capitate, often for a year or so, radiographs appear normal. Lateral tomograms may reveal early erosion of the head of the capitate. Triphasic bone scans are markedly positive in this localized area. Degenerative changes and capitate sclerosis subsequently become more apparent.

Treatment

Limitation of activity, splinting, and antiinflammatory drugs help in early cases. The only effective treatment, however, is surgical fusion of the capitate to the lunate and scaphoid (23).

Localized Arthritic Areas of the Wrist

Radial Carpal Arthritis

Radial carpal arthritis is characterized by pain and tenderness on the radial side of the wrist joint and is aggravated by activity. Often there is swelling, weakness of grip, and limited range of motion of the wrist joint. The scaphoid can be palpated and is tender. (The reader is referred to the earlier section, Physical Examination.) Translocating and compressing the joint are painful, and often there is crepitus. Radiographs should establish the diagnosis, showing sclerosis of the scaphoid and adjacent radius, narrowing the joint space, as well as some cyst formation. Occasionally, when arthritic change is early or quite localized, very little radiographic evidence is noted; bone scan is helpful in that situation. Frequently, this type of arthritic change is associated with a previous ligamentous injury that allows the scaphoid to move excessively and to disengage itself from the contiguous surface of the radius. This motion causes wear of the cartilage and ultimately arthritis. Six-view radiographs should be taken in all cases of scaphoradial arthritic change to determine if a scapholunate change has preceded this condition.

Treatment consists of localized care. If the condition is severe enough, a localized wrist fusion is effective in eliminating pain while maintaining adequate motion across the midcarpal joints. Before performing this procedure, it is important to determine whether there is any arthritic change between the capitate and the lunate in the midcarpal joint of the wrist. In scapholunate separation, the initial arthritic changes develop between the scaphoid and the radius; secondarily, the midcarpal joint from the capitate to the lunate is involved. If this capitate-lunate joint is involved, either a wrist fusion or the scapholunate advanced collapse wrist procedure [as described by Watson et al. (24)] should be performed, rather than a limited wrist fusion of the scaphoid, lunate, and radius.

Trapezial-Metacarpal Arthritis (First Carpal-Metacarpal Arthritis)

This common, painful condition of the wrist is a result of a sliding motion between the first metacarpal and the trapezium. Ligamentous laxity contributes to this problem. It is more common, therefore, in loose-jointed people and is particularly more common in women than in men. It is believed that 50% of women at age 50 years have some degree of arthritic change in this joint, although most are not symptomatic. The usual complaint is pain when grasping a heavy object, and the pain is described as being in the wrist rather than the thumb. Deformity at the base of the thumb and localized tenderness may be present. There may also be a positive grind test, in which the examiner holds the wrist firmly and rotates and compresses the thumb metacarpal against the carpus. Radiographs usually clearly show a narrowing of space between the first metacarpal and the trapezium. Subluxation of that joint and often loose bodies and osseous cysts are present.

Treatment consists of rest with splinting and limiting activity, antiinflammatory medications, intraarticular corticosteroids, and, if the condition is severe enough, surgical replacement. This is commonly done by removing the trapezium and part of the trapezoid and placing an interposition tendon sutured as a ligament in this space. Such a procedure is very effective in relieving pain and increasing stability and strength.

Scaphotrapezial Trapezoid Arthritis

The scaphotrapezial trapezoid joint is 1 cm proximal to the metacarpaltrapezial joint. The difference is often not appreciated clinically, but in scaphotrapezial trapezoid arthritis, careful examination reveals tenderness proximal to the trapezium. The symptoms are essentially the same as those of the basilar thumb joint arthritic condition. Radiographs show a narrowing of the scaphotrapezial trapezoid joint and, frequently, cystic formation in the tuberosity of the scaphoid. Usually, there is an element of first carpometacarpal arthritic change associated with this joint arthritis, but not always. The treatment is wrist splinting, limiting activity, antiinflammatory medications, or surgery. Intraarticular injections are only occasionally indicated. The scaphotrapezial trapezoid joint communicates with the entire wrist-carpal articulation, and multiple cortisone injections within an otherwise normal joint are usually not indicated. Surgical treatment involves either fusing the joint or pantrapezial arthroplasty. Fusion limits wrist motion significantly, while arthroplasty works well and is the surgical procedure of choice. This is the same procedure that is performed for carpal-metacarpal arthritis.

Dorsal Intercalary Segmental Instability with Arthritis

This condition is not rare and is diagnosed in the presence of arthritic changes with narrowing of the joint and cyst formation across the midcarpal area of the wrist. The patient complains of pain and soreness on wrist motion, particularly when loading and with activity, and tenderness in that midcarpal joint. Occasionally, crepitus is present. Lateral radiographs show a dorsal-facing lunate to the capitate; the capitate is almost subluxed dorsally out of the concave surface of the lunate. Dorsal intercalary segmental instability can be congenital or the result of trauma. Because it is frequently bilateral, it is probably more often congenital, but the abnormal mechanics of this wrist articulation allow early wearing of the joint. The joints involved are the scaphotrapezial trapezoid, capitolunate, and triquetral-hamate. If rest, splinting, and antiinflammatory medications do not provide sufficient symptomatic relief, midcarpal fusion is advocated and allows relief while preserving functional motion in the proximal carpal joint.

Pisotriquetral Arthritis

Pisotriquetral arthritis is an unusual, but not rare, painful condition of the wrist, which is not readily apparent on radiographs (Fig. 59-11). The cause is repeated compression injuries involving pressure of the pisiform against the articular surface of the triquetrum. Workers whose jobs entail pounding on the hypothenar eminence (e.g., body and fender repair workers) have a higher incidence of this condition than do others.

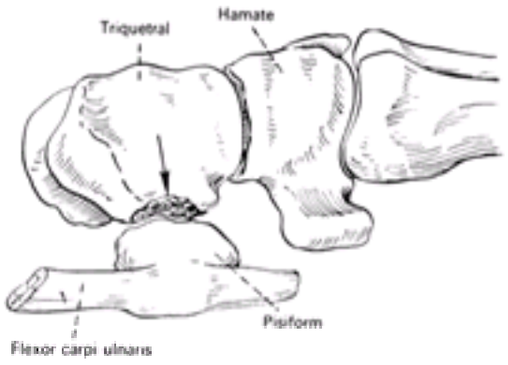

Figure 59-11. Medial view of the wrist depicting pisotriquetral arthritis.

Symptoms and Signs. The patient often complains of diffuse pain, usually on the ulnar side but rarely in the specific anatomic area of the problem. The pain is deep, activity related, and radiates out toward the fingers and the wrist. Pisotriquetral arthritis can be readily diagnosed clinically if the physician is appropriately suspicious. Careful examination, including grinding of the pisiform across the hamate, and carefully positioned radiographs help to establish the diagnosis. Blocking the joint with local anesthetic can relieve the discomfort and confirm the diagnosis. Specific tenderness along the proximal margin of the hypothenar eminence and crepitus characterize this condition.

Treatment. In milder cases, splinting, antiinflammatory medications, and limitation of activity afford adequate treatment for this condition. If this conservative treatment is ineffective, excision of the pisiform with preservation of the enveloping tendon generally affords excellent relief (24). The pisiform is not necessary for mechanical stability of the wrist. Care should be taken, however, to preserve the flexor carpi ulnaris tendon.

Ulnar Impingement Syndrome

In ulnar impingement syndrome, an elongated ulna pushes against the adjacent carpus, namely the triquetrum, producing cartilage damage or bone erosion. This syndrome is related to unusual length of the ulna, which results either from a congenital ulnar-plus variance (present in up to 10% of the population) or from an old fracture of the radius, which results in shortening of the radius and subsequent relative elongation of the ulna.

The patient with ulnar impingement syndrome has pain and tenderness along the ulnar column of the wrist around the distal ulna. Tenderness is most marked over the triquetrum.

Diagnosis

Ulnar-positive variance (Fig. 59-12) is noted on radiographs, often with erosions of the triquetrum. Triphasic scans are positive. Attritional rupture of the triangular fibrocartilage is often present and can be noted on arthrography or arthroscopy. Ulnar deviation accentuates the pain, which is relieved by a diagnostic block with local anesthetic.

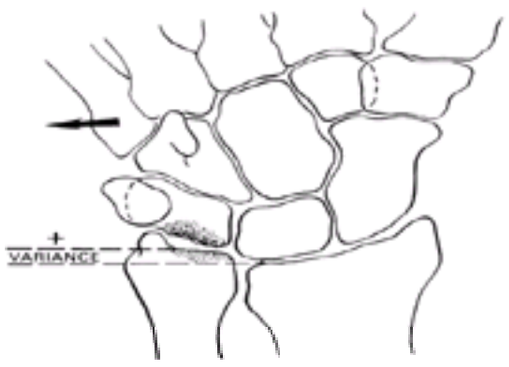

Figure 59-12. Ulnar impingement syndrome. Note variance in ulna length, which is the underlying cause of this syndrome. Ulnar deviation (*arrow*) increases symptoms.

Treatment

Treatment of ulnar impingement syndrome involves either limitation of activity, particularly that involving ulnar deviation, or surgical relief. If there is no arthritis or significant erosion of the triangular fibrocartilage, surgical shortening of the ulna generally produces excellent relief of symptoms. This can be done using a compression plate somewhat proximal to the joint on the shaft of the ulna.

Instability of the Wrist with Ligament Injuries

Instability patterns of the wrist are defined as conditions in which the normal separation or alignment between the carpal bones is exceeded. This can occur only if the ligaments separating the carpal joints have been ruptured or stretched. These instability patterns have been recognized for a long time, but the clinical significance and the magnitude of the problems created by such conditions have been only more recently appreciated. Although there are many ligaments in carpal articulations, we discuss only three of the most common injuries: scapholunate separation, ulnar column instability, and midcarpal instability.

Diagnosis

Scapholunate separation. is a separation between the lunate and the scaphoid bones beyond the normal limits, defined as 3 mm (Fig. 59-13). When the tear is complete, the separation is readily diagnosed with appropriate radiographs. In some cases, however, the tear is incomplete or the scaphoid remains relatively stable unless stressed (25,26). It is, therefore, important to obtain a true lateral wrist radiograph, with metacarpal and radius parallel, and to measure the angle between the long axis of the scaphoid and the radius. If this angle is greater than 70 degrees, it is abnormal.

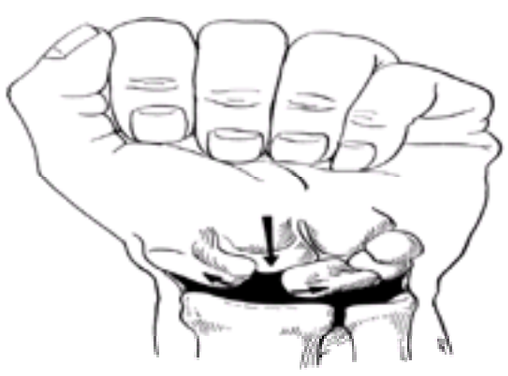

Figure 59-13. Diagrammatic anteroposterior view of scapholunate separation (*arrows*).

Scapholunate separation is most readily seen when the hand is radiographed in the palms-up position. The wrist should be radially deviated and then ulnarly deviated; then the patient makes a tight fist, compressing the bones together. Such anteroposterior radiographs may reveal scapholunate separation even when the standard series of posteroanterior radiographs is normal. The normal maximum separation between the lunate and scaphoid bones is 3 mm; any separation greater than this almost always is abnormal. Cineroentgenograms may also show instability of the scaphoid, even when static radiographs are normal. Clinical tenderness and ballottement of the proximal pole of the scaphoid between the finger and thumb of a discerning examiner can also diagnose this condition.

Ulnar-column instability. involves excessive motion between the triquetrum, hamate, and ulna. This general diagnosis refers to several specific disorders including torn meniscus, torn triquetral-ulnar ligaments, and torn triquetral-hamate ligaments (27,28 and 29).

Patients with this condition generally present with rather severe pain and tenderness on the ulnar side of the wrist. The patient may complain of a *clunking* sensation. Palpation, particularly over the triquetrum, gives an often dramatic sense of looseness. The carpus tends to supinate away from the plane of the distal ulna and radius (Fig. 59-14). Arthrograms can demonstrate triangular fibrocartilage disruption and separation between the lunate and triquetrum. Triphasic bone scan is usually markedly positive (Fig. 59-15), although it may be negative when the patient has only chronic triangular fibrocartilage tears. Small erosive lesions often are noted in the triquetrum adjacent to an old triquetral-lunate joint disruption. These may become apparent only on tomograms.

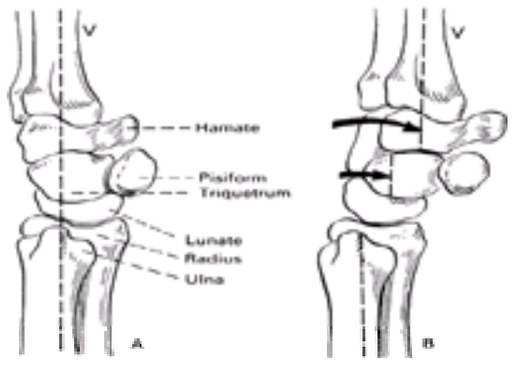

Figure 59-14. **A:** A normal, well-aligned ulnar column, as indicated by the dashed line. **B:** Ulnar column instability, which is characterized by excessive movement (*arrows*) between the distal ulna, triquetrum, and hamate. This condition, which causes pain on mobility, can be caused by trauma or attritional rupture of the constraining ligaments. Palpating the resistance to movement between each of these bones defines the instability. Because there are great individual variations in ulnar-wrist column motion, comparison with the contralateral limb is helpful in making the diagnosis. Mobility and bilateral comparisons are helpful.

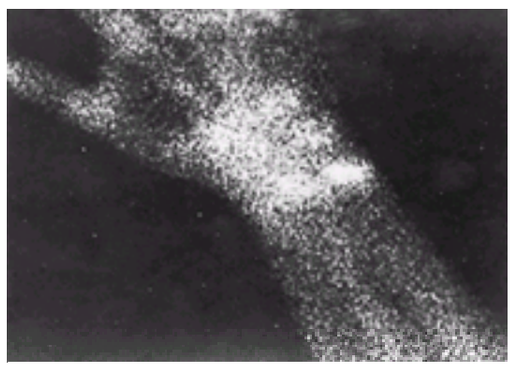

Figure 59-15. Positive technetium 99m scan reflecting a synovitis and cartilage erosion in a chronically lax ulnar column.

Midcarpal joint instabilities, in which there is volar or dorsal rotation of the lunate, produce tender areas of pain in that joint (30). Opinions vary as to the amount of variation between the longitudinal axis of the capitate and the longitudinal axis of the lunate that is accepted as normal. Some authors state that a 10-degree variance is abnormal, but most agree that the variance must be 30 to 40 degrees to be considered abnormal (Fig. 59-16).

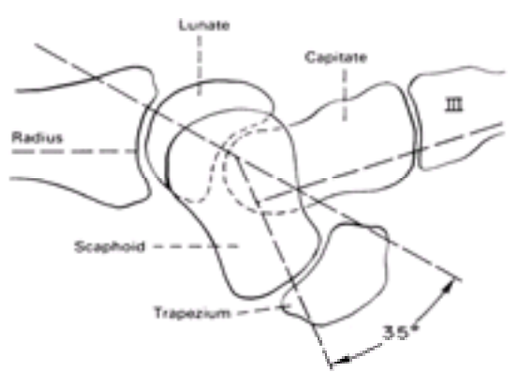

Figure 59-16. Volar intercalary segmental instability, a condition characterized by lax or ruptured ligaments, which allow the midcarpal joint (the joint between the capitate and the scaphoid and lunate) to tilt palmarward to a degree that is almost dislocating. The axis of the radius, lunate, and capitate should be nearly parallel in lateral radiographs. Note the concave surface of the lunate facing palmarward instead of straight ahead.

Stress radiographs, in which the distal segments of the carpus are forced volarly and dorsally, can demonstrate the variance in comparison with the opposite side. In some stress lateral radiographs, the capitate seems to dislocate from the lunate. The normal parameters of this have not been determined, but the injured side should always be compared with the uninjured side. Some patients have a congenital laxity.

Treatment

Treatment for carpal instability is difficult and not clearly defined. For scapholunate separation and for midcarpal instabilities, either extensive ligament repairs (grafting, drilling holes through the capitate, scaphoid, lunate, and radius, and attachment of ligaments), or limited fusions are generally performed. In triangular fibrocartilage tears, excision of the cartilage, such as is done in the knee, can lead to increased instability. Shortening of the ulna sometimes affords relief, particularly if arthritic changes have not yet developed in the adjacent triquetrum and lunate. Direct repair of peripheral TFCC tears seems to be the treatment of choice (31,32).

Tenosynovitis

Etiology. Tenosynovitis of the wrist is a noninfectious, activity-related inflammation along the parietal and visceral tenosynovium. It is particularly common in the wrist and finger area, where a great deal of movement of tendons occurs in a relatively enclosed space; the resulting friction can activate an inflammatory response. Everyone probably has a threshold for activity-related inflammation, but the specific threshold varies among individuals. In some people, a relatively minimal amount of activity triggers this response. Other factors, such as cold temperature, excessive or unusual hormone level (inflammatory responses are more common in pregnancy), and repetitive activity, seem to contribute to the onset of tenosynovitis of the wrist (33).

Diagnosis

DeQuervain's tenosynovitis, the most specific tendon inflammation in the wrist, involves the tendons of the abductor pollicis longus and extensor pollicis brevis within a relatively tight first extensor compartment (Fig. 59-17). It is usually readily diagnosed and has well-known specific symptoms, namely pain with activity of the wrist and thumb. The pain is deep and aching, and sometimes has a burning quality. It is at times associated with a nerve irritation or tingling sensation over the dorsum of the thumb. Tenderness is specific over the first dorsal osseous canal at the radial styloid. Finkelstein's test, full flexion of the thumb along with ulnar deviation of the wrist, causes pain. Injection of a local anesthetic into the first extensor compartment relieves the discomfort and establishes the diagnosis (34).

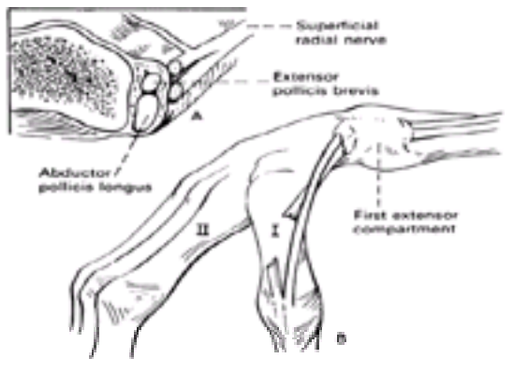

Figure 59-17. DeQuervain's tenosynovitis. **A:** Cross-section of the wrist showing the tendons of the abductor pollicis longus and extensor pollicis brevis encased in an edematous, swollen first extensor compartment. **B:** Superolateral view showing the swollen mass, which can often be palpated at the radial styloid.

Flexor carpi radialis tendinitis, which is more obscure diagnostically, is characterized by volar pain radiating to the hand (Fig. 59-18). The pain is deep, nonspecific, and activity related. Tenderness is augmented by flexing the wrist, particularly against resistance. Sharp pain and tenderness are localized in the flexor carpi radialis sheath. Because this tendon sheath runs deep beneath the thenar eminence to the second metacarpal base, the tenderness is located especially in the thenar area. Relief of pain by blocking the tendon sheath with a local anesthetic establishes the diagnosis (35).

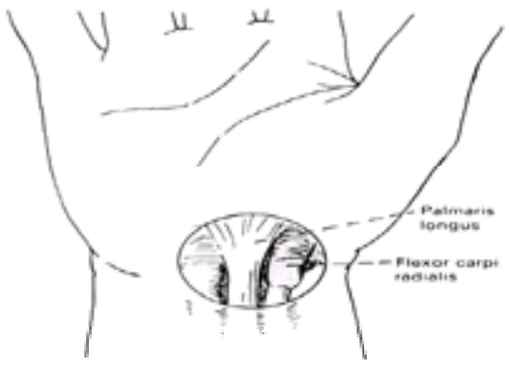

Figure 59-18. Tendinitis of the flexor carpi radialis tendon.

Inflammation of the sixth interosseous canal is occasionally seen, with and without locking. Specific tenderness, snapping, and relief from tendon sheath blocking establish the diagnosis.

In *extensor carpi ulnaris tendinitis*, the tendon may become irritated, the capsule thickened, and a stenosing type of tenosynovitis develops. This can be associated with snapping as the swollen, irritated, or roughened tendon moves out from under the confines of the tendon sheath over the distal ulna. The snap is noted when the examiner radially deviates the wrist joint. There is localized tenderness and often swelling in the ulnar styloid area. Subluxation of this tendon can produce similar symptoms. In supinating and pronating the wrist a snap is felt, and the tendon can be palpated as it slips out of the bony groove on the ulna.

Treatment

Initial treatment of tendinitis in the wrist is similar to that in other areas (i.e., splinting, rest, and antiinflammatory medication) and results in improvement in most patients. The next level of treatment, for more recalcitrant cases, is injection of a long-acting corticosteroid in the tendon sheaths. If these measures are not successful, surgical decompression generally gives quite good relief. When symptoms are significant enough, a subluxing tendon can be reconstructed surgically.

Nonspecific Inflammation

Several inflammatory arthritides, not associated with specific collagen diseases, cause wrist pain. Acute calcific tendinitis of the wrist usually is characterized by severe or excruciating pain that is well localized to the wrist and often is associated with swelling and erythema; later, the pain radiates to the elbow and fingers. Radiographs may show subtle calcific deposits (Fig. 59-19). Aspiration of the deposits often yields liquefied calcium crystals.

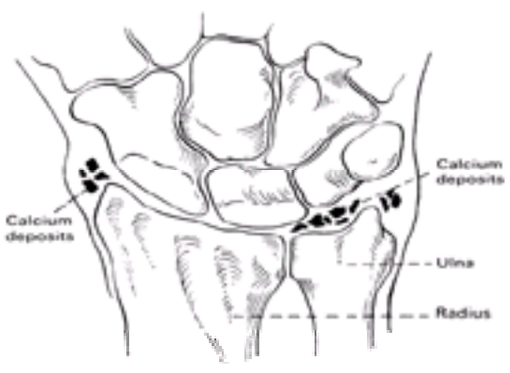

Figure 59-19. Calcific tendinitis of the wrist joint, a condition characterized by an acute inflammatory and swollen wrist joint. The traumatic-looking calcification seen

on radiographs helps to differentiate this from aseptic arthritis.

Gout and pseudogout also cause painful wrist with swelling and tenderness. Elevated uric acid levels differentiate the diagnosis of gout. In pseudogout, there may be radiograph-positive deposits in the triangular fibrocartilage. Aspiration samples demonstrate needlelike calcium pyrophosphate crystals with 11 degrees of positive birefringence. Radiographs of the knee may show calcification in the meniscus, which is a pathognomonic sign for pseudogout. Collagen disease can also begin in the wrists. If symptoms indicate, appropriate tests should be ordered to establish these diagnoses (see Chapter 27).

Treatment depends on the specific diagnostic entity. Acute calcific tendinitis responds rather dramatically to rest and antiinflammatory medications. Gout and pseudogout respond to colchicine and to antiinflammatory medications. Surgery is not indicated in any of these conditions.

Tendon Ruptures

Nontraumatic tendon ruptures, those not associated with laceration or acute trauma, can develop across the wrist. They are most common on the radial side of the wrist in the long extensor to the thumb. Such a rupture is described as a sudden mild soreness in the wrist, often with swelling and tenderness, and the patient notes a subtle change of function in the thumb. There is a drop of the distal joint of the thumb, which can be partial and is not readily recognized by the patient. The extensor carpi ulnaris is another tendon that occasionally ruptures spontaneously. The same symptoms can occur on the ulnar side of the wrist, with swelling and soreness, and examination reveals a lack of strength on ulnar deviating and extending the wrist.

Rupture of the flexor tendons is somewhat less common, and the flexor carpi radialis is perhaps the most common of those tendons that rupture. This condition is usually associated with tenderness and swelling. The lack of flexion function is very subtle. Rupture of the finger flexors also occurs, both the superficialis and profundus tendons. Pain and soreness are noted, and occasionally carpal tunnel syndrome develops. This usually occurs in patients with rheumatoid arthritis but may occur in otherwise normal individuals. All the tendon ruptures may be associated with roughness of the adjacent bony structures and an erosive proclivity to the adjacent tendon.

Treatment of tendon ruptures depends on the tendon involved. The thumb extensor should almost always be repaired, but because rupture can occur over a wide area (i.e., several centimeters of disrupted tendon), simple repair is seldom possible. It usually requires a tendon graft or transfer of an adjacent tendon to that area. In the thumb, that would be the indicus proprius tendon. The flexor carpi radialis tendon need not be repaired, as loss of its function is insignificant. The sublimus tendons likewise need not be repaired, but profundus tendon ruptures are generally considerably disabling and require repair.

Triangular Fibrocartilage Complex Injuries

The TFCC is a bonelike structure occupying a space between the triquetrum and the distal ulnar. It is attached to the radius and to the collateral ligaments between the ulna and the triquetrum. It is a stabilizing as well as articulating surface. It is subject to injury, particularly rotational injury, and traumatic tears. In older patients, tears occur from attritional changes, generally in the central portion of the TFCC and often associated with an elongated ulna that would produce more pressure across that structure. The traumatic tears result in avulsion of either the radial or the peripheral ulnar attachments to the TFCC.

Frequently, a clicking associated with pain is present when rotating or extending the wrist. There is tenderness distal to the ulnar styloid in the sulcus between it and the triquetrum. There is often laxity in the carpus in relation to the ulna and radius. Radiographs are usually negative, although if a large portion of the ulnar styloid is avulsed with the injury, that will be apparent, and painful nonunions can develop in the area. Chronic injury to the TFCC can lead to arthritic changes on the proximal surface of the triquetrum and lunate. Small erosive areas are noted on radiographs, and bone scans are positive. Diagnosis of tears of the TFCC, particularly radial or central tears, is done by arthrography or arthroscopy.

Traumatic tears are often relatively self-limiting, and a conservative clinical trial of splinting is warranted. On occasion, persistent significant problems develop and repair of the radial or peripheral tear is warranted. Central tears, if symptomatic, can be debrided. When arthritic changes are present between the lunate and triquetrum, shortening of the ulna to decompress the area gives moderate relief.

Acute Infection

Symptoms and Signs

Acute infection of the wrist produces a severe, deep, unrelenting pain radiating as far as the elbow and shoulder. The hand and wrist are barely movable. There is usually swelling, but erythema may not be widespread in the early stages. The infection is usually within the tendon sheath or within the wrist joint itself. *Staphylococcus* and *Streptococcus* are the most frequent causative organisms in adults. In children, particularly those younger than 4 years of age, infection with *Haemophilus influenzae* is common. In very young children, gram-negative organisms are often seen. The infection is usually blood borne (36).

Diagnosis

Differentiating between osteomyelitis adjacent to a joint and a septic arthritis often is difficult. Early diagnosis is critical for successful treatment. Appropriate radiographs, technetium 99m bone scans, and aspiration of the joint are important diagnostic tools, but the most significant factor in establishing a diagnosis is a high degree of suspicion on the part of the physician.

Treatment

Treatment depends on the stage at which diagnosis is made. Early diagnosis allows nonsurgical treatment, including appropriate and heavy doses of antibiotics; occasionally, aspiration of the joint by needle, splinting, and immobilization are required. Surgical decompression may be necessary if pus has accumulated under pressure; this is mostly likely to occur when treatment is begun later than 4 days after symptoms commence. If treatment is delayed more than 7 days after commencement of symptoms, permanent joint damage is highly likely (37). Treatment of osteomyelitis adjacent to a joint also may require removal of a sequestrated portion of the bone.

Kienböck's Disease

Kienböck's disease is an aseptic necrosis of the lunate, generally thought to be the result of loss of blood supply from a stress fracture. The initial incident often is obscure (38,39).

Symptoms and Signs

Often the first specific finding is a painful, mildly swollen wrist, with tenderness localized in the dorsal midcarpal area. Initial radiographs may not show abnormality, but within 2 to 3 months a fracture, sclerosis, or both of the lunate becomes apparent. This can progress to fragmentation of the lunate and secondary arthritic changes (Fig. 59-20).

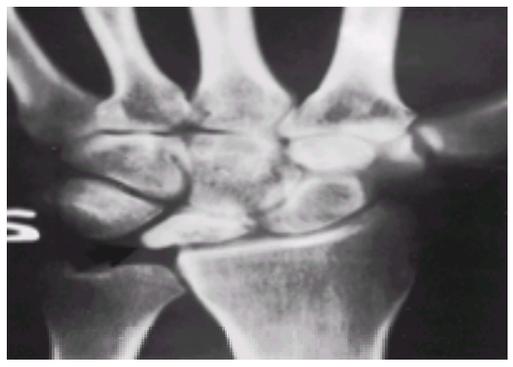

Figure 59-20. Radiograph of wrist joint affected by Kienböck's disease. Note the fragmentation and collapse of the lunate, characteristic of late stages of this disease.

Treatment

Treatment depends on the stage of the disease. Decompression of the lunate in the early phases by shortening the radius or the capitate, or by lengthening the ulna, is common and has had good results. If fragmentation of the lunate has occurred, decompression would not seem reasonable; limited fusions or tendon arthroplasty replacement have proven effective in this late stage (40).

Preiser's Disease: Aseptic Necrosis of Scaphoid from Nonunion

Aseptic necrosis of the scaphoid not associated with a fracture is called *Preiser's disease*, an idiopathic loss of circulation. The proximal pole scaphoid becomes sclerotic and often begins to disintegrate, producing considerable wrist pain, swelling, and disability. It is imperative to take multiple radiographic views to determine whether any preexisting nonunion of the scaphoid is present. MRI clearly shows the aseptic process. Treatment of early cases is by complete rest. If there is marked disintegration of the scaphoid, aggressive surgical reconstruction is necessary, with either limited fusions or a combination of fusion and arthroplasty. Osteocartilaginous bone grafting can be performed in some patients with spectacular results. In nonunion of the scaphoid, bone grafting and internal fixation should be performed if arthritis has not developed. If arthritis is present in the scaphoradial joint, the treatment is the same as for an arthritic joint.

Nonunion of the Scaphoid

The initial cause of nonunion of the scaphoid, a remarkably common condition, is traumatic injury, often a sports injury, from dorsiflexion of the wrist. The injury may have seemed relatively minor to the patient, and its details only vaguely remembered (41).

Symptoms and Signs

Symptoms of nonunion of the scaphoid may not become apparent for years when inflammatory changes develop around the excessively mobile fragments of the scaphoid. By the time symptoms appear, arthritic changes may already have occurred in the adjacent scaphoid surface. Tenderness is maximized on the radial side of the wrist in the anatomic snuffbox, just distal to the radial styloid. There may be limitation of motion. Radiographs establish the diagnosis.

Treatment

In established nonunions, prolonged casting does not produce a union. Bone grafting of the fracture fragments, with or without internal fixation, is necessary to afford healing of the nonunion, but to relieve the symptoms this must be done before arthritic changes develop. Grafting should also halt the progression of arthritic processes between the scaphoid and the radius, the usual sequelae to nonunion. Resection of the radial styloid also affords some relief. When arthritis has already developed, limited fusion is recommended (42).

Nonunion of the Hook of the Hamate

The hook of the hamate is a small, bony, horn-shaped structure protruding from the body of the hamate toward the flexor side, deep within the hypothenar space. It forms the ulnar margin to the carpal canal. Injuries such as those caused by vigorous swinging of a baseball bat or by striking the earth while hitting a golf club can avulse the hook of the hamate. This produces tenderness localized 1 cm distal to the flexion crease of the wrist and in the proximal hypothenar area. Such a fracture or nonunion is seldom seen on normal radiographic evaluation. A skyline view showing the hook of the hamate tangentially, taken on a hyperextended wrist, is the method of choice. Treatment is by excising the hook of the hamate. It requires careful dissection as the deep branch of the ulnar nerve is just at its distal ulnar border.

Osteoarthritis

The wrist is a relatively common site of early osteoarthritic changes. It often is difficult to identify a specific cause, but old or repetitive trauma or congenitally lax ligaments allowing excessive mobility are the likely culprits (43). It can occur in relatively young people and some hereditary predisposition seems likely.

Symptoms and Signs

Symptoms of osteoarthritis of the wrist include a mechanical type of deep, aching pain, aggravated by activity. The pain is often accentuated by cold weather and approaching storms. Indeed, many patients can forecast changes in the weather by the amount of discomfort in the wrist joint. Swelling following activity is common (43).

Diagnosis

Appropriate radiographs of the wrist, localized tenderness in the affected area, and a diagnostic joint block with local anesthetic generally can establish the diagnosis of osteoarthritis of the wrist. Under specific conditions, triphasic bone scans show an area of fibrillating articular cartilage and adjacent inflammation. Arthroscopy may be necessary when radiographs do not show the early changes.

Treatment

Treatment usually begins with rest, antiinflammatory medications, and corticosteroid injections in the affected joint. Joint arthroplasty or limited fusion may ultimately be required. Arthroplasty of the scaphotrapezial and trapeziometacarpal joints has given very satisfactory results.

PAINFUL CONDITIONS OF THE HAND

Painful conditions of the hand are less common than those of the wrist. Most pain associated with the hand reflects a specific injury such as laceration, fracture, previous amputation, or torn ligament. These specific entities are discussed in Chapter 31. This section deals with less obvious and more chronic conditions involving the hand. A specific diagnosis should be pursued and usually dictates the treatment.

Nonspecific Synovitis of Flexor Tendon Sheaths

Perhaps the single most common chronically painful condition in the hand is synovitis of the flexor tendon sheath.

Etiology

This condition is usually the result of nonspecific inflammatory processes, perhaps associated with unusual or strenuous activities. It can also be caused by rheumatoid arthritis or other collagen diseases. Acute infectious tenosynovitis may occur following a puncture wound.

Symptoms and Signs

Pain along the flexor aspect of the finger, markedly aggravated by activity, is characteristic of flexor tenosynovitis. Chronic synovitis of the tendon sheath may be associated with triggering, a phenomenon in which the finger or fingers go into a flexed position and either cannot be straightened or straighten with a *snap*. The snap is felt at the distal joint, but the pain and tenderness are at the MCP joint level on the flexor surface. Acute infectious tenosynovitis produces more marked pain, redness, and swelling (Fig. 59-21).

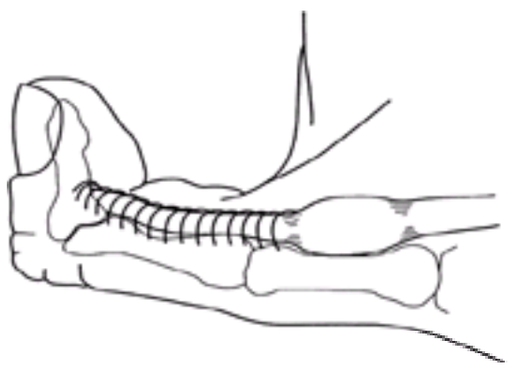

Figure 59-21. Trigger thumb. Note the bulge in the flexor tendon that locks the interphalangeal joint of the thumb (or distal interphalangeal joint of the finger) in flexion. It often can be released with a snap that feels like a joint problem.

Diagnosis

It is critical to differentiate between infectious and nonspecific tenosynovitis. Acute infectious tenosynovitis is a fulminating inflammatory process in the flexor tendon sheath causing marked pain and diffuse swelling of the finger. The finger is mildly bent. Tenderness extends from the distal flexor sheath of the finger to the palmar crease. Nonspecific tenosynovitis can develop quite acutely, often following excessive activity. The pain is acute and triggering may be present (44).

Treatment

Acute bacterial tenosynovitis, which is a closed-space infection, needs immediate drainage. Pus under pressure in the closed space impedes the mesentericlike blood supply to the flexor tendon, resulting in ischemic necrosis of the flexor tendons.

Chronic nonspecific tenosynovitis is often effectively treated with rest and corticosteroids injected directly into the tendon sheath. Most triggering phenomena can be successfully treated this way. The needle is introduced directly into the tendon sheath at the MCP joint level. The placement is tested by wiggling the finger and noting the motion at the tip of the needle. The needle is then withdrawn slightly until the space is identified. A maximum of one or two injections of long-acting corticosteroid should be given. With recalcitrant triggering or extensive and prolonged tenosynovitis, synovectomy or pulley release is necessary and very effective.

Synovitis of the Joints of the Hand

Etiology

Inflammatory response in a joint, which can be an early manifestation of osteoarthritic changes, has a variety of causes. It may be caused by excessive activity and stress, which trigger inflammatory responses in the lining of the joint. Injuries such as jamming or compressing the joint surface can cause an inflammatory response with hemorrhaging into the joint, which may last for weeks.

Chronic instability of a torn ligament produces a mechanical abnormality, which promotes synovitis and pain. A common example of this is *gamekeeper's thumb*, in which the ulnar collateral ligament of the MCP joint of the thumb has been ruptured. The term for this condition originated in Britain, where the hunter's assistant would wring the necks of wounded fowl or small game, incurring chronic sprain of the thumb and ultimately a lax ligament. Today this injury is frequently seen as a result of industrial and athletic injuries, especially ski injuries. The instability results in swelling, pain, and, ultimately, degenerative changes. The MCP joints and PIP joints of the other digits are also susceptible to this problem, but only rarely the distal joints.

Symptoms and Signs

The pain and swelling are localized over the joint. Stressing the joint in almost any position or direction causes pain, a deep, diffuse, aching discomfort, with considerable radiation to adjacent areas. For instance, synovitis in the index finger MCP joint can produce pain as far distally as the tip of the index finger and as far proximally as the wrist joint. Activity certainly aggravates these symptoms.

Diagnosis

Tenderness at the joint level and abnormal findings on stress testing are noted on examination. Stress radiographs show excessive mobility. Arthrograms may show rupture of the joint. Triphasic bone scans are positive, but seldom necessary, because the diagnosis is usually readily apparent by examination and history. Injection of 0.5 mL of 1.0% lidocaine into the joint relieves the discomfort and is a useful diagnostic tool.

Treatment

Treatment of synovitis depends on its cause. If it is activity related, rest, antiinflammatory medication, or both are often sufficient. With more severe or chronic cases, intraarticular injections of a long-acting corticosteroid such as triamcinolone produce good relief for several months. If the inflammation is secondary to instability, surgical reconstruction of the ligaments may be necessary. If arthritic changes have developed in the joint, ligament reconstruction is not sufficient to relieve the symptoms, and fusion or arthroplasty is necessary (45).

Arthritic Conditions

Osteoarthritic conditions not associated with specific instability patterns are common in the hand. They are most frequent in the distal joint, less common in the PIP joints, and least common in the MCP joints. The tendency to develop arthritic changes seems to occur in families and is much more common in women than in men. Repeated heavy injuries, old injuries or fractures, chronic instability, and hereditary predilection are the causes.

Symptoms and Signs

The symptoms are those typical for joint pain: deep, aching discomfort aggravated by activity and relieved by rest. Diagnostic blocks with a local anesthetic help to establish the specific diagnosis. Often, several joints are involved. Radiographs usually can establish a diagnosis; these show sclerosis of the margins, small cystic

formation of the bone, loss of joint space, and often osteophytes. Small ganglion cysts may come from the joint spaces, particularly the distal joints of the fingers. The nails may be deformed by the pressure of the cyst on the germinal plate of the nail.

Treatment

Treatment is usually symptomatic, including rest and pain control with nonsteroidal antiinflammatory drugs. Injection of corticosteroids and, occasionally, limited fusion or joint arthroplasty sometimes are necessary.

Rheumatoid Arthritis

Rheumatoid arthritis is a generalized disease and is discussed in Chapter 27. Frequently, it develops initially as a pain in the hand associated with persistence, swelling of the MCP or PIP joints, and occasionally persistent inflammation along either the extensor or flexor tendons. In the early stages of the disease radiographs may be negative. In patients with persistent swelling, soreness, and pain across the joints or the flexor or extensor tendons and no apparent specific cause, a laboratory evaluation for rheumatoid arthritis and other collagen diseases is in order (46). Such evaluations are discussed in Chapter 27.

Gout and Crystalline Synovitis

Inflammatory changes in the joints may result from crystalline inflammation, as in gout or pseudogout. Tophaceous development across the joints, visible as subdermal white deposits, is pathognomonic for gout, but subtle, painful rheumatoid or osteoarthritic changes may occur in the early stages. There are no distinguishing characteristics of this type of inflammatory change. It presents with swelling, soreness, redness, and tenderness at the joint levels. Chemical evaluation of serum uric acid should define gout. Crystalline synovitis of pseudogout is more difficult to establish. Interarticular aspiration and evaluation of the crystalline structure establishes the diagnosis. Sarcoidosis is another, relatively rare, condition causing painful hand. The pain is deep, periarticular, and associated with lytic phalangeal lesions observed by radiography.

Extensor Tendon Tenosynovitis

Extensor tendons of the hand have fewer inflammatory problems in general than their counterparts on the flexor side. Inflammatory changes do occur, particularly on the back of the hand, from chronic overuse or repetitive activity. The extensor retinaculum over the metacarpals, particularly the third and fourth metacarpals, can rupture, allowing the tendons to subluxate into the groove between the metacarpal heads. This produces friction synovitis, which sometimes results in the inability to completely straighten the finger.

Diagnosis of extensor tendon synovitis is established by careful examination, noting whether the tendon subluxates, and palpation of the tender or swollen extensor tendons. Diagnostic block injected into the tendon sheath helps establish the diagnosis.

Treatment of extensor tendon synovitis depends on its specific cause. If the cause is repetitive activity and use, oral antiinflammatory medications and rest usually suffice. Occasionally, tendon sheath injections with corticosteroids are necessary. Repeated injections should not be given because of the danger of rupture of the extensor tendons. If the retinaculum of the extensor tendon of the MCP joint is subluxating, surgical reconstruction is indicated. At times, this may require grafting of the extensor tendon retinaculum over the joint.

Mallet Finger Deformity

Mallet finger deformity is another type of irritation of the extensor tendon (Fig. 59-22). It develops when the distal portion of the extensor tendon is avulsed from the bone. A piece of the distal phalanx may be avulsed as well, but not necessarily. This is often a relatively minor injury that can be caused by actions such as pulling on socks, for example, if the finger gets caught. Initially it may not be painful, but soreness and swelling develop across the distal joint on the extensor surface, and the finger has an extensor lag. If untreated, the joint tends to become more flexed and often increasingly painful. Simple continuous splinting of the DIP joint in the straight position for 8 weeks is a very effective treatment in almost all cases.

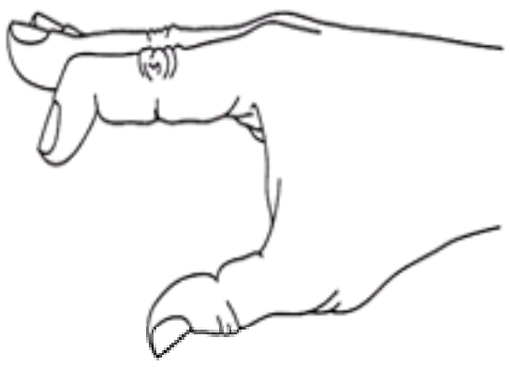

Figure 59-22. Mallet finger deformity. Avulsion or laceration of the extensor tendon insertion at the distal joint causes this deformity.

Boutonnière Deformity

Boutonnière deformity is a similar avulsion of the central slip of the extensor tendon over the PIP joint, often following a blunt injury to the back of the finger (Fig. 59-23). It need not be an extensive injury. Presumably, the tendon is devascularized and stretches over time. The joint develops a flex position, cannot be actively extended, and may become moderately painful as well as awkward. Immediate splinting of the PIP joint, continued for 8 weeks, is likewise an effective treatment, although if delayed it probably is not beneficial. In severe cases, surgical reconstruction, though difficult, can be achieved.

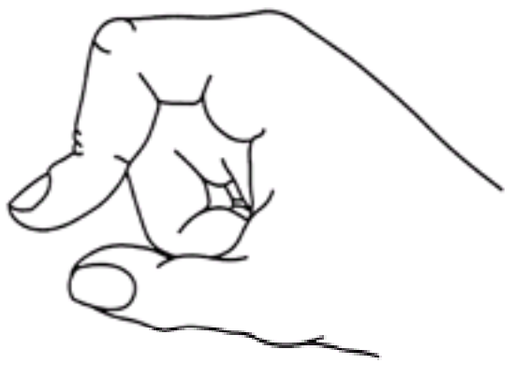

Figure 59-23. Boutonnière deformity. Loss of integrity of the central slip insertion of the extensor tendon at the proximal interphalangeal joint results in this deformity.

Swan-Neck Deformity

The swan-neck deformity occurs when the volar plate on the flexor aspect of the PIP joint ruptures or is stretched, and the PIP joint goes into hyperextended position (Fig. 59-24). This occurs congenitally in some people with lax joints, but if it is traumatic or extensive, the PIP joints can become locked in extension, an awkward and moderately painful condition. This is not uncommon in rheumatoid arthritis, nor is boutonnière deformity. Occasionally, it is seen with intrinsic tightness, when the interosseous muscles in the hand develop contractures. The PIP joint subsequently hyperextends and cannot flex, particularly when the MCP joint is in extension. When the MCP joint is in flexion, the muscles are relaxed and the PIP joint can relax. Swan-neck deformity can be treated by reconstructing the volar ligaments of the PIP joint, usually using a slip of the superficial tendon. If intrinsic tightness is present, releasing the intrinsic tendons is beneficial.

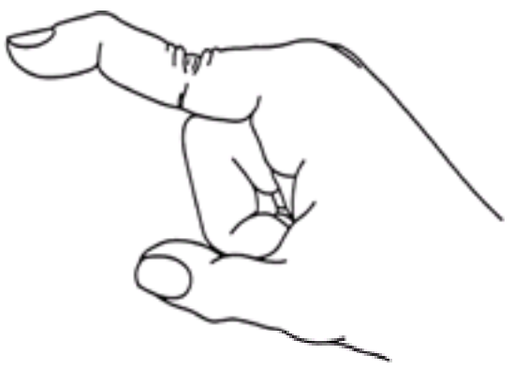

Figure 59-24. Swan-neck deformity. Loss of stability of the volar plate ligament at the proximal interphalangeal joint coupled with over-pull of the extensor tendon causes this deformity.

Sesamoiditis

Sesamoiditis is an unusual and painful condition occurring over the flexor aspect of the thumb. It probably is related to repetitive use of the thumb and pressure on the small sesamoid bones in the flexor aspect of the MCP joint of the thumb. It is most common on the radial side of the thumb, where the condyle of the metacarpal is less congruous with the surface of the sesamoid. There is tenderness directly over the sesamoids, aggravated by direct pressure in that area. The pain is relatively localized and usually activity related. Radiographs are rarely diagnostic of sesamoiditis except in advanced cases. Tomograms are helpful to outline bony change, and a triphasic bone scan demonstrates positive uptake in the area of the joint.

Treatment of sesamoiditis consists of rest, antiinflammatory medications, or both. An injection of a local anesthetic is usually helpful. In severe cases, surgical excision of the afflicted sesamoid is required.

Writer's Cramp

Etiology

Writer's cramp, a fairly common debilitating and painful condition of the hand, is brought on by repetitive activity, such as prolonged writing. The exact causes are obscure but include ulnar nerve compression syndrome and chronic increased compartmental pressure within the dorsal compartments of the hand, most frequently the first dorsal interosseous. Abnormalities of calcium metabolism should also be considered. Most cases are considered idiopathic (47).

Symptoms and Signs

During an episode of writer's cramp, the hand is forced into an intrinsic-plus position, with the MCP joints flexed and the PIP joints extended; often the thumb is adducted into the palm. A deep, aching pain radiates into the fingers and up the arm.

Diagnosis

Musicians and pianists, in addition to writers, often complain of this problem. It can be differentiated from a true nerve compression problem by the lack of associated numbness and negative electromyographic results. Specific testing for ulnar nerve irritation should be done. Compartmental pressure testing may show high levels of activity-related extracellular fluid pressure.

Treatment

Although decompression of compartments of the hand has been reported to give good results in some patients, treatment is often difficult and unsatisfactory. Some patients are helped by changing their writing style or reducing repetitive activities of the hand. Muscle relaxants, such as diazepam, have helped, as has biofeedback. If a more general condition is present, with specific or prolonged muscle spasticity, a diagnostic brain scan for tumor should be done. We have encountered four cases of writer's cramp in which the brain scan has revealed an unsuspected tumor.

Cysts and Ganglia

Cysts and ganglia along the flexor tendon sheaths are fairly common. Characterized by a tender mass on the flexor aspect, just distal to the MCP joint, they are often noted after periods of increased hand activity. They may be painful, especially when the patient grasps hard objects with the hand. They usually respond to simple cortisone injection, but occasionally it is necessary to excise them.

Cysts on the dorsal surface of the hand generally arise from joints and are usually not painful. They may be associated with arthritis, in which case it is the arthritis that causes the pain, not the cyst. Removal of the cyst itself, therefore, seldom relieves the discomfort.

Dupuytren's Contracture

Dupuytren's contracture is a relatively common condition, particularly in people of northern European extraction. Men are more commonly affected than women (48). This disease is characterized by an increasingly flexed position of the palmar surface of the hand and fingers. A firm mass can be palpated, and dimpling of the skin is often observed. The ring and little finger are most commonly affected, but all fingers can be involved. Dupuytren's contracture is sometimes associated with tender nodules in the dorsal aspect of the PIP joints (*knuckle pads*). Occasionally, there are tender nodules in the palm, more commonly in women than in men. The only effective treatment for Dupuytren's contracture is excision of the palmar fascia that has hypertrophied and caused the fingers to contract. No other treatment modalities have proven successful. Excision is indicated, however, only when significant contracture of the fingers has developed.

Self-Inflicted Lesions

Self-inflicted lesions peculiar to the hand and wrist are sometimes encountered. Pain in the hand and wrist, particularly on the nondominant side, associated with ecchymotic lesions, chronic swelling, or unexplained ulcerations or open wounds may be the result of self-mutilation. The lesions can be severe and present in a patient who otherwise seems mentally healthy. The diagnosis often is difficult to confirm and may require seeing the patient many times. If the lesions heal after extended protective casting, self-infliction should be suspected.

Ischemia

Ischemic conditions of the hand are usually associated with a systemic propensity. They often present with extremely painful, tender fingers, with some color changes, either whiteness or in more severe cases with dark areas of ischemia on the fingertips. Careful diagnostic evaluation is necessary. If the condition is unilateral and localized, arterial thrombosis should be suspected and appropriate diagnostic procedures undertaken. The reader is referred to the diagnostic section in the initial part of this chapter.

Palmar hammer syndrome occurs when the patient has used the butt of the hand as a hammer, and aneurysm or occlusion of the ulnar artery in Guyon's canal develops. Localized ischemia, primarily to the ulnar side of the hand, is the result, with a positive Allen's test for lack of ulnar blood flow. If the ulnar nerve is irritated enough, the patient may present with tingling in the little and ring fingers. Localized resection and vascular grafting are extremely effective. The evaluation for general ischemic conditions of the hand associated with collagen diseases is discussed in Chapter 27.

Raynaud's disease and *white-hand syndrome* are intermittent vascular conditions of the hand. Raynaud's disease is associated with swelling and redness, followed by whitish and then bluish color, often with the stimulus of cold or emotional tension. The fingers become very painful, numb, and tingling. The cold pressor test, immersing the hand in cold water and observing sudomotor activity, often establishes the diagnosis. Usually, the patient's complaints are specific enough to raise a high degree of suspicion.

White-hand syndrome is associated with outdoor workers who are exposed to persistent cold and who use vibratory tools such as chain saws. Symptoms are whiteness of the fingers with an aching pain, usually relieved by warming the hands. This condition may become chronic. Vibratory neuritis may be a component of this syndrome, which otherwise presents as arterial insufficiency.

Treatment of these problems is difficult and varied; vasodilating medications and avoidance of cold are foremost in the treatment plan. Occasionally, an interdigital neurolysis is warranted to excise the digital sympathetic nerve branches to the artery and, rarely, sympathetic ganglion resection at the cervical level. Sympathetic block often gives dramatic temporary relief.

Tumors of the Hand

A few benign tumors characteristically produce pain in the hand and wrist and therefore are considered in this chapter (49,50 and 51).

Pathophysiology

Osteoid osteoma is a small vascular tumor of bone characterized by sclerotic or reactive bone formation, which may be quite small, often with a tiny lucent area in the center of the sclerosis. Tomography often can help establish the diagnosis. The pain is deep and unrelenting and seems to respond well to aspirin.

Glomus tumor is a small benign vascular tumor, frequently located beneath the nail. It is characterized by marked pain and exquisite tenderness to pressure on the nail just in the affected area.

Enchondroma is a benign tumor of cartilage. Generally, it is not tender until a fracture occurs. Often just a small stress fracture produces enough osseous mobility to cause discomfort.

Giant cell tumor of the tendon sheath may present as a painful swelling from a joint or tendon. It is usually seen in the second and third decades of life. This tumor should be differentiated from a giant cell tumor of bone, a low-grade malignant growth within bone that is usually not painful.

Inclusion cysts are small benign cystic lesions thought to result from a puncture wound that carries squamous epithelium within the body. The epithelium then grows and expands in a closed space. When a low-grade infection ensues, pain results.

Hemangiomas of small capillaries and cavernous hemangiomas may be slow growing and moderately painful. They are characterized by bluish discoloration. Arteriography is diagnostic but not usually necessary.

Malignant tumors are rare in the hand. A dark lesion, particularly on the palmar aspect of the skin, with irregular borders and changing color is suspicious of melanoma. A dark lesion underneath the fingernail is highly suspicious of this condition and almost always should be biopsied. Those conditions usually are not painful. Squamous cell carcinoma of the skin presents as an irregular, sometimes ulcerating, raised dermal lesion, erythematous in color. Biopsy establishes the diagnosis, and wide excision, often with grafting, is usually curative. Metastatic tumors produce lytic areas in the bones of the hand. These are rare but may be painful and may produce pathologic fractures. If primary lesions are not apparent, diagnostic biopsies should establish the primary site. Primary malignant bone lesions of the hand also are very rare and may present as painful masses or areas where lytic lesions are apparent by radiograph. Biopsies define the lesion, and treatment varies with the type of lesion diagnosed.

Treatment

Surgical treatment of benign tumors of the hand is dictated by the tumor itself. Usually excision is indicated. For osteoid osteoma, *en bloc* excision of the mass is necessary, and often a small bone graft is required afterward. Glomus tumor needs surgical excision beneath the nail. The nail must be removed and the tumor localized; it is usually a small, firm mass within the sterile matrix of the nail. An enchondroma is treated by excision, including, of course, biopsy specimen, thorough curettage, and bone grafting. Giant cell tumors of tendon sheath, inclusion cysts, and hemangiomas should be excised.

NEUROPATHIC DISORDERS OF THE WRIST AND HAND

In this section we discuss pain in the hand or wrist associated with neuropathic conditions (i.e., abnormalities of the nerve itself). Although a stretch injury can result in neuropathy (e.g., following hyperextension injury to the wrist with ligamentous strain), this is relatively uncommon. Generalized disease processes such as diabetes, vitamin deficiency, and metabolic toxicity can result in neuropathy (see Chapter 19). Diabetic neuropathy, in particular, can cause numbness and some dysesthesia, but this is not consistently encountered. Other such neuropathies are not difficult to diagnose and seldom cause much pain within the hand and wrist.

Neuropathy in the hand and wrist can be the result of virus infection. Herpes zoster, the classic example, occurs in dermatomal patterns, and the characteristic rash establishes the diagnosis. Treatment of this condition is discussed in Chapter 22. Painful neuropathies of the wrist and hand having a mechanical cause, which are the most common, are discussed in detail in this section (see Table 56-3 and Figure 56-4, Figure 56-5, Figure 56-6, Figure 56-7 and Figure 56-8 for more information).

Median Nerve Entrapment Syndromes

Carpal Tunnel Syndrome

The vast majority of painful neuropathies of the hand and wrist result from nerve compression, most frequently compression of the median nerve in the carpal tunnel (Fig. 59-25A). Brain described this syndrome in 1948, and it has been well documented in the medical literature since then (52,53).

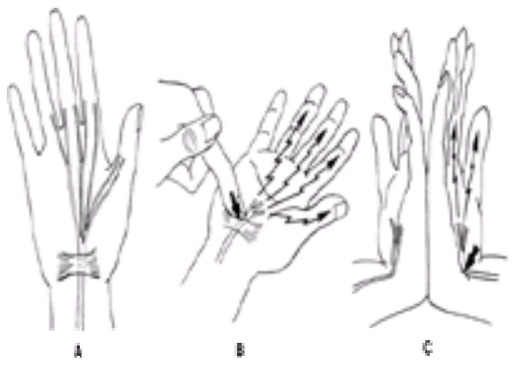

Figure 59-25. **A:** Normal distribution of the median nerve. **B:** Elicitation of Tinel's sign in a patient with carpal tunnel syndrome by percussing the wrist over the carpal tunnel. **C:** Modified Phalen's sign, which is elicited by holding both wrists in extreme flexion, is a painful numbness in the thumb and the second, third, and fourth fingers.

Symptoms and Signs. Carpal tunnel syndrome is characterized by a numbness and pain, usually in the distribution of the median nerve, but not limited to it. The pain varies from sharp and severe, with itching and burning associated with numbness, to hyperesthesia. It is characteristically present at night, causing the patient to wake from sleep. Flexing and extending the wrist seem to aggravate the pain, which frequently is first noted following unusual or prolonged repetitive activity. Carpal tunnel syndrome is a major concern of industry because of the resultant loss of time at work. It is associated with pregnancy, patients who undergo kidney dialysis, diabetic neuropathy, hypothyroidism, and acromegaly (54).

The cause can be unusual activity, collagen disease (rheumatoid arthritis, lupus erythematosus, and so forth), a ganglion within the carpal canal, or occasionally a tumor (soft tissue or calcified). A mechanical problem in the wrist joint also can produce the symptoms of carpal tunnel syndrome. The wrist joint occupies the dorsal surface of the tunnel; swelling there, because of nonunion of the navicular with secondary arthritis, scapholunate separation, or even lunate dislocation, may present itself as a carpal tunnel syndrome. For this reason, radiographs should be obtained when carpal tunnel syndrome is suspected.

Amyloid disease and calcinosis can cause deposits within the lining around the synovium, and acromegaly can cause narrowing of the bony aspects of the canal. These entities can produce carpal tunnel syndrome. Most patients with the syndrome, however, have no other specific etiologic disorders, and the neuropathy usually is the result of swelling of the synovium around the flexor tendons.

Diagnosis. A positive Phalen's sign, which is indicative of carpal tunnel syndrome, refers to numbness or increasing numbness, primarily in the median nerve distribution, when the wrist is held in a flexed position (Fig. 59-25C). Tinel's sign, produced by tapping over the median nerve at the wrist, with resultant shocklike sensation, is also a common finding (Fig. 59-25B). Tests of sensation, including two-point discrimination, light touch, and vibratory touch, frequently produce positive findings. In more severe cases, the patient has muscle weakness and atrophy of the thenar musculature. Electromyographic and nerve-conduction studies showing reduced conduction velocity across the carpal tunnel (greater than 4 milliseconds between the flexion crease of the wrist and the thenar musculature) should lead one to suspect carpal tunnel syndrome (see Chapter 13). Fibrillation, positive waves, and diminished amplitude in recruitment isolated to the thenar muscles also suggest this condition.

Differential diagnosis is important when symptoms suggest carpal tunnel syndrome. The compressive neuropathy in this syndrome is not due to a problem in the nerve itself but is a result of swelling around the nerve and the resultant interference of the nerve's blood supply. This is usually caused by thickening or inflammation along the flexor tendon's synovium within the canal. The cause of the synovitis should be determined, if possible.

Treatment. Treatment of carpal tunnel syndrome depends on the cause of the neuropathy (55). Most patients get better with conservative treatment, which includes splinting of the wrist in neutral position for rest, oral antiinflammatory medication, and corticosteroid injection into the ulnar bursa of the flexor aspect of the wrist (Fig. 59-26). The injection should *not* be made into the carpal tunnel itself, because this risks injecting the corticosteroid directly into the median nerve, which is not desirable. Favorable response to vitamin B_6 therapy has also been reported, but controlled studies and personal experience do not confirm positive responses from these types of treatments.

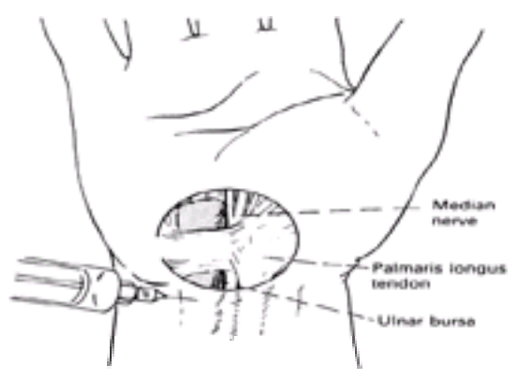

Figure 59-26. Injection of the ulnar bursa for the treatment of carpal tunnel syndrome.

If these treatments fail and the symptoms warrant, surgical decompression of the carpal canal, with or without localized flexor tendon synovectomy, is indicated. This treatment has produced favorable results in a large percentage of patients. Recurrences do happen, but probably in fewer than 10% of patients. Both open and endoscopic carpal tunnel releases have been successful.

Other Median Nerve Entrapment Syndromes

Several other neuropathies of the median nerve cause symptoms that mimic carpal tunnel syndrome.

Supracondylar Process Syndrome. Approximately 2.5% of the population has an aberrant spur of bone on the anteromedial surface of the humerus approximately 5 cm above the median epicondyle. This structure, called the *supracondylar process*, is often connected to the medial epicondyle by a fibrous band called the *ligament of Struthers*. Usually, the median nerve and often the brachial artery pass behind the process and then anteriorly between the fibrous band and the bone. Moreover, the upper fibers of the pronator teres arise from the process and the band. Consequently, the median nerve can be compressed by the ligament or by the fibers of the pronator teres (see Fig. 56-8). Persons who have this entrapment syndrome experience pain above the elbow and local tenderness in the region of the ligament. Radiographs of the elbow show the bony process above the median condyle of the humerus, and a positive Tinel's sign is present (see Fig. 59-25B).

Pronator Teres Syndromes. As the median nerve crosses the elbow, it first passes posterior to (beneath) the lacertus fibrosis (a thick fascial band extending from the biceps tendon to the ulnar forearm fascia), then between the superficial and deep heads of the pronator teres, and then beneath the flexor digitorum superficialis arch (54). Consequently, the nerve sometimes is compressed beneath the lacertus fibrosis or by the hypertrophied pronator teres or a fibrous band within the pronator teres. The nerve also can be compressed by a tight fibrous arch of the flexor digitorum superficialis.

The pronator syndrome produces mild to moderate aching pain in the proximal forearm, which may radiate to the wrist and hand and is associated with tingling and numbness, symptoms similar to those of carpal tunnel syndrome. The pain is usually aggravated by heavy use of the forearm and arm and repetitive elbow motions; as the pain intensifies, it may radiate proximal to the elbow even to the shoulder. These syndromes are associated with a positive Tinel's sign at the cubital crease,

weakness in the flexor muscles of the forearm, and a numbing sensation when the pronator muscle is stretched against resistance to produce compression of the nerve at that level.

Anterior Interosseous Nerve Syndrome. Anterior interosseous syndrome, another neuropathy of the median nerve, usually involves only the anterior interosseous branch as it leaves the median nerve just distal to the elbow. The syndrome is characterized by loss of strength of the flexor to the thumb and the flexor profundus to the index finger, not associated with numbness (56). It often commences with a deep aching pain in the forearm following unusual activities. Patients characteristically do not recognize their limited thumb or index finger strength for some period of time.

Treatment. Median nerve neuropathies at the elbow are initially treated conservatively with antiinflammatory medication and rest, which provide adequate relief in many patients. If symptoms persist and electromyographic changes are significant, decompression is warranted. The median nerve should be released well above the elbow down through the pronator and beyond the insertion of the two heads of the flexor digitorum superficialis.

Ulnar Nerve Entrapment Syndromes

Pain in the hand and wrist may result from a compressive neuropathy of the ulnar nerve, of which there are three general types.

Thoracic Outlet Syndrome

Neuropathy of the ulnar nerve due to compression by the lower trunk of the brachial plexus as it passes over the first rib, scalenus anticus, or medius muscles is commonly referred to as *thoracic outlet syndrome*. It produces an aching pain along the ulnar nerve distribution in the forearm and hand, and often some numbness in the little and ring fingers. Activities that stretch the scalenus muscle, such as Adson's maneuver, result in loss of pulse, vascular changes, or both in the hand. These changes suggest this syndrome.

Cubital Tunnel Syndrome

Cubital tunnel syndrome (compression of the ulnar nerve at the elbow) can manifest itself by pain in the hand and pain and numbness in the little and ring fingers. Generally, ulnar nerve neuropathy involves only the little finger and the ulnar half of the ring finger, but in a significant number of people it involves the entire ring finger and part of the middle finger. Neuropathy of the ulnar nerve from this level produces numbness on the dorsum of the hand, which differentiates it from ulnar neuropathy at the wrist level (Guyon's canal syndrome).

Cubital tunnel syndrome sometimes is associated with cubitus valgus position from an old injury or fracture at the elbow. It also can result from chronic subluxation of the ulnar nerve at the elbow. In some patients, it is associated with osteoarthritis of the elbow joint in which swelling compresses or irritates the nerve. Frequently, however, cubital tunnel syndrome is not associated with any particular predisposing condition (53).

Guyon's Canal Syndrome

Guyon's canal is the anatomic structure through which the ulnar nerve and ulnar artery pass from the flexor compartment of the forearm to the hand. It is the site of a compressive neuropathy of the ulnar nerve much like median nerve neuropathy in the carpal tunnel. This compression produces pain and numbness in the ulnar nerve distribution (usually the little and ring fingers) with loss of strength in the ulnar-innervated intrinsic muscles. It does not, however, result in numbness on the dorsum of the ulnar side of the hand. The deep branch of the ulnar nerve may be the only structure involved (particularly when the compression is associated with a ganglion), and therefore there is no numbness, just intrinsic muscle wasting. Muscle wasting and strength are best tested by spreading the fingers against resistance and radially deviating the index finger while palpating the first dorsal interosseous muscle.

Differential Diagnosis

The three types of ulnar neuropathies can be differentiated by an electromyographic study and a careful clinical evaluation (54). MR neurography (see Chapter 14) may also delineate the site of a lesion. As mentioned earlier, Adson's maneuver gives characteristic findings in thoracic outlet syndrome. Guyon's canal syndrome produces numbness of the fingers and intrinsic muscle atrophy but not numbness of the dorsum of the hand; this last symptom is characteristic of cubital tunnel syndrome.

Treatment

Treatment of ulnar neuropathies obviously depends on the area of involvement. In thoracic outlet syndrome, shoulder-elevating exercises, rest of the arm, and antiinflammatory medication are often sufficient. In severe cases with muscle loss and persistent numbness, resection of the first rib or release of the scalenus muscles is indicated, although this operation is often unsuccessful and can lead to major complications.

Initial treatment of mild cubital tunnel syndrome for the ulnar nerve involves padding the elbow and keeping the elbow relatively straight for a period of time. Often the condition improves, particularly in cases in which the ulnar nerve is subluxating. If symptoms persist and electromyographic changes are significant, surgical release is warranted. The author has become more surgically aggressive with experience, believing that continuing too long with conservative treatment can result in intraneural scarring and produce less satisfactory results than early surgical treatment. In extremely mild cases of cubital tunnel syndrome, simple release of the nerve as it goes around the epicondyle and through the decussations of the origin of the flexor carpi ulnaris muscle may be sufficient, although a fairly high rate of recurrence has been noted with this treatment. If significant neuropathy is present, submuscular transfer of the nerve is an option. In this procedure, the ulnar nerve is placed near the median nerve and the muscles are sutured relatively loosely back to the epicondyle, leaving plenty of room for the nerves. Fairly early motion is recommended after this procedure. The results, in the author's estimation, have been very good.

In Guyon's canal syndrome, surgical release is warranted in any documented case that is at all persistent. Occasionally, inflammation or blockage of the ulnar artery at the wrist accompanies this condition and may require resection of a thrombosis or a small aneurysm. The incision should be the same as that for carpal tunnel syndrome, and the neurologically sensitive hypothenar area should be avoided.

Radial Nerve Entrapment Syndromes

Etiology and Pathophysiology

Compression of the radial nerve proximally at the level of the axilla produces symptoms and signs of *Saturday night palsy*, characterized by paralysis of the wrist extensor and digital extensor muscles and sensory deficit over the dorsum of the hand, sometimes with little or no pain.

Just below the elbow, the radial nerve divides into a superficial sensory branch and a deep motor branch called the posterior interosseous nerve, which supplies the extensor muscles of the wrist and hand. The posterior interosseous nerve enters the supinator muscle under the arcade of Frohse and at this point can be compressed by tumors, ganglia, or synovitis. Spontaneous compression also can occur at the point of passage through this arcade (54). The patient develops weakness or total paralysis of the extensors of the wrist and fingers. Half of patients also have pain in the elbow and proximal forearm, which lasts a few days. Tenderness is often found over the nerve within the extensor muscle mass immediately distal to the radial head. Electromyographic changes are diagnostic.

Pain in the hand and wrist caused by radial nerve neuropathy is relatively uncommon and relatively mild, except following trauma to the radial styloid. Three to five branches of the radial nerve course over the radial styloid, a bony prominence on the radial side of the wrist. These branches frequently can be compressed at that level because there is relatively little soft tissue padding to protect them. Radial nerve neuropathy can be caused by direct blunt trauma, such as a striking force, by swelling from a ganglion or inflamed tendon, and even by a tight wristband. Most cases, however, are associated with surgical or accidental lacerations. Surgery for DeQuervain's disease or for removal of a ganglion frequently produces some temporary neuropathy due to retraction or severance.

Symptoms and Signs

Radial nerve neuropathy is characterized by a burning pain in the dorsum of the thumb, index, and middle fingers, with dysesthesia, numbness, or both. It seems to produce an extraordinary amount of pain and disability, considering that the radial nerve is relatively small and relatively unimportant to sensation. Because this nerve does not govern sensation in the flexor surface of the hand, its function is not as critical as that of the median or ulnar nerve.

Treatment

Treatment of radial nerve neuropathy depends on the cause. Rest usually suffices to reduce the compression forces resulting from watches, casts, or blunt trauma. Occasionally, surgical removal of the cause of the compression (e.g., a ganglion) is necessary. When the radial nerve has been lacerated, treatment is more complicated. Repair of the nerve is sometimes warranted, even if it requires nerve grafting, to lessen its sensitivity and the possibility of neuroma formation. A procedure involving resection of the nerve and burial of the neuroma has been performed in serial sections up to the level of the elbow, but it is frequently unrewarding (54).

Entrapment Syndromes of Other Nerves

Lateral Cutaneous Nerve

The distal branches of the lateral cutaneous nerve to the forearm can innervate the base of the thumb. This is the distal branch of the musculocutaneous nerve, not the radial. Occasionally, neuropathy of the cutaneous branch of the musculocutaneous nerve results from impingement at the elbow. This produces a burning pain in the distal forearm, wrist, and the palmar portion of the proximal thumb. The cause is entrapment of the nerve as it exits from a deep space at the level of the cubital fossa. Treatment with rest and antiinflammatory medications usually is satisfactory, but occasionally the treatment of choice is surgical decompression.

Palmar Cutaneous Nerve

Injury to the palmar cutaneous branch of the median nerve can produce a burning, dysesthetic pain in the flexor aspect of the thumb in the thenar area. The discomfort may be excruciating. The median nerve itself is not involved. A positive Tinel's sign is present at 4 to 6 cm proximal to the flexion crease of the wrist. This neuropathy is usually associated with a sharp injury, including surgical scar. Resection or burial of the neuroma or release of the nerve is the preferred treatment.

Digital Nerve

Occasionally, a digital neuropathy develops because of a mass irritating the nerve. An osteophyte at the PIP or DIP joint, a ganglion, and other tumors are typical examples. The result is diminished sensation in the distribution of the nerve. Sharp pain when the nerve is tapped over the site of compression (Tinel's sign) is diagnostic. *Bowler's thumb* causes a similar problem. It is a neuroma on the digital nerve of the thumb that develops because of chronic impingement between the metacarpals and a poorly fitting bowling ball grip.

Complex Regional Pain Syndrome Type I

Another cause of pain in the wrist and hand is a group of disorders known now as *complex regional pain syndrome*, formerly called *reflex sympathetic dystrophy*. It is mentioned in this section only for the sake of completeness and is described in detail in Chapter 20. The shoulder-hand syndrome, a similar type of symptom complex, is described in Chapter 58.

A relatively uncommon cause of hand and wrist pain, complex regional pain syndrome produces diffuse burning and aching pain and often is associated with vascular changes of the distal part of the limb. There is also a diffuse tenderness and mild to moderate swelling, shininess of the skin, and temperature lability (57,58). Reflex sympathetic dystrophy can be caused by minimal trauma to soft tissue or damage to a nerve in the hand and wrist. It sometimes follows iatrogenic complications or disease of viscera or the central nervous system. Unfortunately, because complex regional pain syndrome is often misdiagnosed and appropriate therapy is not carried out, progression of the disease is common.

Vibration Neuritis

In vibration neuritis, a chronic vibratory force on the hands produces pathologic changes in the small nerves of the fingers. Tools such as chain saws, vibrating sanders, and ultrasonic instruments can be the offending agents. Symptoms include pain and tingling in the fingers, sensitivity to cold, and vascular instability. Symptoms can mimic carpal tunnel syndrome. Electromyographic and nerve studies for carpal tunnel syndrome should be normal. Very detailed testing for sensitivity and specifically testing for vibratory thresholds at varying frequencies are diagnostic. Treatment is withdrawal from irritating mechanisms.

CHAPTER 60

General Considerations of Pain in the Chest

John J. Bonica and Daniel O. Graney

The chest is among the most common sites of pain and suffering encountered in clinical practice. Chest pain can be caused by disease of the thoracic viscera or by disorders of muscles, bones, and other pain-sensitive structures of the chest wall. It can also be projected from disease of the spinal cord or spinal nerves or referred from structures outside of the chest, or it can be a combination of two or more of these conditions. It is important for the clinician to have a thorough knowledge of the functional anatomy and physiology of the thorax and related structures to interpret the history properly and to carry out a meaningful general physical, neurologic, and orthopedic examination, prerequisites for making an accurate diagnosis and developing and implementing the most effective therapeutic strategy.

This chapter, like other chapters that introduce the management of pain in various regions of the body, provides a concise discussion of these various considerations. The material is presented in three major sections: (a) Basic Considerations, including anatomy of the thorax and the muscles attached to it, a brief description of the thoracic spinal cord and thoracic spinal nerves, and a general description of the sympathetic and parasympathetic nerve supplies to the chest; (b) Innervation of the Thoracic Viscera; and (c) History and Examination. Additionally, a table is provided containing a summary of the characteristics of pain and other symptoms and signs in the chest that should help the clinician to make a differential diagnosis. Detailed information on pathophysiology as related to pain in the chest is given in subsequent chapters. Further discussions are found in relevant textbooks and reviews of anatomy and neuroanatomy (1,2,3,4,5,6,7,8 and 9).

BASIC CONSIDERATIONS

In this first section, we discuss the clinically relevant aspects of the anatomy of the thoracic spine, chest, and abdominal wall, including a brief description of vertebrae, joints, ligaments, and muscles attached to these structures. (The muscles of the posterior chest are discussed with those of the lumbosacral spine in Chapter 75.) This is followed by a brief description of the thoracic spinal cord, spinal nerves, and the structures they supply in the chest and abdominal wall; these are presented here because the course of thoracic spinal nerves and the structures they supply (the chest and abdominal wall) are similar.

Anatomy of the Thorax

Skeletal Structures

Figure 60-1 depicts the skeletal parts of the thorax or chest, which form an osseocartilaginous cage that protects the principal organs of respiration and circulation (1). The thoracic cage extends inferiorly over the upper part of the abdomen and covers a portion of certain abdominal viscera. Its conical shape is a result of the fact that its superior or cervical inlet is of a lesser diameter than its inferior abdominal part. In transverse section the thorax appears to be kidney shaped because of projection of the vertebral bodies into the cavity. The thoracic cage is formed by the ribs, with their costal cartilages attached anteriorly to the sternum (see Fig. 60-1A) and posteriorly to the thoracic vertebrae of the spinal column (see Fig. 60-1B).

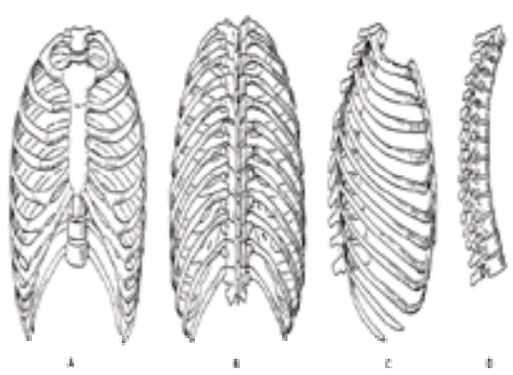

Figure 60-1. Anatomy of the thoracic cage. **A:** Anterior view. Note that all 12 of the ribs articulate with their respective thoracic vertebrae, but only the first seven attach directly to the sternum; the eighth, ninth, and tenth ribs attach to the cartilages of the seventh rib on each side, while the eleventh and twelfth pairs have no anterior articulation. **B:** Posterior view. Each rib articulates with its respective thoracic vertebra and, as the ribs encircle the trunk, they proceed in an inferolateral direction. **C:** Lateral view from the right side. Initially the ribs course in an anterolateral direction from the vertebral column and then proceed inferomedially to reach the costal cartilages and the sternum. **D:**View of the right side of the thoracic part of the vertebral column. (Modified from Clemente CD. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:148–150.)

The thorax is bounded posteriorly by the twelve thoracic vertebrae and the posterior parts of the 12 ribs, anteriorly by the sternum and the costal cartilages, and laterally by the ribs. These are separated from each other by the 11 intercostal spaces, within which are located the intercostal muscles and membranes, nerves, and vessels. The superior opening of the thorax, formed by the T-1 vertebra, the cranial margin of the sternum, and the first rib on each side, is broader from side to side than anteroposteriorly. The plane of the aperture slopes inferiorly from the spinal column down to the sternum, and its upper part lies 3 to 5 cm below the upper border of the body of the T-1 vertebra. The inferior opening, or thoracic outlet, is formed posteriorly by the 12 thoracic vertebrae, laterally by the eleventh and twelfth ribs, and ventrally by the cartilages of the seventh to tenth ribs, which slope on each side to form the infrasternal angle of the xiphoid process.

The thorax of female subjects differs from that of male subjects in the following respects: Its capacity is less; the sternum is shorter; the cranial margin of the sternum is on a level with the inferior part of the body of the T-3 vertebra, whereas in the male subject it is on a level with the inferior part of the body of the T-2 vertebra; and the upper ribs are more movable, permitting a greater expansion of the superior part of the thorax (1).

Thoracic Spine. The thoracic spine, composed of the 12 thoracic vertebrae, is concave anteriorly and articulates with the ribs, thus forming the supporting structure of the rib cage. Figure 60-2 depicts the anatomy and articulating surfaces of a typical thoracic vertebra, as well as its articulation with the head, neck, and proximal portion of the rib.

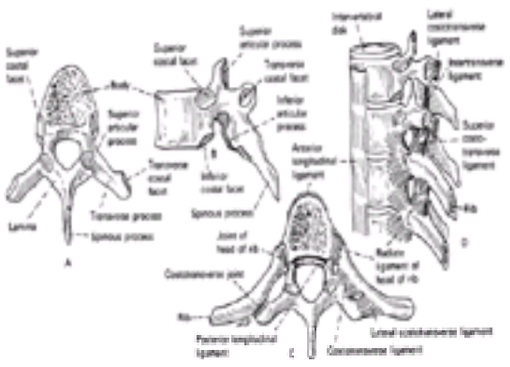

Figure 60-2. Anatomy and articulations of the thoracic vertebrae. **A:** Superior view. **B:** Lateral view. The articular facets and the posteroinferior direction of the spinous processes are shown. **C:** Superior view. The synovial cavities of the joint of the head of the rib and the costotransverse joint are on the left, and the various ligaments are on the right. **D:** Lateral view of four thoracic vertebrae depicting the ligaments of the costovertebral joints.

The thoracic vertebrae are intermediate in size between the cervical and lumbar vertebrae, providing a gradual transition from the small cervical vertebrae superiorly to the large lumbar vertebrae inferiorly. The body of a thoracic vertebra is larger posteriorly than anteriorly. The thoracic vertebrae are distinguished by the presence of costal facets on the side of the body for articulation of the heads of the ribs and by other articular facets in the transverse processes of the upper 10 thoracic vertebrae for articulation with the tubercles of the ribs. The T-1 vertebra has an entire articular facet for the head of the first rib and a demifacet for the cranial half of the head of the second rib on each side of the vertebral body. The T-2 to T-8 vertebrae have similar demifacets, the T-9 vertebra has only one demifacet above, and the T-10, T-11, and T-12 vertebrae have one entire facet.

The pedicles of the thoracic vertebrae are directed dorsally and slightly superiorly from the transverse process; the inferior vertebral notches are large and extend more superiorly than in any other region of the vertebral column, thus making the intervertebral foramina ample for the exit of the nerves. The laminae are broad, thick, and imbricated, with the one superiorly overlapping the next inferiorly like tiles on a roof. The spinous processes are long, triangular in coronal section, and directed obliquely inferiorly, and end in a tuberculated extremity. The spinous processes of the T-5 to the T-8 vertebrae are oblique and overlap to a greater degree than those of the upper and lower thoracic vertebrae.

Ribs. The ribs are flattened narrowed elastic arches of bone that form a large part of the thoracic skeleton. The first 7 of the 12 ribs are called *true* or *vertebrosternal* ribs; they connect dorsally with the vertebral column and ventrally with the sternum by means of costal cartilages. The remaining five pairs are *false* ribs and consist of two types; the eighth to tenth ribs have their cartilages attached to the cartilage of the rib above (vertebrochondral), while the eleventh and twelfth ribs are free at their anterior extremities and are therefore referred to as *floating* or *vertebral* ribs, because they do not attach to the sternum. Figure 60-3 depicts the anatomy of the typical central rib of the left side viewed from below and from the side, and shows the peculiar anatomy of the second and first ribs.

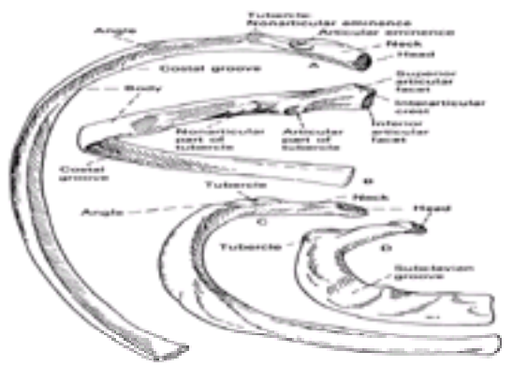

Figure 60-3. Anatomy of the ribs. **A:** Inferior aspect of a typical central rib from the left side. The principal parts of the bone include the head, neck, tubercle (which possesses an articular eminence and a nonarticular eminence), and curved body of shaft. The costal groove contains the intercostal vessels and nerves. **B:** Typical central rib from the left side, viewed from behind. The vertebral extremity at the end of the head of the rib contains a large inferior facet for the numerically corresponding vertebra and a smaller facet for the adjacent vertebra above; the interarticular crest attaches to the intervertebral disk between the two facets. **C:** Right second rib, viewed from above. **D:** Right first rib, viewed from above; the subclavian groove below the head of the large tubercle is occupied by the subclavian artery and brachial plexus and the more anterior groove by the subclavian vein. (Modified from Clemente CD. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:154–155.)

The *costal cartilages* are bars of hyaline cartilages that go along the ribs anteriorly and render the chest wall more elastic to accommodate, for example, the movements of respiration. The first seven pairs are connected to the sternum, the next three pairs articulate with the lower border of the cartilage of the preceding rib, and the last two pairs have pointed anterior extremities that end in the musculature of the abdominal wall.

Sternum. The sternum is an elongated flat bone that forms the middle portion of the anterior wall of the thorax and is composed of the manubrium, body, and xiphoid process. The upper portion of the manubrium articulates with the clavicle and the first and second ribs. The body articulates with the cartilage of the second to the seventh ribs, while the xiphoid process is a thin elongated structure that is cartilaginous in children but is more or less ossified proximally in adults (Fig. 60-4; see Fig. 60-1A).

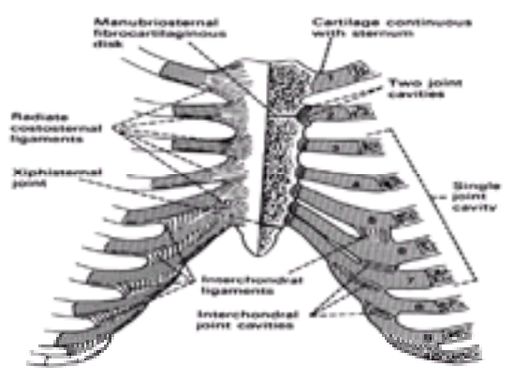

Figure 60-4. Anterior view of the sternum and costal cartilages showing the sternocostal and interchondral articulations. On the left side of the sternum the synovial cavities are exposed by coronal section of the sternum and cartilages. (Modified from Clemente CD. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:356.)

Joints and Ligaments

Joints and Ligaments of the Vertebral Column. The joints and ligaments of the thoracic portion of the vertebral column are similar to those discussed in Chapter 54 in relation to the cervical spine (1). These include the intervertebral disks and the anterior and posterior longitudinal ligaments (see Fig. 60-2C and Fig 60-2D). The intervertebral disks of the thoracic spine are nearly of uniform thickness, and the anterior concavity of this part of the column is almost entirely a result of the shape of the vertebral bodies; as mentioned previously, these are larger posteriorly than anteriorly. The intervertebral disks adhere to thin layers of hyaline cartilage that cover the superior and inferior surfaces of the vertebral bodies. Each disk is composed of an outer lamina of fibrous tissue called the *annulus fibrosis* and an inner core of a soft gelatinous and highly elastic substance called the *nucleus pulposus*.

The anterior longitudinal ligament, which extends from the occipital bone to the sacrum, is narrower but thicker in its passage over the anterior surface of the vertebral bodies than over the intervertebral disk. It consists of dense longitudinal fibers that adhere closely to the intervertebral disks and the prominent margins of the vertebrae but are not attached firmly to the middle parts of the body, where it is thick and fills the concavities of the anterior surfaces, thus giving the anterior aspect of the vertebral column a more even contour. This anterior aspect is composed of several layers of fibers that vary in length but are closely interlaced with each other. The most superficial fibers are the longest and extend across four or five vertebrae; a second subjacent set extends between two or three vertebrae; and a third set, the shortest and deepest, reaches from one vertebra to the next.

The posterior longitudinal ligament extends from the axis to the sacrum and passes over the dorsal surface of the bodies of the vertebrae and the intervertebral disks. Superiorly, it is continuous with the tectorial membrane. Inferiorly, it is narrow and thick over the center of the bodies, from which it is separated by the basivertebral veins, and broadens over the intervertebral disks. It is composed of longitudinal fibers that are denser and more compact than those of the anterior ligaments.

Joints between the Vertebral Arches. Joints between the articular processes of the thoracic (and other) vertebrae are plain or gliding joints enveloped by capsules lined by synovial membrane (see Fig. 60-2B and Fig. 60-2C). The articular capsules are thin and loose and are attached to the margins of the articular processes of adjacent vertebrae. The ligamenta flava connect the laminae of adjacent vertebrae. Each ligamentum flavum consists of yellow elastic tissue attached to the anterior and inferior surfaces of the lamina above and to the posterior surface of the lamina below. The fibers of the ligamenta flava are almost perpendicular to the laminae to which they are attached. They are thin in the cervical region, thicker in the thoracic region, and thickest in the lumbar region. Their marked elasticity permits separation of the laminae during flexion of the vertebral column and also helps to preserve the upright posture (Fig. 60-5).

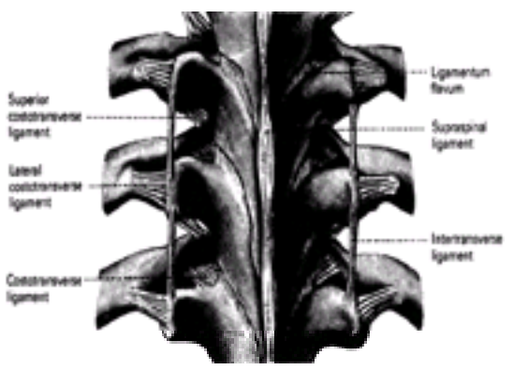

Figure 60-5. Posterior aspect of part of the thoracic spinal column showing the supraspinal, intertransverse, and costotransverse ligaments and the ligamentum flavum. (From SOBOTTA. *Atlas der anatomie des menschen*, 20th ed. Munich: Urban & Schwarzenberg, 1993.)

The interspinous ligaments are thin and membranous and interconnect adjoining spinous processes, extending from the root to the apex of each process. The supraspinous ligament is a strong fibrous cord that connects together the apices of the spinous processes from the C-7 vertebra to the sacrum (see Fig. 60-5). Fibrocartilage develops into ligament at its point of attachment to the tips of the spinous process and, in older persons, this can extend into the interspinous portions of the ligament. The intertransverse ligaments are interposed between the transverse processes, which in the thoracic region are rounded cords that are intimately connected with the deeper muscles of the back.

Movement. Normally, the movements permitted in the vertebral column include flexion, extension, lateral flexion, circumduction, and rotation. In the thoracic region, however, notably in its upper part, all movements are limited to minimize interference with respiration (1). The almost complete absence of the upward inclination of the superior articular surfaces prohibits any marked flexion, whereas extension is checked by the contact of the inferior articular margins with the laminae and by the contact of the spinous processes with one another. The mechanism of the inferior end of the cervical spine limits extension and also serves to limit flexion of the thoracic region when the neck is extended. Rotation is free in the thoracic region; the position of the articular processes allows rotation around a vertical axis that passes through the bodies of the midthoracic vertebrae but is anterior to the vertebral bodies of the upper and lower thoracic vertebrae. The direction of the articular facets would allow free lateral flexion, but this movement is considerably limited by the resistance of the ribs and sternum.

Costovertebral Joints. The articulation of the ribs with the vertebral column can be divided into two sets, one connecting the heads of the ribs with the bodies of the vertebrae and the other uniting the necks and tubercles of the ribs with the transverse processes (1).

Articulation of the Heads of the Ribs. A series of plane or gliding joints is formed by the articulation of the heads of the typical ribs with the facets on the contiguous margin of the bodies of the thoracic vertebrae and with the intervertebral disks between them (see Fig. 60-2C and Fig. 60-2D). Although the heads of the second to ninth ribs each articulate by means of two facets, the articulation is considered to be a single joint because only one articular capsule is present, even with two synovial sacs. Figure 60-2C depicts two parts of this joint, the articular capsule and the radiate ligament. The radiate ligament connects the anterior part of the head of each rib with the sides of the bodies of two adjacent vertebrae and the intervertebral disks between them. The intraarticular ligament, situated in the interior of the joint, consists of a short flat band of fibers attached by one extremity to the crest separating the two articular facets on the head of the rib and by the other to the intervertebral disk. It divides the joint into two cavities, each of which is lined by a synovial membrane.

Costotransverse Joints. The articular surface on the tubercle of the upper ten ribs forms a plane or gliding joint with the articular facet on the adjacent transverse process of the corresponding vertebra (see Fig. 60-2C and Fig. 60-2D). This articulation is missing in the eleventh and twelfth ribs. These joints include an articular capsule, which is a thin fibrous membrane attached to the circumference of the articular surface.

The superior costotransverse ligament is attached to the sharp crest of the superior border of the neck of the rib and passes obliquely upward and laterally to the lower border of the neck of the transverse process immediately above. It is composed of two layers; the anterior layer blends laterally with the internal intercostal membrane and is crossed by the intercostal nerves and vessels, while the posterior layer blends laterally with the external intercostal muscle. Its medial border is thickened and free and bounds an aperture that transmits the posterior division of the spinal nerves and posterior branches of the intercostal vessels.

The costotransverse ligament, sometimes called the ligament of the neck of the rib, consists of short strong fibers that connect the rough surfaces on the back of the neck of the rib with the anterior surface of the adjacent transverse process.

The lateral costotransverse ligament is a short, thick, and strong fasciculus. It passes obliquely from the apex of the transverse process of the vertebra to the rough and nonarticular portion of the tubercle of the corresponding rib.

Movement at the Costotransverse Joints. The heads of the ribs are so closely connected to the bodies of the vertebrae by the radiate and intraarticular ligaments that only slight gliding movements of the articular surfaces on one another can take place (1). Similarly, the strong ligaments binding the necks and tubercles of the ribs to the transverse process limit the movements of the costotransverse joints to a slight gliding motion. The joints at the head of the ribs and the costotransverse joints move simultaneously in the same direction, with the total effect being that the neck of the rib moves as if on a single joint. The chief movement of the necks of the upper six ribs is one of rotation around their own long axes, with only slight upward and downward movements. Thus, backward rotation of the neck of the rib results in lowering of the anterior end of the rib, whereas forward rotation of the neck of the rib causes elevation of the anterior end. The necks of the seventh to the tenth ribs can move either upward, backward, and medially, or downward, forward, and laterally, thereby altering the shape of the rib cage with only a slight rotation

accompanying these movements (1).

Articulation with the Sternum

Sternocostal Joints. The medial ends of the costal cartilages fit into the slight concavities along the lateral border of the sternum to form the sternocostal joints, which have an articular capsule and are strengthened by the radiate sternocostal ligaments, the intraarticular sternocostal ligaments, and the costal xiphoid ligaments (see Fig. 60-4). These joints are supplied by the anterior perforating branches of the intercostal nerves. Sternocostal joints permit only a slight gliding movement.

Interchondral and Costochondral Joints. The contiguous borders between the sixth and seventh, seventh and eighth, eighth and ninth, and sometimes even those of the ninth and tenth costal cartilages, articulate with each other by small smooth oblong facets. Each joint is enclosed in a thin articular capsule lined by synovial membrane and strengthened laterally and medially by the fibrous interchondral ligaments (see Fig. 60-4).

The lateral end of each costal cartilage is received into a slight depression of the sternal end of the rib. The cartilage and bone are bound together by the periosteum of the bone, which becomes continuous with the perichondrium of the cartilage.

Articulation of the Sternum

Manubriosternal and Xiphisternal Joints. The interior surface of the manubrium is united with the superior surface of the body of the sternum by a fibrocartilaginous disk, which is shaped to conform to the hyaline cartilage-covered bony surfaces. The lateral margins of this synthesis are contiguous with the second sternocostal joints. At this joint site, the manubrium and sternal body usually present a slight anteriorly projecting ridge called the *sternal angle*, which is palpable beneath the skin and serves as an important surface landmark for clinicians. The articulation between the xiphoid process and the inferior border of the sternal body is cartilaginous but, by 30 years of age, this joint has usually become ossified. The joint is secured laterally by radiating fibers of the sternocostal ligaments. Generally, the seventh costal cartilage articulates with the sternum at the lateral margin of the xiphisternal junction (see Fig. 60-4).

Muscles of the Thorax

The muscles considered in this section are primarily those attached to the ribs and concerned with movements, especially in relation to respiration. In addition, brief mention is made of the deep muscles of the back attached to the thoracic spine and ribs. The anterior muscles of the chest, including the pectoralis major, pectoralis minor, subclavius, and serratus anterior, were considered in the preceding section in connection with the shoulder.

Muscles of Respiration. The most important muscles that influence movement of the ribs and are concerned with respiration are listed in Table 8-2, which also presents their primary action and nerve supply. Only a brief description of these muscles is given here, particularly of the intercostal muscles, to provide a background for discussion of the position of the intercostal nerves. Before doing so, however, it is necessary to mention the fascia that covers the thoracic cage proper, composed of ribs and the intercostal muscles. The cage is covered internally and externally by thin layers of deep fascia. The outer layer essentially covers the external intercostal muscles, whereas the inner layer, consisting of loose areolar tissue called the *endothoracic fascia*, lines the internal aspect of the thoracic cage. It covers the inner surface of the intercostal muscles and intervening ribs, along with the subcostal and transversus thoracis muscles and the diaphragm. It lies between the parietal pleura and the thoracic cage, which in the absence of adhesions can therefore be easily separated. Posteriorly, the endothoracic fascia continues over the bodies of the vertebrae and intervertebral disks. In this mediastinal region, certain structures such as the azygos and hemiazygos veins, the thoracic duct, the sympathetic chain, and the splanchnic nerves are partially or completely surrounded by the fascia. Superiorly, the endothoracic fascia extends over the apices of the lung where, somewhat thickened, it forms the suprapleural membrane, or Sibson's fascia. Inferiorly, it becomes thin over the superior surface of the diaphragm but is continuous with the internal investing fascia of the abdominal cavity, dorsal to the diaphragm at the lumbosacral arches and through the aortic hiatus (1).

Intercostal Muscles. The intercostal muscles are composed of three thin layers of muscular and tendinous fibers that occupy each of the intercostal spaces. The external intercostal muscles, 11 on each side, extend from the tubercles of the ribs posteriorly to the cartilages of the ribs anteriorly, where they each end as a thin fibrous sheet, the external intercostal membrane, which continues forward to the sternum (1). Each external intercostal muscle arises from the lower border of the rib above and is inserted into the upper border of the rib below. In the lowest two spaces, the muscles extend to the ends of the cartilages, while in the uppermost two or three spaces they do not quite reach the ends of the ribs. These muscles are thicker than the internal intercostals; the fibers are directed obliquely inferolaterally on the posterior part of the thorax and inferolaterally and somewhat ventrally on the anterior aspect of the thorax (Fig. 60-6).

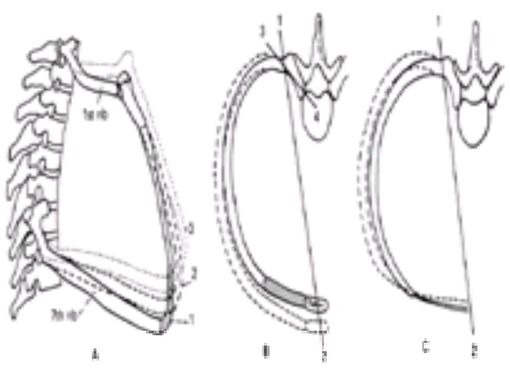

Figure 60-6. **A:** Superior view of the intercostal space showing the various intercostal muscles and a thoracic spinal nerve dividing into posterior and anterior primary divisions, the latter becoming the intercostal nerve. **B:** Anterior view of the chest showing the relation of the intercostal nerves and their branches and the relation of the intercostal nerves to the sympathetic chain. **C:** Cut section of two adjacent ribs and the intercostal muscles showing the intercostal vessels and nerves. Note the direction of the fibers of the muscles. See text for details. (Modified from Clemente CD. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:11.)

The internal intercostal muscles, also 11 on each side, begin anteriorly at the sternum in the interspaces between the cartilage of two ribs and at the anterior extremities of the cartilages of the false ribs, and extend posteriorly as far as the angles of the ribs, where they continue to the vertebral column by thin aponeuroses, the internal intercostal membranes. Each muscle arises from the ridge on the inner surface of the rib above as well as from the corresponding costal cartilage, and inserts into the upper border of the rib below. These fibers are directed obliquely but pass in a direction perpendicular to that of the external intercostal muscles.

The innermost (intimi) intercostal muscles are frequently considered to be the deepest parts of the internal intercostal muscles. They are located deep to the intercostal nerves and vessels interposed between these structures and the parietal pleura (see Fig. 60-6). They extend between the costal groove of the rib above to the inner lip of the upper margin of the rib below. The fibers generally course in the same direction as those of the internal intercostal muscles. The intimi intercostal muscles are not well developed and might be absent in the upper four or five interspaces.

The subcostal muscles consist of oblique muscular and aponeurotic fasciculi located on the inner surface of the posterior part of the chest. Usually they are well developed only in the lower part of the thorax (1). Each arises from the inner surface of one rib posteriorly near its angle and is inserted into the inner surface of the second or third rib below. Their fibers run in the same direction as those of the intimi intercostal muscles and, similarly, separate the intercostal nerves and vessels from the pleura (1) (see Fig. 60-6).

The sternocostalis, or transversus thoracis muscles, are a thin plane of muscular and tendinous fibers situated on the inner surface of the anterior chest wall. They are situated deep to the intercostal nerves and vessels and deep to the internal thoracic artery. They arise on each side from the inferior third of the inner surfaces of the body of the sternum, xiphoid process, and second to sixth costal cartilages. The fibers fan out from the back of the body of the sternum and xiphoid process to the costal cartilages of the second to sixth ribs; the upper fibers are ascending, while the lower fibers are horizontal and in continuity with the transversus abdominis muscle.

Levatores Costarum. The levatores costarum, 12 on each side, are located in the posterior surface of the thoracic cage. They consist of tendinous fleshy bundles that arise from the ends of the transverse process of the C-7 and T-1 to T-11 vertebrae. The muscles pass obliquely inferolaterally like the fibers of the external intercostals in this posterior region. Each is inserted into the outer surface of the rib immediately below the vertebra from which it takes origin, between the tubercle and the angle. They elevate the ribs and bend the vertebral column laterally, rotating it slightly toward the opposite side. The intercostal nerves also supply these muscles.

Action. All the intercostal muscles and levatores costarum are supplied by the intercostal nerves, which constitute the anterior division of the thoracic spinal nerves (see following discussion). The external intercostal muscles raise the ribs during inspiration but can also be active during expiration (1,2 and 3). The action of the internal intercostal muscles varies; the anterior portion of the upper four or five intercostal muscles that interconnect the costal cartilages elevates the ribs during inspiration, whereas the more lateral and posterior of these muscles depress the ribs during expiration. The intimi intercostal muscles also depress the ribs, while the transversus thoracis muscles draw the ribs downward (2,3). The levatores costarum elevate the ribs and then the vertebral column laterally and rotate it slightly to the opposite side.

Diaphragm. The diaphragm is a dome-shaped musculofibrous septum that separates the thoracic cavity from the abdominal cavity. Its convex upper surface forms the floor of the thorax, while its concave inferior surface forms the roof of the abdomen. Its peripheral part consists of three groups of muscular fibers that originate from the circumference of the thoracic outlet and converge to be inserted into a central tendon. The sternal part of the muscular fibers arises from two fleshy slips from the dorsum of the xiphoid process; the costal part arises from the inner surface of the cartilages and from adjacent portions of the last six ribs on each side, interdigitating with the transversus abdominis muscle, and the lumbar part arises from two aponeurotic arches on each side (the medial and lateral arcuate ligaments) and from the lumbar vertebrae by two pillars, or crura. The most central portion of the diaphragm is innervated by the phrenic nerves, which arise from the two cervical plexuses (C-3 to C-5), while its peripheral muscular fibers are supplied by the sixth to the eleventh or twelfth intercostal nerves.

Biomechanics of the Thorax

Through the action of the various muscles mentioned previously, and of others, the thoracic cage either increases or decreases in size. Each rib possesses its own range of movements but, in combination, the ribs allow respiratory excursions of the thorax. Each rib can be regarded as a lever, the fulcrum of which is situated immediately lateral to the costotransverse joint so that the neck of the rib is depressed when the shaft of the rib is elevated, and vice versa (1). Because the arms of the lever are of different lengths, a slight movement at the vertebral end of the rib is greatly magnified at the anterior extremity.

The anterior ends of the rib lie at a more inferior plane than the posterior ends; thus, when the shaft of the rib is elevated, the anterior extremity is also thrust forward. Because the middle of the shaft of the rib lies at a plane inferior to one passing through the two extremities of the rib, the shaft is elevated at the same time as it is thrust forward from the median plane of the thorax (Fig. 60-7A). Moreover, each rib forms the segment of a curve that is greater than that of the rib immediately above it, and therefore the elevation of the rib also increases the transverse diameter of the thorax.

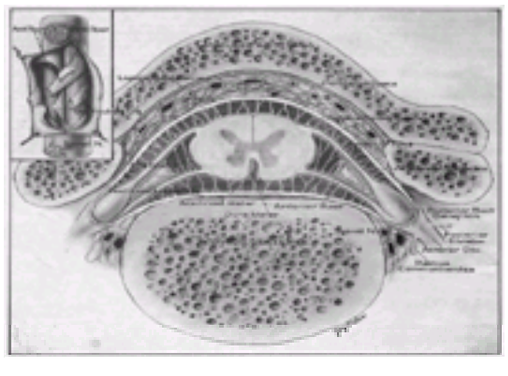

Figure 60-7. Schematic depiction of the biomechanics of the thorax during respiration. **A:** Lateral view of the first and seventh ribs showing the movements of the sternum and ribs in ordinary expiration (1), quiet inspiration (2), and deep inspiration (3). **B:** Axes of movement (1 to 2 and 3 to 4) of the vertebrosternal rib. **C:** Axis of the movement (1 to 2) of the vertebrochondral rib. See text for more details. *Dotted lines,* position of rib during inspiration. (Modified from Clemente CD. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:365.)

The first pair of ribs moves with the manubrium as a single piece, with the anterior portion being elevated by rotary movements of the necks of the ribs near the vertebral extremities. During normal quiet respiration the movement is virtually nonexistent. Movement of the second pair of ribs is also slight in normal respiration because their anterior extremities are fixed to the manubrium and are therefore prevented from moving upward. Elevation of the third to the sixth ribs raises the thrust of their anterior extremities forward, with the greater part of the movement being affected by rotation of the rib neck (Fig. 60-7B).

The vertebrochondral ribs (eighth to tenth), along with the seventh rib, have movements that assist in enlarging the thorax for respiratory purposes but that also increase the upper abdominal space for viscera displaced by the action of the diaphragm (Fig. 60-7C). The costal cartilages of the sixth to tenth ribs articulate with one another so that each pushes up the costal cartilage above, with the final thrust being directed to pushing the lower end of the body of the sternum forward and upward. Slight rotation of the rib neck permits only a limited elevation of the anterior extremity. Elevation of the rib shaft is accompanied by an outward and backward movement that results in a considerable increase in the transverse diameter and a decrease in the median anteroposterior diameter of the lower chest and upper abdomen.

Even more important than the action of the ribs, and of the muscles that control their movements, is the action of the diaphragm. Acting from their attachment on the ribs and lumbar vertebrae, the muscle fibers of the diaphragm draw the central tendon downward and forward during inspiration. This tends both to increase the volume and decrease the pressure within the thoracic cavity and to decrease the volume and increase the pressure within the abdominal cavity.

All these structures take part in the respiratory cycle of inspiration and expiration, which is the result of the increase and decrease in the capacity of the thoracic cavity. Inspiration, the increase in the volume of the cavity, results from the muscular action of the descent of the diaphragm, which increases the vertical dimension of the thorax, and from the action of the muscles in the ribs, sternum, and vertebral column, which increases the transverse and anteroposterior dimensions of the thorax. Expiration, associated with a decrease in the volume of the thoracic cavity, is primarily a passive process because of the elastic recoil of the thoracic wall and of the tissues of the lungs and bronchi. Thoracic volume can also decrease, however, as a result of the action of the abdominal muscles, which force the diaphragm upward by increasing the abdominal pressure, and by the action of certain muscles of the ribs and vertebral column, which actively contract the thoracic wall.

Neurologic Considerations

The canal of the thoracic portion of the spinal column in the adult contains more than two-thirds of the spinal cord. Although variations occur in most individuals, this portion of the canal contains the second thoracic to first sacral segments inclusively. As discussed in Chapter 54, the spinal cord only partially fills the spinal canal, its diameter being approximately half the diameter of the latter. Figure 60-8 shows the relationship of the spinal cord to the vertebral canal and depicts the thoracic spine, meninges, and attachment of spinal nerves to the spinal cord. Because this was discussed in previous chapters, the remainder of this section describes the anatomy of the thoracic spinal nerves and the phrenic nerves because they supply motor fibers to the diaphragm and sensory fibers of the pericardium and other structures in the chest and abdomen.

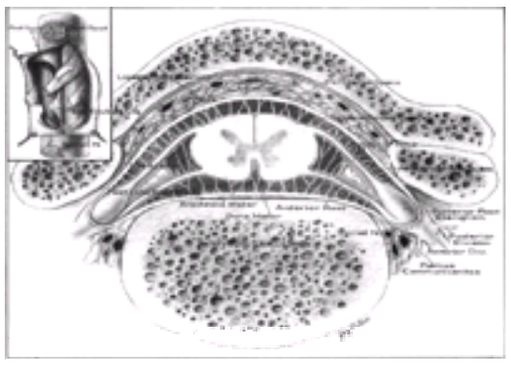

Figure 60-8. Cross-section of the thoracic spine showing detailed anatomy of the spinal cord and its meninges and the subarachnoid and epidural spaces. The section was taken between dentate ligaments (not shown). Inset: Attachment and coverings of the roots of spinal nerves.

Thoracic Spinal Nerves

The thoracic nerves consist of 12 pairs of somatic spinal nerves derived from homologous spinal cord segments located between the seventh cervical and ninth thoracic vertebrae (see Fig. 8-2). Generally, they retain their segmental relationship throughout their distribution by coursing below the corresponding rib to supply segments of muscles, skin, and other somatic structures of the thorax and abdomen. They also supply the parietal pleura and peritoneum.

Soon after they are formed within the spinal canal by the union of the anterior and posterior roots, the thoracic spinal nerves emerge below the corresponding vertebrae through the intervertebral foramen, and each divides into a posterior primary division and an anterior primary division (see Fig. 60-6). Just before dividing, each of these nerves gives off a recurrent branch that returns through the foramen to supply the corresponding vertebra and its ligaments and a segment of the meninges covering the cord. Also before dividing, the formed thoracic spinal nerves are connected to the thoracic sympathetic chain by white rami communicantes, which contain myelinated preganglionic fibers and visceral afferents, and by gray rami communicantes, which contain unmyelinated postganglionic fibers.

The smaller posterior primary divisions diverge from their anterior counterparts and run posteriorly to supply the muscles and skin of the back through medial and lateral branches. In the upper six thoracic (and all cervical) segments the medial branches supply chiefly the skin and subcutaneous tissue, with the lateral branches almost entirely supplying muscles; in the lower thoracic (and lumbar and sacral) segments the reverse is true. The posterior division of each thoracic spinal nerve, often involved in painful conditions of the vertebrae and muscles, migrates within muscles inferiorly for a progressively greater distance before emerging from the muscle to supply the skin and subcutaneous tissue over the spinous process and the paravertebral region (see Chapter 8 and Fig. 8-9). Thus, the cutaneous branch of the posterior division of the T-6 nerve supplies the skin of the T-9 to T-10 dermatomes (posteriorly), the T-10 nerve supplies the skin of the L-2 to L-3 region, and the T-12 nerve supplies that of the L-5 to S-1 region (see Table 8-1).

Each of the larger anterior primary divisions, after leaving the posterior primary division, proceeds laterally below the corresponding rib to become distributed to the parietes of the thorax and abdomen. The first 11 are situated between adjacent ribs and are therefore named the *intercostal nerves*, while the twelfth nerve is called the *subcostal nerve*. The intercostal nerves are distributed chiefly to the parietes of the thorax and abdomen. They differ from other spinal nerves in that each pursues an independent course and, except for the first intercostal nerve, does not enter into the formation of plexuses.

The anterior primary division of the first thoracic nerve, after leaving the posterior primary division, divides into a larger superior branch and a smaller inferior branch. The superior branch runs in a superior and lateral direction across the neck of the first rib, leaves the thoracic cavity, and enters the interval between the anterior and middle scaleni muscles, where it joins the anterior primary division of the eighth cervical nerve to form the lower trunk of the brachial plexus. The inferior branch, which can be considered as the true first intercostal nerve, runs within the first intercostal space in the same fashion as other typical thoracic intercostal nerves. Usually, it does not give off a lateral cutaneous branch, but sends a small branch to the intercostobrachial nerve.

Thoracic Intercostal Nerves. The anterior primary divisions of the second through sixth thoracic nerves are often called the *thoracic intercostal nerves*, because they supply the parietes of the chest. All these have a similar course and distribution and are therefore discussed as a group. After emerging through the intervertebral foramina they proceed laterally, each becoming situated for a short distance midway between the neck of the rib above and the neck of the rib below, lying between the pleura and the internal (posterior) intercostal membrane. Approximately 3 cm lateral to the foramina they pierce the intercostal membrane and run obliquely across the interspace toward the angle of the rib above to enter the costal groove, where they come to lie below the intercostal vein and artery and between the innermost (intimi) intercostal muscles and the internal intercostal muscles (see Fig. 60-6).

They continue their distal course between the two muscles as far as the junction between the ribs and costal cartilages, where they enter the interval between pleura and muscle. Proceeding within this interval they pass anteriorly to the internal thoracic artery and the transverse thoracic muscle to within 1 to 2 cm of the lateral border of the sternum, where they pierce the internal intercostal muscle, the anterior intercostal membrane, and the pectoralis major to become the anterior cutaneous branches. Each of these branches supplies a segment of skin over the anterior chest and breast and sends filaments that overlap 2 cm beyond the midline to supply the skin of the opposite side. The anterior branch of the first intercostal is often absent, and that of the second frequently communicates with the medial supraclavicular nerves of the cervical plexus. The latter nerves supply the skin over the first, second, and often the third thoracic segments.

Collateral and Lateral Cutaneous Branches. At or near the neck of the rib, each intercostal nerve gives off a collateral branch and a lateral cutaneous branch (Fig. 60-9; see Fig. 60-6). The collateral branch runs along the lower border of the intercostal space and ends anteriorly as a separate cutaneous nerve or by rejoining the main nerve to supply the skin and other structures in the anterior chest.

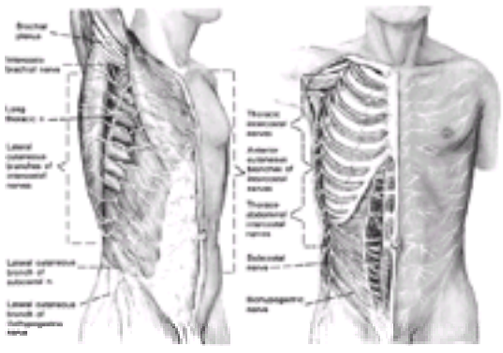

Figure 60-9. Distribution of the intercostal nerves. **A:** Anterolateral view of the lateral cutaneous branches of the intercostal nerves emerging from the muscles and deep fascia and dividing into anterior and posterior subdivisions. Note especially the distribution of the lateral cutaneous branch of the twelfth thoracic nerve, which supplies the anterior part of the gluteal region. The anterior cutaneous branches are also shown. **B:** Anterior view of the chest with the muscles removed on the right side to depict the location and distribution of the intercostal nerves. The anterior parts of the intercostal nerves enter the rectus abdominis muscle to provide motor branches to the muscle and then pass anteriorly through the muscle and its fascia to supply the cutaneous structures of the middle part of the abdominal wall.

The lateral cutaneous branch accompanies the main intercostal nerve as far as the midaxillary line before piercing the internal intercostal muscle and then runs obliquely through that muscle, the external intercostal muscle, and the serratus anterior muscle to reach the subcutaneous tissue, where it divides into anterior and posterior subdivisions. The anterior subdivisions run anteromedially to supply the skin of the lateral and anterior parts of the chest and breast; those of the fifth and sixth nerves also supply the superior digitations of the obliquus externus abdominis (see Fig. 60-9). The posterior subdivisions supply the skin over the posterolateral

and posterior parts of the chest that overlie the latissimus dorsi muscle and the scapular region.

The lateral cutaneous branch of the second intercostal nerve, the intercostobrachial nerve, does not divide; it crosses the axilla to reach the medial side of the arm, where it pierces the deep fascia, communicates with branches of the medial and posterior brachial cutaneous nerves, and then proceeds to supply the skin of the upper half of the medial and posterior parts of the arm. The anterior subdivision of the lateral cutaneous branch of the third intercostal nerve often gives off a large filament that joins the intercostobrachial nerve to supply the axilla and upper medial aspect of the arm. Injury or sacrifice of the intercostobrachial nerve during axillary surgery results in hypesthesia of the skin on the medial surface of the arm.

Muscular Branch. The upper thoracic nerves give off numerous muscular branches to the intercostals, the subcostals, the levatores costarum, the serratus posterior superior, and the transversus thoracis muscles. At the anterior part of the thorax some of these muscular branches cross the costal cartilages from one intercostal space to another (1).

Thoracoabdominal Intercostal Nerves

The anterior primary divisions of the seventh to eleventh nerves, often called the *thoracoabdominal intercostal nerves*, have the same course as those already described as far as the anterior end of the intercostal space. Here they run anteromedially to pass behind (posterior to) the costal cartilages and to enter the interval between the transversus abdominis and internal oblique muscles. They run medially within this interval as far as the semilunar line, where they perforate the posterior sheath of the rectus abdominis muscle near its lateral margin. They then follow a medial course within the muscle, to which they give numerous filaments, and then abruptly turn anteriorly, piercing the anterior sheath of the rectus abdominis muscle to become the anterior cutaneous branches.

The anterior cutaneous branch of the sixth intercostal nerve supplies the skin over the xiphoid process, those of the eighth and ninth supply the skin between the xiphoid process and umbilicus, that of the tenth supplies the skin around the umbilicus, and that of the eleventh supplies the skin just below the umbilicus.

The lateral cutaneous branches of these lower intercostals have similar subdivisions and distribution as the upper intercostals except that the anterior subdivisions supply the skin of the abdominal wall as far as the lateral margin of the rectus abdominis (linea semilunaris), while the posterior subdivisions supply the skin over the posterior part of the back as far as 4 to 5 cm from the midline (see Fig. 60-9).

Muscular Branches. The thoracoabdominal intercostals give off muscular branches that supply the corresponding intercostals, the transversus abdominis, the external and internal oblique and rectus abdominis muscles, and the peripheral part of the diaphragm. The latter three also supply the serratus posterior inferior muscles.

Twelfth Thoracic Nerve. The anterior primary division of the twelfth thoracic nerve, the subcostal nerve, is much larger than the others. After emerging from its intervertebral foramen it gives off a branch that joins the first lumbar nerve and then passes laterally under the lateral lumbocostal arch in front of the quadratus lumborum to reach the transversus abdominis muscle, which it perforates to enter the interval between this and the internal oblique muscle. After this, its course and distribution are the same as those of the other lower intercostals, except that after perforating the muscles its lateral cutaneous branch does not divide but descends over the iliac crest to supply the skin of the anterior portion of the gluteal region as far as the greater trochanter. Its anterior cutaneous branch supplies a segment of skin 3 to 4 cm above the pubis.

Phrenic Nerves

The phrenic nerves, generally considered to be the motor nerves of the diaphragm, also contain many sensory and sympathetic fibers. Each nerve is formed by a large root from the anterior primary division of the C-4 nerve, but is also augmented by fibers from the anterior division of the C-3 and C-5 nerves (Fig. 60-10). Each phrenic nerve receives gray rami communicantes from the superior and middle cervical sympathetic ganglia, and often from the vertebral ganglion and ansa subclavia. The three roots unite at the superolateral border of the anterior scalenus muscle. The nerve then passes downward on the anterior surface of that muscle, gradually crossing from its lateral to its medial side. It descends under cover of the sternocleidomastoid muscle and is crossed by the anterior belly of the omohyoid muscle and by the transverse cervical and suprascapular vessels. The nerve continues with the scalenus anterior between the subclavian vein and artery, and as it enters the thorax it crosses the origin of the internal thoracic artery and is joined by the pericardiophrenic branch of this artery. It then passes downward over the cupula of the pleura, and anterior to the root of the lung, and along the lateral aspect of the pericardium between it and the mediastinal pleura until it reaches the diaphragm, where it divides into its terminal branches.

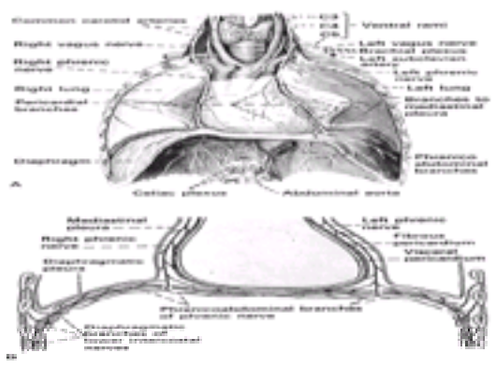

Figure 60-10. Anatomy of the phrenic nerves. **A:** Anterior view of the chest with the lungs reflected to show the origin, course, and distribution of both phrenic nerves. **B:** Schematic depiction of the distribution of the motor and sensory fibers of the phrenic nerves. The sensory fibers contribute to the sensory innervation of the pericardium, the central portion of the superior and inferior surface of the diaphragm, and send branches to the inferior phrenic plexus (a subsidiary of the celiac plexus), through which the sensory nerves of the phrenic nerves supply a number of upper abdominal viscera. (Modified from Netter FH. *The CIBA collection of medical illustrations*. Nervous system. Part I, Anatomy and physiology. West Caldwell, NJ: CIBA Pharmaceutical, 1983:114.)

The right phrenic nerve is situated more deeply, is shorter, and runs more vertically downward than the left nerve. In the upper part of the thorax it is lateral to the right brachiocephalic vein and the superior vena cava. The left phrenic nerve is longer than the right because of the inclination of the heart toward the left and because of the more inferior position of the diaphragm on this side (see Fig. 60-10). At the thoracic inlet the left nerve passes anterior to the subclavian artery behind the termination of the thoracic duct and proceeds downward between the left subclavian and left common carotid arteries. As it crosses the left side of the arch of the aorta it is lateral to the vagus nerve. It continues downward anterior to the root of the left lung and between the mediastinal pleura and fibrous pericardium covering the left surface of the heart to reach the diaphragm.

While passing through the thorax, both phrenic nerves supply nerve filaments to the fibrous pericardium, to the costal and mediastinal pleura over the apex of the lung, to the mediastinal pleura along its length, and to the central region of the diaphragmatic pleura. As previously mentioned, the sensory nerves to the margin of the diaphragm and to the corresponding areas of the overlying pleura and peritoneum are provided by lower intercostal nerves. The left phrenic nerve often sends a twig to the left pulmonary plexus and the right nerve supplies filaments to the inferior vena cava, with both nerves communicating with the greater splanchnic nerves.

The right phrenic nerve pierces the central tendon of the diaphragm through or near the orifice of the inferior vena cava, while the left nerve penetrates the diaphragm close to the anterior edge of its central tendon just lateral to the cardiac apex. Each nerve divides into three diverging phrenicoabdominal branches below the diaphragm. These supply the diaphragm from its inferior surface and also supply sensory fibers to most of the peritoneum covering the diaphragm except for marginal areas, which receive their nerve supply from the lower intercostal nerves. Sensory fibers also supply the coronary and falciform ligaments of the liver. On the right side a branch near the inferior vena cava communicates with the inferior phrenic plexus, a subsidiary of the celiac plexus, which accompanies the inferior phrenic arteries. A small phrenic ganglion is usually found at the point at which the filaments from the phrenic nerve join the phrenic plexus. Filaments from the inferior phrenic plexuses pass through the gastroesophageal junction, the cardiac end of the stomach, the porta hepatis, and the adrenal (suprarenal) plexuses.

Thoracic Sympathetic Nerves

The thoracic portion of the sympathetic trunk consists of a series of paravertebral ganglia situated on each side of the thoracic vertebral column. Although it is usually stated that one ganglion is found on each side of each vertebra, with 12 ganglia in each of the two trunks, this occurs only rarely. In most cases, the first ganglion fuses with the inferior cervical ganglion to form the stellate ganglion. According to Hovelacque (4), the second thoracic can also take part occasionally in the formation of the stellate ganglion. In addition, fusion of two lower thoracic ganglia or of the twelfth thoracic and first lumbar ganglia can occur, so that the number is reduced further. In most instances, therefore, ten, and not infrequently 11, ganglia, can be found in each of the thoracic sympathetic trunks (Fig. 60-11).

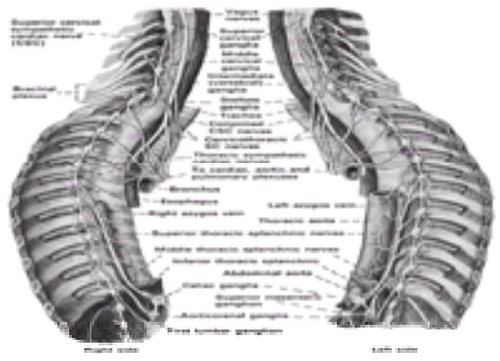

Figure 60-11. The cervical, thoracic, and upper lumbar sympathetic trunks and their branches. Note their relation to the vertebrae and ribs at various levels. (SC, sympathetic cardiac.)

These ganglia vary greatly in size and shape. In most cases they are triangular or quadrangular and are 8 mm long and 3 mm wide. The first and second ganglia are the largest and the twelfth is next in size, whereas in the midportion of the trunk the ganglia can be so small as to be almost indistinguishable from the interganglionic cord.

As they emerge from the intervertebral foramina the spinal nerves pass posterior to the interganglionic cord. The pleura is immediately in front of and in close relation to the ganglia, separated from them by the thin endothoracic fascia.

Hovelacque (4) described the branches of the thoracic ganglia as internal and external, although currently they are termed *medial* and *lateral* branches. The lateral (external) branches consist of one, two, sometimes three, and rarely four gray rami communicantes and one white ramus communicans, which pass to the adjacent spinal nerves. There is usually one white ramus connecting the anterior primary rami of spinal nerves T-1 through L-1 (L-2) to the respective sympathetic ganglion. None of the other sympathetic ganglia has white rami. Although the emphasis of this chapter is the thoracic viscera, it should be noted that preganglionic fibers of T-1 are the sole sympathetic fibers of the head and face. Interruption of these fibers results in Horner's syndrome. This topic is well reviewed by Bannister and Matthias (9). The medial (internal) are vascular and visceral branches, with those of the upper four or five ganglia supplying the thoracic viscera and the thoracic aorta and its branches and those derived from the lower six or seven ganglia contributing to the formation of the splanchnic nerves. The thoracic visceral branches reach the viscera either directly or by first passing through the pulmonary, esophageal, and cardiac plexuses. The cardiac and pulmonary plexuses are described in the next section.

Splanchnic Nerves. The splanchnic nerves arise from the medial border of the lower seven ganglia and pass to the celiac plexus to effect a connection between this structure and the sympathetic trunk (5,6). Usually three groups of these nerves are found on each side: the greater splanchnic nerves, the lesser splanchnic nerves, and the least splanchnic nerves. DeSousa-Pereira (7) found a fourth splanchnic nerve in 4% of cases, and he called it the *accessory splanchnic nerve*.

Greater Splanchnic Nerve. The greater splanchnic nerve is formed by roots that arise from the midportion of the thoracic sympathetic chain. According to Hovelacque (4), it is usually formed by three roots, less frequently four, sometimes only two, and rarely five or six. This description of its formation, subsequently corroborated by the work of DeSousa-Pereira (7), who carefully dissected and studied the splanchnic nerves in 100 cadavers, is different from the usual textbook description, which states that it is most frequently formed by five or six roots. The roots are usually given off by the seventh, eighth, and ninth ganglia, each ganglion giving off only one filament. Sometimes, however, the uppermost root takes origin from the sixth or fifth ganglion, rarely the fourth or third, while the lowest root originates from the tenth ganglion. In most cases the roots are given off by adjacent ganglia but in some cases are given off from a superior group and an inferior group, with two or three ganglia in between that do not contribute any fibers. These roots run inferiorly, anteriorly, and medially on the anterolateral aspect of the vertebral column and come together at the level of the ninth or tenth vertebra to form the greater splanchnic nerve. Near the origin of the formed nerve an enlargement called the *splanchnic ganglion* is usually found (70% of cases).

The greater splanchnic nerve is of considerable size, firm, and white. In its downward course it passes over the anterolateral aspect of the vertebrae, being separated at intervals from the vertebrae by the intercostal vessels and throughout its extent by the azygos vein on the right and by the hemiazygos vein and aorta on the left (see Fig. 60-11). It is in close relation with the pleura, behind and medial to it. It passes through the diaphragm within the space that separates the internal from the external crura and enters the abdominal cavity. Its course within this cavity is short, never more than 2 cm (4), and is in an anteromedial and inferior direction. The nerve usually breaks up into its terminal branches, which spread out like a fan and terminate in one or more ipsilateral celiac ganglia (see Fig. 65-6 and Fig. 104-31).

During its course the greater splanchnic nerve gives off fine collateral filaments that join the intercostal vessels, the azygos veins, and the aortic plexus and others going to the diaphragm and the spinal cord. In addition, some filaments join the lesser splanchnic nerve.

Lesser Splanchnic Nerve. The lesser splanchnic nerve is usually formed by two roots, sometimes by one or three, which arise from the lower portion of the thoracic chain. The roots are given off by the tenth and eleventh ganglia, and rarely by the twelfth ganglion (4). Soon after their origin these roots converge into one trunk, which descends inferiorly, anteriorly, and medially on the anterolateral aspect of the vertebral column. It lies between the sympathetic chain, which is posterolateral to it, and the greater splanchnic nerve, which is anteromedial to it. It leaves the thoracic cavity and enters the abdominal cavity by passing through the diaphragm lateral to and accompanied by the greater splanchnic nerve to terminate in the celiac or aorticorenal ganglion.

Least Splanchnic Nerve. The least splanchnic nerve is usually formed by one root that arises from the twelfth thoracic ganglion. This nerve is a fine cord that passes anteriorly, medially, and slightly inferiorly below the lesser splanchnic nerve. It perforates the diaphragm along with the other two splanchnic nerves to enter the abdominal cavity, where it proceeds toward and ends in the aorticorenal ganglion.

Accessory Splanchnic Nerve. The accessory splanchnic nerve, when present, arises from the twelfth thoracic ganglion, has the same course as (but is independent of) the least splanchnic nerve, and ends in the aorticorenal ganglion.

INNERVATION OF THE THORACIC VISCERA

This section presents a detailed description of the anatomy of the nerves to the heart, aorta, lungs, and other visceral structures in the chest. More detailed reviews of these various aspects have been presented by Hovelacque (4), Kuntz (5), Mitchell (6), Miller (8), White and colleagues (9,10,11 and 12), Mizeres (13), and Hirsch and Borghard-Erdle (14).

Innervation of the Heart

The nerve supply of the heart is complex and, like other visceral organs, is composed of efferent and afferent sympathetic and parasympathetic efferent fibers (Fig. 60-12). Most of the nerves arise well above the cardiac level because the heart develops initially in the neck region and later migrates to the thorax (4). Efferent and afferent fibers are involved in important reflexes and are influenced in their activities by centrifugal and centripetal impulses from many parts of the body. This is not

surprising, considering the prime importance of the heart and major vessels in the body's physiologic economy, represented at every level in the nervous system (Chapter 8 reviews the central and peripheral portions of the autonomic nervous system). Here, only those aspects relevant to the innervation of the heart are considered.

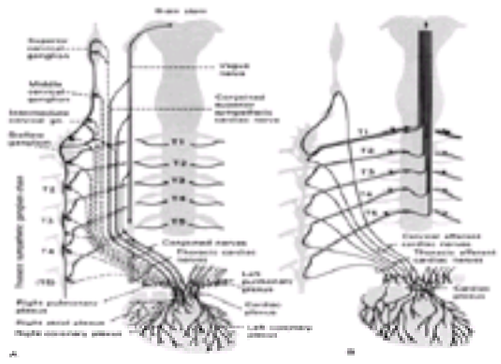

Figure 60-12. Nerve supply of the heart. **A:** On the left is shown the sympathetic preganglionic fibers (*solid lines*), which have their cell bodies in the intermediolateral column of the T-1 to T-5 segments. These preganglionic axons synapse with cell bodies of postganglionic fibers (*dashed lines*), some of which join vagal fibers to form conjoint nerves. **B:** Sympathetic afferents. These transmit nociceptive information and have their cell bodies in the dorsal root ganglion. The proximal axons synapse with dorsal horn neurons whereas the distal axons pass through the white rami communicantes and thence through the sympathetic chain and the various cardiac sympathetic nerves that contribute to the cardiac plexus and its various subsidiary plexuses that supply the heart. No interruption or synapse of these fibers is found anywhere along their course. See text for details.

Sympathetic Nerves

The sympathetic nerves to the heart contain both efferent preganglionic and postganglionic fibers and afferent fibers. The sympathetic preganglionic cardiac fibers are the axons of cells located in the intermediolateral column of the spinal cord at the level of the T-1 to the T-4 or T-5 spinal segments (in an undetermined percentage of individuals, a cranial or caudal shift of one or even two segments might be present) (6). The representation is inverted, with the fibers destined for the ventricles arising above those destined for the atria (6). As emphasized in the following section, these cells are influenced both by impulses coming from the heart and by impulses descending from the sympathetic centers in the hypothalamus, which in turn is influenced by higher centers of the brain as well as by impulses ascending from the neuraxis. These preganglionic myelinated axons leave the spinal cord via the ventral roots of the upper four or five thoracic spinal nerves and pass through the white rami communicantes to reach the paravertebral sympathetic chain. Some of these axons synapse with ganglionic cells in the ganglia that they enter, while most ascend in the trunk to end in the inferior, intermediate, middle, or superior cervical sympathetic ganglion.

The postganglionic axons have thin myelin sheaths, so thin that they appear to be unmyelinated when ordinary staining methods are used. The axons destined for the heart, aorta, and other large vessels pass through the superior, middle, and inferior cervical sympathetic cardiac nerves and the thoracic cardiac nerves. Like the parasympathetic nerves the sympathetic cardiac nerves vary in number, site of origin, size, and distribution. The following discussion is in accordance with the views of Hovelacque (4), Mitchell (6), and Mizeres (13) (Fig. 60-13).

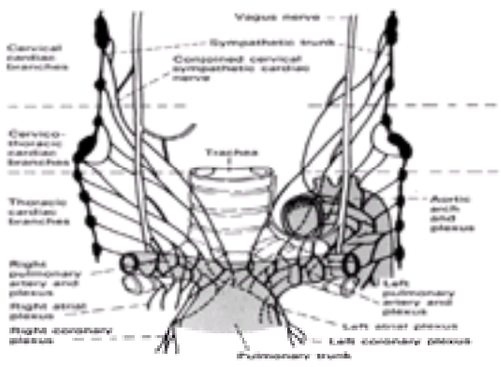

Figure 60-13. The cardiac plexus and its subsidiary plexuses. See text for details. (Modified from Mizeres NJ. The cardiac plexus of man. *Am J Anat* 1963;112:141–151.)

Superior Cervical Sympathetic Cardiac Nerve. The superior cervical sympathetic cardiac nerve originates by one, two, or occasionally three rootlets from the lower and medial parts of the superior cervical sympathetic ganglion or can arise from any part of the upper cervical sympathetic chain, from its upper pole down through the level of the lower border of the C-6 vertebra (5). The rootlets often unite and soon thereafter often join with a corresponding cervical vagal branch to form a conjoined nerve that descends behind the common carotid sheath and its contents near the main sympathetic trunk and laterally through the trachea and esophagus. *En route*, it communicates through slender filaments with the pharyngeal, laryngeal, carotid, and thyroid plexuses and with other cervical cardiac nerves. It then proceeds behind the ipsilateral subclavian artery at the root of the neck to reach the cardiac plexuses.

On the right side the nerve passes posterolateral to the innominate artery and aortic arch to end in the cardiac plexus. On the left side the nerve is in contact with the left side of the left common carotid artery and passes between this and the left subclavian artery or around the root of the latter vessel before curving downward across the left side of the aortic arch to the cardiac plexus. This nerve is often connected with the middle, or inferior, group of cardiac branches of the left vagus nerve somewhere between the root of the neck and the aortic arch, and always communicates with the middle and inferior cervical sympathetic cardiac nerves or with vagal branches. As described in the following sections, as these partially commingled nerves descend across the ipsilateral side of the aortic arch they give off three to six filaments, which form the preaortic plexus.

Middle Cervical Sympathetic Cardiac Nerve. The middle cervical sympathetic cardiac nerve originates by rootlets from the middle cervical ganglion or from the adjacent part of the sympathetic trunk and also receives rootlets contributed by the intermediate cervical (vertebral) sympathetic ganglion. Mitchell (6) stated that this is the largest of the sympathetic cardiac nerves. On the right side the nerve enters the thorax behind the subclavian and innominate arteries and reaches the cardiac plexus by passing between the tracheal bifurcation and aortic arch. On the left side it runs between the left common carotid and subclavian arteries or around the root of the latter and crosses the left side of the aortic arch to reach the cardiac plexus. Mitchell (6) and Mizeres (13) agree that often this nerve cannot be distinguished as a complete and separate entity at the level of the aortic arch because of its intercommunication with other sympathetic and vagal cardiac branches. On both sides the nerve communicates with the thyroid, tracheal, esophageal, and aortic nerves and with filaments from the left recurrent laryngeal nerve. The nerve furnishes one or two filaments to the preaortic plexus.

Inferior Cervical Sympathetic Cardiac Nerves. The inferior cervical sympathetic cardiac nerves consist of a variable number of filaments arising from the stellate ganglion, the intermediate cervical (vertebral) sympathetic ganglion, and the ansa subclavia. When the inferior cervical and first thoracic ganglia are not fused into the stellate ganglion, the inferior cervical cardiac nerves arise from separate filaments from each ganglion. Their course is similar to that of the middle cervical sympathetic cardiac nerve. Mizeres (13) pointed out that, because these branches often arise from the sympathetic trunk at the level of the C-7 and C-8 and T- 1 vertebrae (which include the stellate ganglion, ansa subclavia, and vertebral or intermediate ganglion), they should be called the *cervicothoracic cardiac sympathetic nerves*. These nerves often fuse with the vagal branches to become conjoined nerves that pass inferiorly by coursing between the aorta and the bronchi to contribute to the cardiac and both pulmonary plexuses and to the plexus of the aortic arch, with some proceeding directly to the coronary plexuses. An inconstant communication

exists between these nerves and the phrenic nerves.

Thoracic Cardiac Sympathetic Nerves. The cervical sympathetic cardiac nerves were recognized nearly 400 years ago by Fallopius (c. 1600 ad) and by many others thereafter. It was not until 1927, however, that the thoracic sympathetic cardiac nerves were identified. Their clinical importance was emphasized independently and simultaneously by Braeucker (15) and by Ionesco and Enachesco (16), although Mitchell (6) pointed out that they were noted in a calf by Weber (1815) and in humans by Swan (1830). Obviously, these small anatomic structures are important clinically because they provide direct connection between the sympathetic trunk and the cardiac plexus. Usually three, four, or five rather slender branches on each side originate from the T-2 to the T-4 or T-5 (rarely the T-6) sympathetic ganglia, or from the interganglionic portion of the sympathetic trunk.

These nervelets pass anteriorly and medially; some enter the cardiac plexus directly or unite with neighboring filaments destined for the trachea, esophagus, aorta, or pulmonary structures, and then separate again as they approach the heart to contribute to the cardiac plexus. Mizeres (13) found that nervelets on the right side fuse immediately with at least one of the cervicothoracic cardiac sympathetic nerves and with one of the thoracic cardiac vagal nerves, and contribute directly to the right pulmonary and atrial plexuses. In contrast, on the left side, they do not fuse but proceed individually and send filaments into the plexus on the arch of the aorta, directly into the thoracic vagal trunk, and also to the left pulmonary and atrial plexuses.

Cardiac Branches of the Vagus Nerves

The vagus nerves that supply the heart and thoracic aorta have both preganglionic parasympathetic fibers and afferent fibers. The parasympathetic preganglionic fibers are contained in the vagus and in the cranial part of the accessory nerve that joins the vagus. The cell bodies of these preganglionic parasympathetic fibers are located in the dorsal motor nucleus of the vagus, which is an elongated structure that extends inferiorly to the upper cervical part of the spinal cord. These preganglionic axons course through each vagus nerve and through the cardiac vagal nerves on both sides to end in the terminal extrinsic ganglia in the cardiac plexus or in the small intrinsic cardiac ganglia in the subepicardial tissue of the heart and the myocardium. The finely myelinated preganglionic parasympathetic axons synapse with the cell bodies of the thinly myelinated or unmyelinated postganglionic fibers; these are short and, in contrast to the sympathetic postganglionic fibers, have a rather circumscribed distribution.

The vagal cardiac branches arise both in the neck and thorax and vary in size, number, and distribution. Nevertheless, it is generally agreed that these vagal cardiac nerves can be divided into three groups: the superior [referred to by Mizeres (13) as the cervical vagal cardiac nerves]; the middle or cervicothoracic vagal cardiac nerves; and the lower or thoracic vagal cardiac nerves.

Superior (Cervical) Vagal Cardiac Nerves. The superior vagal cardiac nerves originate from any part of the cervical part of the vagus as far inferiorly as the lower border of the C-6 vertebra (13). In some instances, two or three filaments arise just below the superior laryngeal nerve, whereas in others the vagus gives off only a single branch. In any case, they soon coalesce to form a single nerve; as mentioned previously, this invariably joins the superior cervical sympathetic cardiac nerve to form a conjoint nerve. The rootlets of the nerve itself often communicate with the pharyngeal and superior laryngeal nerves and occasionally with the carotid nerve. Mizeres (13) found that the right branch usually courses posteriorly to the aorta and enters the right pulmonary plexus, while the left branch descends anteriorly to the carotid sheath and arch of the aorta, contributing to its plexus and to the coronary plexuses. Occasionally both course anteriorly to the aortic arch.

Middle (Cervicothoracic) Vagal Cardiac Nerves. These nerves can consist of one, two, or three rootlets arising from the vagus in the lower half or third of the neck. They almost always communicate with the cervical sympathetic cardiac nerves and not infrequently course as conjoined nerves before reaching their destination. If these nerves remain separate they pass directly to the cardiac plexus, lying posterolaterally to the innominate artery and aortic arch on the right side and laterally to the left common carotid aortic arch on the left side. Mizeres (13) found that the right cervicothoracic vagal cardiac nerve usually arises from filaments from the right recurrent laryngeal nerve and from the vagal trunk at the level of the C-7 and T-1 vertebrae. Near their origin the filaments usually join the right cervical and cervicothoracic sympathetic cardiac nerves and course inferiorly as conjoined nerves posterolaterally to the innominate artery and aortic arch before reaching their destination, which is usually the right pulmonary plexus, a subsidiary of the cardiac plexus. The one or two left cervicothoracic vagal cardiac branches arise from the left vagal trunk at the level of the C-7 and T-1 vertebrae and usually course laterally to the left common carotid and subclavian arteries and then pass anteriorly to the arch of the aorta, contributing to the plexus on the arch and to the left atrial plexus.

Inferior (Thoracic) Vagal Cardiac Nerves. The two to four right thoracic vagal cardiac nerves arise from the thoracic vagal trunk between the level of the lower border of the T-1 vertebra and the pulmonary hilus. They soon join the cervicothoracic or thoracic cardiac sympathetic nerves before coursing anteriorly to the right bronchus, where some filaments join the right pulmonary plexus and others proceed to the right atrial plexus. The left thoracic vagal cardiac branches arise from the left vagus at approximately the level of the origin of the left subclavian artery and run across the left side of the aortic arch to the cardiac plexus. Mizeres (13) found that in many instances one root arises from the left recurrent laryngeal nerve and another from the left vagal trunk just below it. Of the group of filaments that arise from the left recurrent laryngeal nerve, one group courses posteriorly to the arch of the aorta and joins the left atrial plexus directly while the other group courses anteriorly to join the left pulmonary plexus and proceeds in the fold of the left superior vena cava posteriorly to reach the left atrial plexus.

Afferent (Sensory) Fibers

The sensory fibers that supply the heart and great vessels pass centrally through the vagus nerves and the sympathetic nerves. Those associated with the vagus nerves have their cell bodies in the ganglion nodosum with the distal axons passing through the vagus and the cardiac vagal nerves to terminate in the heart, while the proximal axons enter the medulla to end in the nucleus of the tractus solitarius. The afferent fibers associated with the vagus that supply the heart carry impulses concerned with the subconscious reflex mechanisms that regulate cardiac action and blood pressure. Although some have suggested that some afferent fibers in the vagus convey all nociceptive impulses from the heart, clinical evidence does not support this notion (10,11 and 12,17,18). It has been shown that interruption of sympathetic afferents that pass into spinal cord segments T-1 to T-5 produce virtually complete relief of cardiac pain in the chest, arms, and neck, thus indicating they are the primary pathways for cardiac pain (10,11 and 12,17,18). Interruption of these sympathetic afferents may not relieve pain in the lower jaw, however, and does not eliminate the dyspnea and the feeling of constriction or tightness of the throat. It is possible that these sensations, which are the earliest and most frequent symptoms of myocardial ischemia in many patients, are transmitted by vagal afferents. Moreover, studies indicate that stimulation of the cardiac vagal afferents can activate cells in the brain stem; in turn, these cells produce descending modulating impulses that inhibit high-threshold and wide dynamic range cells of spinothalamic and other ascending systems at T-1 to T-5 levels known to be involved in transmission of nociceptive *pain* information to the brain (19,20 and 21). It has been suggested that this might be one of the mechanisms for the absence of pain in patients with silent myocardial infarction (19,22) (see Chapter 61 for details).

The afferent fibers associated with the sympathetics, now commonly known as *sympathetic afferents* (23), are tonically active and not only mediate nociceptive impulses, but also mediate impulses involved in segmental and suprasegmental reflexes. These fibers are mainly excitatory in nature with positive-feedback characteristics and thus contribute to the neural regulation of circulatory functions (23). These sympathetic afferent fibers pass centrally through all the cardiac sympathetic nerves except those that arise from the superior cervical ganglia (see Fig. 60-12B). The cell bodies of these sympathetic afferents are located in the posterior root ganglia of the upper four or five thoracic spinal nerves. Their central branches course to the spinal cord dorsal horn while their long peripheral branches pass distally through the upper four or five thoracic white rami communicantes and through the upper four or five thoracic ganglia and the inferior, intermediate, and middle cervical sympathetic ganglia to reach the heart through the thoracic, cervicothoracic, and middle cervical sympathetic cardiac nerves. These peripheral branches travel uninterrupted in the ganglia or plexuses and terminate as typical sensory nerve endings in the pericardium, walls of the heart, and adventitial plexuses of the coronary arteries and the aorta. Many of these sensory fibers are of the A-d and C categories, characteristic of nociceptive pathways (see Chapter 61).

Cardiac Plexus

All vagal and sympathetic cardiac nerves and associated afferent fibers converge on the cardiac plexus, which is contained in the thoracic cavity (Fig. 60-14; see Fig. 60-13). Although it has generally been stated that the plexus lies between the concavity of the aortic arch and the tracheal bifurcation (1,26), Mizeres (13), in his careful dissection of 36 cadavers of different ages, found that the cardiac plexus lies on the anterior and posterior walls of the pulmonary trunk at its bifurcation (see Fig. 60-13). Moreover, he, like Mitchell (6), believed that although the cardiac plexus is described as consisting of superficial and deep parts, this separation is an artifact created by dissection. The plexus, in its position on the adventitial wall of the pulmonary trunk, consists of the following subsidiary plexuses: the right and left pulmonary plexuses; the right and left coronary plexuses; the right and left atrial plexuses; and a plexus on the arch of the aorta. The pulmonary plexuses and the plexus on the arch of the aorta are discussed later in this chapter.

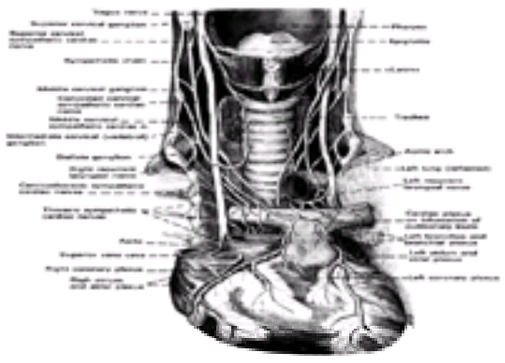

Figure 60-14. Anterior view of the chest depicting the anatomy of the nerves that contribute to the cardiac plexus and its subsidiary plexuses, including the coronary plexuses that follow the coronary vessels.

Coronary and Atrial Plexuses. The coronary plexuses are formed mainly by extensions of the right pulmonary plexus, with some contribution from the left pulmonary plexus and from the plexus on the arch of the aorta. The coronary plexuses can also receive direct contributions from the cervical and thoracic cardiac branches, and usually send filaments into the anterior surfaces of the walls of both ventricles. Each coronary plexus follows its analogous artery and its branches, giving off subsidiary plexuses throughout the heart (see Fig. 60-13 and Fig. 60-14).

The right atrial plexus is usually formed as an extension of the right pulmonary plexus, passing between the superior vena cava and aorta to end in the right atrium. The left atrial plexus is an extension of the left pulmonary plexus, coursing directly into the left posterior atrial wall and sending filaments into both posterior walls of the two ventricles. The plexus on the arch of the aorta sends filaments that course to the wall of the pulmonary arterial trunk, ending in both the left and right coronary plexuses. All these plexuses are interconnected.

Although sympathetic and vagal efferent and afferent fibers intermingle and lose their identities within the cardiac plexus, a tendency toward subdivision into right and left halves exists, from which fibers are distributed to the heart along the two coronary arteries by the left and right coronary plexuses (5,6). The right atrial and right coronary plexuses distribute mainly to the right atrium and ventricle, while the left plexuses are distributed to the corresponding parts of the heart on the left side.

The coronary nerves give off branches that ramify in the subepicardial tissues that overlie all the cavities of the heart. Whereas the larger branches of the nerves lie alongside the main coronary arteries, many of the smaller nerves run independently of vessels over the surface of the heart.

Several small extrinsic cardiac ganglia, in which a proportion of the vagal preganglionic fibers synapse with short postganglionic fibers, are present in the cardiac plexus. The largest is usually called the *ganglion of Wrisberg*, and is seldom more than 2 or 3 mm in diameter (6). Mizeres (13) found that this ganglion is not constant. The small intrinsic cardiac ganglia are located in the subepicardial tissue of the heart and, less commonly, in the myocardium.

Distribution of Nerves in the Heart. The heart is richly supplied with motor and sensory nerves containing myelinated and unmyelinated fibers derived from both sympathetic and vagus (parasympathetic) nerves. Hirsch and Borghard-Erdle (14) suggested that for purposes of orientation, the innervation of the heart can be categorized according to the distribution of the nerves to the several anatomic structures: the coronary arteries, the myocardial muscle tissue, the conducting system, and the supporting stroma, including the valves and their leaflets.

Innervation of the Coronary Arteries. Coronary arteries and their branches have abundant motor and sensory nerves contributed by both sympathetic and parasympathetic nerves (5,6,24). Indeed, it has been authoritatively stated that the coronary arteries in the heart have the richest nerve supply of all the arteries in the body (25). The following summary is based on the findings of Hirsch and Borghard-Erdle (14) in their studies of the human heart (except as otherwise noted). The adventitial fibrous tissue of the arteries has many large and small rounded nerve trunks containing myelinated and unmyelinated nerve fibers. These nerves accompany the arteries toward the endocardium and, at the arteriolar level, are diminutive round or flat structures. The thicker nerve trunks, which have vagal fibers, supply the adventitial and periadventitial fibrous tissue, while the thinner sympathetic nerves innervate the smooth muscle cells of the media of the coronary arteries to the level at which the contractile tissues disappear.

The coronary arterioles and precapillary blood vessels are supplied only by vagal fibers. At the precapillary level the vagal fibers have flat segments, but beyond this level they continue into or send terminal branches into the nearby myocardium, where they end either in a bulbous tip or in a brushlike terminus amidst the myocardial syncytium. These nerves have fine and slightly coarser fibrils that are in close continuity with the myocardial cells.

Innervation of the Myocardium. In addition to contributions by the coronary nerves, some large and small nerve trunks enter the myocardium directly and not in association with branches of the coronary arteries. These nerves divide dichotomously at considerable intervals in the heart muscle and some rather large ones reach the endocardium to divide further, being distributed in muscle tissue near the endocardial lining. After they have penetrated into the myocardium these nerves have scanty perineurium, and the fine nerve fibrils in them appear to extend directly into the contiguous myocardial cells. Motor end-plates resembling those of cell muscle have not been found in studies of the human heart (14).

The existence of sensory nerve endings in the heart was first suggested by Berkley (26) in 1894, and subsequently by others, who demonstrated that these sensory nerves are associated with both the vagus and sympathetic nerves to the heart (19). Early work by Wollard (25) and later by Nonidez (27), based on nerve degeneration following bilateral stellectomy, suggested that the largest proportion of cardiac sensory nerve endings are of vagal origin. Studies entailing the resection of the thoracic ganglia, however, showed that a significant proportion are associated with sympathetic nerves and are made up of myelinated and nonmyelinated afferents (28,29).

In the heart the sensory fibers terminate as complex unencapsulated endings that are usually distinguished as either diffuse or compact (19,27,29,30). The sensory nerve terminals exist in the subendocardial tissue as well as in the depth of the myocardium and around the coronary vessels. These sympathetic afferents innervate the same regions and layers of the heart as the vagal fibers. Moreover, the sympathetic afferents and endings frequently lie side by side with afferent fibers and endings of the vagus nerves (30).

Innervation of the Conducting System. Much evidence has shown that the sinoatrial node of Keith and Flack, the atrioventricular node of Tawara, and the atrioventricular bundle of His are abundantly supplied with nerve fibers and terminal networks around their constituent cells (5,6,14). Clusters of nerve cells are closely associated with these nerve bundles and plexuses, and belong to the intrinsic cardiac ganglia (5,6,14).

Innervation of Stroma Tissues. The fibrous tissues about the coronary arteries and their branches, down to the precapillary level, have a rich nerve supply that is mainly vagal. Nerve trunks extend throughout the myocardium, divide dichotomously, and split into compound terminal plexuses (14). The presence of myelinated fibers in nerves of supporting noncontractile tissues suggests that they are sensory fibers. Fibers in these nerves and their branches innervate the supporting stroma as well as form the endocardial plexus that extends into the leaflets of the valves.

Pericardium

The innervation of the pericardium varies according to its two major layers. The serous pericardium, which is composed of a single layer of mesothelial cells that covers the atria and the ventricles and extends beyond along the great vessel for 2 or 3 cm, is supplied by nerves derived from the cardiac, coronary, and epicardial plexuses containing sympathetic, parasympathetic, and afferent fibers. The serous layer that lines the inner surface of the fibrous pericardium, often called the *parietal pericardium*, together with the fibrous pericardium is supplied by sensory fibers derived from the phrenic nerves and the anterior parts of the thoracic intercostal nerves, and also receives sympathetic and vagal fibers through the cardiac plexus (6). Nociceptive information is transmitted by the sensory fibers principally in the phrenic nerves, by a few fibers from the intercostal nerves, and perhaps by sympathetic afferents.

Innervation of the Thoracic Aorta

The ascending aorta and arch of the aorta are supplied by both sympathetic and parasympathetic vagal fibers, many of which are afferent in nature and are distributed mainly in the adventitial plexus of the ascending aorta (4,5 and 6). Some vagal twigs enter the vessel directly, and others reach it through the cardiac plexus. The sympathetic fibers for the ascending aorta and the aortic arch arise from the stellate and upper thoracic ganglia and are often incorporated in the thoracic cardiac nerves, although occasionally separate filaments can be traced directly to the aorta (6). Aortic fibers in the thoracic cardiac sympathetic nerves pass to the cardiac and preaortic plexuses without interruption and reach the adjacent parts of the aorta in fine short branches (Fig. 60-15). The various aortic vagal and sympathetic filaments break up to form terminal plexuses in the walls of the aorta. The adventitial plexus is especially well marked around the ascending aorta, which is a special pressoreceptor area.

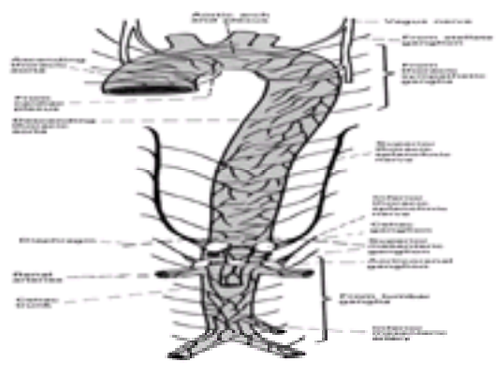

Figure 60-15. Innervation of the thoracic aorta. See text for details.

The small aortic arch body is a chemoreceptor structure similar to the carotid body and is usually located in the angle between the aortic arch and the ligamentum arteriosum and occasionally found at other points in the adventitia of the aortic arch. Additional small masses with similar morphologic characteristics sometimes exist in or adjacent to the adventitia of the ascending aorta or of the innominate artery.

Extensions from the aortic arch plexus continue along and supply the intrathoracic parts of the innominate, left common carotid, and left subclavian arteries.

The descending thoracic aorta is innervated by a variable number of direct filaments from the T-4 and T-5 sympathetic ganglia and from the greater splanchnic nerves or their rootlets of origin. Mitchell (6) pointed out that, in approximately 10% of individuals, on the right side and less often on the left side, a delicate paraaortic nerve is found lying along the posterolateral aspect of this part of the aorta and helps to supply it. This nerve interconnects the lowest thoracic cardiac nerve and the lower aortic and esophageal branches, and rarely extends above the level of the T-4 or T-5 vertebra.

Afferent fibers associated with both the vagus and sympathetic nerves supply the ascending aorta and arch of the aorta. White (12), White and associates (11,18), Bonica (17), and others (31) suggested that the afferents that transmit nociceptive impulses from the ascending aorta and aortic arch, as well as from the descending aorta, pass through the neuraxis via sympathetic pathways. They produced symptomatic relief of the severe pain of aortic aneurysm by injecting the upper thoracic sympathetic ganglia with a local anesthetic. Bonica (17) followed the diagnostic and prognostic injections with block of the sympathetic chain by alcohol. Injection of the ganglia on the right side is indicated for pain caused by aneurysm of the ascending aorta, but, if the arch or descending aorta is involved, the ganglia must be blocked on the left side or bilaterally to provide relief (17,18,31) (see Chapter 102).

Reichert (personal communication, 1952) relieved severe pain from an aneurysm involving the lower part of the thoracic aorta by injecting the T-2 to T-6 ganglia with a local anesthetic. In one of White's patients, severe pain produced by a large aortic arch aneurysm that expanded upward into the thoracic inlet was referred to wide areas supplied by the cervical and intercostal nerves, suggesting it might be caused by pressure on neighboring structures, yet it was completely relieved by alcohol injection of the upper thoracic sympathetic ganglia (18).

The branches of the descending thoracic aorta, the most important of which are the bronchial, pericardial, mediastinal, esophageal, phrenic, posterior intercostal, and subcostal, all receive prolongations from a periarterial nerve plexus around the thoracic aorta. The bronchial arteries receive reinforcing filaments within the lungs. The esophageal arterial plexus is supplemented by twigs from the esophageal plexus, and branches of the phrenic nerves have been noted close to the pericardial and phrenic arteries, helping to innervate them. The posterior intercostal and subcostal arterial plexuses are also joined by small bundles of fibers from the adjacent intercostal and subcostal nerves, which contain a relatively high complement of sympathetic fibers, and from the thoracic splanchnic nerves at the points where the vessels pass behind them (5,6).

Innervation of the Lungs

The lungs, including the trachea and bronchi, are innervated by both sympathetic and parasympathetic nerves, which contain efferent and afferent fibers. The nerves to the lungs reach the pulmonary vessels and lung tissue through the pulmonary plexuses. These are apart from filaments supplying the extrapulmonary parts of the bronchial arteries, which as noted previously are extensions from the parent periaortic plexus surrounding the descending thoracic aorta.

Pulmonary Plexuses

The pulmonary plexuses are composed of larger vagal and smaller sympathetic contributions. The sympathetic pulmonary nerves are the axons of postganglionic sympathetic fibers that have already synapsed in sympathetic ganglia with preganglionic fibers. The cell bodies of the latter are located in the intermediolateral column of the spinal cord at the level of the T-2 to T-6 or T-7 segments. The synapse with postganglionic fibers takes place in the T-2 to T-6 or T-7 thoracic ganglia and occasionally in the stellate ganglion. The postganglionic fibers pass anteriorly and inferiorly and often merge with the thoracic cardiac, aortic, and esophageal branches and separate from them as they approach their destination. The sympathetic nerves, which also contain afferent nerves, run primarily to the posterior pulmonary plexus but also travel to the anterior pulmonary plexus (Fig. 60-16A). They unite with the corresponding branches of the vagus and are distributed along with them to the vessels, bronchi, and glands in the lungs.

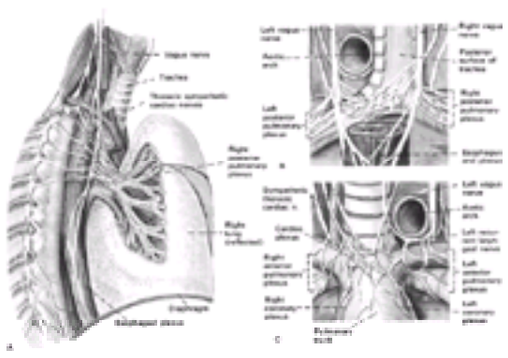

Figure 60-16. Anatomy of the pulmonary plexuses and their distribution. **A:** Right parasagittal view showing origin, course, and termination of the nerves that contribute to the right pulmonary plexus. **B:** Posterior view. **C:** Anterior view of the trachea and two primary bronchi to show relation of the pulmonary plexus to these structures.

The vagal pulmonary nerves contain both preganglionic and afferent fibers, the former originating in dorsal vagal nuclei and the latter having their cell bodies in the inferior vagal (nodose) ganglia. Just above the root of the lung each vagus nerve divides into smaller anterior and larger posterior parts, which embrace the lung root (Fig. 60-16B and Fig. 60-16C). Most of the pulmonary branches of the vagus derive from the larger part of the nerve lying behind the root of the lung but three or four branches are also given off before the main nerve splits, and smaller twigs are supplied by the smaller part of the nerve that passes anterior to the lung (4,5 and 6). The various branches form smaller anterior and larger posterior pulmonary plexuses. The nerves do *not* subdivide and reunite frequently, as shown in most illustrations, but rather they spring from the parent nerves almost perpendicularly and run straight outward anterior and posterior to the roots of each lung (6). They do divide as they enter the lung, however, and become dispersed around the vascular and bronchial structures. The posterior pulmonary branches are much more conspicuous than the anterior branches and receive direct or indirect contributions from the upper thoracic sympathetic ganglia.

The pulmonary plexuses always communicate with the cardiac, aortic, and esophageal plexuses, and the left anterior pulmonary plexus is often interconnected by delicate strands with the left phrenic nerve. The pulmonary plexuses proceed distally and, immediately after entering the lungs, the nerve filaments become partly segregated into groups that accompany the main bronchi and vessels and bronchial arteries. No plexus formation is noted around these structures, with the nerve bundles merely winding around them and giving off branches at irregular intervals. A plexus formation is well in evidence, though, by the level of the third-order bronchi and their accompanying vessels (6). Segregation between the perivascular and peribronchial nerves and plexuses is not at all complete; they are frequently interconnected by small bundles of fibers. Coburn (32) has described preganglionic vagal fibers synapsing in ganglia along the tracheobronchial tree.

The supply to the various vessels within the lungs varies in richness: the small bronchial arteries have the best supply; the pulmonary arteries are less richly innervated; and the pulmonary veins have a poor supply limited to their extrapulmonary parts and large intrapulmonary branches (6). The larger bundles of pulmonary arterial nerve fibers are located on the side of the vessels facing the bronchi and can be traced to the extremities of these vessels, with some extending beyond them to the visceral pleura (6). The filaments passing through the bronchial arteries come from the adjacent extrachondral parts of the bronchial nerve plexus. Although some investigators have described rich nerve plexuses around the walls of the capillaries in the lung parenchyma (33), others could not confirm these findings (34).

Both myelinated and unmyelinated fibers have been found in the pulmonary nerves and plexuses. Some of these fibers have sensory receptors in the pulmonary blood vessels and are involved in reflex control of the pulmonary circulation, which apparently has vasoconstrictor and vasodilator fibers supplied by the sympathetic and parasympathetic efferent nerves, respectively.

The lung also has two types of receptors that probably have nociceptive function: the type J receptors with C afferents, and the *lung irritant receptors* with afferents in the A-d range all running in the vagus nerves (35). The type J receptors are located in the interstitial space close to the capillaries, whereas the lung irritant receptors are found in the epithelial lining of the lung and its airways. These are activated by various stimuli that produce mechanical distortion within the lung, such as pulmonary congestion, microembolism, atelectasis, pneumothorax, and chemical irritants. It is likely that this pain, caused by mechanical or chemical damage of the lung, is mediated by these A-d and C fibers (35).

Larynx, Trachea, and Main Bronchi

Larynx. The nerves to the larynx are derived from the vagus nerve by way of the internal and external branches of the superior laryngeal nerve and by the recurrent laryngeal nerves. The internal laryngeal branch, which is sensory, enters the larynx by piercing the posterior part of the thyrohyoid membrane above the superior laryngeal vessels and divides into three branches. One is distributed to both surfaces of the epiglottis, a second to the aryepiglottic fold, and a third, the largest, supplies the mucous membrane over the back of the larynx and communicates with the recurrent laryngeal nerve. The external laryngeal branch supplies the cricothyroid muscle. The recurrent nerve passes superiorly beneath the inferior border of the inferior pharyngeal constrictor muscle immediately dorsal to the cricothyroid joint. It supplies all the muscles of the larynx except the cricothyroid. The sensory branches of the laryngeal nerves form subepithelial plexuses from which fibers end between cells that cover the mucous membrane. Fibers from the sympathetic nerves supply the blood vessels and glands of the larynx.

Trachea and Main Bronchi. The trachea and main bronchi are supplied by filaments from the vagus and the recurrent laryngeal nerves and by fibers from the sympathetic trunk. These filaments are distributed to the trachealis muscles and between the epithelial cells. As mentioned in Chapter 8, the sympathetic postganglionic nerve fibers produce relaxation of the trachealis muscles and increase the size of the trachea and bronchi, whereas the parasympathetic nerves have a bronchoconstrictor effect. Morton and colleagues (36) demonstrated that the sensory nerves that transmit nociceptive impulses are afferents of the vagus nerves and their branches. They carried out experiments in human volunteers in which electric stimulation of the tracheobronchial tree through a bronchoscope produced pain that was referred to the anterior chest or lower part of the neck (Fig. 60-17). They noted that points of the areas of reference were ipsilateral to the site of stimulation. Moreover, they demonstrated in patients with carcinoma that section of the vagus below the recurrent laryngeal nerve but above the pulmonary plexus abolished the pain on the side of vagotomy (37). In a few cases, following section of the one vagus nerve, pain of tracheobronchial origin was referred to the contralateral side, probably because of interconnection between nerves of each side.

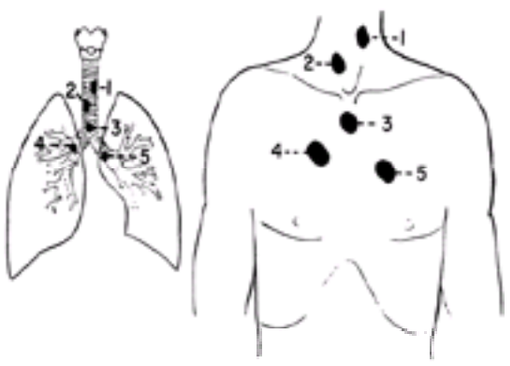

Figure 60-17. Pain referred to the anterior chest stimulation of the mucous membrane of the tracheobronchial tree. The areas of pain are ipsilateral to the sites of stimulation. (Modified from Morton DR, Klassen KP, Curtis CM. Clinical physiology of human bronchi. I. Pain of tracheobronchial origin. *Surgery* 1950;28:669–704.)

Similar findings were reported by Teodori and Galletti (38). They noted that electrical stimulation of the normal mucosa produces little pain, but stimulation in patients with inflammation of the mucosa of the tracheobronchial tree produced pain in the anterior chest wall, even when the stimulus was applied to the posterior wall of the trachea and bronchi. When the stimulation was applied to the carina or at the beginning of the primary bronchi, painful sensation was localized in the parasternal region occupying the area between the first and the fifth intercostal spaces, whereas when the stimulation was applied more distally the pain extended as far as the sixth intercostal space. They also noted a decrease in electrical skin resistance limited to the T-2 to T-5 segments. In subjects with inflammation of the tracheobronchial mucosa, the stimulation was followed hours later by cutaneous hyperalgesia.

Pleura

The visceral pleura is supplied by sympathetic fibers that have a vasomotor function. It has afferent fibers, but these have no nociceptive function because the visceral pleura is insensitive to noxious stimuli and pain does not arise from disorders of the visceral pleura (39,40). The visceral pleura also receives parasympathetic fibers through the pulmonary plexuses (35,36).

The parietal pleura is supplied by the intercostal nerves on its lateral aspects, by the T-1 spinal nerve on its apex, and by the phrenic nerves on the diaphragmatic surface (Fig. 60-18). In addition, the parietal pleura receives parasympathetic and sympathetic nerves through the pulmonary plexuses, and these nerves accompany the ramification of the bronchial arteries.

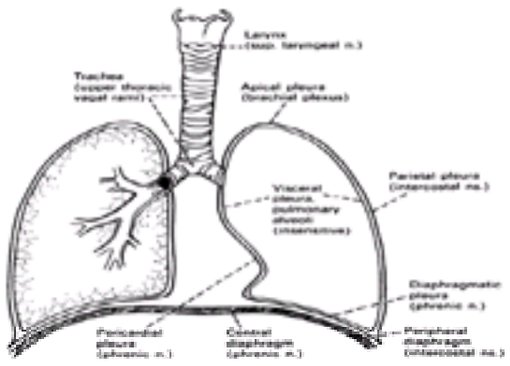

Figure 60-18. Schematic of the sensory nerve supply to the tracheobronchial tree, parietal pleura, upper surface of the diaphragm, and the diaphragmatic pleura. (Modified from White JC. Sensory innervation of the viscera: studies on visceral afferent neurons in man based on neurosurgical procedures for the relief of intractable pain. In: Wolff HG, Gasser HS, Hinsey JC, eds. *Pain*. Baltimore: Williams & Wilkins, 1943:373–390.)

HISTORY AND EXAMINATION

A general consideration of the approach to diagnosing the specific cause(s) of pain in the chest is presented here. It is intended as a supplement to Chapter 12, which contains a detailed discussion of the evaluation of patients with pain. Comments made here are relevant to pain in the chest. Chapter 61, Chapter 62 and Chapter 63 provide a more detailed discussion of diagnostic procedures for patients with pain of cardiac and aortic origin, pain of pulmonary origin, and pain of esophageal origin. This section and Table 60-1 are intended to help determine diagnostic possibilities, followed by a more detailed assessment of the probable cause(s) of pain in the chest.

TABLE 60-1. General physical examination for chest pain [a]

In many instances, the diagnosis of chest pain becomes relatively simple after the patient relates the story of the pain. Occasionally, the cause is difficult to determine because so many lesions can cause similar pain. This is not surprising when one considers that the afferent nerves of the heart, aorta, esophagus, lungs, and upper chest wall have a common pathway in the spinal cord, and that visceral pain has somewhat similar qualities regardless of the organ affected (17,41). The clinical application of this knowledge indicates that neither the location, quality, or area of reference of chest pain arising from these organs can denote the origin or nature of the underlying disorder with certainty. This information can only be obtained from a thorough history of the pain, particularly of the factors or circumstances that reproduce, aggravate, or relieve the pain, and from the history and character of the associated signs and symptoms. Diagnostic tests can also help confirm clinical impressions.

Of course, the approach to the diagnosis of chest pain varies according to the circumstances in which patients are seen. Patients who present in acute distress require a vigorous investigation performed with dispatch, slanted initially either to establish or exclude life-threatening disease of the cardiorespiratory systems, such as myocardial infarction, large pulmonary embolism, and dissecting aneurysm of the aorta (41). The approach in such acute situations should be brisk; common sense dictates that in some circumstances (e.g., patients are in a state of collapse) immediate supportive treatment, such as clearing of the airway, adequate oxygenation, and maintenance of cardiac action and blood pressure, takes precedence over the formulation of an exact diagnosis.

With most patients who are seen in the physician's office or who present themselves at the emergency room, time can be taken to obtain an abbreviated history and physical examination and to perform a few tests, such as electrocardiography and chest radiography, before transferring patients to an intensive care unit. Patients with obvious acute myocardial infarction should be sent to a coronary care unit without delay, accompanied by someone who can perform cardiopulmonary resuscitation.

By contrast, with patients who come to the physician for consultation after having experienced chest pain that has dissipated, or who are in between episodes of recent pain, it is not necessary to hurry. The physician should take the time to carry out a detailed history and comprehensive physical examination supplemented by appropriate radiographic, electrocardiographic, and other laboratory tests and therapeutic trials. In such cases diagnosis can be made at the first visit or thereafter, when additional tests and trials have been done.

In assessing patients with chest pain, the following characteristics of the pain should be elicited through a detailed and meticulous history: speed of onset of the pain, site, radiation, quality, and intensity of the pain, temporal characteristics (i.e., is the pain continuous or episodic and, if intermittent, what is the duration of each episode or attack? What time of day is it worse and when is it better? What is the time-intensity curve and what is its relationship to meals and position of the body?). Patients should be specifically asked to indicate the precise effect on pain of physical exertion, mental stress, breathing, coughing, straining, swallowing, defecation, urination, motion of the trunk, and motion of the neck (forward flexion, lateral flexion, extension, rotation). What effect does motion of the upper extremities, such as swinging of the arms or lifting, have on the pain? How does walking influence the pain?

Perhaps the most important information to elicit is determination of those activities or factors that aggravate the pain, relieve the pain, and have no influence on the pain (17,41). Thus, a history of sharp aggravation by breathing, coughing, or other respiratory movements usually indicates disorders of the pleura, pericardium, mediastinum, or chest wall. Similarly, the pain that regularly appears with rapid walking and vanishes in a few minutes on standing suggests a diagnosis of angina pectoris, although orthopedic disorders can also cause such chest pain.

Also important is obtaining a history of any *associated phenomena* such as the following: palpitation, dyspnea, coughing, expectoration, or hemoptysis, suggestive of lung disease; nausea, vomiting, distension, or abdominal tenderness, suggestive of gastrointestinal disease; and dysphagia or odynophagia (pain on swallowing), suggestive of esophageal disorders. Following elucidation of the characteristics of the pain, the past medical and family histories, and demographic data, a physical examination is carried out. Table 60-1 suggests the most important parts of such an examination.

The following points can help the clinician to determine the probable cause of pain and to make a tentative diagnosis. Bonica (17) and Levene and associates (41) have suggested that it is most practical to consider chest pain in several categories: (a) central chest pain caused by disease of viscera within the chest; (b) lateral pleuritic, musculoskeletal, or neurologic chest pain; (c) chest pain referred from disorders of structures outside the chest; and (d) chest pain primarily of psychological origin.

Visceral (Central) Chest Pain

Structures producing central chest pain include the esophagus, the myocardium, the trachea and bronchi, the pericardium, the pulmonary arteries, and the aorta, in approximately that order of frequency (41). The following points in the history help to determine the causative factor.

History

Speed of Onset. The sudden and severe onset of pain suggests dissecting aneurysm, ruptured esophagus, or pulmonary embolism. A less abrupt onset occurs with acute myocardial infarction, reflux esophagitis, and pneumothorax.

Location and Radiation. Retrosternal chest pain with radiation to the jaw and arms suggests myocardial ischemia. Radiation of the pain to the back should suggest esophagitis, esophageal spasm or rupture, pancreatitis, or dissecting aortic aneurysm.

Duration. Stable angina pectoris is characterized by short-lived pain, while the pain of unstable angina or myocardial infarction lasts longer, frequently much longer. Pain coming from other organs also lasts for minutes to hours.

Aggravating Factors. Pain brought on by general body exertion, emotional stress, or anger is considered to be caused by myocardial ischemia until proven otherwise. Exertion is a nonspecific stimulus, however, that can produce effects other than those on the cardiovascular system. For example, pain occurring with unaccustomed snow shoveling might be anginal but could also be caused by strain on the pectoral muscle or sternoclavicular joint. Pain after meals can either be esophageal or myocardial in origin, while pain after vomiting implicates the esophagus.

Effects of Posture. Pain that worsens on bending over, lying down, or stooping should suggest gastroesophageal reflux, pericarditis, or pancreatitis. Pain worsened by standing suggests a pneumothorax or emphysema. Pain made worse by deep breathing, coughing, sneezing, or laughing and relieved by quiet breathing suggests pleuritis (pneumonia, infarction, infectious process), or it can suggest fracture of the ribs, cartilages, sternum, or vertebra, or muscle strain.

Pain-Relieving Factors. Pain relieved by antacids indicates an upper gastrointestinal pathophysiologic process. Nitroglycerin relieves the pain of stable angina completely, partially relieves the pain of unstable angina or esophageal spasm, but does not relieve the pain of myocardial infarction.

Preceding Symptoms of Disease. Preceding or concomitant symptoms should direct attention to various organs: heartburn to the esophagus, angina to the heart, and alcohol abuse to the pancreas (41). Dyspnea should suggest left-sided heart failure from myocardial infarction or right-sided heart failure from massive pulmonary embolism. Recent postoperative immobilization or the use of contraceptive drugs should raise the suspicion of pulmonary embolism (41).

Physical Examination

Central chest pain associated with shock should suggest the following, in approximate order of frequency: acute myocardial infarction, massive pulmonary embolism, pericarditis or tamponade, dissecting aortic aneurysm, and acute pancreatitis (41).

Jugular venous distension implicates the cardiovascular system (myocardial infarction, pericardial tamponade, pulmonary embolism). Kussmaul's sign (distension of the jugular veins on inspiration) is seen in tamponade caused by pericarditis or mediastinal tumor.

Significant pulsus paradoxus (marked decrease in the pulse volume during inspiration) should immediately raise suspicion of pericardial tamponade unless airway obstruction is present.

Asymmetric pulses in a patient with central chest pain suggest dissecting aneurysm as the first consideration (41). Cardiac arrhythmias and gallop rhythms are commonly seen in acute myocardial infarction. Moreover, the murmur of mitral regurgitation is heard in myocardial infarction, whereas the initial appearance of the murmur of aortic regurgitation is a clue to the presence of a dissecting aortic aneurysm.

Systemic hypertension is seen in both acute myocardial infarction and dissecting aneurysms, while subcutaneous emphysema indicates a ruptured viscus.

A pericardial friction rub occurring simultaneously with the onset of pain suggests a dissecting aortic aneurysm or acute pericarditis, whereas that beginning more than 24 hours after onset of pain suggests acute myocardial infarction.

Lateral Pleuritic, Orthopedic, and Neurologic Chest Pains

The most common structures that cause pain in the lateral chest wall are disorders of the chest wall, pleura, or thoracic spine.

History

Abrupt onset of lateral chest pain suggests a torn muscle, rib fracture, pulmonary embolism, or pneumothorax, in approximately that order (37). Aggravation of the pain by movement of the thorax during deep breathing or relief by immobilization suggests a rib fracture or torn muscle.

Purulent sputum accompanying the pain suggests bronchopulmonary infection, and bloody sputum suggests pulmonary embolism. Immobilization after recent operation and use of birth control pills can precede pulmonary embolism, whereas preceding symptoms of coryza or malaise suggest infection.

Segmental pain followed by a vesicular eruption suggests the onset of acute herpes zoster (see Chapter 22). Pain localized to the sternal region is usually caused by fracture of the sternum, chondritis, muscle strain, myofascial pain syndromes, mediastinal tumor, referred pain of herniated cervical disk, foreign body, or carcinoma of the tracheobronchial tree, or diseases of the esophagus (retroesophageal esophagitis, carcinoma, ulcer). Less common causes are necrosis of the sternum, multiple myeloma, mediastinal tumors, mediastinitis, or mediastinal abscess.

Localized pain in the side of the chest is usually caused by muscle strain, myofascial syndromes, fractured ribs (trauma, carcinoma, osteoporosis), pleuritis, pneumonia, infarction, carcinoma, deep axillary abscess, diaphragmatic pleurisy, subphrenic abscess, and empyema. Less common causes include uncommon lesions of the ribs such as actinomycosis, myeloma, and periostitis, neurofibromata, epidemic pleurodynia, distension of the colon (left side), cholecystitis (right side), disseminated lupus erythematosus, and neurosis.

Pain localized in the back of the chest is usually caused by postural deformities, postural osteoarthritis, facet syndrome, and other disorders of the vertebral column, osteoporosis of the vertebrae or ribs, fracture of the vertebrae or ribs, displaced ribs, myofascial syndromes (particularly levator scapulae, latissimus dorsi, multifidi, rhomboids, and iliocostalis thoracis), fracture of the scapula, tuberculosis of the spine (Pott's disease), tumors of the vertebrae or posterior portion of the ribs, congenital disorders of the spine or thorax, osteomyelitis of the vertebrae, infectious arthritis, Kümmell's disease (traumatic spondylitis), osteitis deformans (Paget's disease), infectious vertebral epiphysitis (Scheuermann's disease), and herniated thoracic disk.

Physical Examination

Acute tenderness to palpation of the painful site strongly suggests that the lesion is in the chest wall, the site of tenderness indicating the diagnosis. Lumps suggest fractures, rib tumors, or inflamed costochondral or chondrosternal joints. In patients with rib fractures, mild compression of the ribs both in the lateral and anteroposterior planes produces intense pain.

Palpation of the muscles of the chest wall can reveal the presence of trigger areas indicative of myofascial pain syndromes. Tensing and stretching of each of the various muscles of the chest wall will cause pain if there has been an acute muscle strain or tear.

Palpation of the trachea can reveal deviation (to the opposite side) in pneumothorax. Percussion at the site of pain can produce acute tenderness if one or more

underlying ribs are fractured. Dullness on percussion suggests consolidation of the lung or fluid in the pleural space. Hyperresonance suggests pneumothorax.

Auscultation can reveal clicking of the ribs or the grating of rib fractures. A pleural rub suggests irritation caused by infection or embolism, whereas rales at the site of pain suggest underlying lung disease.

Pain from nerves and nerve roots is almost always lateralized and has a segmental pattern. The most common cause is herpes zoster, although spinal arthritis and disorders of the neuraxis can also cause segmental pain (neuralgia).

Chest Pain Referred from Extrathoracic Disorders

Pathology in Cervical Spine

Unilateral sharp or deep aching pain in the pectoral region associated with pain in the neck and upper limb is frequently caused by compression of lower cervical nerve roots by posterolateral herniation of a disk, osteophyte fracture, or other pathologic process. Lesion of C-8 on the left side produces anginalike pain in the left chest and medial arm, but the pain is unaffected by effort if the arm and neck are not moved. Pain is aggravated by ipsilateral neck flexion, head compression, cough, sneezing, and straining; it is relieved by head traction associated with sensory and reflex changes in the limb.

Pain in the upper anterior chest can be also caused by thoracic inlet syndromes, but pain that is most severe in the shoulder and limb, unaffected by effort but aggravated by extreme abduction of the arm, is often associated with signs of vascular compression.

Pancoast's syndrome often causes pain in the scapular region and anterior chest, but the pain is most severe in the shoulder and in the medial aspect of the arm. The pain is associated with paresthesia, dysesthesia, hypesthesia, and weakness of the muscle supplied by the ulnar nerve. Fullness and tenderness may be noted in the medial supraclavicular and paravertebral regions.

Abdominal Disease

Gas entrapment syndrome produces abdominal pain with radiation to the lower chest. Gastric distension produces pain in the entire epigastrium and anterior and left lateral chest up to the xiphoid or the lower sternal region. Gas entrapment in the hepatic flexure produces pain in the right upper quadrant of the abdomen and right lateral anterior chest. Gas in the splenic flexure produces pain in the left upper abdominal quadrant and left anterior and lateral chest. Signs include abdominal distension, abdominal tympany, and positive radiographic evidence in the standing position.

Biliary colic produces pain in the epigastric or right subcostal regions, but the pain frequently extends to the back at the inferior angle of the scapula and sometimes into the low central anterior chest. Mild subcostal tenderness can be noted.

Biliary tract disease can provoke angina pectoris in patients with preexisting coronary disease associated with T-wave changes. Cholecystitis is associated with nausea, vomiting, fever, jaundice, and a tender mass in the right upper quadrant of the abdomen.

Gastric ulcer located in the cardia (this is an uncommon site) is a frequent cause of laterally radiating pain in the central anterior and lower part of the chest. Gastric ulcer at other sites is not associated with chest pain. Duodenal ulcer can produce pain that radiates to the xiphoid, but chest pain is rare.

Some patients with acute pancreatitis complain only of chest pain that simulates the pain of myocardial infarction and often is associated with transient electrocardiographic abnormalities. The pain often radiates to the back; it is relieved by forward bending. It may be associated with diaphragmatic irritation resulting in pleuritic chest pain.

Distension or inflammation of the liver or spleen produces pleuritic pain in the chest and often in the shoulder. The pain is aggravated by breathing but is unaffected by effort. Subphrenic abscess produces inflammation of the diaphragm with consequent pleuritic pain on the side of the chest, shoulder, or both. Usually, there is sign of infection.

Chest Pain Primarily of Psychological Origin

Anxiety, depression, hypochondriasis, and other psychological factors can produce chest pain that is atypical in location, quality, and duration. Pain is usually in the left precordial or cardiac apical region. Chest pain does not always keep the patient from sleep, but it is present on awakening. Acute anxiety is usually associated with dyspnea, hyperventilation, palpitation, dizziness, perspiration, weakness, increased muscle tension, and diffuse chest tightness.

Chronic anxiety may produce what has been called cardiac neurosis (*soldier's heart*), or neurocirculatory asthenia. The pain is usually dull and is felt at the cardiac apex; it can be associated with attacks of sharp pain. The pain varies in severity and location and is often related to physical activity. Patients complain of weakness, low energy level, dyspnea, and palpitation.

Pain can be caused by endogenous depression associated with signs of depressive illness, anorexia, weight loss, fatigue, low energy level, malaise, and insomnia.

A positive diagnosis of pain of psychological origin is made by exclusion of disease of the heart and lungs and positive evidence acquired through psychological tests.

SUMMARY

Pain in the chest can be caused by various factors (Table 60-2), and it is therefore most important for the physician to distinguish disorders that are not life-threatening from those that are serious. An incorrect diagnosis of a hazardous condition such as angina pectoris is likely to have harmful psychological and economic consequences and can lead to unnecessary complex procedures such as coronary arteriography. Failure to recognize a serious disorder such as coronary artery disease or mediastinal tumor could result in a dangerous delay of much needed treatment. The situation must therefore be carefully assessed. (The most important points in examining a patient with chest pain are listed in Table 60-1.)

CHAPTER 61

Cardiac and Aortic Pain

Marshall A. Corson and Robert R. Phillips

Many types of cardiac diseases can produce pain in the chest, including coronary heart disease, valvular heart disease, cardiomyopathy, pericardial disease, and aortic disease. Of these, coronary heart disease is by far the most common cause of cardiac pain and is of the greatest public health importance. Coronary heart disease remains the leading cause of death in the United States, currently estimated to cause 1 in every 4.8 deaths (1). Cardiac death is preceded by symptoms referable to the cardiovascular system in most patients. Moreover, because only a minority of heart disease deaths are the result of progressive ventricular dysfunction, prevention strategies should favorably impact on the natural history of coronary atherosclerosis. The recognition of a cardiac pain or discomfort syndrome is the single most powerful diagnostic tool available for the diagnosis of coronary heart disease. The pain of chronic coronary heart disease can generally be relieved by medications or revascularization. Thus, not only is cardiac pain easily treatable, but it is also important as a diagnostic tool in the recognition of coronary heart disease and the prevention of death. Advances in diagnosis and treatment have continued to reduce morbidity and mortality, such that the primary goal in the contemporary evaluation of a chest pain syndrome is to use subjective and objective data to determine its risk potential. Diseases of the thoracic aorta are much less common causes of chest pain, but when they do occur, a prompt, correct diagnosis and appropriate therapy are highly effective. If left untreated, many patients die. These various cardiovascular disorders are among the most important causes of severe pain that require effective management, and therefore deserve detailed consideration.

This chapter contains a current and comprehensive overview of cardiac and aortic pain. The material is presented in four parts: Mechanisms of Cardiac Pain, including a historic overview of cardiac pain, characteristics of cardiac pain, and neuropathophysiology; Myocardial Ischemic Syndromes, including stable angina pectoris, variant angina, unstable angina, and acute myocardial infarction (AMI); Chest Pain from Other Cardiac Diseases, including aortic valvular disease, hypertrophic cardiomyopathy, and acute pericarditis; and Aortic Chest Pain, with emphasis on dissection of the thoracic aorta. The present work represents the revision of an original chapter in this textbook by Hammermeister and Bonica. Major cardiology textbooks provide more detailed consideration of both coronary heart disease and aortic dissection (2, 3 and 4).

MECHANISMS OF CARDIAC PAIN

Historical Overview of Cardiac Pain

The history of chest pain caused by disease of the heart goes back to the time of Hippocrates. In the *Corpus Hippocraticum*, specific reference is made to“palpation and piercing (pain) sensation felt in the breast and pain in the vertebral column” caused by“fluxions of humours in the heart” (5). In ancient Rome *angina* and *angor* were described by Celsus in his *De re Medicina* (30 AD) (6). A clear description of coronary pain is found in the work of Caelius Aurelianus, a Roman physician of the fifth century ad who used the term *passio cardiaca propria to* indicate pain of cardiac origin specifically. Like Celsus, he also used *angina* and *angor* to indicate acute disease characterized by a sense of choking and strangling (7). Although the condition was undoubtedly known throughout the Middle Ages, literary references to it were few until the Renaissance. Bartolomeo Castelli (8), in 1598, wrote that“angor est nativi caloris cordis contractio, et in centrum retractio, ad quam sequitur eiusdem cordis dolor, palpitatio et tristitia” (angor is a contraction, and a retraction toward the center, of the natural heat of the heart, which is followed by heart pain, palpitation and anguish). Some three decades later Girolamo Mercuriale, writing about diseases of the viscera, first used the term *cardialgia* to indicate heart pain (5). At the beginning of the eighteenth century, Bonet wrote in *Sepulchretum* that the *dolor pectoris* (chest pain) is a serious symptom and described the case of a patient with chest pain who died suddenly; on autopsy the coronary arteries were found to be occluded (9). During the ensuing seven decades, references to a relationship between recurrent heart pain and sudden death were frequent.

Notwithstanding these precedents, credit for the first description of angina pectoris goes to William Heberden who, in 1768, presented a lecture titled“Some Account of a Disorder of the Breast” before the Royal College of Physicians in London and published it 4 years later (10). Heberden's description is lucid, concise, and contains many important diagnostic clues used today:“There is a disorder of the breast . . . . they who are afflicted with it, are seized while they are walking (more especially if it be uphill, and soon after eating), with a painful and most disagreeable sensation in the breast, which seems as if it would extinguish life, if it were to increase or continue; but the moment they stand still, all this uneasiness vanishes.” Heberden also recognized the progressive nature of angina pectoris and its predilection for evolving into an unstable pattern:“After it has continued a year or more, it will not cease so instantaneously upon standing still; and it will come on not only when the persons are walking, but when they are lying down, especially if they lie on their left side, and oblige them to rise up out of their beds. In some inveterate cases, it has been brought on by the motion of a horse, or a carriage, and even by swallowing, coughing, going to stool, or speaking, or any disturbance of mind” (10).

The term *angina* was used by Heberden not only to signify a sense of choking and strangling (according to Celsus), but also to indicate a terrible anxiety and anguish experienced by the patient (*angor animi*). In fact, the word is derived from the Indo-European root *agh*, which means“to choke, to oppress, to suffer.” Although Heberden rightly deserves the recognition of being the first to describe the syndrome, it is not commonly recognized that he did not believe that angina originated in the heart, even though he implied this belief in the title of his monograph. Even in a later discussion, Heberden failed to associate angina pectoris with disease of the coronary arteries. This was surprising because toward the end of the eighteenth century, several British physicians strongly believed in a relationship between angina pectoris and myocardial ischemia. In 1786 Edward Jenner carried out a necropsy on the body of a patient whom he had treated for angina pectoris and noted that the coronary arteries were so severely calcified that cutting through them produced an intense grating sound. Subsequently, after observing other necropsies in which“cartilaginous” obstruction of the coronary arteries was noted, he became convinced that coronary artery disease was the cause of angina pectoris:“the importance of the coronary arteries and how much the heart must suffer from their not being able duly to perform their functions . . . it is possible that all the symptoms may arise from this one circumstance” (11).

Dr. Caleb Parry, a close friend of Jenner, was familiar with Jenner's belief about angina pectoris. Using personal clinical material and Jenner's account of his

experiences, as well as that of others, he published his monumental book on angina pectoris in 1799 (12). Parry wrote that “Though a quantity of blood may circulate through the arteries, sufficient to nourish the heart, as appears in some instances, from the size and firmness of the organ, yet there would probably be less than what is requisite for ready and vigorous action. Hence though a heart so diseased may be fit for the purposes of common circulation, during a state of bodily and mental tranquility, and of health otherwise good, yet when any unusual exertion is required, its powers may fail under the new and extraordinary demand.”

Even in the nineteenth century, controversy regarding the cause of angina pectoris persisted. Home, Warren, Desportes, and others (see 5 for references) proposed that cardiac spasm was the cause of angina pectoris. They noted that in some cases of angina pectoris no coronary sclerosis was demonstrated, whereas in other cases severe coronary sclerosis observed at autopsy had not induced any anginal attack. Despite all the efforts of these physicians, for more than 150 years angina was not related to myocardial ischemia by *mainstream* physicians, including such stalwarts as Sir Clifford Allbutt, Regius Professor of Medicine at Cambridge University, and probably also Sir William Osler, his fellow Regius Professor at Oxford. Allbutt, in 1915, in his two-volume *Diseases of the Arteries Including Angina Pectoris* (13), stated that“angina pectoris is anything you please . . . a very popular sentiment.” Allbutt and others attributed angina to disease of the aorta, perhaps distension. Beginning with Heberden, this discrepancy probably arose because the major cardiac diagnostic technique of that time, palpation of the pulse, often revealed no abnormalities in patients with angina; this was Heberden's observation during his own anginal episode (10). Nine years after Allbutt's proposal, Wenckebach (14) similarly postulated that the sudden distension of the aorta or distension of the coronary arteries proximal to the point of occlusion stimulated the nerve plexuses.

At about the time that Allbutt was contesting the basis for myocardial ischemia, Herrick's (15) experiments provided strong support to the concept of a causal relationship between coronary insufficiency and cardiac pain. This was reaffirmed by Keefer and Resnik (16) in 1928 in their classic paper on angina pectoris, in which they stated that this symptom“was due to anoxemia of the myocardium . . . the attacks occur when the oxygen supply to the heart is inadequate to meet the oxygen demands of the heart.” Further work in support of this theory was reported by Sutton and Lueth (17) and White and coworkers (18), who carried out experiments on dogs that manifested pseudoaffective reactions (signs of pain) by repeated and intermittent occlusion of the orifices of coronary arteries. These painful reactions could be produced by occluding the orifices of the coronary arteries without causing distension; in contrast, acute mechanical distension of the cavity of the left ventricle, the aortic ring, or the aortic arch produced no pain. At about the same time, Wood and Wolferth (19) clearly demonstrated a causal relationship by observing electrocardiographic (ECG) changes during angina; thus the concept of the ischemic origin of angina became widely accepted.

Paul Dudley White is generally credited with ushering in the *modern era* of twentieth century cardiology. Development of powerful new diagnostic techniques, such as electrocardiography (ECG) (20) and echocardiography (21), constituted the basis for current noninvasive evaluation of chest pain, whereas the advent of cardiac catheterization and selective coronary angiography (22) heralded the era of coronary artery bypass surgery (23) and percutaneous coronary revascularization (24). These technical innovations have been matched by progress in the development of pharmacologic agents, such as antagonists of the sympathetic nervous system (25), renin-angiotensin systems (26), and thrombolytic agents (27).

Characteristics of Cardiac Pain

The chest pain experienced by patients with coronary ischemic syndromes, aortic stenosis or regurgitation, and hypertrophic cardiomyopathy all have the common denominator of myocardial ischemia. Thus, the pains of each of these conditions may have similar characteristics. Cardiac pain is visceral in nature (i.e., initially the pain is often vague, diffuse, poorly localized, and referred to varying anatomic areas). Patients often find it difficult to describe. Many patients refuse to use the word *pain* in describing angina pectoris, preferring instead to call it a discomfort, a tightness, a constricting feeling in the chest,“a band across the chest . . .a weight on the center of the chest” or a strangling sensation. It was for this reason that Heberden chose the word *angina*, which means strangling. Ischemic myocardial pain often carries with it the feeling of impending doom or death; Heberden used the Latin phrase *angor animi* to express this feeling of terror (10).

Patients often feel the need to stand or sit absolutely motionless when they experience angina. Ischemic myocardial symptoms can also be described as paresthesia or a numbness or weakness, particularly in the arms. Ischemic myocardial pain is commonly mistaken for pain of gastrointestinal origin because it can be epigastric in location, similar to the *heartburn* of esophagitis, and accompanied by an intense desire for eructation. It is not uncommon for patients suffering from angina pectoris to feel that they could obtain relief if only they could belch. The pain of AMI shares many of these characteristics, although usually it is more severe and of longer duration. Pain of myocardial ischemia is not pleuritic, and it is not exacerbated by deep breathing or coughing. It generally does not vary with position, as does the pain of acute pericarditis. The identification of precipitating factors, such as exercise or emotion, is an essential part of the diagnosis of stable angina pectoris (see General Principles of Diagnosis, later in this chapter); unstable angina and variant angina, by definition, do not have recognizable external precipitating stimuli. It is also now recognized that more than 30% of patients with demonstrable coronary ischemia have either no symptoms or atypical symptoms, such as dyspnea only, so-called anginal equivalents.

The visceral nature of cardiac pain provides a basis for its clinical differentiation from chest wall pain or pain from superficial structures. These differences in pain perception and in the stimuli required to evoke pain are summarized in Table 61-1. Pain from the skin can be localized precisely and is superficial and often sharp in nature. Pain from the chest wall (e.g., muscles, ribs, ligaments, parietal pleura) is intermediate in localization, depth, and sharpness (see Chapter 12 and Chapter 60). Also, chest wall pain is often exacerbated by movement, such as with breathing or coughing.

Structure	Effective stimulus	Conscious pain perception
Skin	Discrete touch, pinprick, heat, cold	Precisely localized, superficial, burning, sharp
Chest wall	Deep pressure, movement	Intermediate in localization, aching, sharp or dull
Heart and thoracic viscera	Ischemia, distension, movement, muscle spasm	Vague, diffuse, deep, aching, usually dull

TABLE 61-1. Differences in pain perception from heart, chest wall, and skin

Although ischemic myocardial pain can occur almost anywhere between the diaphragm and the mandible, it is commonly felt in the anterior chest, retrosternally, with radiation to one or both arms, to the throat and mandible, or to all these areas. Less commonly, the pain or discomfort is confined to the throat, arms, epigastrium, or even the interscapular region. Because of its visceral origin, ischemic myocardial pain or discomfort is generally referred to an area of substantial size, such as the patient's fist or a larger area. Pain that is discretely confined to a small area on the chest or that can be localized by the patient with a single finger is usually not pain of myocardial ischemia but is chest wall pain. It is generally believed that the intensity and size of the area of true visceral and referred visceral pain are influenced to a significant degree by the degree and size of the myocardial ischemia or myocardial necrosis. The greater the degree and area of myocardial ischemia, the greater the nociceptive barrage into the neuraxis, with consequent spread of neuropathophysiology into the spinal cord and probably the brainstem and, consequently, the greater the spread and intensity of the pain. In addition to the pain, the patient may develop hyperalgesia in the spinal segments involved.

Ischemic myocardial pain generally lasts 5 to 15 minutes for stable exertional angina, 15 to 30 minutes or longer for unstable angina and variant angina, and 1 to 8 hours or more for AMI. The acute pain of infarction is usually intense, often accompanied by a strong alarm reaction and a feeling of impending death, and not infrequently by nausea, vomiting, and profuse sweating. After a period of several hours, some AMI patients feel the pain to be localized more precisely, originating in the thoracic wall or upper limbs. Some authors consider this to be the second phase of AMI and have described (28) that, among their patients, many experienced muscle tenderness in the pectoralis major, the deep muscles of the interscapular region, the muscles of the forearm, and less frequently the trapezius.

Fleeting pain lasting from a few seconds to a minute is almost certainly not pain of myocardial ischemia. Likewise, pain that persists for days is unlikely to be ischemic myocardial pain. In typical angina pectoris, chest pain relief usually occurs within 2 to 5 minutes after taking sublingual nitroglycerin. Some patients might require a second nitroglycerin for complete relief, but the beginning of subsidence of the pain occurs within 3 to 5 minutes. Pain that takes 15 minutes or longer to be relieved by rest or nitroglycerin either is not caused by myocardial ischemia or is a more severe form, such as unstable angina or AMI. It is also true that nitroglycerin provides relief of noncardiac chest pain, due to its actions as a smooth muscle relaxant; therefore, its specificity for the conclusive diagnosis is low. Nitroglycerin is a somewhat

unstable compound, especially when exposed to heat or sunlight, and can lose its vasoactive potency. Use of old nitroglycerin is another reason for failure of prompt relief of angina. Many patients can recognize nonpotent nitroglycerin because it does not sting under the tongue or give a feeling of fullness in the head, as does fresh, potent drug.

Neuropathophysiology

The development of sophisticated electrophysiologic and histologic techniques since 1950 has permitted numerous studies that have greatly complemented and supplemented our knowledge of neuroanatomy (see Chapter 3 and Chapter 60). These studies, reviewed by Malliani (29), have formed the basis for our understanding of the location and function of the sympathetic and vagal afferent nerves and of their roles in activating homeostatic reflex mechanisms, as well as contributing to the pathophysiologic states caused by cardiac disease.

Agostini and colleagues (30) demonstrated that the heart has a substantial afferent innervation of A-d and C fibers from the vagus nerves. Others have shown that many of these afferent fibers respond to bradykinin and to ischemia, as well as to various mechanical stimuli (31,32). The precise role of these fibers in pain sensation (i.e., nociception) is still controversial (33). Evidence from animal studies since 1925 seemed to indicate that nociceptive information is transmitted primarily by sympathetic afferents (18,34), which are also involved in reflexes that control cardiovascular homeostasis. Whether sympathetic afferents transmit all ischemic pain sensations to the central nervous system has been called into question, however, by a number of clinical studies that reported the degree of anginal amelioration in patients treated in the early to mid-twentieth century with ablation of cervical, thoracic, or both sympathetic afferents (reviewed in 33). Thoracic sympathectomy or dorsal rhizotomy was poorly tolerated, with death rates approaching 10% in most series. Six studies, each inclusive of greater than or equal to 50 treated patients, all agreed in their findings of complete relief in only 50% to 60%, partial relief in 30% to 40%, and no relief in 10% to 15% of such treated patients. These consistent results suggest that the pain of cardiac ischemia may be transmitted at least in part through parasympathetic (vagal), as well as sympathetic, afferents. Vagal afferents may also play a role in modulation of cardiac pain (see Central Mechanisms, later in this chapter).

Roughly equal numbers of myelinated A-d and unmyelinated C fibers run in the cardiac sympathetic nerves. Direct recordings show that both fiber types are spontaneously active under ambient conditions (29,35). Single-unit recordings from white rami communicantes or dorsal roots of the thoracic sympathetics to the heart have shown that during coronary occlusion the activity of A-d and C fibers increases significantly (36,37 and 38). The responses of many A-d units are slow (mean, 80 seconds), appear to depend on myocardial stretching, and have spontaneous active discharge that occurs in synchrony with cardiac rhythm. Moreover, sympathetic afferent activity increases when the pressure within the heart increases (29,39). Responses of most C-fiber units are quicker, with a latency of 10 to 20 seconds following coronary occlusion, and the resulting irregular firing is unrelated to mechanical factors or to cardiac rhythm. These characteristics have led to the proposal that most A-d and a few C fibers serve a *mechanosensitive* function following either internally derived mechanical perturbation or on blunt probing or mechanical deformation of the heart or surrounding structures, and are concerned with the reflex regulation of circulation. Serotonin, histamine, bradykinin, and acids markedly excite both C and some A-d sympathetic afferents (40,41 and 42), and the effects of bradykinin are markedly enhanced by prostaglandins (42,43). It has thus been held that most C fibers and a few A-d fibers function in a *chemosensitive* mode (38). An evolving model emphasizes increasing recognition of *polymodal* fibers that may function in both mechanosensitive and chemosensitive modes (44). It has been suggested that cardiac pain is produced by the release of humoral (algogenic) agents from ischemic myocardial muscles, which sensitize or frankly activate the terminals of these afferent neurons. Because bradykinin and prostaglandins are formed and released in heart muscles following ischemia (45,46), and because prostaglandins have been shown to potentiate the algogenic effects of bradykinin in other tissues (see Chapter 3), a classical view is that angina results from the excitation of afferent terminals by the joint release of neurohumoral substances such as prostaglandins (43), serotonin (47), adenosine (38), bradykinin (43), or all of these.

The early work of investigators such as Brown and Malliani (48) postulated the existence of specific cardiac nociceptors, but with increasing characterization of afferent sympathetic fibers (presence of spontaneous baseline activity, responsiveness to hemodynamic events) an alternative explanation was needed. A modified version of the *intensive theory* (see Chapter 3) was proposed as a working hypothesis: Cardiac pain can result from the extreme excitation of a spatially restricted population of afferent sympathetic fibers, hence from an afferent code based on a peculiar spatiotemporal pattern (49).

The definitive explanation for the perception of ischemia remains elusive, however (50). While there appears to be agreement that both sympathetic and vagal afferents participate in the transmission of ischemic pain, the precise *sensor* of ischemia remains to be determined. Some answers may be forthcoming from the combination of classical physiology with molecular biology. The superfamily of degenerin/EnaC ion channels participates in mechanotransduction in phylogenetically diverse organisms ranging from *Caenorhabditis elegans* to mammals (51). A proton-gated ion channel member of this superfamily has been described (52), which is an intuitive candidate for nociception in the myocardium (53), given the known wide swings in pH under pathologic conditions of ischemia and infarction (54). Innovative methods of patch clamping with tissue culture may enable further characterization of an alternate candidate nociceptor family, the ATP-sensitive P2X3 ligand-gated ion channels (55).

Central Mechanisms

Myocardial ischemia, whether caused by atherosclerotic coronary artery disease or another cause of myocardial oxygen supply and demand imbalance, produces true visceral pain, felt deep in the chest and described as vague, poorly localized, and aching in character, and frequently radiating to sites outside of the chest, especially the inner aspects of the arms, neck, and occasionally the jaw. The mechanism(s) of visceral pain has not been precisely defined, but it is probably a result of nociceptive impulses passing to the upper thoracic spinal cord, where they excite cell bodies of spinothalamic tract (STT) neurons and possibly the neurons of other ascending systems. Although STT cells that respond specifically to visceral nociceptive impulses but not to cutaneous inputs have not been found, clinical evidence suggests that this is the mechanism for true visceral pain (56).

The mechanisms of *referred* visceral pain are discussed in Chapter 3 and Chapter 4. Some experimental studies concerning the neuropathophysiology of the referred pain produced by myocardial ischemia have been carried out. Foreman and associates (57,58) have studied the effects of electrical stimulation of sympathetic afferents, the application of bradykinin into the heart, and noxious stimulation of the skin and muscle and of coronary artery occlusion in monkeys. They noted that these interventions all excited high-threshold and wide dynamic range spinothalamic neurons located primarily in laminae IV and V (68%), but also in laminae VII (24%) and I (8%) of the upper four or five thoracic segments. Of these STT cells, 64% were high-threshold neurons, 26% were wide dynamic range neurons, and almost 10% were high-threshold inhibitory neurons. Those in the latter category consisted of cells that were excited by pinch of the skin but inhibited by blowing hair on the skin (59). The following results were obtained: (a) these STT cells respond to A-d and C sympathetic afferents but not to A-b afferents; (b) all the STT cells receive a convergent input from A-d and C nociceptors in the skin and underlying muscles, as well as from the heart; and (c) the receptive fields of the cutaneous and muscle afferents are located in the ipsilateral upper anterior and lateral chest and in the medial and lateral aspects of the ipsilateral forelimb. In one study it was found that approximately 40% of STT cells received input from both A-d and C sympathetic afferents, 50% received only A-d fiber input, and 10% received only C fiber input. These and other data support the *projection-convergence* theory of Ruch (Fig. 61-1), which provides an explanation for cardiac pain being felt in the anterior chest and arms (see Chapter 3 and Chapter 4 for detailed discussion of this and other theories of referred pain). Moreover, it has been shown that neurons in the thalamic nuclei, where the axons of STT cells terminate, respond to noxious cutaneous input and to noxious stimulation of the viscera. Viscerosomatic convergence has also been found in the somatosensory cortex.

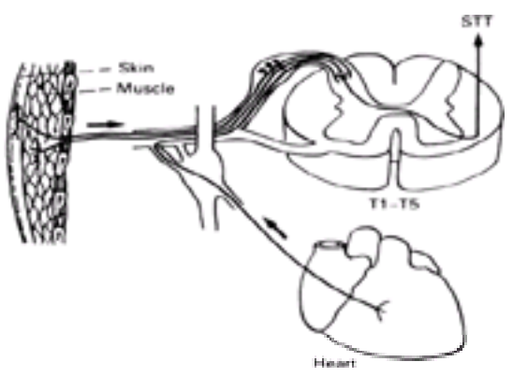

Figure 61-1. Schematic depiction of the projection-convergence theory of Ruch to explain the mechanism of cardiac pain. Afferent sympathetic fibers from the heart, skin, and muscles converge on the same spinothalamic tract (STT) cell and the cell of spinoreticulothalamic tract that transmits the impulses to the lateral and medial thalamus, respectively. Because the spinoreticulothalamic tract is a multisynaptic network, it mediates nociceptive impulses slowly and these are perceived as diffuse aching visceral pain. The spinothalamic tract cells project to the lateral thalamus that is concerned with the sensory discriminative function. (See Chapter 3, Chapter 4

and Chapter 5 for details.)

Ammons and associates (60) demonstrated that electrical stimulation of the left thoracic vagus nerve caused inhibition of the spontaneous activity of 61% of STT cells in the T-1 to T-5 segments. Moreover, left thoracic vagal stimulation inhibited 100% of the STT cells that responded to noxious somatic stimulation. Stimulation of the cardiac vagal branch could produce similar results, but stimulation of the vagal fibers below the heart could not produce inhibition. Effects of vagal stimulation completely disappeared after the vagi were transected in the cervical region. Vagal stimulation also inhibited the response of the STT cells to intracardiac injection of bradykinin (61). These results indicate that activation of descending pathways initiated by cardiac or cardiopulmonary vagal afferents is powerful enough to depress cell activity, even when the cell receives noxious input. It was also suggested that vagal inhibition of STT neurons was mediated by activation of descending systems that are part of the system for pain modulation (see Chapter 4). Stimulation of the nucleus raphe magnus inhibited all the STT cells in the upper thoracic segments that responded with an increased discharge to the intracardiac injection of bradykinin (60). It was postulated that the afferent vagal impulses that reach the nucleus of the tractus solitarius activate efferent fibers that project to the medial reticular formation and the hypothalamus, which in turn causes stimulation of the nucleus raphe magnus (58). These interactions may have implications for the high incidence of painless myocardial ischemia or infarction (see following discussion). One possibility is that vagal input into the brainstem powerfully activates descending inhibitory pathways, which in turn reduce the responsiveness of STT cells to the excitatory effects of sympathetic afferent fibers (62).

A limited amount of clinical data consistent with the previously mentioned observations is available. Studies indicate that as many as 70% of episodes of myocardial ischemia may be clinically silent, while 30% of AMIs are painless (63). Silent ischemia is clinically important because it is associated with an increased risk of adverse events subsequent to an episode of unstable angina (64) or AMI (65). Individual patients may have both painful and painless ischemic episodes that could be determined by the severity of ischemia but may be determined by other factors. To explore this issue, Rosen et al. used positron emission tomography as a measure of regional neuronal activation in a defined group of patients with two- or three-vessel coronary artery disease and silent ischemia, compared with a well-matched control group with clinical angina (66). Ischemia was induced and quantified by standard dobutamine stress echocardiography, using a graded infusion of the synthetic catechol to increase the determinants of myocardial oxygen consumption: heart rate, contractility, and blood pressure. In the silent ischemia group, seven of nine patients became aware of a forceful heartbeat, one experienced chest wall warmth, and one was asymptomatic, while ischemic ST segment depression was detected by ECG and wall motion abnormalities observed by echocardiography. In contrast, seven of seven of the symptomatic group experienced typical angina pectoris; both the time to significant ECG change and the extent of changes were similar between the groups. By positron emission tomography, both groups experienced equivalent dobutamine-dependent increases in thalamic activation, but the extent of cortical activation was significantly greater in the angina group. Cortical regions activated in the angina group included the bilateral anterior and ventral cingulate cortex, mesial orbitofrontal, and basal frontal cortex and left temporal lobe. This study has several implications. Equivalent ischemic stress in patients with or without angina pectoris was associated with a similar degree of thalamic activation; the absence of angina was thus unlikely due to the failure of peripheral sensing or transmission to the thalamus. The cerebral areas activated in the angina group may represent specific cortical projections within a pathway mediating the proprioception of cardiac pain. Failure of these areas to be activated in the silent ischemia group may have been due in part to differential gating of impulses at the thalamic level. Clarification of these mechanisms will require further study.

Effects of Myocardial Ischemia and Pain

Tissue damage from myocardial ischemia and mechanical changes of the ventricles consequent to an acute infarct produce local biochemical changes and stimulate vagal and sympathetic afferents to produce pain and segmental and suprasegmental reflex responses (67). In addition to the excitation of these sympathetic afferents by the algogenic substances that excite and sensitize the sympathetic afferents directly, they can also be stimulated directly by physiologic motion of ischemic myocardium to produce a further increase in sympathetic reflex activity. Cardiac vagal afferents are mechanoreceptors that can also become sensitized after AMI and provoke abnormal reflexes.

Reflexes elicited by AMI involve afferents and efferents of both cardiac vagi and cardiac sympathetic nerves, which produce symptoms and signs characteristic of vasovagal and sympathosympathetic reflexes (29,67). Under normal conditions these two extrinsic neurogenic controls of cardiac function have reciprocal neural organization, so that stimulation of sympathetic afferents not only elicits an increased action of sympathetic afferents but also, simultaneously, reduces the discharge of vagal efferents and vice versa. Under pathologic conditions, however, this typical response is disturbed. Consequently, in most AMI patients, both systems are overactive. The one that predominates is determined by many interrelated factors, including the presence and intensity of pain and the size and location of the infarct; sympathetic overactivity predominates in cases of anterior infarction, while parasympathetic overactivity predominates in patients with inferior infarctions (67,68).

An example of the potential danger of abnormal vasovagal reflexes is the Bezold-Jarisch reflex of severe bradycardia, atrioventricular (AV) block, peripheral vasodilation, and consequent severe hypotension. The concurrent sympathetic hyperactivity increases myocardiac contractility and can be considered to be an important mechanism for opposing ventricular dilatation and cardiogenic shock. On the other hand, these potentially protective sympathetic reflexes can be detrimental by imposing a demand for increased oxygen consumption on the myocardium (67). Moreover, animal experimentation has shown that the a-adrenergic portion of the sympathetic nervous system can exert a vasoconstrictor effect on the coronary vessels, with a consequent decrease in both coronary blood flow and myocardial oxygen supply (69,70). In addition to the sympathosympathetic reflexes, stimulation of sympathetic afferents by mediation of nociceptive (pain) impulses can elicit widespread cardiac, vascular, and hormonal changes.

Thus, it appears that segmental and suprasegmental sympathetic reflexes, anxiety, and psychological stress may increase the workload of the heart and its oxygen consumption. Moreover, increased coronary vasomotor tone can further decrease blood flow in the already compromised atherosclerotic coronary circulation, worsening supply and demand mismatch, leading to further ischemia and possibly expanding the infarction. One or more of these responses can be a critical factor in causing the death of the patient. Therefore, it is essential to relieve the pain, anxiety, and mental stress and decrease or eliminate the abnormal reflexes promptly and effectively.

MYOCARDIAL ISCHEMIC SYNDROMES

Etiology and Pathophysiology of Coronary Artery Disease

Manifestations of myocardial ischemia can be classified according to clinical presentation, pathologic anatomy, and pathophysiology. The pathophysiology of these *syndromes* is incompletely understood, and there may be overlap between clinical presentations (Table 61-2). This discussion concentrates on atherosclerotic coronary artery disease because it accounts for 95% or more of patients with a myocardial ischemic syndrome caused by coronary artery disease. Myocardial ischemia can occur in the absence of anatomic coronary artery disease because of an activated clotting system, abnormal vasoreactivity (spasm), or marked myocardial hypertrophy. The most common pathophysiologic substrate for myocardial ischemia in patients with normal coronary arteries is severe ventricular hypertrophy, such that the oxygen requirements of the myocardium exceed its capacity to increase its blood supply (e.g., aortic stenosis or regurgitation, severe hypertension, hypertrophic cardiomyopathy). Although the pathogenesis is different, the underlying biochemical mechanisms, symptoms, and ECG manifestations are often similar to those of ischemia resulting from coronary artery disease.

Syndrome	Clinical presentation	Pathoanatomy	Pathophysiology
Stable angina	Exertional chest pain	Atherosclerotic coronary stenosis ≥50%	Provoked by increase in myocardial oxygen demand
Unstable angina	Chest pain at rest	Atherosclerotic coronary stenosis with platelet thrombus	Reduction in coronary blood flow by partially occluding thrombus or enhanced vasoreactivity
Acute myocardial infarction			
Q-wave infarction ST elevation	Severe unprovoked chest pain	Atherosclerotic coronary stenosis completely occluded by thrombus	Precipitating event unknown, possibly rupture of plaque, platelet aggregation, hemorrhage into plaque, or all three
Non-Q-wave infarction	Severe unprovoked chest pain	Atherosclerotic coronary stenosis partially occluded	Reduction in coronary blood flow due to severe coronary spasm or partially occluding thrombus
Silent myocardial ischemia	Ischemic ST changes without pain	Uncertain; probably atherosclerotic coronary stenosis ≥50%	Defect in pain recognition versus subclinical ischemic episodes

TABLE 61-2. Classification of myocardial ischemia syndromes

Prior mantle radiation for mediastinal cancer or syphilis can produce obstruction at the origins of the coronary arteries, the latter through extension of the aortitis to the coronary ostia; the myocardial ischemic syndrome is the same as if the obstruction were produced by atherosclerosis. Collagen vascular diseases can produce obstruction of the coronary arteries, usually smaller branches, through an arteritis. Kawasaki's disease, a periarteritis-like disease of infants, can produce aneurysms of coronary arteries and other medium-sized arteries. Congenital anomalies of the coronary arteries can also produce myocardial ischemia; the most serious of these are the origin of a coronary artery from the pulmonary artery and the anomalous origin of the left coronary artery from the right coronary sinus with passage between the aorta and pulmonary artery.

Dissection of the aorta can produce acute occlusion of a coronary artery if the dissection extends proximally to include the orifice of a coronary artery. Acute embolic coronary occlusion can occur with endocarditis or in patients with prosthetic aortic valves. Rarely, blunt chest trauma, such as with a steering wheel injury, can produce damage to a coronary artery, usually the left anterior descending coronary artery. Rarely, coronary artery obstruction is caused by iatrogenic intimal damage by a catheter or cannula; this has been observed in coronary angiography, coronary angioplasty, and aortic valve replacement, in which the coronary arteries are often perfused with a cannula.

The pathophysiology of atherosclerosis involves the deposition of cholesterol and other lipids, the proliferation of smooth muscle cells, and the laying down of collagen in the subendothelial intima of medium-sized and large arteries. In large arteries the atherosclerotic process can damage the media and result in the formation of aneurysms, as occurs commonly in the abdominal aorta. In medium-sized arteries the atherosclerotic process more commonly results in obstruction through the heaping up of the atheroma to impinge on the vessel lumen, as in the coronary and cerebral arteries. Development of atheroma probably begins in childhood and usually takes 30 to 50 years to progress to the stage at which clinical manifestations are produced (71).

The pathogenesis of atherosclerosis has been the subject of intense research activity for the past 40 years, but the basic pathophysiologic mechanisms are still largely speculative. Three hypotheses have been proposed: the response to injury hypothesis, proposed by Ross and Glomset (72); the monoclonal hypothesis of Benditt and Benditt (73), who proposed that the atheroma is essentially a benign tumor; and the lipogenic hypothesis, which emphasizes altered lipid metabolism. Presently, the response to injury hypothesis seems best able to explain the available epidemiologic and biochemical data. According to this theory, the endothelium is damaged by any of various noxious stimuli (e.g., mechanical forces, hyperlipidemia, homocysteine, immunologic factors, toxins, such as those from cigarette smoke, or viruses), resulting in abnormal permeability or even denudation. If the stimulus ceases, healing of the intima can occur. If the intimal injury is sufficiently severe or prolonged, however, transudation of lipids occurs together with egress of abnormal cells (smooth muscle cells and macrophages) into the subintimal region. As the process continues, collagen is laid down and cholesterol and its esters are taken up by cells in the lesion. Studies demonstrate that the media enlarges to accommodate the developing plaque, but once the area within the media has increased by approximately 40%, the vessel can no longer enlarge and the plaque begins to significantly decrease the lumen area (74). Destabilization of such a plaque can then trigger an acute coronary syndrome, as discussed here.

General Principles of Diagnosis

History

The patient's history is the single most important diagnostic tool in the evaluation of coronary artery disease. The nature, location, duration of the pain, and the factors that provoke and relieve it constitute the most useful information obtained from the history. In the vast majority of patients with angina pectoris the diagnosis can be made from the history alone, provided that proper history-taking skills are combined with knowledge of the wide variation in symptoms that can occur. Historical (subjective) elements can then be combined with readily obtained objective data (physical examination and ECG) to formulate a provisional explanation for the occurrence of acute chest pain syndromes (Table 61-3). Ischemic myocardial pain can be located anywhere between the diaphragm and mandible; most often it is initially retrosternal (true visceral pain), but soon involves the anterior chest and radiates to both arms, neck, and occasionally the jaw. By its nature, ischemic myocardial pain is vague, diffuse, and ill defined, hence the *visceral nature*. Many patients find it difficult to describe such vague symptoms; this is the setting in which directed yes or no questions can easily result in an incorrect database. The importance of initiating the history taking with nondirected questions cannot be overemphasized. The question“Do you have chest pain?” invariably produces an affirmative response, because everyone has chest pain at one time or another, and a more productive line of inquiry may center on the nature of the patient's“chest discomfort.”

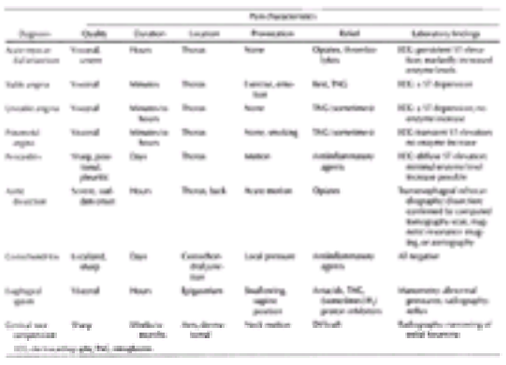

TABLE 61-3. Differential diagnosis of acute chest pain syndromes

It is useful to quantify the amount of exertion required to precipitate pain in patients with exertional angina. Even though the exertion required might vary within the same patient, a classification based on the level of precipitating activity is useful in assessing the severity of the disease, the patient's disability, the effects of therapy, and the progression of the disease. The guidelines of the Canadian Cardiovascular Society are particularly useful because they were designed specifically for angina (75):

- Class 1: Angina occurs only with strenuous or rapid or prolonged exertion at work or recreation. Ordinary physical activity, such as walking or climbing stairs, does not cause angina.
- Class 2: Angina results in slight limitation of ordinary activity. It can be produced by walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, exercise in cold or during emotional distress, or exercise in the first hours after awakening.
- Class 3: Angina results in marked limitation of ordinary physical activity. It can be produced by walking one or two blocks on the level or climbing one flight of stairs in normal conditions and at a normal pace.
- Class 4: Angina results in the inability to carry on any physical activity without discomfort. Angina can be present at rest.

Physical Examination

The physical examination is often overlooked as an important and useful diagnostic tool in patients with coronary heart disease, because it is so often normal. Nevertheless, a careful physical examination is essential, even for the negative information it produces. Reversible risk factors for atherosclerosis can be detected by identifying hypertension, xanthomas of hyperlipidemia, or nicotine stains caused by cigarette smoking. The adequacy of myocardial function can be assessed by examining for evidence of congestive heart failure, such as elevated jugular venous pressure, pulmonary rales, gallop rhythm, cardiomegaly, or peripheral edema. Noncoronary causes of myocardial ischemia, such as aortic valve disease or hypertrophic cardiomyopathy, are usually detected on physical examination.

Routine Laboratory Studies

Routine laboratory studies are often normal, but still important, like the physical examination. Severe anemia must be excluded as a cause of angina. Diabetes as a risk factor for atherosclerosis needs to be identified and treated. Assessment of renal function is essential, particularly in patients being considered for coronary arteriography or coronary artery bypass surgery. Serum lipid measurements with determination of high-density lipoprotein and low-density lipoprotein are also

essential to identify risk factors and initiate treatment. The West of Scotland Coronary Prevention Study demonstrated that a high baseline high-density lipoprotein was a strong negative predictor of coronary events, and lowering the low-density lipoprotein using pravastatin prevented coronary events by 31% in men without prior AMI (76). Both the 4S and CARE trials demonstrated similar benefits for patients with hypercholesterolemia when statin therapy was initiated after AMI (77,78). The release of myocardial isoenzymes, such as the MB fraction of creatine phosphokinase or Troponin I, is particularly useful in detecting myocardial necrosis and is discussed further (see Acute Myocardial Infarction, later in this chapter).

Resting Electrocardiography

The resting ECG is a cost-effective tool in the evaluation of patients with chest pain, provided that its limitations are recognized. It is normal in approximately 50% of patients with angina but no previous AMI; thus a normal resting ECG does not exclude severe coronary artery disease (79). The presence of left ventricular hypertrophy or ST wave changes consistent with myocardial ischemia favors the diagnosis of angina pectoris; the presence of significant Q waves makes coronary artery disease very likely (80). The presence of arrhythmias and atrioventricular (AV) or conduction system blocks on the resting ECG generally increases the probability of coronary artery disease, but these findings are also prevalent enough with other forms of cardiac disease as to lack specificity in the prediction of ischemic heart disease likelihood. An ECG obtained from a patient actively experiencing angina is abnormal in approximately 50% of patients with coronary artery disease and a normal resting ECG. If the patient is at rest this finding may define an unstable coronary syndrome and indicate that early coronary angiography is appropriate for risk stratification (81).

Chest Roentgenography

Most patients with coronary artery disease and preserved left ventricular function have normal cardiovascular structures on the chest roentgenography. The primary value of the chest roentgenogram is in the assessment of heart failure. Important signs of heart failure are cardiomegaly, pleural effusions, redistribution of the pulmonary venous pattern to the upper lobes, and signs of interstitial edema and dilated lymphatics (Kerley B lines). The physical examination is notoriously insensitive in detecting cardiac enlargement; although less sensitive than echocardiographic or angiographic techniques, the chest roentgenogram is a cost-effective way of assessing cardiac chamber enlargement. Furthermore, the heart size on the chest roentgenogram is an important prognostic indicator (82). In the absence of severe valvular regurgitation an inverse relationship between left ventricular size and ejection fraction (fraction of end-diastolic volume ejected with each beat) can be seen. Thus, significant left ventricular enlargement in the absence of valvular regurgitation is almost always associated with severe, chronic left ventricular dysfunction; the status of left ventricular systolic function is one of the two most powerful predictors of survival in patients with coronary artery disease (83).

Calcification of the coronary arteries is an uncommon finding on the chest roentgenogram but almost always indicates severe coronary atherosclerosis and often obstruction. Calcification seen in the region of the left ventricle can represent a calcified thrombus in a ventricular aneurysm. The chest roentgenogram is insensitive in the detection of left ventricular aneurysms, but deviation of the midportion of the left ventricular silhouette superiorly and to the left on the posteroanterior film can be a sign of an anterolateral aneurysm.

Exercise Stress Test

The exercise stress test yields valuable information not only from serially obtained ECG traces, but also from other physiologic responses to exercise and the maximum exercise capacity. The exercise stress test has been the traditional noninvasive method for evaluating patients with chest pain syndromes and has also been widely applied as a useful indicator of subsequent risk following AMI. The stress test is also useful for assessing disability and evaluating the results of therapy. Exercise stress testing is frequently misused, however, either because the wrong questions are asked about it or because attention is focused on the ECG and the other important data available are overlooked.

The application of Bayes' theorem has been useful in deciding which patients are most likely to have the benefit of greater assuredness of diagnosis from the addition of exercise stress testing to the history, physical examination, and routine laboratory data, including the resting ECG (84). Patients whose pretest probability of coronary artery disease is in the intermediate range benefit most diagnostically from the performance of the test. Examples of such patients would be a middle-aged man with risk factors for coronary heart disease and a chest pain syndrome not fully typical of angina pectoris, or a postmenopausal woman with typical angina pectoris. In both of these examples the probability of coronary artery disease causing the symptoms from the information given is in the range of 30% to 60%.

An exercise stress test with greater than 1 mm horizontal or down-sloping ST-segment depression persisting 80 milliseconds after the J point (junction of terminal QRS component and the ST segment) significantly increases the probability of finding a significant coronary artery obstruction on angiography, whereas no significant ST-segment depression at maximal exercise significantly reduces this probability (85,86). In patients in whom the history and other data obtained before the exercise test provide a high degree of certainty regarding the diagnosis (i.e., the pretest probability of obstructive coronary artery disease is either extremely high or extremely low), exercise stress testing is not indicated for the sole purpose of establishing the diagnosis. For example, in the man with risk factors and typical angina who has a pretest probability of obstructive coronary disease of more than 90%, a positive ST-segment response on exercise testing increases this probability only minimally, whereas a negative ST-segment response is not sufficient to exclude obstructive coronary artery disease. In studies designed to eliminate workup bias, by commitment of intermediate probability patients with chest pain to both exercise treadmill testing and coronary angiography, the sensitivity of stress testing has ranged from 45% to 50% and the specificity from 85% to 90% (87,88).

Exercise testing is also important for assessing the severity of disease, assessing prognosis, and evaluating the results of therapy. Many patients with angina whose diagnosis is clear from the history and resting ECG should have exercise stress testing to assess the severity of the disease, to provide an estimate of the likelihood of future cardiac events, and to aid in determining the need for coronary angiography. Whereas the ST-segment response to exertion is the most commonly used diagnostic criterion (usually depression greater than or equal to 1 mm), the ST segment has more limited usefulness in the assessment of prognosis. In an analysis of patients in the Seattle Heart Watch Coronary Arteriography Registry, the duration of exercise or maximal workload achieved, maximum heart rate, and maximum systolic blood pressure were the most powerful predictors of prognosis in patients with known coronary artery disease (83). In a multivariate analysis, the rate-pressure product (the product of maximal heart rate and maximal systolic blood pressure during exercise) included all the prognostic information available in the exercise test. In other studies marked ST-segment depression (greater than or equal to 2 mm) has been shown to be a useful adverse prognostic indicator (89). Such functional information is also most useful in patients undergoing low-level post-AMI stress testing.

The absolute contraindications to exercise testing include AMI within 2 days, cardiac arrhythmias causing symptoms or hemodynamic compromise, symptomatic and severe aortic stenosis, symptomatic heart failure, acute pulmonary embolus or pulmonary infarction, acute myocarditis or pericarditis, and acute aortic dissection. Relative contraindications include known left main coronary stenosis (greater than or equal to 70%), moderate aortic stenosis, electrolyte abnormalities, systolic blood pressure greater than 200 mm Hg, diastolic blood pressure greater than 110 mm Hg, uncontrolled tachyarrhythmias or bradyarrhythmias, hypertrophic cardiomyopathy or other forms of outflow tract obstruction, mental or physical impairment leading to an inability to exercise adequately, and high-grade AV block (90). Unstable angina was previously considered to be a contraindication to exercise testing, but more recent studies have shown that both exercise treadmill (91,92), and pharmacologic (93,94), testing are safe in low- or intermediate-risk patients hospitalized with unstable angina who have had AMI ruled out and are free of angina and congestive heart failure.

Stress Imaging Modalities

Both the sensitivity and the specificity of ECG stress imaging for detection of coronary ischemia can be increased through the concomitant use of an imaging modality such as nuclear perfusion imaging (95) or echocardiography (96,97). Nuclear perfusion imaging typically uses intravenously injected agents that are taken up from the circulation by myocardial cells; both intact regional blood flow and viable myocardium are required for normal uptake. Agents used include thallium 201, a potassium analog that is avidly taken up and accumulated by normally perfused myocardium, and technetium 99m–tagged synthetic organic complexes such as tetrofosmin or sestamibi. The latter group of agents, in contrast to thallium, is maximally taken up during the first pass through the coronary circulation, lending itself to increasing use in the assessment and risk stratification of chest pain in the emergency setting. The technetium 99m–based agents decay with production of higher energy g-rays, improving the signal-to-noise ratio in large patients or those with obstructive airways disease, and enabling faster data collection.

Patients are usually exercised with a standard treadmill stress protocol or the infusion of a coronary vasodilator such as dipyridamole. At the time of development of angina or shortly before maximal stress has been achieved, the imaging agent is injected through a peripheral vein. Imaging of the myocardium commences immediately with a standard gamma camera or with a tomographic system, such as single photon emission computed tomography (SPECT), which yields three-dimensional computer-generated cardiac images. If an area of myocardium is supplied by a significantly (greater than or equal to 50% to 70%) stenotic coronary artery, it becomes transiently ischemic because the restricted coronary flow cannot meet the increased metabolic demands. This area does not take up the imaging

agent and is visualized as a defect on the image obtained immediately on completion of exercise. Over a period of several hours, thallium redistributes to the area that showed a defect on the early image; thus, an image obtained 3 or 4 hours after exercise shows normal uptake in the area of the defect on the early image. In contrast, scar caused by AMI cannot take up thallium either on the rest or stress image. Because technetium 99m–based agents do not redistribute, it is necessary to reinject the agent after a several-hour or overnight hiatus. An alternative used increasingly frequently is the stress dual isotope study, in which resting thallium SPECT images are compared with SPECT images obtained directly thereafter using a technetium 99m–based agent at peak stress (98). The scintigraphic window for technetium 99m imaging can be set so as to eliminate any signal from the weakly emitting thallium.

Coupling of two-dimensional echocardiographic imaging of the heart with physical or pharmacologic stress can also provide useful diagnostic and prognostic information regarding coronary heart disease. Stress echocardiography requires highly skilled and experienced sonographers and thus likely should be performed routinely in a practice setting or not offered. Current-generation echocardiographic equipment can typically display a series of resting cardiac cycles in each of a number of transducer projections through the heart. At maximal stress, imaging is repeated with attempts to recreate identical three-dimensional images, and the rest and stress images are then compared side by side. Sensitivity and specificity are greatest in younger, thin individuals with normal resting wall motion, who develop regional wall motion defects indicated by impaired systolic wall thickening (99). A purported advantage of the induction of ischemia with an inotropic agent (dobutamine) is the ability to administer graded stimuli (e.g., starting at 5 µg per kg per minute and increasing in increments of 5 to 10 µg per kg per minute to a maximal dose of 40 µg per kg per minute), with serial imaging at each infusion level. This protocol may be optimal for recreating the physiology of a graded exercise test response in patients who have noncardiac reasons for inability to exercise to an adequate stress level on a treadmill. The presence of significant wall motion abnormalities at rest limits the predictive value of changes observed with typical (exercise or pharmacologic) stress, in essence limiting the usefulness of the procedure to those with normal rest studies, with one exception. In patients with significant areas of viable but markedly hypoperfused (so-called hibernating) myocardium, the detection of improved wall motion with low doses (less than 10 µg per kg per minute) of dobutamine in areas that were at baseline markedly abnormal may indicate the potential for return to normal function with revascularization (100,101).

Cardiac Catheterization and Coronary Angiography

Selective coronary angiography, introduced by Sones in 1959, led to a totally new understanding of coronary anatomic pathology and made possible the development of surgical and percutaneous coronary revascularization. In this diagnostic procedure the coronary arteries (shown in Fig. 61-2) are selectively cannulated with separate preformed catheters for the right and left coronary arteries, introduced percutaneously through the femoral artery in the groin (Judkins' technique). Injecting 3 to 10 mL of iodinated radiographic contrast material and filming the output phosphor of a radiographic image intensifier provide excellent definition of the coronary arteries. In skilled hands the risk of coronary angiography is low, even in acutely ill patients such as those with AMI. The risk of coronary angiography is highest in the newborn, the elderly, the acutely ill, and those with severe left ventricular dysfunction. Selective coronary angiography is the only procedure currently available that accurately defines the location and severity of coronary arterial obstructions. As such, it is an invaluable tool in the evaluation of patients with chest pain syndromes. It is an essential prerequisite to consideration of coronary revascularization. It is useful in patients whose chest pain syndrome cannot be diagnosed noninvasively. In addition, it provides much vital prognostic information, because prognosis is strongly related to the amount of myocardium placed in jeopardy by severe proximal coronary arterial stenoses.

Stable Angina Pectoris

History

Angina pectoris can be defined as chest discomfort of a visceral nature precipitated by exertion or emotion and promptly relieved by rest or nitroglycerin. It is the most common symptomatic manifestation of stable coronary heart disease. Angina can occur in a stable pattern in many patients for a prolonged period of time (months to years). It differs from unstable angina in that a precipitating factor can generally be identified (usually exercise), and that relief occurs promptly with the removal of the precipitating factor or with the administration of sublingual nitroglycerin. The importance of angina pectoris is that it is often the most valuable clue to coronary artery disease, it is often disabling, and some patients with angina are at high risk for AMI or sudden cardiac death.

Stable angina pectoris occurs when the myocardial oxygen demand transiently exceeds the myocardial oxygen delivery because of an increase in a determinant of oxygen demand (Table 61-4). The pathologic substrate in the vast majority of patients is a significant coronary artery obstruction caused by an atherosclerotic plaque. The clinical syndrome of angina pectoris can also occur in patients who have hypertension (102), severe aortic valve disease (see Aortic Stenosis, later in this chapter), and hypertrophic cardiomyopathy. Most patients can be diagnosed on the basis of the history. The most important information to elicit from the history regarding angina regards the factors that precipitate the attack and how the patient relieves it. Typical precipitating factors are exertion and emotion. Isometric exertion, such as lifting over the head, is more likely to precipitate angina than isotonic exertion because of the marked increase in blood pressure that occurs with sustained isometric muscle contraction. Exertion performed after a large meal, during times of emotional distress, or on cold exposure is more likely to precipitate angina than exertion under other conditions. Angina tends to occur more frequently and with less provocation in the first hours after awakening. Stable angina is relieved within minutes by stopping exertion, alleviating the precipitating factor, or taking sublingual nitroglycerin.

Myocardial oxygen demand	Myocardial oxygen delivery
Heart rate	Coronary blood flow
	Transcoronary pressure gradient
Contractility	Aortic diastolic pressure
	Left ventricular diastolic pressure
Left ventricular wall stress	Coronary vascular resistance
Left ventricular systolic pressure	
Left ventricular size (radius)	Oxygen extraction
	Arterial saturation
	Arterial-coronary sinus oxygen difference

TABLE 61-4. Determinants of myocardial oxygen demand and delivery

The nature and location of angina also provide useful diagnostic clues. Angina is diffuse and vague; it is often described as a pressure sensation, a weight on the chest, or a constricting feeling in the chest and often in the neck. The patient may use a clenched fist to illustrate the constricting nature of the discomfort. Angina is not pleuritic and does not usually change with change in posture, as does pericardial pain. Angina is not fleeting; brief stabbing pains in the chest lasting only

seconds are probably neuritic in origin. The duration of angina is generally 5 to 15 minutes. Although angina can occur almost anywhere between the diaphragm and mandible, it is typically retrosternal with radiation into one or both arms, throat, and mandible. Occasionally, it can occur only in the arms, only in the mandible, or only in the interscapular region. Sometimes the pain can occur in the epigastrium and might be mistaken for gastrointestinal pain by the physician or patient, such as esophagitis or peptic ulcer. Because of its visceral nature, anginal pain generally encompasses a substantial area and is deep seated; pain that is localized to a small area on the chest wall (e.g., smaller than 1 to 2 inches in diameter) or that is superficial is generally not angina. Pain localized by the patient with a single finger is not likely to be angina. Table 61-5 lists historical features of angina.

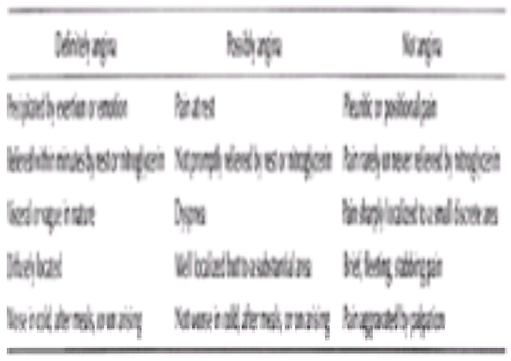

TABLE 61-5. Diagnostic clues of angina pectoris from the history

Physical Examination

Physical examination is typically the least useful of the diagnostic tools, but some helpful information can be obtained. Often, no cardiovascular abnormalities are detected. Particular attention to the major controllable determinants of myocardial oxygen consumption, heart rate, and systolic blood pressure is essential (see Table 61-4). Other causes of angina or anginalike pain, such as aortic valve disease, hypertrophic cardiomyopathy, or mitral valve prolapse can be excluded by careful examination for the appropriate murmurs or midsystolic click. Reproduction of the pain by firm palpation of the chest or by pressing on the ribs is useful in diagnosing chest wall pain. Costochondritis, a specific but uncommon inflammation of the costochondral junction, is best diagnosed by eliciting exquisite pain with light pressure over the costochondral junction approximately 1 to 2 inches lateral to the sternum. Symptoms and signs of congestive heart failure, such as elevated jugular venous pressure, pulmonary rales, or gallop rhythm, should be sought. Treatment of heart failure can also improve angina by lowering the left ventricular diastolic pressure, thereby improving the perfusion gradient for coronary blood flow and reducing the wall stress.

Routine Laboratory Testing

The resting ECG is often normal. Q waves provide evidence of old AMI and thereby of coronary heart disease but do not necessarily help to identify the cause of the presenting chest pain. An ECG taken during an anginal episode may be diagnostically useful when it shows ST-segment depression. The chest roentgenogram is helpful to the extent that it permits assessment for cardiomegaly and evidence of congestive heart failure. Routine blood tests exclude severe anemia (hematocrit below 25%) as a precipitating factor for angina and examine for risk factors of atherosclerotic heart disease such as diabetes or hyperlipidemia, but are of little direct value in determining whether the presenting complaints are the result of myocardial ischemia.

Stress Testing

The exercise stress ECG has been the traditional noninvasive diagnostic tool for the evaluation of angina pectoris, as was discussed previously. This study can often provide unique information such as objective documentation of a patient's exercise tolerance, the threshold for ischemia, and the efficacy of vasoactive and antianginal therapy in controlling the blood pressure and heart rate response to strenuous exercise. Most diagnostic laboratories use the protocol developed by Dr. Robert Bruce at the University of Washington, which is a graded protocol using 3-minute stages at increasing speed and walking grade. Each successive stage requires a defined amount of work from the patient, which has been correlated with many activities of daily life. Exercise testing should be considered for two principal indications: for diagnosis of the presence or absence of coronary artery disease and for the assessment of prognosis in patients with known coronary artery disease. Large-scale studies, such as the prospective Duke series (103), demonstrate the utility of treadmill stress testing for the detection of high-risk patients such as those with left main coronary artery disease, severe triple-vessel disease, and critical aortic stenosis. For example, in this series, patients who demonstrated inducible ischemic ECG changes and were unable to complete the first or second stage of the Bruce protocol had a prevalence of significant coronary artery disease of 98% and a prevalence of severe three-vessel coronary artery disease of 50% to 70%. Nearly 25% of these patients had left main coronary disease. Furthermore, the CASS registry found that the prognosis of patients who developed greater than or equal to 2 mm of ST depression in the first stage of the Bruce protocol is poor, with an annual mortality greater than 5% (104). In contrast, patients with a normal ECG at high workload carry a very favorable prognosis. Those completing stage III or higher with less than 1-mm ST depression were found to have an annual mortality of less than 1%. Thus, exercise testing is important for assessing severity of disease, prognosis, and response to therapy. Many patients whose diagnosis is suggested by the history should undergo exercise testing to determine whether further diagnostic tests, such as coronary angiography, are indicated or if coronary artery bypass grafting needs to be performed. Whereas the ST-segment response to exertion is the most commonly used diagnostic, the ST-segment response has more limited usefulness in prognostication (83). It is similarly underpowered to predict the stenotic vessel(s), for reasons that are unclear.

Stress Testing with Cardiac Imaging

Combining stress testing with imaging of the heart has also been useful both in establishing the diagnosis and assessing prognosis (105). Commonly combined modalities include exercise or pharmacologic stress testing with radionuclide perfusion SPECT imaging or echocardiographic wall motion analysis. These techniques are most useful in patients whose baseline ECG precludes obtaining diagnostic ST-segment changes with exercise testing (e.g., left ventricular hypertrophy with repolarization abnormalities or left bundle branch block). Such imaging techniques are required for the assessment of perfusion (or its surrogate cardiac wall motion by echocardiography) in patients undergoing pharmacologic stress.

Coronary Angiography

Despite major advances in sophisticated noninvasive diagnostic procedures, coronary angiography is the only technique that can reliably determine the location, number, and severity of coronary artery obstructions. It can be performed with relatively low morbidity and mortality (0.1%), but it is expensive, uses ionizing radiation, and does carry a small risk. For patients with stable angina, the following indications for diagnostic angiography have been included in the current guidelines: patients with angina pectoris who have been successfully resuscitated after an episode of sudden cardiac death; patients who cannot undergo noninvasive testing, or in whom such assessment has resulted in uncertainty of diagnosis; patients suspected of having a nonatherosclerotic cause of myocardial ischemia not revealed by noninvasive testing; and those with high pretest probability of left main or three-vessel coronary artery disease (81).

Treatment

Medical Therapy. Following diagnosis and assessment of risk for a major coronary event through noninvasive and invasive studies, if appropriate, the first step in therapy of stable angina should involve minimizing coronary artery disease risk factors and eliminating factors that aggravate angina. Hyperlipidemia (see Acute Myocardial Infarction, later in this chapter), cigarette smoking, and hypertension are the major controllable risk factors. Pipe and cigar smoking have also been associated with an increased risk of AMI or death, but to a lesser degree than cigarette smoking, probably because the dose is lower as a result of less inhalation of the pollutants. Weight reduction in obese patients, control of hyperglycemia in diabetics, correction of arterial hypoxemia in patients with pulmonary disease, control of tachycardia (particularly that caused by b-agonists used as bronchodilators), and a program of moderate isotonic exercise such as walking are also appropriate initial measures. Other medical conditions that aggravate angina, such as severe anemia, thyrotoxicosis, or congestive heart failure, should be diagnosed and treated.

Aspirin. Because the primary mechanism for events in patients with coronary atherosclerosis is destabilization of a plaque with formation of mural thrombus, it is

intuitive that all patients with atherosclerosis in general, and chronic stable angina in particular, use aspirin regularly if tolerated (106). The antithrombotic effects of aspirin are due to the inhibition in platelets of thromboxane A_2 synthesis (107). Although the benefits of aspirin therapy were initially demonstrated in the context of AMI and unstable angina, more recent studies have shown that risk of coronary events is reduced by aspirin use. The Physicians' Health Study included approximately 300 male physicians with chronic angina, but without prior AMI, who were shown to have an 87% reduction in the risk of AMI during 5 years of follow-up with the use of 325 mg of aspirin every other day (108). Similar reductions in the risk of AMI and sudden death were also observed in a mixed gender population (109) with the use of low-dose aspirin (75 mg per day).

b-*Adrenergic Blockers.* b-Adrenergic blockersare highly effective in reducing the frequency of anginal attacks and in improving exercise tolerance in patients with stable exertional angina (25). Their primary mechanism of action is most likely the reduction of myocardial oxygen demand by decreasing resting and exercise heart rates and, to a lesser extent, systolic blood pressure. More recent data indicate that b-blockade may also improve myocardial oxygen supply; continuous ambulatory ECG and blood pressure monitoring reveals a reduction in transient ischemic events (110). The most common side effects are fatigue, mental depression, exacerbation of congestive heart failure in patients with severe left ventricular dysfunction, and bronchoconstriction. b- Adrenergic blockers should be used cautiously in patients with a history of severe congestive heart failure or who have a left ventricular ejection fraction lower than 0.30, although studies suggest that such patients who can tolerate b blockade have a significant survival advantage (111,112). Nonselective b-adrenergic blockers are also relatively contraindicated in patients with severe obstructive airways disease resulting in arterial desaturation or CO_2 retention. b_1-Selective agents such as metoprolol have been developed to minimize bronchoconstriction, but in the larger doses often required for control of angina they lose their selectivity and can cause bronchospasm. b-Adrenergic blockers are also relatively contraindicated in patients with insulin-dependent diabetes because they block the sympathetic response to hypoglycemia, thereby prolonging the episode and impairing its recognition.

Nitroglycerin. Nitroglycerin has been a mainstay of treatment of symptomatic anginal attacks ever since the first description of the response to amyl nitrate by Brunton in 1867 (113) and to nitroglycerin by Murrell in 1879 (114). The mechanism of action of nitroglycerin is still the subject of some debate. It reduces myocardial oxygen demand through reducing left ventricular wall stress by decreasing afterload, and may increase coronary blood flow to ischemic myocardium through dilation of the coronary stenoses (115). Sublingual nitroglycerin (0.4 mg) can be used therapeutically for exertional angina or prophylactically prior to performing exercise likely to precipitate angina, such as climbing stairs or sexual intercourse. If complete relief is not obtained with a single tablet, a second can be used in 5 to 10 minutes. Ischemic myocardial pain not responding to three nitroglycerin tablets within 15 to 20 minutes requires immediate medical attention. The duration of action of sublingual nitroglycerin is brief, usually 15 to 30 minutes; therefore, its use is not practical as a long-term prophylactic drug. A number of long-acting nitrate preparationswith mechanisms of action similar to that of sublingual nitroglycerin are available. Among the most commonly used are the oral organic nitrates, isosorbide dinitrate and isosorbide mononitrate, and various types of topical nitrates. Isosorbide dinitrate can be begun at a dose of 10 mg three times a day and increased at 5- to 7-day intervals to 40 mg of the sustained-release form three times a day. Isosorbide mononitrate in sustained-release form has the theoretical advantage of much less first-pass metabolism in the liver. At 120 to 240 mg daily, it has been shown to reproducibly increase treadmill exercise in patients with chronic stable angina as effectively after 6 weeks of use as on the first day of use (116). This sustained benefit is important because of the phenomenon of nitrate tolerance, by which the sensitivity of the vasculature to the antiischemic effects of nitroglycerin is lost without a 10- to 12-hour daily nitrate-free period (117).

Calcium Channel Blockers. There is considerable controversy about the use of calcium channel blockers in patients with coronary artery disease (118). Immediate-release nifedipine is contraindicated in patients with coronary artery disease or suspected acute coronary syndrome. Amlodipine, diltiazem, and verapamil are effective at reducing angina and do not cause excess mortality in those with coronary artery disease or acute coronary syndrome in the absence of significant congestive heart failure. These drugs cause vascular smooth muscle relaxation by selectively inhibiting the inward calcium current through the conventional L-type calcium channel in the cell membrane, and they have proven to be effective in the treatment of angina (119). Although their mechanisms of action at the cellular or organ level are similar to those of the nitrates, their biochemical site of action is different; therefore, these agents can be synergistic with nitrates in the treatment of angina. In contrast to nitrates these agents are also myocardial depressants, with verapamil being the most potent. Verapamil should be used cautiously or not at all in patients with severe congestive heart failure or left ventricular dysfunction. Amlodipine has proved safe in patients with congestive heart failure (120). Both verapamil and diltiazem slow AV conduction and are relatively contraindicated in patients with advanced degrees of AV block or sick sinus syndrome. Calcium channel blockers commonly produce minor ankle edema that can usually be easily controlled with a diuretic. Because these are potent vasodilators, headache and orthostatic hypotension are common side effects, particularly when used in combination with large doses of nitrates.

The history is useful in choosing the first antianginal agent to initiate treatment. In patients whose angina is primarily exertional or is provoked by other stresses that increase myocardial oxygen demand, b-adrenergic blocking agents are highly effective, as are the nitrates and calcium channel blockers. In patients with angina at rest, in whom the mechanism might be a spontaneous reduction in coronary blood flow caused by normal coronary vasoreactivity or spasm, nitrates or calcium channel blockers are probably preferable over b-adrenergic blockers; the latter could theoretically exacerbate coronary spasm by leaving the a-constrictor tone unopposed. These three classes of antianginal drugs are useful in combination in patients with severe angina. Medical therapy is often not considered to be *maximal* unless the patient is receiving a drug from all three classes in therapeutic doses.

Surgical Revascularization. Various surgical procedures were tried for relief of severe angina in the 1950s, but none was demonstrated to be more effective than a placebo or sham operation (121). With the description of the aortocoronary bypass operation by Favalaro in 1969, a truly effective way of improving myocardial blood flow at an acceptable risk was introduced (23). The operation is based on the angiographic observation that, in the earlier phases of symptomatic coronary artery disease, the atherosclerotic obstructions are in the proximal portions of the coronary arteries, leaving the distal portions of the vessels relatively free of disease. Direct surgical attack on the obstructive lesions (i.e., endarterectomy) did not work because of the small size of the arteries. The construction of a bypass conduit of saphenous vein from the ascending aorta to the coronary artery distal to the obstruction has been shown to be highly effective in relieving anginal symptoms and improving exercise tolerance. The operation, which requires the use of cardiopulmonary bypass to allow the delicate anastomoses to be made on the arrested heart, can now be performed with an operative mortality of approximately 1% to 3%. The probability of early graft patency is high (90%), as is the initial relief of symptoms (80%). As atherosclerosis progresses in the native coronary arteries and develops in the saphenous veins, however, symptoms return at a rate of 3% to 4% per year so that by 5 years after surgery approximately 30% of operated patients are again symptomatic. The internal mammary artery is now used as the bypass conduit of choice to coronary arteries on the anterior surface of the heart because it does not appear to develop atherosclerotic obstruction, resulting in better late patency rates (122).

Whereas the beneficial symptomatic results of coronary bypass surgery in patients who are severely limited by angina preoperatively are quite clear, the effect of surgery on survival has been more controversial. With the publication of three large randomized trials comparing survival of surgically and medically treated patients (123,124 and 125), it was established that survival is improved with surgical therapy in patients with significant obstruction of the left main coronary artery (123) and in patients with three-vessel coronary artery disease and left ventricular dysfunction (125). No study has shown improved survival in patients with single-vessel coronary artery disease. A European randomized trial showed substantially improved survival in symptomatic patients with three-vessel disease and normal left ventricular function (124). The Coronary Artery Surgery Study conducted in the United States and Canada, however, showed no survival benefit for minimally symptomatic patients with three-vessel disease and normal left ventricular function (125). Although neither the Veterans Affairs Cooperative Study nor the Coronary Artery Surgery Study showed improved survival in patients with two-vessel disease, some data from the European study suggest that, if one of the two involved vessels is the anterior descending coronary artery, survival might be prolonged with surgery (124). These classic studies performed in the 1970s and 1980s were of great value in demonstrating the benefits of surgical revascularization in high-risk groups. However, with the technical improvements of shorter bypass pump runs, increasing use of arterial conduits, and early (within 12 to 24 hours) postsurgical patient mobilization, the applicability of these large trials to current decision making has been somewhat reduced (126). The concomitant improvements in catheter-based revascularization continue to redefine the options for patients with symptomatic coronary atherosclerosis.

Percutaneous Coronary Intervention. In selected patients, percutaneous coronary intervention procedures such as percutaneous transluminal coronary angioplasty (PTCA) provide effective revascularization without a surgical procedure. This catheterization procedure, developed by Gruntzig in the late 1970s (127), consists of passing a flexible guidewire across the coronary artery stenosis and following with a balloon catheter over the guidewire. The balloon is inflated and the stenosis is dilated. In skilled hands, the procedure promptly relieves the obstruction in approximately 90% of attempts, but a small risk of occluding the artery or damaging it is involved, so that emergency surgery is sometimes required. A major unresolved problem is the recurrence of the stenosis in approximately 30% of patients within 6 months of the procedure. The introduction of intracoronary stents has reduced the frequency of complications requiring emergent surgery and reduced the rate of stenosis recurrence by approximately 50%. The addition of aggressive antiplatelet regimens, with a combination of aspirin, ticlopidine (or, more recently, clopidogrel), and abciximab (a glycoprotein IIb/IIIa inhibitor), has reduced the incidence of early thrombotic occlusion and may also contribute to a reduction in recurrent stenosis (128). Catheter-based interventions have become the treatment of choice for single- or double-vessel disease, and increasingly for patients with three-vessel disease (129). The need for repeat intervention and sometimes coronary artery bypass graft remains the major problem for catheter-based interventions.

Variant Angina

Clinical Description and Pathophysiology

Variant angina is a useful descriptor for chest pain syndromes that may have both typical and atypical features. The two primary pathophysiologic mechanisms of variant angina are epicardial coronary artery spasm (Prinzmetal's angina) and microvascular angina. Prinzmetal's angina was described as anginal pain at rest accompanied by ST-segment elevation in the absence of an exertional component (130). Prinzmetal postulated that it might be caused by transient narrowing as the result of changes in the vasomotor tone of proximal coronary artery stenoses. Subsequent angiographic investigation of patients fitting this definition has shown findings that vary from normal coronary arteries to severe atherosclerotic coronary artery disease; thus, it is not a single disease entity, with the latter group overlapping with unstable angina patients. Nevertheless, it appears that a small group of patients has predominantly unprovoked, at-rest angina, with dramatic ST-segment changes and sometimes malignant ventricular arrhythmias. Many patients are premenopausal women who smoke cigarettes. Anginal attacks are most frequent in the morning hours, with marked variability over time in the disease activity. The mechanism of the coronary spasm is unknown, although in approximately 25% of patients evidence has been found of a more generalized vasospastic syndrome, such as Raynaud's phenomenon or migraine headaches. Microvascular angina is often said to be present in patients with exertional chest pain, abnormal measures of myocardial perfusion under physical or pharmacologic stress (with or without adjunct imaging), and angiographically normal coronary arteries (131). Microvascular angina, also known as *syndrome X*, may be part of a continuum of disorders, characterized by some or all of the following symptoms: abnormal sensitivity to cardiac stimulation (enhanced visceral nociception), esophageal dysmotility, and various types of psychosocial disorders, including panic disorder (132).

Diagnosis

The diagnosis of Prinzmetal's angina is best made by demonstrating marked ST-segment shifts during episodes of unprovoked angina in a patient who otherwise has normal exercise tolerance. Coronary angiography during an anginal episode usually shows spasm in the coronary artery predicted by the ECG ST-segment changes. Because anginal episodes occur unpredictably, however, such an episode might not occur spontaneously during coronary angiography. Provocative testing with ergonovine, a serotonin- and a-adrenergic receptor agonist, has been used in the past for diagnosis in the catheterization laboratory, and more recently has been replaced in some centers by methylergonovine (Methergine). The diagnosis of microvascular angina may be somewhat more difficult to prove, given that it requires a clinical component, abnormal noninvasive studies, and angiographically normal epicardial coronary arteries.

Treatment

Both nitrates and calcium channel blockers are generally effective in these patients, either separately or in combination. Of course, cessation of smoking should be advised. The prognosis in patients with angiographically normal coronary arteries is good, although rarely AMI can occur.

Unstable Angina

Clinical Description and Pathophysiology

Unstable angina can be defined as angina occurring at rest or with little or no provocation. Previously, patients with new-onset angina and patients with a crescendo pattern to their exertional angina were included with those in the unstable angina group, but these two subgroups probably have differing pathophysiologies and prognoses.

Patients with unstable angina generally have a severe stenosis (greater than or equal to 90% in one or more major coronary arteries), but the vessel is still patent. The angina occurs without any change in the determinants of myocardial oxygen demand, and therefore must be the result of a reduction in coronary blood flow caused by an increase in coronary vascular resistance (see Table 61-4). The increase in resistance is thought to occur primarily at the severe atherosclerotic stenosis because of partial occlusion by a platelet thrombus, by an increase in vasomotor tone producing a small reduction in lumen area that can effect a large increase in resistance, or by a combination of both these mechanisms. Rarely, an unstable angina pattern can occur in patients with angiographically normal coronary arteries; in these patients coronary spasm must be the primary mechanism.

Diagnosis

As with stable angina, the history provides most of the diagnostic information required. The pain is similar to that of stable exertional angina; within the same patient, the nature and location of the pain are usually the same as those experienced with exercise. The major difference is that the pain comes on at rest with no change in heart rate or blood pressure preceding the onset of pain. The pain can be more severe than that of the exertional pain and can last 30 minutes or longer. In a patient without previous objective evidence of coronary heart disease, such as prior AMI or typical exertional angina, the presenting complaint of chest pain at rest can be difficult to distinguish from noncardiac pain on the basis of the history alone. The pain is often less responsive to sublingual nitroglycerin than exertional angina.

As in stable angina, the physical examination is often unrevealing. Nevertheless, evidence of congestive heart failure, aortic valve disease, uncontrolled hypertension, tachycardia, fever, severe anemia, and marked anxiety should be sought. Most patients with unstable angina have transient ST-segment depression or elevation or T-wave inversion with the anginal episode. The absence of ECG changes with the pain, however, does not exclude the diagnosis. Frequently, unstable angina can only be differentiated from a non–Q-wave infarction by the absence of an increase in serum enzyme levels. The pain pattern and ECG changes alone do not distinguish unstable angina from a non–Q-wave infarction. In view of this consideration, a newer conceptualization of the continuum of unstable angina and non–Q-wave AMI is represented by characterizing such patients as experiencing an acute coronary syndrome. Excluded from this classification are patients with persistent ST elevation, and a high clinical priority is to further exclude from this category patients with noncardiovascular causes of chest pain.

Thallium myocardial imaging during an episode of unstable angina reveals a perfusion deficit that returns to normal following relief of pain. This observation forms the basis for our understanding of the pathophysiology (i.e., transient reduction in coronary flow), but thallium imaging is generally not required to establish the diagnosis. Exercise testing is generally contraindicated in patients having chest pain at rest. In most patients whose age and general medical condition make them potential candidates for revascularization, coronary angiography should be performed during the same hospital admission for two reasons. First, the incidence of severe coronary artery disease requiring surgery for prolongation of survival (e.g., left main coronary artery obstruction or three-vessel disease) is higher in patients with unstable angina than in those with other manifestations of coronary heart disease. Second, failure of medical therapy resulting in readmission for recurrent unstable angina or AMI has been relatively common.

Treatment

Patients with unstable angina should be admitted to the hospital and placed at bed rest in a quiet, anxiety-free environment. If arterial hypoxemia is present, oxygen should be administered. Factors that increase myocardial oxygen demand or coronary artery resistance should be vigorously treated; the most important of these are hypertension and cigarette smoking. Because of the difficulty in distinguishing unstable angina from non–Q-wave AMI, and because their pathophysiologies are similar, with acute thrombus formation causing partial or temporary occlusion, it is logical that antiplatelet therapies are effective in reducing the incidence of AMI and recurrent angina in patients presenting with unstable angina.

Aspirin, intravenous heparin, and nitrates have been the mainstays of medical therapy. If oral or topical nitrates are unsuccessful in providing prompt relief of pain, nitroglycerin should be given intravenously starting at 10 µg per minute, increasing by 10 µg per minute every 10 minutes until the initial rate of 50 µg per minute is achieved. If the pain persists or recurs, nitroglycerin can be titrated upward to a maximal dose of 300 µg per minute, provided that the systolic arterial blood pressure does not fall below approximately 100 mm Hg. If the patient has been on a b-blocker at the time of admission, it should be continued unless congestive heart failure or marked bradycardia is present. Sudden withdrawal of b-adrenergic blockers has been associated with a rebound phenomenon, resulting in more severe angina or AMI. If the patient is not already on a b-blocker, consideration should be made for initiating therapy at the time of admission.

Randomized trials have shown a marked beneficial effect of aspirin in the prevention of AMI and death over the subsequent several months (133). Intravenous heparin use has also been associated with a reduction in combined outcome of death, AMI, and recurrent angina in other studies (134). More recently, low-molecular-weight heparin has been shown to be at least as good if not better than unfractionated heparin (135). Current clinical practice includes some form of heparin for the first 24 to 48 hours of hospitalization for unstable angina. Finally, there is much enthusiasm about the possible role of glycoprotein IIb/IIIa inhibitors for the treatment of unstable coronary syndromes. Initial studies demonstrate a reduction in the composite end point of death and AMI that has been durable for up to 60 days. The ultimate role of these new therapies will be determined by the results of several recent trials (136,137). High-risk unstable angina patients with significant

ST depression, low-grade positive troponin levels, or prior AMI may have incremental benefit from treatment from the use of glycoprotein IIb/IIIa inhibitors (138).

Revascularization is the therapy of choice for patients whose angina cannot be controlled by antianginal agents and for those in whom surgery prolongs life (see Stable Angina: Surgical Therapy, previously in this chapter). The decision to pursue surgical versus catheter-based revascularization depends on the number of diseased vessels and the patient's comorbidities. The intraaortic balloon is highly effective for the temporary control of pain and can probably prevent infarction until coronary angiography and surgery can be performed for those patients whose angina cannot be controlled by intravenous nitroglycerin. The mechanism whereby the intraaortic balloon affords myocardial protection involves augmentation of diastolic aortic pressure, increasing coronary flow, and reducing systolic pressure, thus reducing myocardial oxygen demand.

Acute Myocardial Infarction

Approximately 1,500,000 patients experience AMI annually in the United States, and approximately 250,000 die before reaching the hospital (139). Approximately 50% of deaths caused by AMI occur within 1 hour of onset of symptoms, mostly the result of malignant ventricular arrhythmias and ventricular fibrillation. Many of these *electrical* deaths are preventable with better public education regarding the symptoms of AMI, as well as improved access to cardiopulmonary resuscitation and defibrillation. The challenge has been to bring medical care to the patient quickly enough, or vice versa. Of patients hospitalized with AMI, approximately 6% to 10% die during hospitalization (most of left ventricular failure) and another 5% die in the first year after hospitalization of recurrent infarction or arrhythmia. These figures represent substantial improvement in prognosis of AMI, based on advances in reperfusion therapies, risk stratification, and risk factor modification.

Pathophysiology

AMI is irreversible myocardial cell death resulting from ischemia. The key diagnostic feature of AMI for rapid assessment purposes is the finding of sustained regional ST elevation by ECG. Based on subsequently obtained cardiac enzyme studies and evolution of the ECG, AMI may be classified as *Q-wave infarction* (formerly known as *transmural*) and *non–Q-wave infarction* (formerly known as *subendocardial*). Further classification can be made according to location, as determined from the ECG. Q- wave infarctions are most often (greater than 80%) the result of total occlusion of a proximal coronary artery by a recent thrombus superimposed on a severe atherosclerotic lesion (140). In non–Q-wave infarctions the artery is usually still partially patent but severely obstructed by an atherosclerotic plaque, with or without superimposed thrombus. The basic mechanisms leading up to the acute infarction are still controversial. Two main theories have been proposed: (a) hemorrhage into a plaque, causing expansion of the plaque and further obstruction of the lumen; and (b) denuded or damaged endothelium over the plaque, leading to attachment of a platelet thrombus, which in turn leads to more thrombus formation and total occlusion of the artery.

Symptoms and Signs

The clinical presentation is usually that of severe oppressive chest pain accompanied by diaphoresis and lasting from 20 minutes to several hours. Up to 50% of patients have a prodrome of intermittent anginalike pain lasting up to several days, but with onset at rest (i.e., unstable angina). The prodromal pain can be so mild or transient that patients do not seek medical attention. The discomfort of AMI is sometimes epigastric, accompanied by a desire to belch, and often mistaken by both patient and physician for gastrointestinal upset. The pain can occasionally be interscapular, only in the arms, or only in the mandible. Data from the Framingham study, however, showed that AMI can be clinically silent in approximately 25% of patients. Other commonly associated symptoms are dizziness and weakness from low cardiac output, marked diaphoresis from autonomic discharge, and palpitations or syncope from ventricular arrhythmia.

Despite relatively typical and severe symptoms in most cases, the average delay from onset of symptoms to arrival at a hospital is 1 to 3 hours in a number of studies (139); during this period the acutely ischemic myocardium is most unstable electrically and ventricular fibrillation is most likely to occur. Further patient and public education is needed to make at-risk patients knowledgeable of symptoms and aware of the danger of delay in seeking attention. Physicians must also be prepared to deal with false alarms in emergency rooms and some ultimately unnecessary hospital admissions.

When a complete database is available (history, ECG, and serum enzymes) the diagnosis is usually not difficult, but the pain is sometimes atypical or even absent in 25% of AMI patients. Other diseases that should be considered in the differential diagnosis are acute pericarditis, mitral valve prolapse, acute pulmonary embolism, aortic dissection (which can cause AMI by occluding the coronary ostium), stable angina, unstable angina, variant (Prinzmetal's) angina, costochondritis and other chest wall pain, esophageal spasm, biliary disease, cervical root compression, and psychosomatic pain. Acute pulmonary embolism can occasionally be particularly difficult to distinguish from AMI because it can produce visceral pain, acute decrease in cardiac output, an autonomic response to this decrease, and ECG changes, all of which can resemble those of AMI.

The presenting physical signs can be surprisingly few. Either hypotension from low cardiac output or hypertension from sympathetic discharge can be present. Similarly, either bradycardia from vagal discharge (common in inferior infarction) or heart block or tachycardia from reduced stroke volume or sympathetic stimulation can be observed. In a minority of patients pulmonary congestion can be manifested by tachypnea, dyspnea, rales, or even frank pulmonary edema with frothy sputum. Examination of the heart is often normal; some patients, though, might have an S_3 gallop, a murmur of mitral regurgitation caused by papillary muscle dysfunction, or a precordial bulge reflecting dyskinetic myocardium (left ventricular wall moving outward with systole).

Diagnosis

The clinical approach to the patient must usually be chosen on the basis of rapid assessment of history, cardiac risk factors, and ECG data. For this reason a focus on the presence or absence of prolonged ST elevation by ECG is critical in determining whether the patient should receive medical or catheter-based coronary reperfusion. Current American Heart Association/American College of Cardiology guidelines advocate institution of revascularization therapy within 30 minutes of presentation for thrombolytic agents or 60 minutes by percutaneous coronary revascularization (141).

In patients with prolonged ischemic chest pain who do not have ST elevation, hospitalization and antiischemic and antithrombotic measures are instituted as described previously (see Unstable Angina). Some of these patients are found to *rule in* for AMI on the basis of serial measurements of cardiac enzymes. The dying myocardial cell releases some of its enzymatic contents into the bloodstream; the detection of these enzymes in serum is diagnostically useful. Creatine phosphokinase (CPK) is usually detectable within a few hours of the onset of symptoms, peaks at 12 to 24 hours, and is fully renally excreted within 48 to 72 hours. CPK-MB isozyme increases the specificity, and most criteria for enzymatic confirmation of AMI include a twofold rise in total CPK and an increased CPK-MB with CPK-MB percentage typically greater than 5% to 7% of the total CPK. Alternatively, a distinct rise above the normal range of CPK-MB mass by radioimmunoassay correlates highly with myocardial necrosis and may be used in tandem with one of the newer troponin assays. Serum lactate dehydrogenase (LDH) is now rarely used diagnostically; it is first detectable in serum 24 to 48 hours after onset of symptoms, peaks at 3 to 6 days, and is present at elevated levels for as long as 8 to 14 days. It is this latter characteristic that makes determination of the serum LDH level useful diagnostically in patients who do not seek medical care for several days after the onset of symptoms. Additional predictive value is conferred by the finding of an LDH1/ LDH2 isozyme reversal (142). Cardiac troponins offer the advantage of higher specificity. Cardiac troponin T (cTn-T) and cardiac troponin I (cTn-I) are currently used in clinical practice (143). Since very little cTn-T and no cTn-I is produced by skeletal muscle or other tissues, they are the most specific markers of myocardial necrosis. Levels of cTn-T and cTn-I on admission correlate with hospital and 30- to 45-day mortality data. The troponins first appear in the serum approximately 3 hours after infarction and peak in 12 to 24 hours. They have the advantage of lasting 7 to 14 days, allowing diagnosis of distant AMI and thus precluding the need for measurement of LDH.

Imaging of the heart by echocardiography, radionuclide SPECT, or magnetic resonance reveals abnormalities in AMI. These modalities may be used to confirm the clinical impression of AMI, and an emerging strategy receiving increasing support is to use these diagnostic methods for their negative predictive value (i.e., to assist in ruling out acute myocardial ischemia/injury) (144). One additional imaging modality occasionally used is technetium 99m pyrophosphate scanning. This is the same radiopharmaceutical used for bone scans; the pyrophosphate complexes with calcium in the bone and carries with it the attached technetium 99m radionuclide. The mechanism of uptake by infarcting myocardial cells is presumably similar to that of uptake by bone. Infarcting myocardial cells collect large amounts of calcium in their mitochondria, to which the technetium 99m pyrophosphate complexes. This technique has its greatest use in patients with an atypical history and a preexisting ECG abnormality that precludes a diagnosis (e.g., left bundle branch block or paced rhythm).

Treatment

Treatment of AMI has evolved from a historically passive supportive role aimed primarily at prevention and treatment of lethal ventricular fibrillation to an aggressive interventional approach aimed at reestablishing myocardial perfusion and minimizing myocardial necrosis. The primary reason for the evolution in treatment is the contemporary recognition that AMI is most frequently the result of coronary thrombosis. Three approaches have been used in humans to restore myocardial blood

flow promptly: emergent coronary bypass graft surgery, thrombolytic therapy, and percutaneous coronary intervention. Although emergency bypass surgery can be performed in selected patients and has acceptable morbidity and mortality, it has never been adequately scrutinized with a controlled clinical trial; moreover, it is expensive and is extraordinarily demanding on acute care resources. Intravenous administration of thrombolytic agents, alone or in combination with antiplatelet agents, has been shown to significantly reduce the mortality and complications resulting from AMI. Thrombolytic therapy or percutaneous coronary intervention is now an accepted standard of care for a patient presenting with ST elevation within 12 hours of the onset of continuous symptoms (141).

Thrombolytic therapy has been demonstrated to be effective in multiple randomized controlled trials for treatment of AMI. Trials have demonstrated the efficacy of streptokinase (SK), anistreplase (APSAC), tissue plasminogen activator (t-PA), and recombinant plasminogen activator (r-PA). Initial studies, including GISSI and ISIS-2, demonstrated the efficacy of SK versus placebo and that acetylsalicylic acid is required in conjunction with SK therapy (145). They also demonstrated that early therapy is required if mortality benefit is to be achieved. Subsequent trials have compared various treatment regimens to SK. Initial comparisons suggested similar efficacy for SK, APSAC, and t-PA. With refinement of the treatment strategies, it now appears that front-loaded t-PA is superior to SK or APSAC, which are equivalent. GUSTO-I randomized 41,021 patients to (a) SK and subcutaneous heparin, (b) SK and intravenous heparin, (c) t-PA and intravenous heparin, and (d) t-PA and SK and intravenous heparin. Acetylsalicylic acid was given to all patients. Thirty-day mortality was (a) 7.2%, (b) 7.4%, (c) 6.3%, and (d) 7.0%. t-PA therefore produced a 14% benefit of reduced mortality over SK and heparin (146). GUSTO-III has since demonstrated equal efficacy for r-PA and t-PA (147).

Current recommendations for treatment of AMI with thrombolytic therapy state that treatment should be considered for those with ST elevation of 0.1 mV in two contiguous leads, or for those with new left-bundle branch block and a typical clinical history for AMI, with symptom duration of greater than 20 minutes and less than 12 hours (141). Once these criteria are met, careful consideration of absolute and relative contraindications must be made prior to therapy. Absolute contraindications include recent surgery or major trauma within 14 days, active internal bleeding, aortic dissection (must be excluded if significant clinical suspicion), any hemorrhagic stroke ever, or an ischemic stroke within the past year, and known AV malformation. Relative contraindications include severe hypertension at presentation, with systolic blood pressure greater than 180 mm Hg or diastolic blood pressure greater than 110 mm Hg; cardiopulmonary resuscitation for more than 10 minutes, severe liver disease, oral anticoagulants with prothrombin time greater than 15 seconds; puncture of a noncompressible vessel; and traumatic endotracheal intubation (141). The decision regarding the appropriate regimen must take into account the patient's age and symptom duration, because the risk of intracerebral hemorrhage increases with age and benefit decreases with time.

An alternative to thrombolytic therapy is primary PTCA. Because of the benefit of early restoration of coronary flow and the common existence of contraindications to thrombolytic therapy, primary PTCA has been increasingly used. PTCA has since proven to be superior to thrombolytic therapy when both are immediately available. In the PAMI-1 trial, primary PTCA was compared with t-PA; in the PTCA group, the composite end point of reinfarction or death was reduced during hospitalization (12.5% versus 5.1%) and at 6 months (17% versus 8.2%) (148). The indications for primary PTCA are similar to those for thrombolytic therapy and can usually be performed when thrombolysis is immediately available and when thrombolytic therapy is contraindicated.

Adjunctive Medical Therapy. Established forms of therapy for AMI include hospitalization in a coronary care unit with continuous ECG monitoring, treatment of pain with narcotic analgesics, administration of supplemental oxygen, and attempts to minimize myocardial oxygen demand through attention to the determinants of myocardial oxygen consumption (see Table 61-4). The use of oxygen is now accepted as a routine measure for all patients with acute coronary syndromes. Oxygen therapy may limit both the size of myocardial injury as well as reduce the ST elevations in AMI. After initial stabilization, oxygen therapy can be discontinued for those with uncomplicated AMI. For those with oxygen saturation less than 90% or with complications such as pulmonary edema or hypotension, oxygen therapy should be continued.

Aspirin should be administered in a dose greater than or equal to 160 mg to all patients (provided they have no known hypersensitivity) with suspected acute coronary syndrome or AMI. The second International Study of Infarct Survival (ISIS-2) demonstrated that acetylsalicylic acid alone reduced the mortality of evolving AMI by 23% (145). Acetylsalicylic acid inhibits platelet aggregation by an almost complete inhibition of thromboxane A_2 production. The benefit is additional to those of thrombolytic therapy.

Morphine sulfate given intravenously in 2- to 4-mg increments is the preferred analgesic agent because of its potency, safety when given intravenously, lack of myocardial depressant effects, and generally minimal hemodynamic changes in the supine patient (149).

b-Blockers have been shown to reduce mortality both in the early (hospital) and chronic post-AMI periods. In ISIS-1 atenolol was administered within 12 hours of diagnosis and reduced hospital mortality from 4.3% to 3.7%. Similar results were seen in the MIAMI trial and in TIMI-II, where early intravenous metoprolol (within 2 hours) followed by oral dosing reduced mortality, reinfarction, and recurrent ischemia. The benefits were evident by day 1 and were sustained throughout the follow-up period. Three large well-done randomized trials have demonstrated that institution of a b-blocking agent prior to discharge for AMI reduces subsequent mortality significantly over the next several years (150,151).

Early treatment with inhibitors of the angiotensin-converting enzyme has been shown in several studies to decrease the incidence of future mortality and recurrent AMI. The only trial that did not demonstrate a mortality benefit used intravenous enalapril, which caused excessive hypotension, especially in the elderly. Current recommendations are to start treatment within 24 to 48 hours of all AMIs, especially anterior AMIs, with an angiotensin-converting enzyme inhibitor, as tolerated by blood pressure greater than 100 mm Hg (141). Intravenous angiotensin-converting enzyme inhibitor should be avoided in the acute period. Those with persistent left ventricular dysfunction receive continued benefit from its long-term use (152).

Nitrates are also commonly used in the treatment of AMI. They are indicated in patients with AMI and congestive heart failure, large anterior AMI, recurrent angina, persistent ischemia, or pulmonary edema. Caution should be used in those with right ventricular infarction, systolic blood pressure less than 90 mm Hg, or bradycardia. Nitrates act by dilating the capacitance veins, and coronary and peripheral arteries. Anginal pain is likely relieved by a combination of increasing myocardial blood flow, decreasing ventricular preload, and reducing left ventricular afterload (thus reducing myocardial O_2 demand). Intravenous nitrates are preferred because they are easily titrated to effect and systolic blood pressure.

The use of anticoagulants following AMI is still subject to debate and investigation. Studies using two-dimensional echocardiography showed that intraventricular thrombus is seen with moderate frequency in patients with anterior AMI. Thus, it seems reasonable to anticoagulate patients with anterior AMI for approximately 1 month, provided that no contraindications exist. Others would anticoagulate those patients in whom a thrombus can be detected by echocardiography; these patients are generally anticoagulated for 3 to 6 months.

Risk Assessment

Patients with uncomplicated AMI are hospitalized for 3 to 7 days. Near the end of the hospitalization, it has become accepted practice in patients who did not receive early coronary angiography to perform a low-level exercise test to look for symptoms or signs of ischemia at a low workload. Provided that patients with severe left ventricular dysfunction or severe congestive heart failure, or patients manifesting myocardial ischemia at rest or on minimal activity are excluded, the low-level exercise test can be performed safely. Some studies have shown a markedly increased risk for a future coronary event in patients who exhibit ischemia in the form of angina or ST-segment depression, or hemodynamic instability (lack of adequate heart rate or blood pressure increase) on the low-level exercise test. Thus, it has become accepted practice to recommend coronary angiography in patients exhibiting symptoms of myocardial ischemia either spontaneously or on the low-level exercise test following AMI. Such patients generally have multivessel coronary artery disease, and well-controlled clinical trials in this subgroup of patients have been performed to demonstrate that coronary artery bypass surgery or percutaneous coronary intervention improves outcome compared with medical therapy.

Complications

The most common complication of AMI is ventricular arrhythmia, which occurs in some form in more than 90% of patients in the first 72 hours following onset of the infarction. Premature ventricular beats are almost universal; more complex forms, such as couplets, triplets, and nonsustained ventricular tachycardia, are also commonly seen early after AMI. The value of treatment for these rhythms when asymptomatic has not been demonstrated; however, ventricular tachycardia (or ventricular fibrillation), when hemodynamically destabilizing, must be treated aggressively, with intravenous lidocaine and direct current cardioversion. Accelerated idioventricular rhythm also occurs relatively commonly in those with AMI. It must be distinguished from ventricular tachycardia (on the basis of a rate between 50 and 110 beats per minute) because the former is generally benign and requires no treatment.

AV conduction disturbances are relatively common and important complications of AMI. First-degree AV block (PR interval greater than 0.20 seconds) occurs in approximately 10% of patients and is almost always intranodal and benign. Progression to complete AV block only occurs in the small proportion of patients in whom

the first-degree AV block is below the bundle of His; this is generally associated with a wide QRS caused by bifascicular block. Mobitz type I second-degree AV block or Wenckebach block occurs in 4% to 10% of patients with AMI (usually inferior), is associated with a narrow QRS complex, is usually transient (up to 72 hours), is presumably caused by ischemia of the AV node, rarely progresses to complete AV block, and generally does not require pacing. Mobitz type II second-degree AV block is rare in those with AMI (less than 1% of all cases), is caused by disease below the bundle of His, is associated with a wide QRS, often progresses to complete AV block, is more often associated with anterior infarction, and generally requires pacing. When complete AV block occurs in patients with inferior infarction, it is caused by relatively well-localized ischemia of the AV node, the escape rhythm is most often nodal with a rate of 40 to 60 beats per minute, and generally well tolerated (141).

The mortality of acute inferior infarction complicated by complete AV block (20% to 25%) is moderately increased over that of inferior infarction alone. This is in contrast to anterior infarction complicated by complete AV block; there the block is a result of interruption of each of the three major fascicles below the bundle of His, meaning that the mass of infarcting myocardium is large. The escape rhythm is idioventricular, slow (less than 40 beats per minute), and subject to asystole. The mortality of anterior infarction complicated by complete AV block is high (70% to 80%), mostly as a result of the extent of the infarction. Although some have argued that pacing does not improve the relatively benign prognosis of AV block in inferior infarction, and nothing short of myocardial salvage can improve the disastrous prognosis of anterior infarction complicated by AV block, temporary ventricular pacing is generally recommended for all AMI patients with complete AV block.

Cardiogenic shock is another major complication of AMI, which occurs in 10% to 15% of hospitalized AMI patients when greater than or equal to 40% of the left ventricular myocardium has been destroyed by new and old infarction. Cardiogenic shock is defined as a cardiac output insufficient to meet the needs of vital organs despite an adequate intravascular volume and ventricular filling pressures. The hemodynamic findings in cardiogenic shock are hypotension (systolic pressure less than 80 mm Hg), left ventricular filling pressure greater than or equal to 18 mm Hg, and cardiac index less than 1.8 L per minute per m^2. Peripheral manifestations of inadequate end-organ perfusion are oliguria, cool diaphoretic skin, and altered mental status. When caused by left ventricular dysfunction, cardiogenic shock has a mortality of over 90% and is the most common cause of death in hospitalized AMI patients. It is essential to exclude hypovolemia when presented with a patient with signs of shock because it is easily treatable. Physical signs, such as venous pressure and pulmonary rales, and radiographic findings, such as Kerley B lines, correlate poorly with left ventricular filling pressure, so nothing can substitute for direct invasive measurement of left and right ventricular filling pressures in patients with suspected cardiogenic shock. The Swan-Ganz catheter can generally be passed percutaneously through a vein (usually the internal jugular) at the bedside without fluoroscopic guidance through the right side of the heart to the pulmonary artery to measure the pulmonary artery wedge pressure, which is a good approximation of left atrial pressure and left ventricular diastolic pressure.

Another correctable cause of cardiogenic shock is right ventricular infarction, which often requires intravascular volume overexpansion to right atrial pressures greater than or equal to 10 mm Hg to achieve an adequate cardiac output. Ventricular septal rupture and papillary muscle rupture each occur in 1% to 3% of hospitalized AMI patients and generally result in cardiogenic shock. These can be corrected surgically, although with a high operative mortality. When hypovolemia, right ventricular infarction, and rupture of the septum or papillary muscle have been excluded, acute left ventricular dysfunction involving 40% or more of the left ventricle is the likely cause of the cardiogenic shock. Temporary improvement in hemodynamic status can be obtained with the use of a mechanical support device such as the intraaortic balloon; by inflating in diastole and deflating in systole this balloon can reduce left ventricular afterload and increase coronary perfusion pressure. The intraaortic balloon alone, however, is rarely sufficient. The best chance for short-term survival is conferred by early cardiac catheterization with primary angioplasty of the culprit stenosis for early reperfusion. In patients who undergo such treatment successfully, several weeks after recovery significant residual ischemia should be treated by appropriate means to favorably impact on long-term survival (141).

CHEST PAIN FROM OTHER CARDIAC DISEASE

Aortic Stenosis

Pathophysiology

Aortic stenosis is a disease state resulting from increasing left ventricular outflow tract obstruction that results in pressure overload and hypertrophy of the left ventricle, with symptoms of angina, dyspnea, and syncope (153). Critical aortic stenosis constitutes a high risk for sudden cardiac death. In the middle-aged adult, aortic stenosis may become manifest as a result of a congenitally abnormal valve. The valve might have been originally bicuspid, one of the most common congenital cardiac anomalies, or might have had three unequal sized cusps. The valve functions with little or no hemodynamic derangement for the first three or four decades of life. The abnormal anatomy predisposes to fibrotic thickening and deposition of calcium, however, until the valve becomes severely stenotic in middle life. This is a disease that is more common in men. Also presenting in middle age is rheumatic aortic stenosis. The inflammatory process of rheumatic fever produces thickening and shortening of the leaflets with commissural fusion; this usually results in the hemodynamic findings of mixed stenosis and regurgitation. In almost all cases the mitral valve is also affected by the rheumatic process. In the past 20 years the incidence of senile calcific aortic stenosis has increased to the point where it is the most common cause of aortic stenosis (154). A spectrum of disease severity is seen, ranging from the combination of a moderate systolic ejection murmur and mildly thickened leaflets seen on echocardiography, to a more severe and progressive variety that ultimately requires surgical valve replacement.

The thickening and calcification of the aortic valve leaflets progressively impede the ejection of blood from the left ventricle. The left ventricle hypertrophies (increases its wall thickness) in response to this *pressure overload* and can only maintain a normal stroke volume by markedly increasing the intraventricular systolic pressure from the normal 120 mm Hg to (frequently) over 200 mm Hg. The normal aortic valve produces no measurable pressure gradient between the left ventricle and aorta, but in severe aortic stenosis this pressure gradient can be as high as 100 mm Hg (Fig. 61-3). The left ventricle might be able to compensate for this marked pressure overload for many years, but eventually myocardial failure may develop (155). The left ventricle increases its preload (filling pressure) to maintain the falling stroke volume. With increasing preload come ventricular dilatation and a falling ejection fraction. The rising diastolic pressure required to maintain cardiac output results in pulmonary venous hypertension, decreased pulmonary compliance, and the sensation of dyspnea. Natural history studies performed before the era of valve replacement surgery showed that once the full syndrome of congestive heart failure is present, the prognosis of untreated aortic stenosis is guarded; 50% of such patients die within 2 years if the valve is not replaced (156).

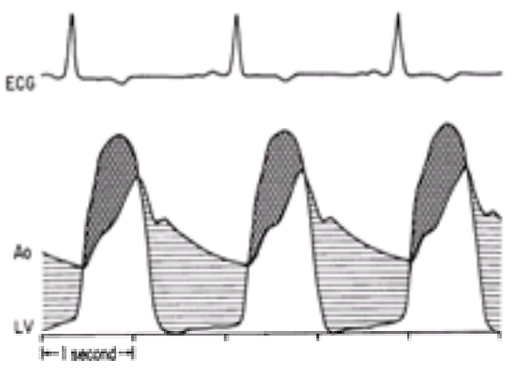

Figure 61-3. Electrocardiographic and pressure recordings from a patient with moderately severe aortic stenosis (calculated valve area = 1.0 cm^2). The cross-hatched area indicates the pressure gradient between the aorta (Ao) and the left ventricle (LV); normally, no gradient is measurable. The area marked by horizontal lines represents the diastolic pressure gradient across the coronary bed (i.e., the head of pressure driving blood through the coronary arteries). Because of the low aortic diastolic and increased left ventricular diastolic pressures, this driving gradient is reduced.

Symptoms and Signs

The symptoms of aortic stenosis vary considerably from patient to patient. Dyspnea is common, resulting from increased left ventricular diastolic pressure producing pulmonary venous hypertension, which in turn results in transudation of fluid into the pulmonary interstitium. This transudation reduces pulmonary compliance and impairs oxygen transport, with both resulting in the symptom of dyspnea. Angina is a relatively common symptom in patients with severe aortic stenosis. The pathophysiology is similar to that of angina caused by atherosclerotic coronary artery disease in that it is the result of myocardial ischemia (157). It differs in that significant coronary artery disease is present in 50% or less of adult patients with aortic stenosis. In patients without obstructive coronary artery disease, the

myocardial ischemia is the result of increased oxygen demand caused by the high left ventricular wall stress resulting from the high left ventricular systolic pressures required to overcome the obstructed valve. The impaired coronary blood flow is caused by the reduced driving pressure across the coronary bed as a result of the elevated left ventricular diastolic pressure and reduced aortic diastolic pressure. Finally, the myocardial fiber hypertrophy can exceed the capillary growth, worsening ischemia. Even in patients with obstructive coronary artery disease, similar pathophysiology of angina may pertain, because aortic valve replacement alone usually relieves the angina.

Diagnosis

The most common clinical presentation is that of a relatively asymptomatic middle-aged man with a systolic ejection murmur and possibly evidence of left ventricular hypertrophy on the ECG (158). Although the symptoms of angina, congestive heart failure, and syncope were emphasized in the past, dyspnea on exertion is the most common early symptom. Because the anginal pain of aortic stenosis is the result of myocardial ischemia, it shares many characteristics with that of angina caused by obstructive coronary artery disease. It is vague, diffuse, retrosternal, often exertional, and promptly relieved by rest. Although it can be promptly relieved by nitroglycerin, the administration of nitroglycerin might present some risk to patients with left ventricular outflow obstruction. The drop in peripheral resistance cannot be compensated for by increased left ventricular ejection; hence, the arterial pressure can fall precipitously and produce dizziness or syncope.

Physical Examination

Physical signs are useful in determining that aortic valve disease is present, but are less useful in assessing the severity of the stenosis. The characteristic finding is a systolic ejection murmur in the aortic area, with radiation to both carotid arteries. Often, however, the ejection murmur is clearly heard, or even is loudest, at the apex. In severe stenosis the peripheral pulses can have reduced amplitude and slowed upstroke, described as *pulsus parvus et tardus*. Abnormal peripheral pulses are often modulated by the compliance of the vascular system, however, and have not been consistently useful in judging severity. The left ventricular impulse is often sustained, a sign of hypertrophy, but is in the normal location if dilatation has not occurred. A thrill palpable over the upper sternum is uncommon but, when present, usually indicates severe stenosis. Because the thickened calcified leaflets are relatively immobile they do not make a sound when closing, so splitting of the second sound is not heard in adults with aortic stenosis. Similarly, a systolic ejection click is almost never heard in adults but is often present in children with aortic stenosis, in whom it is caused by the valve's snapping upward at the onset of ejection.

Electrocardiography and Chest Roentgenography

The ECG provides important clues to the presence of left ventricular hypertrophy, which in the absence of systemic hypertension often means significant stenosis. The chest roentgenogram is generally of little help in assessing the severity of the stenosis. It is useful in evaluating for the presence of left ventricular dilatation and pulmonary vascular congestion, both signs of myocardial failure. Rarely, evidence of calcification can be seen on the chest roentgenogram. The absence of valve calcification in the adult means that the stenosis is not severe; obviously this is not the case in children with congenital aortic stenosis.

Echocardiography

Two-dimensional and Doppler echocardiography have become the imaging modalities of choice for diagnosing aortic stenosis and estimating its severity. Two-dimensional echocardiography is useful for differentiating valvular aortic stenosis from the relatively uncommon (in the adult) cases of supravalvular or subvalvular stenosis. Additional information regarding ventricular wall thickness and motion as well as atrial size can be obtained using this modality. The measurement of blood velocity by the Doppler principle has proven to be so useful in the noninvasive assessment of the severity of aortic stenosis as to form the basis for therapeutic decisions regarding surgical valve replacement. To maintain a normal stroke volume the blood passing through the narrowed aortic orifice must do so at an increased velocity. Using the Bernoulli equation relating pressure drop across a stenosis to change in velocity, the instantaneous aortic valve gradient can be reliably estimated from blood velocity in the aortic root measured by Doppler ultrasound (159). Meticulous attention must be directed toward ensuring that the Doppler beam is parallel to the stenotic jet to ensure that the severity of the stenosis is fully recognized.

Cardiac Catheterization

Cardiac catheterization has in the past been the procedure of choice for defining the severity of aortic stenosis, assessing ventricular function, and determining whether associated coronary artery disease is present. Now, with accurate echocardiographic techniques for quantitating the severity of aortic stenosis and radionuclide or echocardiographic techniques for assessing ventricular function, some younger patients can undergo valve replacement without prior cardiac catheterization. Cardiac catheterization is still the preferred definitive diagnostic study in older patients with a substantial risk of concomitant coronary artery disease (over the age of 40 years), however, because it is the only reliable technique for identifying and localizing coronary artery obstructions.

Treatment

Medical therapy has little to offer in symptomatic patients other than minimizing the risks of valve replacement by optimizing hemodynamic status. It is now widely believed that all patients with angina, syncope, or congestive heart failure caused by aortic stenosis should be offered valve replacement if their general medical condition makes the risk of surgery acceptable and allows a meaningful life following valve replacement (158). In patients with symptomatic aortic stenosis, cardiac catheterization usually shows a mean aortic valve gradient of 40 mm Hg or more and an estimated valve orifice area of 1 cm^2 or less. It is still controversial whether asymptomatic patients with severe aortic stenosis should also be offered valve replacement (160).

Aortic valve replacement can be accomplished with an average operative mortality of less than 5% (158). Reparative procedures on the aortic valve have been tried but are not effective, either because of failure to relieve the stenosis or because of rapid recurrence of the stenosis. Several types of prosthetic valves are currently in common use and are generally of two types, mechanical prosthetic valves (tilting-disk and bileaflet) and bioprosthetic valves (stented or stentless heterografts or homografts). Because both homograft and heterograft valves are avascular, and perhaps because of their sterilization and treatment with glutaraldehyde, they are nonantigenic. Nevertheless, each is a nonliving biological structure; the stresses imposed by millions of openings and closings under pressure result in gradual disintegration of the collagen and elastic fibers in the valve. Thus, biological valves are expected to have a finite lifespan, ranging from 10 years (porcine heterograft) to perhaps 15 to 20 years (cadaveric homograft). On the other hand, they are relatively nonthrombogenic and generally do not require anticoagulation, with its attendant risk of bleeding (161). Mechanical prostheses are durable but are thrombogenic and require permanent anticoagulation with warfarin. An increasingly used procedure with advantages to the younger aortic stenosis patient is the Ross procedure. A pulmonary autograft is performed, in which the patient's own native pulmonary valve and main pulmonary artery are excised and grafted into the aortic position, with reimplantation of the coronary arteries. Typically, a heterograft is placed in the pulmonic position. Postsurgical anticoagulation is not required, early results indicate better graft survival relative to aortic homograft, and the valve and root can continue to grow if the patient is a child or adolescent (162).

Prognosis

Patients with aortic stenosis who are asymptomatic and maintain normal exercise tolerance probably have a good prognosis (160). On the other hand, the prognosis changes precipitously with the onset of symptoms; 25% die in the first year and 50% within 2 years of the onset of symptoms. The prognosis is worst if the symptoms are those of congestive heart failure, with nearly all patients dying within 2 years. Unfortunately, although valve replacement improves prognosis in patients with congestive heart failure caused by aortic stenosis, the prognosis is worse than in aortic stenosis patients without heart failure undergoing valve replacement.

Aortic Regurgitation

Pathophysiology

Aortic regurgitation has many causes; some of the more common are a congenitally bicuspid valve, rheumatic heart disease, endocarditis, many connective tissue disorders, and collagen vascular diseases. To compensate for the loss of a portion of left ventricular ejection back into the left ventricle, the left ventricle increases its stroke volume by dilating to as much as five times its normal volume. Rarely, patients with pure aortic regurgitation and no coronary artery disease experience angina pectoris (163). The pathophysiology is analogous to that presented for aortic stenosis. The marked left ventricular dilatation that represents the compensation for significant chronic volume overload results in increased left ventricular wall stress. Although left ventricular systolic pressures are usually normal, the increased radius of the left ventricle results in increased wall stress (and, thereby, increased myocardial oxygen demand) according to the Laplace relationship. Coronary blood flow can be impaired both by a low aortic diastolic pressure from the low-resistance runoff back into the left ventricle and by an increased left ventricular diastolic pressure,

leading to relative tissue ischemia.

Symptoms and Signs

Aortic regurgitation can be asymptomatic for many years, even if it is severe. Like aortic stenosis, the most common symptom is dyspnea on exertion. Late in the course of the disease the full picture of congestive heart failure can be seen, including marked fatigue, orthopnea, paroxysmal nocturnal dyspnea, and edema.

Diagnosis

The diagnosis is usually easily made from the physical examination, which reveals the typical diastolic, decrescendo, high- pitched murmur at the left sternal border, wide pulse pressure, bounding peripheral pulses, and a displaced cardiac impulse caused by the left ventricular dilatation. Echocardiography and Doppler ultrasound are useful in confirming the diagnosis and in assessing left ventricular size and function and the severity of the regurgitation. Echocardiography is now considered appropriate for decision making regarding aortic valve replacement (164). Cardiac catheterization is helpful in assessing coronary artery disease, quantitating the severity of the regurgitation, evaluating for other valve involvement, and assessing left ventricular function.

Treatment

Medical therapy should include prevention of endocarditis with prophylactic antibiotics. Afterload reduction with nifedipine was shown to be of benefit in delaying the need for valve replacement in one series (165); whether inhibition of the renin-angiotensin system will be of equal or greater benefit is unknown. Even more than is the case with aortic stenosis, the timing of aortic valve replacement in patients with severe aortic regurgitation is critical (166). Because in many patients the left ventricle is capable of sustained compensated function, premature valve replacement may unnecessarily expose the patient to increased thrombotic or bleeding complications. However, if surgery is unduly delayed, left ventricular dysfunction may become irreversible. Therefore, current indications for aortic valve replacement in aortic regurgitation include symptoms of left heart failure, impaired exercise tolerance and falling exercise ejection fraction, or end-systolic diameter larger than 55 mm by echocardiography (166).

Prognosis

Valve replacement in appropriately selected patients is usually associated with amelioration of cardiac symptoms and enhancement of survival.

Mitral Valve Prolapse

Pathophysiology

Chest pain is frequently associated with mitral valve prolapse, although the exact pathogenesis of chest pain is unclear. Mitral valve prolapse is one of the most frequent cardiovascular abnormalities, occurring in 3% to 5% of the population, with female subjects affected approximately twice as frequently as male subjects (167). In the milder forms the distinction from normal is often unclear. The full syndrome consists of typical auscultatory findings of a midsystolic click and late systolic murmur, atypical chest pain, and arrhythmias (168). Although there are multiple causes, the common denominator appears to be a mitral apparatus that is too large. In early systole the valve might be competent, but as the ventricle becomes smaller with systolic ejection, the mitral leaflets prolapse into the left atrium, resulting in mitral regurgitation and a late systolic murmur. The chordae are too long, and the mitral leaflets large and redundant. Histologic examination of the leaflets reveals a loose myxomatous material in the leaflets. Haphazard arrangement and disruption of the collagen can be seen on electron microscopy. Although mitral valve prolapse can be seen in those with known connective tissue disorders such as Marfan's and Ehlers-Danlos syndromes, most patients with prolapse do not have another identifiable connective tissue disorder. Nevertheless, it is thought that mitral valve prolapse can be a specific genetic syndrome because it is inherited in many patients, often with a characteristic body habitus including pectus excavatum and an asthenic appearance (169).

Symptoms and Signs

Mitral valve prolapse should be considered in the differential diagnosis of most types of chest pain, especially if the pain is not typical of angina and the patient is female. The pain often is sharp, stabbing, and nonexertional. It usually does not respond to nitroglycerin. The pathophysiology of the pain is unknown. Some have attributed it to abnormal tension on the papillary muscles, but proof is lacking. Palpitations from the cardiac arrhythmias associated with this syndrome are also common. Rarely, the arrhythmias can produce alterations in cardiac output resulting in dizziness, syncope, or even sudden cardiac death (170).

Diagnosis

The diagnosis can be made from the physical examination alone if the typical findings of midsystolic click and late systolic murmur are present. Only a portion of the classic findings can be present, however, and the physical signs are dynamic, varying greatly with the hemodynamic state. Some patients can have a pansystolic murmur indistinguishable from that of other forms of mitral regurgitation. Thus, a set of diagnostic criteria has been developed, based on the presence of symptoms, signs, and findings on echocardiography (171). Cardiac catheterization is rarely required unless the mitral regurgitation is severe enough to lead to consideration of mitral valve replacement or repair. If the patient has palpitations or symptoms of transient cerebral ischemia, evaluation for arrhythmias should be done. The 24-hour ambulatory ECG is the most useful tool, although sometimes the arrhythmias can be identified on the resting or exercise ECG. The full range of arrhythmias from atrial or ventricular premature beats to supraventricular and ventricular tachycardias has been observed.

Treatment

Most patients have an excellent prognosis and require no treatment. Patients who have mitral regurgitation should receive endocarditis prophylaxis for dental and other procedures in which bacteremia is likely to occur (172). For those with significant chest pain, b-adrenergic blockers can be effective therapeutically as can long-acting calcium channel antagonists. These agents can also ameliorate palpitations in mitral valve prolapse due to supraventricular or nonsustained ventricular tachycardia. However, individuals with hemodynamically significant ventricular arrhythmias should be treated aggressively with amiodarone or implantable defibrillator. Mitral valve prolapse is a manifestation of myxomatous valve disease, a syndrome now most frequently etiologically implicated as the cause of mitral regurgitation requiring valve replacement surgery in the elderly population (173).

Hypertrophic Cardiomyopathy

Pathophysiology

Hypertrophic cardiomyopathy is an uncommon, genetically mediated disease with a heterogeneous presentation, including angina, dyspnea, syncope, and, in a small high-risk subset, sudden cardiac death. Contemporary molecular genetic studies have demonstrated that mutations of many of the contractile protein genes (e.g., b-myosin heavy chain, a-tropomyosin, and troponin T) are associated with the bizarre myofiber disarray, endocardial plaquing, and interstitial fibrosis that characterize the myocardium in patients with this disease (174). The pathophysiologic features of hypertrophic cardiomyopathy are mediated by regional (septal more than basal more than lateral) ventricular hypertrophy resulting frequently in dynamic, and less commonly in fixed, obstruction to flow through the left ventricular outflow tract (175). Systolic function of the ventricle is preserved or even supernormal in the earlier stages of the disease. The dyspnea and exercise intolerance are the result of diastolic dysfunction secondary to abnormal ventricular compliance caused by the massive hypertrophy of the ventricular walls. Some patients have disproportionate hypertrophy of the interventricular septum (asymmetric septal hypertrophy) that may result in displacement of the anterior leaflet of the mitral valve, further contributing to left ventricular outflow tract obstruction.

Symptoms and Signs

Many patients with hypertrophic cardiomyopathy are asymptomatic. The diagnosis may be suspected by a family history of sudden cardiac death or hypertrophic cardiomyopathy, by an ECG showing unexplained left ventricular hypertrophy, or by the murmur in those patients with the obstructive variety of the disease. Physical examination is notable for a markedly sustained apical impulse, which may be accompanied by a palpable presystolic augmented atrial contraction. Jugular venous pressure may be increased with a prominent A wave, reflecting abnormal diastolic function of the right ventricle. Ventricular gallops, S_4 more commonly than S_3, may

be heard and the carotid upstroke has a distinctive bifid character. The most distinctive physical finding is a harsh systolic murmur heard across the entire precordium, which may be accompanied by a separate mitral regurgitation murmur. The ejection murmur is unique in being augmented by maneuvers (squat-to-stand or strain phase of Valsalva) that decrease venous return and reduce ventricular loading, worsening the obstruction. The most common symptom among symptomatic patients is dyspnea on exertion. The chest pain is anginal in character and is usually the result of myocardial ischemia that can often be demonstrated objectively by perfusion. Although the epicardial coronary arteries are typically large and free of obstructive disease, an imbalance exists between myocardial oxygen demand and supply due to narrowing of small intramyocardial coronary arteries (176). Other factors predispose to the finding of frank ischemia in obstructed patients: increased left ventricular wall stress because of the high systolic pressures, high diastolic pressure in the left ventricle, and outstripping of capillary growth by the marked myocardial fiber hypertrophy. Besides dyspnea and chest pain, both atrial and ventricular arrhythmias are relatively common and can produce palpitations, dizziness, syncope, or sudden cardiac death.

Diagnosis

The ECG is nearly always abnormal, most commonly showing the QRS voltage and repolarization abnormalities of left ventricular hypertrophy. Also, abnormal Q waves, which are sometimes confused with AMI, are seen in 30% to 50% of patients (177). The diagnostic procedure of choice is the echocardiography (178). The increased left ventricular wall thicknesses and normal ventricular cavity size are usually easily identified. Systolic anterior motion of the anterior mitral valve leaflet can be visualized and the degree of obstruction characterized in response to diagnostic maneuvers (e.g., Valsalva's). Risk stratification and treatment of arrhythmia in these patients are complex due to the underlying myocardial substrate, and probably should be performed in centers with extensive experience in this evaluation (179).

Treatment

No specific therapy is required for asymptomatic patients, unless mitral regurgitation is present, indicating the need for antibiotic prophylaxis. Echocardiography of family members and genetic counseling, however, should be recommended for all patients with this disorder. Current therapeutic approaches include medications [b-adrenergic antagonists, nondihydropyridine calcium channel blockers, and occasionally potent negative inotropic medications such as disopyramide (180)], dual-chamber pacing to reverse the pattern of ventricular contractile activation (181), and resection of the disproportionately increased myocardium, a procedure known as myotomy-myectomy (182). Although useful in aggregate for symptom control, no form of therapy has been clearly shown to reduce the risk of sudden cardiac death.

Acute Pericarditis

Pathophysiology

Acute pericarditis is caused by inflammation of the pericardium and produces a characteristic pain syndrome, pericardial friction rub, and ECG changes. Other forms of pericarditis, such as subacute effusive pericarditis and constrictive pericarditis, are not discussed here, because these usually do not produce pain but cause hemodynamic abnormalities.

Pathologic examination reveals acute inflammatory cells within both the visceral and parietal pericardium. The inflammation can invade the myocardium beneath the visceral pericardium, which probably accounts for the characteristic ECG changes (see following discussion). Fibrin becomes deposited on the pericardium, giving it a shaggy, reddened appearance; an accompanying pericardial effusion may be present. Most cases of acute pericarditis heal, leaving little in the way of residual changes except for a few clinically insignificant adhesions between the visceral and parietal pericardium. In a few cases, however, acute pericarditis leaves marked fibrotic changes in both layers of adherent pericardium, resulting in constriction of the heart.

The following are some common causes of acute pericarditis:

- Idiopathic
- Infection: viral; pyogenic bacteria
- Immunologic disorders: acute rheumatic fever; rheumatoid arthritis; systemic lupus erythematosus; scleroderma; post-AMI (Dressler's syndrome; postpericardiotomy syndrome)
- AMI
- Drugs: procainamide; hydralazine; isoniazid.

It is thought that viral infection (particularly coxsackie B and echovirus type 8) accounts for a large percentage of cases of acute pericarditis, although documentation of viral infection is often not possible. Uremia and drugs (procainamide and hydralazine) are other common causes of acute pericarditis. Bacterial infection is a rare but potentially lethal form of acute pericarditis that requires immediate diagnosis and treatment with drainage and antibiotics (183).

Symptoms and Signs

Acute pericarditis characteristically produces severe sharp chest pain that worsens in the supine position and is partially relieved by sitting. It is often markedly exacerbated by deep breathing, leading to confusion with pleuritis (which can accompany acute pericarditis). Some patients experience a pulsating nature to the pain with each heartbeat. The pain is more often retrosternal but can radiate to the anterior neck, the mandible, and the trapezius ridge (184). Patients can be dyspneic because of the marked increase in severity of the pain with normal respiration. The prime physical sign is the pericardial friction rub. Since the time of Laennec, the rub has been described as sounding like creaking leather. Typically, three separate components to the rub have been noted: systole, rapid ventricular filling in early diastole, and atrial contraction. Often only one or two components are present, however, with the systolic component usually being the last to disappear. In its complete form the rub is easily distinguishable from cardiac murmurs but, if only the systolic component is present, this distinction is often unclear. The rub often changes with position; to exclude a pericardial friction rub the patient must be examined in multiple positions, including on hands and knees.

Diagnosis

The diagnosis can generally be made by the history of typical positional pain, as described previously, the physical signs, and the ECG. The typical ECG finding is widespread ST-segment elevation associated with upright T waves, observed in more than 90% of cases (185). Besides the noncoronary distribution of ST elevation, it is usually more saddle-shaped or concave than in AMI. Later, T- wave flattening, inversion, or both can develop. New Q waves never develop; this is a feature that distinguishes acute pericarditis from an acute Q-wave AMI. The distinction from non–Q-wave infarction is much more difficult, however, and requires the identification of the rub, no or minimal changes in cardiac enzyme levels, and a rapid response to antiinflammatory agents. ST-segment elevation in this context is nonspecific; in addition to occurring in the early stages of AMI, ST-segment elevation can be a normal variant known as *early repolarization*, a sign of a ventricular aneurysm, or a sign of coronary artery spasm.

The chest roentgenogram is of relatively little value. If an accompanying pericardial effusion is present, the cardiac silhouette can be enlarged. Levels of cardiac enzymes, creatine kinase and LDH, are most commonly within the normal range, but occasionally minor elevations with positive isozymes can be found. The echocardiogram, although commonly ordered, provides little specific information. Whereas the echocardiogram is the best diagnostic tool available for pericardial effusion, effusion is often absent in acute pericarditis.

Treatment

The pain of acute pericarditis usually promptly responds to institution of antiinflammatory agents. If the pain is mild, aspirin, 650 mg three or four times a day, can be adequate. For more severe cases, a nonsteroidal antiinflammatory agent should be used at effective doses; indomethacin, 25 to 75 mg three or four times a day, seems to be highly effective in most cases. In fact, the pain relief can be dramatic and rapid, within 4 to 8 hours. If no relief has been obtained in 24 to 48 hours, prednisone may be started at a dose of 60 to 80 mg daily in divided doses; this can usually be tapered and stopped after about 2 weeks of therapy. The response to antiinflammatory agents is so characteristic that failure to respond to the above regimen should lead to questioning of the diagnosis. If the pain is severe, narcotic analgesic agents should be used until relief is obtained with antiinflammatory agents.

In a minority of patients acute pericarditis can recur weeks or months after completion of the initial course of therapy, requiring repeat treatment. In a few patients

pericardiectomy might be required to control the pain of multiple recurrence and avoid the side effects of sustained prednisone therapy. Recent studies suggest that colchicine may be of benefit in this setting (186). In most patients the pericarditis heals without recurrence or late sequelae. A few patients, however, develop chronic constrictive pericarditis.

AORTIC CHEST PAIN

Fortunately, acute emergency room presentations of aortic chest pain are relatively uncommon. However, due to their high-risk potential they need to be aggressively sought in at-risk patients. The major aortic causes of chest pain include dissection, aneurysm, and ulcer. Of these, the most commonly encountered is acute aortic dissection, accounting for approximately 2,000 cases annually in the United States (187).

Aortic Dissection

Clinical Description and Pathophysiology

Aortic dissection is the most common clinical catastrophe involving the aorta, far exceeding rupture of the abdominal aorta. It is characterized by severe, sharp chest pain in 75% to 90% and hypertension in 60% to 75% of patients. This uncommon but potentially lethal event begins with an intimal tear followed by progressive formation of a plane within the media of the aorta, consisting of extravasating blood intermixed with evolving thrombus. Untreated, it is lethal in most patients because of rupture of the aorta. In a large natural history series 21% died within 24 hours of onset of symptoms, 37% by 48 hours, and 74% within 2 weeks (188). Dissection occurs in all adult age groups, but has its greatest incidence in middle age and older. Other than a history of hypertension, patients are often completely healthy right up to the acute event, which in some cases may be precipitated by abrupt motion. Male subjects predominate over female by a ratio of 2 to 3:1. The most common associated risk factor is hypertension. The incidence of aortic dissection appears to be increased in pregnant women and in patients with congenitally bicuspid aortic valves, Marfan's syndrome, or Ehlers-Danlos syndrome.

Cystic medial necrosis is a common pathologic finding in aortic dissection. It is seen in the unaffected aortic wall of many patients dying of aortic dissection; both elastic and collagen fibers degenerate, with cystic spaces developing within the media. Although a similar pathologic picture is seen in patients with Marfan's syndrome, an autosomal dominant connective tissue disorder susceptible to aortic dissection, an inherited biochemical defect cannot be identified in most patients with dissection. The cystic medial necrosis can be the result of excessive mechanical stress and strain, because it increases in frequency in patients with systemic hypertension or hypertension of the ascending aorta caused by coarctation of the aorta. This observation is the source of the controversy regarding the role of cystic medial necrosis because it seems to occur with equal frequency in hypertensive patients without dissection as in patients with dissection, most of whom have also had hypertension (188). Nevertheless, many authorities believe that the weakening of the media of the aorta through degeneration of elastic and collagen is an important factor in the pathogenesis of dissection of the aorta (189).

A tear of the intima of the aorta can be identified in most but not all autopsied cases of aortic dissection; this tear can also frequently be seen by imaging methods used clinically (see following discussion). The intimal tear is seen twice as frequently in the ascending aorta, where the hydrodynamic forces of left ventricular ejection are the greatest, than elsewhere in the aorta. Variables that seem to be important are the rate of rise of aortic pressure (dP/dT), the systolic pressure, and the pulse pressure (systolic pressure minus diastolic pressure). The stress within the wall of the aorta is a function of both the intraluminal pressure and the radius (the Laplace relationship). Thus, for a given aortic pressure, the stress in the wall of the aorta is greater in a dilated aorta than in a nondilated one. Similarly, the increased stroke volume and decreased vascular resistance of pregnancy, resulting in a widened pulse pressure and increased aortic dP/dT, might be why dissection appears with increased frequency in pregnant women. Once the intimal tear allows intraluminal blood access to the media of the aorta, the hydrostatic forces of each heartbeat result in further tearing and separation of the media. The dissection can extend as far distally as the iliac arteries and proximally to the aortic valve cusps and ostia of the coronary arteries. A second lumen to the aorta is formed, known as a *false lumen*, which can be detected by angiography, transesophageal echocardiography (TEE), and CT scanning. Sometimes the false lumen can rejoin the true lumen distally through a second tear in the intima; this can relieve some of the pressure in the false lumen and slow or stop the dissecting process. As the dissection passes the orifice of a side branch of the aorta, the displaced intima can result in obstruction of that branch. Thus, loss of distal limb pulses or occlusion of a coronary artery resulting in AMI is frequently seen in aortic dissection. Also, the blood supply to other vital organs, such as the kidney and bowel, can be disrupted by this process. If the dissection extends retrograde to the aortic valve, the support of the valve leaflets can be altered so that aortic regurgitation ensues. Although the interruption of blood supply to vital organs can be devastating, the usual cause of death is external rupture, either into the pleural space or the pericardial space.

Aortic dissection has been classified according to several schemes. The DeBakey classification was based on point of origin of the medial tear and encompassed three variants: type I, involving ascending aorta, arch, and descending aorta; type II, involving ascending aorta only; and type III, involving descending aorta only. Because of the implications for treatment, the Stanford criteria have become more commonly used in recent years (190). By this scheme type A dissection involves proximal (ascending) aorta, with or without involvement of arch, descending aorta, or both, whereas type B dissection involves the descending aorta only. As discussed, the signs and symptoms of each type may be distinctive.

Symptoms and Signs

Pain, which is usually excruciating, is a presenting symptom in over 90% of patients with dissection and the predominant presenting symptom in over 75% (191). The pain is usually maximal in intensity at its onset in contrast to the pain of myocardial ischemia or infarction, which often waxes and wanes. The pain is sometimes described as a tearing or ripping sensation. The pain can migrate from an anterior retrosternal location to posterior or back pain as the dissection propagates. The location of the pain is of some value in localizing the dissection (191). Two-thirds of patients with dissection in the ascending aorta have anterior chest pain, compared with only 27% of patients with dissection in the descending thoracic aorta. Nearly all (94%) patients with dissection in the descending thoracic aorta have pain in the back, but 50% of patients with dissection in the ascending aorta also have back pain. Commonly associated with the pain are symptoms and signs of autonomic nervous system hyperactivity such as diaphoresis, bradycardia or tachycardia, apprehension, nausea, and vomiting. Other presenting symptoms are syncope, stroke, paraplegia from interruption of the spinal arteries, pulse loss with resultant limb ischemia, and congestive heart failure from aortic regurgitation. In the large series from Massachusetts General Hospital, only 8 of 124 patients had no pain: four presented with congestive heart failure, two with stroke, and two with an abnormal chest roentgenogram (191).

Hypertension, sometimes severe, is commonly present, more frequently with dissection of the descending thoracic aorta than the ascending. In one series 60% of patients with dissection of the descending aorta had a diastolic pressure exceeding 120 mm Hg, and in 42% it exceeded 140 mm Hg. Conversely, up to 20% of patients with ascending aortic dissection can be hypotensive. Loss of one or more arterial pulses is common, having been reported in 50% of patients with dissection involving the ascending aorta and in 16% of those with dissection of the descending thoracic aorta (188). This sign is particularly useful if the state of the pulses has been carefully recorded previously. One-half to two-thirds of patients with dissection of the ascending aorta develop the high-pitched decrescendo murmur of aortic regurgitation. It may be heard along the right sternal border in contrast to the more common types of aortic regurgitations, which are best heard along the left sternal border. The other well- known signs of severe aortic regurgitation (e.g., bounding peripheral pulses, wide pulse pressure, left ventricular heave), however, might not be present early in the course of dissection because not enough time has passed for left ventricular dilatation and increased stroke volume to occur.

Although rupture of the dissection into the pericardial space is usually promptly fatal and is the most common cause of death from dissection, a few patients can have a limited leak into the pericardium. These patients can exhibit a pericardial rub or hypotension and pulsus paradoxus from pericardial tamponade. Approximately 20% of patients have neurologic deficits on presentation. Hemiparesis with or without change in consciousness occurs most commonly in patients with dissection of the ascending aorta, while neurologic compromise of the lower extremities (e.g., paraparesis) is seen more commonly with dissection of the descending thoracic aorta (192).

Diagnosis

The definitive diagnosis of aortic dissection is based on demonstration of the separation of the aorta into true and false lumens. Given the overlap of sensitivity and specificity of several useful diagnostic approaches, the technique of choice is often defined by local clinical practice. Aortography by selective injection of radiographic contrast material into the ascending aorta accurately distinguishes aortic dissection from other types of aortic aneurysms and is still considered the gold standard diagnostic procedure in many centers. The combination of transthoracic and TEE can identify virtually all the major features of dissection, including the intimal flap, communications between the false and true lumina, aortic root dilation, thrombus formation, aortic regurgitation and pericardial effusion or tamponade. Multiplane ultrasound imaging has greatly enhanced the value of TEE, allowing practitioners to take advantage of its safety, portability and rapidity of application in unstable patients to yield a definitive diagnosis (193). Alternative techniques, including magnetic resonance imaging and contrast-enhanced chest CT scanning, are reported to

be as sensitive as TEE with slightly enhanced sensitivity. Thus, a common-sense approach may be to choose the diagnostic approach based on the clinical and hemodynamic stability of the patient: Unstable patients may be most rapidly assessed with TEE and triaged to early operative intervention if appropriate, while those who are more stable may be more effectively evaluated with MRI, CT or angiography (192).

Treatment

Pharmacologic therapy should be initiated as soon as the diagnosis of aortic dissection is suspected. The goals are to reduce aortic pressure and dP/dT, to reduce the likelihood of acute rupture. For this purpose, intravenous nitroprusside to reduce blood pressure and an intravenous b-blocking agent (intermittent bolus metoprolol or continuous infusion esmolol) are appropriate. Typically, reduction of systolic blood pressure to the 110 to 120 range is the objective. This can also be achieved in some cases with intravenous use of the combined a-, b-blocker labetalol.

For patients in whom a type B dissection is confirmed, continued antihypertensive therapy with close observation for complications such as increasing aortic diameter, saccular aneurysm formation, or persistent chest pain is appropriate. For patients experiencing these complications surgical intervention is most safe and effective after 2 to 3 weeks of medical stabilization, if possible. The surgical procedure involves replacement of a relatively short segment of the descending thoracic aorta by a left lateral thoracotomy, obliterating the false lumen at both the distal and proximal anastomoses in the process. Surgery is recommended for type A dissections provided that the status of other organ systems does not impose an excessive surgical mortality and provides the possibility of satisfactory quality of life. This surgery consists of resection of the ascending aorta from just above the sinus of Valsalva to the origin of the innominate artery, followed by replacement with a Dacron prosthesis. The false lumen is obliterated while making the distal anastomosis if the dissection extends beyond, as it often does. Generally, no attempt is made to resect all of the involved aorta if the dissection involves the arch or the descending aorta. If coronary occlusion or significant aortic regurgitation has occurred, however, the aortic valve is also replaced and the coronary arteries are reattached to the aortic prosthesis. Improvements in operative technique have improved surgical survival rates to the range of greater than or equal to 95% at 30 days postsurgery (194).

Aortic Ulcer

Clinical Description and Pathophysiology

A clinical entity that has been increasingly recognized as a cause of acute chest pain, and which may have distinct implications for therapy, is the penetrating aortic ulcer (195). An aortic atheromatous plaque may ulcerate, with progressive disruption of the internal elastic lamina and burrowing through the intima into the media. As a consequence, localized intramedial dissection may occur, in association with a variable degree of intramural hematoma formation and the possibility of pseudoaneurysm formation in the adventitia or frank rupture with hemothorax. Virtually all patients with aortic ulcer have severe aortic atherosclerosis as the predisposing factor.

Diagnosis

The majority of cases of penetrating aortic ulcer occur in the descending aorta. Characteristic features most commonly encountered include midscapular pain affecting an elderly person with hypertension. Frequently, an abdominal aortic aneurysm is also present, perhaps serving as a marker of the severity of the atherosclerotic process within such patients. As is the case with aortic dissection, the diagnostic methods of choice include TEE, contrast CT, magnetic resonance imaging, or contrast angiography. These studies reveal an ulcer crater and variable amounts of intramural hematoma but no evidence of intimal flap. The natural history and risk of penetrating aortic ulcers may be greater than for more typical forms of aortic dissection, possibly because of the involvement of more layers of the aorta by penetrating ulcer in comparison with the usual occurrence of dissection within the middle to outer third of the media. Penetrating ulcers of the ascending aorta are therefore considered an absolute indication for urgent surgical repair, whereas the approach to descending aorta–penetrating ulcer is more controversial. A higher index of suspicion for complications must be maintained for penetrating ulcer of the descending aorta, and in patients in whom other factors would predict intermediate-term survival and good functional status, operative intervention after an initial period of stabilization is appropriate (195).

Aortic Aneurysm

Clinical Description and Pathophysiology

Aneurysm of the thoracic aorta is an uncommon cause of chest pain that most often presents in a subacute fashion related to its size and location within the thorax. Ascending thoracic aneurysms are typically not due to atherosclerosis, but rather to other forms of aortopathy, such as cystic medial necrosis, giant cell arteritis, or following chest trauma. Descending aortic aneurysms, in contrast, usually are associated with severe atherosclerosis. Patients with dilation of the ascending aorta may experience left-sided heart failure as a result of aortic annular dilation and aortic valvular insufficiency. Alternatively, enlargement of the sinuses of Valsalva due to aortic root dilation may be associated with direct compression of the coronary arteries or coronary arterial thromboembolism. Such a sinus of Valsalva aneurysm may rupture into the right ventricular cavity, the right atrium, or the pulmonary artery causing heart failure. Thoracic aortic aneurysms may exist in a clinically quiescent state for a long time but eventually may cause symptoms on the basis of compression of thoracic structures, such as dyspnea or cough due to airway compression, superior vena cava syndrome, or pulmonary artery stenosis. Such aneurysms may also rupture into the mediastinum, pleural space, or esophagus.

Diagnosis and Treatment

As with other forms of thoracic aorta disease, contemporary imaging methods including TEE, contrast CT scan, magnetic resonance imaging, and aortography are diagnostically useful. It is generally agreed that primary prophylactic operation is indicated in cases in which the aneurysm has reached 6 cm in maximal diameter or 5 cm in patients with Marfan's syndrome (192). Recurrent symptoms or progressive enlargement are probably indications for more urgent operative intervention.

CHAPTER 62

Painful Disorders of the Respiratory System

David D. Ralph

This chapter includes discussion of painful disorders of the trachea, bronchi, lungs, and pleura. Because the primary focus of this book is on pain, many nonpainful respiratory disorders are not considered here. Examples of disease not included are chronic obstructive pulmonary disease (COPD), adult respiratory distress syndrome, asthma, and pulmonary fibrosis. Moreover, because disorders of the upper airway (nose and mouth, pharynx and larynx) are discussed in Chapter 47 and Chapter 52, they are not considered here. The information is presented in five parts: basic considerations, painful disorders of the tracheobronchial tree, pain caused by diseases of the lung, disorders of the pulmonary circulation, and chest pain caused by disorders of the pleura. As with most other chapters in the book, only key references are included. More detailed discussion can be found elsewhere (1,2). Cancer of the lung is discussed in Chapter 35, Chapter 36, and 64.

BASIC CONSIDERATIONS

Anatomic and Neurologic Aspects

This section contains a summary of the anatomy of the trachea, bronchi, lungs, and pleura and is presented as a review. This supplements the information in Chapter 60. More detailed discussion can be found elsewhere (3,4,5 and 6).

Anatomy of the Trachea, Bronchi, and Lungs

Trachea and Bronchi. The trachea is a cartilaginous membranous tube that extends from the larynx on a level with the C-6 vertebra to the upper border of the T-5 vertebra, where it divides into the right main bronchus and the left main bronchus. The trachea is nearly but not quite symmetric and is flattened posteriorly. It is approximately 11 cm (10 to 12 cm) long and its diameter from side to side ranges from 2.0 to 2.5 cm, being greater in the male than in the female. The trachea is smaller, more deeply placed, and more movable in the child than in the adult (3,6).

The right main bronchus is wider, shorter, and less abrupt in its divergence from the trachea than the left main bronchus. It usually continues approximately 2.5 cm before the right upper lobe bronchus branches off laterally, but in a study of approximately 20 cadavers, Bonica and Hall (7) found that the right main stem bronchus varied from 0.3 to 2.5 cm long. The left bronchus is smaller in caliber but longer than the right bronchus, usually being approximately 5 cm long. Each main bronchus gives off secondary bronchi for each lobe of the lung, and these in turn give off tertiary bronchi for each lobule of the lung. Figure 62-1 depicts the anatomy of the tracheobronchial tree.

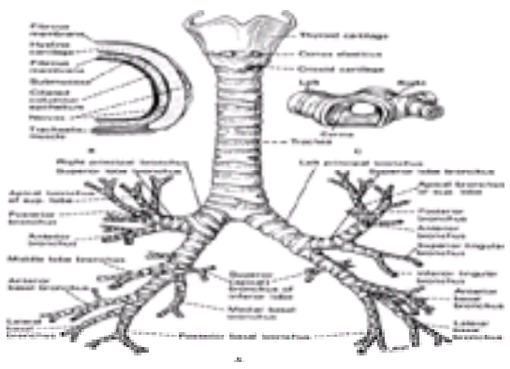

Figure 62-1. Anatomy of the tracheobronchial tree. **A:** Anterior view of the trachea and primary and secondary bronchi and tertiary bronchial tubes. The right main stem bronchus makes an angle of approximately 20 degrees with the midsagittal plane, whereas the left main stem bronchus makes an angle of 40 degrees. **B:** Cross-section of the adult trachea showing the nerves that supply the submucosa and mucosa. **C:** Bifurcation of the trachea viewed from above. The interior shows the carina as it would be seen through a bronchoscope. (Modified from Clemente CD. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985.)

Lungs and Pleura. The two lungs and the parietal pleura are shown in Figure 62-2. Each lung is invested by two layers of serous membrane, the pulmonary, or visceral, pleura and the parietal pleura. The visceral pleura covers the surface of each lung and dips into the fissures between its lobes. The parietal pleura lines the inner surface of the chest wall, covering the diaphragm, and is reflected over structures occupying the middle of the thorax. The two layers are contiguous with each other and on and below the root of the lung; normally they are in actual contact with each other, with a small amount of liquid in the potential pleural space, permitting movement of the two layers without friction (see Chest Pain Caused by Disorders of the Pleura).

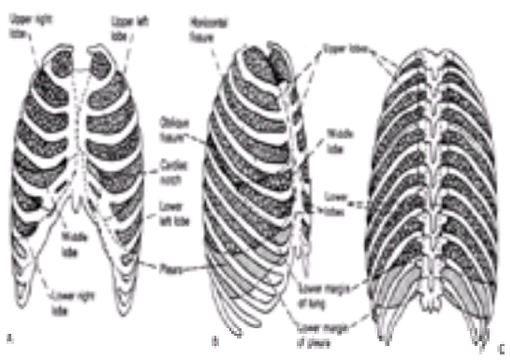

Figure 62-2. Anterior **(A)**, lateral **(B)**, and posterior **(C)** views of the thorax showing the relationship of the pleurae and lungs to the chest wall. The pleura from each side approaches the other behind the midportion of the manubrium. The extension of the caudal portion of the pleurae is seen in **B** and **C**.

When the lung collapses, or when air or fluid collects between the two layers, the cavity becomes apparent. The right and left pleural sacs are entirely separate from each other; between them are the thoracic viscera (see Fig. 62-2A). The parietal pleural sacs touch each other only for a short distance anteriorly behind the upper part of the body of the sternum. In the center of the chest cavity the two pleural sacs are separated by the mediastinum.

Different portions of the parietal pleura have special names to indicate their position: The costal pleura lines the inner surface of the ribs and the intercostal muscles; the diaphragmatic pleura covers the convex (superior) surface of the diaphragm; the mediastinal pleura covers the medial aspects of the lungs and is in contact with other thoracic viscera; and the cupola of the pleura (cervical pleura) arises in the neck and overlies the apex of the lung.

Neurophysiology

Trachea, Bronchi, and Lungs. Chapter 60 contains a description of the nerve supply to the tracheobronchial tree, the pulmonary vessels, the lungs, and the pleura. Figure 62-3 and Figure 62-4 are reproduced here from Chapter 60 for the convenience of the reader. Figure 62-5 is a schematic depiction of the segmental nerve supply to the lungs.

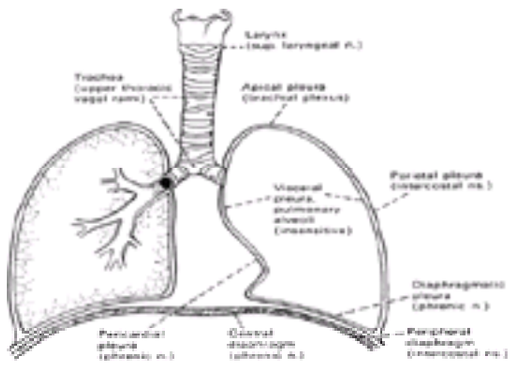

Figure 62-3. Schematic representation of the sensory nerve supply to the tracheobronchial tree, parietal pleura, and upper surface of the diaphragm, as well as to the diaphragmatic pleura. (Modified from White JC. Sensory innervation of the viscera. In: Wolff HG, Gasser HS, Hinsey JC, eds. *Res Publ Ass Nerv Ment Dis: Pain.* Vol 23. Baltimore: Williams & Wilkins, 1943: Fig. 97, p. 377.)

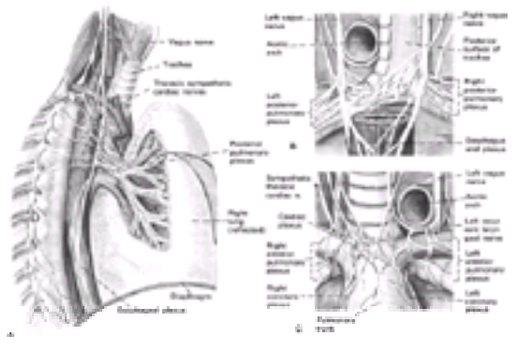

Figure 62-4. Anatomy of the pulmonary plexuses and their distribution. **A:** Right parasagittal view showing origin, course, and termination of the nerves that contribute to the right pulmonary plexus. **B,C:** Posterior and anterior views of the trachea and two primary bronchi to show the relation of the pulmonary plexus to these structures. (Developed from data in Mitchell GAG. *Cardiovascular innervation*. London: E & S Livingstone, 1956:196–238; and Netter FH. *The CIBA collection of medical illustrations.* Vol 7, The respiratory system. West Caldwell, NJ: CIBA Pharmaceuticals, 1979:28.)

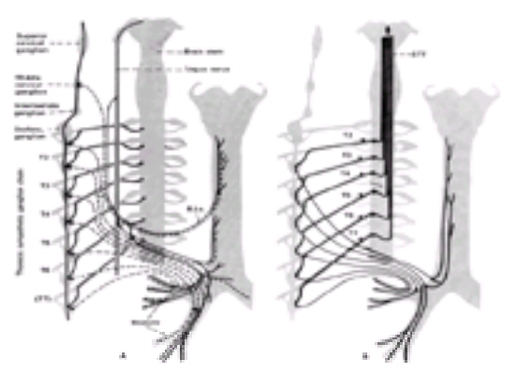

Figure 62-5. **A:** Schematic representation of the segments of the spinal cord and sympathetic chain that provide sympathetic efferent and afferent nerves and of the vagal nerves that supply parasympathetic efferent and afferent fibers to the tracheobronchial tree, the lungs, and their blood vessels. Preganglionic sympathetic and parasympathetic fibers are shown as solid lines, and postganglionic sympathetic fibers are shown as dashed lines. **B:** The sympathetic afferents are depicted with their cell bodies in the dorsal root ganglia, their proximal branches synapsing in the dorsal horn of the spinal cord, and the distal branches accompanying the sympathetic nerves. Both sympathetic efferents and afferents pass through the white rami communicantes, the thoracic sympathetic chain, the thoracic cardiac and aortic nerves, and the esophageal nerves and then proceed to their destination. (R.l.n., recurrent laryngeal nerve; STT, spinothalamic tract.)

The tracheobronchial tree receives contributions from the vagus, which contains preganglionic parasympathetic and afferent fibers, and also from the sympathetic postganglionic fibers derived from the T-2 to the T-6 or T-7 sympathetic ganglia and occasionally the stellate or middle cervical ganglia. The trachea receives some vagal afferent and efferent fibers through the recurrent laryngeal nerve, which is frequently joined by fibers from the middle cervical sympathetic ganglion. The lower part of the trachea receives vagal fibers directly from the vagus nerves and postganglionic sympathetic fibers from the stellate and T-1 ganglia.

The two bronchial trees and the pulmonary vessels derive their nerve supply from a larger posterior pulmonary plexus and a smaller anterior pulmonary plexus located at the beginning of each pulmonary artery on each side (4). Each pulmonary plexus contains vagal efferent and afferent fibers, as well as sympathetic efferent and afferent fibers, which leave the root of the lung and proceed distally. Immediately after entering the lungs the nerve filaments become partially segregated into groups that accompany the main bronchi, the pulmonary vessels, and the bronchial arteries. At the level of the main bronchi is a subepithelial plexus, located between cartilaginous plates and the bronchial musculature, and a deep plexus, located between cartilaginous plates in the submucous and mucous membranes.

From the walls of the smaller bronchi the two plexuses blend into a single plexus that can be traced as far as the respiratory bronchioles, but nerve fibers running either singly or in small bundles continue still further into the walls of the atria (4). Afferent fibers extend distally as far as the proximal end of the alveolar duct (Fig. 62-6).

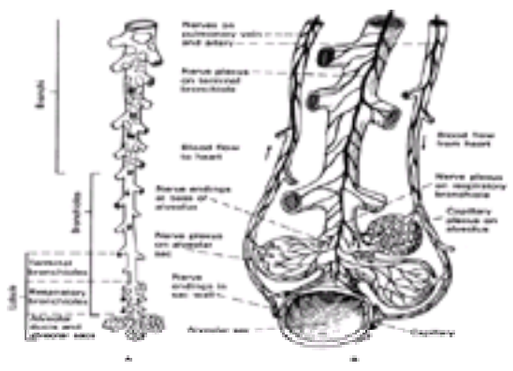

Figure 62-6. **A:** Anatomy of the distal part of a tertiary bronchus and of the bronchioles, alveolar ducts, and alveolar sacs. **B:** Nerve supply to the terminal portion of the pulmonary artery, the pulmonary vein, and respiratory bronchioles, all of which contribute to the nerve supply of the alveolar ducts and alveolar sacs. The number of alveolar sacs has been greatly reduced for the sake of clarity. Note the nerve endings within the wall of the alveolar sac that has been cut. (**A** and part of **B**modified from Netter FH. *The CIBA collection of medical illustrations.*Vol 7, The respiratory system. West Caldwall, NJ: CIBA Pharmaceuticals, 1979:28. Distal part of **B** was developed from data of Fillenz M, Widdicombe JG. Receptors of the lungs and air-ways. In: Neil E, ed. *Handbook of sensory physiology*. Vol 3/1. Berlin: Springer-Verlag, 1972:81–112.)

The nerve supply to the various vessels within the lungs varies in richness: The small bronchial arteries have the best supply, the pulmonary arteries are less richly innervated, and the pulmonary veins have a poor supply, limited to their extrapulmonary parts and the large intrapulmonary branches (5). The larger bundles of the pulmonary arteriolar nerve fibers are located on the side of the vessels, facing the bronchi, and can be traced to the extremities of these vessels; some extend beyond them to the visceral pleura. Filaments passing through the bronchial arteries come from the adjacent extrachondrial parts of the bronchial nerve plexus.

Both myelinated and unmyelinated fibers have been found in pulmonary nerves and plexuses. Many of these have sensory receptors in the pulmonary blood vessels and are involved in the reflex control of the pulmonary circulation, with vasoconstrictor and vasodilator fibers supplied by the sympathetic and parasympathetic efferent nerves, respectively. The lungs have two types of receptors that probably have a nociceptive function: type J receptors of C afferents and“lung irritant” receptors with afferents in the A-d range, all running in the vagus nerves (4,8). The type J receptors are located within the interstitial space, close to the capillaries, whereas the lung irritant receptors are found in the epithelial lining of the lung and its airways. These receptors are activated by various stimuli that produce mechanical distortion within the lung, such as pulmonary congestion, microembolism, atelectasis, and pneumothorax, and biochemical irritants. Pain caused by mechanical or chemical damage of the lung is probably mediated by these A-d and C fibers. The sympathetic afferents might have a role in the transmission of nociceptive impulses and are involved in reflex control of the circulation and of the tracheobronchial tree.

The sensory nerves that transmit nociceptive impulses from the trachea and bronchi are afferents of the vagus nerves and their branches (see Chapter 60; also see Fig. 60-17). It appears that each side of the tracheobronchial tree derives its sensory supply from the ipsilateral vagus nerve because, when the mucous membrane of the tree is noxiously stimulated, the area of pain reference is ipsilateral to the site of stimulation. Section of the vagus nerve below the recurrent laryngeal nerve but above the pulmonary plexus has been found to abolish the pain caused by carcinoma of the bronchus.

Pleura. The visceral pleura is supplied by sympathetic fibers that have a vasomotor function; these have afferent fibers that apparently have no nociceptive function because noxious stimulation of the visceral pleura does not result in pain. As previously mentioned, the visceral pleura also receives parasympathetic fibers through the pulmonary plexuses. In contrast, the parietal pleura is richly supplied by nerves containing sensory fibers that carry nociceptive information. The costal pleura is supplied by the intercostal nerves. The cupola of the pleura (cervical pleura) is supplied by the first thoracic spinal nerve, while the mediastinal pleura and diaphragmatic pleura are supplied by sensory fibers contributed by the phrenic nerves (see Fig. 60-8).

Evaluation of the Patient

Evaluation of patients who present with pain in the chest suspected of being caused by disease of the tracheobronchial tree, lung, or pleura requires a detailed history, physical examination, and, frequently, chest imaging studies. The history and physical examination should be carried out as discussed in Chapter 12 and Chapter 60. Pulmonary function tests; arterial blood gas analysis; chemical and microbiological tests; or special studies such as computed chest tomography (CT), magnetic resonance imaging scan, endoscopy, biopsy, or radionuclide scanning might also be necessary. Because disorders of the respiratory system are frequently a manifestation of a systemic process, attention must be focused not only on the chest but also on the comprehensive evaluation of the patient's entire health status.

History taking provides essential information and initiates the physician's understanding of the patient as a person, the patient's environment, and the type and place of work, as well as the patient's expectations and fears. As discussed in Chapter 12, data should include past and present history; information on previous illnesses, medications, and other therapies; a family history; and history of the occupation. If warranted, information should be obtained about travel history; exposure to pets or other animals; or exposure to such hazards as tobacco, smoke, asbestos, coal, silica, beryllium, iron oxide, tin oxide, cotton dust, titanium, silver, and nitrogen dioxide (9).

Obviously, much time should be devoted to obtaining a detailed description of the presenting chest pain and other major respiratory symptoms, such as cough, dyspnea, wheeze, and hemoptysis. The most important respiratory system disorders that produce pain include inflammation of the tracheobronchial tree or of the pleura, as in pneumonia, pulmonary thromboembolism, and malignancy. Pleuritic pain is usually localized to one side of the chest and is related to movements of the thorax and to respiration. Lesions confined to the pulmonary parenchyma do not produce pain except as previously mentioned, when pathophysiologic processes stimulate the J or the lung irritant receptors. Detailed information must be obtained about the various characteristics of the pain, including the speed of onset, location, radiation, intensity, duration, and factors that aggravate and relieve the pain (see Chapter 60) (9). A detailed history and a comprehensive physical examination, carried out along the lines summarized in Table 60-1, together with a review of Chapter 60C, permit a presumptive diagnosis. Important diagnostic points (see Table 60-2) should also help the physician to make a differential diagnosis among pain caused by respiratory disorders, pain of the chest wall resulting from orthopedic or neurologic problems, and pain referred to the chest from diseases of the abdominal viscera or from neck and upper limb disorders.

Epidemiology

Acute respiratory disorders afflict more Americans than any other group of acute conditions. The 1992 estimates published by the National Center of Health Statistics based on the National Health Interview Survey, indicated that, of a total of 445 million acute conditions, 209 million (47%) involved the respiratory system (Table 62-1) (10). Because the survey excluded those conditions that did not involve restricted activity or medical attention, the actual figure is even larger. The next most frequent group of acute conditions included approximately 62 million injuries and 54 million infectious and parasitic diseases. As noted in Table 62-1, these respiratory disorders caused 707 million days of restricted activity, 345 million days of bed disability, and nearly 129 million days lost from work among those 18 years of age or older who were fully employed outside the house. In addition, respiratory disorders caused more than 82 million days of school absence in those younger than 18 years of age.

Conditions	Total number	Restricted activity (days)	Bed disability (days)	Work loss (days)	Attended by physicians: Percentage of conditions	Attended by physicians: Total physician visits
Common cold	66.8	148.5	42.4	21.6	41.9	27.9
Other upper respiratory infections	30.9	74.9	11.6	10.8	80.9	25.0
Influenza	90.4	195.4	170.1	69.3	36.2	32.7
Acute bronchitis	12.1	67.2	27.9	11.5	90.7	11.0
Pneumonia	4.2	64.3	40.0	11.0	90.7	4.1
Other acute respiratory conditions	5.2	23.3	13.6	3.2	89.1	4.6
All	208.9	757.5	345.6	129.4	50.1	104.4

From National Center for Health Statistics. Current estimates from the National Health Interview Survey: United States 1992. Vital Health Stat 10:190. DHHS Pub. No. (PHS)93-1518. Hyattsville, MD: National Center for Health Statistics, 1993.

TABLE 62-1. Incidence and impact of acute respiratory disorders (numbers in millions)

Table 62-1 lists the percentage of acute respiratory conditions that resulted in at least one visit to a physician. As might be expected, the highest percentage of medical attention was obtained for upper respiratory infections, acute bronchitis, and pneumonia. The number of physician visits for each condition (last column) was computed by multiplying the total number for each condition by its percentage. The total was nearly 105 million visits.

With regard to chronic respiratory conditions, 1994 information for certain disorders is available (11): chronic bronchitis, 14.0 million; asthma, 14.6 million; emphysema, 2.0 million; chronic sinusitis, 34.9 million; and other chronic respiratory conditions, 26.1 million (12). This does not include data on neoplasms (see Chapter 64). No figures are available about the number of restricted activity days, bed disability days, and days of lost work, but it is likely that the numbers are significantly larger because of the chronicity of these disorders.

PAINFUL DISORDERS OF THE TRACHEOBRONCHIAL TREE

Acute Tracheobronchitis

Acute inflammation of the upper respiratory tract causes mild to moderate pain, which is perceived as soreness and irritability of the airway. The patient can also experience retrosternal burning or soreness, often associated with a sore throat or laryngeal irritation. The condition is generally self-limiting, with eventual complete healing and return of function. Although often mild, bronchitis can be serious in debilitated patients and in those with chronic lung or heart disease. Bacterial pneumonia can be a critical complication (13).

Etiology

Acute bronchitis can be caused by an infectious process or by various irritants. An acute infectious process, most prevalent in winter, is often part of an acute upper respiratory infection. Not infrequently this develops after a common cold or other viral infection of the nasopharynx, throat, or tracheobronchial tree and is often complicated by a secondary bacterial infection. Exposure to air pollutants and possibly chilling, fatigue, or malnutrition are predisposing or contributing factors (13). Recurrent attacks often complicate chronic bronchopulmonary disease, and impair bronchial clearance mechanisms. Repeated infections can be associated with chronic sinusitis or bronchiectasis.

Various irritating gases can also cause inflammation of the tracheobronchial tree. Acute irritative bronchitis can also be caused by various mineral and vegetable dusts and by fumes from strong acids, ammonia, certain volatile organic solvents, chlorine, hydrogen sulfide, sulfur dioxide, or chlorine. Polluted air can settle over an area, and highly irritant gases such as sulfur dioxide and nitrogen peroxide can increase in concentration until clinical symptoms result. Inhalation of extremely hot air produces a burning in the upper airway that is exceedingly painful and slow to heal (13). When associated with inhalation of soot and burning particles, such a burn can be rapidly fatal.

Pathophysiology

Acute infectious tracheobronchitis initially causes hyperemia of the mucous membranes followed by desquamation, edema, leukocytic infiltration of the submucosa, and production of a sticky or mucopurulent exudate. The protective function of the bronchial cilia, phagocytes, and lymphatics is disturbed, and bacteria can invade the normally sterile bronchi and cause accumulation of cellular debris and mucopurulent exudate. Coughing, although distressing, is essential to eliminate bronchial secretion. Airway obstruction can result from edema of the bronchial walls, retained secretions, and, in some cases, spasm of the bronchial muscles. Direct thermal injury from inhalation of hot air, if not fatal, causes the patient to cough up eschar before recovering. The healing process is prolonged and difficult.

Symptoms and Signs

Acute infectious bronchitis is often preceded by symptoms of upper respiratory infection: coryza, malaise, chills, slight fever, back and muscle pain, and sore throat (13). The onset of tracheobronchitis is signaled by a cough that is initially dry and nonproductive but raises small amounts of viscid sputum for a few hours a day and then becomes more abundant and mucopurulent. At this time patients can feel retrosternal irritation and discomfort or frank pain. Patients with frequent coughing episodes can experience pain due to strains of the intercostal or abdominal muscles. In severe or complicated cases, fever up to 38.3°C or 38.9°C (101°F or 102°F) can be present for 2 to 5 days, after which a few symptoms subside while the cough can continue for several weeks. Some patients continue to cough and some bring up abundant mucoid or mucopurulent sputum. Dyspnea, which is secondary to the underlying obstruction, can be experienced.

Auscultation in patients with uncomplicated acute bronchitis reveals scattered high- or low-pitched rhonchi, occasional crackling or moist rales, or both at the base of the lungs. Wheezing after coughing is commonly noted. Patients with acute irritative bronchitis usually have a dry nonproductive cough, but with invasion of bacteria, patients develop the same symptoms and signs as those of acute infectious bronchitis.

Patients who manifest persistent or increased fever may be developing bronchopneumonia, which can produce persistent localized signs of consolidation. This and other serious complications are seen most commonly in patients with underlying chronic respiratory disorders. In such patients, acute bronchitis can lead to worsening blood gas abnormalities.

Diagnosis

Diagnosis is presumptively made through a detailed history and physical examination. If the symptoms and signs are serious or persist, a chest roentgenogram should be taken to rule out other diseases or complicating pneumonia. When serious underlying chronic respiratory disease is present, arterial blood gases should be monitored at frequent intervals. Microbiological smears and cultures can be obtained in an attempt to determine the infective organism.

Treatment

Treatment consists of rest until pain subsides, fluids in amounts of 3 to 4 L per day during the febrile course, and the administration of nonsteroidal antiinflammatory drugs (NSAIDs) to reduce the fever and relieve the muscle pain that most of these patients have. NSAIDs should be given in sufficient doses to provide effective analgesia and achieve an antipyretic effect. For example, aspirin in doses of 600 mg every 4 hours should be given, but if this does not provide effective relief, the dose should be increased to 1,000 mg every 4 hours. Of course, in patients who are allergic to aspirin, other NSAIDs should be used. In any case patients should be monitored closely for any adverse side effects (see Chapter 83). If the patient has a severe cough that continues to produce muscle pain and interferes with sleep, codeine in doses of 32 to 64 mg should be added to NSAIDs. Care should be taken if patients also have COPD. Other measures include steam inhalation or a vaporizer for coughing and bronchodilators for wheezing.

In patients in whom a high fever persists and who have purulent sputum or in those who have a concomitant underlying disorder such as COPD, antibiotics should be

given (13,14). A chest film should be obtained to exclude the development of pneumonia. Oral amoxicillin, 250 mg every 6 hours, or trimethoprim-sulfamethoxazole is adequate for most patients without underlying diseases. In COPD patients it is important to cover *Streptococcus pneumoniae*, *Hemophilus influenzae*, and *Moraxella catarrhalis*. Cefaclor, azithromycin, or clarithromycin are alternative effective antibiotics in COPD patients (14). Sputum smear evaluation and culture plus chest imaging can guide antibiotic choice if symptoms persist or recur or in patients with unusually severe disease.

Bronchiectasis

Bronchiectasis is an irreversible focal dilation of the bronchioles, often accompanied by infection. Although pain is not the most severe symptom, many patients experience some retrosternal and general chest pain (15,16).

Etiology and Pathophysiology

Acquired bronchiectasis results from direct bronchial wall destruction after infection, inhalation of bronchial chemicals, immunologic reaction, or vasculopathy that interferes with bronchial nutrition, or alternatively from mechanical alterations secondary to atelectasis or loss of parenchymal volume that leads to bronchial dilation and secondary infection. Acquired conditions commonly leading to bronchiectasis include the following: (a) severe pneumonia (especially complicating measles, pertussis, or certain adenovirus infections in children); (b) necrotizing infection at any age caused by *Klebsiella*, staphylococci, influenza virus, fungi, mycobacteria, and perhaps *Mycoplasma*; and (c) bronchial obstruction from any cause such as foreign bodies, enlarged lymph nodes, mucous infection, or lung cancer. Inherited causes of bronchiectasis include conditions such as cystic fibrosis and ciliary dyskinesis syndromes (17).

Bronchiectasis can be localized or extensive and is most common in the lower lobes in conditions other than tuberculosis. Upper lobe involvement is common with tuberculous bronchiectasis. Pathologic examination of the airway reveals extensive inflammatory destruction, chronic inflammation, increased mucus, and loss of cilia.

Symptoms and Signs

Although patients might be completely asymptomatic, chronic cough and sputum production are the most characteristic and common symptoms in infected patients; these usually begin insidiously after a respiratory infection and tend to worsen gradually over a period of years (15,16,18). As the condition progresses, the cough eventually becomes more productive, occurring with typical regularity in the morning on arising, late in the afternoon, and on retiring, but many patients are affected with cough during intervening hours. Concurrent pneumonia and hemoptysis are common, and the latter can be the first and only symptom in so-called dry bronchiectasis. Physical findings are not specific, but persistent rales can occur over the affected part of the lungs. Pulmonary functional and hemodynamic changes depend on the extent of the accompanying pathologic changes, such as diffuse chronic bronchitis, pulmonary emphysema, or pulmonary fibrosis, and can include reduction in lung volumes and air flow rates, ventilation or perfusion defects, hypoxemia, and, in severe cases, pulmonary hypertension.

Pain is not a common symptom but it can occur and produces significant discomfort, particularly in patients in whom the bronchiectasis is associated with osteoarthritis, so-called rheumatic bronchiectasis. Such patients have pain not only in the chest but also in the limbs. Teodori and Galletti reported a number of cases (19) in which patients with bronchiectasis had pain in the chest and in the arms that was moderate and poorly localized. Ten of 18 patients with bronchiectasis had deep marked diffuse pain of variable location. Figure 62-7 depicts the most frequent sites of the pain, cutaneous hyperalgesia, and deep hyperalgesia. It was concluded that the pain was a referred phenomenon from stimulation of the tracheobronchial tree, whereas the cutaneous and deep hyperalgesia were caused by viscerocutaneous reflexes (19).

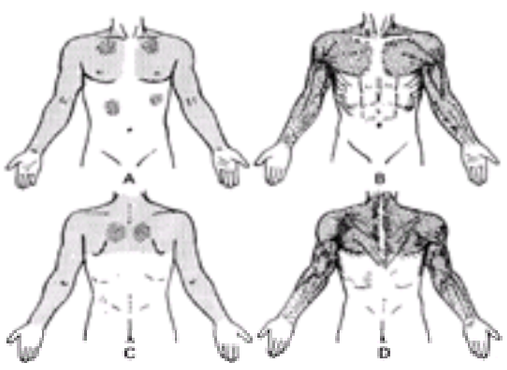

Figure 62-7. Distribution of pain and of cutaneous and deep hyperalgesia in patients with bilateral bronchiectasis. **A,B:** Anterior views of distribution of the pain, indicated by heavy stipples and of the cutaneous hyperalgesia, indicated by the cross-hatched areas. **C,D:** Posterior views showing the distribution of deep hyperalgesia involving muscles of the chest. (Modified from Teodori U, Galletti R. *Il dolore nelle affezioni degli organi interni del torace*. Rome: L Pozzi, 1962:262.)

Diagnosis

Diagnosis of bronchiectasis is made by history and physical examination and by symptoms and signs as described above. Standard chest radiographs can show increased bronchovascular markings, areas of honeycombing, or cystic areas with or without fluid levels, but often the radiographs are nondiagnostic in early stages of disease. CT scanning of the chest is necessary to confirm the diagnosis and extent of the lesions, especially if surgery is being contemplated (15,16).

Treatment

Treatment consists of appropriate antibiotics, other drugs, and physical therapy to promote bronchial drainage. In patients without cystic fibrosis, the flora in the sputum are usually mixed gram-positive and gram-negative microorganisms, and anaerobes commonly inhabit the bronchiectatic cysts. A broad-spectrum antibiotic such as amoxicillin, 250 to 500 mg orally every 6 hours, or trimethoprim-sulfamethoxazole is continued until the sputum is nonpurulent and less voluminous, usually for 1 to 2 weeks. Antibiotics should be repeated at the first sign of returning infection; if it recurs frequently, prolonged chemoprophylaxis with amoxicillin or trimethoprim-sulfamethoxazole can be tried but is often disappointing. If bronchopneumonia or serious respiratory infection occurs, a parenteral antibiotic guided by Gram's stain and culture/sensitivity studies is indicated. Cystic fibrosis patients may develop early staphylococcal colonization and as their course progresses will eventually become colonized with mucoid *Pseudomonas*species, which require intermittent active treatment (17). Effective methods to improve drainage of secretions in cystic fibrosis patients include exercise, chest percussion with postural drainage, positive expiratory pressure devices, vest/compressor oscillation systems, and possibly hand-held oscillation flutter devices (20).

The mild to moderate pain that is usually present in a number of patients should be managed with NSAIDs in moderate to high doses (650 to 1,000 mg aspirin every 4 hours). If these are not effective and the patient has a persistent cough, moderate doses of codeine can be added to the NSAIDs. If physical examination reveals the presence of a superimposed myofascial syndrome, trigger points should be injected with a local anesthetic and other therapy should be carried out (see Chapter 29 and Chapter 64).

PAIN CAUSED BY DISEASES OF THE LUNG

Lung tissue is generally considered to be insensitive to noxious stimuli; accordingly a large number of common lung diseases are not discussed in this chapter. However, under certain pathophysiologic conditions, the J receptors in the interstitial space near the capillaries, the lung irritant receptors in the epithelial lining of the lung and its airways, or both types of receptors are excited by stimuli that produce mechanical distortion within the lung tissue, such as pulmonary congestion. In addition, infectious diseases such as pneumonia or lung abscess can extend to produce inflammation of the pleura and cause pleuritic pain. Disorders of the pulmonary circulation such as pulmonary hypertension and pulmonary embolism can also be a source of chest pain.

Pulmonary Infections

Pneumonia

Pneumonia is defined as an inflammation in the lung parenchyma in the portion distal to the terminal bronchioles and composed of the respiratory bronchioles, alveolar ducts, alveoli, and interstitial tissues (21,22). Patterns of pneumonia can be classified based on roentgenographic or pathologic evidence. In lobar pneumonia the infection is confined to an entire lobe; in segmental or lobular pneumonia it is confined to a segment of the lobe; in bronchopneumonia it is confined to alveoli contiguous to the bronchi; and in interstitial pneumonia it is confined to the interstitial tissues.

Etiology and Epidemiology. The most common causes of pneumonia in adults are bacteria: *S. pneumoniae*, *Staphylococcus aureus*, *H. influenzae*, *Klebsiella pneumoniae*, and other gram-negative bacilli. Legionella can occur in several serotypes; the frequency of legionella infection varies from community to community. *Mycoplasma pneumoniae* can cause pneumonia, especially in older children and young adults. Various other types of bacteria can also cause specific types of pneumonia.

Predisposing factors include respiratory viral infection, alcoholism, age extremes, debility, immunosuppressive diseases and immunosuppressive therapy, compromised consciousness, pulmonary aspiration, and exposure to transmissible agents (22). The usual mechanism is either inhalation of droplets small enough to reach the alveoli or aspiration of secretions from the upper airways. Other mechanisms include hematogenous dissemination or through the lymphatics or directly from contiguous infection. An important contributing factor is postoperative or posttraumatic decrease in chest wall and pulmonary compliance, with consequent hypoventilation, impairment of the cough reflex, bronchial spasm, and dehydration. All these cause retention of bronchial secretions, which lead to segmental atelectasis and in turn to lung infection.

Another unusual but important cause of pneumonia is aspiration of gastric contents (Mendelson's syndrome), which causes chemical pneumonitis with serious lung pathophysiology. This disorder is the most frequent cause of anesthetic morbidity and mortality among patients who receive general anesthesia (23).

Other contributing factors are weakness from malnutrition or neuromuscular diseases, thoracic deformities such as severe kyphoscoliosis, or severe lung disease that prevents the full inspiration and brisk expiration necessary to generate an effective cough (22).

In the United States 3 to 4 million people develop community-acquired pneumonia annually; approximately 16% require hospitalization, and of these 75,000 to 125,000 die from pneumonia (24). Pneumonia is the most common lethal infection and ranks sixth among all disease categories as cause of death; it is the most frequently occurring fatal hospital-acquired infection. In addition to diarrheal illnesses, lower respiratory tract infections are a major cause of death in developing countries. Despite this impressive prevalence, few infections have causative agents that are so frustratingly difficult to identify. In up to 50% of patients no pathogen can be identified, despite a strong clinical impression of bacterial pneumonia (25).

Pathophysiology. The earliest stage of pneumonia is congestion characterized by extensive serous exudation, vascular engorgement, and rapid bacterial proliferation. The next phase is called *red hepatization*, reflecting the liverlike appearance of the consolidated lung or lobule. The air spaces are full of polymorphonuclear cells, with vascular congestion; extravasation of red blood cells provides the basis for the reddish discoloration on gross examination (21). The parenchyma can be intact, but the usual air-containing spaces change into a solid organ with a dense inflammatory response; hence, the term *hepatization*. The next stage is *gray hepatization*, in which accumulation of fibrin is associated with inflammatory white and red blood cells in various stages of disintegration, and the alveolar spaces are packed with an inflammatory exudate. The final stage is resolution, characterized by resorption of the exudate, often with little or no permanent scarring or loss of function.

Symptoms and Signs. The major symptoms of pneumonia occur in varying combinations of cough, fever, chest pain, dyspnea, and the production of sputum, which can be mucoid, purulent, or even bloody. In some patients extrapulmonary features such as confusion or disorientation are prominent features. Occasionally, in elderly, alcoholic, or neutropenic patients, respiratory symptoms and signs are absent altogether.

Chest pain occurs predominantly in lobar pneumonia that involves the peripheral lung tissues, frequently sparing the airways (22). The inflammation involves the pleura early and thus pleuritic pain is an initial symptom. The onset of pain may be fairly rapid, occurring over a few hours and mimicking the pain associated with pulmonary embolism. Pleurisy is frequent with pneumococcal lobar pneumonia, occurs not infrequently with *Klebsiella* pneumonia, but is noted infrequently in mycoplasmal and viral pneumonia. Because the pleura is unaffected in bronchopneumonia and interstitial pneumonia, pain is usually not a prominent symptom in these conditions.

The common physical findings are fever, tachycardia, and tachypnea; patients with severe hypoxemia appear cyanotic. Chest examination usually reveals a decreased respiratory excursion on the affected side because of the pleuritic pain and dullness to percussion from pneumonic consolidation or an accompanying pleural effusion (22). Among the earliest auscultatory findings is the presence of high-pitched end-inspiratory crackles originating from fluid-filled alveoli. Consolidated lung surrounding a patent bronchus produces bronchial breath sounds. Examination of the skin with a pinprick or pinch reveals cutaneous hyperalgesia in the same segments supplying the pleura. If the diaphragmatic pleura is involved, the hyperalgesia is found in dermatomes C-3 to C-5 and perhaps in T-9, T-10, and T- 11 (see Chapter 60 for details of innervation of the pleura).

Patients with lower lobe involvement also have hyperalgesia of the chest, whereas if the pneumonia involves the upper lobes, the hyperalgesia is present in T-2 to T-5 or T-6. In addition, pinch reveals deep hyperalgesia and increased muscle tension. Both the cutaneous and deep types of hyperalgesia are present on the side ipsilateral to the pneumonia (19).

Diagnosis. A presumptive diagnosis is usually made through a detailed history, physical examination, and roentgenographic studies, which invariably show the pulmonary infiltrate. Culture and staining of appropriate specimens are unfortunately often of limited usefulness in identifying the pathogen (25). A complete blood cell count, electrolytes, and renal and hepatic function testing have prognostic significance but rarely point to a specific pathogen. For definitive diagnosis it is necessary to demonstrate the pathogen in pleural fluid, blood, or lung or transtracheal aspirate (21,25).

Treatment

General Therapy. Treatment of patients with pneumonia includes general measures such as rest, fluids, and antibacterial agents for the bacterial pathogen. Initial antibiotic therapy usually must be chosen before the infectious etiology is definitively known. One commonly used set of guidelines for the initial antibiotic choice in treating community-acquired pneumonia was developed by the American Thoracic Society (25). These guidelines define four patient categories and directed therapy toward the pathogens most commonly occurring in each category. The first category includes patients age 60 years or younger who have no comorbid conditions. *S. pneumoniae*, *M. pneumoniae*, and *Chlamydia pneumoniae* are common etiologic agents in this group. A macrolide such as erythromycin, clarithromycin, or azithromycin is the first choice for such patients, with tetracycline the alternative choice for those allergic to or intolerant of the macrolides. The second group includes patients older than 60 years of age or patients of any age with comorbid conditions who are not sick enough to require initial hospitalization. Antibiotic coverage in these patients is broadened to include greater coverage of *H. influenzae*, other aerobic gram-negative bacilli, and *S. aureus*. Appropriate antibiotic choices include either a second- generation cephalosporin or trimethoprim-sulfamethoxazole or a b-lactam/b-lactamase inhibitor combination with optional addition of a macrolide. The third group of patients are ill enough to require hospitalization (mortality rate of 5% to 25%). Polymicrobial infections can occur in this group. Recommended initial antibiotic coverage is similar to the second group but without the option of trimethoprim- sulfamethoxazole. The fourth group contains patients with severe pneumonia (mortality up to 50%). These patients may have a severe pneumonia caused by the common pathogens (*S. pneumoniae*, *S. aureus*) or by aerobic gram-negative bacteria and so need treatment with a macrolide plus either an antipseudomonal third-generation cephalosporin, such as ceftazidine, or with other antipseudomonal agents, such as imipenem/cilastatin or ciprofloxacin.

Nosocomial pneumonias have a high mortality, as they often occur in patients with short- or long-term immune defects and often are caused by gram-negative organisms; accordingly they must be presumptively treated with potent broad-coverage antibiotics. With either community-acquired or nosocomial pneumonia, the antibiotic coverage should be narrowed to more specific coverage if a recognized pathogen is clearly identified through cultures (25).

Pain Therapy. The treatment of pain associated with pneumonia depends on its severity. Patients with mild pain should be given NSAIDs in the medium range of dosages listed in Chapter 83. For moderate pain it might be necessary to give high doses (e.g., 1,000 mg of aspirin together with 64 to 128 mg of codeine or other narcotics). Because the pain is severe in many of these patients, it may be necessary to combine NSAIDs with morphine or other potent narcotics. A highly effective

way of providing good pain relief with potent narcotics is by the use of patient-controlled analgesia (see Chapter 84).

In patients with severe pain that is not adequately relieved by systemic analgesics, consideration should be given to having an anesthesiologist carry out posterior intercostal block of the segments involved with pain using a long-acting local anesthetic, such as bupivacaine. To obviate the minimal discomfort from the needle punctures, a bolus of 150 mg of thiopental sodium will produce amnesia (not anesthesia) for 3 to 5 minutes, during which time the needles are inserted. This procedure provides complete pain relief for 8 to 12 hours and also eliminates the reflex segmental and suprasegmental responses described in Chapter 9.

An alternate technique for managing severe pain is the use of epidural opioid analgesia, which is achieved by placing a catheter in the lower thoracic epidural space and injecting appropriate doses of a narcotic. Although this is not as effective in blocking nociceptive impulses as the use of local anesthetic, it usually provides excellent pain relief and has the advantage over the use of intercostal block of involving only one puncture. Because the pain only lasts 3 or 4 days with effective antibiotic therapy, all these therapeutic procedures to manage pain are practical and are associated with only minimal adverse side effects. An epidural catheter can be placed to provide many days of pain relief with local anesthetics and opioids.

Lung Abscess

A lung abscess consists of a localized pus-containing cavity resulting from necrosis of lung tissue and surrounding pneumonitis. It can be a cause of chest pain, especially if the inflammation extends to the parietal pleura.

Etiology and Pathophysiology. Lung abscesses are usually caused by aspiration of infected material from an upper airway when a patient is unconscious or obtunded from alcoholism, central nervous system disease, general anesthesia, or excessive sedation. Lung abscesses are usually produced by anaerobes and are not infrequently associated with periodontal disease. Sometimes multiple organisms act synergistically. Bacteria cultured from a lung abscess include the common pyogenic bacteria and nasopharyngeal flora, particularly anaerobes and, less often, aerobic bacteria and fungi. Bronchogenic carcinoma can obstruct an airway and cause a distal lung abscess (26).

A single abscess is most common, but multiple abscesses that are usually unilateral also occur and can develop simultaneously or spread from a single focus (26). In abscesses caused by aspiration, the superior segment of the lower lobe and the posterior segment of the upper lobe are most frequently affected because these locations are connected to airways that are gravitationally dependent in a person who is supine. The solitary abscess consequent to bronchial obstruction or an infected embolus starts as necrosis over the major portion of the involved bronchopulmonary segment, with its base adjacent to the chest wall and the pleural space; the affected part is often obliterated by inflammatory adhesions. Abscesses occurring in multiple sites in noncontiguous parts of the lung are usually a result of hematogenous spread and are frequently caused by *S. aureus* (22,26).

An abscess usually ruptures into a bronchus and its contents are expectorated into the air and fluid-filled cavity. With adequate drainage, the walls usually collapse and contract, eventually obliterating the cavity. If drainage is inadequate the abscess becomes fibrotic and rigid, and healing does not occur. Occasionally an abscess ruptures into a pleural cavity, resulting in empyema and not infrequently in a bronchopleural fistula. If the abscess ruptures into the airway, acute suffocation or diffuse pneumonia may result.

Symptoms and Signs. Symptoms can develop acutely or be insidious. Early symptoms are often those of pneumonia, characterized by malaise, anorexia, sputum-producing cough, and fever. Unless the abscess is completely walled off, the sputum is purulent and is frequently blood-streaked. Approximately 60% of patients with abscess caused by anaerobic bacteria develop a putrid odor discernible at some distance from the patient (26). Some patients manifest severe prostration and a temperature of 39°C to 40°C.

Chest pain occurs invariably with pleural involvement. Teodori and Galletti (19) carefully studied the location, quality, and intensity of pain in 15 patients with lung abscess. They noted that all but two patients had pain that was dull and aching in character, and it was mild in two, moderate in eight, and severe in three. Pain caused by abscess in the superior lobe was usually referred to the ipsilateral scapula, pain from the midportion of the lung was usually referred to the ipsilateral shoulder and arm and mammary region, and pain that involved the lower part of the lung was usually referred to the shoulders bilaterally. In the latter case it is likely that the diaphragmatic pleura was involved in the inflammatory reaction. Pain was continuous in eight of the patients and occurred at intervals during the day in the rest. All the patients had cutaneous hyperalgesia, and 12 had deep muscular hyperalgesia. Figure 62-8 shows the distribution of spontaneous pain and the cutaneous hyperalgesia in one patient who had unilateral pain.

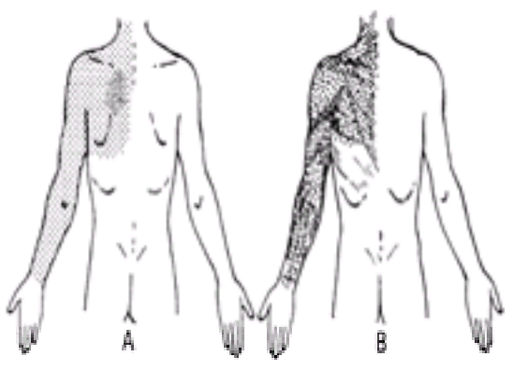

Figure 62-8. Distribution of pain and of cutaneous hyperalgesia in patients with an abscess in the left lung. **A,B:** Posterior views showing the distribution of the pain, indicated by *heavy stipples*, and of the cutaneous hyperalgesia, indicated by the *cross-hatched areas*. (Modified from Teodori U, Galletti R. *Il dolore nelle affezioni degli organi interni del torace*. Rome: L. Pozzi, 1962:72.)

Physical signs of lung abscess include a small area of dullness indicating localized pneumonic consolidation, suppressed rather than bronchial breath sounds, and fine or medium moist rales.

Diagnosis. The presumptive diagnosis can be made through a history and physical examination that reveals the aforementioned signs (9). Chest roentgenography initially shows a segmental or lobar consolidation that becomes globular as it distends with pus. After a rupture into a bronchus, a cavity with a fluid level appears on the film. Failure of an area of pneumonia to resolve should always suggest abscess formation or an obstruction such as a tumor in the airway. The patient should be followed with roentgenography or CT scanning at 1- to 2-week intervals in search of central areas of diminished density. The sputum should be examined by smear and cultured for bacteria, including mycobacteria. If anaerobes are suspected as the causative agents, consider obtaining a specimen of bronchial secretions by transtracheal aspiration to avoid contaminating the specimen with oral anaerobic organisms. If there is a mass within the radiographic cavity, the sputum should be examined for *Aspergillus*.

Treatment. Prompt and complete healing of a lung abscess depends on prolonged adequate antibiotic treatment and drainage; most patients recover without surgical intervention. As soon as the sputum and blood have been collected for culture and sensitivity testing, antibiotic therapy should be initiated promptly. Clindamycin, 600 mg intravenously three or four times a day, or the combination of a penicillin plus a b-lactamase inhibitor or metronidazole has replaced penicillin alone as the initial antibiotic choice based upon data that 15% to 20% of patients do not respond to penicillin alone (26). Treatment should be continued until the pneumonitis has resolved and the cavity has disappeared or stabilized on serial roentgenograms. Cavity closure often requires 2 to 3 months of treatment. Postural drainage can be a helpful adjunct but can also cause spillage to other bronchi, with extension of the process or acute obstruction. If the patient is too weak to cough up secretions, suctioning or intubation should be considered. Occasionally, bronchoscopic aspiration might be required to remove tenacious sputum. Pulmonary resection is the procedure of choice for an abscess resistant to medical therapy, particularly if bronchogenic carcinoma is suspected. Management of the chest pain associated with the lung abscess is similar to that described above for pneumonia.

DISORDERS OF THE PULMONARY CIRCULATION

Pulmonary Arterial Hypertension

Pulmonary hypertension can develop acutely, as in the patient with a large pulmonary embolism, or gradually, as in the patient with primary pulmonary hypertension or pulmonary hypertension secondary to progressive systemic sclerosis or other systemic diseases. Acute pulmonary hypertension can cause severe pain, often in the center of the chest, which is crushing or gripping in quality and is easily confused with the pain of acute myocardial infarction (27,28). In contrast to the pain of myocardial infarction, however, the pain of acute pulmonary arterial hypertension does not radiate to the jaw or to the arms, and seldom to the back. The gradual development of chronic pulmonary hypertension is less likely to be associated with chest pain, but these patients can develop a form of exertional anginalike pain associated with right ventricular ischemia (29).

Etiology and Pathophysiology

When pulmonary hypertension occurs acutely, such as in an acute pulmonary embolism in a patient with previously normal right heart function, the pulmonary artery systolic pressure usually cannot rise acutely to more than 50 mm Hg, after which the pressures does not rise further but right heart failure ensues. Davies (27) suggested that chest pain can be produced by acute dilatation of the main pulmonary artery or its major branches because acute distension of a large blood vessel anywhere in the body can cause pain, and this is also true of pulmonary arteries. A fall in Pa O_2 is a potent and immediate cause of rapid small pulmonary arterial constriction, leading to a rise in pulmonary arterial pressure with consequent distension of the larger vessels, which in turn may cause pain. Davies believed that pain can occur in a previously healthy patient with an acute rise in pressure or in a patient with chronic pulmonary hypertension when an extra load raises pressure still further (27).

The mechanisms causing pulmonary hypertension in primary pulmonary hypertension and many cases of secondary pulmonary hypertension are poorly understood, but some possible factors have been suggested. Destruction of vessels is one factor in emphysema and pulmonary fibrosis. In addition, neurohumoral vasoconstrictor mechanisms may be involved in some disorders. Support for this view is provided by the observation that the pulmonary vascular resistance can be acutely reduced in some patients by administration of vasodilators or by breathing oxygen (28). The anorexic agents that can cause pulmonary hypertension may do so through a serotoninlike effect on vascular growth (29). A role for immune mechanisms is suggested by the association and occurrence of Raynaud's disease or scleroderma, disseminated lupus erythematosus, rheumatoid arthritis, and dermatomyositis.

Pathologic examination of patients with chronic primary pulmonary hypertension will usually reveal findings confined to the right side of the heart and lungs, with the right atrium often enlarged and right ventricle hypertrophy present. Frequently, the large pulmonary arteries exhibit atherosclerotic plaques. The small pulmonary arteries (30 to 300 µm in diameter) exhibit muscular hypertrophy and intimal hyperplasia, sometimes with fibrosis (29).

With the development of severe pulmonary vascular disease, abnormal elevation of pulmonary arterial pressure occurs, often to a striking degree, and the pulmonary arterial pressure can be equal to that of the systemic arterial pressure. The cardiac output increases inadequately with exercise and eventually decreases even at rest. The pulmonary capillary pressure is normal, as the vascular restriction is upstream (except in pulmonary venoocclusive disease or left heart disease), and no intracardiac shunts are detected unless the patient develops a stretched foramen ovale because of the high right atrial pressure (29). In patients with advanced disease, the mean right atrial pressure is increased and the *a* wave in the right atrium is markedly elevated, which is an indication of the forceful atrial contraction necessary to fill the hypertrophied right ventricle. Mild systemic arterial oxygen desaturation is quite common, even in the absence of heart failure, and is a result of ventilation-perfusion mismatching within the lungs. Results of spirometry and lung volume measurements are often normal but the diffusion capacity is often reduced. Chronic hyperventilation may be present.

Symptoms and Signs

Patients with acute pulmonary hypertension may have severe central chest pain located retrosternally, often associated with anxiety and sense of impending death (27). Patients with chronic primary pulmonary hypertension relate a history of gradual onset of symptoms dominated by exertional dyspnea and fatigue; 50% to 60% may have angina-type chest pain (28). Hoarseness or dry cough caused by compression of the left recurrent laryngeal nerve by the enlarged pulmonary artery occurs in approximately 6% to 8% of patients (29).

Patients with acute pulmonary arterial hypertension can be in shock from low cardiac output. Cyanosis is usually present with acute pulmonary hypertension. The jugular pulse shows a prominent *a* wave, a right ventricular heave is present, and a pulse can be felt in the region of the main pulmonary artery. The pulmonary closure sound is markedly accentuated and often palpable (28). An atrial valve sound is heard at the lower left sternal border, and in some patients, an ejection murmur at the pulmonic area or the early diastolic murmur of pulmonic regurgitation is heard. Chest roentgenograms can show cardiac enlargement of the right ventricle and right atrial prominence, with marked dilatation of the pulmonary artery segments.

Diagnosis

Acute pulmonary hypertension can be confirmed by echocardiography with measurement of the elevated velocity of tricuspid regurgitation, allowing calculation of the degree of pulmonary hypertension, and examination of the degree of inferior vena cava dilation, examination of the right atrial size, and examination of the right ventricular size and systolic function, yielding an assessment of the components of cardiac function. The diagnosis is best confirmed by right heart catheterization with concomitant measurements of oxygen contents so that intracardiac shunts can be excluded. Measurement of pulmonary artery wedge pressure and cardiac output allows the best characterization of the degree of hemodynamic compromise and will help guide therapy.

The pathology of many types of pulmonary hypertension is similar. Accordingly, many clinicians group with primary pulmonary hypertension forms of pulmonary hypertension related to the use of diet pills or related to cirrhosis and portal hypertension. Secondary causes of pulmonary hypertension include progressive systemic sclerosis and other so-called collagen vascular diseases, left-to-right cardiac shunts, diffuse pulmonary diseases such as emphysema, chronic left heart disease, and chronic pulmonary thromboembolism. Diagnosis requires not only a thorough history but also a complete physical examination and special tests, including pulmonary function tests, cardiac catheterization, angiography, and radioactive lung scanning studies.

Treatment

Acute pulmonary hypertension is a medical emergency best treated by eliminating the causative factor. For pulmonary embolism, treatment would include anticoagulant or thrombolytic therapy. Inhalation of high concentrations of oxygen can sometimes be effective in decreasing the pulmonary arterial pressure and, consequently, the pain.

In patients with chronic primary pulmonary hypertension, the downward course is progressive in many patients, despite treatment. Right-sided heart failure should be treated with cardiotonic and diuretic regimens. If the patient is hypoxemic, oxygen therapy is essential to remove any component of active hypoxic vasoconstriction. Based upon studies of patients with primary pulmonary hypertension, the response to direct vascular smooth muscle relaxants (e.g., nitroprusside, diazoxide, and hydralazine), to b agonists, and to a-adrenergic blockers is often disappointing. High-dose calcium channel–blocker therapy is well established but effective in a minority of patients (29). Effective in the majority of patients is the constant infusion of epoprostenol (prostacyclin), which has led to successful therapy of many patients who are unresponsive to all other treatments (29). Before instituting long-term therapy, measurements of the acute responses of the pulmonary artery pressure, pulmonary vascular resistance, cardiac output, and systemic arterial pressure are indicated to guide the selection of therapy and to aid in prognosis.

The management of pain depends on the severity and duration. In patients with severe and excruciating central pain caused by acute pulmonary hypertension, avoidance of exertion or elimination of the causative factor, such as giving oxygen to patients who have pain at high altitudes, is usually sufficient. If the severe, excruciating pain persists after a reasonable trial period, intravenous narcotics should be administered. In patients with chronic pulmonary hypertension, the pain is usually not severe and can be managed with NSAIDs given alone or in combination with codeine.

Pulmonary Embolism

Acute pulmonary embolism is a relatively common event, particularly in hospitalized, acutely ill patients (30,31). The incidence of symptomatic pulmonary embolism in the United States has been estimated at 600,000 annually (30). Evidence of acute or chronic pulmonary emboli can be found in up to 60% of autopsies, but most are probably clinically insignificant (31). However, pulmonary emboli cause or contribute to approximately 5% of deaths and yet only 30% of these emboli are diagnosed

or suspected premortem. Acute pulmonary embolism might be the most common cause of acute pulmonary disease in hospitalized patients and is one of the most common causes of sudden unexpected death in this population (32).

Etiology

The pulmonary embolus can consist of thrombus, air, amniotic fluid, fat, or bone marrow (30). Ninety-five percent of pulmonary emboli arise from thrombi forming in the leg or pelvic veins (30,31). Thrombi occur in the right cardiac chambers or other veins and account for most of the remaining 5% of pulmonary emboli. Amniotic fluid, fat, or bone marrow emboli represent less than 1% of all cases of pulmonary embolism. The most significant risk factor for the formation of thrombus and subsequent pulmonary embolism is venous stasis, such as that which occurs postoperatively, with prolonged periods of bed rest, with low cardiac output from any cause, and with prolonged immobility during lengthy travel.

Other predisposing factors include the use of oral contraceptives, pregnancy and the postpartum period, obesity, malignancy, hematologic disorders (e.g., polycythemia vera), vascular injuries from minor trauma, and prolonged immobilization of patients with chronic disease states (33). When a patient seems to have inadequate risk factors for embolism or repeated episodes of embolism, a hypercoagulable state should be sought. Examples of hypercoagulable states include resistance to activated protein C (abnormal factor five), antiphospholipid syndromes, antithrombin 3 or protein C or S deficiency, and dysfibrinogenemias (30,33). Several studies have shown that patients undergoing hip surgery with general anesthesia have a significantly greater incidence of thromboembolism than those undergoing the same surgery with regional anesthesia (33).

Once released into the venous circulation, emboli are distributed to both lungs in 65% of cases, unilaterally in 35%. The lower lobes are involved four times more often than the upper lobes, probably because of their greater blood flow.

Pathophysiology

Most of the consequences of pulmonary embolism can be explained by obstruction of the pulmonary vasculature to produce hypoxemia, acute pulmonary hypertension, right ventricular failure, and reduced cardiac output or cardiogenic shock. Hemodynamically significant pulmonary embolism is associated with obstruction of approximately 30% or more of the segments of the pulmonary arterial tree (34). Acute obstruction of the right or left main pulmonary artery with a balloon, however, produced relatively few hemodynamic changes or symptoms (34). Therefore, it is generally thought that the acute pulmonary embolism leads to the release of humoral substances such as serotonin, prostaglandins, and histamine, resulting in constriction of the pulmonary arterial bed (30,34).

The combined effect of the mechanical obstruction by thrombus and vasoconstriction leads to ventilation-perfusion mismatching, resulting in the arterial hypoxemia that is common but not universal. Pulmonary vascular resistance, pulmonary arterial pressure, right ventricular systolic and diastolic pressures, and right atrial pressure are increased, whereas the cardiac index is decreased. If pulmonary vascular resistance increases acutely to the extent that the right ventricle cannot generate sufficient pressure to maintain cardiac output, arterial hypotension results, and this can progress to shock. In patients without preexisting cardiopulmonary disease, this occurs only after massive embolization involving at least 50% and usually 75% of the pulmonary vascular bed (31). In patients with prior cardiopulmonary disease, shock can occur with a lesser extent of embolization.

Symptoms and Signs

The most common symptoms of pulmonary embolism are chest pain, dyspnea, and tachypnea (35,36). The frequency of these and other symptoms and signs reported by 327 patients in large clinical trials of thrombolytic therapy for pulmonary embolism (37) is shown in Table 62-2. The chest pain was pleuritic in more than 75% of patients. The pleurisy is often caused by pulmonary infarction, which produces inflammation on the pleural surfaces, a pleural rub, and pleuritic pain. The pleuritic pain can be a relatively late finding because it can take several days for pulmonary infarction and pleural inflammation to develop. The pleuritic pain is characteristically severe and persistent, lasting several days longer than that of pneumonia, for example (27). Indeed, the persistence of pleuritic pain for more than 7 days in an acutely ill patient should suggest pulmonary embolism (Fig. 62-9).

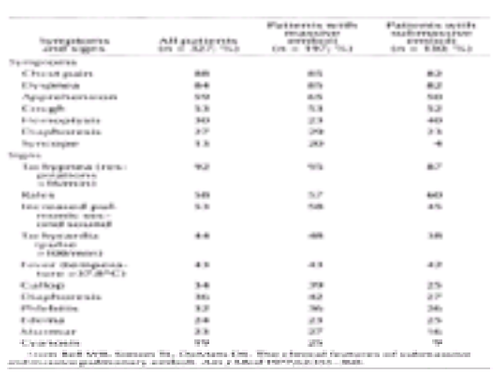

TABLE 62-2. Symptoms and signs in 327 patients with acute pulmonary embolism

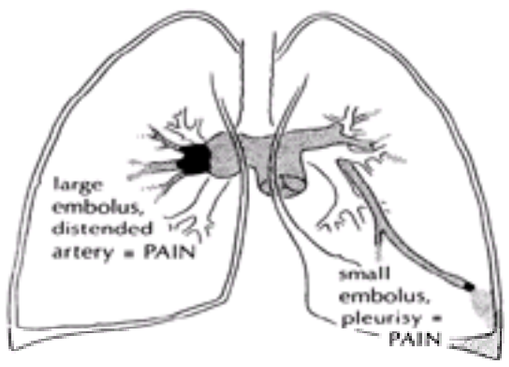

Figure 62-9. The origin of pain in pulmonary embolism. (From Levene DL, Billings RF, eds. *Chest pain: an integrated diagnostic approach*. Philadelphia: Lea & Febiger, 1977:77.)

Patients with large pulmonary emboli usually experience a severe, visceral, retrosternal (deep) crushing pain at the time of the embolism, similar to that of myocardial ischemia, except that the pain does not radiate. This is thought to be caused by sudden distension of the pulmonary artery, right ventricle, or both, or even by right ventricular ischemia resulting from sudden increase in wall stress and myocardial oxygen demand. When this type of pain occurs together with T-wave or S-T segment changes, distinction from unstable angina or acute myocardial infarction can be difficult. Unfortunately, the clinician is often not alert to the diagnosis, as the classic triad of hemoptysis, pleuritic chest pain, and a pleural rub is uncommon (36).

In patients with massive pulmonary artery obstruction, consequent marked increase in pulmonary artery pressure can cause right ventricular failure, with resultant distension of cervical veins and other signs of right ventricular failure. In such patients auscultation reveals a right ventricular heave and a right ventricular presystolic and protodiastolic gallop. Cyanosis is usual with massive pulmonary embolism, but not with a lesser degree of obstruction. Examination of the lungs is usually normal in the absence of pulmonary infarct. Wheezing is sometimes heard, particularly if underlying bronchopulmonary or cardiac disease is present.

Tachypnea, often with dyspnea, almost always occurs after an embolic episode; it appears to be of reflex origin, most likely caused by stimulation of juxtacapillary

receptors in the alveolar membrane by swelling of the alveolar interstitial space (31,33). This stimulation increases vagal afferent activity that in turn stimulates medullary respiration, with consequent alveolar hyperventilation manifested by a lower Pa CO_2.

Diagnosis

All the symptoms, signs, and routine laboratory data in acute pulmonary embolism are nonspecific; their usefulness lies in leading to a suspicion of the diagnosis. The diagnosis rests on establishing a defect in pulmonary artery perfusion that cannot be explained by coexisting lung disease. The gold standard for the diagnosis of pulmonary embolism remains a technically adequate pulmonary arteriogram (30,33,38). The passage of a catheter to the main pulmonary artery and the angiogram can be performed by a trained angiographer, with minimal risk (approximately 0.2% mortality rate). The use of perfusion imaging to guide the angiographer in performing subselective angiography with small doses of contrast material reduces this risk even further. The identification of filling defects within the pulmonary arteries or abruptly cut-off terminated arteries establishes the diagnosis of pulmonary embolism. Thrombi lyse over a period of 7 to 10 days; therefore, pulmonary angiography (and radionuclide imaging) are most sensitive in the first few days after the onset of symptoms.

Pulmonary angiography is now the initial diagnostic test in only a minority of patients with suspected pulmonary embolism because of greater confidence in the use of radionuclide ventilation-perfusion scintigraphy (39,40) or helical CT scanning (41). At most hospitals, $\dot{V}/\dot{Q}$ scanning is the primary diagnostic tool for most patients with suspected pulmonary embolism. The Prospective Investigation of Pulmonary Embolism Diagnosis study was critical in defining the uses and limitation of $\dot{V}/\dot{Q}$ scanning (38,39). Many clinicians will proceed to treat for embolization if the $\dot{V}/\dot{Q}$ scan and clinical suspicion indicate a greater than 85% chance of embolism and will forego further workup or treatment if the combined scan and clinical impression indicate less than a 10% chance of embolism (38,40). Unfortunately, a large number of patients still have an intermediate chance of embolism after these studies. In these patients, some clinicians go straight to angiography for a definitive diagnosis, whereas others scan the legs for clots because a positive finding of clots in the leg would lead to a decision to initiate anticoagulant therapy in any case. Because the decision making can become complex, it is often important to have the decisions as to the steps in the diagnostic workup guided by a clinician very experienced with pulmonary embolism. The newer technique of spiral CT scans can be highly reliable in detecting central clots (41). To what extent spiral CT may eventually replace ventilation-perfusion scanning in the initial workup of a patient with suspected pulmonary embolism will depend on the sensitivity of the CT technique when applied to large populations of previously unscreened patients.

Electrocardiographic changes in acute pulmonary embolism are nonspecific and do not aid in differentiating from other causes of chest pain and acute dyspnea. The typical electrocardiographic pattern of right heart strain (right axis deviation of the QRS wave and T- wave inversion in the right precordial leads) is seen in only approximately 19% of patients with pulmonary embolism. T-wave inversion and S-T segment shifts that might suggest myocardial ischemia are seen in 30% to 40% of patients (31).

The chest roentgenogram is similarly nonspecific. The most common finding is no acute change because most pulmonary emboli do not cause pulmonary infiltrates. The classic pleural-based wedge-shaped infiltrate is uncommon. When preexisting pulmonary infiltrates are present the diagnosis becomes more difficult because the ventilation-perfusion scan is less reliable. These are patients in whom pulmonary angiography might be necessary if establishment of the diagnosis is required.

Treatment

Prophylaxis. The most important aspect of treatment is prevention. Early ambulation after surgery or acute myocardial infarction is thought to be effective. Alternatively, a number of studies have shown that subcutaneous low-dose heparin (5,000 U two times a day) is highly effective in preventing venous thrombosis, pulmonary embolism, or both (42,43). Patients undergoing hip or knee replacement or prostatic surgery need more aggressive anticoagulation (44). Guidelines generated by professional societies for prophylactic therapy have been published and are updated periodically (43). With the use of these prophylactic measures, the incidence of clinically significant pulmonary embolism has decreased substantially. As previously mentioned, several studies have shown that patients undergoing hip replacement operations under regional anesthesia have significantly less incidence of thromboembolism than those managed with general anesthesia (43).

General Therapy. Treatment of the acute event is usually primarily aimed at preventing further pulmonary embolism, supporting the circulation, and administering oxygen until the natural lytic processes result in dissolution of the emboli. If the diagnosis is strongly suspected and no significant contraindication to anticoagulation is present, therapy with heparin should be started even before the diagnosis is established by ventilation-perfusion scanning or pulmonary angiography. Heparin can be given as a loading dose of 80 units per kg, followed by a weight-adjusted continuous intravenous infusion of approximately 18 U per kg per hour or by a dose sufficient to prolong the activated partial thromboplastin time (aPTT) twofold. Anticoagulation to a therapeutic aPTT within the first 24 hours of treatment lessens the risk of recurrent embolization. Following a weight-based algorithm results in attaining a prolongation of the aPTT to over 1.5 times control within the first 12 to 24 hours in 96% of patients (45). Several algorithms for dose adjustments have been published. Oral anticoagulation with warfarin is then instituted for a period of 3 to 6 months. If no prior embolism has occurred and the inciting cause has resolved (e.g., recent surgery), it seems to be of little benefit to continue anticoagulation therapy beyond 3 to 6 months (46). A few patients with recurrent pulmonary embolism and persisting risk factors need to remain on chronic anticoagulation indefinitely.

Thrombolytic therapy has been carefully studied (47). The administration of urokinase or streptokinase results in more rapid lysis of the emboli and restoration of normal hemodynamics but produces no overall decrease in the mortality rate. Presently, thrombolytic therapy is therefore reserved for patients with massive emboli with marked hemodynamic compromise or little reserve. Pulmonary embolectomy using cardiopulmonary bypass has also been used in patients in cardiogenic shock from pulmonary emboli but carries a high operative mortality rate (48); it is rarely used at present. If contraindications to anticoagulation exist or if pulmonary embolism recurs while patients are adequately anticoagulated with heparin or warfarin, interruption of the inferior vena cava by the percutaneous placement of an umbrella should be considered. Because sizable collateral channels develop with time around the site of the filter, a few patients will eventually have recurrent embolization even after a filter is placed.

Pain Therapy. The management of the pain associated with pulmonary embolism depends on the rate of onset, severity, duration, and quality. The patient who experiences sudden, severe crushing central pain caused by a large pulmonary obstruction should be given morphine or another potent narcotic intravenously slowly. The initial dose of 4 to 5 mg diluted in 5 mL of saline solution is injected over a period of 2 or 3 minutes. This should produce some relief in 5 minutes and good relief in 10 to 15 minutes. If the patient still experiences severe pain a second dose of 5 mg should be administered and the patient monitored closely. Usually the second dose provides ample pain relief, but if it does not within 15 to 20 minutes of the injection, a third dose should be given; after this the patient can be managed with a continuous infusion of opioids or patient-controlled analgesia.

An even more effective alternative is the use of a cervicothoracic sympathetic block with a long-lasting local anesthetic, provided, of course, that a physician expert in its administration is available in the hospital. This procedure produces complete pain relief ipsilateral to the injection within 5 to 8 minutes of injection, and the pain relief will last for 6 to 10 hours. Leriche and colleagues (49) were the first to suggest the use of this procedure in the treatment of pulmonary embolism; they believed that it not only relieved pain by blocking afferent impulses from the lungs but that it also interrupted efferent impulses taking part in the production of sympathetic reflex mechanisms thought to be involved in the pathophysiology. More recent data did not substantiate this claim but suggested that reflexes involved in the pathophysiology are mediated primarily by the vagus nerves (50). Nevertheless, the procedure is effective in relieving the central type of pain (51). Moreover, because it blocks some of the sympathetic afferent input to the neuraxis, it should decrease the segmental and suprasegmental reflex responses that are invariably associated with severe pain and nociceptive input (see Chapter 9). Another relatively new procedure for relief of the pain is the use of intraspinal narcotics.

Patients who develop pleuritic pain can usually be relieved with NSAIDs combined with a potent narcotic agent given orally or parenterally. If the patient has experienced severe pleuritic pain unrelieved by systemic analgesics, however, a posterior intercostal block with bupivacaine should be considered (see Chapter 102). The procedure is carried out in the manner described for the pleurisy of pneumonia.

CHEST PAIN CAUSED BY DISORDERS OF THE PLEURA

The most important disorders of the pleura that produce chest pain are either of inflammatory origin, as in pleuritis, or from mechanical distortion, as in pneumothorax.

Pleuritis

Inflammation of the pleura can occur with underlying pulmonary diseases, including pneumonia, lung abscess, pulmonary infarct caused by an embolus, and neoplasm (52). As discussed above, pleuritis is associated with localized chest pain. Pleural pain in the absence of physical and radiographic findings or underlying

disease suggests the diagnosis of epidemic pleurodynia, infection of the pleura, or a connective tissue disorder such as systemic lupus erythematosus.

Pleurodynia, also known as *Bornholm disease* and *epidemic myalgia*, is characterized by malaise, sore throat, and anorexia, followed by increased debility; fever; and sudden onset of muscle, pleuritic, and abdominal pain (52). The pain is sharp, severe, and paroxysmal over the lower ribs or substernal area. It is markedly aggravated by moving, breathing, coughing, sneezing, and hiccuping and can be referred to the shoulders, neck, scapula, or chest. In approximately 50% of patients pain and spasm of the anterior abdominal muscles occur in combination with chest pain. Many patients complain of cutaneous hyperalgesia, hyperesthesia, and paresthesia in the area of the pain.

Pleurodynia usually occurs as an epidemic and lasts 3 to 7 days, but relapses can occur (52). Coxsackie B viruses were isolated from the striated muscle of patients with pleurodynia during an epidemic (53). Occasionally the pleuritis is accompanied by pleural effusion, and the virus has been isolated from the pleural fluid. Bornholm disease can occur in those of any age but is most common in children and young adults. Early in the course of the illness meningitis, myocarditis, or hepatitis can ensue. Later, jaundice or orchitis may appear.

Treatment

Because of the absence of effective antibiotics, the treatment of pleuritis is directed toward the underlying disease and relief of pain. In patients with mild to moderate pain, NSAIDs given alone or in combination with codeine in optimal doses usually suffice. For more severe pain, potent narcotics with NSAIDs should be tried. Systemic analgesics, even in optimal doses, do not, however, completely relieve the pain associated with deep breathing and coughing. Untreated pain can prevent the patient from bringing up secretions and increase the risk of a subsequent bacterial pneumonia. In such patients, serious consideration should be given to the use of posterior intercostal blocks or segmental epidural analgesia with long-lasting anesthetic agents such as bupivacaine. Intraspinal opioids, although not quite as effective, are a good alternative. These procedures require the skills of an anesthesiologist.

Occasionally, acute pleuritis leads to chronic adhesive pleuritis as a sequela of empyema, hemothorax, or tuberculosis. Adhesive pleuritis is characterized by marked thickening of the pleura, which can interfere with pulmonary function. Under these circumstances, the thickened pleura encases the lung and“traps” it so that the lung behaves as if it were small and stiff, despite having intrinsically normal mechanical processes. If symptoms such as dyspnea are severe, surgical removal of the thickened pleura (decortication) might be indicated (52).

Pleural Effusion

Although not usually painful, pleural effusion is discussed briefly here for the sake of completeness. The visceral and parietal pleurae form a continuous membrane that encloses a potential space that normally contains only a small amount of liquid. This liquid is dynamic, and as with all movements of liquid between vascular and extravascular compartments, the principle of Starling's equation applies (52). Under normal circumstances the liquid is filtered out of the parietal pleura, which is supplied by systemic capillaries at a mean pressure of 30 cm H_2O; most of this is taken up at the visceral pleura, supplied by the pulmonary circulation with a mean capillary pressure of 11 cm H_2O. For the removal of macromolecules plus some liquid, there are in addition lymphatic stomata in the diaphragmatic and vascular portions of the parietal pleura.

An abnormal accumulation of liquid, designated as pleural effusion, occurs with changes in hydrostatic and oncotic forces (transudation) or with an alteration in membrane permeability (exudation), such as with inflammation or neoplastic involvement. The finding of pleural effusion in the absence of parenchymal disease suggests primary tuberculosis, subdiaphragmatic abscess, mesothelioma, or primary bacterial infection of the pleural space. Many pleural effusions, even large ones, are asymptomatic, but patients can complain of dyspnea, pleuritic chest pain, or a dull, uncomfortable sensation in the chest (51). Physical signs include deviation of the trachea to the contralateral side, dullness on percussion, and diminished breath sounds over the affected side.

Empyema is the presence of infected liquid or frank pus in the pleural space and is usually a complication of pneumonia, abscess from the lung, or diaphragmatic or esophageal perforation. Chest pain, fever, cough, night sweats, and weight loss are common complaints.

Treatment of symptomatic pleural effusion or empyema includes adequate drainage of the pleural space, directed antimicrobial therapy, and the control of pain as discussed in previous sections.

Pneumothorax

In pneumothorax a collection of gas in the pleural space occurs that results in complete or partial collapse of a lobe or entire lung. When air enters the pleural space, pleural pressure in the affected hemithorax tends to approach atmospheric pressure, thus eliminating the normal negative pressure that keeps the lung expanded (54). The less negative the pleural pressure, the greater the degree of lung collapse. The normal elastic recoil of the unaffected lung causes a shift of the mediastinum from the affected to the unaffected side. If pressure inside the pneumothorax increases above atmospheric pressure, as with a one-way leak into the pleural space (“ball valve leak”), or when a pneumothorax occurs as a complication of positive pressure ventilation, a tension pneumothorax is present. Under these circumstances the affected lung is compressed, the mediastinum is further shifted toward the unaffected side, and cardiac output can be severely compromised because of the positive intrathoracic pressure that decreases venous return to the heart.

Tension pneumothorax is a medical emergency (54). Pneumothorax can occur spontaneously or can be secondary to underlying lung disease, chest trauma, mechanical ventilation, or perforated esophagus. Spontaneous pneumothorax most commonly occurs in previously healthy adults between 20 and 40 years of age. In many of these patients air leaks into the pleural space as a result of rupture of small blebs on the surface of the visceral pleura. The cause of the blebs is unclear, but they tend to be located around the apex of the lung.

Symptoms and Signs

Spontaneous pneumothorax usually manifests itself by sudden chest pain of pleuritic type, localized to one side and associated in most cases with a sensation of dyspnea. The most helpful feature of the pain is its sudden onset, so that often patients can describe their activities at the moment it appeared (27,52,54). The severity of pain and degree of dyspnea at onset are not indicative of the size of the pneumothorax. Usually both pain and dyspnea disappear within 2 to 3 hours after a small pneumothorax in healthy people. Persistence of dyspnea and pain that increases in severity suggest a large pneumothorax and perhaps intrapleural hemorrhage.

The sudden change in volume of the lungs with shift of the mediastinum is likely to cause a visceral-type deep central pain, retrosternal pressure, or heaviness, but this usually does not persist and is overshadowed by the pleuritic pain.

Physical examination reveals tachypnea, asymmetric expansion of the chest on the affected side (because of outward recoil of the chest wall as the lung collapses), mediastinal shift with deviation of the trachea, cardiac dullness and apex beat away from the pneumothorax, hyperresonance to percussion, and diminished breath sounds over the affected side. Chest roentgenograms reveal a visible visceral pleural edge with no lung markings between this edge and the chest wall (54). It is important to take the chest roentgenograms with the patient in the upright position because, in a supine posture, upward movement of air with approximation of the visceral and parietal pleura can obscure the presence of a pneumothorax. A pneumothorax may be easier to detect on an expiratory film because expiration makes the lung appear darker due to crowding of the parenchymal element, leading to greater contrast with the air-containing pneumothorax space. Inspiratory films, however, are better for estimating or serially following the size of a pneumothorax because the lung volume of the film in inspiration is more reproducible.

Treatment

Treatment depends on the size of the pneumothorax. A small spontaneous pneumothorax in a stable patient is best managed by reassuring the patient and close observation, because the air leak has usually sealed by the time the patient presents to the physician. The pain is generally managed easily with systemic analgesics given orally. Large pneumothoraces are usually accompanied by moderate to severe pain that requires therapy in the form of evacuation of air and the use of a combination of an NSAID and a narcotic. Aspiration of air can be accomplished with a small needle attached to a one-way flutter valve or with closed thoracostomy tube drainage (54). Spontaneous tension pneumothorax is unusual but, if present, should be treated as an emergency by immediate aspiration through a wide-bore needle placed in the pleural space at the level of the second intercostal space anteriorly in the midclavicular region.

CHAPTER 63

Chest Pain of Esophageal Origin

Charles E. Pope, Jr.

Although the esophagus normally transports solids, liquids, and gas to—and occasionally from—the stomach without discomfort, it can generate pain indistinguishable from the pain experienced from myocardial infarction as well as other less threatening kinds of unpleasant sensations. Chest pain in the Western world is usually interpreted by both patient and physician as a manifestation of coronary artery insufficiency and often leads to worry, multiple tests, and inappropriate hospitalizations. Chest pain of esophageal origin is quite common; of 204 consecutive patients admitted to a coronary care unit and found not to have an acute myocardial infarct, the pain was attributed to the esophagus in 76 (32%) of these patients (1). This would suggest that after heart disease has become unlikely as a result of appropriate testing, it is well to consider the esophagus as a potential pain source. This chapter discusses some of the clinical features and diagnostic/therapeutic tests that establish the esophagus as the source of the discomfort. As is discussed, such establishment is not a simple matter.

It has long been suggested that esophageal pain can arise both from the esophageal mucosa and from the esophageal muscle. A third possibility is currently under active investigation—that pain can be experienced by abnormal central nervous system (CNS) processing of afferent impulses from the esophagus that are normally not perceived. Mucosal disease can be recognized and documented; there are often specific forms of therapy that allow confirmation of a diagnostic impression by a therapeutic trial. In contradistinction, attributing chest pain to malfunction of esophageal muscle is a more uncertain task. The therapeutic options for esophageal muscle problems are less precise, and the opportunity for a therapeutic trial may not be possible because of the lack of effective forms of therapy. Determining the potential role of aberrant CNS function in the genesis of esophageal chest pain has only just begun. Most studies of CNS-esophageal relationships are still confined to control subjects.

The information in this chapter is divided into six sections: basic considerations, including the anatomy and physiology of the esophagus; esophageal mucosal disorders; esophageal muscular disorders; role of the CNS in the generation of esophageal pain; other painful disorders of the esophagus; and approach to the patient with chest pain. More detailed information can be obtained from review articles (2,3 and 4).

BASIC CONSIDERATIONS

Anatomy of the Esophagus

General Structure

The esophagus is a tube consisting of striated muscle in the upper one-third and smooth muscle in the remainder of the organ. It is approximately 35 cm long, 3.0 cm in lateral diameter, and 1.9 cm in anterior-posterior diameter (Fig. 63-1). It begins at the cricopharyngeus muscle, which separates the esophagus from the pharyngeal muscle, with which the esophagus is closely tied functionally. It passes through the mediastinum, traverses the hiatus of the diaphragm, and ends in the lower esophageal sphincter (LES) muscle, which separates the esophageal lumen from the gastric lumen. Careful dissections in human cadavers show a thickening of the circular, but not longitudinal, muscle in the LES zone as well as an unusual distribution of the circular muscular fibers (5). The esophagus is lined with stratified squamous epithelium that is lubricated by specialized mucous glands located in the submucosal layer. The esophagus contains no specialized adventitial layer, which accounts for some of the difficulties encountered by surgeons making anastomoses in the esophagus.

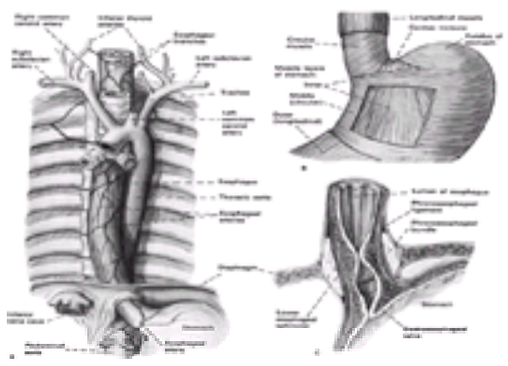

Figure 63-1. Anatomy of the esophagus. **A:** Relationship of the esophagus (except the uppermost part, which has been resected) to the lower trachea, the proximal bronchi, and the aorta, and its arterial blood supply. **B:** Lower esophagus and upper stomach showing the direction of the longitudinal and circular muscle fibers of the lower esophagus and the upper part of the stomach. **C:** Coronal section depicting the component parts of the gastroesophageal junction and the component parts of the antireflux barrier, including the lower esophageal sphincter, made up of thick circular musculature. The phrenoesophageal ligament arises from the circumference of the hiatus as an extension of the inferior fascia of the diaphragm and breaks up into an ascending and descending leaf; the former passes cephalad for several centimeters above the hiatus, where it is inserted circumferentially into the adventitia of the esophagus, and the descending leaf passes downward and is inserted around the cardia deep to the peritoneum. Within the cavity, thus formed by the phrenoesophageal ligament and below the diaphragmatic hiatus, lies a ring of dense fibroareolar and fatty tissue that together with the ligament make up the phrenoesophageal bundle. Also, the gastroesophageal valve is created by the acute angle of His and consists of a flat lateral leaf approximating against the mucosa of the lesser curvature of the stomach. (**A** and **B** modified from Netter FH. *The CIBA collection of medical illustrations.* Vol 3, Digestive system. Part I, Upper digestive tract. Caldwell, NJ: CIBA Pharmaceuticals Co., 1959:38– 41. **C** was developed from data in Hill LD, Thor K, Mercer D. Surgery for hiatal hernia and esophagitis. In: Hill LD, ed. *The esophagus: medical and surgical management*. Philadelphia: WB Saunders, 1988:98.)

Blood Supply

The arterial supply to the cervical esophagus comes from the terminal branches of the inferior thyroid artery. The thoracic portion is supplied mainly from bronchial arteries at the level of the carina (6). Branches of the left gastric and splenic arteries supply the lower thoracic and abdominal portions of the esophagus.

The venous drainage of the cervical esophagus is into the inferior thyroid vein, which empties into the brachiocephalic veins. The thoracic esophagus is drained by the periesophageal plexus, which empties into the azygos system. The lowest portion of the thoracic and abdominal esophagus drains into the gastric veins which, in turn, empty into the portal vein.

Nerve Supply

Studies in animals and humans have made it necessary to alter this section of the chapter markedly from previous editions. The present description is based on the chapters by Sengupta and Gebhart (7), Cervero and Foreman (8), Conklin and Christensen (9), and Clouse and Diamant (10). More specific details can be found in these references.

Two systems mediate sensation from the esophagus. Vagal fibers arise in the submucosa and muscle layers and run to the CNS with their cell bodies in the nodose ganglion. The fibers terminate in the nucleus tractus solitarius, which sends input to the thalamus, the limbic cortex, and the primary somatosensory cortex. Visceral afferent fibers arise in the same location and travel with the sympathetic nerves to the dorsal root ganglia, where their cell bodies are located. They may make contact with some somatic afferent nerves in the dorsal root ganglia or go on to the spinal cord, where they make contact with secondary neurons whose cell bodies are in the gray matter (lamina I and V) and that travel to the brain via the spinothalamic tract, the spinoreticular tract, and the spinomesencephalic tract.

Motor nerves of the esophagus arise in the pons and medulla from the dorsal motor nucleus and the nucleus ambiguus. They travel down the vagal trunks and contact second-order neurons located in the myenteric plexus. Axons from these second order neurons innervate the smooth muscle of the esophagus as well as other nerve bodies within the myenteric plexus.

Another command and control center is located within the wall of the esophagus: the enteric nervous system of the esophagus. This consists of a sensory portion; the submucosa, or Meissner's plexus; and the myenteric, or Auerbach's plexus. Neurons in the myenteric plexus have both excitatory and inhibitory activity on the esophageal smooth muscle. A great deal of intrinsic capability is built in to this system so that it can function without any external input. The relative importance of the intrinsic control system and the modifications produced by vagal motor input is not thoroughly worked out at the present time. Figure 63-2 presents a simplified block diagram of the system.

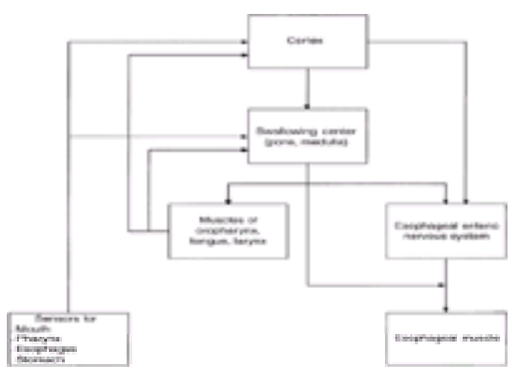

Figure 63-2. Block diagram of afferent and efferent connections between esophagus and brain.

Physiology of the Esophagus

Motor function

In the resting state, the cricopharyngeus muscle is tonically contracted by impulses from the CNS. Constant electrical spike activity is recorded from the muscle, which is inhibited when swallowing commences. The sphincter is physically opened by the laryngeal muscles lifting the larynx and the cricoid cartilage upward and forward, literally pulling the sphincter open. Changes in bolus volume and viscosity alter the timing of upper esophageal closure.

A stripping peristaltic wave begins just below the cricopharyngeus and traverses the striated muscle, creating a relatively high intraluminal contraction amplitude with a rapid rate of rise of pressure to the peak. Contraction of the smooth muscle portion of the esophagus seems to follow without a break, and for many years, the peristaltic wave was considered to be continuous. Some studies, however, suggest that the wave in the striated muscle actually ends, and the presence of the bolus in the esophagus causes a separate contraction to begin in the smooth muscle and proceed down to the area just above the LES, where a third wave may be generated (11).

Intraluminal pressure measurements taken from the LES zone show a resting pressure of 15 to 20 mm Hg that falls at the same time as laryngeal elevation during swallowing. There is still a physical barrier between the esophagus and the stomach after this relaxation, as the negative intraesophageal pressure does not equilibrate with the positive intragastric pressure. Two other types of LES relaxation are recognized. One, transient LES relaxation, is associated with belching and with reflux (12). The other type of relaxation can be produced by injection of small quantities of water into the pharynx; its physiologic role remains to be defined (13).

This motor activity of the esophagus is controlled by a “swallowing center” located in the pons and the medulla. This center receives input from the cerebral cortex and from afferent vagal and visceral fibers. The center also organizes efferent impulses to the tongue, larynx, pharynx, and esophagus so that the act of swallowing can be tightly coordinated. The striated muscle of the cricopharyngeus and the proximal esophageal musculature receive fibers from the nucleus ambiguus of the swallowing center.

Peristaltic organization of the esophageal smooth muscle is more complex. There is sequential activation of progressively more distal smooth muscle by efferent vagal fibers from the dorsal motor nucleus of the swallowing center acting on the cell bodies of the enteric nervous system; there is intrinsic control from the enteric nervous system itself; there may be a myogenic component to the peristaltic wave, which is resident in the muscle. The methods by which these complex systems interact have not been defined. Certain nerves in the enteric nervous system that probably release nitric oxide can inhibit the muscle of the distal esophagus when a proximal contraction is present. In humans, inhibition of nitric oxide production by recombinant hemoglobin can lead to disorganization of peristalsis, increase in peristaltic amplitude, and chest pain (14).

Intramural excitatory nerves that release acetylcholine and are sensitive to atropine set the tone and function of the LES. Inhibitory nerves in the same location that release nitric oxide and possibly vasoactive intestinal polypeptide balance their action.

Sensory Function

The esophagus can respond to distension, to change in wall tension, to changes in chemical or osmotic concentrations, and to alterations in temperature. A great deal of afferent information is produced by normal peristalsis and intraluminal contents and transmitted by vagal fibers. There do not appear to be specialized nerve endings to sense tension or pH; it is still not certain whether afferent neurons can respond to a variety of different stimuli or whether specific nerves mediate specific sensations.

In the opossum, an animal with both striated and smooth muscle in the esophagus (but rather distant from humans phylogenetically), individual fiber studies have demonstrated vagal afferent fibers that respond both to distension and to the presence of normal peristalsis (15). In the same animal, there are visceral afferent fibers

that travel with the sympathetic fibers (16). Single-fiber recordings show two types of these fibers responding to distension. One type fires in response to both balloon distension and to normal peristalsis and is called a *wide-dynamic-range mechanonociceptor*. The other type responds only to elevated intraluminal pressures. Both types are believed to be specific nociceptors. Fibers could also be categorized as rapidly adapting or slowly adapting to prolonged balloon distension. Both are sensitive to bradykinin, a substance released during ischemia and inflammation (17).

Studies of afferent spinal single neurons have been undertaken in cats (18). Most fibers responded with an increase in firing rate to balloon distension; a significant minority decreased their rate of firing during stimulation. Of interest was the observation that somatic stimulation also caused increased rates of firing of the visceral afferent neurons, suggesting cross-talk between somatic and visceral receptors. Chemical inflammation of the esophagus decreased the balloon volumes necessary for excitation of these neurons.

Such studies are not possible currently in humans, but evidence obtained by brain positron emission tomography (PET)scans of central excitation by balloon excitation has been reported (19). When esophageal balloon inflation is just enough for the subject to be aware of a sensation, there is increased blood flow activity along the central sulcus, insular cortex, and the operculum. When inflation is increased to a level perceived as painful, activity in these areas increases. In addition, the anterior insular cortex on the nondominant side is activated, as is the anterior cingulate gyrus. Preliminary studies in control subjects using functional magnetic resonance imaging to measure changes in cerebral blood flow show that areas in the occipital, parietal, and superior frontal lobes are activated by the perfusion of acid but not saline (20). Balloon distension in the same patients activates separate areas than those stimulated by acid (parietal-occipital areas).

Sites of Pain Reference

Perhaps because of the overlap in the dorsal root ganglia between somatic sensory nerves and visceral afferent nerves, pain due to disease of the esophagus is referred to the chest, epigastrium, and, occasionally, to the back. Numerous investigators have attempted to delineate the areas of pain referenced by mechanical distension of the esophagus with a balloon; electrical or chemical stimulation has also been used. Jones carried out a series of experiments in which he distended the esophagus at different levels (21). He noted that moderate distension produced substernal pain experienced at the level of the balloon (Fig. 63-3). Pain arising from the upper esophagus was felt in the midline over the upper portion of the manubrium, whereas that produced by distension at the cardiac end of the esophagus was felt at the level of the xiphoid cartilage.

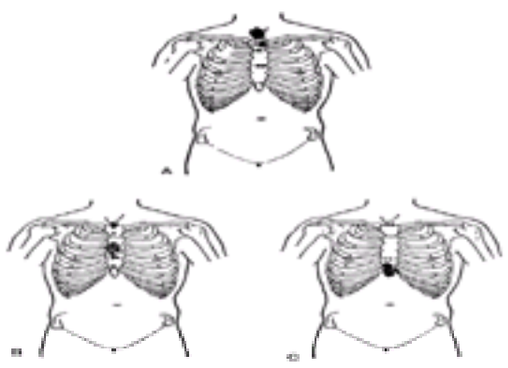

Figure 63-3. Sites of referred pain from inflation of a balloon in the upper **(A)**, middle **(B)**, and lower **(C)** esophagus. Each dot represents one subject. Compare with Fig. 63-4. (From Jones CM. *Digestive tract pain*. New York: Macmillan, 1938:11, with permission.)

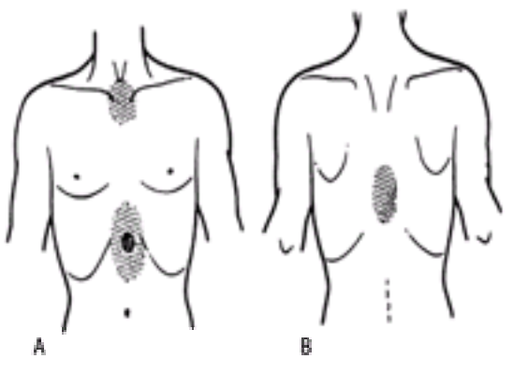

Figure 63-4. **A:** Anterior view showing reference of pain caused by inflation of the upper third and lower third of the esophagus. **B:** Posterior view showing reference of pain in the back from mechanical stimulation of the lower esophagus. (From Teodori U, Galletti R. *Il dolore nelle affezioni degli organi interni del torace*. Rome: L. Pozzi, 1962:169–178, with permission.)

Teodori and Galletti, in studies using an esophageal balloon, determined not only the site of pain but also changes in electric skin resistance at those sites (22). They reported that rapid inflation of the balloon with 30 to 50 mL of air produce moderate to severe pain, the site of which depended on the level of distension. Distension in the upper third of the esophagus produced pain referred to the area of the manubrium and upper part of the sternum without producing any pain in the back. In contrast, stimulation of the lower third of the esophagus produced pain in the xiphoid process and the epigastric area. Posteriorly, the pain was felt in the midline at the level of the sixth to seventh thoracic vertebrae (Fig. 63-4). They noted that the referred pain produced by stimulation of the middle third of the esophagus usually was less intense and more variable in location. In some subjects, the pain was felt in both the manubrium and xiphoid processes; in others, in one or the other; and, in still others, in the retrosternal region. The areas of decreased electrical resistance were consistently in the same sites as the area of referred pain (Fig. 63-5). Cutaneous hyperalgesia developed in most subjects in the epigastric region and in the skin overlying the lower portion of the sternocleidomastoid muscles bilaterally.

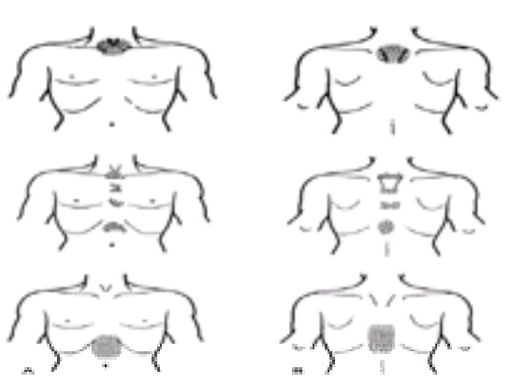

Figure 63-5. Zones in which there was a reduction in the cutaneous electrical resistance (RCER) consequent to mechanical stimulation of the esophagus with an inflated balloon that produced pain in the anterior **(A)** and posterior **(B)** portion of the chest. The top panel shows the areas of RCER from stimulation of the upper third of the esophagus. Posteriorly the area of the pain overlies the midline and paravertebral region at the level of the seventh cervical to the first thoracic vertebrae, inclusive. The middle panel shows the area of RCER from stimulation of the middle third of the esophagus. Note the variability. The bottom panel shows the area of RCER from stimulation of the lower third of the esophagus. Posteriorly this area overlies the paravertebral region at the level of the sixth to the eleventh thoracic vertebrae. PAINFUL ESOPHAGEAL MUCOSAL DISORDERS

Gastroesophageal Reflux Disease

Etiology and Pathophysiology

The most common inciting agent for painful esophageal mucosal disease is pathologic gastroesophageal reflux. All humans have some esophageal reflux, usually in the postprandial period, but when the exposure time of the esophageal mucosa becomes too long, reflux damage can occur. The increase in exposure time in turn is determined by an increased number of transient relaxations of the LES (12). Reflux into the esophagus during such unguarded moments of transient relaxation can be facilitated by the presence of a hiatus hernia, which serves as a storage area for gastric acid close to the sphincter zone (23). Decreased gastric emptying, found in approximately one-half of patients with severe reflux, also allows an increased amount of gastric contents to be potentially available for reflux. Once refluxed, defects in peristalsis may retard clearance and increase contact time of this fluid.

The increased contact time of gastric contents may not produce any grossly visible endoscopic evidence of reflux, but well-oriented biopsies of the esophageal mucosa show basal cell hyperplasia and extension of the papillary pegs toward the surface (24). Careful examination of the basal cell zone shows that there are increased spaces between these cells, perhaps allowing hydrogen ions access to bare nerve endings below the epithelium, which might mediate the sensation of heartburn or of chest pain (25).

Once the acid has penetrated the epithelium and stimulated nervous elements, the subsequent pathways in humans have not been fully worked out. In animals, production of rather severe esophagitis by chemical means decreases the threshold of spinal nerves for other stimuli such as balloon distension (18). A similar lowering of the threshold for balloon stimulation has been shown in humans as well (26). Thus, acid can produce a direct effect or sensitize the esophagus so that other stimuli may reach perception.

Effects of esophageal mucosal stimulation by acid on production of pain by other organs must also be considered. In patients with fixed coronary artery narrowing and S-T changes associated with angina, exercise capability can be sharply limited by acid perfusion of the esophageal mucosa (27). Intraesophageal acid perfusion can also lower coronary blood flow in patients with exertional chest pain, normal coronary arteries, and electrocardiographic changes during exercise (syndrome X) (28).

Symptoms

The most common symptom of reflux is heartburn. This term is used by lay individuals to refer to a disparate group of symptoms; further questioning is always in order if the patient volunteers that he or she is troubled by heartburn. Reflux-induced heartburn is usually substernal, with radiation up into the neck. Usually, it is described with an open hand moving up and down over the sternum. The most common phrase used to describe the sensation of heartburn is “burning.” “Pain” is not a common descriptor. Heartburn may come in waves and be accompanied by increased salivation and swallowing. Relief by swallowed antacids, albeit transiently, is an essential feature of heartburn. Patients with untreated achalasia, for instance, who would not be expected to have much reflux because of their hypertensive nonrelaxing LES, occasionally complain of substernal burning. However, they do not find relief of this burning by ingestion of antacids.

Chest pain due to reflux is usually described as an oppressive weight on the chest that tends to spread laterally more than the sensation of heartburn usually does. It may radiate to the back, neck, jaw, shoulder, or arm. “Pressure,” “boring,” or “aching” are adjectives often used. Unlike the discomfort of heartburn, which usually responds to a dose of antacids, chest pain due to reflux remains after a single dose of an acid-neutralizing compound. Only prolonged acid suppression is of benefit.

Sometimes the symptoms of heartburn and chest pain coexist in the same patient. Heartburn can increase in intensity until it passes from a sensation of burning to a sensation of pain. More commonly, an individual patient reports both sensations, but states that they often occur independently from one another rather than merging from one sensation to the other.

Other clinical manifestations of gastroesophageal reflux disease may be present, such as regurgitation of gastric contents when bending over or when lying supine. Extraesophageal manifestations of reflux, such as hoarseness, persistent cough, or repeated clearing of the throat, may signal laryngeal irritation. Mild dysphagia is a common result of pathologic reflux. It usually does not cause the patient to have to regurgitate the bolus, but only to reswallow or wash the bolus down with liquids.

Diagnosis

There have been four basic approaches to attempt to establish the diagnosis of chest pain due to gastroesophageal reflux. The first approach attempts to measure the prevalence of abnormal reflux in patients with chest pain of unknown origin. The second approach is to correlate episodes of chest pain with periods of esophageal acidification, as detected with a pH electrode. The third approach instills acid into the esophagus to provoke chest pain; the fourth approach is to perform a therapeutic trial by inhibiting the retrograde flow of gastric acid into the esophagus by either pharmacologic or surgical methods.

Table 63-1 lists the prevalence of pathologic reflux detected by prolonged pH monitoring in patients with chest pain of unknown origin (29,30,31,32,33 and 34). Most of the patients enrolled in these studies were thought not to have coronary artery disease on the basis of either invasive or noninvasive cardiac tests. It can be seen that reflux is quite commonly found in such patients. This does not automatically demonstrate that there is a direct causal relationship between mucosal acid exposure and the production of pain. Perhaps acid exposure sensitizes the esophagus to other stimuli such as distension. Such sensitization has been demonstrated in patients with noncardiac chest pain and normal esophageal function tests (26).

TABLE 63-1. Prevalence of pathologic reflex in chest pain

The technological advances in pH monitoring that allow 24-hour recording in ambulatory patients have allowed attempts to correlate episodes of chest pain with episodes of reflux. Table 63-2 shows some results from the literature of such correlation (30,33,35,36). These estimates are probably high, as some authors accept even one episode of simultaneous pain and reflux as showing a causal relationship. If there are many episodes of reflux but only a few episodes of chest pain, the relationship may well have occurred by chance. It has been suggested that an attempt to document the relationship more firmly can be done by dividing the period of monitoring into 2-minute epochs and then creating a 2 × 2 table of the relationship between chest pain and reflux (37).

TABLE 63-2. Correlation of reflux with pain

Simultaneous recording of chest pain and reflux episodes has allowed another important subgroup of acid-sensitive patients to be described. These individuals have normal total acid exposure values, yet they respond to their infrequent episodes of reflux with chest pain. These patients respond as well to acid-suppressive therapy as do patients with abnormally increased reflux times.

Acid infusion tests (Bernstein test) would be expected to pick out patients with chest pain due to an acid-sensitive esophageal mucosa. However, as Table 63-3 demonstrates, fewer patients have a positive acid perfusion test than have abnormal acid exposure times (34,38,39 and 40). When both studies are done in the same patient, discordant results are often found. In one study, 18 patients had a positive acid perfusion test; only nine had abnormal 24-hour pH results (41). Conversely, ten additional patients had abnormal 24-hour pH exposure but negative acid perfusion studies.

TABLE 63-3. Provocation of pain with acid infusion

With the advent of powerful acid suppressive medications, the proton pump inhibitors, the possibility of a therapeutic trial to discover the place of acid reflux in the production of chest pain became a reality. The results of a placebo-controlled trial of such agents show a significant decrease in both the intensity and occurrence of chest pain on those patients receiving active medication (42). However, it is equally important to realize that none of the treated patients became totally asymptomatic.

Treatment

The choice of treatment modality depends on the strength of the evidence that acid is the culprit responsible for chest pain. The choice is also dictated by other factors such as concurrent endoscopic or laryngoscopic evidence for reflux and by the preferences of both the patient and the health care resources available.

If medical therapy is thought to be the best choice, current practice would suggest that proton pump inhibitors in adequate dose be used. Omeprazole, 40 mg daily, or lansoprazole, 30 mg daily, should be the starting dose. If these doses eliminate the chest pain, attempts to lower the dose of medication can be made. Alternatively, if the evidence that acid has played a role in the chest pain (e.g., erosive esophagitis on endoscopy) is strong, but this dose of medication does not solve the problem, the dose can be doubled. Failure of a double dose might lead to a reevaluation of the place of acid reflux in the production of chest pain. If the patient has had a positive 24-hour pH test result before therapy, it might be worthwhile to repeat the monitoring while the patient takes full-dose medication, as there are a few patients in whom the proton pump inhibitors do not suppress acid.

Antireflux surgery has become more acceptable now that laparoscopic techniques have decreased the morbidity of the procedure. However, the choice of whether to offer such surgery to someone with chest pain depends on several factors. If the patient complains of ordinary heartburn and has erosive esophagitis or Barrett's epithelium, surgery can be offered to treat these manifestations with the hope that chest pain will also vanish postoperatively. If chest pain is the only manifestation of reflux, a positive therapeutic trial of acid suppression should be sought before surgery is offered.

How effective is antireflux surgery? In a large surgical experience, 11 patients were specifically operated on because of chest pain documented to occur with bursts of acid reflux. Total relief of chest pain was found in ten of these patients (29). In a series in which chest pain was specifically sought for both before and after Nissen fundoplication, 46 of 88 patients with preoperative chest pain became totally asymptomatic (43). In one laparoscopic series, 49 of 66 patients lost their chest pain postoperatively (44).

Infections and Physical Agents

Infections and physical agents primarily affect the esophageal mucosa and produce a characteristic symptom that helps to guide the clinician to the correct diagnosis. The symptom is odynophagia, or pain on swallowing. The pain is not necessarily bolus related; even a “dry swallow” containing only a small amount of saliva can cause exquisite pain. The mucosa usually has visible lesions that allow endoscopy to be useful in diagnosis. Therapy depends on the inciting agent. This topic has been thoroughly reviewed by Baehr and McDonald (45).

Infections

Etiology and Pathogenesis. The immunocompromised host is the most common individual attacked by the agents shown in Table 63-4. Herpes simplex is the only virus that can produce symptoms in the completely normal host. The immunologic lesion can be subtle (diabetes, malignancy) or marked (acquired immunodeficiency syndrome, radiation therapy, chemotherapy). Steroid use, even topical therapy, can allow some of these infections to occur.

Agent	Immunocompromised	Appearance
Candida albicans	Yes	Adherent glaques
Herpes simplex	Usually	Ulcers, raised edges
Cytomegalovirus	Yes	Deep serpiginous ulcers
Varicella zoster	Yes	Ulcers, raised edges
Human immunodeficiency virus	Yes	Giant deep ulcer

TABLE 63-4. Infectious agents

Symptoms and Signs. Odynophagia is the hallmark of symptomatic infection, although occasionally other symptoms, such as unexplained nausea, lead to the endoscopy that establishes the diagnosis. Oral thrush can suggest contiguous esophageal involvement in a patient with human immunodeficiency virus infection and is probably evidence enough for a therapeutic trial. Pharyngeal vesicles (early) and shallow ulcers (later) can suggest herpes simplex infection in both normal and immunocompromised patients.

Diagnosis. Endoscopy is the preferred method of evaluating the esophageal lining and obtaining adequate samples for definitive culture or immunodiagnosis. Blind scraping with a sheathed cytology brush occasionally obtains diagnostic material in patients with *Candida* or viral illnesses if endoscopy is not feasible. Double-contrast radiology can show small lesions, but it is not sensitive or specific enough when compared with the results obtained by endoscopy. All ulcerated lesions should be biopsied for histologic and cultural diagnosis. Biopsies should be directed both at the edges of the ulcer and at the base of an ulcer in the case of cytomegalovirus infection.

Treatment. Adequate treatment depends on adequate diagnosis. Several of these infections have indistinguishable appearances from one another, so cultural, immunodiagnostic, and histologic criteria are essential in establishing a cause for infection. Treatment suggestions are given in Table 63-5.

Infection	Treatment
Candida albicans	
Light infection	Nystatin, 50,000 units q4h p.o.
	Clotrimazole, 10 mg 5 times/day p.o.
Moderate infection	Fluconazole, 100 mg/day for 10 days, p.o.
Severe infection	Amphotericin B, 0/5 mg/kg q8h for 7–10 days, i.v.
Herpes simplex	Acyclovir, 250 mg/m^2 q8h for 7–10 days, i.v.
Varicella zoster	Same as herpes simplex
Cytomegalovirus	Ganciclovir, 5 mg/kg q12h for 14 days, i.v.
Human immunodeficiency virus	Prednisone, 40 mg qd for 2 weeks

TABLE 63-5. Treatment of esophageal infections

Physical Agents: Radiation

Etiology and Pathogenesis. The esophageal mucosa is sensitive to ionizing radiation and is often included in the fields used to treat lung and thyroid cancers. Odynophagia often appears after 25 to 30 Gy and usually lasts until the radiation is stopped. Biopsies of the mucosa show shrunken pyknotic nuclei. In animals and sometimes in humans, there is disturbance in peristalsis, as the muscles and nerves of the esophagus are also sensitive to radiation.

Symptoms. Patients complain of both pain and dysphagia, usually for solid boluses. Pain tends to be constant and is exacerbated by attempts to swallow food. This often leads to poor nutrition for the patient and can become a real clinical problem.

Diagnosis. A clinical history is all that is necessary to make the diagnosis. Endoscopy does not offer added information; it will increase the patient's discomfort.

Therapy. Topical anesthetic agents and pain medication will be necessary to control symptoms. There are currently no agents that will protect the esophageal mucosa from ionizing radiation.

Physical Agents: Pill Esophagitis

Etiology and Pathogenesis. Studies in control patients show that even young healthy individuals will have temporary (and unrecognized) arrests of swallowed gelatin capsules. Several swallows of water are often necessary for complete transport into the stomach. Transit is even worse if the pills are swallowed in a recumbent position. When motor abnormalities of the esophagus or luminal obstruction such as a stricture are added, transport becomes even more perilous. Sometimes pills containing timed-release granules are opened by the patients and mixed with food. This can cause quite a burn to the esophageal mucosa.

Table 63-6 lists the most common offenders; however, the list is long and should be consulted if pill esophagitis seems to be in the differential diagnosis.

Antibiotics	Doxycycline, tetracycline
Nonsteroidal antiinflammatory drugs	Aspirin, ibuprofen
Quinidine	–
Alendronate	–
Potassium chloride	Especially sustained-release capsules
Iron preparations	–

TABLE 63-6. Pills causing frequent esophageal damage

Symptoms. The usual clinical syndrome is characteristic enough to be easily recognized. A previously healthy individual will suddenly develop rather severe chest discomfort that is steady and exacerbated by swallowing. Additional history will reveal that the patient has recently started a new pill preparation.

Diagnosis. A characteristic history is sometimes all that is necessary to offer a firm diagnosis of pill esophagitis. If the situation is not clear, esophagoscopy will usually demonstrate a circumscribed ulcer at the level of the aortic arch or just above the LES. Cases have been reported in which adherent material from the offending capsule(s) still remain in the bed of the ulcer.

Treatment. Reassurance and stopping the offending medication or giving it in a noncapsule liquid form will alleviate the distress within 3 or 4 days. Preventive medicine is best. Encourage patients to take a drink of water before the pill is taken, swallow the pill with a large mouthful of water, and then take two to three additional swallows of water. All this should be done in the upright position, not lying down in bed. The practice of taking a handful of pills at once is to be discouraged.

Physical Agents: Caustics

Etiology and Pathogenesis. The esophagus can be exposed to caustic agents, either accidentally in the case of children or alcoholics, or with suicidal intent. Injury with lye is instantaneous; attempts to neutralize the alkali should not be made. Some of the granular bowl cleaners contain strong caustics.

Symptoms and Signs. There is often poor correlation between signs of burns in the oral cavity and damage to the esophagus. The patient may spit out the caustic before swallowing it, which will produce oral damage without esophageal damage. Conversely, a normal oropharynx does not guarantee a burn-free esophagus. Respiratory stridor suggests a laryngeal burn and the possible need for airway control.

Diagnosis. Although earlier articles on this subject suggested that endoscopy should not be done after caustic ingestion for fear of perforation, the advent of modern small-caliber flexible endoscopes has allowed safe inspection of the esophagus in this situation. If the mucosa appears normal, further therapy directed toward the esophagus is not necessary and the appropriate social or psychiatric therapy can be started. Signs of a severe burn with a necrotic appearance might prompt rapid surgical consultation, especially if liquid lye has been the ingestant.

Therapy. The acute pain of ingestion will need to be controlled with appropriate intravenous narcotics. Both antibiotics and steroids have been advocated for caustic injury of the esophagus; there are no controlled trials showing benefit of either form of therapy. A controlled trial of steroid therapy in children showed no benefit; stricture formation was a function of extent of injury and not the presence or absence of steroids (46).

PAINFUL ESOPHAGEAL MOTOR DISORDERS

The concept of chest pain arising from disturbances in esophageal muscle function has long been held by clinicians. Osler mentioned esophagismus and spasm in the late 1800s (47). The first objective confirmation that esophageal motor abnormalities could cause pain was provided by Evans, who demonstrated radiologically disordered peristalsis in 40% of patients with chest pain; two control groups (n = 1,400) had only a 1% to 5% prevalence of such motor disturbances (48). When manometric techniques were introduced, patients with chest pain were found to have diffuse esophageal spasm (49) and high-amplitude long-duration contractions associated with pain (50). This section examines the role of abnormal esophageal muscle contractions as an etiologic agent in chest pain.

Etiology and Pathophysiology

Several possibilities exist that might explain how motor abnormalities of the esophagus could cause chest pain.The most obvious one is that increased tension during a contraction might activate receptors in the esophageal wall. Contractions of the uterus during labor are perceived as painful—why not “labor pains” of the esophagus? This possibility, although attractive, will have to await methodology that can sample the intensity of afferent nerve impulses arising in the wall of the esophagus.

Prolonged high-amplitude contractions might interfere with the blood flow in the esophageal wall and produce ischemic pain. It is not possible to measure blood flow directly in the esophageal musculature, nor is it possible to examine the esophageal venous effluent to look for biochemical indicators of ischemia. Disturbances in blood flow were inferred from an experiment that measured esophageal rewarming after a short infusion of cold water (51). It was found that there was a significant delay in rewarming in patients with esophageal contraction abnormalities and chest pain. Other investigators producing chest pain with edrophonium stimulation noted no change in rewarming time in patients who developed chest pain when compared with those who did not develop chest pain (52).

A change in muscle compliance has been demonstrated with a balloon system in which a cross-sectional area of stimulation could be constantly monitored (53). This study showed that balloon volume alone did not necessarily measure cross-sectional distension dimensions and that the esophageal muscle of patients with chest pain of unknown origin was stiffer than the esophageal muscle of control patients.

Another provocative preliminary finding is that the longitudinal muscle of the esophagus, demonstrated by intraluminal ultrasound, contracts before the onset of chest pain (54). These changes were not detected by intraluminal pressure measurements, which showed no changes when the pain occurred.

Symptoms and Signs

Pain associated with contraction abnormalities is usually described by the patient as a sense of pressure—a boring or aching sensation. This can range in intensity from a feeling of slight constriction to an intense pressure associated with diaphoresis, a gray color, and a feeling of impending death. This pain is usually felt substernally but rarely can be felt only in the neck or epigastric area (Fig. 63-6). Radiation through to the back is a clinical clue that the pain under consideration might be of esophageal origin. Radiation into the neck, jaw, teeth, and shoulder is common. Occasionally, pain radiates to the left arm or to both arms as it does in myocardial ischemia.

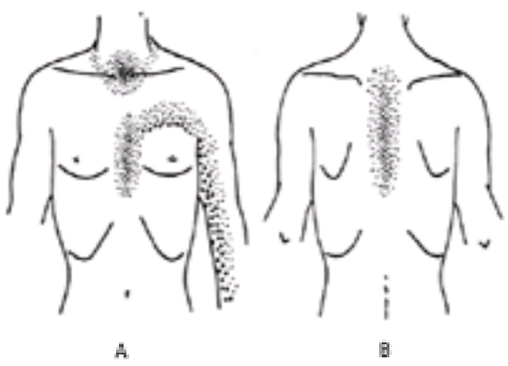

Figure 63-6. Area of pain reference from esophageal colic. The pain is usually felt substernally, but it can be felt also in the neck or the epigastric area **(A)** and almost always in the back **(B)**. Radiation occurs into the neck, jaw, teeth, and shoulder and occasionally to the left or both arms.

The duration of motor pain can be from a few seconds to many hours. It can be clinically indistinguishable from the pain due to coronary artery disease, not only in location but also in the factors that aggravate or relieve it. An exercise-related component is present in approximately one-half of the patients whose pain is eventually found to be of esophageal origin. It tends to be quite variable in the amount of exercise related to stimulate pain from day to day. Sometimes the ingestion of cold beverages produces an attack.

Patients with esophageal motor disorders producing pain also often give a history of intermittent dysphagia, usually not during attacks of pain. Most patients will not eat or drink during an attack. If they do take liquid, and it regurgitates back into the nasopharynx, a motor disorder of the esophagus is most probably present. It is

uncommon for bolus ingestion to produce chest pain due to contraction abnormalities of the esophageal muscle.

Diagnosis

Intraluminal manometry remains the most common method of searching for abnormalities of motor function. Interpretation of tracings is more objective than interpretation of radiographic images. During the 1990s, many hospitals and clinics obtained the equipment necessary to perform esophageal manometry.

A discussion of manometric techniques is beyond the scope of this chapter, but it is available in the comprehensive book by Castell and Castell (55). There is still a lack of uniformity in the performance and interpretation of esophageal manometric tests. Some of this is due to different forms of catheters and recording apparatus; operator interpretation is also not uniform.

When patients with chest pain thought not to be due to coronary artery disease are investigated with manometry, esophageal motor abnormalities are present in 23% to 63% of the patients (Table 63-7) (40,56,57,58 and 59). These estimates exclude patients with achalasia, a motor disorder of the esophagus in which chest pain can be present at the beginning of the illness. In most series, high-amplitude waves, often of increased duration, are the most common finding, present in approximately one-half of those with abnormal findings (Fig. 63-7). Diffuse esophageal spasm (Fig. 63-8) is quite an uncommon finding.

TABLE 63-7. Motor disorders in patients with chest pain

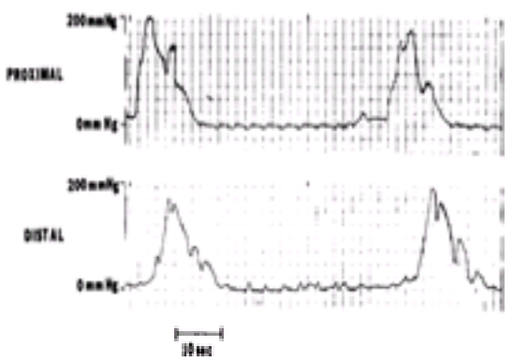

Figure 63-7. Manometric record of high-amplitude peristaltic contraction. Tracings obtained for two tips 5 cm apart shows waves of very high amplitudes (175 to 200 mm Hg, compared with normal values of 60 to 100 mm Hg), long duration (14 to 16 sec, compared with normal values of less than 6 sec), and slow velocity of propagation (50 to 60 cm/sec, compared with a normal value of 4 cm/sec). Pain can be present throughout the duration of such waves.

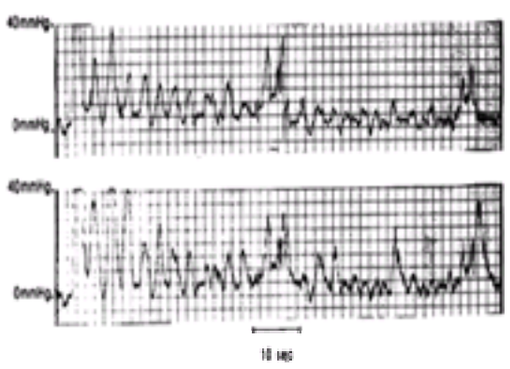

Figure 63-8. Manometric record of diffuse spasm of the esophagus. Note elevation of the baseline pressure on the left side of the tracings with superimposed simultaneous contractors. The baseline pressure returns to normal in the center of the tracings. A peristaltic contraction is recorded on the far right portion of the tracings. Pain, if present, would be experienced during the period of baseline elevation.

The mere presence of a motor abnormality does not establish a causal relationship between the abnormal pattern and the chest pain. If the patient can be studied during an episode of pain and the onset, intensity, and disappearance of discomfort predicted by watching the manometric tracing, a relationship has been established. This is an uncommon event; in one early study, 38 of 160 patients had discomfort during testing; of these, 14 had abnormal motor patterns that correlated with the chest discomfort (56). This is only a yield of approximately 9%. Another group of investigators found no correlation between chest pain and manometric abnormalities when the patient was studied in the middle of an attack (60).

When the technology of ambulatory manometry became available, it was hoped that the increased period of observation with the patient in his or her own environment would increase the yield of positive studies. Even when patients with daily pain were investigated, this hope was not fulfilled. Table 63-8 shows the number of patients demonstrating pain-related esophageal motor patterns (31,32 and 33,35,39,41,61). There is a wide range, from no relationship whatsoever to a 29% positive yield. The best results seem to be obtained when the testing is undertaken soon after a patient enters a coronary care unit and is ruled out for myocardial ischemia (62). Ambulatory motility units are quite expensive, and the low sensitivity shown in the reported studies does not inspire confidence in this technique.

TABLE 63-8. Correlation of abnormal motility with chest pain

Provocative Tests

The relatively low yield of esophageal motility monitoring has led to attempts to find a good provocative test that might uncover abnormal motility. Table 63-9 lists some of the agents that have been used for this purpose. Unfortunately, none of these agents has been found to increase the yield of pain-related motility abnormalities to any great extent. In one series, when a group of 62 patients with chest pain of unknown origin was exposed to acid, edrophonium, and bethanechol, only 9 of the 62 responded with pain and a positive-related manometric pattern (63).

Agent	Dose
Ice water	–
Acid infusion	0/1 N hydrochloric acid, 30 gtt/min for 30 min
Edrophonium (Tensilon)	100 μg/kg i.v.
Bethanechol	40 or 80 μg/kg s.q.

TABLE 63-9. Provocative agents for motor disorders

Even more confusing is the relationship between provocative testing and the occurrence of reflux-related pain and motor abnormality–related pain. In a series of 33 patients investigated with prolonged as well as standard manometry, pH monitoring, acid perfusion, and edrophonium testing, there was no consistent relationship between spontaneous pain and induced pain (36). All combinations were possible (Fig. 63-9). Some patients (labeled as those with an irritable esophagus) would respond with identical pain to either motor disorder (spontaneous or provoked) or to acid reflux/infusion.

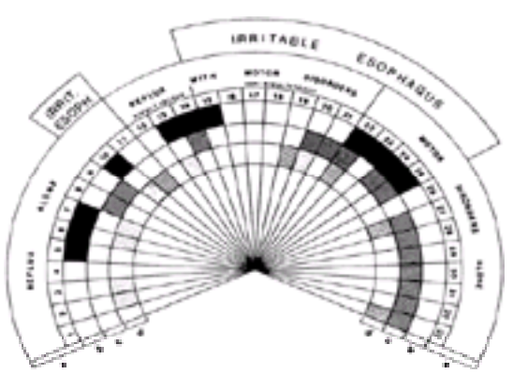

Figure 63-9. Diagram to show results in 33 patients with anginalike chest pain of esophageal origin. *a*, 24-hour pH and pressure results; *b*, positive acid-perfusion test; *c*, conventional manometry; *d*, edrophonium stimulation test. It can be seen that 24-hour tests do not always predict the results of provocative tests. Some patients ("irritable esophagus") respond to multiple agents. (IRRIT. ESOPH., irritable esophagus.) (From Vantrappen G, Janssens J, Ghillebert G. The irritable oesophagus—a frequent cause of anginalike pain. *Lancet* 1987;I:1232–1234, with permission.)

In a position paper on the diagnostic usefulness of esophageal manometry, this lack of diagnostic yield has led to a recommendation that provocative tests not be used (64). This report also suggests that contraction abnormalities are not clearly the cause of esophageal pain; thus, their demonstration does not lead to therapeutic decisions. My own opinion is that in the rare situation when motor abnormalities can be directly associated with pain, an esophageal origin is established. Even the existence of contraction abnormalities suggests an esophageal origin—this suggestion can lead both patient and physician to reduce the use of medical resources (65).

Treatment

The sentence used in the second edition of this textbook (1990) is still correct: "No uniformly effective forms of medical therapy for esophageal motor disorders are available at the present time." Drugs that have been used to treat esophageal motor disorders are listed in Table 63-10.

Agent	Dose
Nitroglycerin	0/4 mg sublingual prn
Isosorbide dinitrate	10 mg q6h p.o.
Dicyclomine	20 mg qid p.o.
Diltiazem	30 mg qid to 60 mg qid to 90 mg qid p.o.
Trazadone	50 mg qd to tid p.o.
Imipramine	50 mg qhs

TABLE 63-10. Pharmacologic treatment of motor disorders

Nitroglycerin

The ease with which nitroglycerin can be taken at the onset of chest pain is an advantage; the accompanying headache often limits its clinical use. Long-acting forms, such as isosorbide or nitropaste, can be tried if the short-acting form provides relief. There may be a selection bias in the patients referred for esophageal testing. If a patient responds to nitroglycerin, that patient may receive a cardiac label, and a contraction abnormality of the esophagus is not considered. Failure of nitroglycerin therapy may predispose to referral to an esophageal laboratory. Therefore, the true prevalence of patients with pain of esophageal origin responding to nitroglycerin may be underestimated.

Calcium Channel–Blocking Drugs

Because high-amplitude waves are a major part of those contraction abnormalities associated with pain, attempts have been made to decrease the amplitude of the peristaltic wave with calcium channel–blocking drugs. Although nifedipine decreases peristaltic amplitude, it does not decrease chest pain (66). One small double-blind trial suggests that diltiazem may offer some relief (but not complete relief) of chest pain (67).

Antidepressive Drugs

Impressed by the degree of psychological problems in patients with chest pain of unknown origin, Clouse et al. undertook a double- blind trial of low-dose trazadone (68). Although the patients on therapy had better quality of life, the amount of chest pain and contraction abnormalities did not change. In a trial of low-dose imipramine in patients with chest pain of unknown origin (41% had abnormal esophageal motility tracings), treatment led to alleviation (but not disappearance) of chest pain (69).

Botulinum Toxin

After botulinum toxin (Botox) injected into the LES zone of patients with achalasia was shown to decrease the intrasphincteric pressure and to increase esophageal emptying, this medication was tried in other motor disorders. In a heterogeneous group of esophageal motor disorders, pain was relieved in 30% of the patients and improved in the rest of them (70). Further controlled trials of this approach would seem to be in order.

Surgical Therapy

Although there have been scattered case reports of alleviation of chest pain by long myotomy in patients with varying contraction disorders of the esophageal muscle, only a few series with more than four or five patients have been published. Ellis reported on 42 patients operated on in the period from 1970 to 1991; relief of pain was experienced in all but five patients (71). DeMeester's group reported alleviation of pain in 14 of 17 patients subjected to a long myotomy (72). Eight of ten patients treated with a thoracoscopic myotomy had their chest pain disappear or markedly improve (73). The decreased morbidity of minimally invasive surgery may lead to larger series of patients in the future.

CHEST PAIN AND THE CENTRAL NERVOUS SYSTEM

Lack of a clear-cut relationship between either mucosal acid sensitivity or esophageal motor activity and the production of chest pain has led to the examination of the role of afferent nerve input and its central processing in the genesis of chest pain of esophageal origin. Several lines of investigation suggested this possibility. The concept of the “irritable esophagus” put forward by Vantrappen and his colleagues takes note of the fact that several different stimuli can produce identical pain syndromes (36). Could this mark use of the same nervous pathways by different stimuli, or does this suggest central processing of different inputs leading to a common sensation?

Balloon stimulation demonstrated a clear increased sensitivity to lower balloon volumes in patients with chest pain of unknown origin when compared with control subjects (74). This led to the concept that there was altered visceral sensitivity in these patients, although it did not differentiate between peripheral and central processing. Repeat balloon distensions caused increased pain in chest pain subjects but not in controls or patients with dysphagia, suggesting changes in either afferent nerve sensitivity or differences in central processing (75).

Is balloon distension merely a convenient form of esophageal stimulation, or does it suggest a possible mechanism for the production of pain? The latter possibility is supported by experiments that infused air into the esophagus to produce distension (76). It was found that most control subjects and patients with chest pain would belch easily to remove the infused air. There were a few patients who could not belch easily; they were the same patients who had their chest pain reproduced by balloon distension. In a subset of these nonbelching patients, their pain was reproduced when gastric distension with gas-forming compounds led to esophageal regurgitation of air and chest pain.

Can the set point at which distension is perceived be changed? Acid infusion into the esophagus of control subjects can sensitize the esophagus so that it responds to smaller balloon volumes (26). Patients with chest pain and ongoing reflux disease do not show a response to acid infusion by a drop in balloon volume; they presumably have already been sensitized. The set point can also be affected by installation of benzocaine, a lipid-soluble anesthetic, into the esophagus of volunteers (77). This installation causes an increase in the balloon volumes necessary to reach thresholds of both perception and pain.

To study possible central differences in processing, cerebral-evoked potentials were measured in chest pain patients and in controls with either balloon (78) or electrical (79) stimulation. Both groups noted a decrease in the amplitudes of the evoked potential (Fig. 63-10), suggesting CNS modification in the chest pain patients. Caution must be used in interpreting amplitude changes of cerebral-evoked potentials, as they can be influenced by levels of attention, external stimuli, and other factors that might be difficult to control (80). A change in the amplitude of the evoked potential can also be caused by neuropathy in the visceral afferent supply, commonly present in diabetic patients (81).

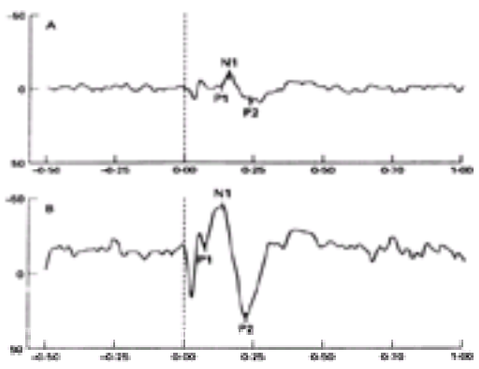

Figure 63-10. Brain-evoked potentials after stimulation of the esophageal mucosa. The stimulus was delivered at time 0.00. P1, N1, P2 are the inflection points of the potentials. Note the reduced voltages in the chest pain patient **(A)** as compared with those recorded from the control subject **(B)**. (From Frobert O, Arendt-Nielsen L, Bak P, et al. Pain perception and brain evoked potentials in patients with angina despite normal coronary angiograms. *Heart*1996;75:436–441, with permission.)

Brain function during balloon stimulation in control subjects has been investigated with PET scanning (19), which showed activation in the insular and primary somatosensory cortex areas for nonpainful stimuli. An increase in balloon diameter to a level producing pain caused increased blood flow in these same areas, as well as activation of the right anterior insular cortex and the anterior cingulate gyrus. No similar studies have yet been reported in patients with chest pain of unknown

origin.

PET scanning has also shown that areas of activation of the brain are important in whether pain is perceived. Some patients with narrowed coronary arteries do not develop chest pain when exercised (82). They are classified as having “silent ischemia.” When such patients have PET scans during stress, they show activation of the thalamic areas, as do patients who develop angina during exercise. Those with “silent ischemia” do not activate areas in the anterior and ventral cingulate cortex and left temporal pole, as do patients with ordinary angina. Cause and effect are not indicated in these studies, but pain is reported only when anterior cingulate cortex is activated.

It is an attractive hypothesis that changes in visceral sensitivity can explain why some patients with chest pain and normal esophageal tests can develop chest pain. An increase in normal visceral information carried either in the vagal nerve or in the visceral afferents might be amplified even further centrally so that impulses that would not normally be perceived would produce a sensation interpreted as pain. Acid reflux might decrease the threshold values at which distending or contraction abnormalities might be felt. Abnormal motor activity might produce increased visceral afferent activity that would be produced as pain. Alternatively, abnormal cortical activity might cause a decrease in inhibitory motor neurons, which would produce abnormal motor activity similar to that seen in volunteers whose normal inhibitory neurons were blocked by a nitric oxide inhibitor (14). Methodology is being developed that might allow some of these possibilities to be investigated in human subjects. A great deal remains to be learned.

Are there any therapeutic possibilities in attempting to modulate CNS activity? As has been pointed out, low-dose imipramine has been of some value in patients with chest pain and contraction abnormalities (69). Trazadone has also been shown to allow patients to cope with their disease (68). Three trials of cognitive therapy in the treatment of chest pain show that coping behavior increased, although the actual amount of chest pain was not much decreased (83,84 and 85).

OTHER PAINFUL DISORDERS OF THE ESOPHAGUS

Effort Rupture of the Esophagus (Boerhaave's Syndrome)

Etiology and Pathogenesis

The act of vomiting is a very violent one indeed; it is amazing that more injuries to the esophagus do not result from this athletic endeavor. Vomiting is rather a coordinated activity between diaphragm, abdominal muscles, the LES, and the upper esophageal sphincter. Studies in animals and a few humans show that there are a few preliminary twitches of the diaphragm during the phase of nausea. A sudden descent of the diaphragm rapidly increases gastric pressure. The LES is presumably inhibited, as are the central muscular fibers of the diaphragm that normally support the LES. The rapid rise in gastric pressure and contraction of the abdominal musculature propel the gastric contents forcefully up the passively distended esophagus and through the presumably relaxed upper esophageal sphincter. If there is incoordination of these various actions, pressure builds up in the esophageal lumen to the point of a through-and-through tear of the esophageal muscle, allowing gastric contents to enter the pleural space. This tear is usually directed to the left lateral aspect of the esophagus in the distal portion. Classically, this is most likely to occur in the postprandial period, especially after alcohol ingestion.

Symptoms and Signs

The classic presentation of Boerhaave's syndrome is to have a patient develop postprandial nausea and vomiting, followed by the onset of crushing chest pain. In truth, patients found later to have a rupture of the esophagus do not always give a history of proceeding vomiting. The pain may be overwhelming, leading to the diagnosis of a myocardial infarct, a large pulmonary infarct, or a suspected dissecting aneurysm. The patient may be short of breath, directing attention to the lungs and heart rather than to the esophagus. Subcutaneous emphysema may be noted and suggest a perforation with accompanying mediastinal air. This is not an easy clinical diagnosis; delayed recognition of the perforation can occur in up to one-half of the cases.

Diagnosis

A chest film done because of pulmonary problems often suggests a rupture when a pleural effusion is seen or mediastinal or subcutaneous air is recognized. Unless the diagnosis is clinically obvious, a contrast study of the esophagus using water-soluble dye usually provides evidence of a free perforation. In one series, 23 of 24 contrast studies showed evidence of a perforation (86). It is preferable to begin the examination with water-soluble dye rather than barium sulfate, as extravasation of the former agent will not lead to long-term consequences as will the spilling of barium into the pleural cavity. A diagnostic thoracentesis usually shows acidic fluid; rarely, food particles will be aspirated by the needle.

Treatment

Surgical repair of the esophageal rent is in order—it is hoped within 12 hours of the original insult. Unlike perforations due to instrumentation, delay in diagnosis and therapy does not seem to be too harmful (86). The defect in the wall is identified, sutured, and occasionally covered with a flap of thickened pleura or with a gastric patch to protect the suture line. Nonoperative management has occasionally been tried with success, but surgical control of the rupture is still the preferred treatment.

Paraesophageal Hernias

Etiology and Pathogenesis

There is a grading system of gastric herniation. The common sliding hernia is considered to be grade I. A hernia in which the gastroesophageal junction remains below the diaphragm and the fundus or antrum passes through the diaphragmatic hiatus is considered to be grade II. A combined type, in which both the gastroesophageal junction and the fundus are up into the mediastinum but the fundus is higher than the gastroesophageal junction, is considered to be grade III. Grades II and III are interchanged often in the literature. Classically, the grade II hernias do not have an increased incidence of reflux, as the gastroesophageal junction functions normally. Grades I and III have reflux; grade III may in addition have obstructive symptoms similar to those seen with a grade II hernia. Volvulus of a portion of the herniated stomach may lead to ischemia and pain. Volvulus may also lead to obstruction with colic.

Symptoms and Signs

Pain from a paraesophageal hernia can come in two forms. The more common form is a postprandial fullness and pressure. It may be accompanied by a gurgling sensation as the patient moves in bed. The patient may complain of shortness of breath after a particularly large meal. The other type of pain is more severe and may resemble that experienced during a myocardial infarct. It may be due to ischemia of the stomach as the blood supply is compromised by a partial or complete volvulus. The pain is not relieved by antacids; belching may signal the return of the herniated stomach to a more normal position.

Diagnosis

A plain film of the chest may show a retrocardiac mass with an air-fluid level contained within it. A barium esophagram shows the esophagus disappearing behind a displaced fundus (Fig. 63-11). An esophagoscopy can present a truly confusing appearance, as the normal relationships of gastroesophageal junction, fundus, and antrum are not present. The endoscopic view will be of two separate passages, one leading to the pylorus, the other to the fundus.

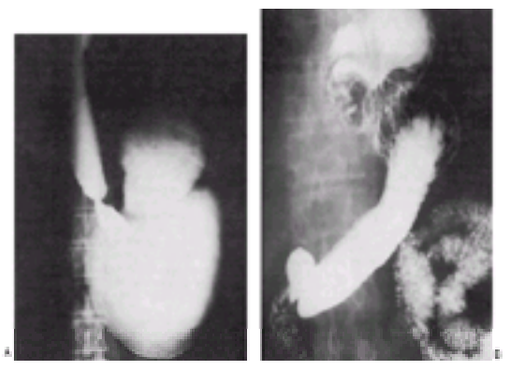

Figure 63-11. **A:** Paraesophageal hernia. Note that the esophagogastric junction is located well down in the abdomen and that the fundus rises into the chest. **B:** Large hiatus hernia. The impression of the diaphragm is seen in the midfundal region. The gastroesophageal junction is located high in the mediastinum. (Radiographs courtesy of C.A. Rohrmann, M.D.)

Therapy

This anatomic defect requires an anatomic solution—corrective surgery. However, there is still disagreement as to the place of corrective surgery when a totally asymptomatic hernia is picked up on a chest x-ray. Chest pain, especially the type resembling a myocardial infarct, would suggest the need for corrective surgery even though these hernias tend to occur in elderly patients with many other medical problems. Symptoms of fullness and obstruction call for a more individualized approach. Most patients will be better off when the hernia is corrected. If there has been blood loss in the patient, another indication for surgery is present. Hernias can be repaired either with an open operation or laparoscopically. The latter less morbid procedure is gradually gaining popularity. However, it is more demanding than the ordinary laparoscopic antireflux repair.

APPROACH TO THE PATIENT WITH CHEST PAIN

Clinical judgment is still the most important tool when investigating a patient with chest pain. In the immunocompromised patient, viral or yeast infection is a strong possibility and should lead to immediate endoscopy, with procurement of adequate samples for viral and fungal study. In the standard patient, the scheme shown in Fig. 63-12 might be used.

Figure 63-12. Algorithm for the approach to a patient presenting with chest pain. See text for definition of steps. (PPI, proton pump inhibitor; R/ O, rule out.)

A cardiac evaluation would seem to be the best place to begin the evaluation in view of the anxiety produced both in patient and physician by the symptom of chest pain. The intensity of the evaluation depends on the age of the patient and risk factors for coronary artery disease such as hypertension, smoking, hyperlipidemia, and diabetes (see Chapter 61).

A careful examination by palpation of the spine and chest wall will be productive in 10% to 15% of patients presenting to a cardiac clinic or general internist (87). Pressure over the spinous processes of T-3 and T-4, which reproduces the anterior chest pain, strongly suggests a musculoskeletal origin of the pain, and physiotherapy can then be used for relief.

Ultrasound scanning for gallstones may uncover the reason for chest pain of unknown origin, as colic from the gallbladder may be perceived as chest pain instead of the more common right upper quadrant location. A finding of gallstones leads to their removal; it is hoped the chest pain will be removed with the stones.

A 24-hour pH test would seem to be the next best step. This allows both the quantitation of the amount of reflux present as well as an evaluation of the frequency of coincident reflux with pain. If this is positive, a therapeutic trial with high doses of proton pump inhibitors such as omeprazole, 20 mg twice a day, or lansoprazole, 30 mg twice a day, can be done for 8 weeks. If this is effective, a clinical choice between continuing the medication or consideration of antireflux surgery can be made.

If the trial fails, it is probably worth repeating the 24-hour pH monitoring while the patient continues to take medication to make certain that the patient is not one of the small group of patients who do not respond to proton pump inhibitors at this dose. If reflux is still shown at this dose, the dose can be raised even higher or antireflux surgery can be considered.

If the initial 24-hour pH probe result is negative, an endoscopy can be done to make certain that the period of monitoring is not a false-negative response. My own experience is that such an endoscopy is usually negative, although there is support for the concept of finding signs of erosive esophagitis even without the usual symptoms of reflux (88).

Standard manometry can then be used to discover if a contraction abnormality of the esophagus is present, especially if the patient also complains of dysphagia. Should there be evidence of high-amplitude waves or the more uncommon diffuse esophageal spasm, a trial of diltiazem, 30 mg four times a day, rising to 60 and then 90 mg four times a day, can be done. Should the patient respond, the drug may be continued. If standard manometry is normal and the frequency of chest pain is daily, ambulatory manometry can be considered. If the drug trial has failed, endoscopic ultrasound can be used to look for an increase in thickness of the esophageal wall. If positive, the patient might be considered for myotomy, especially if dysphagia is also present. If negative, cognitive therapy can be tried.

Although this is a plan, it must be stated that it is not one that has been tested in the real-world situation. With the exception of controlling acid and, it is hoped, the accompanying chest pain, the remainder of the algorithm is on uncertain ground. To improve it, major advances in technology still will be necessary before a good understanding of chest pain of esophageal origin will be obtained.

CHAPTER 64

Chest Pain from Other Disorders Including Cancer

Jonathan R. Gavrin

This chapter covers chest pain not caused by the specific disorders addressed in the preceding chapters of Section C, Part IV. It is divided into two parts: Neoplastic Chest Disease and Nonneoplastic Chest Disease. Lung and breast cancers make up the overwhelming majority of thoracic neoplasms; except for metastases to lung, which are common, thoracic cancers other than primary lung and breast are rare. Nonneoplastic chest disease is a large and varied collection of syndromes that often present a perplexing set of diagnostic and therapeutic dilemmas.

NEOPLASTIC CHEST DISEASE

In developed countries, cancer continues to be the second leading cause of death, behind cardiovascular disease. Cancers account for approximately one-third of all deaths yearly and equal or exceed the death rates for coronary artery disease, exclusive of other cardiovascular diseases such as stroke, high blood pressure, or rheumatic heart disease (1) (http://www.americanheart.org/). Lung cancer and breast cancer each account for approximately 14% of the 1.2 million estimated new cancer cases per year, and together account for roughly 30% of all cancer deaths annually (1) (Table 64-1). Sadly, the age-adjusted death rate for lung cancer in female subjects has been rising since the late 1980s, rapidly approaching the death rate for men with lung cancer (1,2 and 3). For male subjects, even though the total death rate from lung cancer remains unacceptably high, in 1990 there began a slow but consistent decline (1) (Fig. 64-1).

Parameter	All cancers	Lung cancer	Breast cancer
New cases			
Total	1,228,600	171,500	180,300
Female	600,700	80,100	178,700
Male	627,900	91,400	1,600
Deaths			
Total	546,800	160,100	43,900
Female	270,600	67,000	43,500
Male	294,200	93,100	400

Reprinted from American Cancer Society: Cancer Facts and Figures – 1998. New York: American Cancer Society, 1998, with permission.

TABLE 64-1. Estimates of new cases and deaths from lung cancer and breast cancer

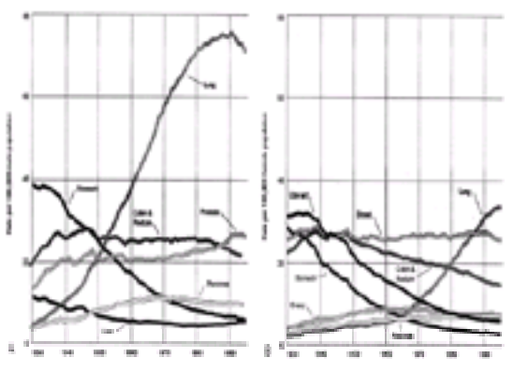

Figure 64-1. Age-adjusted death rates for males **(A)** and females **(B)** in the United States from cancer of selected sites, 1934 through 1994. Rates are per 100,000 and are age adjusted to the 1970 U.S. standard population. Due to changes in International Classification of Diseases coding, numerator information has changed over time. Rates for cancers of the liver, lung, and colon and rectum are affected by these coding changes. (Reprinted with permission of the American Cancer Society, Inc.)

Together, breast and lung malignancies not only make up a huge proportion of lethal cancers, but also lead to myriad painful and other aversive symptoms, be they from primary disease, metastasis, or treatment. The ensuing discussion highlights general characteristics and then explores the specific chest symptoms related to these two diseases; it does not consider global principles of cancer pain management or palliative interventions that previous chapters address (see Chapter 36 and Chapter 40). For completeness, a brief review of other thoracic neoplasms follows the material on breast and lung cancers.

Cancer of the Lung

Basic Considerations

The term *lung cancer* properly refers to tumors of respiratory epithelial origin (bronchi, bronchioles, and alveoli) (4). This chapter also includes discussions of mesothelioma and metastatic lung disease. The former, of pleural origin, is frequently associated with chest pain, cough, and other symptoms associated with primary lung tumors. Metastatic lung disease, the symptomatology of which resembles primary lung cancers, is exceedingly common, occurring in approximately 30% of all cancer patients (nearly 20% of patients dying from pulmonary metastases have no other detectable focus of disease) (5).

The bronchogenic carcinomas [squamous cell (epidermoid), adenocarcinoma, bronchioalveolar carcinoma, large cell carcinoma, and small cell (oat cell) carcinoma] account for approximately 90% of primary lung tumors; undifferentiated carcinomas, carcinoids, bronchial gland, and other rare tumors account for the remaining 10% (4). Adenocarcinoma has now replaced squamous cell (epidermoid) cancer as the most frequent lung tumor (6). Histologic subtyping into small cell lung cancers and non–small cell lung cancers has major clinical importance, determining treatment decisions. Typically, small cell lung cancers have spread by the time of diagnosis; chemotherapy and radiation are the only realistic treatment options and sometimes are effective. For non–small cell lung cancers that are localized at the time of

diagnosis, surgery or radiation may be curative, but metastatic disease is resistant to chemotherapeutic interventions (4).

Smoking is the single most important etiologic factor in pulmonary tumors (7,8) and is present in 90% of patients. The causal relationship between other environmental exposures and lung cancer is also well established, including passive smoke inhalation (9,10 and 11), asbestos, silica dust, dichlorodiphenyltrichloroethane (DDT) (12), certain occupations, and living situations, including poverty and proximity to industrial regions (1213,14,15,16,17,18,19,20,21,22, and 23). Asbestos-related disease, most importantly pleural mesothelioma, should peak in the next two decades and then decline, due to control of industrial exposures.

No truly satisfactory curative treatment exists for any of the lung-related tumors, primary, metastatic, or pleural (24,25,26 and 27). Five- year survival rates for all but the most localized disease are dismal, and half of those people with local disease will be dead within 5 years (1) (Table 64-2). Therapeutic advances in the past three decades have made only modest improvements in overall survival with lung cancer, from 8% to 14%. However, many efforts to improve the quality of supportive and palliative measures have developed. Pain and other somatic symptom management, along with psychological support, are central to quality care and have improved significantly in this time period (28,29, and 30).

Malignancy	All stages (%)	Local disease (%)	Regional disease (%)	Distant disease (%)
Breast (female)	84	97	76	21
Lung	14	49	18	2

TABLE 64-2. Five-year survival for lung cancer and breast cancer

Clinical Features

The overwhelming majority of patients with lung cancer present with some sign or symptom, with only 5% to 15% of patients asymptomatic at diagnosis, usually by routine chest radiograph. Typically, at the onset of tumor growth or invasion, lung cancers produce signs and symptoms arising from local enlargement, invasion of adjacent structures, regional growth, lymphatic spread, or growth in distant metastatic sites from hematogenous dissemination. Clinical manifestations may also occur from remote effects of lung tumors, in particular paraneoplastic syndromes that may result from ectopic secretion of peptide hormones (4,31). Except for pleural pain and vague pains thought to be of visceral origin and typically involving the ipsilateral hemithorax, chest pain in lung cancer patients is not common. Rather, cough, dyspnea, hemoptysis, and syndromes associated with compression or obstruction of vascular and airway structures are the predominant symptoms (32) (Table 64-3). The approach to patients with lung cancer, therefore, is of a general palliative nature, encompassing much more than just pain relief (see Chapter 40).

Symptoms secondary to central or endobronchial growth of the primary tumor
Cough
Hemoptysis
Wheeze and stridor
Dyspnea from obstruction
Pneumonitis from obstruction (fever, productive cough)
Symptoms secondary to peripheral growth of the primary tumor
Pain from pleural or chest wall involvement
Cough
Dyspnea on a restrictive basis
Lung abscess syndrome from tumor cavitation
Symptoms related to regional spread of the tumor in the thorax by contiguity or by metastases to regional lymph nodes
Tracheal obstruction
Esophageal compression with dysphagia
Recurrent laryngeal nerve paralysis with hoarseness
Phrenic nerve paralysis with hemidiaphragm elevation and dyspnea
Sympathetic nerve paralysis with Horner's syndrome
Eighth cervical and first thoracic nerves with ulnar pain and Pancoast's syndrome
Superior vena cava syndrome from vascular obstruction
Pericardial and cardiac extension with resultant tamponade, arrhythmia, or cardiac failure
Lymphatic obstruction with pleural effusion
Lymphangitic spread through lungs with hypoxemia and dyspnea
(Adapted from Carbone KKH. Signs and symptoms of bronchogenic carcinoma. In: Straus AM, ed. Lung cancer: clinical diagnosis and treatment. New York: Grune & Stratton, 1967:85–98.

TABLE 64-3. Common signs and symptoms of lung cancer

In patients with superior pulmonary sulcus syndrome, metastatic plexopathy, or bone involvement, pain is caused by peripheral (nociceptive) mechanisms or peripherocentral (deafferentation) mechanisms. Nociceptive pain is usually localized and continuous and increases with time, caused by tumor invasion of the nearby vertebrae, the cupola of the pleura, and other soft tissue. Deafferentation pain is caused by compression, infiltration, and destruction of the involved spinal nerves, which produces burning pain with allodynia, hyperalgesia, hyperesthesia, dysesthesia, and hyperpathia in a segmental distribution. In patients with costopleural syndrome, the pain is predominantly caused by a peripheral mechanism, but if intercostal nerves are involved, deafferentation pain may play a prominent role in the patients' discomfort.

Symptoms Due to Intrathoracic Spread. Intrathoracic spread of lung cancer, either by direct extension or by lymphatic metastasis, produces regional disease symptoms in the thorax; the same is true for metastatic disease to the lung from other primary carcinomas. Involvement of the superior pulmonary sulcus, for example, produces Pancoast's syndrome (see Pancoast's Syndrome, later in this chapter) (Fig. 64-2). Tracheal obstruction and irritation can be associated with retrosternal and anterior chest wall pain, as well as with cough and hemoptysis (4,31,33). Entrapment of the recurrent laryngeal nerve produces vocal cord paralysis with hoarseness and, because of the longer intrathoracic course of the left nerve, these symptoms more commonly occur on the left side than on the right side. Involvement of the phrenic nerve can lead to paralysis and elevation of the hemidiaphragm, with resulting dyspnea.

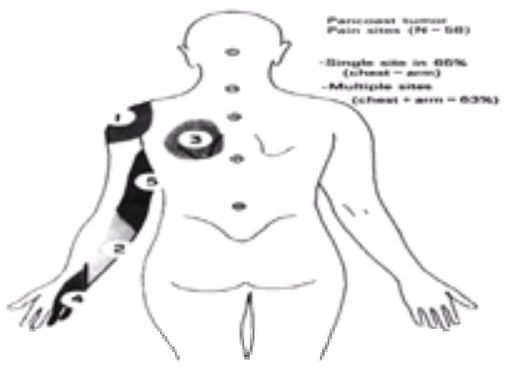

Figure 64-2. Sites of pain in Pancoast's syndrome in order of frequency. Of 58 patients, 28 (49%) had pain in the shoulder, 24 (41%) in the medial forearm, 23 (40%) in the scapula, 9 (15.5%) in the fourth and fifth fingers, and 4 (7%) in the medial part of the upper arm. (Reprinted from Watson PN, Evans RJ. Intractable pain with lung cancer. *Pain* 1987;29:163–173, with permission.)

Compression of the esophagus by the tumor can lead to dysphagia, odynophagia, and, not infrequently, deep visceral pain caused by the involvement of sensory nerves to the esophagus. Also, dysphagia of both solids and liquids can result with recurrent laryngeal nerve paralysis; because this nerve supplies part of the cricoid musculature and proximal esophagus, aspiration of gastric contents can result. Compression of the thin-walled low-pressure system of the superior vena cava by a right-sided tumor or large lymph nodes in the mediastinum produces the superior vena cava syndrome (see Superior Vena Cava Syndrome, later in this chapter).

Tumor extension into the pericardium and heart can produce pericardial tamponade or congestive heart failure. Other problems of regional spread include lymphatic obstruction with resulting pleural effusion, and lymphangiectatic spread to the lungs, with production of hypoxemia and dyspnea. Bronchioalveolar carcinoma can spread transbronchially with tumor growing along the multiple alveolar surfaces, resulting in impairment of oxygen transfer, respiratory insufficiency, dyspnea, hypoxemia, and production of large amounts of sputum. Some of these patients have deep, retrosternal, diffuse visceral-type pain.

Symptoms Due to Extrathoracic Metastatic Disease. Metastatic disease, found in 50% to 90% of autopsies of patients with lung cancer, can involve nearly any organ, but most commonly affects pleura, lung, bone, pericardium, and liver. Other sites of metastasis include adrenals, central nervous system, meninges, gastrointestinal tract, esophagus, and thyroid gland (4,31).

These produce common clinical problems, which include neurologic deficit from brain metastasis, pain from bone metastases and pathologic fractures, biochemical liver dysfunction, anorexia and cachexia, and biliary obstruction with pain. Some patients with metastases to the lymph nodes in the supraclavicular region, and occasionally in the axilla and groin, have pain and ulceration. Extension of tumor into the vertebral column frequently causes spinal cord compression, with consequent neurologic signs and symptoms.

Paraneoplastic Syndromes. Paraneoplastic syndromes, which are remote effects of cancer, are common in patients with lung cancer and can be the initial finding or the first sign of recurrence of the lung cancer. In addition, a paraneoplastic syndrome can mimic metastatic disease and, unless detected, might lead to inappropriate palliative rather than curative treatment. Successful treatment of the tumor can relieve paraneoplastic syndromes, so this is the basis for therapy (4,31,33).

Pancoast's Syndrome (Superior Pulmonary Sulcus Tumor). First discussed in the English literature by E. S. Hare in 1838 (34), it was Pancoast's classic 1932 paper that described the clinical features of superior pulmonary sulcus tumor as “pain around the shoulder and down the inner side of the arm and often the ulnar side of the forearm, loss of power and wasting of the muscles of the hand, Horner's syndrome, and signs mainly of dullness in the apex of the chest” (35). In fact, Pancoast's syndrome can result from a variety of conditions affecting the apex of the lung (Table 64-4A; see Fig. 64-2); it is associated with 3% to 5% of pulmonary tumors and probably occurs more frequently in men (36). The superior pulmonary sulcus is located just below the lower trunk of the brachial plexus. A growing mass irritates and eventually compresses nerve roots C-7 through T-2, causing the characteristic pain and motor and sensory disturbances in the distribution of the ulnar and intercostobrachial nerves. Frequently, the discomfort becomes excruciating, often associated with the lancinating pains of deafferentation. Although all of the patients in Pancoast's original report exhibited Horner's syndrome, subsequent published reports suggest an incidence closer to 60%. Less frequently, there is hoarseness from involvement of the recurrent laryngeal nerve or symptoms of spinal cord compression secondary to extension along the nerve roots into the epidural space (37,38,39 and 40) (Table 64-4B).

Bronchogenic carcinomas
Tuberculosis
Pulmonary abscess
Laryngeal tumors
Branchial cleft tumors
Myeloma
Cervical rib
Neoplasms of the cervical sympathetic ganglia

NS, not stated.
*Seventeen percent at presentation, but 72% eventually developed plexopathy.

TABLE 64-4B. Signs and symptoms of Pancoast's tumors in percentage of patients studied

Other Brachial Plexopathies. Brachial plexopathy is a well-known complication of cancers, most frequently from metastatic disease (metastatic brachial plexopathy), but also associated with radiation therapy (radiation brachial plexopathy), surgery, or regional tumor growth. In metastatic brachial plexopathy, pain is the most common presenting symptom, while radiation brachial plexopathy typically presents as dysesthesia or weakness of the arm. In patients with brachial plexopathy from tumor infiltration, approximately 70% have primary lung or breast cancer (41,42).

Costopleural Syndrome. The costopleural syndrome results from tumor invasion of the pleura, soft tissue, and ribs, often with involvement of the intercostal nerves. Costal pleural irritation causes a sharp aching or burning sensation usually overlying the pathologic process. Central lesions of the diaphragmatic pleura typically cause well-localized sharp or aching pain in the shoulder or ridge of the trapezius, while lesions in the pleura overlying the muscular portion of the diaphragm tend to cause a referred dull and aching pain to the upper lumbar region of the back and the upper two-thirds of the abdomen. Tumor infiltration of the cupola of the lung usually produces pain in the upper interscapular or vertebral area and in the medial aspect of the arm. Mediastinal pleural invasion produces pain felt deep in the central portion of the chest and also in the shoulder and trapezius region. Deep breathing, coughing, and movement all exacerbate pleural pain. Metastatic lesions to soft tissue and ribs cause somatic nociceptive pain; compression, irritation, or damage to intercostal nerves produces a continuous neuropathic pain with accompanying burning, dysesthesia, and sensory loss that is unilateral and segmental (Fig. 64-3).

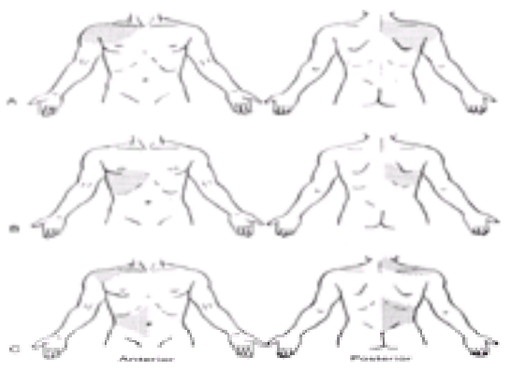

Figure 64-3. Sites of pain in various costopleural syndromes. **A:** Pain pattern from pathology in the right upper part of the thoracic cage, or apical parietal pleura. **B:** Pain pattern of the right middle part of the chest and parietal pleura. **C:** Pain pattern from irritation of the right portion of the diaphragmatic pleura producing pain in the shoulder, outer abdomen, and back (parts supplied by the phrenic nerves and the lower thoracoabdominal intercostal nerves), respectively.

Superior Vena Cava Syndrome. Obstruction of venous drainage in the upper part of the chest, the superior vena cava syndrome, is associated with malignancy approximately 90% of the time; of those malignancies, lung cancers make up roughly 85%. Its overall incidence in cancers is 3% to 8%. The superior vena cava, a thin-walled, low-pressure vessel, lies in a tight compartment of the anterior-superior mediastinum behind the rigid sternum, adjacent to the right mainstem bronchus, and completely encircled by the chains of lymph nodes that drain the entire right chest and the lower portion of the left chest cavity. Clinical diagnosis is relatively easy. Venous engorgement in the thorax and neck, with consequent facial edema and tachypnea, are the hallmarks. Chest pain, cough, dysphagia, edema of the upper extremity, and signs and symptoms of increased intracranial pressure, including severe intractable headache, are variably present (43,44 and 45) (Table 64-5).

Sign or symptom	Approximate incidence (%)
Dyspnea	65
Venous distension in the thorax	55
Venous distension in the neck	65
Facial edema	50
Cough	25
Facial plethora	20
Cyanosis	20
Upper extremity edema	15
Chest pain	15

TABLE 64-5. Signs and symptoms of superior vena cava syndrome

Pain Syndromes Caused by Vertebral Metastases. The vertebral column, particularly the thoracic and lumbar regions, is the most frequent site of bone metastasis from primary lung, breast, and prostate tumors (46) (Fig. 64-4). Almost all patients with vertebral metastases have local or radicular pain, or both, depending on the extent of vertebral body or nerve root involvement. In extreme cases, epidural spinal cord compression can occur.

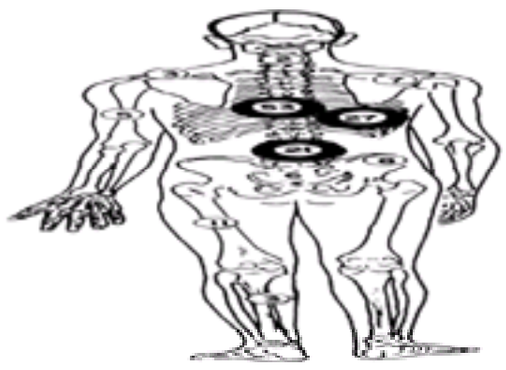

Figure 64-4. Sites of intractable pain caused by skeletal metastasis in 64 patients consequent to lung cancer. The circles contain the number of metastases at various sites. The most frequently involved regions of the 101 painful sites were the thoracic vertebrae, the ribs, and the lumbar vertebrae. The sites indicated do not relate to lateralization. (Reprinted from Watson PN, Evans RJ. Intractable pain with lung cancer. *Pain* 1987;29:163–173, with permission.)

Postthoracotomy Syndrome. Moderate to severe pain in the distribution of one or more intercostal nerves, persisting beyond the usual course of postoperative pain, characterizes the postthoracotomy syndrome. Even though incisional nerve injury (traumatic neuroma) appears to play a minor role compared with ongoing pain from recurrent or persistent tumor in the distribution of the thoracotomy scar (38), nerve block or local anesthetic injection of suspected neuromas carries minimal risk and may aid greatly in diagnosis and treatment planning. Pain due to direct tumor involvement may respond to palliative antitumor therapies, but proper management of systemic or regional analgesic techniques remains the linchpin of pain relief. If systemic medications are ineffective or cause unacceptable side effects, posterior multidermatomal intercostal nerve or thoracic epidural blocks may provide prolonged relief. Thoracic paravertebral block is also a safe technique for unilateral pain relief in chronic postthoracotomy pain (47).

Epidural Spinal Cord Compression. Epidural spinal cord compression is the second most common neurologic complication of systemic cancer, occurring in 5% to 10% of patients. Although usually associated with advanced cancers, spinal metastases can occur any time during the disease; in as many as 8% of patients with spinal involvement, it is the first manifestation of the underlying malignancy (48,49). Epidural spinal cord compression occurs most commonly in the thoracic spine, and pain is the initial symptom in 90% of patients, typically occurring days or weeks before other neurologic signs and symptoms (50). It is, therefore, imperative to make this diagnosis as early as possible and intervene preemptively when feasible. Corticosteroids for acute symptoms and radiotherapy to prevent or delay progression are the mainstays of treatment. Response to systemic chemotherapy generally is poor. Surgical decompression by laminectomy or vertebral body resection seems to be as effective as radiation and may have value in patients who are relatively healthy systemically (49,50 and 51). When a patient is not known to have cancer, misdiagnosis as pain of musculoskeletal origin can occur. If recumbent position exacerbates thoracic pain, and it is progressive and unremitting despite appropriate interventions for musculoskeletal pain, the practitioner should obtain appropriate imaging studies, which usually establish the diagnosis.

Benign Neoplasms of the Lung. Less than 5% of all lung neoplasms are benign. Adenomas and hamartomas account for approximately 90% of such lesions, the remainder being a collection of uncommon neoplasms (chondromas, fibromas, lipomas, hemangiomas, leiomyomas, teratomas, pseudolymphomas, and endometriosis). Similar to malignant lung neoplasms, these syndromes typically present with cough, hemoptysis, obstruction, infection, or asymptomatically as a pulmonary nodule on radiography (4). Pain is uncommon. Cure is by surgical removal.

Mediastinal Tumors. Various benign and malignant tumors and cysts occur within the mediastinum. Although one-third to one- half of these tumors are asymptomatic, found on routine chest radiography, the remainder produce chest pain or tightness, dyspnea, hoarseness, general malaise, anorexia and cachexia, and other symptoms and signs secondary to compression of mediastinal structures. Severity and character of the manifestations are related to tumor size and location

(44,52,53). Mediastinal tumors produce a wide variety of systemic syndromes, many due to ectopic hormone secretion (Table 64-6A and B, Fig. 64-5 and Fig. 64-6).

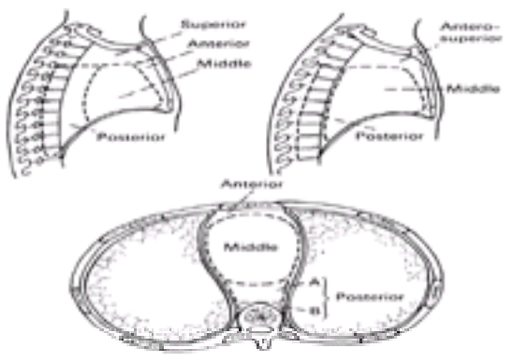

Figure 64-5. **A,B:** Two different classifications of the compartments of the mediastinum. **C:** Cross-section showing the compartment including the posterior compartment as classified in **A** and **B**.

Cancer of the Breast

Basic Considerations

Breast malignancies arise from the epithelial cells lining the ducts or lobules of the breast and are the most common cancer in women, exclusive of skin cancers (54). Malignant breast disease accounts for approximately 30% of all new cancer cases and a little more than 15% of all cancer-related deaths in women each year; it occurs in more than twice as many women as lung cancer, although lung cancer now causes more deaths annually (1) (see Table 64-1). Mammography is the only reliable test for detecting nonpalpable early breast cancer, at which time 90% are curable (55). Approximately 75% of women with newly diagnosed breast cancer have no identifiable risk factors, the most obvious of which is age; there is a straight line increase in incidence with every year of life until menopause, at which time the incidence slope begins to decrease (54,56). The genetics of breast cancer is a topic of intense inquiry (57), but only approximately 10% currently are linked directly to genetic mutations (54). No proof exists that environmental factors, including diet, play a major role and, although administration of exogenous estrogen has long been thought to contribute to breast cancer risks, evidence is still inconclusive (58,59 and 60). The endogenous hormone-dependent nature of the disease, however, is clear; early menarche, delayed first full-term pregnancy, and late menopause (natural or surgical) are major factors. There is consensus that ". . . length of menstrual life—particularly the fraction occurring before the first full-term pregnancy—is a substantial component of the total risk (and) can account for 70–80% of the variation in breast cancer frequencies in different countries" (54).

Infiltrating ductal carcinomas comprise the vast majority of invasive breast cancers (approximately 70% to 75%), while medullary carcinomas, lobular carcinomas, and mucin-producing tumors each account for 3% to 6% of breast cancers. Worth special mention are two cutaneous manifestations, Paget's disease, occurring in 1% to 4% of all patients with breast cancer, and inflammatory breast cancer, characterized clinically by skin redness and warmth with an erysipeloid margin on the underlying skin (54,61).

Management of primary cancers localized to the breast or regional lymph nodes has changed since the mid-1980s. Many randomized, controlled clinical trials have demonstrated that breast-conserving surgery (i.e., lumpectomy) is as effective, based on 10-year survival, as more extensive procedures such as mastectomy or

modified radical mastectomy. Adjuvant radiation may reduce rates of local or regional recurrence and is indicated for women with high-risk primary tumors (positive margins, positive nodes). Breast-conserving surgery is not appropriate for large tumors, tumors involving the nipple-areolar complex, intraductal cancers involving multiple quadrants, for women with collagen vascular disease, for women who lack motivation for breast conservation, or in those cases where adjuvant radiotherapy is indicated but not readily available. Systemic chemotherapy, although imperfect, is life-saving in more than one-fourth of women who would otherwise die from metastatic breast cancer (54).

The natural history of malignant breast disease remains poorly understood. Indeed, one-half of all recurrences appear more than 5 years after initial therapy, and nearly one-half of all patients treated for local disease develop, and ultimately succumb to, distant metastases, primarily soft tissue, bone, and viscera (lung and liver) (54).

Clinical Features

Breast pain is a common and highly nonspecific symptom, usually caused by a benign cyst, but it does not preclude malignancy. Failure to recognize the significance of a painful breast mass is a frequent cause of delayed diagnosis and demands careful clinical evaluation and mammography. If these are negative for cancer, the most likely explanation for breast pain is *fibrocystic* change or influence of menstrual cycle (56). Small breast malignancies rarely cause pain or other symptoms, underscoring the importance of routine mammographic screening in patients at risk. Larger tumors (greater than 2 cm in diameter), however, often are the basis for a dull aching pain, in proximity to the breast, probably caused by compression or irritation of nociceptors in the underlying soft tissues. Regional lymph node involvement can cause localized, nociceptive pain in the axilla. More important, irritation or compression of the intercostobrachial nerve or nerves of the brachial plexus causes burning neuropathic syndromes, frequently accompanied by episodic lancinating pain. Patients who neglect seeing a physician can present with necrosis and ulceration of the skin and deeper tissues of the breast associated with a severe burning and aching pain that is predominantly in the affected region, but that can radiate to the anterior chest and axilla.

Metastases to bone and various viscera are associated with pain and other symptoms and signs, depending on the site. Of particular importance are metastases to the ribs, which produce localized chest pain frequently associated with intercostal neuralgia, and metastases to the vertebral column, which often produce localized back pain or signs and symptoms of spinal cord compression. Radicular pain also occurs with metastatic vertebral fracture and sudden compression of the spinal nerves. Invasion of the brachial plexus results in metastatic brachial plexopathy.

Postmastectomy Pain Syndrome. Postmastectomy pain syndrome consists of persistent pain in the anterior chest, axilla, and medial and posterior parts of the arm that follows any surgical procedure on the breast. It can occur after a relatively simple procedure, such as lumpectomy, but more commonly occurs following radical procedures, especially those involving extensive axillary node dissection. Onset varies from 2 weeks to 6 months after operation and has a reported incidence from 5% to 20% (62,63). The syndrome develops from damage to the intercostobrachial nerve, which is a branch of the second intercostal nerve, with frequent contribution also from the third intercostal nerve. Radical mastectomy can also damage cutaneous branches of the fourth and fifth nerves. Postmastectomy pain syndrome occurs more frequently in patients who have had postoperative complications, such as wound infection or fluid retention (62,64,65).

The pain of postmastectomy syndrome is tight, constricting, and burning, often associated with bouts of lancinating pain, paresthesia, dysesthesia, hyperpathia, hypesthesia, and hyperesthesia in the distribution of the injured nerves. Movement of the arm exacerbates the pain; immobilization relieves pain but enhances lymphedema of the arm due to impaired venous return, making movement even more uncomfortable. Sometimes the allodynia and hyperesthesia are so intense that even contact with undergarments triggers pain. Without adequate pain relief and active physical therapy, patients are at risk for a variety of upper extremity problems, including frozen shoulder and varying manifestations of chronic nociceptive and neuropathic pain syndromes. To preserve upper extremity function, posterior multidermatomal intercostal nerve block, thoracic paravertebral block, or epidural analgesia may be necessary, the same techniques used for postthoracotomy pain syndrome (47).

Brachial Plexopathy. Brachial plexopathy in breast cancer is more likely to be radiation induced than the brachial plexopathies associated with lung cancers, which tend to be from metastatic disease (see previous discussion). Treatment is as for other radiation-induced plexopathies or those associated with tumor invasion (see Chapter 36).

Phantom Breast Pain. Phantom breast syndrome (PBS) is a significant problem after radical or modified mastectomy, occurring in one-fourth to one-half of women undergoing such procedures (66,67,68,69 and 70). PBS can be painful, can manifest as itch, or can be a nonpainful sensation that the missing breast is still present. PBS typically develops within 3 months after surgery, with duration varying from a few seconds to a few minutes (70).

Studies suggest that psychosocial factors, such as poor emotional support from the surgeon, damaged body image, impaired sexual function, and occupation outside the home, may be important risk factors for development of PBS (66,67); at operation, women who later develop PBS tend to be younger and premenopausal with children, and have a history of preoperative breast sensations including pain (69,70). External radiation, iridium implantation, adjuvant chemotherapy, site, side, and even extent of surgery seem to play little role in the development of PBS (66,68,69).

NONNEOPLASTIC CHEST DISEASE

The number and variety of pain disorders in the chest are huge. Lesions or diseases of the upper six segments of the thoracic spinal cord; pathology that affects the rootlets, roots, or short formed nerve trunks of the upper six spinal nerves; or lesions and diseases limited to the anterior primary division of these nerves, referred to as the *thoracic intercostal nerves*, can cause chest pain. If the pathologic process affects the lower six segments of the thoracic spinal cord or the rootlets, roots, or formed nerve, the pain distributes in the affected segments of the abdomen, lower thoracic and lumbar spines, and paraspinal regions. Diseases or lesions of the thoracoabdominal intercostal nerves produce pain in the anterior abdominal wall and the lateral aspect of the trunk, depending on the site of the pathologic process (Table 64-7).

TABLE 64-7. Chest pain caused by neuropathic, musculoskeletal, and other disorders

Many chest pain syndromes have characteristics not specifically related to the thorax except by accident of location. Neuropathic pain from herpes zoster in the T-4 dermatome and musculoskeletal pain from strained pectoralis muscles, for example, do not differ intrinsically from similar pathology elsewhere, except that they occur in the chest. Other chapters of this book address diagnosis and treatment of such syndromes, so it suffices here to list them without detailed discussion. Other syndromes are specific to the chest, because they relate to unique anatomic structures, are referred to the chest from extrathoracic sites, or have psychological ramifications; these are worthy of more extensive description.

Chest Pain of Neuropathic Origin

Virtually any process that impinges on or damages nerves that distribute to the thorax results in neuropathic pain in the chest (Table 64-8). Thoracic myelopathy,

radiculopathy, neuropathy, and intercostal neuralgia belong in the differential diagnosis of chest pain without an obvious visceral etiology.

TABLE 64-8. Chest pain primarily of neuropathic origin

Thoracic Myelopathy

Contrary to general belief, disorders of the spinal cord are common causes of pain in the chest as well as in the abdomen and back. The lesion or disease can be intrinsic within the spinal cord, extramedullary but within the meninges, located in the epidural space, or a combination of these (see Chapter 60).

Radiculopathy and Neuropathy (Segmental Neuralgia)

Irritation of sensory (dorsal) rootlets or roots produces radiculalgia. Neuropathy of the short formed thoracic spinal nerves before they divide and form the primary anterior and posterior divisions produces segmental neuralgia. Patients experience discomfort in the skin and subcutaneous tissue supplied by part or all of the affected nerve(s); usually it has a sharp burning or constricting quality, sometimes accompanied by brief bouts of stabbing or lancinating pain. Often the pain is worse at night. Movements of the thoracic spine (twisting and bending) and changes in intraspinal pressure from coughing, sneezing, or straining exacerbate the pain. Hyperalgesia, hyperesthesia, and hyperpathia of the affected segments usually accompany the pain. The extensive overlap of adjacent thoracic spinal nerves can make clinical demonstration of sensory loss impossible; involvement of several contiguous roots allows the careful practitioner to demonstrate hypesthesia in the dermatome(s) in the middle of the band of hyperalgesia.

Intercostal and Peripheral Neuropathy

Trauma, surgery, infection, and compression can injure one or more intercostal nerves. Postthoracotomy and postmastectomy syndromes (discussed previously) are specific examples of such conditions.

The intercostal nerves, in their positions immediately inferior to each rib, are vulnerable to rib trauma. Fracture of a rib can cause injury to the subjacent nerve, followed by a sharp superficial burning pain in its distribution. Respirations or movements of the rib cage aggravate the pain and mimic pleurisy. There is not much sensory deficit unless there is injury at several contiguous levels because there is significant overlap of the intercostal nerves. Palpation usually elicits superficial and deep tenderness, particularly over the site of the rib fracture. If the fracture becomes displaced, it can lacerate the pleura and damage the lung.

When the history and physical examination reveal evidence of chest wall trauma, it is easy to make the diagnosis. If the trauma is remote and forgotten, the examiner will not be able to elicit rib tenderness and the diagnosis can be extremely difficult. In such cases, an appropriately located fracture line or rib callus on chest radiography can aid in diagnosis.

Systemic analgesics usually suffice for pain management, but patients with severe intercostal neuralgia may benefit from posterior intercostal block with a long-acting local anesthetic, such as 0.25% to 0.50% bupivacaine.

Chest Pain of Musculoskeletal Origin

Musculoskeletal conditions cause at least 10% of all cases of noncardiac chest pain (71). In patients with chest pain and angiographically normal coronary arteries (less than 30% stenosis in all arteries), the incidence of musculoskeletal disorders is much higher, in the 40% to 70% range (72,73). Table 64-9) lists the most important musculoskeletal disorders that produce pain in the chest. Arthritis of the rib articulations with sternum and thoracic spine, chest wall trauma, benign overuse myalgia, and fibrositis are some of the most common syndromes (74), as well as myofascial pain syndromes. More general discussion of muscular pain syndromes, including those of the spine, is found in Chapter 28 and Chapter 29. The discussion here focuses primarily on the skeletal structures unique to the chest (i.e., ribs, costal cartilages, and the sternum) (Fig. 64-7).

TABLE 64-9. Chest pain primarily of musculoskeletal origin

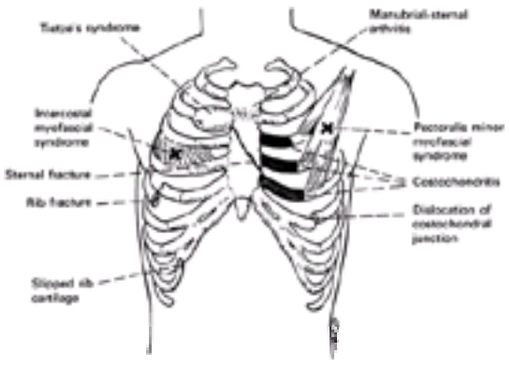

Figure 64-7. Schematic diagram of the chest showing some of the most important musculoskeletal disorders that cause chest pain.

Pain Associated with Disorders of the Ribs

Costovertebral Arthritis. Arthritis of the costovertebral and costotransverse joints is uncommon, but may be associated with osteoarthritis, ankylosing spondylitis, and, infrequently, other arthritides. Deep breathing, coughing, or direct compression of the chest typically makes the pain worse (74). The anatomic characteristics and increased mobility of the first, eleventh, and twelfth costovertebral joints make them more susceptible to degenerative changes than other levels. Rarely, arthritis of the first costovertebral joint causes thoracic outlet syndrome (75).

Rib Trauma and Fractures. Fracture of one or more ribs is one of the most common causes of acute musculoskeletal chest pain. In most cases, fractures result from direct trauma, but they can also occur as so-called tussive fracture during severe paroxysms of coughing, a condition first described in 1773 (76). Patients with severe osteoporosis or metastatic cancer may experience spontaneous rib fracture.

Several investigators have shown that epidural analgesia is more effective, and may result in better outcome, than systemic opioids for treatment of rib fracture after major trauma (77,78 and 79). The optimum combination of epidural local anesthetic and opioid is unknown, and the superiority of epidural over other intrapleural or extrapleural regional techniques remains to be seen (80,81, and 82). In chest wall trauma with less than three ribs involved, there is no evidence to suggest that epidural techniques are superior to carefully titrated systemic analgesia.

Rib trauma without fracture is fairly common, resulting in point tenderness and occasionally local swelling at the site of injury. Movement, deep breathing, and cough aggravate the pain, and radiographs are normal. Metastatic disease from lung, breast, prostate, and other solid tumors may present as isolated rib swelling and tenderness. Radiographs and other imaging techniques confirm the presence of bony pathology (see Fig. 64-7).

Slipping Rib Syndrome. Davies-Colley first described the slipping rib syndrome in 1922 (83). Other names for the syndrome include clicking rib, rib gliding, rib-tip syndrome, slipping rib cartilage, displaced ribs, and nerve nipping at the costal margin. The syndrome, thought to be of traumatic origin, is characterized by chest or abdominal pain at the costal margin due to irritation of the intercostal nerve. It is associated with increased mobility of the sternal tip of the costal cartilage, most often of the tenth rib, but occasionally that of the eighth and ninth ribs. The syndrome occurs most often in middle-aged adults, equally in men and women, and with no predilection for either side; uncommonly, there is bilateral pathology (84). It is an unusual cause of pain in children (85,86).

The upper seven ribs articulate directly with the sternum by their respective cartilages, but the cartilages of the eighth, ninth, and tenth ribs articulate with the cartilage above by endochondral synovial membrane surrounded by fibrous tissue; this is the weakest point in the chest, particularly vulnerable to trauma (see Fig. 64-7). Injury in the area can cause separation of the costal cartilages, following which the cartilaginous ends curl upward, creating an up and down slipping with respiration or other chest movement. The rib can also slip anteriorly and posteriorly over the border of the upper cartilage, with a click and pain that are diagnostic.

The *hooking maneuver* is the pathognomonic test (87). The examiner places curled fingers under the inferior rib margin and pulls anteriorly. A positive test produces a clicking noise and exacerbates the pain. The same maneuver on the contralateral side, except in the rare instances of bilateral slipping rib, is negative. Infiltration of local anesthetic (e.g., 5 mL of 0.5% lidocaine) into the space between the detached cartilage and rib renders the hooking maneuver painless.

Conservative treatment of slipping rib syndrome consists of reassurance and nonopioid systemic analgesics. Serial injection of the painful site with local anesthetic plus corticosteroid often provides prolonged relief. Surgical excision of the affected rib and costal cartilage is a reasonable alternative in those patients who do not respond to conservative measures (88,89).

Tietze's Syndrome. This syndrome, first described by Tietze in 1921 (90), consists of a nonspecific, benign, self-limiting, nonsuppurative, painful swelling of the costal cartilages, most often the second and occasionally the third. The swelling can progress to an irregular mass that obliterates the adjacent intercostal spaces. True Tietze's syndrome is a relatively rare condition affecting young people (including children), with a predilection for those in their second and third decades without preponderance of either gender. The causes are unknown, but rheumatic conditions often precede the onset of chest pain (91) and respiratory straining, such as severe cough, heavy manual work, and deficient nutrition, have been suggested as causative factors (92).

There is isolated involvement of the second costochondral junction in 60% of patients with Tietze's syndrome (93). Involvement of the chondrosternal, manubriosternal, sternoclavicular, and xiphisternal articulations is less frequent. Lesions are unilateral and single in more than 80% of patients (94). The disorder usually runs a self-limited course of remissions and exacerbations (90,91,94,95 and 96). The pain can cease spontaneously within 2 to 3 weeks, but not infrequently it lasts months, and the residual swelling can persist for much longer, even several years (92).

The predominant symptom of Tietze's syndrome is pain of variable intensity in the anterior chest wall. It is usually localized to the involved synchondrosis but can radiate widely over the anterior chest wall, occasionally to the shoulder and neck. In some patients the pain is similar to that produced by a heavy weight pressing on the chest, reminiscent of cardiac or esophageal pathology, but in others it is a vague soreness or tightness. Coughing, deep breathing, and lying prone typically aggravate the pain. Tenderness and swelling are present in the affected costal cartilage(s), but the overlying skin shows no alteration and moves freely over the tender bulbous or fusiform swelling. Heat, erythema, and constitutional symptoms are absent.

Careful history and thorough examination of the chest and exclusion of other conditions affecting the costal cartilages, such as rheumatoid arthritis, pyogenic arthritis, tumors, and relapsing polychondritis, make the diagnosis (97). Although plain radiographs are normal, x-ray tomography may be a useful confirmatory examination (98,99). Bone scan may show abnormal accumulation of radionuclide at the involved costochondral joint, but is nonspecific, as this is also found in costochondritis (93). Laboratory tests may exclude other conditions but are not helpful in diagnosing this syndrome.

Costochondritis (Anterior Chest Wall Syndrome). Costochondritis, also called *anterior chest wall syndrome*, *chest wall syndrome*, *costosternal syndrome*, and *costosternal chondrodynia* (100,102,103 and 104), is a relatively frequent cause of anterior chest pain, both as a primary condition and in combination with coronary artery disease. It simulates cardiac pain and thus is a great source of confusion and concern among clinicians; its etiology is unknown.

Pain of the anterior chest wall that often radiates widely, sometimes into the back and abdomen, is the primary characteristic of costochondritis. Palpation of the affected portions of the thoracic cage elicits local tenderness at multiple sites and also reproduces radiation of the pain. In contrast to Tietze's syndrome, in which only one level is involved in 80% of patients, multiple sites are present in 90% of patients with costochondritis. The second to fifth costal cartilages are most frequently affected (94,100). Usually, the pain and tenderness are located more easily than with Tietze's syndrome and, in contrast to Tietze's syndrome, no local swelling is present. The condition occurs more frequently in women (a ratio of 3:1) and at a later age in life (two-thirds of patients are over the age of 40). Respiratory symptoms occur only in approximately 12% of patients with costochondritis, as compared with approximately 85% of those with Tietze's syndrome. Movement of the chest and body can frequently aggravate the pain (Table 64-10).

Feature	Tietze's syndrome	Costochondritis
Frequency	Rare	More common
Age group most commonly affected	<40 yr	≥40 yr
Number of sites affected	One in 80%	More than one in 90%
Costochondral junctions most commonly involved	Second (occasionally third)	Second to fifth
Local swelling	Present	Absent
Associated conditions	Respiratory tract infections	Cervical strain syndrome, coronary artery disease, myofascial syndrome

Modified from Fam AG, Smythe HA. Musculoskeletal chest wall pain. CMAJ 1980;122:379–88.

TABLE 64-10. Tietze's syndrome and costochondritis

Inflammation of the upper costal cartilages can cause intense chest pain that clinicians often mistake for that of cardiac disease, initiating referral to a cardiologist (100,104). When the condition involves the lower costal cartilages, the pain is in the upper abdomen, which may prompt referral to a gastroenterologist (105).

This condition is important in causing chest or abdominal pain in adolescents. In a study of 100 patients in an adolescent outpatient clinic who complained of chest or upper abdominal pain, 79 had only tender costal cartilages. In this group the pain usually was located in the anterior chest, but in a number of patients, it radiated to the back and abdomen. The condition was more often unilateral than bilateral, affecting the left side more often than the right side, the left fourth sternocostal cartilage being most frequently involved. A simple program of mild analgesics and reassurance was sufficient treatment for all patients (106).

Comprehensive history and physical examination, including complete neurologic and musculoskeletal evaluation, are essential in making the diagnosis of costochondritis, because this syndrome can mimic more serious conditions in the chest and abdomen. Several maneuvers reproduce pain similar in quality and location to the spontaneous pain and are useful in establishing the diagnosis of anterior chest wall syndrome (105). Firm, steady pressure applied to the sternum and to the left and right parasternal junctions, the intercostal spaces, the ribs, the inframammary area, and the entire pectoralis major muscle elicits the pain of costochondritis. The *horizontal flexion test* consists of having the arm flexed across the anterior chest and applying steady prolonged traction in a horizontal direction, while at the same time the patient's head is rotated as far as possible toward the ipsilateral shoulder. The *crowing rooster maneuver* involves having the patient extend the neck as much as possible by looking toward the ceiling while the clinician, standing behind the patient, exerts traction on the posteriorly extended arms (105). Epstein and coworkers used radionuclide cineangiography performed at rest and during symptom-limited exercise to visualize regional wall motion abnormalities in the heart. Eleven of the 12 patients studied experienced pain at rest, and eight had episodes of pain that awakened them from sleep. One patient with isolated chest wall syndrome described what was considered to be classic angina pectoris. All patients had chest wall tenderness, the location of which is shown in Figure 64-8. The most common site of tenderness was the left parasternal region, followed by the inframammary region, the left pectoral muscles, including their insertions, and the sternum. Of the 12 patients, 11 had a positive horizontal flexion test and four had a positive crowing rooster test. All patients with the chest wall syndrome had a normal ejection fraction and normal regional wall motion at rest and during exercise. The investigators concluded that the radionuclide cineangiographic test, which is invariably positive in patients with coronary artery disease, is a sensitive method for differentiating between anterior chest wall syndrome and cardiac pathology (105).

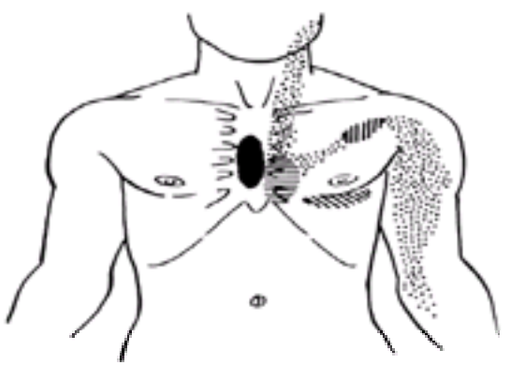

Figure 64-8. Pattern of pain in patients with anterior chest wall syndrome showing the regions in the anterior chest in which spontaneous pain was most frequently experienced and where tenderness could be elicited. The black and striped areas represent primary sites of pain and of tenderness and the stippled areas represent radiation of the pain. (Modified from Epstein SE, Gerber LH, Borer IS. Chest wall syndrome: a common cause of unexplained cardiac pain. *JAMA* 1979;241:2793–2797.)

In patients who have the chest wall syndrome in association with organic heart disease, the characteristics of the pain and tenderness also help in differentiating between the two conditions (see Fig. 64-8). In most patients with anterior chest wall syndrome, the pain is localized mainly in the precordium or the left parasternal region, usually at the level of the left third or fourth intercostal space, and often radiating superiorly toward the left shoulder and down the left arm, characteristics that differ from the more generalized pain of myocardial ischemia. Moreover, the pain usually occurs at rest and lasts for many minutes to hours, which also distinguishes it from pain of cardiac origin. In the relatively small percentage of patients in whom the pain is indistinguishable from that of typical angina pectoris caused by coronary disease, careful questioning often discloses that the pain has atypical precipitating features more closely related to postural changes and to stresses imposed on chest wall structures than to physical exertion *per se*. Although the prompt pain-relieving effect of nitroglycerin is usually considered good evidence that the pain is a result of myocardial ischemia, some patients with chest wall pain and no evidence of any organic heart disease have reported relief after taking sublingual nitrate.

The most critical finding establishing the diagnosis of chest wall syndrome is the detection of chest wall tenderness on physical examination, which is present in all patients. Tenderness located in the region of origin of spontaneous pain, particularly when the quality of the pain evoked by the physician reproduces the spontaneous pain, together with a negative radionuclide test, provides the strongest evidence of chest wall syndrome.

A highly reliable and effective differential diagnostic procedure in such patients is producing intercostal block at the posterior axillary line. This provides complete relief of pain from chest wall pathology, but has little or no effect on cardiac pain because the nociceptive pathways from the heart are in the sympathetic afferents located in the paravertebral region. Bone scintigraphy helps delineate the extent and location of costochondral lesions (107).

Treatment of costochondritis, or chest wall syndrome, consists of reassurance, the use of nonsteroidal antiinflammatory drugs (NSAIDs), alone or in combination with an opioid as needed, heat application, and other physical therapeutic measures. Reassurance that the pain is of benign origin is probably the most important intervention, thus avoiding the emotional and financial burdens often associated with an erroneous diagnosis of organic heart disease. Admission to coronary care units is common, and patients may exhibit chronic anxiety, largely because they believe the chest pain of costochondritis, particularly when it radiates into the anterior chest or even down the left arm, is a harbinger of imminent death (105). Reassurance that the pain is from a non– life-threatening condition can often lead to dramatic symptomatic improvement and rehabilitation. Intercostal block at the posterior costal margin provides complete pain relief for several hours; the procedure demonstrates to patients that the condition is in the chest wall and not from the heart (see Table 64-10).

Tumors of the Costal Cartilages. Cartilaginous tumors of the ribs are rare, usually noticed because of a growing mass rather than the onset of an obscure chest pain. Conditions such as tuberculosis, fungal abscess, gumma, malunited fractures, deformities, and Tietze's syndrome are part of the differential diagnosis. When a tumor mass is felt, diagnosis is easy. Pain can be a heavy, chronic, boring distress but may also be pleuritic in nature, referred along the course of the intercostal nerve. Surgical excision is the primary treatment.

Costochondral Dislocation. Dislocation at the costochondral junction, secondary to trauma, causes pain at the site of injury. The condition, frequently seen in people younger than 30 years of age, typically produces a continuous, dull, aching, and burning pain, with discomfort localized to an area of the costal margin and occasionally referred to the back. Sometimes the pain exhibits the sharp and lancinating character of radicular pathology. Local tenderness invariably is present, and palpation may reveal a mass probably due to accumulation of excess cartilaginous material at the site of injury. In some cases, the pain is more disabling than that associated with simple rib fracture.

Treatment consists of reduction of the dislocation with subsequent pain relief. Infiltration of the area with local anesthetic or, more effective, intercostal nerve block above and below the site of dislocation permits manipulation and reduction; the injection site may be at the anterior axillary or midclavicular line.

Chest Pain Caused by Pathology of the Sternum and Its Articulation

Trauma and Arthritis of the Sternoclavicular Joint. Pain arising from the sternoclavicular joint can radiate to the anterior chest wall simulating pain of visceral origin. The major causes of sternoclavicular joint arthritis include osteoarthritis, rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, and infection (74,108,109). Infectious etiologies are diverse (108,110,111) and have been reported after subclavian vein catheterization (112) and in intravenous drug users (113). Traumatic subluxation or dislocation, as well as tumor metastases, also can cause pain in the sternoclavicular joint. Shrugging of the shoulders aggravates the pain, and

palpation of the joint elicits severe tenderness. Treatment consists of NSAIDs with or without an opioid. Infectious cases require antibiotic therapy, while noninfectious cases may respond well to local injection with anesthetic and corticosteroid.

Sternocostoclavicular Hyperostosis. Sternocostoclavicular hyperostosis (or sternoclavicular hyperostosis) is a peculiar syndrome manifested by bilateral chronic painful swelling of the clavicles, sternum, and first ribs, with associated aseptic joint destruction and arthritis. The condition frequently occurs in association with palmoplantar pustulosis, a seronegative arthrosteitis (114,115,116 and 117). Abnormalities on plain radiograph may take years to evolve despite the frequent occurrences of clinical symptoms (118). However, bone scintigraphy and computerized tomography are sensitive in the early stages of the syndrome (119,120 and 121). Previously thought to be a specific disorder of the sternoclavicular joint, studies using computed tomography suggest that the sternoclavicular joint is not primarily involved; hyperostosis develops around the costal cartilage including periosteum, perichondrium, and ligamentous structures with sparing of the sternoclavicular joint space (119). Laboratory values are usually normal except for occasional persistent elevation of erythrocyte sedimentation rate. Rarely, the syndrome involves the cervical spine and may manifest as a swelling in the neck (122,123).

Sternocostoclavicular hyperostosis follows a relapsing course; bone enlargement and extension of the inflammatory process can lead to occlusion of the subclavian vein or can cause thoracic outlet syndrome (116). Treatment is symptomatic, consisting of antiinflammatory medications, including NSAIDs and corticosteroids. In severe cases, radiotherapy may be beneficial (101).

Manubriosternal Arthritis. Arthritis of the manubriosternal joint can cause localized pain in the upper sternal region. The condition occurs in association with rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, gout, and palmoplantar pustulosis (124,125,126,127,128,129 and 130). Trauma from sports injury (131) or even due to seizures (132) can predispose to arthritis in this joint. Infectious causes are rare (133,134) but intravenous drug use, as with other septic arthritides, appears to be a risk factor (135). The pain may localize to the joint or it may radiate widely along the upper ribs to the shoulders, mimicking anginal pain. Pain may be constant or intermittent (92). Motion of the chest, including deep breathing, coughing, sneezing, and yawning, aggravate the discomfort.

Diagnosis should include identification of the pathologic process. Imaging studies of the chest may be helpful (136). Treatment consists of NSAIDs, and the pain control may require opioid analgesics. In noninfectious cases, infiltration with local anesthetic and corticosteroids may provide prolonged relief.

Trauma to the Sternum. Blunt injury to the sternum can cause strain or even partial subluxation of the manubriosternal joint. At the time of or soon after injury, the patient experiences sharp pain localized to the area of the angle of Louis. Pain can also radiate into a broader area. Conservative management of simple joint sprain with systemic analgesics and the application of heat usually suffices. If the patient has severe pain, local infiltration of the joint with local anesthetic and corticosteroid produces effective relief. Occasionally, the displacement is sufficient to require surgical intervention in which case neural blockade of the intercostal nerves (at the level of the second and third ribs in the midclavicular line) provides excellent postoperative analgesia.

Xiphoidalgia Syndrome. Spontaneous pain in the anterior chest associated with discomfort and tenderness of the xiphoid process defines the xiphoidalgia syndrome. This relatively rare condition also goes by the names *painful xiphoid syndrome*, *hypersensitive xiphoid*, and *xiphoid cartilage syndrome*. Little is known about the etiology and pathophysiology of this ailment, but it sometimes occurs concomitantly with coronary artery disease, intestinal disease, arthritis, and neurologic or metabolic disorders, making diagnosis somewhat confusing when it occurs independently (92). The xiphoid receives its nerve supply from the phrenic nerves and the T-4 to T-7 intercostal nerves, so that pain is usually widespread. Typical pain is intermittent, low substernal or epigastric radiating into the precordium or abdomen, often making it difficult to distinguish from serious visceral pathology by history. However, examination reveals tenderness at the xiphoid, and palpation duplicates the pain and its radiation. Lipkin and colleagues described the pain as “a deep slightly nauseating ache, somewhat like that experienced after a blow to the celiac plexus” (137). The intensity varies considerably from an annoying, slight, aching discomfort to an agonizing pain that can be terribly frightening (92).

Movements that act on the xiphoid, such as bending, stooping, and turning, precipitate or aggravate the pain of xiphoidalgia, particularly after a full meal, which itself increases the pressure behind the xiphoid (92). Usually, exercise does not aggravate the pain, but careful questioning may be necessary to determine whether a particular movement rather than general exertion brings on the pain. Unlike many other types of chest pains, the discomfort of xiphoidalgia does not subside immediately after an aggravating movement has ceased. The frequency of pain is variable but can occur several times a day. Its duration varies from minutes to several hours, but it usually lasts for an appreciable time after it is provoked. In addition to reproducing the spontaneous pain and its radiation, externally applied pressure can cause patients to feel pain deep in the chest (retrosternal), shoulder, and back.

The disorder ordinarily persists for weeks or months, but usually disappears spontaneously without special treatment. Nonopioid systemic analgesics, with or without the addition of an appropriate opioid, control mild to moderate pain. If these prove ineffective in patients with severe pain, injection of a local anesthetic and a corticosteroid into the xiphosternal joint usually provides effective relief for hours and sometimes days. In extreme cases one could consider surgical resection, but this rarely is necessary.

Chest Pain Caused by Myofascial Pain Syndromes

Myofascial pain syndromes are discussed in Chapter 29. Myofascial pains in the chest usually develop gradually, but the occasional sudden onset may cause patients and physicians to mistake the symptoms for those of cardiac ischemia. Trauma or repetitive use of a muscle can result in a myofascial pain syndrome, which can vary from a slight ache to severe, unrelenting, and disabling discomfort. It is critical to identify myofascial pain syndromes in the patient with chest pain to avoid the emotional and financial costs of cardiac evaluation. Table 64-11) lists the various myofascial pain syndromes of the chest. Figure 64-9,Figure 64-10,Figure 64-11,Figure 64-12,Figure 64-13,Figure 64-14 and Figure 64-15 illustrate pain patterns and trigger points for various myofascial pain syndromes in the chest.

Location of pain	Muscle involved
Anterior chest	Sternalis; pectoralis major; pectoralis minor; scaleni muscle; sternocleidomastoid (sternal head); subclavius; iliocostalis cervicis
Upper thoracic back	Levator scapulae; trapezius multifidi
Midthoracic back	Latissimus dorsi; rhomboid; serratus posterior superior; trapezius serratus anterior
Low thoracic back	Serratus posterior inferior; iliocostalis thoracis multifidi

TABLE 64-11. Myofascial syndromes causing chest pain

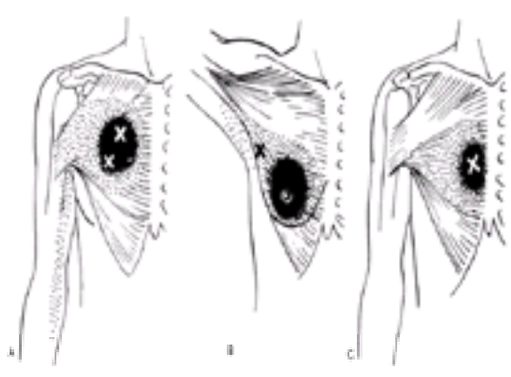

Figure 64-9. Patterns of pain provoked by trigger points in different parts of the right pectoralis major muscle. **A:** Pattern provoked by trigger points (*X*) in the intermediate sternal section of the muscle. **B:** Pain and trigger points in the lateral margin of the muscle. **C:** Trigger point (*X*) in the medial margin of the muscle. The

black area depicts the essential zone of pain, while the stippled area shows the spillover zone.

Other Painful Muscular Disorders

Traumatic Muscle Strain. Trauma to muscles of the chest can cause injury to fibers throughout the entire muscle. Repeated stress or excessive muscular activity, such as lifting, painting a ceiling, chopping wood, coughing, or exercising untrained muscles may result in traumatic strain. These are the same causative factors that produce myofascial syndromes with trigger points; in some patients, however, widespread *strained* muscles may be painful and tender over their entirety. Maneuvers that tense or stretch the muscle usually make the pain worse. Careful examination of the muscle does not reveal any localized tender or trigger points but indicates generalized tenderness over the entire muscle. Treatment consists of reassurance, local application of heat or ice, use of systemic analgesics, rest of the injured muscles, and avoidance of the precipitating activities. In patients who have severe pain, infiltration of a dilute solution of a long-acting local anesthetic (e.g., 0.125% bupivacaine) throughout the muscle produces prompt pain relief.

Precordial Catch Syndrome. The precordial catch syndrome is an unusual, benign, self-limited condition that does not radiate and is characterized by sudden, brief, periapical pain. Pain occurs randomly, without warning or obvious precipitant. Onset of the syndrome usually is in adolescence or childhood in otherwise healthy individuals. The pain can occur at rest or during mild activity but does not occur on exertion (138,139,140 and 141).

The sharp stabbing pains known as *catches* or *stitches* typically are in the anterior chest wall, usually in the left parasternal area or near the cardiac apex. Duration is from 30 seconds to 3 minutes. Some patients report the onset of pain while slouching or bending over. Deep breathing aggravates the pain, and shallow breathing provides relief. Moderate activity and correct posture may also relieve the catch. No local tenderness is associated, such as that with most other chest wall pain syndromes.

The cause is unknown. Treatment consists of reassurance. The unpredictability, short duration, and benign nature of precordial catch syndrome make analgesics unnecessary and ineffective.

Chest Pain Caused by Diseases of the Mediastinum

In addition to the tumors discussed previously in this chapter, two other mediastinal disorders deserve mention, mediastinal emphysema and mediastinitis.

Mediastinal Emphysema

Air within the planes of the mediastinum can appear spontaneously or can be secondary to chest trauma; perforation of the esophagus, trachea, or bronchus; or spread from fascial planes of the nasopharynx or dissection from the retroperitoneal space. Spontaneous mediastinal emphysema or spontaneous pneumomediastinum occurs with no apparent cause. Air probably dissects from the alveoli to the interstitial space into the vascular adventitia and into the hilum, from where it moves into the mediastinum, neck, or retroperitoneal space.

If the volume of air reaching the mediastinum is small, the resulting pain can be severe while other physiologic disturbances might be minimal. Occasionally, the condition is self-limited, with spontaneous recovery. When great volumes of air accumulate, as in what Wehrmacher (92) called “malignant mediastinal emphysema,” profound physiologic disturbances result. Compression of the great veins to the heart causes circulatory shock, impaired gas exchange across the alveoli, and cardiovascular collapse that can progress to death if there is not prompt intervention to relieve increased mediastinal pressure.

Spontaneous pneumothorax produces rather sudden onset of pain in the absence of effort while the patient is quietly standing, sitting, or lying. The pain usually begins beneath the sternum and sometimes radiates to the back, neck, or shoulders, but rarely to the arms. Physical examination can reveal subcutaneous crepitus in the upper body, and one can often hear a crunching sound over the precordium synchronous with the heartbeat (Hamman's sign). Fever and mild leukocytosis are common with uncomplicated mediastinal emphysema.

A radiograph of the chest in a patient with spontaneous mediastinal emphysema demonstrates air in the mediastinum and usually a small pneumothorax. It is much more difficult to demonstrate mediastinal air than pneumothorax; identification usually is easiest along the pleural line parallel to the left heart border on films made during full expiration (92).

Therapy for the benign type of mediastinal emphysema is purely symptomatic, but for malignant emphysema, surgical drainage of the mediastinum is essential to release the entrapped air. Oxygen therapy might be necessary to relieve dyspnea and cyanosis. Systemic analgesics or thoracic epidural and sedatives control the pain; appropriate monitoring of the patient is essential to detect any adverse side effects.

Mediastinitis

Acute mediastinitis occurs as an extension from a mediastinal lymphadenitis secondary to pulmonary or pleural infections, from inflamed neighboring structures, such as sternotomy incision, or from rupture of the esophagus or trachea. The infection can be nonsuppurative, phlegmonous, or suppurative, and an abscess can result. Wehrmacher described a rather peculiar chronic cicatrizing mediastinitis of uncertain origin that manifests extensive fibrosis with retraction and displacement of various mediastinal structures (92).

The usual symptoms of acute mediastinitis are those referable to the underlying infection. Rupture of the esophagus usually produces severe, excruciating, retrosternal pain simulating that of acute myocardial infarction. Esophageal perforation is a surgical emergency. Esophageal diseases are discussed in Chapter 63.

Systemic manifestations often overshadow other causes of mediastinitis. Treatment varies according to the cause of mediastinitis but invariably requires antibacterial therapy. Pain management is contingent on the severity of the pain, usually requiring systemic opioids.

Chest Pain Caused by Disorders of the Diaphragm

The diaphragm can be the site of inflammatory diseases, tumors, hemorrhage, edema, and degeneration. Previous chapters have discussed the various causes of pleuritis involving the diaphragmatic pleura, including viral infection (pleurodynia) and other infectious processes involving the thoracic viscera, diaphragmatic hernia, and many causes of diaphragmatic peritonitis. Here, the discussion focuses on three conditions: acute primary diaphragmatitis, sustained diaphragmatic spasm, and diaphragmatic flutter.

Acute Primary Diaphragmatitis

Acute primary diaphragmatitis, also known as *Heddron's syndrome*, is manifested by moderate to severe pain in the lower chest, upper abdomen, and shoulder. The

cause of this condition is unknown, but some (92) have suggested that it can follow chilling or acute nasopharyngeal infection and is attributed to a primary myositis of the diaphragm, bearing no relationship to lesions of the pleura, lungs, or subphrenic organs.

Clinically, the pain limits the respiratory effort beyond a fixed depth, invariably with spasm of the abdominal muscle below the costal margin, associated with pain in the upper quadrants but no deep tenderness. The costal margins flare and remain relatively immobile; fluoroscopy shows the diaphragm to be immobilized in midposition during the acute phase. As the myositis subsides and fibrous tissue replaces the muscles, flattening of the diaphragm persists. Symptoms usually subside within 1 or 2 weeks, but can recur during inclement weather (92). Treatment of this condition is symptomatic and should include encouragement, reassurance, and effective pain control with systemic analgesics.

Sustained Spasm of the Diaphragm

Rare cases of persistent contraction of the diaphragm can cause chest pain (92). In each instance, a characteristic disorder of diaphragmatic function is demonstrable by fluoroscopic observation: Inspiration becomes jerky, and the excursion of the diaphragm during inspiration is extended, so that during expiration the structure assumes a progressively lower position. When the state of contracture of the diaphragm is such that adequate respiratory excursions are no longer possible, dyspnea occurs, with the feeling of inability to take a breath. During attacks of sustained diaphragmatic contractions, patients experience pain in the pericardium or elsewhere in the chest, with radiation to the shoulder. In some cases, pallor, sweating, hypotension, and angor animi, simulating that of acute myocardial infarction, accompany the attacks. In others, diaphragmatic spasm causes occlusion of the esophagus, with consequent dysphagia and odynophagia.

Such patients require a thorough workup to exclude severe thoracic visceral disorders. Because emotional conflicts may provoke attacks, psychological management is especially important. If patients have severe dyspnea, supplementary oxygen is helpful. Pain control is with systemic analgesics. In patients who have severe contraction, unilateral or bilateral phrenic nerve blocks might be necessary to relieve the spasm.

Diaphragmatic Flutter

Diaphragmatic flutter is a rare but disturbing cause of chest pain that usually escapes recognition for a long time. The cause of the condition is frequently unknown, but some have reported it to be precipitated by excitement, emotional tension, severe cough, pressure on the upper abdomen, exercise, and sneezing. Deep inspiration, swallowing, or supraclavicular pressure sometimes can suppress symptoms, as can a period of natural sleep (92).

Diaphragmatic flutter causes pain in the chest, shortness of breath, and palpitations. The pain occurs along the diaphragmatic attachment, in the epigastrium, and over the precordium, and radiates into the neck, shoulder, and down the arm. Clocklike sounds and plethysmographic oscillation at the base of the lung as visualized by fluoroscopy demonstrate the rapid movement of the diaphragm.

Management should be conservative for patients in whom the condition does not cause significant emotional or physiologic disturbances. In those in whom the condition persists, or does cause severe emotional and physiologic disturbances, injection of 5 to 10 mL of local anesthetic on the anterior surface of the scalenus anticus establishes a phrenic nerve block. Unilateral block may be sufficient, but occasionally bilateral block is indicated. If effective, and if the patient has no respiratory difficulties, one should consider a continuous infusion block.

Chest Pain of Tegumentary Origin

Table 64-7 lists a number of skin disorders that can cause chest pain, including burns and scars. This section describes three rather unusual conditions that one should consider in the differential diagnosis of chest pain.

Idiopathic Chronic Mastalgia

Chronic severe pain in the entire breast that persists for years without a demonstrable cause characterizes idiopathic mastalgia. Onset is typically in the third or early fourth decade of life. Although many clinicians believe the condition has a psychological basis, clinical reports reveal no emotional or psychological abnormality (142,143). Pain can be unilateral or bilateral and is usually cyclical, but upward of 25% of women experience noncyclic pain (144,145 and 146). Approximately 85% of women respond to adequate reassurance, but 10% to 20% of patients require medical therapy (147). A hormonal event such as menopause, pregnancy, or use of oral contraceptives often provides relief (146). Treatment with danazol appears to be the most effective therapy, followed by bromocriptine, tamoxifen, and evening primrose oil (145,148,149 and 150). Cyclical mastalgia responds better to drug treatment than does the noncyclic variety (147,148,151).

Adiposis Dolorosa (Dercum's Disease)

In 1892 Dercum described a syndrome characterized by painful subcutaneous fatty tumors in various parts of the body, especially the lower extremities (152). If present in the breast, adiposis dolorosa can cause long-term pain. No truly satisfactory treatment exists for this condition, but reports suggest that intravenous lidocaine, oral mexiletine, and liposuction may offer relief (153,154 and 155).

Mondor's Disease

Mondor's disease is a form of phlebitis of the anterior lateral chest usually due to thrombosis of the superficial vein of the thoracic wall, primarily affecting middle-aged women with pendulous breasts (92,156,157 and 158). Intravenous drug use is another risk factor (159). Typically there is a palpable painful cord within the skin. Many practicing physicians are unaware of this condition, leading to considerable patient anxiety, especially when it involves the breast (160).

The initial inflammatory phase consists of the rather sudden appearance of a painful, tender, subcutaneous cord running somewhat obliquely across the thorax in the distribution of one or more of the superficial subcutaneous veins. The cord can be linear or Y-shaped, corresponding to the linear or branching course of the affected vein. During the inflammatory phase the lesion can grow as if a worm were crawling beneath the skin (92). After the initial inflammatory phase, usually lasting several weeks, an indolent phase follows with little or no discomfort, and only the palpable cord, extending like a catheter beneath the skin, remains as evidence of the disorder.

Laboratory studies are of little value, although the eosinophils in the peripheral blood might be slightly increased. Biopsy usually reveals a white indurated cord that macroscopically appears as a small caliber vessel.

The most important feature in the management of this disorder is its recognition so that the patient can be spared unnecessary anxiety and apprehension. The disease is self-limited and requires nothing more than symptomatic relief of the pain with systemic analgesics, including NSAIDs (161).

Referred Chest Pain from Extrathoracic Disorders

Many diseases or lesions outside the thoracic cavity can refer pain to the chest. Included are disorders of the neck, cervical disk syndromes, thoracic outlet syndrome, and disorders of the abdominal viscera. These conditions are discussed in greater detail in Chapter 54, Chapter 55, Chapter 56 and Chapter 57 and Chapter 65, Chapter 66, Chapter 67, Chapter 68 and Chapter 69; brief comments relevant to the chest follow here.

Cervical Disk Disease

Herniation of intervertebral disks in the lower part of the cervical spine can cause pain in the anterior upper part of the chest. Cervical roots C-5 to C-7 form the lateral and C-8 to T-1 form the medial pectoral nerves that supply the pectoral muscles and fascia. Posterolateral herniation of a cervical intervertebral disk causes anterior chest pain that is deep, aching, steady, and, at times, severe. The pectoral muscles can be tender when they are the seat of the referred pain and there is almost always referred pain in the shoulder and upper limb. Coughing, sneezing, straining, and lateral flexion to the affected side aggravate the pain (see Chapter 56).

Thoracic Outlet Syndrome

In addition to neurovascular conditions in the upper extremity, thoracic outlet syndromes can refer pain to the chest. Careful history and physical examination allow the diagnosis to be made (see Chapter 55).

Disorders of the Abdominal Viscera

Gas entrapment syndromes, biliary tract disease, pancreatitis, peptic ulcer disease, tumors of the gastric cardia, subphrenic abscess, hepatic abscess, enlarged spleen, and a variety of other disorders of abdominal visceral can give rise to pain in the chest. These are discussed in Chapter 65, Chapter 66, Chapter 67, Chapter 68 and Chapter 69.

Chest Pain and Psychological Factors

The heart deceives, because it is never anything but the

expression of the mind's miscalculations.

. . .

I don't know what the heart is, not I:

I only use the word to denote the mind's frailties.

Marquis de Sade (1740–1814)

The affective dimension of chest pain is enormously complex; the symbol of the heart and its representation in culture and art truly place it at the core of human emotions. The stark connection between the health of the pump inside the thorax and life or death amplifies reactions to chest pain and creates a whole genre of disease and disability. It is well beyond the scope of this chapter to explore the psychological factors associated with chest pain in great detail. Instead, the following brief discussion addresses generally the emotional reactions to organic chest pain and describes the most common psychological contributors to nonorganic chest pain.

Emotional Reactions to Organic Chest Pain

Patients with sudden acute chest pain, regardless of the cause, experience varying degrees of anxiety, apprehension, and fear, depending on their interpretation of the cause of pain. Those who believe that they are experiencing a heart attack become extremely frightened of possible impending death. Many patients who have acute myocardial infarction pass through reactions of denial, anxiety, depression, and, finally, acceptance (162). In acute myocardial infarction patients, anxiety and apprehension provoke a marked increase in general neural sympathetic tone and produce an increase in the neuroendocrine response to stress that can aggravate the existing pathophysiology and prove deleterious to the patient. It is therefore essential to relieve the pain and also the associated anxiety and apprehension promptly to minimize or prevent these serious psychophysiologic responses.

Patients with persistent angina pectoris frequently develop reactive depression as a consequence of the limitation imposed by the illness, which is seen as a threat affecting the patient's lifestyle, self-image, status, family relationships, and security (162). The depression frequently aggravates the physical disability and, if it remains untreated, it sets up a vicious circle that produces progressive physical and psychological deterioration. Reactive depression is an even greater problem in patients with chronic cancer- related chest pain, not only because of the significance of the pain but also because of the progressive physical and psychological deterioration that these patients undergo.

Chest pain caused by nonmalignant musculoskeletal or neuropathic disorders provokes a great deal of anxiety and apprehension until patients have been reassured about the *benign* nature of the painful condition. In most patients, reassurance about the nonthreatening nature of the pain decreases or eliminates the depression. Some patients, however, in whom pain persists because its cause remains unknown or because the pain remains unrelieved, are also likely to develop reactive depression if the pain is intense enough to affect work and lifestyle.

In addition to assessing the patient to diagnose the primary cause, it is also important to assess the emotional reactions to, and psychological impact on, the patient's pain and pathologic process. Comprehensive treatment aims at both the pain and the emotional reactions to it.

Chest Pain Primarily Resulting from Psychological Mechanisms

Precise epidemiologic data are absent, but chest pain with no evidence of physical pathology often results from psychological mechanisms. The most common causes are anxiety disorders, affective disorders, operant mechanisms, psychophysiologic factors, and somatoform disorders.

The assessment of psychological factors is not easy when a patient first presents at the physician's office or in the emergency room. The diagnosis of chest pain primarily of psychological origin demands systematic exclusion of organic pathology and positive findings for positive psychological factors. Because of the potential seriousness of a physical cause of the chest pain, a complete and thorough history, physical examination, and full investigative procedures are essential prerequisites to the diagnosis. When pain primarily of psychological origin is suspected, the examiner should proceed in a reassuring way to avoid undue concern in the patient.

Billings (162) suggested the following as indications that the patient's complaints are primarily of psychological origin:

- The pain is usually located in the precordial region at the apex of the heart and is rarely central (Fig. 64-16).

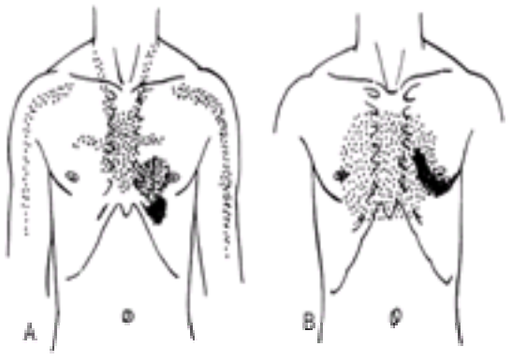

Figure 64-16. Patterns of pain provoked by psychological factors. **A:** Pattern of pains in a patient who has true angina (*light stipple*) coexisting with psychological pain usually felt at the cardiac apex or over the area where the patient thinks the heart lies (*heavy stipple*). **B:** Pattern of pain in acute anxiety felt diffusely throughout the chest or precordially. In patients with conversion pain, it is usually also felt precordially at the cardiac apex or along an operative scar if one is present.

- Description of the pain is atypical and stated in dramatic terms, such as “tearing pain through the chest wall” or “stabbing pain like a knife cutting through the heart.” Thus, it does not fit an organic syndrome nor does it follow a physiologic pattern.
- The distribution is not anatomically explicable and the development of the pain involves events that are not physiologically related.
- Often, more than one system is involved or several different pain patterns are noted on different occasions.
- *Psychogenic* pain does not awaken patients from sleep but can be present on awakening or soon thereafter.

- In most patients, an emotional precipitant usually precedes the development of acute pain, and patients manifest symptoms and signs of anxiety, depression, or other neurotic patterns.
- In contrast with pain of organic origin, which responds consistently to appropriate analgesics or other forms of therapy, pain primarily of psychological origin is more likely to show a variable response on different occasions.

Practitioners should tailor treatment of patients who have acute or persistent chest pain primarily of psychological origin according to the primary psychological disorder involved. In patients with an acute anxiety attack, reassurance, relaxation techniques, anxiolytic drugs, sedatives, tranquilizers, and time reduce anxiety. In patients with chronic anxiety, winning and retaining their confidence and providing reassurance are the most important therapeutic measures. In addition to obtaining a detailed history and physical examination, it is important to demonstrate a complete understanding of, and an interest in, patients' symptoms. Reassurance should not stop with the exclusion of organic heart disease but should include an emphasis on a good prognosis for life expectancy and a low incidence of disability. The practitioner should identify precipitating factors and deal with them in terms of patients' lifestyle, attitudes, and emotional reactions.

Acute Anxiety Attack. An acute anxiety attack usually begins as a sudden unexpected sense of terror, a feeling of apprehension, which increases in severity, leads to dyspnea, and is associated with a sense of choking or smothering, palpitations, and chest pains that are often so severe patients believe they are having a heart attack or dying. Dyspnea, or a feeling of air hunger, can produce the hyperventilation syndrome, characterized by a marked increase in ventilation producing severe respiratory alkalosis that leads to marked cerebral vasoconstriction and decreased blood flow. As a result of these changes, patients experience tachycardia, sweating, tremor, dizziness, and increased muscle tension, which can be accompanied by a diffuse chest tightness and paresthesia, a feeling of tingling in the hands, feet, face, or throat, feelings that cause patients to conclude that their initial fears are substantiated and they are suffering from a fatal heart attack (162).

The chest pain associated with an acute anxiety attack can occur even without hyperventilation and is described by patients as a severe, sharp, precordial pain or pain in the left inframammary region (see Fig. 64-16). The pain can be diffuse in the chest but is rarely retrosternal. The pain does not occur during physical effort but can develop after the effort has ceased. After the acute pain subsides, patients may have a dull ache or mild pain that persists. Chest pain may become the focus of concern and the complaint that initiates a trip to the physician or emergency room.

An acute anxiety attack usually lasts for a few minutes, rarely for more than 30 minutes. Following the attack, people can feel fatigued and exhausted. As the attacks recur, some of the symptoms mentioned previously become the focus of the patient's attention. Frequently, this focus comprises the sensation of palpitations, dyspnea, and chest pain, which can become recurrent complaints.

Chest pain caused by an acute anxiety attack is clinically important. Hurst, a world authority on heart disease, once stated that “The most common cause of chest pain is not related to cardiovascular disease, but is associated with anxiety” (163). Moreover, because elevated plasma catecholamine levels often accompany acute anxiety, it is a common precipitant of angina. Indeed, in patients who have some degree of coronary artery disease, myocardial infarction can occur during periods of sustained anxiety (162). Early diagnosis and treatment of the anxiety attack are critically important and crucial in the prevention of chronicity.

Chronic Anxiety State. In patients with chronic anxiety, chest pain and various other symptoms and signs are present in a common pattern that has been called the syndrome of *cardiac neurosis*, in which cardiovascular, respiratory, and nervous symptoms are prominent features in the absence of an explanatory diagnosis. This syndrome has been known for more than a century; in 1871 Da Costa referred to it as *irritable heart syndrome* (164). Since then, this condition has undergone many name changes, including *soldier's heart* (165), *Da Costa's syndrome* (166), *effort syndrome* (167), *neurocirculatory asthenia* (168), and *vasoregulatory asthenia* (169).

Patients with this syndrome complain of a moderate to severe shortness of breath, usually described as an inability to fill the lungs, palpitations, chest pain, nervousness, anxiety, fatigue, generalized weakness, and low energy level. Among the most important precipitating or aggravating factors are emotion-provoking situations, illness, hard physical labor, pregnancy, and military service (162). Billings (162) theorized that this syndrome tends to develop in patients who have problems relating to dependency needs and who are attempting to function in a situation that is taxing their coping ability. Anxiety and concern about the heart can develop in response to this stress, and one symptom is precordial pain. Physician uncertainty about the diagnosis and the use of unnecessary tests may refocus attention on the heart, thereby exacerbating the situation.

Patients feel pain at the cardiac apex, often described as a dull ache, with or without attacks of sharper pain in the same area (162) (see Fig. 64-16). The patient might relate the pain to physical exertion, but it usually occurs after the physical exertion has ceased and is associated with fatigue rather than effort. The shortness of breath, usually described as an inability to fill the lungs, is a prominent symptom, as are generalized weakness and low energy levels. Other manifestations of anxiety can be present but are not prominent.

This condition tends to persist for years, with periods of exacerbation and remission. A number of patients can recover entirely and some show improvement (162,170). The prognosis for disappearance of symptoms is poor if a serious psychiatric background and a long history of symptoms are present or the syndrome appears after relatively brief and minor physical strain (170). Cardiophobia is an extreme form of chronic, recurring anxiety focused on the heart (171).

Other Psychiatric Disorders. Depression, conversion reactions, hypochondriasis, and operant (learned) behavior sometimes manifest as chest pain. Specific therapy aimed at the underlying psychiatric condition is the only sensible approach to patients with these disorders. Chapter 24, Chapter 25 and Chapter 26 discuss these conditions in greater detail.

CHAPTER 65

General Considerations of Abdominal Pain

John J. Bonica and Daniel O. Graney

The abdomen is one of the most frequent sites of regional acute pain; there are numerous chronic pain syndromes caused by disorders of the abdominal viscera or referred to this region by diseases of the thoracic viscera. Pain in the abdomen can also be neuropathic due to disease of the spinal cord or of the lower six thoracic nerves. Injury and disease of muscles and the fascia and other somatic structures that are part of the abdomen are also causes of abdominal pain. This chapter, like others that introduce pain in various body regions, is intended to provide information on the anatomic, neurologic, and pathophysiologic bases of pain in the abdomen and a general approach to its diagnosis. Although the pelvis is considered to be part of the abdominal cavity, the various pain syndromes in this region are discussed separately in Section E (Part IV) to emphasize their importance and also because pain in the pelvis is often related to diseases of the perineum and external genitalia.

The information in this chapter is presented in four major sections: Basic Considerations, including an overview of the most common causes of pain in the abdomen and their mechanisms, and a brief discussion of the epidemiology of abdominal pain; Anatomy and Neurologic Aspects of the abdomen and viscera contained therein, including anatomy of the muscles of the abdomen, a brief description of the peritoneum, the nerve supply to these structures, and a general description of the autonomic and afferent nerve supplies to the abdominal viscera; Summary of Evaluation of the Patient and Differential Diagnosis of patients presenting with abdominal pain; and a table that presents all possible causes of abdominal pain, the characteristics of the pain, and other symptoms and signs that should help to make a differential diagnosis. The subsequent four chapters are more detailed and present specific information on these various aspects as they pertain to the disease of each viscus.

BASIC CONSIDERATIONS

Classification of Abdominal Pain

Pain in the abdomen is usually caused by disorders of the viscera contained within the abdominal cavity, including the pelvic viscera. Referred pain to the abdomen from diseases of the chest is the next common cause and often is a source of difficulty in differential diagnosis, because the lower thoracic cavity and the abdomen, other than the pelvis, can be considered as one neurologic unit: The somatic and visceral nerve supplies of both regions have a common segmental distribution in the spinal cord. To be more specific, the lower half of the thoracic parietal pleura, the periphery of the diaphragmatic pleura, and approximately the upper 85% of the abdominal wall are supplied by the lower six or seven thoracic (and the first lumbar) somatic spinal nerves. Moreover, the proximal ends of the afferent nerves, mediating nociceptive and other sensory impulses from the abdominal viscera (except the pelvis), synapse in the same spinal cord segments as the somatic spinal nerves. It is not surprising, therefore, that lesions of these various structures produce pain with similar localization in the trunk. These neuroanatomic and neurophysiologic factors also explain the common features of pain in the chest and abdomen caused by neuropathic disorders. The same neurologic lesions of the spinal cord or of the lower six or seven thoracic and first lumbar spinal nerves or their roots frequently produce a similar type of pain in the lower chest or the abdominal wall, depending on the level of the lesion. Less common causes of abdominal pain are disorders of muscles and certain systemic diseases.

Abdominal Visceral Disease

The characteristics and mechanisms of pain caused by abdominal visceral disease are discussed in detail in Chapter 9. To briefly recapitulate, cutting and tearing or crushing of the viscera does not result in pain or in other perceptible sensation (1). Tension or stretching of the walls of hollow viscera, traction or stretching of the peritoneum, and increased tension caused by rapid stretching of the capsule of solid viscera constitute the *adequate stimulus* for visceral pain, specifically the following (2,3,4 and 5): (a) spasm of the smooth muscle of a hollow viscus; (b) sudden abnormal distension, stretching, or tearing of any part of the gastrointestinal tract (including the biliary ducts) or of the genitourinary system (including the ureters, urinary bladder, and uterus); (c) contraction of a hollow viscus under isometric conditions (i.e., the outlet of the viscus is obstructed); (d) rapid abnormal stretching of the capsule of such solid organs as the liver, spleen, or kidney; (e) traction, compression, or twisting of the mesentery, parietal peritoneum, ligaments, or blood vessels; (f) rapidly developing ischemia of the viscera; and (g) inflammation and necrosis of the pancreas or other viscera.

Inflammation, whether of bacterial or chemical origin, or ischemia of a viscus liberates algogenic (pain-producing) substances such as bradykinin, serotonin, histamine, and prostaglandins that stimulate and sensitize nerve endings and thus lower their threshold for the adequate stimulus to activate sensory nerve endings. Thus, whereas pinching the wall of the healthy gastric mucosa or applying faradic stimulation or chemical irritants to it produces no pain, such procedures do produce pain of considerable intensity when done to inflamed, congested, and edematous gastric mucosa (5). Severe ischemia has a similar effect by increasing the concentration of these algogenic substances in the region of nerve endings.

Pain in the abdomen can be separated into two types according to the origin of the nociceptive impulses: visceral pain and parietal (somatic) pain. Based on localization, either type can be felt in or near the structure from which it arises or can be felt at a region that is removed from the structure that is the seat of noxious stimuli. Thus, four types of pain are associated with visceral disease: (a) unreferred or true visceral pain; (b) referred visceral pain; (c) unreferred or local parietal pain; and (d) referred parietal pain.

Unreferred Visceral Pain. Unreferred or true visceral pain is dull, poorly localized in the epigastrium, periumbilical region, or lower midabdomen, and usually felt around the midline, because with few exceptions the abdominal organs are supplied with afferents bilaterally. Exceptions to this are the kidneys, ureters, cecum, ascending colon, and descending and sigmoid colon, which have unilateral innervation. The poor localization of the pain occurs because innervation of most viscera is multisegmental and the viscera contain fewer nerve endings than the skin. The quality of the pain is usually gnawing, cramping, and associated with nausea, sweating, vomiting, perspiration, and pallor. When the nociceptive input is intense, the pain is referred to the skin and deeper somatic tissue.

On the basis of the lack of evidence for a sensory channel specifically concerned with the transmission of visceral sensory impulses and the considerable amount of experimental data on viscerosomatic convergence in the central nervous system, Cervero and Tattersall (6) dispute this century-old classic concept of true visceral pain.

Referred Visceral Pain. Referred visceral pain is somewhat more localized than true visceral pain. It is located in the dermatomes and myotomes that are supplied by the same spinal cord segments as the affected viscus and is the result of the convergence-projection mechanism (see Chapter 9). Thus, distension of the intestine with a balloon causes a vague, aching, poorly localized discomfort at first but, with greater distension, the pain is referred to the abdominal wall and back (7).

Unreferred Parietal Pain. Parietal pain is considered to be unreferred or local when the inflammation of the parietal peritoneum produces pain localized in the body wall directly over the site of the inflammation, such as the localized pain in acute appendicitis produced by inflammatory involvement of the parietal peritoneum at

McBurney's point. The pain results from stimulation of nociceptive fibers in the parietal peritoneum in the right lower quadrant.

Referred Parietal Pain. Referred parietal pain is characterized by pain felt in an area that is remote from the site of nociceptive stimulation. A typical example is the pain felt in the shoulder when the parietal peritoneum of the middle portion of the diaphragm is inflamed and stimulated.

Pain of Neuropathic Origin

Lesions of the spinal cord, such as primary or metastatic tumors, or spinal cord compression causes pain in the abdomen when the lesion involves one or more of the lower six thoracic segments of the spinal cord. The pain can be dull, aching, and not well localized or radicular, depending on the lesion. Compression or inflammation of the rootlets and roots of the lower six or seven thoracic nerves, such as in herpes zoster, tabes dorsalis, or compression from vertebral tumors or herniated disks, produces sharp, burning, segmental pain in the abdomen and is associated with hyperalgesia, hyperesthesia, and other sensory disturbances. Intercostal neuropathy produced by mechanical or inflammatory processes can also cause pain in the anterior abdomen.

Pain Caused by Musculoskeletal Disorders

In addition to producing radiculopathy or neuropathy with segmental pain, disorders of the lower thoracic spine can cause local or regional pain in the back or occasionally referred to the side of the trunk. Fracture or dislocation of the lower ribs or their cartilages causes localized pain on the side of the injury. Fracture or subluxation of the cartilages causes sharp localized epigastric pain that is aggravated by movement and pressure. Myofascial pain syndromes involving muscles of the abdomen are much less frequent causes of pain from the abdomen than from other parts of the body. Trauma with hemorrhage to the anterior abdominal wall can cause localized pain. In all these conditions, the pain is fairly well localized and sharp and is associated with tenderness. Postoperative pain is a source of moderate to severe discomfort, especially following operation in the upper abdomen. This type of pain is markedly aggravated by movement, coughing, and straining and is often associated with reflex muscle spasm and other segmental and suprasegmental responses (see Chapter 41).

Other Causes of Abdominal Pain

Various systemic, toxic, allergic, hematologic, and endocrine disturbances can cause episodes of severe, deep abdominal pain that can simulate that of visceral disease. The pain of porphyria or lead colic is usually difficult to distinguish from that of intestinal obstruction because severe hyperperistalsis is a prominent feature of both (8). The pain of uremia or diabetes is nonspecific, and the pain and tenderness frequently shift in location and intensity. Black widow spider bites produce pain and rigidity of abdominal muscles and of back muscles, an area not frequently involved in disease of intraabdominal origin.

Disease of intraabdominal arteries and veins can cause severe, diffuse pain as in embolism or thrombosis of the superior mesenteric artery or rupture of abdominal aortic aneurysm, or it can cause mild continuous diffuse pain for 2 or 3 days before vascular collapse or evidence of peritoneal inflammation appears (8). The early, seemingly insignificant, discomfort is caused by hyperperistalsis rather than by peritoneal inflammation. The absence of tenderness and rigidity and the presence of continuous diffuse pain in a patient likely to have vascular disease are characteristic of occlusion of the superior mesenteric artery (8).

Pain primarily caused by psychological or emotional factors varies enormously in type, location, and other characteristics, usually has no relation to meals, and is often accentuated during the night; nausea and vomiting are rarely observed and no reflex spasm of abdominal muscles is seen. Frequently, the site of the pain varies from visit to visit.

Table 65-1 presents the most common causes of abdominal pain. (A more detailed listing is given later in Table 65-6, which contains the important diagnostic features of each condition.)

TABLE 65-1. Major causes of abdominal pain

TABLE 65-6. Summary of etiology and differential diagnoses of abdominal pain

Epidemiology

The precise incidence and prevalence of abdominal pain are not known, but data from the 1986 National Health Interview Survey (9) suggest that nearly 15 million Americans suffered acute disorders of the digestive system, and approximately 2 million had acute disorders of the kidney and ureters in 1986. These conditions resulted in more than 105 million days of restricted activity, approximately 44 million days of bed disability, and approximately 25 million days of lost work. In addition, more than 30 million people were listed as having “selected chronic digestive conditions,” including 4.5 million patients with ulcers, nearly 3 million patients with gastritis or duodenitis, 2.5 million patients with enteritis or colitis, 5.3 million patients with frequent recurrent periods of pain caused by indigestion, and more than 1.6 million patients with spastic colon associated with abdominal pain.

The 1986 National Hospital Discharge Survey (10) indicated that approximately 5.8 million patients were hospitalized for digestive and kidney diseases in 1986, resulting in nearly 38 million days of hospitalization. Moreover, approximately 6.7 million operations were performed to diagnose and treat digestive and renal disorders (Table 65-2).

	Inpatient Discharges			Operations	
Disease	No. of patients (in thousands)	Average length of stay (days)	Total hospital days (in thousands)	Type	Total (in thousands)
Digestive tract				Digestive tract	
Peptic ulcer	395	7.1	2,805	Endoscopy	442
Gastritis or duodenitis	196	4.5	882	Gastrectomy	79
Appendicitis	250	4.9	1,225	Appendectomy	271
Inguinal hernia	184	5.0	912	Cholecystectomy	382
Enteritis or colitis	439	4.8	2,059	Repair of inguinal hernia	179

TABLE 65-2. Hospitalizations and operations performed for digestive and renal diseases in 1986

The 1987 estimates of the American Cancer Society (11) included 224,000 new cases of cancer of the digestive organs and 22,000 new cases of cancer of the kidney and ureters, while the total deaths from each group of cancers were 125,000 and 9,400, respectively (Table 65-3). The total of new cases and deaths from cancer of the digestive system is the highest of any organ system or cancer site.

	Estimated new cases			Estimated deaths		
Site	Male	Female	Total	Male	Female	Total
Digestive organs						
Esophagus	6,000	2,900	8,900	6,400	2,400	8,800
Stomach	15,000	9,600	24,600	8,900	5,900	14,800
Small intestine	1,300	1,200	2,500	400	400	800
Large intestine	47,000	51,000	98,000	25,000	27,000	52,000
Rectum	23,000	20,000	43,000	4,000	3,900	8,000
Liver and biliary passages	7,000	4,900	14,000	5,000	5,000	10,000
Pancreas	13,000	13,200	26,200	12,500	12,000	24,500
Other cancers	2,000	1,200	4,000	600	600	1,200
Subtotal	114,000	110,000	224,000	62,600	57,500	125,100
Kidney	13,000	8,000	21,000	5,700	3,700	9,400

TABLE 65-3. Estimates of new cancer cases of the digestive and renal systems and cancer deaths in 1987

Computations based on the incidence of pain with these various abdominal and renal conditions, and data on the incidence of cancer pain with various types of cancers (see Chapter 35), suggest that in 1986 approximately 20% of Americans had abdominal pain that required medical attention. The Nuprin Pain Report suggested that these numbers underestimate the actual figures and noted that in 1985, 46% of Americans had abdominal (*stomach*) pain (12).

ANATOMIC AND NEUROLOGIC ASPECTS

Anatomy of the Abdomen

The abdomen, the region of the trunk below the diaphragm, is composed of an upper part, the abdomen proper, and a lower part, the lesser pelvis (13,14). The anatomy of the pelvis is described in Chapter 70. The abdomen is largely bounded by muscles, and its shape and size can thus be altered under different conditions, such as varying degrees of distension of the hollow organs contained therein and the different phases of respiration. Moreover, the tone of the muscles is important in maintaining the abdominal (and pelvic) viscera in position.

The abdomen proper is bounded anteriorly by the rectus abdominis muscles, the pyramidalis, and the aponeurotic parts of three muscles: the external oblique, internal oblique, and transversus abdominis. It is bounded at its sides by the fleshy parts of these three muscles and by the iliac muscles and iliac bones and posteriorly by the lumbar part of the vertebral column, the crura of the diaphragm, the psoas and quadratus lumborum muscles, and the posterior part of the iliac bones. Superiorly it is bounded by the diaphragm and inferiorly by the superior aperture of the lesser pelvis. Because of the dome shape of the diaphragm, a considerable part of the abdominal cavity extends superiorly and is inside the framework of the thorax. The abdomen proper contains the greater part of the gastrointestinal tract as well as the liver, pancreas, spleen, kidneys, part of the ureters, supraadrenal glands, and numerous blood vessels, lymph vessels, lymph nodes, and nerves.

For purposes of location of the viscera, especially in clinical practice, the abdomen is divided into nine regions by imaginary planes. Two horizontal and two sagittal planes pass through the cavity, with the edges of each plane being indicated by lines projected onto the surface of the body (Fig. 65-1). Figure 65-2 depicts the relationship of various abdominal viscera and other structures to the dermatomes and to the ribs.

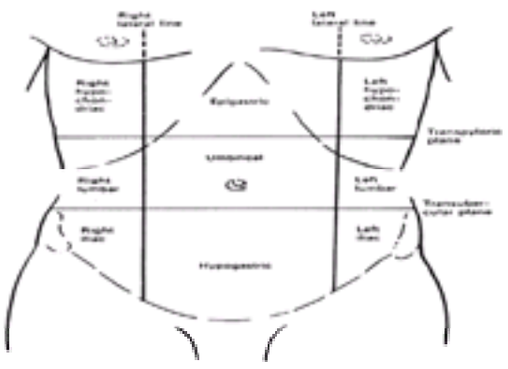

Figure 65-1. Regions of the abdominal wall. The wall is divided into nine regions by four imaginary lines, of which two pass horizontally around the body and two vertically. The upper horizontal line or plane, also called the *transpyloric plane*, is at a level midway between the suprasternal notch and the symphysis pubis, intersects the front of the body of the first lumbar vertebra near its lower border, and meets the costal margin at the tip of the ninth costal cartilage. The lower transtubercular plane is at the level of the top of the crests of the iliac bones and intersects the front of the body of the fifth lumbar vertebra near its upper border. The vertical lines, one on each side of the body, descend from the cartilages of the eighth rib to the center of the inguinal ligament.

(Modified from Clemente CD, ed. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985.)

Muscles

The muscles of the abdomen are conveniently divided into an anterolateral group and a posterior group. The anterolateral group consists of four large, flat muscular sheets that form the anterior abdominal wall, including the internal and external oblique, the transversus and rectus abdominis, and two smaller elements, the cremaster and pyramidalis, which are involved in the suspension of the testes and in the tensing of the midline tendinous raphe of the abdominal wall. The posterior muscles of the abdomen include the psoas major and minor, the iliacus, and the fasciae covering them, as well as the quadratus lumborum muscle. The superior part of the abdomen is composed of the inferior surface of the diaphragm, which, although discussed briefly in connection with the chest, is considered in some detail here; the other muscles are then described briefly.

Diaphragm. Figure 65-3 depicts the inferior surface of the diaphragm with the various nerves and some of the major vessels, but without any of the other structures. This dome-shaped musculofibrous sheet, which separates the thoracic from the abdominal cavities, consists of the central tendon, which consists of a thin but strong aponeurosis of closely interwoven fibers situated near the center of the dome, and the peripheral part, which consists of muscular fibers that are attached to the circumference of the thoracic outlet and converge into the central tendon (13,14).

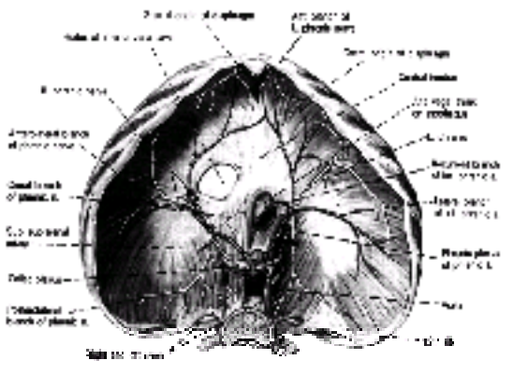

Figure 65-3. Abdominal surface of the diaphragm depicting the phrenic nerves (n.) and arteries (a.) and the phrenic plexus, as well as the major openings. See text for details. (Modified from Netter FH. *The CIBA collection of medical illustrations.* Vol 2, Digestive system. Part III, Lower digestive tract. Summit, NJ: CIBA, 1979:21.)

The musculofibers are grouped into three portions: the sternal part, arising from two fleshy slips from the back of the xiphoid process; the costal part, arising from the internal surface of the cartilage and from adjacent parts of the lower six ribs on each aide and interdigitating with the transversus abdominis muscle; and the lumbar part, arising from two aponeurotic arches, from the medial and lateral arcuate ligaments, and from the lumbar vertebrae by two pillars, or crura.

The diaphragm has three large openings—the aortic, esophageal, and vena caval—and a number of smaller ones that transmit the greater and lesser splanchnic nerves. The aortic aperture is the lowest and most posterior of the large openings and is situated at the level of the lower border of the T-10 vertebra and the thoracolumbar intervertebral disk, slightly to the left of the median plane. In addition to being an opening for the passage of the aorta, the aortic aperture also transmits the thoracic duct and occasionally the azygos and hemiazygos veins.

The esophageal aperture is an elliptic opening in the muscular part of the diaphragm at the level of the T-10 vertebra that is formed by the splitting of the medial fibers of the right crus (14). In addition to transmitting the esophagus, it allows the passage of the vagal and sympathetic nerves that surround the lower esophagus and then proceed to the stomach, the esophageal branches of the left gastric vessels, and some lymphatics. The fascia on the inferior surface of the diaphragm, which is continuous with the transversalis fascia and is rich in elastic fibers, extends upward into the opening in a conical fashion to be attached to the wall of the esophagus approximately 2 cm above the gastroesophageal junction, with some of the elastic fibers penetrating to the submucosa of the esophagus. This fascial extension, often called the *phrenico-esophageal ligament*, is an important structure in the treatment of esophageal reflux (see Fig. 65-12). The vena caval aperture is the highest of the three large openings and is situated at approximately the level of the disk between the T-8 and T-9 vertebrae. It transmits the inferior vena cava and some branches of the right phrenic nerve, which is the major motor nerve supply to the diaphragm and also contains some sensory fibers (see Chapter 60).

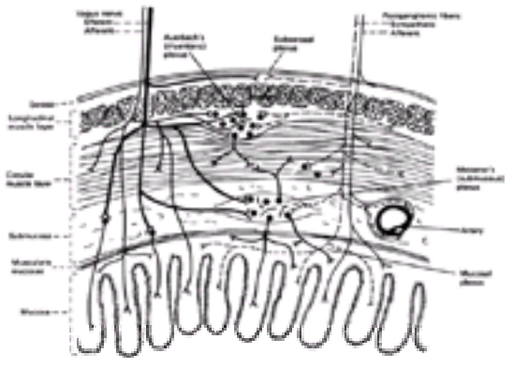

Figure 65-12. Arrangement of nerve cells and nerve fibers in the intramural plexuses in the intestine. The axonal endings of the parasympathetic preganglionic neurons synapse in the wall of the intestine, whereas the axonal endings of postganglionic sympathetic neurons are largely distributed to the intramural ganglia and the blood vessels. (Modified from Kuntz A. *Autonomic nervous system*, 4th ed. Philadelphia: Lea & Febiger, 1953:215.)

Anterolateral Muscles

The anterolateral group of muscles of the abdomen is covered by a fascia that is divisible into two layers, between which are superficial vessels, nerves, and superficial inguinal lymph nodes. The superficial layer of the fascia is thick, is areolar in texture, and contains a varying quantity of fat in its meshes. Below, it passes over the inguinal ligament and is continuous with the superficial fascia of the thigh. The deep layer of the fascia is more membranous than the superficial, contains

elastic fibers, and is loosely connected by areolar tissue to the aponeurosis of the external oblique muscle except in the medial plane, where it adheres intimately to the linea alba and to the symphysis pubis (Fig. 65-4).

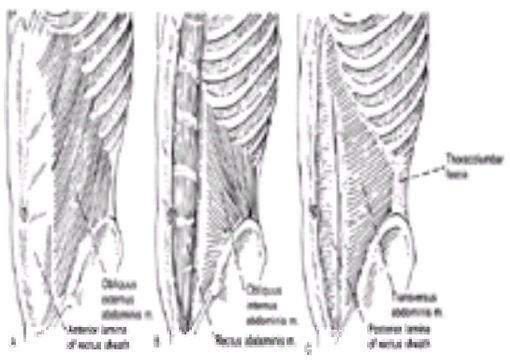

Figure 65-4. Muscles and fascia of the abdominal wall. **A:** External oblique muscle and anterior lamina of the rectus sheath. **B:** Rectus abdominis and internal oblique muscle. **C:** Transversus abdominis, thoracolumbar fascia, and posterior lamina of the rectus sheath.

External Oblique Muscle. The external oblique muscle, the largest and most superficial of the three flat muscles, arises by eight fleshy slips from the external surfaces and inferior borders of the lower eight ribs; these slips interdigitate with the serratus anterior and latissimus dorsi (see Fig. 65-4A). The fibers diverge from these attachments as they pass into their insertion: Those from the lower two ribs pass inferiorly to become attached to the outer lip of the iliac crest, whereas the middle and upper fibers are directed inferiorly and anteriorly, and end in an aponeurosis that is a strong tendinous sheath and whose fibers are directed downward and medially. In the medial plane its fibers end in the linea alba, which is a tendinous raphe that stretches from the xiphoid process to the symphysis pubis. At the raphe it is continuous with the aponeurosis of the opposite muscle, and together these two cover the anterior part of the abdomen. The margin of the aponeurosis between the anterior superior iliac spine and the pubic tubercle is a thick band formed and then turned on itself to present a grooved upper surface. This is the inguinal, or Poupart's, ligament.

Internal Oblique Muscle. The internal oblique muscle is internal to and is thinner and less bulky than the external oblique muscle. It arises by muscular fibers from the lateral two-thirds of the grooved upper surface of the inguinal ligament, from the anterior two-thirds of the intermediate line of the iliac crest, and from the thoracolumbar fascia (see Fig. 65-4B). The posterior fibers pass cephalad and laterally to the inferior border of the lower three or four ribs and are continuous with the internal intercostal muscles. The fibers from the inguinal ligament arch across the spermatic cord in the male and the round ligament of the uterus in the female, become tendinous, and attach to the corresponding part of the aponeurosis of the transversus abdominis muscle to the crest in the medial part of the pecten ossis pubis, forming the conjoint tendon or falx inguinalis. The rest of the fibers pass anteriorly and anterosuperiorly, ending in an aponeurosis that gradually broadens from below upward. In its upper two-thirds, this aponeurosis splits at the lateral border of the rectus abdominis into two layers, which pass around it and reunite in the linea alba that they help to form.

Transversus Abdominis. The transversus abdominis is the innermost of the flat muscles of the abdominal wall and is internal to the internal oblique abdominis. It arises from the lateral third of the inguinal ligament, the anterior two-thirds of the inner lip of the iliac crest and thoracolumbar fascia between the iliac crest and the twelfth rib, and the internal aspects of the lower six costal cartilages, where it interdigitates with the diaphragm (see Fig. 65-4C). The muscle fibers pass anteriorly and end in its aponeurosis. The lower fibers of the aponeurosis pass inferiorly and medially, together with those of the aponeurosis of the internal oblique, to the crest and pecten of the pubis; these contribute to the falx inguinalis, while the rest pass horizontally over the aponeurosis toward the medial plane and blend with the linea alba.

Rectus Abdominis. The rectus abdominis muscle is a long, thick, rather narrow muscle that extends along the whole length of the front of the abdomen and is separated from its counterpart by the linea alba. It arises by two tendons, a lateral and larger tendon attached to the crest of the pubis and a medial tendon that interlaces with the larger one and becomes connected with ligamentous fibers of the symphysis pubis (see Fig. 65-4B). Superiorly, each muscle is inserted by three fascicles of unequal size to the fifth, sixth, and seventh costal cartilages. The muscle fibers of the rectus are interrupted by three fibrous bands called *tendinous intersections*. The rectus abdominis is enclosed in the rectus sheath, which is the aponeurosis of the oblique and transverse muscles. Figure 65-5 depicts a transverse section through the anterior and posterior abdominal walls showing the termination of the abdominal muscles and the fascia that covers them.

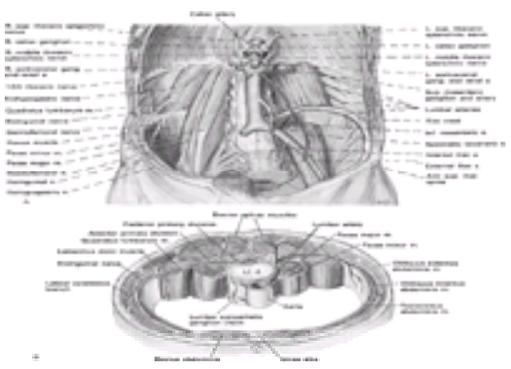

Figure 65-5. **A:** Posterior wall of the abdomen showing the blood vessels on the right (*black*) and the lumbar nerves on the left (*white*), as well as the muscles that make up the posterior boundary of the abdomen proper. **B:** Cross-section of the trunk depicting the anterior and posterior abdominal muscles and course of the lumbar artery (the reader's right) and the first lumbar nerve on the reader's left. (**A** modified from Netter FH. *The CIBA collection of medical illustrations*. Vol 3, Digestive system. Part II, Lower digestive tract. Summit, NJ: CIBA, 1979:35, 43.)

Only the quadratus lumborum is described here because the other posterior muscles of the abdomen are muscles of the lower limb and are described in Chapter 75. The quadratus lumborum is an irregularly quadrilateral-shaped muscle that is broader inferiorly (see Fig. 65-5). It arises below by aponeurotic fibers of the iliolumbar ligament and by the adjacent portion of the iliac crest for approximately 5 cm, while above it is inserted into the medial half of the lower border of the last rib and to the apices of the transverse processes of the upper four lumbar vertebrae by four small tendons. Anterior to the quadratus lumborum are the colon, kidney, psoas major and minor, and diaphragm.

Peritoneum

The peritoneum is the largest and most complexly arranged serous membrane of the body. In men, it consists of a closed sac; part of this lines the abdominal wall and the remainder is reflected over viscera. In women, the lateral ends of the uterine tube open into the peritoneal cavity. The part that lines the abdominal wall is called the *parietal peritoneum*, while that reflected over the viscera is the *visceral peritoneum*. The free surface of the membrane is covered with a layer of flattened mesothelium and is kept moist and smooth by a thin film of serous fluid, so that the viscera can glide unrestricted over each other on the wall of the cavity.

A fairly large amount of areolar connective tissue intervenes between the parietal peritoneum and the abdominal wall, blending with the fascia lining. This structure, known as the *extraperitoneal tissue*, varies in quantity and contains a varying amount of fat in different regions. The areolar connective tissue is loosely connected to parietal peritoneum in the abdominal wall but is dense in adherence on the inferior surface of the diaphragm and behind the linea alba. It is especially loosely arranged in some places to allow alteration in size of certain organs, such as the urinary bladder. The extraperitoneal tissue is usually heavily laden with fat on the posterior abdominal wall in relation to the kidney. The visceral peritoneum, on the other hand, is firmly united to the viscera that it covers and cannot be easily stripped off. Indeed, the connective tissue layer, the subserous fascia of the visceral peritoneum, is directly continuous with the fibrous tissue stroma of the viscera.

The parietal and visceral layers of the peritoneum are in actual contact, the peritoneal cavity being the potential space between them. The peritoneal cavity consists of a main region, called the *greater sac*, and a diverticulum from this called the *omental bursa*, or *lesser sac*. The neck or communication between the greater and lesser sacs is the *epiploic foramen*, or *foramen of Winslow* (13).

Omenta

Lesser Omentum The lesser omentum is the fold of peritoneum that extends to the liver from the lesser curvature of the stomach and the beginning of the duodenum. It is continuous with the two layers that cover the anterosuperior and posteroinferior surfaces of the stomach and approximately the first 2 cm of the duodenum. A portion of the lesser omentum that extends between the liver and stomach is known as the *hepatogastric ligament*, and that between the liver and duodenum is known as the *hepatoduodenal ligament*.

Greater Omentum. The greater omentum is the largest peritoneal fold. It consists of a double sheet folded on itself so that it is made up of four layers. The two layers that descend from the stomach and the beginning of the duodenum pass downward in front of the small intestine for a variable distance. They then turn on themselves and ascend as far as the anterosuperior aspect of the transverse colon. They adhere to but are separable from the peritoneum on the upper surface of the transverse colon and the upper layer of the transverse mesocolon.

Mesenteries

The peritoneal fold, collectively known as the *mesenteries*, includes the mesentery of the small intestine, called the *mesentery proper*, and the mesoappendix, the transverse mesocolon, and the sigmoid mesocolon. The mesentery of the small intestine is a broad, variably shaped fold of peritoneum that connects the convolutions of the jejunum and ileum to the posterior abdominal wall. The part attached to the posterior wall of the abdomen is called the *root of the mesentery*. The mesoappendix is a triangular fold of peritoneum around the vermiform appendix that is attached to the back of the lower end of the mesentery close to the ileocecal junction. Its layers include the blood vessels, nerves, and lymph vessels of the appendix, together with a lymph node. The transverse mesocolon is a broad fold that connects the transverse colon to the posterior abdominal wall. Its two layers pass from the anterior surface of the head and the anterior border of the body of the pancreas to the posterior surface of the transverse colon. The sigmoid mesocolon is a fold of peritoneum that attaches the sigmoid to the pelvic wall. These structures are important because they contain blood vessels, nerves, and lymph vessels and, when stretched, provoke nociceptive impulses.

Vessels and Nerves

The parietal and visceral layers of the peritoneum are developed from the somatopleural and splanchnopleural layers of the lateral plate mesoderm, respectively. Correlated with their embryologic origin is the fact that the parietal peritoneum derives its nerve supply from the spinal nerves, which also supply the muscles and skin of the parietes (the same applies to its arterial supply and to drainage of the venous systems). The visceral peritoneum, which is considered to be an integral part of the viscera themselves, derives its nerve supply from the autonomic nerves supplying the viscera. The difference in the sensibility of the two layers of the peritoneum is thus correlated with the different innervation. In conscious patients, pain can be elicited by noxious stimuli applied to the parietal peritoneum, but these stimuli are ineffective when applied to the visceral peritoneum or to the viscera themselves. The region of the gastrointestinal tract that is insensible to stimuli that are normally painful when applied to the skin and other than somatic structures extends from approximately the middle of the esophagus down to the junction of the endodermal and extradermal parts of the anal canal. Conversely, tension or stretch applied to the viscera or the visceral peritoneum, such as overdistension of the hollow viscera or traction of the mesentery that stretches the nerve plexus in the walls of the organs or the nerves in the mesentery, produces pain. Other effective stimuli are spasm or contraction of the visceral muscle, particularly under isometric conditions, ischemia, and inflammation, which lowers the threshold of nerve endings.

The somatic nerve supply of the parietal peritoneum also supplies the corresponding segmental area of the skin and trunk muscles, and noxious stimuli applied to these structures produce pain and reflex muscle contraction or spasm. The parietal peritoneum of the undersurface of the diaphragm is supplied centrally by both phrenic nerves and peripherally by the lower six intercostal and subcostal nerves, so that inflammation or irritation of the peripheral part of the diaphragmatic peritoneum causes pain, tenderness, and muscular rigidity in the distribution of the lower intercostal nerves, whereas stimulation of the central portion produces pain in the distribution of the cutaneous branches of the C-3 to C-5 nerves (neck and shoulder regions). (Chapter 60 and Figure 60-9 describe the thoracoabdominal intercostal nerves in more detail.)

Autonomic and Sensory Nerve Supply to the Abdominal Viscera

This section presents a general overview of the anatomy of the parasympathetic, sympathetic, and afferent (sensory) nerves to the viscera of the abdomen proper. The information that follows is an extension of the description of the nerves to the thoracic viscera to the abdomen, which includes a discussion of the origin and course of the thoracic splanchnic nerves (see also Figure 60-11). The nerves to the pelvic viscera and the nerves to the structures of the pelvis are described in Chapter 70.

Figure 65-6,Figure 65-7,Figure 65-8,Figure 65-9,Figure 65-10,Figure 65-11,Figure 65-12 and Figure 65-13 depict the anatomy of the parasympathetic, sympathetic, and sensory nerves that supply the viscera in the abdomen proper. The parasympathetic efferent (motor) and afferent (sensory) fibers are contributed by branches of the vagus nerves and by the sacral splanchnic nerves (nervi erigentes). The sympathetic supply is provided by thoracic and lumbar splanchnic nerves as described in Chapter 60. Descriptions of the course and distribution of the vagus nerves, splanchnic nerves, and celiac and subsidiary plexuses are given below.

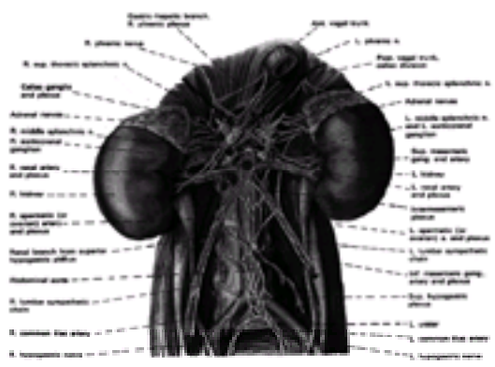

Figure 65-6. Anterior view of the abdomen showing the celiac plexuses and the ganglia as well as the subsidiary plexuses, including the phrenic, suprarenal, renal, testicular, and superior and inferior mesenteric plexuses. (Modified from Mitchell GAG. *Cardiovascular innervation*. Edinburgh, UK: Livingstone, 1956:258.)

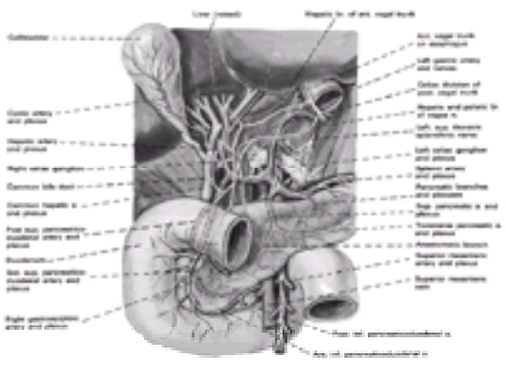

Figure 65-7. Hepatic plexus and its various subsidiary plexuses. For the sake of clarity, the celiac ganglia in this and other illustrations in this chapter are shown as two large masses instead of several separate portions scattered on each side.

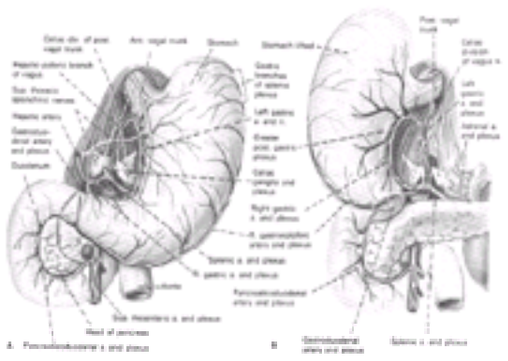

Figure 65-8. Autonomic nerve supply to the stomach and duodenum. **A:** Anterior view showing the anterior vagal trunk and its direct contribution to the hepatic plexus and the celiac plexus, which gives off the left gastric plexus that meets with the right gastric plexus; all of these supply the lesser curvature of the stomach. The gastroduodenal plexus supplies the duodenum and head of the pancreas; the greater curvature of the stomach is supplied by the right gastroepiploic plexus and gastric branches of the splenic plexus. **B:** The stomach has been shifted to the right to show the celiac, gastric, right gastroepiploic, and other plexuses and nerves that supply the stomach. (Modified from Mitchell GAG. *Cardiovascular innervation*. Edinburgh, UK: Livingstone, 1956:242.)

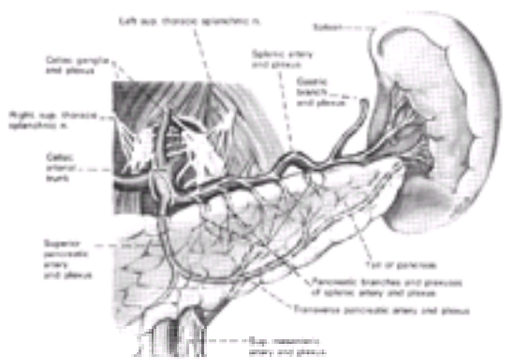

Figure 65-9. Splenic plexus. Note its origin and distribution to the pancreas, spleen, and stomach. (Modified from Mitchell GAG. *Cardiovascular innervation*. Edinburgh, UK: Livingstone, 1956:249.)

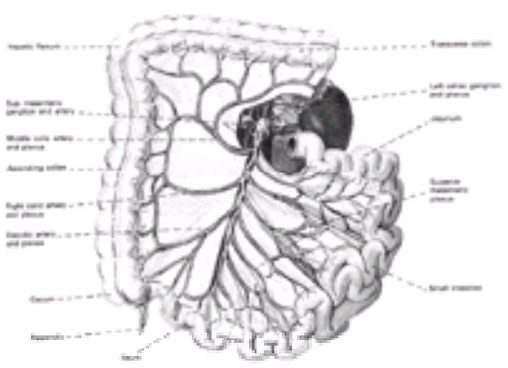

Figure 65-10. Superior mesenteric plexus. (Modified from Mitchell GAG. *Cardiovascular innervation*. Edinburgh, UK: Livingstone, 1956:251.)

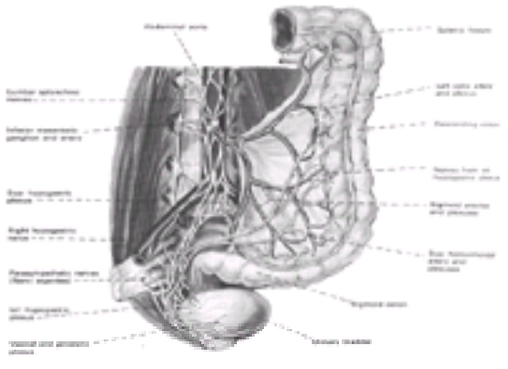

Figure 65-11. Inferior mesenteric plexus. (Modified from Mitchell GAG. *Cardiovascular innervation*. Edinburgh, UK: Livingstone, 1956:245.)

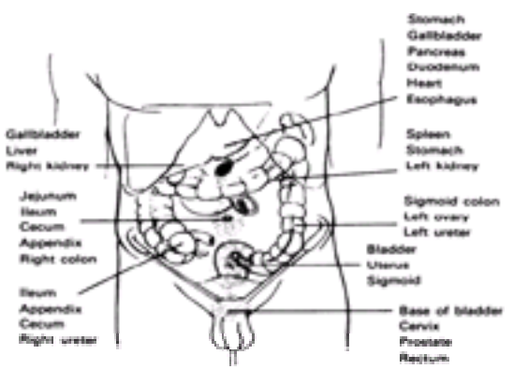

Figure 65-13. Abdominal pain according to site. Visceral pain occurs mostly in the midline epigastric, periumbilical, and hypogastric regions. Parietal pain occurs because of involvement of the parietal peritoneum that causes reference to the right and left lateral regions. (From Currie DJ. *Abdominal pain*. New York: McGraw-Hill, 1979:188.)

Vagus Nerves

The vagus nerves supply parasympathetic preganglionic fibers and sensory nerves to the viscera of the abdomen proper, except the left half of the transverse colon and the descending colon, which are supplied by the sacral parasympathetic nerves. As discussed in Chapter 8 and Chapter 60, the cell bodies of the parasympathetic preganglionic fibers are located in the dorsal motor nucleus of the vagus in the medulla of the brainstem, while the cell bodies of the sensory nerves are located in the inferior (nodose) ganglion, with the proximal processes entering the medulla and the distal processes incorporated into the vagus nerves. The two vagus nerves pass vertically from the base of the skull down the neck within the carotid sheath until they reach the root of the neck. The further course of the nerve differs on the two sides of the body.

Right Vagus Nerve. On the right side, the vagus descends posteriorly to the internal jugular vein. It crosses the first part of the subclavian artery, enters the thorax, and descends through the superior mediastinum, lying posterior to the right brachiocephalic vein. It then passes to the right of the trachea posteromedially to the superior vena cava and medially to the pleura and lung, passing posteriorly to the right principal bronchus to reach the posterior aspect of the root of the right lung, where it breaks up into posterior pulmonary branches that unite with filaments from the thoracic sympathetic nerves to form the right posterior pulmonary plexus. From the lower part of the posterior pulmonary plexus two or three branches descend on the posterior aspect of the esophagus and, with a branch from the left vagus, form the posterior esophageal plexus.

From the posterior esophageal plexus a trunk is formed that continues posteriorly to the esophagus to enter the abdomen through the esophageal opening in the diaphragm. This is the *posterior vagal trunk*, which contains fibers from both vagus nerves. In the abdomen, the posterior vagal trunk divides into a small gastric branch, which supplies the posteroinferior surface of the stomach with the exception of the pyloric canal, and a large celiac branch, which ends chiefly in the celiac plexus but also sends fibers directly to the splenic, hepatic, renal, suprarenal, and superior mesenteric plexuses.

Left Vagus Nerve. The left vagus nerve enters the thorax between the left common carotid and left subclavian arteries, posterior to the left brachiocephalic vein, and then descends through the superior mediastinum and crosses the left side of the aortic arch to pass behind the root of the left lung, where it divides into posterior pulmonary branches that unite with the sympathetic fibers and form the left posterior pulmonary plexus. Two branches descend from this left posterior pulmonary plexus in front of the esophagus, where they form the anterior esophageal plexus with a twig from the right posterior pulmonary plexus.

From the anterior esophageal plexus a trunk containing fibers from both vagus nerves continues in front of the esophagus, enters the abdomen through the esophageal opening of the diaphragm, and becomes the anterior vagal trunk. In the abdomen, the *anterior vagal trunk* sends branches to the cardiac antrum and then divides into right and left branches. The fibers of the left group follow the lesser curvature of the stomach and supply the anterosuperior surface of this viscus. The right group consists of three main branches. One proceeds between the layers of the lesser omentum toward the porta hepatis. Here, it divides into an upper branch that enters the porta hepatis and a lower branch that chiefly supplies the pyloric canal, pylorus, superior and descending parts of the duodenum, and the head of the pancreas. The second branch is distributed to the anterosuperior surface of the body of the stomach, and the third branch follows the lesser curvature of the stomach as far as the angular notch.

Sympathetic Nerves

The viscera of the abdomen proper are supplied by sympathetic efferent (motor nerves) whose cell bodies are located in the T- 5 to L-2 spinal cord segments and whose axons pass through the anterior nerve roots, short formed nerves, and white rami communicantes to reach the sympathetic chain. These axons pass through the chain without synapsing and pass through the splanchnic nerves to end in the three prevertebral ganglia—the celiac, aorticorenal, and inferior mesenteric ganglia—where they synapse with cell bodies of postganglionic neurons (see Chapter 8). The axons of the postganglionic neurons, together with axons of preganglionic parasympathetic fibers and afferent fibers, make up the celiac plexuses and then proceed as subsidiary plexuses that supply the various abdominal viscera. Although the origin and course of the thoracic splanchnic nerves are described in Chapter 60 and depicted in Figure 60-11, a brief discussion of their course and origin, their contribution to the celiac and subsidiary plexuses, the origin and course of the lumbar splanchnic nerves, and the anatomy of the celiac plexus and its subsidiary plexuses is presented here.

Greater Splanchnic Nerve. The greater thoracic splanchnic nerve, consisting mainly of myelinated preganglionic sympathetic and afferent fibers, is formed by three or four roots that are given off by the T-5 or T-6 to the T-9 or T-10 ganglia inclusively. These roots run inferiorly, anteriorly, and medially on the anterolateral aspect of the vertebral column and come together at the level of the ninth or tenth vertebra to form the nerve. Near the origin of the formed nerve is usually found (70% of cases) an enlargement called the *splanchnic ganglion of Lobstein* (14). Its downward course in the thorax is described in Chapter 60 (see Figure 60-8). It passes through the diaphragm within the space that separates the internal from the external crus and enters the abdominal cavity. In the abdomen it has a short course in an anteromedial and inferior direction before it breaks up into its terminal branches, which spread out like a fan and terminate in the celiac ganglia; some also terminate in the ipsilateral aorticorenal ganglion. In its course it gives off fine collateral filaments that join the esophageal and aortic plexuses, intercostal vessels, azygos veins, and aortic plexus. Some filaments supply the diaphragm and contents of the spinal canal, and some filaments join the middle thoracic splanchnic nerve.

Lesser Splanchnic Nerve. The lesser splanchnic nerve is usually formed by two roots that arise from the tenth and eleventh ganglia and soon thereafter converge into one trunk that descends inferiorly, anteriorly, and medially on the anterolateral aspect of the vertebral column. This then passes through the diaphragm accompanied by the superior thoracic splanchnic nerve to terminate in the ipsilateral aorticorenal ganglion, although some fibers can terminate in the celiac ganglia, and one or two filaments pass to the renal plexus, or superior mesenteric plexus.

Least Splanchnic Nerve. The least splanchnic nerve is usually formed by one fine root that arises from the last thoracic ganglion and then passes anteriorly, medially, and a little inferiorly below the middle thoracic splanchnic nerve. It perforates the diaphragm along with the other two thoracic splanchnic nerves to enter the abdominal cavity, where it proceeds to and ends in the posterior renal ganglion and the adjacent part of the renal plexus.

Lumbar Splanchnic Nerves. The lumbar splanchnic nerves, usually four, arise from the lumbar portion of the paravertebral sympathetic chain and pass anteriorly to join the celiac intermesenteric (abdominal aortic) and superior hypogastric plexuses. The L-1 splanchnic nerve arises from the uppermost lumbar ganglion and joins the celiac, renal, and intermesenteric (aortic) plexuses (see Fig. 65-6). The L-2 splanchnic nerve arises from the second (and sometimes third) ganglia and joins the lower part of the aortic plexus. The L-3 splanchnic nerve arises as two or three stouter roots from the second, third, or fourth ganglia and passes in front of the common iliac vessels to join the superior hypogastric plexus. The lowest (usually the L-4) splanchnic nerve arises from the lowest lumbar ganglion and passes posterior to the common iliac vessels to join the lower part of the superior hypogastric plexus or the hypogastric nerve. On one or both sides it supplies twigs to the aorta, inferior vena cava, and common iliac artery and communicates with the gonadal (spermatic or ovarian) and ureteral plexuses.

Celiac Plexus and Subsidiary Plexuses

The celiac plexus, also called the *solar plexus* and sometimes the *epigastric plexus*, is the largest prevertebral plexus. It is composed of two or more large aggregates of ganglion cells, the right and left celiac ganglia, a number of smaller ganglia, and a dense network of parasympathetic and sympathetic efferent and afferent fibers that enmesh these ganglia (see Fig. 65-6). The plexus is situated in the epigastrium just anterior to the crura of the diaphragm and the body of the first lumbar vertebra, surrounding the celiac artery and the root of the superior mesenteric artery. The entire plexus lies posterior to the stomach and the omental bursa. The right half of the plexus lies behind the upper part of the head of the pancreas, the small part of the duodenum, the lower end of the portal vein, and the inferior vena cava. The left half is also covered by the pancreas and splenic vessels. In the midline, the plexus rests anterior to the beginning of the abdominal aorta. The inferior phrenic arteries are superior and the renal vessels inferior to the plexus, while the suprarenal vessels often pass through interstices in the plexus (14,15,16 and 17).

The celiac plexus and ganglia are joined by the superior and middle thoracic splanchnic nerves of both sides, which contain sympathetic preganglionic and afferent fibers, and also by branches of the vagus nerves, composed of preganglionic parasympathetic and afferent fibers as well as sensory fibers from the phrenic nerves. Many of these fibers cross from one side to the other to form a dense network. Numerous secondary or subsidiary plexuses are derived from the celiac plexus; these follow the branches of the celiac artery and also surround neighboring arteries.

The celiac plexus occupies an area approximately 3 cm long and 4 cm wide. In the transverse plane, it occupies the region between the two adrenal glands and extends beyond the lateral borders of the aorta on both sides. In the longitudinal plane, it occupies the area delineated by the celiac artery above and the renal arteries below. It is thus situated in front of the entire L-1 vertebra and often even the upper portion of the L-2 vertebra. The plexus lies in loose areolar tissue, which

is rich in fat.

Prevertebral Ganglia. The ganglia associated with the celiac plexus and its subsidiary plexuses are, according to the classic description, in three pairs: the celiac, the aorticorenal, and the superior mesenteric. According to Hovelacque (18), however, such a description, although serving the purpose of simplicity, is merely schematic, because the actual number and shape of the ganglia are variable (see Fig. 65-6).

Celiac Ganglia. The celiac ganglia, usually described as two large masses, semilunar in shape and located on each side of the origin of the celiac artery, in reality vary in number, shape, and size (18). In most cases their surfaces are irregular and reddish gray, and they are flattened anteroposteriorly. Sometimes they are semilunar in shape with the concavity facing superomedially or inferolaterally, whereas at other times they are quadrilateral or stellate in shape. Frequently, one or both are divided into several small portions that are scattered around the celiac axis.

Because of the variability in size and shape, it is difficult to give exact measurements. On average, the celiac ganglia collectively are 20 to 25 mm by 10 to 15 mm and 3 to 5 mm in thickness (14,16). The distance separating them also varies, ranging from 6 or 7 mm up to as much as 20 to 25 mm. The ganglia receive the terminations of the ipsilateral superior and middle thoracic splanchnic nerves that synapse with cell bodies of postganglionic neurons contained within the ganglia. The celiac ganglia are covered by a dense network of fibers that cross from one side to the other, some passing anteriorly to the celiac artery and others passing posteriorly to it.

Aorticorenal Ganglia. The aorticorenal ganglia can be regarded as the detached lower and outer portions of the celiac ganglia, to which they are almost always united by one or more bands containing nerve fibers and ganglion cells (16). They are intermediate in size between the celiac and superior mesenteric ganglia and are fusiform or irregular in shape. Usually, they are situated above the origin of the renal arteries, although sometimes they are anterior or anterosuperior to the arteries. Each ganglion receives fibers from the middle and inferior thoracic splanchnic nerves. The two aorticorenal ganglia are often connected by fibers that cross in front of the aorta.

Superior Mesenteric Ganglion. The superior mesenteric ganglion is a small irregular mass approximately 5 mm in diameter that lies on the anterior surface of the aorta just above, or occasionally below, the origin of the superior mesenteric artery.

Secondary (Subsidiary) Plexuses. The secondary plexuses arising from or connected with the celiac plexus include the phrenic, gastric, hepatic, splenic, adrenal, renal, superior mesenteric, intermesenteric (abdominal aortic), spermatic (ovarian), and inferior mesenteric plexuses.

Phrenic Plexus. The phrenic plexus arises from the upper part of the celiac plexus and from some sensory filaments contributed by the phrenic nerves (see Fig. 65-3). Both sets of nerves accompany the inferior phrenic arteries to become distributed to the diaphragm and send a few filaments to the suprarenal glands by way of the suprarenal plexus (see Fig. 65-6). On the right side the plexus closely accompanies the inferior phrenic artery. In addition, the left plexus sends some filaments to the esophagus, while the right plexus sends filaments to the inferior vena cava and to the hepatic plexus. At the point of junction of the right phrenic plexus with the phrenic nerve is a small mass called the *phrenic ganglion* (see Chapter 60). Because this plexus contains sensory fibers that pass to the phrenic nerves and into the spinal cord at the C-3 to C-5 level, it has special clinical importance in regard to referred pain caused by disease in the upper abdomen.

Hepatic Plexus. The hepatic plexus, the largest of the subsidiary plexuses, receives fibers directly from the left and right vagus nerves that do not traverse the celiac plexus and also receives sensory fibers from the right phrenic nerve (see Fig. 65-7). The plexus accompanies the hepatic artery, portal vein, and their branches into the liver; in the liver the nerves are confined to the vicinity of blood vessels. Branches from the hepatic plexus form tertiary plexuses that accompany all the branches of the hepatic artery, including the right gastric, gastroduodenal, and cystic arteries.

The *right gastric plexus* is reinforced by filaments from the pyloric branches of the vagal trunks and supplies sympathetic, parasympathetic, and sensory fibers to the upper parts of the anterior and posterior surfaces of the stomach and also the pylorus (see Fig. 65-8).

The *gastroduodenal plexus* accompanies the gastroduodenal artery and its branches, the right gastroepiploic and superior pancreaticoduodenal arteries. Branches from the gastroduodenal plexus pass to the pylorus and superior part of the duodenum, while many of the nerves that pass with the right gastroepiploic artery supply the right part of the stomach and its greater curvature.

The *superior pancreaticoduodenal plexus* supplies the descending part of the duodenum, head of the pancreas, and lower part of the bile duct. Fibers passing to the gallbladder arise from the cystic plexus, with some branches also passing to the bile ducts. These various plexuses contain both afferent and efferent sympathetic and parasympathetic fibers that supply the liver, gallbladder, stomach, duodenum, and pancreas. The functions of the sympathetic and parasympathetic fibers in these structures are presented in Table 65-4. The sensory fibers associated with the vagus probably constitute the afferent limb of subconscious reflexes, while the sympathetic afferents mediate nociceptive and other sensory impulses.

Structures or organs	Sympathetic stimulation	Adrenergic receptors	Parasympathetic stimulation
Stomach:			
Motility	Decreased	α,β	Increased
Sphincters	Contracted	α	Relaxed
Secretion	Inhibited	α	Increased
Liver	Glycogenolysis Gluconeogenesis	β	
Gallbladder and biliary ducts	Relaxed	β	Contracted
Pancreas	Vasoconstriction		
Insulin secretion	Reduced	α	Increased secretion
Spleen	Contraction of capsule	α	
Intestines			
Motility	Decreased	α,β	Increased
Sphincters	Relaxed	β	Contracted
Secretion	Decreased	α	Increased
Suprarenal glands	Secretion of 80% epinephrine, 20% norepinephrine	α	
Kidneys	Arteriolar constriction	α	Controls glomerular secretion
Ureters, bone and motility	Decreased	α	Increased

TABLE 65-4. Physiologic responses to autonomic stimulation

Left Gastric Plexus. The left gastric plexus is derived from the celiac plexus and from both vagal trunks that pass directly to it. It accompanies the left gastric artery along the lesser curvature of the stomach (see Fig. 65-8B). The plexus supplies fibers to the stomach and to the abdominal portion of the esophagus through the subsidiary plexuses that accompany the two or three esophageal branches of the left gastric artery. The gastric sympathetic nerves are motor to the pyloric sphincter but are inhibitory to the muscular coat of the stomach.

Splenic Plexus. The splenic plexus is formed by branches from the celiac plexus, left celiac ganglia, and posterior vagal trunk. It accompanies the splenic, pancreatic, short gastric, and left gastroepiploic arteries (see Fig. 65-9). The small plexus around the left gastric or left gastroepiploic artery communicates with gastric branches of the posterior vagal trunk and with gastroesophageal branches of the left phrenic plexus that run to the gastroesophageal junction (16,17). The plexus around the pancreatic branch supplies the pancreas. The fibers that terminate in the spleen are principally, if not wholly, sympathetic efferents and afferents, with the efferents terminating on blood vessels and unstriated muscle of the splenic capsule and trabeculae (14,15 and 16). The sympathetic afferents convey nociceptive impulses provoked by rapid distension of the splenic capsule.

The subsidiary plexus that surrounds the pancreatic branches of the splenic artery supplies the neck, body, and tail of the pancreas. The subsidiary plexus that surrounds the short gastric branches of the splenic artery is distributed to the fundus of the stomach, while the plexus around the posterior gastric branch contributes fibers to the fundus and posterior wall of the stomach. The subsidiary plexus surrounding the left gastroepiploic branch contributes fibers to the upper third of the greater curvature of the stomach. The plexuses that continue along the omental branches of the left gastroepiploic artery, and those of the right gastroepiploic artery, supply nerve fibers to the greater omentum.

Suprarenal Plexuses. The suprarenal plexuses are formed by branches from the celiac plexus, celiac ganglia, phrenic plexus, and ipsilateral superior thoracic splanchnic nerves (see Fig. 65-6). The plexuses supply the suprarenal glands, which, relative to their size, have a larger autonomic nerve supply than any other organ (16). Most of the nerve fibers are preganglionic sympathetic fibers that terminate and synapse with the large chromaffin cells, the pheochromocytes, which are

analogous with postganglionic sympathetic neurons. The suprarenal plexuses also have parasympathetic preganglionic fibers and afferent fibers (15).

Renal Plexuses. The renal plexuses are formed by filaments from the ipsilateral celiac ganglion, celiac plexus, aorticorenal ganglion, inferior thoracic splanchnic nerve, L-1 splanchnic nerve, aortic plexus, and superior hypogastric plexus (14,15,16,17 and 18) (see Fig. 65-6). Collections of nerve cells (ganglia) are found in each plexus, with the largest, the renal ganglion, usually lying posteriorly or posterosuperiorly to the commencement of the renal artery. The plexus continues into the kidney around the branches of the renal artery to supply the vessels and renal glomeruli and tubules, particularly the tubules in the cortex of the kidney (19). Most fibers of this plexus are sympathetic efferents that have vasomotor function and sympathetic afferents that transmit nociceptive information. The plexus also has parasympathetic preganglionic fibers that synapse in small ganglia in the hilum of the kidney, but not within its parenchyma (16,17). The renal plexus gives off fibers that contribute to the upper third of the ureteric plexus that supplies the ureter and also contributes to the testicular or ovarian plexuses. The middle third of the ureteral plexus is derived from the superior hypogastric plexus and hypogastric nerve, while the lower part is derived from the hypogastric nerve and inferior hypogastric plexus (these are discussed in detail in Chapter 68, and the testicular and ovarian plexuses are discussed in Chapter 70, which introduces the section on pain in the pelvis).

Superior Mesenteric Plexus. The superior mesenteric plexus is a continuation of the lower part of the celiac plexus but also receives fibers directly from the posterior vagal trunk and from the celiac and aorticorenal ganglia of both sides. The superior mesenteric ganglion is often incorporated into the origin of the plexus (see Fig. 65-10; also see Fig. 66-8). The plexus surrounds the superior mesenteric artery, accompanying it into the mesentery, and divides into a number of secondary plexuses that are distributed to all structures supplied by the artery. These include the following plexuses: (a) the pancreaticoduodenal plexus, which contributes to the nerve supply of the pancreas; (b) the jejunal and ileal plexuses, which supply the small intestine; and (c) the ileocolic, right colic, and middle colic plexuses, which supply the corresponding parts of the large intestine. The sympathetic efferent fibers decrease motility, relax the sphincters, and inhibit secretions of the intestine, while the parasympathetic fibers have opposite effects. The parasympathetic afferents have a subconscious reflex function, while the sympathetic afferents participate in the reflexes but also convey nociceptive information (see Table 65-4).

Abdominal Aortic Plexus. The abdominal aortic plexus, also known as the *intermesenteric plexus*, is formed by fibers contributed by the celiac plexus and ganglia and by the L-1 and L-2 splanchnic nerves (see Fig. 65-6). The plexus is situated on the anterior and lateral parts of the aorta between the origins of the superior and inferior mesenteric arteries. It is continuous above with the celiac plexus and celiac and aorticorenal ganglia and below with the superior hypogastric plexus. Fibers derived from this plexus contribute to the formation of the adrenal, renal, spermatic, inferior mesenteric, iliac, and superior hypogastric plexuses and also supply the inferior vena cava.

Inferior Mesenteric Plexus. The inferior mesenteric plexus is derived chiefly from the aortic plexus but also receives fibers from the L-2 and L-3 splanchnic nerves (see Fig. 65-11). Below the origin of the artery, the plexus is connected by oblique bundles with the superior hypogastric plexus and with parasympathetic fibers from the sacral splanchnic nerve (16,17). Usually, the parasympathetic supply to the distal colon and its vessels runs in fine long nerves that arise on each side by several rootlets from the inferior hypogastric (pelvic) plexus and hypogastric nerves or as direct offshoots from the sacral splanchnic nerves (nervi erigentes), passing upward to join the inferior mesenteric plexus (for a more detailed description of these nerves see Chapter 70). The plexus surrounds the inferior mesenteric artery and then forms a subsidiary plexus. Near its beginning at the origin of the artery, the inferior mesenteric ganglion, or a number of small discrete ganglia, is found. Through its subsidiary plexuses around the superior and inferior left colic arteries it supplies the left part of the transverse colon and the descending colon, and through the superior rectal plexus it supplies the sigmoid colon.

Superior and Inferior Hypogastric Plexuses

The superior hypogastric plexus, considered a continuation of the abdominal aortic plexus with contributions from other parts; the hypogastric nerve; and the inferior hypogastric plexuses are discussed in Chapter 65 because they contribute sympathetic, parasympathetic, and afferent nerves to the pelvic viscera. Illustrations depicting the nerve supply for each of the major organs within the abdomen proper are presented in the respective chapters.

Intrinsic (Enteric) Nervous System

The gastrointestinal tract is supplied by the extrinsic nerves mentioned previously and also by an intrinsic nervous system consisting of cell bodies and short axons. Two major and three minor networks or plexuses of neurons and their axons form the intrinsic nervous system (20,21,22 and 23). The two main ganglionated plexuses are the myenteric (Auerbach's) plexus and the submucosal (Meissner's) plexus (see Fig. 65-12).

Auerbach's plexus lies between the longitudinal and circular muscle layers and consists of three plexiform networks (20,21). The primary network is a coarse structure consisting of large bundles of unmyelinated fibers that link various ganglia. Although its meshes vary within relatively wide limits in regard to size and form, they exhibit primarily a longitudinal arrangement (20). The secondary plexus is intimately connected with the primary one but is made up of more slender bundles of nerve fibers, with few neurons interspersed. This secondary plexus is, in turn, continuous with the tertiary plexus and lies in intimate contact with the circular muscle. Nerve fibers extend from this plexus into the muscles that terminate in relation to muscle cells.

The submucous, or Meissner's, plexus consists of a meshwork of relatively slender fiber bundles, with small ganglia located at nodal points (20). It is not confined to a definitively limited zone in the submucous layer; some fiber bundles lie near the circle of muscle layer and others lie close to the muscularis mucosae. Mechanical separation of the mucosa and submucosa from the outer muscular layer usually effectively removes the submucous from the circular muscle layer.

In addition to these two main plexuses are three variably developed plexuses (22): (a) the subserosal plexus, situated beneath the serosa and consisting of bundles of nerve fiber with few ganglia; (b) the deep myenteric plexus, situated within the circular muscle coat, similar in structure to the tertiary network of Auerbach to which it is continuous, and also connected with the adjacent submucous plexus; and (c) the mucous plexuses, which are widely distributed and are further named according to their positions in the mucosa—namely, subglandular, intraglandular, and intravillous mucous plexuses. These plexuses usually contain no neurons and are mere extensions of submucous plexuses.

Auerbach's plexus is associated with smooth musculature of the gut from the esophagus to the internal anal sphincter, including the biliary tract, and is also present in the striated muscle of the upper esophageal pharynx (21). The function of Auerbach's plexus in the striated muscle is not known, but it might innervate the muscularis mucosae, glands, and blood vessels (22). The density of ganglia in the myenteric plexus varies in different parts of the gut (24). In the esophagus the ganglia are scantier than in the stomach, small bowel, or colon. In the colon, the greatest concentration of neurons occurs in relation to the tenia. Few ganglia are found in the distal 2- to 3-cm segment of the rectum. This should be borne in mind to avoid making a wrong diagnosis of Hirschsprung's disease (25).

The ganglia in the submucous plexus are more abundant in the small bowel than in other parts of the gut. No ganglia are in the submucous plexus in the esophagus or in the anal canal distal to the pectinate line. During development the enteric ganglia first appear in the proximal gut wall and then migrate caudally toward the anus.

Enteric nerves are of three types (26). Type I cells have numerous thick dendrites and a single slender axon that enters one of the fasciculi to reach the target cells. These neurons are thought to have a motor function. Type II cells have long smooth dendrites that arise from the mucosa and are thought to be sensory neurons. Type III cells have dendrites of intermediate length that terminate in the same or neighboring ganglia; they might serve as interneurons or integrating neurons. It is thought that the submucous plexus contains only type II (sensory) neurons.

Electrophysiologic studies have found several distinct types of enteric neurons (27,28): (a) neurons that respond to sensory stimuli; (b) neurons that generate patterned outputs of spontaneously discharged action potential; and (c) neurons that show temporal coupling of firing with other neurons, suggestive of synaptic interaction between neurons. These results suggest that the enteric nervous system is capable of intrinsic integration and is involved in local reflex mechanisms (20).

The axons from the efferent intramural neurons are distributed to various effector cells, including the smooth muscle cells, secretory cells, absorptive cells, and endocrine cells. The axons branch and rebranch as they proceed to their target cells, and as they come into contact with the target cells, they end in a swelling that contains vesicles of neurotransmitters and they make synaptic contacts with the effector cells.

The intrinsic nervous system has contacts with the endings of axons of postganglionic sympathetic and parasympathetic neurons and afferent fibers that connect the intrinsic system with the central nervous system. This makes possible independent function by the intrinsic system; also, however, it can influence and be influenced by the extrinsic nervous system, which of course is under the influence of the central nervous system.

The gastrointestinal tract is rich in various cells that contain hormones and transmitter substances (22,29,30). A number of hormones are found together in the gut and in the brain, including gastrin, somatostatin, substance P, vasoactive intestinal polypeptide, and gastrin-releasing peptide. The gut also contains various chromaffin cells, particularly enterochromaffin cells. Some of these have a common origin in the neural crest and are included in a series of amine precursor uptake and decarboxylation (APUD) cells that share the common property of synthesizing and storing amines such as dopamine, histamine, and serotonin. These cells are probably innervated by the intrinsic autonomic nerves and thus might also influence the function of the intramural system, which appears to play a key role in the neuroendocrine regulation of the function of the gastrointestinal tract (22,31,32).

Summary of Neurologic Function

Parasympathetic and Sympathetic Nerves

The roles of the parasympathetic and sympathetic nerves are summarized in Table 65-4.

Afferent (Sensory) Innervation. The afferent fibers associated with the parasympathetic and sympathetic nerves are widely distributed throughout the gastrointestinal tract and other viscera in the abdomen. Approximately 90% of fibers in the vagus are afferents, and of these 80% to 90% are unmyelinated fibers (33). The rest are myelinated afferents of which the majority are A-d and a smaller percentage are A-b fibers. Studies in cats have shown that each greater splanchnic nerve contains 3,000 to 3,500 afferent fibers, which are less than 20% of the total numbers of fibers in this nerve (the remainder are preganglionic fibers) (6,33,34). The majority of these afferent fibers (2,000 to 3,000) are unmyelinated (C) fibers, 250 to 400 are A-d, and approximately 120 to 350 are A-b fibers. The lesser and least thoracic splanchnic nerves contain another 1,000 to 2,000 afferents, the lumbar splanchnic nerves contain approximately 4,600, and the sacral parasympathetic innervation contains approximately 7,300 afferents. Thus, it appears that a total of 22,000 to 25,000 spinal afferents (associated with splanchnic nerves and the sacral parasympathetics) are responsible for signaling afferent information from the abdominal and pelvic viscera of the cat.

Afferent fibers convey information about mechanical, chemical, thermal, and osmotic changes, which are transduced into impulses that are transmitted to integrating neurons in the neuraxis. In the neuraxis they are subjected to modulating influences and are transmitted either to efferent neurons at segmental levels or to the brainstem to provide information to the hypothalamus, limbic system, thalamic nuclei, and finally the cortex (see Chapter 3, Chapter 4 and Chapter 5).

Under physiologic conditions, these afferent fibers are involved in the regulation of visceral functions, in sensations, and in various spinal and supraspinal reflexes.

The mechanoreceptors consist of two types, those with a slowly adapting response able to detect static and dynamic events and those with a rapidly adapting response able to detect dynamic events only (35,36).

Slowly adapting mechanoreceptors have been shown to exist in the walls of the esophagus, stomach, and intestine; are *in series* with muscle fibers, and act as tension receptors rather than length receptors (37). They are stimulated by balloon distension and by spontaneous or drug-induced muscle contraction. These receptors lie in the muscle layer, and those in the stomach are of two types: receptors with a low-tension threshold that excite gastric centers in the neuraxis and cause reflex gastric activity, and those with a higher threshold that have inhibitory effects (37). It has been speculated that low-tension-threshold receptors help to set the level of smooth muscle contraction in the quiescent stomach, and when the stomach starts to contract, input from these receptors controls the timing and force of contraction. When the contraction becomes strong it can be inhibited by the high-threshold mechanoreceptors. The slowly adapting tension receptors also signal sensations of gastric distension and can mediate hunger pains resulting from gastric contraction in an empty stomach (22,37).

Rapidly acting mechanoreceptors are those that give an *on* and an *off* response when a steady mechanical stimulus is applied and later removed, but give no response while the stimulus is held steady. Rapidly adapting receptors have been found in the mesentery and include pacinian corpuscles beneath the serosa of the small intestine (e.g., movement receptors) and receptors in the muscularis mucosa of the intestine (muscularis mucosa receptors) and in the mucosa (mucosal receptors). The rapidly adapting receptors serve various functions. Mesenteric pacinian corpuscles located at the root of the mesentery and next to the branches of the mesenteric arteries stabilize blood flow through the splanchnic bed. The movement receptors located beneath the submucosa signal distortion of the intestine and the dynamic phase of inflation or deflation of an intraluminal balloon. The muscularis mucosa receptors are thought to act as the flow receptors, while some mucosal receptors are sensitive to tactile stimulation. The transitional epithelium in the anal canal possesses sensitive receptors that can distinguish between gas and liquid (36). They serve to let the flatus pass while retaining the feces.

Chemoreceptors can be activated by a chemical substance that acts as a stimulus either by its structural configuration or by its physical characteristics. Most of the chemoreceptors in the gastrointestinal tract, such as acid receptors and osmoreceptors, are activated by the physical characteristics of chemical substances (35,36,38). Acid receptors have been described in the gastric mucosa and duodenal mucosa and osmoreceptors have been identified in the duodenal mucosa (22,35).

In Chapter 3 and Chapter 7, mention is made of Cervero's experiments on the biliary duct of the ferret, in which he found low-threshold and high-threshold fibers and concluded that the high-threshold biliary afferents probably have a nociceptive function (39). His viewpoint was summarized in 1988 (40). JGnig and Morrison, however, in a comprehensive review (41), concluded that no evidence exists for a population of high-threshold afferents that would qualify as visceral nociceptors. Their analysis of an immense number of data on the functional and morphologic properties of spinal afferent neurons supplying the abdominal viscera led them to conclude that these neurons are functionally homogeneous (i.e., that the same population of afferents encodes various events that give rise to nonnoxious and noxious sensations, a number of reflexes, and to the regulation of viscera).

Most of the available data dispute both concepts and suggest that visceral sensory receptors encode nociceptive events by peripheral recruitment of receptors showing a wide range of threshold (summation). While this interpretation denies the existence of two distinct and separate populations of sensory receptors (nociceptive and nonnociceptive), it also does not support a notionally single population of afferent fibers with a narrow range of excitability threshold as claimed by JGnig and Morrison. Instead, it is based on the existence of different kinds of afferent fibers whose thresholds form a continuum ranging from anoxious to noxious levels. Thus, as the stimulus intensity increases, more and more of these receptors are activated and pain is felt by a process of central summation (38).

SUMMARY OF EVALUATION OF THE PATIENT

This section presents a general approach to the assessment of patients with abdominal pain. Each of the subsequent four chapters contains a more detailed description of the evaluation of patients presenting with disease suspected to involve specific organs. Obviously, other than in patients who are hemorrhaging and require urgent operative intervention, it is essential to obtain a detailed history and carry out a comprehensive physical examination, including a neurologic and orthopedic evaluation, as discussed in Chapter 12 and summarized in Table 60-1. In many cases it is also necessary to obtain laboratory data, including a complete blood count and urinalysis and, in specific cases, roentgenographic studies to detect free air and other soft tissue pathology. The text by Weiner is particularly useful in the differential diagnosis of acute abdominal pain (42).

History

As emphasized in Chapter 12 and elsewhere in this book, an orderly, systematic, and painstakingly detailed history is the most important aspect of the patient's assessment, and often the correct diagnosis can be made on the basis of the information obtained. Particularly important is inclusion of information about the rapidity of onset of the pain, its quality, intensity, duration, and temporal characteristics, and factors that relieve and aggravate it. If the pain has been present for several days before the patient seeks a physician's counsel, it is important to ascertain whether any of its features have changed and what time of the day the pain is better and what time it is worse. The patient should be asked specifically what effects the following activities or functions have on the pain: eating, swallowing, belching, deep breathing, coughing, straining, release of flatus, defecation, urination, lateral or forward flexion of the trunk or other movements, and supine and prone positions. Specific information should be obtained about associated symptoms and signs or phenomena such as nausea, vomiting, dyspnea, hematemesis, hemoptysis, melena, and the presence of weakness or numbness in various parts of the body. Details about the history of the pain are presented below.

Physical Examination

The physical examination should begin with a simple critical inspection of the patient regarding the facies, color, degree of hydration, respiratory movements, and the various other parts of the examination listed in Table 60-1, beginning with the abdomen and then the chest. In regard to the examination, Silen (8) emphasized that the amount of information to be gleaned from the physical examination is directly proportional to the gentleness and thoroughness of the examiner. In a patient

suspected of having peritonitis, one should avoid palpating deeply and eliciting rebound tenderness because this markedly aggravates the pain and increases reflex muscle spasm. The same information can be obtained by gentle percussion of the abdomen (rebound tenderness on a miniature scale, a maneuver that can be far more precise and localizing). Asking the patient to cough elicits true rebound tenderness without the need for placing a hand on the abdomen. Moreover, the brusque illustration of rebound tenderness startles and induces protective spasm in a nervous or worried patient in whom true rebound tenderness is not present. It is especially important to carry out a rectal (and vaginal, if appropriate) examination in every patient with abdominal pain. Similarly, it is essential to examine the chest and spine to exclude referred abdominal pain caused by disorders in these structures.

Laboratory Studies

The results of the laboratory examination, including a complete blood count, should be integrated with the information obtained from the history and physical examination. The urinalysis is helpful in providing some indication of the state of hydration and in ruling out severe renal disease, diabetes, and urinary infection. Determination of blood urea nitrogen, blood sugar, and serum bilirubin levels can also be helpful. Silen (8) emphasized that the serum amylase determination is overrated in helping to reach a diagnosis of acute pancreatitis because many other conditions, such as perforated ulcer, strangulating intestinal obstruction, and acute cholecystitis, can be associated with a marked increase in its value.

Plain and upright or lateral decubitus roentgenograms are useful in helping to reach a diagnosis of intestinal obstruction, perforated ulcer, and various other conditions that can be associated with pneumoperitoneum. Other specialized tests can be used in connection with disease of the gastrointestinal tract, liver, gallbladder, and kidney (see Chapter 66, Chapter 67, Chapter 68 and Chapter 69). There is little question that modern imaging techniques, such as ultrasound, computed tomography, and magnetic resonance scanning and radionuclide studies have led to major improvements in diagnostic accuracy.

Key Points to the Differential Diagnosis

The following points given here, as in Chapter 60, can help the physician in making a differential diagnosis. These include the various characteristics and location of the pain at the time of onset and during the interval between onset and the time the patient is being evaluated, as well as at the time of evaluation, its relation to other bodily functions, and associated signs and symptoms. Much of the information contained in this section is taken from the first edition of this book (43), from material by Currie (44) and others (45,46), and from material contained in the next four chapters.

Characteristics of Pain at Onset

Site of the Pain. The patient should be asked to point to the site of pain when the pain began. It is important to determine, if the pain was in the midline, whether it was located in the epigastrium, periumbilical area, or hypogastric region and, if it was felt on the side, whether it was in the upper or lower part of the side. The conditions that produce pain in these regions are listed in the following sections.

Time Course and Circumstances. Sudden severe pain that occurs instantaneously is a sign of perforated ulcer; rupture of an abscess or hematoma; rupture of the esophagus; rupture of ectopic pregnancy; rupture of infarct of an abdominal organ, heart, or lung; spontaneous pneumothorax; ruptured or dissecting aortic aneurysm; or ruptured spleen. Table 65-5 lists these and other conditions according to the rate or time course of onset (43).

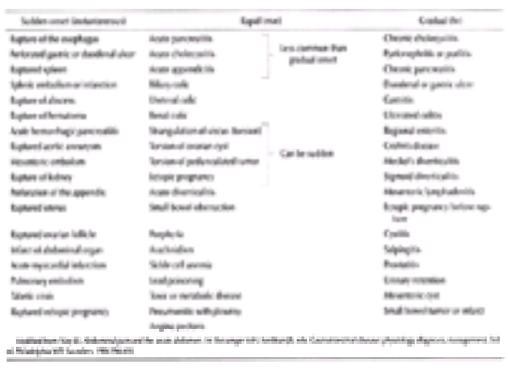

TABLE 65-5. Classification of abdominal pain according to the rate of onset

A clear statement of what the patient was doing at the time of onset of the pain is important (44). Did the pain follow an injury or intake of food, fluids, or alcoholic beverages? Did the pain occur while doing heavy work or carrying out a special movement? An injury to the upper abdomen, or to the lower chest and left flank, followed by sudden pain, should suggest rupture of the spleen. Pain that follows drinking alcohol should suggest pancreatitis, gastritis, peptic ulcer, or esophagitis. Sudden epigastric and lower chest pain that occurs with severe vomiting immediately after a large meal suggests perforation of the esophagus. If the pain developed during sleep and awakens the patient it is usually of organic rather than of psychological origin. Pain following endoscopic examination of any part of the gastrointestinal tract should immediately raise the suspicion of injury and possible perforation. Cramps followed by diarrhea are expected after a laxative, but cramps without diarrhea might indicate an obstruction (44). Sudden pain caused by straining, such as coughing, sneezing, or bearing down, suggests a neuropathic process if the pain is segmental or renewed enlargement of an abdominal aneurysm if the pain does not have a segmental distribution.

Quality. Sharp pain suggests pain of superficial cutaneous and somatic structural origin or pain that is being produced by a neuropathic lesion, such as radiculopathy of herpes zoster or that caused by compression of one or more of the lower seven thoracic spinal nerves. Segmental burning pain felt in the abdominal wall and lower part of the chest can be a result of postherpetic neuralgia or chronic neuropathic lesions of the spinal cord. Burning epigastric pain suggests peptic ulcer, gastritis, or esophagitis. Severe tearing abdominal pain suggests a dissecting aneurysm, while pain of the same quality in the anal region during defecation is caused by an anal fissure. Poorly localized, diffuse, *sickening* abdominal pain, difficult for the patient to describe, suggests abdominal visceral disease.

Intensity and Rate of Onset. The intensity or severity of the pain depends partly on the rate of change and the intensity of the stimuli. If the rate of change is slow, little or no pain is felt even though a pathologic process has progressed to a marked degree, whereas if the rate of change is rapid the pain is intense. Therefore, severe pain occurs with sudden obstruction of hollow organs, abrupt impairment of blood supply, chemical peritonitis caused by a ruptured viscus or hemorrhage, or acute inflammation. Moderate pain occurs with localized or chronic inflammatory disease and with progressive chronic obstruction by tumors or gradual enlargement of the liver, spleen, or kidney, with a consequent progressive increase in tension on the capsule. It is critically important to evaluate the patient's assessment of the intensity or severity of the pain within the framework of the psychological evaluation of the patient, as well as noting the specific manner (e.g., facial expression, pallor, frowning, clenched jaws, body position, movements) and the types of words the patient uses.

Time of Day or Month. Information should be obtained about the time of day and perhaps month that the pain is aggravated or relieved. Peptic ulcer pain, especially that caused by duodenal ulcer, tends to occur several hours after breakfast, at midmorning coffee time, just before lunch, several hours after lunch, immediately before supper, a few hours after supper, and during the night (44). Pain that awakens the patient at night is more frequently seen with duodenal ulcer disease. The pain of peptic ulcer rarely begins before breakfast, which is in contrast to the pain of irritable colon that usually starts early in the morning.

Back pain, especially if it causes the patient to awaken, is significant and usually indicates significant disease. Currie (44) attributed this to the fact that sleep allows increased autonomic activity so that the pain of peptic ulcer and cramping pain can be bothersome at night. Burning retrosternal pain, felt when the patient first lies down, is typical of heartburn caused by esophageal reflux. The constant pain of an infiltrating tumor can also be more distressing to the patient once the distractions of the day cease. Pain of primarily psychological origin rarely awakens the patient but, if such a patient has insomnia, it can produce troublesome discomfort at night (44).

Lower abdominal pain occurring 2 weeks before expected menstruation can be caused by bleeding at ovulation. The problem is not likely to occur in women who take contraceptive pills because these generally suppress ovulation and, consequently, pain from such bleeding is unlikely to occur. Currie (44) stated that a venereal infection can become established more readily during menstruation than at other times, and therefore acute salpingitis associated with lower abdominal pain occurs

more frequently soon after menstruation than at other times in the menstrual cycle.

Characteristics of the Pain since Onset and at Present Time

Any change in location, quality, intensity, and duration of the pain during the interval between onset and the time the patient is being evaluated is important in deciding on the diagnosis. In most diseases of the gastrointestinal tract the initial pain is true visceral pain and is felt as a poorly localized, diffuse, sickening pain in the midline. Spread of the infection and inflammation to the parietal peritoneum causes more localized and rather sharp burning pain in one region of the abdomen. The classic example is the steady or cramping periumbilical pain with acute appendicitis that changes to a well-localized pain at McBurney's point in the right lower quadrant of the abdomen. Similarly, biliary colic initially produces pain usually in the midline but, when this is complicated by acute cholecystitis, the patient begins to have pain in the right upper quadrant and often in the inferior angle of the right scapula (referred parietal pain). If the pathologic process worsens, empyema, gangrene, and perforation with diffuse peritonitis produce diffuse parietal pain and referred parietal pain in the right shoulder and trapezius region.

Steady visceral pain suggests increasing distension or ischemia, whereas cramping pain indicates exaggerated intestinal activity. Most patients with visceral pain are likely to experience change with time and therefore require repeated evaluation. This is especially true of patients with an undiagnosed abdominal pain because of possible changes in the quality and location of the pain and with probable changes in abdominal physical signs, any of which can help in the diagnosis (44). With each examination it is important to assess the location, quality, intensity, and temporal characteristics of the pain, as well as to determine factors that make the pain worse or better. These include such factors as the type and amount of food intake, changes in bodily functions, and, most important, the associated symptoms and signs.

Temporal Features. Acute continuous pain is encountered with peritonitis secondary to a ruptured viscus, impairment of blood supply, hemorrhage into the abdominal cavity, and an increase in the tension of the supporting elements of organs (capsules, ligaments, or mesentery). Intermittent or colicky pain is usually caused by intermittent and recurrent disturbances of the function of a hollow viscus. This can be produced by the following conditions: (a) intrinsic lesions, such as tumors, stones, intussusception, segmental enteritis, or extrinsic factors, such as hernias, tumors, bands, or torsion; and (b) metabolic ileus, which can either be spastic (e.g., lead intoxication, porphyria, uremia, diabetes, arachnidism, endocrine disorders) or mesenteric embolism or thrombosis, hypoxemia secondary to pneumonia, or potassium and sodium deficit. Constant chronic pain suggests a progressively developing or static lesion such as cancer. Constant pain felt in different parts of the abdomen usually implies a functional or emotional disorder rather than a progressive disease such as neoplasm.

Aggravating and Relieving Factors. Food or Fluid Intake.

The type, quality, and quantity of food eaten aggravate various pathophysiologic processes and consequently the intensity, character, and duration of the pain. Appealing and tasty foods, including sweets and such irritants as hot and cold foods, spices, acids, and alcoholic beverages, increase gastric acidity and thus aggravate the pain of peptic ulcer, gastritis, and reflux esophagitis (44). Food roughage is also said to increase the pain of peptic ulcer. Peptic ulcer pain becomes worse several hours after eating, when gastric acid is unbuffered because food has left the stomach. Intake of fatty food delays gastric emptying and thus delays the onset of the peptic ulcer pain that occurs after meals. Fatty foods stimulate the gallbladder to contract and can precipitate or aggravate biliary colic. Protein stimulates pancreatic secretion so that foods rich in protein can exacerbate the pain of pancreatitis. Food or alcoholic beverages tend to aggravate pancreatitis regardless of its cause. Lactose contained in dairy products causes bloating, cramps, and diarrhea in lactase-deficient individuals. Aerophagia, or air swallowing, can cause gastric distension with consequent abdominal distress within a few minutes of eating. Because eating stimulates the gastrocolic reflex that produces stimulation of the lower intestine, pain that might exist in the lower bowel is intensified by eating.

Relieving Factors. Factors that relieve abdominal pain are often opposite to those that aggravate it, although some exceptions to this rule have been noted (44). Fasting does not relieve but rather aggravates the pain of peptic ulcer; this can be relieved by bland, soft, unstimulating foods. Peptic ulcer pain is best controlled by food ingestion and antacid medication. The time that it takes for the medication to relieve burning pain is of significant diagnostic importance (44). Immediate relief on swallowing a liquid antacid localizes the site of irritation to the esophagus, whereas in patients with gastric or stomal ulcer relief occurs within 10 to 15 minutes, and that of duodenal ulcer takes 7 to 15 minutes (44). Avoiding fatty foods does not relieve biliary colic but might prevent some attacks.

Avoiding large meals or food altogether affords some relief in patients with painful lower intestinal disorders. The partial small bowel obstruction in Crohn's disease improves with starvation. Avoidance of lactose-containing dairy products can relieve abdominal bloating, cramps, and diarrhea. Similarly, belching relieves the distress of early postprandial pain caused by air swallowing. Pain from lesions of the lower bowel is relieved by a bowel movement, and urgent defecation followed by relief of periumbilical visceral pain occurs frequently in patients with regional ileitis. Unplugging a colonic obstruction by enemas or intubating a sigmoid volvulus produces immediate relief with passage of flatus and liquid feces. Temporary relief of abdominal pain might not indicate improvement but can be followed by worsening of the patient's condition. Frequent examples are the temporary relief of local pain consequent to rupture of an empyema of the appendix or gallbladder or to rupture of an acute paracolic abscess or other intraabdominal abscess into the peritoneal cavity.

Relation to Other Bodily Functions. Pain intensified by movement of the diaphragm suggests thoracic visceral disease, diaphragmatic disease, or subphrenic abscess or disease of the upper abdominal viscera. Pain aggravated by factors such as movement of the trunk, coughing, or sneezing suggests a radiculopathy or neuropathy caused by tumor or compression in the spine. Pain made worse by the supine position and improved by forward bending suggests acute pancreatitis or cancer of the pancreas. Recumbency, straining, or stooping aggravates the pain of esophageal reflux disease, whereas standing or forward bending relieves it. Back pain or upper abdominal pain that appears while the patient is standing an hour or so after drinking fluids, and is relieved soon after lying down, suggests poor drainage from the renal pelvis. Pain made worse by contraction of abdominal muscles suggests myofascial pain syndromes or trauma with hemorrhage into the muscle.

Associated Symptoms and Signs

Symptoms. The time relation of nausea, vomiting, diarrhea, and obstipation is an important point to aid the differential diagnosis between abdominal visceral disease and extraabdominal causes of pain (43,44,45 and 46). Vomiting without nausea suggests central nervous system disease (4). In patients with abdominal visceral disease, nausea and vomiting are usually accompanied by autonomic reactions such as sweating, pallor, palpitation, weakness, and fainting. Fainting alone can indicate the presence of severe pain. Other than diseases of the central nervous system, vomiting is preceded by anorexia and nausea. Nausea and vomiting occur readily in children with gastroenteritis, in alcoholics, and in adults with peptic ulcer disease. However, recurrent vomiting in children between ages 1 and 10 is more likely to be associated with a posterior fossa brain tumor than diseases of the abdominal viscera. Pyloric obstruction, with which the stomach is greatly distended, causes vomiting of large volumes. The large vomitus can contain recognizable vegetable matter eaten several meals prior to the vomiting but does not contain bile if the pylorus is completely occluded, whereas the presence of bile indicates that the pylorus and biliary ducts are open. Early and frequent vomiting occurs with small bowel obstruction. Toxic vomiting complicates pancreatitis, gastritis, peritonitis with advanced ileus, and high small bowel obstruction.

Signs. The presence of hyperalgesia or hyperesthesia that has a segmental distribution is of diagnostic value because it suggests a neuropathic origin of the pain. Marked localized tenderness to palpation indicates inflammation of visceral disease and, because it usually occurs directly over the involved organ, its diagnostic value is obvious. Reflex spasm of the abdominal muscles occurs with neuropathic and musculoskeletal disorders as well as with intraabdominal visceral disease but, in the latter, the spasm is more marked and is aggravated by deep pressure. In acute abdominal conditions, such as appendicitis, cholecystitis, and acute pancreatitis, spasm of the rectus muscle occurs over the involved structure. It is important to differentiate between voluntary and involuntary (reflex) spasm. The presence of distension indicates obstruction of the gastrointestinal tract (see Table 65-1 for causes). An abdominal mass associated with the pain is of course diagnostically significant because it could be the direct or indirect cause of the pain.

Location and Distribution. The location and distribution of pain at the time of assessment are important diagnostic characteristics. Segmental pain suggests radiculopathy or neuropathy, whereas pain that does not conform to dermatomal or peripheral nerve distribution is either visceral or musculoskeletal in origin. Abdominal visceral diseases have relatively specific areas of pain reference. For example, the pain of hepatic or biliary disease is in the epigastrium or right hypochondrium with radiation to the right posterior chest, lumbar region, and scapula. It is obviously important to know the possible causes of pain in the various regions of the abdomen (see Fig. 65-1).

Generalized Abdominal Pain. Generalized abdominal pain occurs with acute or chronic peritonitis caused by bacteria, tuberculosis, fungal infection, parasitic disease, granulomatous peritonitis, widespread neoplasm of the peritoneum such as primary mesothelioma, secondary carcinomatosis, vasculitis, Henoch-Schönlein purpura, eosinophilic peritonitis, Whipple's disease, and sclerosing peritonitis, as well as with acute intestinal obstruction, gastroenterocolitis, chronic ulcerative colitis, dysentery, epidural spinal cord compression, acute rheumatic fever, brucellosis, typhoid fever, sickle cell anemia, lead poisoning, and other generalized processes that cause metabolic disturbances of the gastrointestinal tract. Psychological and environmental factors are often primary causes of pain in the abdomen, especially in

children and women. This pain can be generalized or frequently can be in the periumbilical region.

Pain in the Epigastrium. Pain in the epigastrium is produced mainly by lesions of the stomach, gallbladder, duodenum, pancreas, liver, lower esophagus, heart, lungs, and certain nervous system disorders (see Fig. 65-13). The most important include chronic peptic ulcer, perforated ulcer, acute gastritis, pylorospasm, gastric carcinoma, acute and chronic pancreatitis (early), cholecystitis with lithiasis (early), perforation of the lower esophagus, chemical or bacterial esophagitis, myocardial infarction, pericarditis, congestive heart failure, and epigastric hernia. Less common causes include ulcer of the lower esophagus, aneurysm of the abdominal aorta, primary or metastatic tumors of the lower thoracic spinal cord, gastric crisis (tabes dorsalis), diaphragmatic hernia, acute hepatitis, diabetic acidosis, myofascial syndromes, pleurisy, and pericarditis.

Pain in the Right Hypochondriac Region. Pain in the right hypochondriac region is usually produced by diseases of the liver and gallbladder, hepatic flexure of the colon, diseases of the right chest or right hemidiaphragm, and disorders of the nervous system, muscle, and bone. The most important diseases include acute and chronic cholecystitis, biliary colic, cancer of the liver or gallbladder, abscess of the liver or pancreas, acute or chronic hepatitis, right hemidiaphragmatic pleurisy, subphrenic abscess, duodenal ulcer, right segmental or intercostal neuralgia, postcholecystectomy syndrome, right-sided slipped costal cartilage, pneumonia, and pleurisy. Less common causes include tender postoperative or posttraumatic scar, gas entrapment at the hepatic flexure of the colon, carcinoma of the hepatic flexure of the colon, and carcinoma of the bile ducts.

Pain in the Left Hypochondriac Region. Pain in the left hypochondriac region is usually caused by disease of the spleen, splenic flexure of the colon, lesion of the left chest, cancer of the tail of the pancreas, and neurologic and musculoskeletal disorders. The most common are embolism or thrombosis of the splenic vessels, splenic infarction, splenic abscess, splenomegaly, colitis, carcinoma of the splenic flexure of the colon, ruptured spleen, left-sided pneumonia, pleurisy, segmental or intercostal neuralgia, gas entrapment syndrome in splenic flexure of the colon, left-sided slipped costal cartilage, diaphragmatic hernia, pericarditis, and angina pectoris. Less common causes include contusion of the spleen, perisplenitis, abscess of the spleen, tuberculosis or amyloid disease of the spleen, congestion of the spleen, and neoplasm of the cardia of the stomach.

Pain in the Right or Left Lumbar Regions. Pain in the right or left lumbar (lateral) region is caused by disease of the kidney, ureters, head or tail of the pancreas, and colon. The most common causes include carbuncle or furuncle of the kidney, perinephritic abscess, pyelitis, pyelonephritis, renal abscess, tuberculosis of the kidney, tumor of the kidney, postnephrectomy pain syndrome, and segmental or intercostal neuralgia of one or more of the T-8 to T-11 nerves resulting from mechanical compression by tumors or vertebral disease.

Pain in the Periumbilical Region. Pain in the periumbilical region is usually a result of disease of the small intestine, appendix, cecum, body of the pancreas, or of neurologic or musculoskeletal disorders. The most common causes are acute intestinal obstruction, acute diverticulitis, chronic intestinal obstruction, Meckel's diverticulitis, embolism of the superior mesenteric artery, metabolic ileus, enterocolitis, regional enteritis, umbilical hernia, tabes dorsalis, bilateral segmental (T-9 to T-11) neuralgia, myofascial syndromes, and postoperative scars. Periumbilical pain in children and women is frequently caused by psychological and environmental factors. Less common causes include peptic ulcer, cholelithiasis, epithelioma of the umbilicus, pancreatic calculi, omphalitis, omental cyst or carcinoma, aneurysm of the abdominal aorta, tumors of the spinal cord, and segmental or intercostal neuralgia.

Pain in the Right Iliac Region. Pain in the right iliac region of the abdomen is usually caused by disorders of the appendix, small intestine, cecum, right kidney and ureter, and right uterine tube or ovary or by neurologic or musculoskeletal disorders. The most important include acute appendicitis, acute salpingitis, ruptured ectopic pregnancy, chronic salpingitis, oophoritis, twisted ovarian cyst, ruptured graafian follicle, acute oophoritis, Meckel's diverticulitis, renal colic (see Table 65-6 for causes), acute pyelitis, carcinoma of the cecum, inguinal hernia, Crohn's disease, iliac adenitis, acute epididymitis, right psoas or midabdominal abscess, segmental neuralgia of T-12 to L-1 nerves, and postoperative scar. Less common causes include inguinal adenitis, ileocecal adenitis, sarcoma of the ilium, suppurative periostitis of the ilium, strangulated retroperitoneal hernia, sigmoid volvulus, and aneurysm of the iliac artery.

Pain in the Left Iliac Region. Pain in the left iliac region is usually caused by disease of the sigmoid colon, left urinary tract, and internal genitalia (female) or by neurologic or musculoskeletal disorders. The most common causes include acute salpingitis, chronic salpingooophoritis, ectopic pregnancy, twisted ovarian cyst, ruptured graafian follicle, acute oophoritis, ulcerative colitis, midabdominal or psoas abscess, acute diverticulitis, carcinoma of the sigmoid colon, sigmoid volvulus, intussusception (children), intestinal obstruction, fecal impaction, inguinal hernia, acute epididymitis, left lower ureteral calculus, radiation of pain from disease of the kidney and pelvis, segmental neuralgia (e.g., herpes zoster, herniated disk, spinal tumor), segmental neuralgia of lower thoracic nerves (e.g., vertebral disease, osteoarthritis, tumors, deformity), iliohypogastric and ilioinguinal neuralgia (e.g., retroperitoneal tumor, infections), lumbar myofascial syndrome, left psoas abscess, and postoperative scar. Less common causes include disease of the hip and sacroiliac joints, aneurysm of the left iliac artery, strangulated retroperitoneal hernia, rectal polyp, and cyst of the canal of Nuck.

Pain in the Hypogastric Region. Pain in the hypogastric region is usually caused by urinary bladder, internal genitalia, and intestinal diseases or by neurologic or musculoskeletal disorders. The most common causes include acute cystitis, urinary bladder distension, prostatitis, seminal vesiculitis, hypertrophy of the prostate, calculi in the urinary bladder, carcinoma of the urinary bladder, ulcer of the urinary bladder, various diseases of female genitalia (including dysmenorrhea, acute salpingitis, ruptured ectopic pregnancy, acute or chronic endometritis, retrodisplacement of the uterus, carcinoma of the uterus, pelvic peritonitis, and prolapse of the uterus), acute diverticulitis, volvulus, intussusception, chronic colitis, rupture of the urinary bladder, tumors of the rectosigmoid, Meckel's diverticulum, chronic constipation, regional enteritis, various neuralgias (see previous discussion), myofascial syndromes, and occasionally postoperative scar.

CHAPTER 66

Painful Diseases of the Gastrointestinal Tract

Richard W. Tobin and Michael B. Kimmey

Pain is an important and common symptom of gastrointestinal tract disease. It can be the first indication of a new pathologic process, or it can signify a change in a known condition. The recognition of the pain pattern and its significance is crucial to the early diagnosis and treatment of these problems. The relief of pain is frequently of diagnostic importance and is often the best indicator of successful treatment.

Abdominal pain is a common complaint. One survey of more than 1 million adults selected randomly from the U.S. population found current complaints of “stomach pain” in 13% and “pain in lower abdomen” in 11% of men and in 17% of women who responded to the questionnaire (1). Because abdominal pain caused by diseases of the gastrointestinal tract can be mimicked by painful conditions of other abdominal and extraabdominal structures, the evaluation of this symptom often requires physicians to use the full breadth of their medical knowledge.

A patient with abdominal pain of gastrointestinal origin can be completely disabled by this symptom. This disability involves all aspects of the patient's life, including bodily functions, employment, and family relations. These problems can be continuous, as in a patient with unresectable cancer or, more commonly, can be intermittent, as in inflammatory bowel disease or the irritable bowel syndrome. The complex interaction between the course of inflammatory bowel disease and psychological factors is a good example of the importance of the patient's family and social environment (2). Recurrent pain can cause the disruption of employment or family structure; psychosocial influences can affect the activity of the inflammatory bowel disease.

Painful gastrointestinal diseases have a large economic impact as well. For example, irritable bowel syndrome is a leading cause of absence from work and is the basis of extensive use of diagnostic facilities; drugs for peptic ulcer disease (PUD) and gastroesophageal reflux, such as the H_2-receptor blockers and proton pump inhibitors (PPIs), are among the most widely prescribed prescription medications.

In this chapter, the diagnostic and therapeutic principles outlined previously are applied to painful diseases of the gastrointestinal tract. The information is presented in four sections: General Considerations of Diagnosis and Management; Diseases of the Stomach and Duodenum; Diseases of the Small and Large Intestines; and Diseases of the Anus and Rectum. The beginning of each section contains a brief discussion and illustrations of the anatomy and nerve supply of each specific viscus, contributed in part by Bonica.

GENERAL CONSIDERATIONS OF DIAGNOSIS AND MANAGEMENT

The management of abdominal pain caused by gastrointestinal disease is based on accurate diagnosis. The history, physical examination, and use of selected laboratory tests and procedures usually yield the correct diagnosis and a list of differential diagnoses, and help to determine further management. The severity and acuteness of pain often determine the pace of further diagnostic testing. This chapter does not discuss extraintestinal or extraabdominal causes of abdominal pain because they are presented in Chapter 65, Chapter 67, Chapter 68, and Chapter 69.

History

The character and location of the pain often help to suggest the mechanism of the pain. The location, intensity, rate of onset, quality, duration, frequency, time of day, and relationship to factors that increase or decrease the pain should be determined for each pain described by the patient. The sudden onset of severe pain that does not diminish, for example, is characteristic of a perforated viscus, embolism, torsion, or hemorrhage. Crampy intermittent pain is commonly caused by intestinal disease, but urinary system and fallopian tube problems can also cause crampy pain. Pain severity can be a misleading feature because of individual differences in pain perception or responses to painful stimulation. Nonetheless, the most severe pains of abdominal origin are caused by intestinal infarction, perforated ulcer, dissecting aortic aneurysm, and ureterolithiasis. Associated symptoms are also useful in diagnosis. Upper gastrointestinal symptoms of nausea, vomiting, anorexia, and bleeding should be sought. Useful lower digestive tract symptoms include diarrhea, constipation, flatulence, and bleeding, as well as stool color and caliber. A review of urinary and gynecologic symptoms should also be obtained. Other systemic symptoms, such as weight loss or fever, are also helpful.

Physical Examination

Physical examination of the patient with abdominal pain often determines the immediate management course. General examination can reveal signs of increased autonomic activity that are associated with visceral pain, such as flushing, diaphoresis, tachycardia, and mydriasis. Body posture can suggest certain diagnoses. Patients with intestinal or renal colic move frequently in an attempt to decrease the pain, often in a writhing fashion; on the other hand, patients with peritonitis lie quietly on their back, usually with knees and hips flexed to reduce pain. Abdominal examination must be thorough and include inspection, auscultation, palpation, percussion, and rectal examination. Signs of peritonitis on examination dictate a more expedient evaluation, usually culminating in surgical exploration of the abdomen.

Laboratory Evaluation

Laboratory evaluation should be directed by the diagnoses suggested by the history and physical examination. Hematocrit, white blood cell count, and urinalysis are useful and inexpensive tests that are obtained on most patients with abdominal pain. Serum liver function tests (e.g., bilirubin, alanine aminotransferase, alkaline phosphatase), creatinine, and amylase or lipase can be useful for excluding diseases of the liver, bile ducts, kidney, and pancreas. Abdominal roentgenograms are useful in the acute setting in patients with moderate or severe abdominal tenderness, after abdominal trauma, and when the clinician suspects bowel obstruction, ischemia, perforation, or renal and biliary calculi (3). *Helicobacter pylori* infection in the stomach has been found to be closely associated with PUD. Evidence for *H. pylori* infection can be obtained by serum antibody testing, urease-based testing (of gastric biopsy specimen or by urea breath test), or by histopathologic examination of gastric mucosa (4).

Contrast radiography and fiberoptic endoscopy of the gastrointestinal tract are complementary in the diagnosis of diseases of the stomach, proximal small intestine, and colon (5,6). The choice of test depends on the clinical situation and on local availability and expertise. A study comparing upper endoscopy and the double-contrast barium meal in patients with upper gastrointestinal symptoms found endoscopy to be particularly useful in patients who were unable or unwilling to cooperate with the maneuvers required for a radiologic examination (5). Several studies have suggested that endoscopy is more specific and sensitive than

roentgenography. Diagnosis of small intestinal disease depends primarily on radiographic examination, although small bowel enteroscopy can be helpful in certain circumstances. Plain abdominal radiographs, contrast examinations, arteriography, ultrasound, and computed tomographic (CT) scanning are useful in the diagnosis and management of intestinal causes of abdominal pain (7).

Pathophysiology

Understanding the mechanism of gastrointestinal tract pain is diagnostically useful. Most pain from the gut begins with stimulation of visceral pain receptors (see Chapter 3). Relatively little is known about the anatomy and physiology of gut pain receptors (8). Mucosal and serosal inflammation, traction on the mesentery, rapid luminal distension, ischemia, and forceful smooth muscle contraction under isometric conditions (i.e., with obstruction distal to the contraction) are known stimulants of these pain receptors (8). These receptors are endings of the A-d and C afferent nerve fibers that accompany the sympathetic nerves from the stomach and small and large intestine, which pass through the celiac plexus and subsidiary plexuses, the splanchnic nerves, the sympathetic chain, and the white rami communicantes and have their cell bodies in dorsal root ganglia of spinal nerves. Pain fibers from the rectum accompany the parasympathetic fibers to the dorsal root ganglia of the S-2 to S-4 spinal nerves. Central nervous system pathways for visceral afferent (nociceptive) fibers are similar to those of somatic afferent nerves. Cortical areas receiving visceral pain sensations are intermixed with those receiving somatic pain input (see Chapter 5).

The characteristics of visceral pain have been described in Chapter 3 and Chapter 12. Visceral pain caused by distension, inflammation, or ischemia of the gut can be a continuous aching or gnawing, or can be of a burning character (9,10). An intermittent cramping sensation is produced when a strong smooth muscle contraction is the source of pain. Forceful gut contraction can be a result of increased peristalsis without obstruction, as in gastroenteritis, or it can be stimulated by distal mechanical obstruction. Visceral pain is generally poorly localized, is often described as deep within the abdomen, and can be associated with signs of autonomic overactivity. This type of pain is most commonly felt in the midline because most areas of the gut have bilateral spinal connections. Some healthy subjects and many patients with the irritable bowel syndrome, however, have lateralizing pain in response to luminal distension (11).

Gastrointestinal diseases cause somatic pain when they involve the parietal peritoneum or the anus. Peritoneal irritation can either be localized or diffuse. When an inflamed organ, such as the appendix, or a colonic diverticulum touches the peritoneum, a well-localized and usually severe somatic pain is felt by the patient. A perforated ulcer, on the other hand, causes a generalized peritonitis with severe diffuse abdominal pain. Either of these pains is usually aggravated by any movement of the patient. The anal canal is also innervated by somatic nerves, so inflammatory and infiltrating diseases in this area can produce a severe, well- localized pain.

Treatment

Management of gastrointestinal pain involves both treatment of the underlying disorder causing the pain and the use of nonspecific pain-relieving measures. Specific treatment of the underlying disease usually leads to improvement of symptoms, which is often the best indicator of successful therapy. On the other hand, use of nonspecific measures, such as systemic analgesics and nerve blocks, is also an important part of the therapeutic approach to patients with abdominal pain. Nonspecific pain relief is indicated in situations in which specific corrective therapy is not available, such as patients with advanced gastric or colon cancer. Nonspecific pain control measures should also be used for patients with benign disease while they are awaiting specific therapy.

Pain relief is an important part of patient management during therapy for gastrointestinal disease. The selection of nonspecific analgesic measures depends on the severity of pain and on the nature of the underlying disease. Simple measures, such as the application of heat or change in diet, are effective in some situations. Potent narcotic analgesics are required in other circumstances. Caution should be exercised, however, in the use of potent analgesics before a diagnosis or specific diagnostic plan is made. Pain might be the only symptom of a significant underlying disease; masking pain could thus delay diagnosis and definitive therapy (12). However, we are unable to locate other references or personal experience to scientifically address the validity of this standard shibboleth.

Complete pain relief should be a management priority in patients awaiting surgical treatment. The use of adequate quantities of narcotic analgesics to relieve pain should not be deterred by concerns of respiratory depression and addiction (see Chapter 84). Pain is a powerful respiratory stimulant, and the short-term use of narcotics does not cause psychological or physical dependence. Pain that is not relieved by parenteral narcotic analgesics can often be managed with subarachnoid or epidural narcotics. Splanchnic and celiac plexus blocks with long-acting local anesthetic agents are also useful in the management of intractable pain while patients are awaiting specific therapy.

DISEASES OF THE STOMACH AND DUODENUM

Basic Considerations

Anatomy

An understanding of the anatomy and embryology of the stomach and duodenum is useful in the diagnosis and management of painful diseases of these organs (Fig. 66-1). The stomach is fixed proximally at its attachment to the distal esophagus, where the esophagus penetrates the diaphragm. This esophagogastric junction is just to the left of midline at the level of the T-10 vertebra. The stomach has a variable shape but lies predominantly in the left upper quadrant. The distal end of the stomach crosses the midline at approximately the level of the L-1 vertebra and is separated from the duodenum by a band of connective tissue and muscle fibers, which constitute the pyloric sphincter. The portion of the duodenum proximal to the papilla of Vater originates from the embryonic foregut. The distal duodenum is derived from the midgut and passes posterior and to the left of the midline to become the jejunum at the ligament of Treitz.

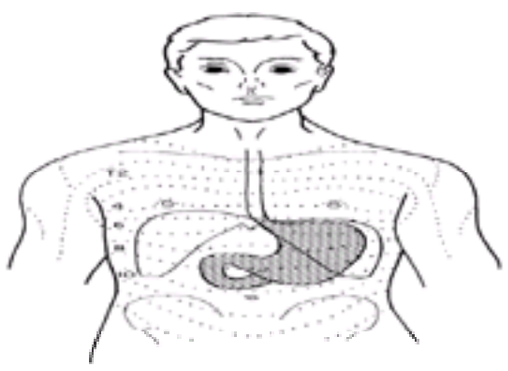

Figure 66-1. Location of the stomach and duodenum in relationship to the diaphragm and the dermatomes.

Nerve Supply

As in the rest of the gastrointestinal tract, pain receptors in the stomach and duodenum are stimulated by distension, traction, and direct pressure generated by contraction of the muscles of these structures. Local inflammation and ischemia lower the receptor threshold to nociceptive stimuli. These nociceptive stimuli are transmitted through afferent pathways that accompany the visceral sympathetic fibers through the celiac plexus, the greater splanchnic nerves, the paravertebral sympathetic chain, and the white rami communicantes, and have their cell bodies in dorsal root ganglia of spinal nerves, which in turn transmit the impulse to the dorsal horn of the spinal cord. Nociceptive impulses from the stomach and proximal portion of the duodenum are transmitted primarily through the T-6 to T-10 roots inclusively, although in some individuals the T-5 or T-10 root (or both) is also involved (10). Nociceptive impulses from the distal portion of the duodenum are transmitted to the spinal cord through the T-8 to T-10 spinal nerves, although T-11 and, rarely, T-12 can also be involved. The nerve supply of the stomach and duodenum is illustrated in Figure 66-2.

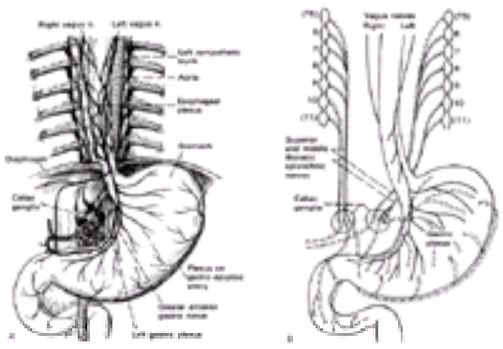

Figure 66-2. Innervation of the stomach and duodenum. **A:** Relationship of the vagus nerves and the thoracic sympathetic chain and their distribution to the lower esophagus and to the stomach and duodenum. As noted, both vagus nerves continue from the esophagus to the stomach, where the anterior vagus trunk passes along the lesser curvature to the stomach, supplying the anterior surface of this viscus as far as the pylorus. The posterior vagus gives off branches that are distributed to the posterior part of the stomach. Both nerves give off one branch that is greater than the others, and hence are called the *greater anterior gastric nerve* and *greater posterior gastric nerve*, respectively. The various gastric branches can be traced for some distance before they sink into the muscle coat, where they synapse with postganglionic parasympathetic neurons. The vagus nerves also give off celiac branches that pass along the left gastric artery and reach the celiac plexus, where they intermingle with sympathetic fibers. Vagal fibers from the celiac branches are distributed to the pylorus and duodenum. Both vagi have afferent fibers that transmit sensory information, except nociception. The sympathetic preganglionic fibers derive from the paravertebral sympathetic chain, pass peripheralward as the superior (greater) thoracic splanchnic nerves, and end in the celiac ganglia, where they synapse with postganglionic neurons. The axons of the latter pass to the stomach and duodenum along the side of the various branches of the celiac and superior mesenteric arteries, around which they form plexuses. These arterial plexuses are comprised mainly of sympathetic efferent and afferent (nociceptive) fibers but also contain some parasympathetic fibers, which, as mentioned previously, reach the celiac plexus by way of the celiac branches of the two vagal trunks. The celiac plexus breaks up into subsidiary plexuses that follow the various arteries to the stomach and duodenum to supply these structures. **B:** Innervation of the stomach and duodenum by the vagus nerves and by the segmental sympathetic and sensory nerve supplies. The solid lines for the vagus and sympathetic nerves indicate preganglionic fibers, the dashed lines indicated postganglionic fibers, and dotted lines indicate the nociceptive pathways. The parentheses for T-5 and T-11 indicate that these are inconstant segments. Frequently, the celiac ganglia are composed of more than two, as shown here. (See Chapter 65 for more details of the origin and relation of these nerve pathways.) (Modified from Netter FH. Innervation of the stomach and duodenum. In: *CIBA collection of medical illustrations.* Vol 3, Digestive system. Part II, The digestive tract. West Caldwell, NJ: CIBA Pharmaceutical Co., 1959:64, 65, and Bonica JJ. *The management of pain*. Philadelphia: Lea & Febiger, 1953:395, 397.)

Characteristics of the Pain

Visceral pain originating in the stomach is usually felt in the midepigastric area (9). Gastric diseases that involve the overlying parietal peritoneum can cause pain in the left upper quadrant alone or can be combined with epigastric pain. Diseases of the duodenal bulb cause visceral pain that is usually felt in the epigastrium, but occasionally also in the right upper quadrant. Diseases of the distal duodenum cause pain that is usually felt in the periumbilical region.

Clinical Considerations

Anatomic Abnormalities

Most congenital abnormalities of the stomach and duodenum present in infancy or early childhood with symptoms of gastric outlet obstruction. Epigastric pain that is exacerbated by eating and relieved by vomiting is characteristic. Hypertrophic pyloric stenosis is most commonly seen in infants, but can rarely be found in adults who present with vomiting, epigastric pain, and weight loss. Partial or complete duodenal obstruction caused by webs or atresia, malrotation, or an annular pancreas can also present with similar symptoms. Treatment by surgical correction of the underlying abnormality is usually successful in these conditions.

Paraesophageal hiatal hernias are caused by a diaphragmatic defect adjacent to the esophagogastric junction, which allows herniation of large portions of the stomach into the thorax. Patients with this disorder often complain of epigastric fullness or mild discomfort. The most feared complication of this anatomic defect is acute gastric volvulus caused by rotation of the stomach on its longitudinal axis (13). Patients with acute gastric volvulus usually present with epigastric pain and forceful vomiting. This diagnosis should be suspected when these symptoms are present, and there is difficulty in passing a nasogastric tube. Radiographic contrast examination should confirm the diagnosis of a paraesophageal hiatal hernia and acute gastric volvulus, if present. Emergency surgery is required in the latter situation. Some surgeons recommend elective surgery in all cases of paraesophageal hernia to prevent the development of a volvulus (13).

Dyspepsia, Nonulcer Dyspepsia, Gastritis, and Duodenitis

In the past, the term *dyspepsia* has been used to describe multiple upper gastrointestinal tract symptoms, including bloating, nausea, belching, and indigestion, but this term is most appropriately used when the predominant symptom is abdominal discomfort centered in the upper abdomen. Dyspepsia is a common complaint in the United States. Approximately one in four persons reports recurrent pain or discomfort centered in the upper abdomen in any 1 year (14), and in 1985 it was estimated that 2% to 5% of all primary care visits in the United States were for dyspepsia, with a cost of more than $1.4 billion (15). Studies that have investigated the cause of dyspepsia in large numbers of patients presenting to their primary care physician with this complaint have revealed that the most common diagnosis in these patients is nonulcer dyspepsia (see Nonulcer Dyspepsia, later in this chapter). Other common diagnoses in patients with dyspepsia include gastroesophageal reflux disease and PUD.

Nonulcer dyspepsia refers to the symptom of dyspepsia for which no organic cause can be identified. Patients with nonulcer dyspepsia may or may not have evidence of gastritis or duodenitis (see Duodenitis, later in this chapter). Nonulcer dyspepsia is a common diagnosis made in patients with chronic upper abdominal pain, particularly in those younger than 40 years of age (16).

Gastritis refers to inflammation of the stomach detected by histologic evaluation of mucosal biopsy specimens. However, this term has also been used to describe erythema or friability seen on endoscopic examination of the stomach, mucosal irregularity seen on radiologic contrast examination of the stomach, and upper abdominal complaints in patients seen by health care providers. However, these endoscopic, radiologic, and clinical uses of gastritis do not correlate well with histologic gastritis. Therefore, it is most appropriate for the endoscopist and radiologist to simply describe what they see, and for the clinician to use the term *dyspepsia* when describing a patient with upper abdominal discomfort. In fact, most patients with gastritis are asymptomatic, and there are no symptoms characteristic of gastritis. In patients with upper abdominal symptoms, it is usually difficult to assign a clear cause and effect relationship between symptoms and the presence of gastritis. Therefore, most patients with upper abdominal discomfort and gastritis without other findings are considered to have nonulcer dyspepsia. Gastritis is commonly classified into acute and chronic (predominantly mononuclear cell infiltrate) forms. The most common types of acute gastritis include acute hemorrhagic and erosive gastritis and acute *H. pylori* gastritis. Common forms of chronic gastritis include *H. pylori* gastritis, chemical gastritis, autoimmune atrophic gastritis, and hypertrophic gastritis (Ménétrier's disease).

Duodenitis is also a histologic diagnosis made on duodenal biopsies. Endoscopic findings of erythema and friability of the duodenal bulb are also frequently termed *duodenitis*. Histologic and endoscopic duodenitis does not correlate well with symptoms (17). Duodenitis can in some cases be part of the spectrum of duodenal ulcer disease (18). The clinical significance of duodenitis without symptoms is unknown. Patients with upper abdominal symptoms and endoscopic or histologic evidence of duodenitis without ulceration are considered to be in the category of nonulcer dyspepsia.

Etiology and Pathophysiology

Dyspepsia. Dyspepsia can arise from several etiologies. The most common diagnoses are nonulcer dyspepsia, gastroesophageal reflux disease, and PUD. Other etiologies are less likely, but include lactose intolerance, irritable bowel syndrome, biliary or pancreatic disease, or gastric cancer (less than 1% in the United States).

Nonulcer Dyspepsia. Nonulcer dyspepsia refers to the complaint of dyspepsia without clearly identifiable organic etiology, and it is likely a syndrome of multiple

causes (16). Possible factors contributing to nonulcer dyspepsia include altered gastric motility (19), psychosomatic disorders (20), and increased sensitivity to gastric distension (21). Whether chronic gastritis secondary to *H. pylori* infection (see following section) could be a cause of nonulcer dyspepsia is a topic of intense debate. Multiple studies examining whether patients with nonulcer dyspepsia improve after eradication of *H. pylori* infection have come to different conclusions, although these studies are often fraught with methodologic difficulties (22). Many prescription and nonprescription medications also cause dyspepsia. These include aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), selective serotonin reuptake inhibitors, bisphosphonates, and others. Endoscopy is usually normal in patients with drug-induced dyspepsia.

Helicobacter pylori *Gastritis.* The understanding of gastritis changed remarkably in the 1990s. The most common cause of gastritis is now known to be *H. pylori* infection. *H. pylori* is a curved gram-negative rod with several specialized properties that allow it to colonize the relatively hostile environment of the stomach. These specialized properties include multiple flagella, release of chemotactic and cytotoxic substances, and presence of urease, an enzyme that converts urea to ammonia and carbon dioxide. *H. pylori* only colonizes gastric mucosa, but may be the most common infection in the world, with an estimated 50% of the world's population harboring this organism (23). The presence of *H. pylori* in the gastric mucosal mucous layer is always associated with mucosal inflammation. Ingestion of the organism can cause an acute gastritis and clinical symptoms of upper abdominal pain, nausea, and vomiting that may last up to a few weeks (24). However, reports of acute *H. pylori* gastritis are uncommon, and the vast majority of patients acquired the infection in childhood and have chronic gastritis. Chronic *H. pylori* gastritis has been associated with the development of PUD, mucosa-associated lymphoid tissue tumors (MALT lymphoma), and gastric adenocarcinoma (23). However, it is unclear whether chronic *H. pylori* gastritis, without one of the previously mentioned complications, can cause symptoms. Certainly, the majority of patients with chronic *H. pylori* gastritis are asymptomatic.

Other Types of Gastritis. Several other types of gastritis are recognized but are not clearly associated with dyspepsia, nausea, or abdominal pain. These include acute hemorrhagic or erosive gastritis, which is seen in association with stressful illnesses such as burns, intracranial diseases, trauma, sepsis, and ingestion of certain drugs, especially aspirin and other NSAIDs (25). *Chronic chemical gastritis* refers to the histologic pattern seen after recurring exposure to extrinsic or intrinsic chemical agents. The most common extrinsic agents are NSAIDs, and the most common intrinsic culprit is bile. Autoimmune atrophic gastritis is an inherited disease in which an immune response is directed against parietal cells of the oxyntic mucosa. With the destruction of parietal cells, intrinsic factor production is decreased, and vitamin B_{12} deficiency, with or without pernicious anemia, may result. Hypertrophic gastropathy (Ménétrier's disease) is a type of nonerosive gastritis of unknown cause characterized by large gastric folds with loss of protein through the gastric mucosa (26). Gastritis can also develop in patients with Crohn's disease, postgastrectomy patients, and in patients with peripheral eosinophilia, allergic conditions, and eosinophilic infiltration in the stomach wall (eosinophilic gastritis). In addition, other bacteria, fungi, and viruses have been associated with the development of gastritis.

Symptoms and Signs. Dyspepsia, by definition, refers to the symptom of upper abdominal discomfort. In 25% of patients the pain radiates to the back. Episodic pain of longer than 3 years' duration is described by more than 90% of patients. Most report no relation of pain to meals, but approximately 25% describe some relief with antacids. Nausea is present in many patients whereas weight loss, nocturnal pain, and a change in bowel pattern are uncommon. Symptoms of depression or psychological tension are frequent. *Nonulcer dyspepsia* refers to dyspepsia without clear organic etiology. There are no clear symptoms or signs that reliably distinguish dyspepsia from nonulcer dyspepsia.

Acute infection with *H. pylori* can cause a syndrome of upper abdominal discomfort, nausea, and diarrhea that can last for a few weeks; this is a rare syndrome.

Upper gastrointestinal hemorrhage and abdominal pain are the most frequent symptoms in patients with acute hemorrhagic or erosive gastritis. Bleeding is the predominant finding in stress-associated gastritis. In the absence of perforation, epigastric pain is present in fewer than 10% of patients. Pain is more commonly reported when erosive gastritis is caused by aspirin and other NSAIDs than when caused by stress. When pain is present with drug-induced erosive gastritis, it is usually epigastric and is frequently relieved by meals and antacids.

Most patients with nonerosive gastritis are asymptomatic. A minority of the subset with atrophic mucosa can develop neurologic symptoms caused by vitamin B_{12} deficiency. Paresthesias, loss of sensation, and dementia can be the only complaints because abdominal pain does not occur in this disease. Symptoms of anemia can also be present with vitamin B_{12} deficiency.

Approximately 75% of patients with hypertrophic gastropathy have abdominal pain. This pain is usually epigastric and is occasionally relieved by meals (26). Anorexia, weight loss, and peripheral edema are frequently associated symptoms. Most patients have a long history of abdominal pain before the diagnosis of hypertrophic gastropathy is made.

Diagnosis. The symptom of dyspepsia alone is not sufficient to separate the diagnosis of nonulcer dyspepsia from gastroesophageal reflux disease, PUD, or gastric cancer. The most efficacious and cost-efficient evaluation and management strategy in patients presenting with dyspepsia is currently in debate. If a patient presents with dyspepsia and warning symptoms, such as bleeding, dysphagia, weight loss, or severe vomiting, then further evaluation should clearly be pursued. If a dyspeptic patient does not have any associated warning symptoms, however, then strategies of empiric acid suppression (27), empiric *H. pylori* testing and treatment (28), and initial endoscopic evaluation have all been advocated (29). Because the risk of gastric cancer increases after age 50 years, initial endoscopic strategies may be more appropriate in this group. If a patient is treated empirically and does not respond, then further evaluation is required. Given current data and resources, a reasonable approach is suggested in Figure 66-3. If a diagnostic procedure is required, upper endoscopy is a more sensitive technique for detecting mucosal abnormality than radiography. Although high-quality air-contrast barium radiography usually excludes significant gastric and duodenal ulcerations and a gastric mass, it may miss smaller mucosal lesions and does not allow for biopsy and histopathologic correlation.

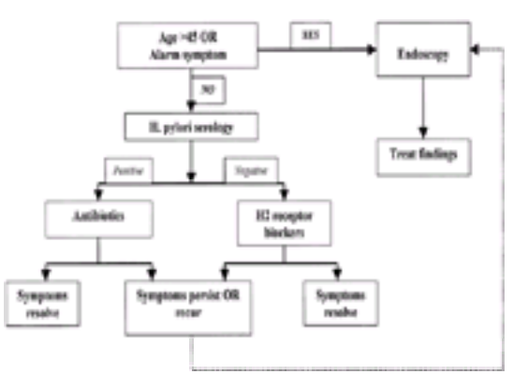

Figure 66-3. Approach to a patient with dyspepsia.

Other diagnostic tests might be required in patients with atypical symptoms or if the diagnosis is unclear after an endoscopy. Patients with low serum albumin levels and large folds on radiographic or endoscopic examination may require endoscopic ultrasonography and large particle gastric biopsy to diagnose hypertrophic gastropathy. Dyspeptic symptoms can be similar to those caused by cholecystitis and chronic pancreatitis. If symptoms are persistent and troublesome, abdominal ultrasonography should be used to evaluate the pancreas, gallbladder, and bile ducts.

Whether to look for and treat *H. pylori* infection in patients with uninvestigated dyspepsia or patients with nonulcer dyspepsia remains controversial. The diagnosis of *H. pylori* can be made by serology, urease-based tests (including the noninvasive urea breath test and urease testing on endoscopic biopsy specimens), and histology. Because of its low cost and excellent sensitivity, serology is the current initial diagnostic test of choice in most patients. The urea breath test is the current noninvasive method of choice to document eradication. Culture of *H. pylori* is expensive and difficult compared with the previously mentioned tests and thus is not generally performed.

Treatment. A key to treating patients with nonulcer dyspepsia remains making a positive diagnosis and providing reassurance (see Fig. 66-3). Many patients do not require medical therapy after a confident diagnosis has been made. In general, patients should be asked to avoid foods that exacerbate their symptoms, eat smaller and more frequent meals, and avoid excessive use of ethanol, caffeine, tobacco products, and NSAIDs. However, attempts to find medications that help relieve the discomfort of patients with nonulcer dyspepsia have been frustrating. Antacids have not been clearly shown to be better than placebo, even though antacids and

placebo lead to temporary relief in a large proportion of these patients. A metaanalysis has suggested that H_2-receptor antagonists may result in symptom improvement of 20% over placebo (30). Preliminary trials with PPI therapy have also shown significant improvement in nonulcer dyspepsia compared with placebo. Prokinetic agents have also been used to treat patients with nonulcer dyspepsia. Studies with metoclopramide, domperidone, and cisapride have suggested that these medications are more effective than placebo. In patients with visceral hyperalgesia and nonulcer dyspepsia, agents that modify the transmission of nociceptive inputs from the gut to the brain are of therapeutic interest, but their clinical efficacy remains unproved (31). Varying with the population studied, approximately 50% of patients with nonulcer dyspepsia have evidence for *H. pylori* infection. Multiple studies evaluating the effect of *H. pylori* eradication in patients with *H. pylori* infection and nonulcer dyspepsia have shown mixed results, and these studies are often fraught with methodologic difficulties (22). Although more research should be done before definitive conclusions can be made, the general guideline of *H. pylori* eradication in these patients cannot currently be supported by available clinical trials. Nonulcer dyspepsia can be chronic and is not associated with decreased longevity. Therefore, any treatment attempted should be monitored and stopped if side effects occur. Systemic analgesics are never indicated for treatment of this category of gastric disorders.

The objectives of therapy of acute and chronic hemorrhagic or erosive gastritis are pain relief and the prevention of complications. The development of acute erosive gastritis and ulceration in patients with serious underlying disease can be prevented if the intragastric pH is kept above 3.5. Oral antacids, H_2-receptor antagonists, and PPIs can all be used to attain a pH of greater than 3.5. Use of these agents to treat erosions is less successful but is generally attempted. Patients with erosive gastritis caused by aspirin and other NSAIDs should stop taking their NSAIDs if possible. When NSAID medication must be continued, NSAIDs that more selectively inhibit the cyclooxygenase-2 enzyme may be less harmful to the gastric mucosa (32) (see Chapter 83).

Patients with hypertrophic gastropathy can do well for years without therapy (26). If pain or hypoalbuminemia from gastric protein loss is disabling, relief can be obtained with gastrectomy. Patients with infectious gastritis other than *H. pylori* should be treated with specific antimicrobial agents whenever possible.

Peptic Ulcer Disease

Despite advances in the understanding of PUD, ulceration of the stomach and duodenum continues to be one of the most important diseases of the gastrointestinal tract. Because PUD results in significant pain and a high morbidity, it is a leading cause of health care expenditures. In the United States, there are approximately 500,000 new cases and 4 million recurrences each year, with an estimated annual direct cost of $3 to $4 billion per year (33). New diagnostic and therapeutic techniques have contributed to this expense, but also dramatically changed the management of patients with ulcers during the 1990s. Gastric and duodenal ulcers are considered together here because of similarities in symptoms, diagnostic approaches, and therapies.

Etiology and Pathophysiology. An ulcer is a localized loss of the normal gastric or duodenal mucosa. Granulation tissue and inflammatory exudate are found in the base of an ulcer, which extends into or through the submucosal layer of the gastrointestinal wall (Fig. 66-4). Ulcers are formed because of an imbalance between ulcerogenic factors and defensive factors that usually protect against mucosal damage (34). *H. pylori* infection and use of NSAIDs are the two most common conditions associated with the development of peptic ulcers. *H. pylori* has been identified in up to 90% to 95% of patients with duodenal ulcer and 60% to 80% of patients with gastric ulcer compared with a 25% to 30% incidence in control groups (35,36). Eradication of *H. pylori* infection in patients with PUD has been shown to dramatically decrease the chance of PUD recurrence (37). However, the exact mechanism by which *H. pylori* is involved in causing PUD remains unclear. Colonization of the gastric antral mucosa by *H. pylori* is known to result in higher levels of gastrin as a result of decreased somatostatin release. Somatostatin normally inhibits gastrin synthesis and release, and lack of this braking mechanism can lead to increased gastrin-mediated acid secretion. *H. pylori* is also known to produce cytotoxins; however, whether these cytotoxins actually play a significant role in producing ulcers remains unknown. Use of aspirin and other NSAIDs has also been associated with PUD. These medications inhibit the production of prostaglandins, which are important in mucosal defense.

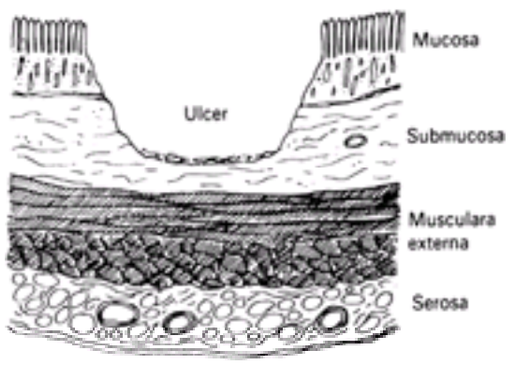

Figure 66-4. Schematic diagram of a peptic ulcer.

The role of gastric acid in the pathogenesis of PUD has long been appreciated. The presence of gastric acid is necessary for the development of a peptic ulcer. Excessive acid can be present in absolute terms, as in the Zollinger-Ellison syndrome, in which a gastrin-producing tumor causes a marked increase in gastric acid production, or the acid might only be increased relative to the ability of the gastric or duodenal mucosa to protect itself.

Symptoms and Signs. Symptoms alone do not differentiate reliably among the diagnoses of duodenal ulcer, gastric ulcer, and nonulcer dyspepsia. In all of these diseases, pain is most often felt in the epigastrium, although right upper quadrant pain is seen in some patients with duodenal ulcer and left upper quadrant pain can be seen with gastric ulcer (Fig. 66-5). The pain is variously described as gnawing or burning, and a sense of fullness is common. Radiation of pain to the back occurs in 20% to 30% of patients. Pain relief by food or antacid ingestion is described by one-half of patients with a duodenal ulcer and by less of those with gastric ulcer and nonulcer dyspepsia. Pain that awakens the patient at night is more frequently seen with duodenal ulcer disease. Nausea, vomiting, heartburn, and anorexia are reported in a significant number of patients with these diseases. Although patients with gastric ulcer tend to be older and patients with nonulcer dyspepsia have milder degrees of pain, these findings do not help to distinguish among these diagnoses in an individual patient. Patients with ulcers associated with NSAID consumption are often asymptomatic until they present with a complication (38). Symptoms also correlate imperfectly with ulcer healing. Patients who become asymptomatic can still have an ulcer crater approximately 15% of the time. Furthermore, two-thirds of patients who are still symptomatic after a 6-week course of antacid therapy are found to have healing of their ulcer at endoscopy.

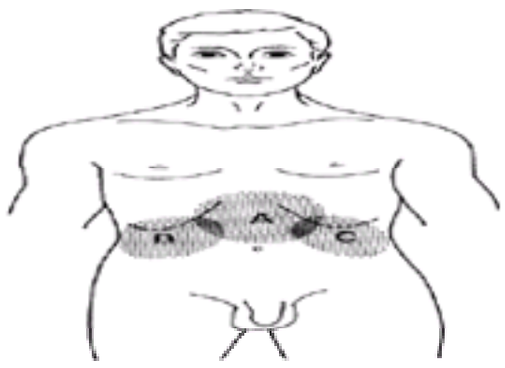

Figure 66-5. Locations of referred pain from peptic ulcer. Most commonly, the pain is referred to the epigastrium (A). In some patients, the pain of duodenal ulcer is referred to the right upper quadrant (B) or left upper quadrant in patients with gastric ulcer (C).

Bleeding, perforation, penetration, obstruction, and intractable pain are the most common complications of PUD. Gastrointestinal bleeding, presenting either as melena or hematemesis, complicates PUD in 10% to 20% of patients. Bleeding can be associated with pain, or it can be the first and only manifestation of the ulcer.

Approximately 5% of patients with ulcers experience perforation. Perforation presents with the sudden onset of severe epigastric pain that quickly spreads to involve the entire abdomen as peritonitis ensues. If a duodenal ulcer perforates and partially seals, it can present as right lower quadrant pain because of the accumulation of gastric contents in the right paracolic gutter. Penetration of a duodenal or gastric ulcer into the pancreas, adjacent omentum, or hepatobiliary system is usually suspected if the patient has severe continuous pain that resists medical therapy. Radiation of pain to the back occurs in more than one-half of patients with posterior penetration. Somatic pain with a radicular quality is also frequently described in this situation, probably because of inflammation of retroperitoneal structures. Gastric outlet obstruction should be suspected in patients with ulcers who develop frequent vomiting, particularly if the vomiting occurs at night or if the emesis contains food residue eaten several hours earlier. Patients who develop pyloric obstruction frequently have a long history of ulcer pain that has recently changed character. With the onset of obstruction, pain can become more continuous and be relieved by vomiting. Intractable pain can be caused by penetration or by inadequate therapeutic regimen.

Surgery for PUD is much less frequent because of improved medical treatments for PUD. Postoperative symptoms occur in 10% to 50% of patients after PUD surgery, depending on the type of operation and the population studied. Abdominal pain, diarrhea, vasomotor phenomena, vomiting, weight loss, anemia, and metabolic bone disease are the most commonly encountered problems. Abdominal pain caused by alkaline reflux gastritis is usually a continuous burning pain, often similar to the initial ulcer pain, and frequently exacerbated by eating. Antacids do not relieve the pain. Vomiting of bitter bile-stained material is frequently described. Crampy or steady epigastric pain occurring 30 to 60 minutes after eating and associated with flushing, diaphoresis, and lightheadedness is referred to as the *dumping syndrome*. Other considerations in the patient with chronic postoperative pain are recurrent ulceration, obstruction of the gastric outlet, and malfunction of the afferent loop in a patient with a Billroth II anastomosis.

Diagnosis. Physical findings and laboratory tests are often not specific for PUD. For example, epigastric tenderness is found just as frequently in patients with ulcers as in those without ulcers (39). The serum amylase level is normal in patients with uncomplicated PUD but may be elevated if the ulcer has penetrated into the pancreas. The serum gastrin level should be measured in patients with multiple ulcers, recurrent ulcers, when ulcers are present in the distal duodenum, or are refractory to medical or surgical therapy, because this picture suggests Zollinger-Ellison syndrome. Zollinger-Ellison syndrome is characterized by the presence of upper gastrointestinal ulcer, marked increase in secretion of gastrin, and a non–beta islet cell tumor of the pancreas, known as a *gastrinoma*.

Demonstration of an ulcer requires radiographic contrast examination or endoscopy. Contrast examinations are less expensive, but endoscopy is more sensitive and has the capability of biopsy. The choice of tests often depends on clinical situation and local availability of these two procedures.

All gastric ulcers should be examined endoscopically. Six to eight biopsies and brush cytology of the ulcer rim should be obtained. Nonhealing gastric ulcers and those ulcers that have a suspicious appearance on initial examination should be reexamined and rebiopsied to exclude malignancy.

Evidence for *H. pylori* infection should be sought in all patients with PUD by serologic tests, urease-based testing, or histologic examination of gastric mucosa (discussed previously).

Postgastrectomy syndromes should be considered in all patients with upper abdominal pain and a history of gastric surgery. A diagnosis of dumping or alkaline reflux gastritis is often based on the characteristic clinical presentation. Recurrent ulceration is best detected by endoscopy because postsurgical changes make radiographic findings difficult to interpret. On the other hand, gastric and afferent loop obstruction are best demonstrated radiographically.

Treatment

Medical Therapy. Historically, therapeutic strategies for PUD have primarily focused on decreasing acid exposure in the stomach. However, with the recognition of the role of *H. pylori*, current strategies involve the use of antibiotics in combination with antisecretory medications to eradicate *H. pylori* and achieve enhanced ulcer healing with decreased recurrence rates.

However, no easy regimen for eradication of *H. pylori* currently exists. Several effective therapies are listed in Table 66-1. In most patients in the United States, a triple-therapy regimen with a PPI, clarithromycin, and metronidazole or amoxicillin is a reasonable choice, with relatively high success rates and good compliance (36,40,41). One downside to PPI-based triple therapies is high cost. Bismuth-based therapies are cheaper and effective; however, compliance with these regimens is often more difficult. A reasonable second-line therapy is ranitidine-bismuth subcitrate, metronidazole, and clarithromycin or amoxicillin.

Regimen	Dose/mg	Schedule	Days of treatment	Success rate	Cost
Proton pump inhibitor	¶	b.i.d.	10–14		
Clarithromycin	500	b.i.d.	10–14	>80%	$$$
Metronidazole or	500	b.i.d.	10–14		
Amoxicillin	2 × 500	b.i.d.	10–14		
Bismuth subsalicylate	2 tablets	q.i.d.	10–14		
Tetracycline	500	q.i.d.	10–14	>80%	$
Metronidazole or	250	t.i.d.	10–14		or
Clarithromycin	500	b.i.d.	10–14		$$
Ranitidine bismuth subcitrate	400	b.i.d.	14		
Clarithromycin	500	b.i.d.	14	>80%	$$
Tetracycline or	500	b.i.d.	14		
Metronidazole	250	t.i.d.	14		

¶Omeprazole 20 mg, or lansoprazole, 30 mg

TABLE 66-1. Triple-therapy regimens for *Helicobacter pylori* eradication

In terms of acid suppression alone, antacids, H_2-receptor blockers, and PPIs have all been shown effective at healing ulcers. Antacids have been shown to heal 80% to 90% of both gastric and duodenal ulcers in 6 to 12 weeks (42,43). Liquid antacid preparations should be taken 1 hour after each meal and at bedtime in doses of 15 to 30 mL. The H_2-receptor antagonists cimetidine, ranitidine, famotidine, and nizatidine are attractive alternatives to antacids because they are equally effective (42), generally have fewer side effects, and are easier to administer. Administration of H_2-receptor antagonists, cimetidine (1,600 mg), ranitidine (300 mg), famotidine (40 mg), or nizatidine (300 mg), given once daily after dinner, are effective at healing PUD. PPIs (such as omeprazole and lansoprazole) inhibit the H^+/K^+ ATPase acid secretory pump in the gastric parietal cell membrane. These medications produce more sustained and robust acid suppression than H_2-receptor antagonists and have been shown to heal ulcers faster than H_2-receptor blockers (44,45), a property that may be important in patients with complicated (e.g., bleeding) ulcers.

Agents that bind to ulcers have also been shown to promote healing. Sucralfate is the only one of these drugs presently available in the United States. Given in a dose of 1 g four times a day, sucralfate is as effective as cimetidine for healing duodenal ulcers. Constipation is an infrequent side effect of sucralfate. Sucralfate should not be taken at the same time as other medications to avoid interference with absorption of the other drugs.

Aspirin, other NSAIDs, and alcohol should be avoided by patients with ulcers. For patients who must continue on NSAID therapy, maintenance therapy with a prostaglandin analog (misoprostol), high-dose H_2-receptor antagonists, and PPIs have been shown to be effective at decreasing the likelihood of ulcer recurrence (46,47 and 48). Other dietary limitations are not associated with improved healing. Patients should be encouraged not to smoke, because smoking impairs ulcer healing. Avoidance of unnecessary stress is always commendable, but too much emphasis on this aspect cannot be recommended on the basis of available information concerning the effects of stress on ulcer formation and healing.

Surgical Therapy. The use of surgical therapy for PUD has dramatically declined with the advent of more effective medical therapy and identification and eradication of *H. pylori*. However, surgery for PUD is indicated for refractory PUD (Zollinger-Ellison syndrome should be excluded), persistent bleeding, obstruction, penetration, and perforation (49). Parietal cell vagotomy by a surgeon experienced in this procedure is the operation of choice for intractable pain. Dumping, diarrhea, and alkaline reflux gastritis are all less frequent with this operation, although recurrent ulcers are more common than with other ulcer surgery and occur in 5% to 10% of patients. Vagotomy with pyloroplasty, and vagotomy with antrectomy and either gastroduodenostomy or gastrojejunostomy, are alternative ulcer operations. Repeat surgery might be needed for complications of severe alkaline reflux gastritis or for obstruction of surgical anastomoses.

All patients with ulcer pain should be managed with the medical and surgical treatments outlined previously. Acid-suppressive medications, and acetaminophen if necessary, generally provide sufficient pain relief during the healing phase. Narcotic analgesics or anesthetic blocks should be used in patients with severe pain caused by perforation or penetration after diagnosis has been made and surgery is planned. Patients should not be left in pain while awaiting surgery.

Neoplasms of the Stomach

Gastric cancer is a leading cause of cancer deaths worldwide. Adenocarcinoma accounts for more than 80% of malignant gastric neoplasms, with lymphoma and malignant stromal tumors making up the remainder. Although the incidence of gastric cancer is decreasing in the United States, this malignancy remains a cause of upper abdominal pain and a therapeutic challenge to physicians. An update on most aspects of gastric neoplasms is available (50). Further discussion about pain associated with cancer can be found in Chapter 35, Chapter 36 and Chapter 37.

Etiology and Pathophysiology. Infectious, environmental, and genetic factors have significant roles in the pathogenesis of gastric cancer. *H. pylori* infection has been implicated as a predisposing factor in the development of gastric adenocarcinoma (excluding cardia tumors) as well as in the development of MALT lymphomas arising in the stomach (51,52). Dietary salt and nitrates have been linked epidemiologically to gastric cancer. An increased incidence of gastric cancer occurs in patients with autoimmune atrophic gastritis and in patients with large adenomatous gastric polyps.

Symptoms and Signs. Patients with early gastric cancer can be asymptomatic, experience a sensation of fullness, or have vague epigastric pain. The pain can be similar to the pain of gastric ulcer. Weight loss, anorexia, vomiting, and occult or overt gastrointestinal bleeding can be present. Local invasion can cause pancreatitis, gastrocolic fistulas, or severe continuous abdominal or back pain. Metastases from gastric cancer can be responsible for ascites, pleural effusions, or jaundice. Physical examination may reveal an epigastric mass, enlarged liver, ascites, or enlarged supraclavicular, axillary, and umbilical lymph nodes.

Diagnosis. A combination of diagnostic procedures is used in the detection of gastric cancer. Upper gastrointestinal roentgenography can reveal a mass or suspicious ulcer. Gastroscopy provides direct visualization and an opportunity to biopsy an ulcer or mass lesion and to brush it for cytology. Biopsies and brushings for cytology should be taken of gastric ulcers and of any irregular appearing mucosa. Endoscopic ultrasound is the most accurate method to establish the depth of wall invasion and the presence of local lymph nodes (53). Endoscopic ultrasound can also direct fine needle aspiration of submucosal lesions or lymph nodes. CT scanning is currently the most useful nonsurgical method for detection of metastatic spread.

Treatment

Cancer Therapy. Treatment of gastric cancer traditionally includes surgery and chemotherapy. Patients who have no evidence of spread of the neoplasm outside the stomach should have a subtotal or total gastrectomy and lymph node dissection. Palliative surgery is also indicated for luminal obstruction and hemorrhage. Patients with locally advanced or metastatic disease can benefit from chemotherapy using combinations of 5-fluorouracil, doxorubicin, mitomycin C, triazinate, and methotrexate (54). Radiotherapy has not been useful in the treatment of locally advanced gastric cancer, but can relieve pain caused by metastases to bone.

Pain Therapy. The treatment of severe pain in patients with advanced gastric cancer is a significant problem and challenge and is discussed in detail in Chapter 36 and Chapter 40. Both visceral and somatic pain mechanisms are usually involved because of abdominal wall or retroperitoneal invasion. For such patients, available therapies include narcotic analgesics, orally or parenterally, intraspinal narcotics, block of the splanchnic nerves or celiac plexus alone or combined with intercostal block, neurostimulation techniques, and ablative neurosurgical operations. Two or more of these techniques are frequently used to provide relief.

Pain can be controlled in most patients with maximum life expectancy of less than 3 months by appropriate use of narcotic analgesics. In patients with mild to moderate pain, NSAIDs are used initially and, if necessary, can be combined with codeine or more potent narcotics such as morphine. Regularly scheduled oral administration of a pain cocktail containing methadone is often effective. A dose of 10 mg every 8 hours is prescribed initially but must then be titrated to the patient's needs. The addition of hydroxyzine (25 to 50 mg every 6 hours) or prochlorperazine to the cocktail is useful for the treatment of nausea and vomiting, which is frequent in these patients. Moreover, hydroxyzine potentiates the analgesic action of narcotics. Intraspinal narcotics are increasingly being used and are effective in many of these advanced cancer patients (see Chapter 102).

Neurolytic blocks are used for the management of a subset of patients with advanced gastric cancer and severe pain. This therapy is usually reserved for situations in which the overall condition of the patient is fairly good and the pain is localized and severe. Significant pain relief has been reported in more than 90% of patients with gastric cancer who have had bilateral celiac plexus block with 50% alcohol solution (55). Pain relief often lasts for months after this procedure. Recurrent pain sometimes responds to repeated injections, but, when these fail, extension of the cancer to the peritoneum or abdominal wall is likely. This requires neurolytic blocks of the involved intercostal nerves. Neurolytic blocks are often combined with pharmacologic therapy or psychological techniques, or both.

Neurostimulation and ablation procedures are sometimes used for the treatment of severe intractable pain in patients with advanced gastric cancer. These procedures should be used when life expectancy is greater than 3 months and when pharmacologic therapy is not effective or is associated with unacceptable side effects (see Chapter 100, Chapter 101, Chapter 105, and Chapter 106).

DISEASES OF THE SMALL AND LARGE INTESTINES

Basic Considerations

Anatomy

The small intestine begins at the distal end of the stomach, the pyloroduodenal junction, and ends as it joins the colon at the ileocecal valve. The proximal 10 in. of small bowel make up the duodenum (the duodenum was discussed previously, with the stomach, because of similarities in the clinical presentation of diseases of these two organs). The remainder of the small intestine, suspended on its mesentery, is approximately 10 ft long and occupies most of the abdomen (Fig. 66-6).

Figure 66-6. Location of the small intestine in relationship to the dermatomes.

The large intestine, or colon, begins at the ileocecal valve and ends at the anus. The cecum is the most proximal aspect of the colon and usually lies in the right lower quadrant. The ascending and descending portions of the colon do not have a mesentery and are relatively fixed in the retroperitoneum. The transverse colon has a mesentery and can form variable-sized loops across the midabdominal cavity. The sigmoid colon also has a mesentery and can stretch to a great length, particularly in the elderly. The rectum, which is fixed in the retroperitoneum, forms the most distal 12 to 15 cm of large intestine. Some disease processes of the distal rectum are clinically similar to anal diseases (see Diseases of the Anus and Rectum, later in this chapter). The positions of the small and large intestines within the abdomen are

shown in Figure 66-6 and Figure 66-7.

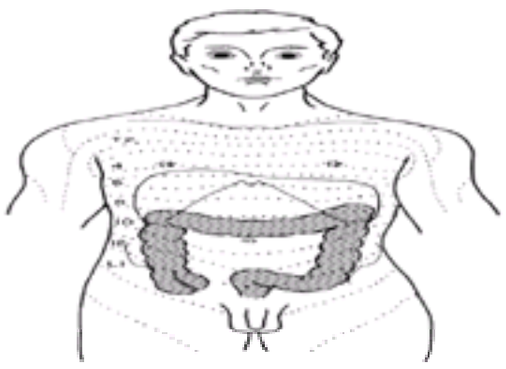

Figure 66-7. Location of the large intestine in relationship to the diaphragm and the dermatomes.

The embryologic development of the intestine accounts for some of the abnormalities encountered clinically. During normal fetal development, the small bowel is transiently occluded by proliferating epithelial cells. Defective recanalization can result in the formation of gut duplications, cysts, and webs, which all can cause problems subsequently. Another embryologic remnant that might be clinically relevant later in life is a Meckel's diverticulum, which forms at the junction of the primitive gut and the vitelline duct. This diverticulum often contains gastric mucosa and can cause abdominal pain and intestinal bleeding.

Nerve Supply

Visceral sensation, including pain from the jejunum and ileum, is carried by sympathetic afferent nerves through the least and lesser splanchnic nerves, and from there through the superior mesenteric and part of the celiac plexuses to enter the spinal cord at the T-8 to T-12 levels (Fig. 66-8). Sensation from the cecum, ascending colon, and right half of the transverse colon is carried by sympathetic afferent fibers that pass through the least and lesser splanchnic nerves, and from these through the inferior mesenteric and superior mesenteric plexuses to enter the spinal cord at the T-10 to L-2 levels. Pain sensation from the left half of the transverse colon and from the descending colon and rectum is mediated by afferent fibers; some of these accompany sympathetic fibers to the lower thoracic and lumbar sympathetic trunks and others course with the parasympathetic nerves through the pelvic plexus and pelvic nerves (nervi erigentes) and then enter the spinal cord at the S-2 to S-4 levels (Fig. 66-9; see Fig. 66-8). In a few persons, afferent sensation can also be carried by the vagus nerve because midgut visceral pain can be felt after spinal cord transection above T-1 as well as after bilateral splanchnic nerve resection (12).

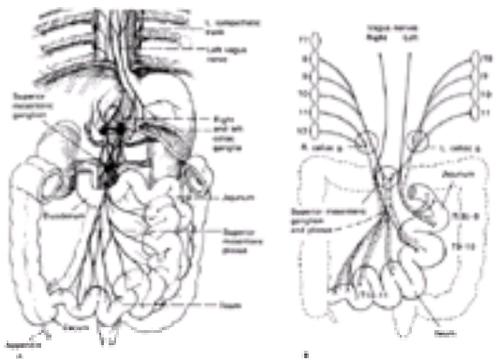

Figure 66-8. Innervation of the small intestine. **A:** Relationship of the vagus nerves, sympathetic trunk, celiac ganglia, superior mesenteric ganglion, and superior mesenteric plexus supplying the small intestine. **B:** Schematic depiction of the nerve supply to the small intestine. The vagus nerves supply the small intestine with parasympathetic preganglionic fibers, which end in the wall of the gut and synapse with short postganglionic fibers. These also contain sensory fibers that convey sensations other than nociception. The small intestine received sympathetic supplies through preganglionic sympathetic fibers (*solid lines*) derived from T-8 to T-12 on the right and T-8 to T-11 on the left. These synapse in the celiac and superior mesenteric ganglia with postganglionic fibers (*dashed lines*). Sensory fibers, which transmit nociceptive information (*dotted lines*), follow the sympathetic nerves and enter the spinal cord at T-8 to T-12 on the right and T-8 to T-11 on the left. The segments that supply sympathetic and sensory fibers to different parts of the small intestine are indicated by numbers. The segments in parentheses in the sympathetic chain are inconstant. (For more detailed information of the origin and course of these nerve pathways, see Chapter 65.) (Modified from Netter FH. Innervation of the stomach and duodenum. In: *The CIBA collection of medical illustrations*. Vol 3, Digestive system. Part II, Lower digestive tract. Summit, NJ: CIBA Pharmaceutical Co., 1979:76–79, and Bonica JJ. *The management of pain*. Philadelphia: Lea & Febiger, 1953:395, 397.)

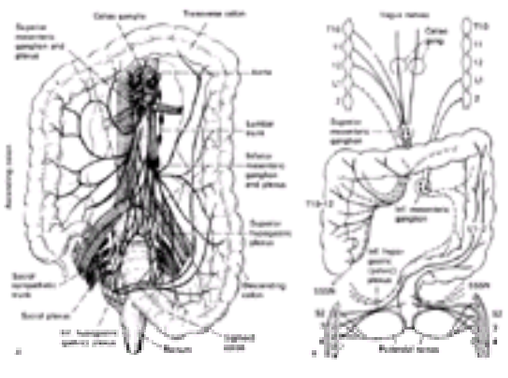

Figure 66-9. Innervation of the large intestine. **A:** Anatomic relationship of the nerve supplying various parts of the colon and rectum. **B:** Schematic depiction of the innervation of the vagus, sympathetic, and sensory fibers. The right and transverse colon up to the splenic flexure is supplied by preganglionic parasympathetic fibers of the vagus nerves, which synapse in the wall of the viscus with short postganglionic fibers. The sympathetic supply is through preganglionic fibers derived from T-10 to T-12 (*solid lines*), which synapse with postganglionic fibers (*dashed lines*) in the superior mesenteric ganglion. This portion of the gut also receives postganglionic fibers from the L-1 ganglion. This part of the colon is supplied by sensory (nociceptive) fibers that accompany the sympathetic nerves and enter the spinal cord at T-10 and L-1 inclusively. The descending colon receives preganglionic sympathetic fibers from L-1 to L-2, which synapse in the inferior mesenteric ganglion with the postganglionic fibers that supply the viscus as far as the sigmoid colon. Postganglionic sympathetic fibers to the rest of the colon from the rectosigmoid junction and rectum are derived from sacral sympathetic splanchnic nerves (SSSN), which are derived from the sacral portion of the sympathetic chain. The descending colon is supplied with parasympathetic preganglionic fibers, which originate in spinal cord segments S-2, S-3, and S-4 and pass through the inferior hypogastric (pelvic plexus) and from there to the colon and rectum, where they end in the wall of the viscus and synapse with short postganglionic fibers. The sensory fibers that conduct nociceptive impulses accompany the parasympathetic nerves and enter the spinal cord in the S-2, S-3, and S-4 segments. Sensory supply to the rectum is through the pudendal nerve. (See Chapter 65 for a more detailed description of the origin and course of these nerve pathways.) (Modified from Netter FH. Innervation of the small intestine. In: *The CIBA collection of medical illustrations*. Vol 3, Digestive system. Part 2, Lower digestive tract. Summit, NJ: CIBA Pharmaceutical Co., 1979:76–79, and Bonica JJ. *The management of pain*. Philadelphia: Lea & Febiger, 1953:395, 397.)

Characteristics of the Pain

Pain from the small intestine is usually felt as a periumbilical cramp or colic. This pain can be triggered by luminal distension or by excessive motor activity. In patients with functional abdominal pain, experiments with balloon distension of the jejunum and ileum produced pain that was felt in various quadrants of the abdomen by different patients (56,57). Steady visceral pain can be caused by intestinal distension or ischemia. Inflammatory and infiltrative processes that extend to the parietal peritoneum can cause localized somatic pain from the involved area of peritoneum. Traction on the root of the mesentery can cause a similar type of somatic pain but usually produces a periumbilical visceral type of pain (58).

Distension of the ascending and right half of the transverse colon generally causes periumbilical pain, although a significant number of patients also have suprapubic pain. Because the right colon is fixed to the retroperitoneum, severe distension causes right-sided pain, similar to that of infiltrating and inflammatory processes. Stimulation of somatic nerves in the underlying peritoneum is the probable mechanism of this type of pain.

Distension of the left half of the transverse colon and descending colon usually produces pain in the midline below the umbilicus and in the suprapubic region. Severe distension causes left-sided pain localized over the region of distension. Sigmoid colon lesions that involve the overlying peritoneum can cause right lower quadrant, suprapubic, or left lower quadrant pain because of the long mesentery from which the sigmoid colon is suspended, which enables it to touch a wide area of abdominal wall. The common positions of referred pain from the small and large intestines are shown in Figure 66-10.

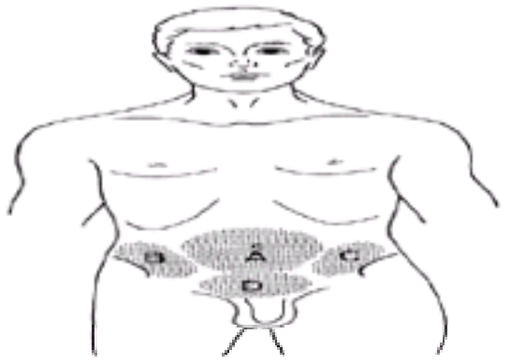

Figure 66-10. Sites of referred pain from diseases of the small and large intestine. Periumbilical pain (A) is caused by distension of disease of the ascending and right half of the colon, but a significant number of patients also have suprapubic pain (D). Pain in the right lower quadrant (B) is caused by severe distension or disease of the appendix and small intestine, as well as of the beginning of the ascending colon. Pain in the left lower quadrant (C) is caused by disease of the descending or sigmoid colon.

Clinical Considerations

Anatomic Abnormalities

Etiology and Pathophysiology. Most congenital anatomic derangements of the intestine that cause abdominal pain do so by producing luminal obstruction. Incomplete canalization of the gut lumen or *in utero* ischemia can cause atresia or stenosis of any part of the intestine. Failure of the intestine to rotate on its mesentery when it reenters the abdomen in the second trimester can result in malrotation of various portions of the bowel. Malrotation can be present without any symptoms. Pain is produced by this anomaly only if intestinal obstruction results from associated fibrous (Ladd's) bands, internal herniation, or formation of a volvulus. Meckel's diverticula are embryologic remnants of the connection of the vitelline duct and terminal ileum. Intestinal obstruction can be induced by these diverticula either by formation of a volvulus or by intussusception. An ulcer can occur in the diverticulum if ectopic gastric mucosa is present.

Symptoms and Signs. Symptoms caused by anatomic abnormalities of the gut are similar to those produced by other causes of intestinal obstruction (see Intestinal Obstruction, later in this chapter). Most congenital abnormalities present in infancy or early childhood. Occasionally, symptoms of these disorders first appear in adults. Therefore, these anomalies should be considered in the differential diagnosis of abdominal pain in adults as well as in children.

Continuous burning or aching abdominal pain can also be caused by anatomic defects. Intestinal duplications usually occur in the ileum and can contain acid-producing gastric mucosa. This can lead to local intestinal ulceration that causes pain directly or after perforation of the gut wall. Ectopic gastric mucosa is also responsible for the pain associated with a Meckel's diverticulum, which is often postprandial. The mucosal ulceration can cause lower gastrointestinal bleeding (59). Inflammation of a Meckel's diverticulum can cause right lower quadrant pain that mimics that of appendicitis.

Diagnosis and Treatment. Most cases of congenital intestinal anomalies are first detected when laparotomy is performed for the relief of intestinal obstruction. Surgical resection of the area of stenosis or duplication is curative. Areas of internal herniation should be reduced and repaired. Meckel's diverticula should be resected.

Patients with less severe symptoms can have their anatomic abnormality diagnosed before laparotomy, usually by radiographic contrast examination. Many of these anomalies are asymptomatic, and thus the challenge is to be certain that the symptoms are actually caused by the anomaly and not by another condition.

Appendicitis

Appendicitis is the most common cause of acute severe abdominal pain that requires surgery. Approximately 10% of the population develops appendicitis at some time (60). Although appendicitis can occur in the very young and the elderly, the peak incidence is in the second and third decades of life.

Etiology and Pathophysiology. More than one-half of appendicitis cases are caused by obstruction of the appendiceal lumen by fecaliths, calculi, or other material. This blockage leads to swelling, mucosal ischemia, and bacterial invasion. Other pathogenic mechanisms can be involved but are largely unknown. Within 24 to 36 hours after luminal obstruction, perforation can occur, leading to peritonitis or abscess formation.

Symptoms and Signs. Patients with acute appendicitis have moderate to severe pain that begins in the epigastric or periumbilical region (61). This initial pain is of a visceral type and is caused by luminal obstruction and distension of the appendix. Pain is most often steady, but some patients have cramping or colicky pain. Movement does not seem to affect this initial pain. The pain generally increases in severity over several hours and then can subside before localizing in the right lower quadrant.

When inflammation extends to the appendiceal serosa, stimulation of overlying parietal peritoneal somatic nerves results in well-localized right lower quadrant pain. This pain is usually severe, continuous, and exacerbated by bodily movement and coughing. Vomiting and defecation do not affect the quality or severity of this pain.

Most patients with appendicitis have anorexia, nausea, and vomiting. A useful diagnostic feature is that nausea and emesis follow the onset of pain. Diarrhea is reported by less than 25% of patients. Some patients report a sensation of constipation.

Diagnosis and Treatment. Diagnosis and treatment of appendicitis requires surgical intervention when symptoms, physical examination, and laboratory findings suggest the diagnosis. Physical examination reveals a temperature of higher than 38°C in 50% of patients. Rebound tenderness and involuntary guarding, usually in the right lower quadrant, are common findings. Tenderness on rectal examination is frequently present. Peripheral leukocytosis is seen in more than 90% of patients. An appendiceal fecalith is seen on plain abdominal roentgenography in less than 10% of patients. Other laboratory findings are nonspecific. Laparotomy must be

done early in the course of the illness to prevent the significantly increased morbidity and mortality associated with perforation.

The physician must also be aware of atypical presentations of acute appendicitis caused by unusual locations of the appendix. Inflammation of a retrocecal appendix causes less severe pain that can remain poorly localized and not cause discrete localized abdominal tenderness. Ureteral irritation can lead to urinary frequency and pyuria. An appendix that hangs down over the pelvic brim can cause severe pain that localizes to the low midline or left abdomen after beginning in the periumbilical region. Rectal and pelvic tenderness is more commonly seen in this group.

In the majority of patients, the diagnosis of appendicitis can be made at the bedside based on clinical suspicion elicited by the patient's history, the physical examination, and the results of laboratory analysis (elevated white blood cell count). In most cases, the decision to operate is made at the bedside, and no further workup is needed. In patients who present with symptoms that are not clearly due to appendicitis, ultrasonography and CT scan can be useful tests. Ultrasonographic criteria have been found to have a 68% sensitivity and a 98% specificity in making an accurate diagnosis (62). CT can also be used in the evaluation of patients with suspected appendicitis. Unenhanced helical CT of patients presenting to the emergency room with suspected appendicitis has been found to have up to 98% accuracy and be cost effective by reducing the number of unnecessary operations (63).

Many diseases that simulate acute appendicitis can sometimes only be excluded by laparotomy. Infectious gastroenteritis, lymphadenitis, ureterolithiasis, and, in women, salpingitis, ruptured ovarian cysts, and ruptured ectopic pregnancy must be considered in the differential diagnosis. Intravenous urography, culdocentesis, and laparoscopy obviate the need for laparotomy in some patients.

The role of laparoscopic surgery versus laparotomy in patients with suspected appendicitis is still debated. A review of studies comparing the two approaches suggests that laparoscopic appendectomy is associated with a reduced risk of postoperative infection, a minimal reduction in hospital stay, and a faster return to normal activity, but longer intraoperative time than laparotomy (64). Once the decision has been made to perform laparoscopy or exploratory laparotomy in a patient with presumed appendicitis, all efforts should be made to relieve the abdominal pain. Parenteral narcotics and segmental epidural analgesic blocks are useful in this situation.

Infectious Enterocolitis

Infections of the small and large intestines are a common cause of self-limited abdominal pain. Infectious enterocolitis should be suspected in any person who develops diarrhea and abdominal cramping.

Etiology and Pathophysiology. Infectious agents that cause enterocolitis include bacteria, protozoans, and viruses. These organisms produce intestinal dysfunction and pain by mucosal invasion, toxin production, or both (65). Specific organisms are considered in the section Diagnosis and Treatment.

Symptoms and Signs. Symptoms of infectious enterocolitis are similar for all organisms that cause this problem. Abdominal cramps are usually intermittent and can be localized to the periumbilical region or lower in the hypogastrium. Rectal urgency is frequent when the rectum is involved. Diarrhea can be watery, bloody, or mucoid; associated symptoms of nausea, vomiting, and fever can be present.

Diagnosis and Treatment. Identification of the causative infectious organism depends on using the known epidemiologic associations to determine appropriate culture media and other laboratory tests. A specific diagnosis is critical to direct appropriate treatment of enterocolitis. Invasive infections are most commonly caused by bacteria and typically cause severe pain and bloody diarrhea. The presence of fecal leukocytes suggests the presence of invasive organisms, but both false-positive and false-negative test results are common. Evaluation of the stool with culture or molecular techniques remains the best initial method to identify the specific organism responsible.

Invasive Organisms. Campylobacter jejuni is the most common cause of invasive infections. *Campylobacter* enterocolitis is treated with erythromycin, 500 mg four times a day for 7 days, if symptoms are persistent, but usually the disease remits spontaneously. Some cases have been associated with household pets, but the source of infection in most patients is unknown. *Salmonella*, *Shigella*, *Yersinia*, and enteroinvasive *E. coli* can cause a similar clinical illness, sometimes associated with eating contaminated foods. Antimicrobial therapy of these infections is usually unnecessary, but might be warranted in selected instances.

Food-Borne Organisms. Food-borne organisms cause enterocolitis that is usually self-limited and requires no treatment. *Staphylococcus aureus*, *Bacillus cereus*, and *Clostridium perfringens* often produce severe abdominal pains and watery diarrhea, which begin several hours after eating contaminated food and last less than 24 hours. *S. aureus* and *B. cereus* infections are frequently associated with severe vomiting.

Traveler's Diarrhea. Travelers to developing countries with tropical climates can develop enterocolitis (66). Contaminated food and water are responsible for transmitting the organism. In addition to the bacterial pathogens mentioned previously, other forms of *E. coli*, and the protozoan organisms *Entamoeba histolytica* and *Giardia lamblia* should also be considered in this setting. Diagnosis of these protozoal agents depends on finding characteristic cysts and trophozoites in the stool of infected patients or by immunofluorescent studies and antigen detection in the stool. Diarrhea and abdominal cramping usually persist for 2 to 7 days. Treatment of traveler's diarrhea includes nonspecific agents to reduce diarrhea (see following discussion) and empiric antibiotics such as quinolones or trimethoprim-sulfamethoxazole. Use of other specific antimicrobial agents requires recovery of a pathogenic agent from the stool.

Enterohemorrhagic Colitis. A specific strain of *E. coli* identified as *E. coli* 0157:H7 has been found to be responsible for numerous sporadic and food-borne outbreaks of bloody diarrhea. Other strains of *E. coli* have subsequently been found to cause this syndrome. This infection is becoming increasingly recognized as a cause of bloody diarrhea (67). Recovery without sequelae is the usual outcome; however, the infection can be associated with the development of hemolytic-uremic syndrome and thrombocytopenic purpura. These complications most often occur in children and older adults, in whom they can be fatal. Treatment is supportive.

Antibiotic-Associated Colitis. Patients who develop abdominal cramping and diarrhea, and who have been on antibiotics in the previous 6 weeks, should be suspected of having pseudomembranous colitis (68). This condition has been associated with the use of nearly all antibiotics, but cephalosporins, ampicillin, and clindamycin are most frequently implicated. Overgrowth of the toxin-producing organism *Clostridium difficile* causes this syndrome by destruction of the colonic epithelium. Diagnosis depends on identifying characteristic pseudomembranes on the rectal mucosa at sigmoidoscopy and by detecting the presence of the *C. difficile* organism and cytotoxin in the patient's stool. Treatment with metronidazole (Flagyl), 250 mg three times a day for 7 days, or oral vancomycin (Vancocin), 250 to 500 mg four times a day for 7 days, is usually curative. A severe colitis can result from this syndrome, producing a serious life-threatening situation.

Diarrhea in Immunocompromised Patients. Patients who are immunocompromised are at risk to develop abdominal pain and diarrhea from other organisms, including cytomegalovirus, mycobacteria, cryptosporidium, *Microsporium*, *Isospora*, and *Blastocystis hominis* among others (69). Diagnosis is usually made by stool examination, or, if necessary, by endoscopy. In neutropenic patients, right lower quadrant abdominal pain and watery or bloody diarrhea can occur as a result of mucosal denudation and bacterial invasion of the proximal colon and distal small intestine in a process called *neutropenic typhlitis*. Diagnosis is made by typical symptoms in an appropriate clinical setting. Treatment is with broad-spectrum antibiotics or surgery.

Supportive Therapy. Supportive therapy for the patient with abdominal cramping and diarrhea caused by an infectious agent is important. Maintenance of hydration with liquids and oral electrolyte solutions is important. Cramping and diarrhea can often be reduced by using bismuth subsalicylate (Pepto-Bismol) in a dose of 30 mL each half hour, up to 8 oz, or until diarrhea and cramps subside. Antiperistaltic agents, such as loperamide, diphenoxylate, and codeine, reduce the severity of diarrhea but should be used cautiously in patients with a fever or bloody diarrhea because of the risk of increasing the severity and prolonging the illness.

Radiation Enterocolitis

Etiology and Pathophysiology. Patients undergoing abdominal or pelvic irradiation for the treatment of neoplasia can develop intestinal complications. These can occur while the radiation is being administered, immediately after completion of treatment, or many months or years after treatment has been discontinued. Most patients so affected have received a total radiation dose of more than 4,000 rads (70). Patients undergoing recent radiation therapy have symptoms produced by mucosal edema and ulceration. Late symptoms after abdominal radiation are usually caused by partial small bowel obstruction from radiation-induced intestinal fibrosis. Diarrhea, when present, is caused by malabsorption, fistulas, or bacterial overgrowth.

Symptoms and Signs. Patients can have gastrointestinal symptoms while undergoing a course of radiation treatment. Nausea, vomiting, and diarrhea can occur, beginning at the end of the first week of treatment. A sensation of incomplete rectal evacuation and tenesmus indicates rectal and lower colonic mucosal involvement.

Increased mucus and blood can be present in the stool. Mid- and lower abdominal cramping is present with significant small intestinal involvement.

Abdominal symptoms can present months to years after radiation therapy has been completed. Symptoms of proctitis, including rectal burning, urgency, and mucoid diarrhea, are most frequent. Decreased stool caliber often indicates the presence of a rectal stricture. Periumbilical cramping pain suggests the presence of partial small or large bowel obstruction caused by stricture formation. If significant obstruction is present, progressive abdominal distension, nausea, and vomiting occur. Rectal bleeding, malabsorption, fistula formation, and perforation can also be late manifestations of radiation injury (71).

Diagnosis. The diagnosis of radiation enterocolitis should be considered in patients with abdominal pain who have a history of undergoing abdominal radiation therapy. The presence of the clinical syndrome described previously is usually sufficient for diagnosis if other causes of pain are excluded. Proctosigmoidoscopy should be done to exclude other diseases, such as colonic cancer. Typical mucosal changes of radiation proctitis, including friability, ulceration, and telangiectasias, can be seen. Infectious enterocolitis needs to be ruled out using stool cultures, particularly in recently treated and potentially immunosuppressed patients with diarrhea. The diagnosis of partial mechanical intestinal obstruction is best made by plain abdominal roentgenography and contrast radiography.

Treatment. Treatment of radiation enterocolitis is directed at the patient's most distressing symptoms. Pain associated with ongoing radiation can respond to a decrease either in radiation dose or frequency of treatments. Stool-bulking agents such as psyllium, 1 to 2 tablespoons daily, anticholinergic drugs such as dicyclomine, 10 to 20 mg four times a day, and antiperistaltic drugs such as loperamide, 2 mg four times a day, can also be helpful in reducing diarrhea and cramping. Rectal symptoms can respond to warm sitz baths and topical 2% lidocaine ointment. Diarrhea and pain in patients with a history of remote radiation treatment can sometimes be reduced by sulfasalazine. More recent treatments have included short-chain fatty acid enemas (72), hyperbaric oxygen (73), and sucralfate enemas (74). Bleeding from radiation proctitis can often be controlled endoscopically using electrocoagulation or laser therapy (75). Surgery can be hazardous in the patient with radiation enterocolitis because of a reduced vascular supply that results in impaired wound healing. Laparotomy is required, however, if tight strictures, complete obstruction, or symptomatic fistulas are present.

Diverticulitis

Etiology and Pathophysiology. Herniation of a small piece of intestinal mucosa and submucosa through the muscular wall of the bowel forms a diverticulum. These diverticula can be caused by increased colonic intraluminal pressure from chronic constipation. Diverticula are frequent in populations whose diets contain low quantities of fiber. Approximately 50% of people in the United States develop colonic diverticula by the ninth decade of life (76). The diverticula are usually multiple and are most frequently found on the left side of the colon. Diverticula rarely cause abdominal pain unless they become inflamed; this condition is called *diverticulitis* and occurs at some time in approximately 10% to 20% of patients with diverticula (76).

Symptoms and Signs. Most patients with diverticulitis are older than 60 years and complain of lower abdominal pain and fever. The pain is generally of moderate severity, can be either steady or cramping, and is frequently associated with nausea, vomiting, and a change in bowel habit (i.e., diarrhea, constipation, or mucus in the stool). Although diverticula are most commonly seen in the left colon, pain is frequent in the right as well as the left lower quadrants, possibly because of a redundant sigmoid colon that loops to the right of midline in many of these patients. Pain sometimes radiates to the back. Fever is usually present, and a peripheral leukocytosis with left shift is seen in most patients. Lower abdominal tenderness is a frequent finding, but significant rigidity and rebound tenderness are unusual. The sigmoid colon can sometimes be felt as a firm, tender cord in the left lower quadrant.

Diagnosis. The clinical diagnosis of diverticulitis can be made without difficulty in most cases. Gentle proctosigmoidoscopy with minimal air insufflation is useful in excluding other mass lesions, such as carcinoma, and diffuse mucosal diseases, such as inflammatory bowel disease and infectious colitis. Ischemic colitis must be considered in this group of patients, particularly when abdominal tenderness and pain are extreme and when antibiotic therapy has little effect. In the majority of patients, radiographic contrast examination is best delayed until patients have clinically improved. However, if the diagnosis is in doubt, the patient is not responding to appropriate treatment, or there is suspicion of a complication (e.g., abscess, fistula), then CT scanning is appropriate. Barium enemas have been reported to cause perforation when performed in patients with acute diverticulitis; however, gentle water-soluble contrast enemas can be helpful in some cases. The presence of diverticula can be confirmed, and areas of luminal narrowing safely defined when the radiographic examination is performed after the fever and pain have subsided.

Treatment. Most patients with diverticulitis respond to medical treatment with broad-spectrum antibiotics, correction of fluid and electrolyte losses, and general supportive care. Severely ill patients should initially be given nothing by mouth and then advanced slowly to a low-residue diet as symptoms improve. Use of parenteral narcotics is best avoided whenever possible to lessen the risk of masking a diverticular perforation or some other process, such as colonic ischemia. Surgical or percutaneous drainage is necessary when radiography shows abscess formation. Surgical intervention may also be required if the patient is not responding to medical therapy, or if colonic obstruction does not resolve. In the latter case, surgical decompression with a colostomy might be necessary. Later, when the area of diverticulitis is less inflamed, the segment can be resected as part of a two- or three-stage surgical procedure.

Crohn's Disease

Crohn's disease is a frequent cause of both acute and chronic abdominal pain, particularly in young people. Crohn's disease is an idiopathic inflammatory disease of the intestine. Either the small or large intestine, or both, are involved with a transmural inflammatory process. Areas of normal mucosa, referred to as *skip areas*, can be present between the inflamed regions of bowel.

Etiology and Pathophysiology. The cause(s) of Crohn's disease remains unknown. More recent theories revolve around the concept of genetically determined defective downregulation of inflammation driven by ubiquitous antigens present in the intestinal lumen (77). Varying bacteria and viral antigens have been postulated to be the triggering agent. More recent work has focused on the possible role of *Mycobacteria paratuberculosis* in Crohn's disease (78). However, it appears likely that Crohn's disease represents a heterogeneous group of diseases that shares similar mechanisms of tissue damage but may have different initiating events and immunoregulatory abnormalities (77).

Symptoms and Signs. Pain in patients with Crohn's disease is caused by either obstruction or inflammation. Inflammatory pain can be found anywhere in the abdomen, depending on the location of the inflamed bowel. Right lower quadrant pain is most frequent because of the common involvement of the terminal ileum and cecum. This pain is a continuous ache and occasionally radiates to the right upper thigh. It can be severe enough to cause the patient to limp. The pain is not necessarily associated with bowel movements but can be exacerbated by eating. Often superimposed on this continuous aching discomfort is a more severe crampy pain, which is located in the periumbilical region and is often relieved by bowel movements. This type of pain is usually a sign of partial intestinal obstruction induced by the inflammatory process and can be associated with nausea and vomiting. Diarrhea, which can be bloody, fever, and weight loss are other frequent symptoms.

Symptoms of anal and rectal involvement can also be prominent in patients with Crohn's disease. Rectal involvement causes a sensation of urgency or tenesmus (a feeling of rectal irritation or discomfort that makes the patient feel that a bowel movement is about to occur, when, in fact, only a small amount of diarrhea might be present, or no stool at all). Perianal pain caused by fistula, fissure, or abscess is found in approximately one-half of patients with Crohn's disease at some time in their illnesses. Severe pain localized to the anus and perianal area, accompanying or following bowel movements, is characteristic of these complications (these anorectal problems are discussed in more detail in Diseases of the Anus and Rectum, later in this chapter).

Patients with Crohn's disease can also have symptoms caused by extraintestinal complications (79). These problems are most common during periods of active inflammation and often respond to medical or surgical treatment of the bowel disease. Arthritis is seen in approximately 25% of patients with Crohn's colitis, but is less frequent when Crohn's disease is limited to the small bowel. A few large joints or multiple smaller joints can be affected. Skin involvement in the form of erythema nodosum, pyoderma gangrenosum, and other rashes is also seen in patients with colonic inflammation. Conjunctivitis, uveitis, and oral aphthous ulcerations are seen in 5% to 10% of patients with colitis. Liver disease, including pericholangitis, fatty liver, and, less commonly, sclerosing cholangitis, is also seen in patients with Crohn's disease.

Diagnosis. The diagnosis of Crohn's disease is usually made by a suggestive history and physical examination, with the aid of radiographic contrast examination endoscopy, and endoscopic biopsies. Small intestinal involvement is best detected with barium radiography. Colonic involvement can be defined by both roentgenography and colonoscopy. It is sometimes difficult to distinguish between Crohn's disease limited to the colon and ulcerative colitis.

Patients presenting with complaints of abdominal pain and diarrhea must have infectious enterocolitis ruled out by appropriate cultures and serologic tests. *Campylobacter*, *Shigella*, *Mycobacteria*, and *Amoeba* can all cause a clinical picture similar to that of Crohn's colitis. Pseudomembranous colitis should be considered

in all patients who have been taking antibiotics. *Yersinia* infection can also cause right lower quadrant pain and diarrhea that mimic Crohn's disease.

Appendicitis, ischemic enterocolitis, and intestinal malignancy should also be considered in patients thought to have inflammatory bowel disease. Patients who have an abrupt onset of ileitis are frequently operated on for presumed appendicitis. Appendectomy should not be done in these patients if the cecum is grossly involved with Crohn's disease at the time of surgery because enterocutaneous fistulas could form at the appendectomy site. Intestinal ischemia should be considered in elderly patients with intestinal inflammatory disease, especially in patients with a history of other atherosclerotic cardiovascular diseases. Colonic cancer and small intestinal lymphoma must be ruled out when a mass is present on radiographic studies of the intestine.

Treatment. Treatment of the patient with Crohn's disease involves a multidisciplinary approach. The gastroenterologist, surgeon, psychologist, and nutritionist all have valuable roles, but it is crucial that the patient maintain close contact with one physician. The emotional support, provided by a trusted and concerned physician, is invaluable over the long course of illness. The role of stressful life events in the exacerbation of inflammatory bowel disease is well recognized and underlines the role of the primary physician for major psychological support. Formal psychotherapy is indicated in selected patients with prominent psychological problems.

Pain is best controlled by appropriate management of the underlying inflammatory disease. Systemic corticosteroids, such as prednisone in a dose of 1 mg per kg, are useful in treating acute exacerbations of Crohn's disease. These drugs must be used cautiously and should be tapered rapidly because of their long-term side effects and the difficulty some patients have in discontinuing the medication. Systemic corticosteroids do not prevent relapses of Crohn's disease, and, thus, long-term use is discouraged. Hydrocortisone enemas are useful in the treatment of rectal and left colonic inflammation. This can be particularly helpful in reducing the troublesome symptom of tenesmus. Newer oral and topical corticosteroids (budesonide, beclomethasone, tixocortol) have been shown to be effective with few or no systemic side effects (80). These agents are either poorly absorbed or rapidly metabolized by the liver.

Oral aminosalicylate agents can also be useful in the management of Crohn's disease. Sulfasalazine (Azulfidine) in a dosage of 2 to 4 g per day is useful in treating flares of Crohn's colitis, but has not been shown to prevent relapse in the patient with quiescent disease. Newer aminosalicylate agents, including mesalamine (Asacol, Pentasa, Rowasa), olsalazine (Dipentum), and balsalazide (Colazide), do not have some of the intolerance or allergic complications of sulfasalazine. These newer aminosalicylate agents are effective in Crohn's ileocolitis and colitis, and, in addition, mesalamine has been shown to be effective in maintaining remission in patients with Crohn's disease (81,82).

Immunosuppressive medications, such as 6-mercaptopurine, azathioprine, and methotrexate, can prevent relapse and decrease corticosteroid requirements in patients with Crohn's disease. Cyclosporin A and tacrolimus may also be useful in patients with chronic active Crohn's disease and in healing fistulae secondary to Crohn's disease (83,84). Metronidazole in a dosage of 15 to 20 mg per kg per day, ciprofloxacin, or both can be helpful in patients with Crohn's disease, particularly for perianal disease (85,86). Other novel therapies under investigation include the use of lipoxygenase inhibitors, interleukins, free radical scavengers, and antibodies to tumor necrosis factor (80).

Narcotic analgesics should be used judiciously in the management of patients with inflammatory bowel disease. The decreased intestinal motility associated with the use of these agents can precipitate toxic megacolon in patients undergoing severe attacks of Crohn's colitis. Paradoxically, narcotics can increase pain in some patients by increasing intestinal spasm. Nevertheless, the less potent narcotics are helpful in managing the chronic diarrhea and cramping. Four to eight tablets daily of codeine, loperamide, or diphenoxylate with atropine are commonly used. Anticholinergic drugs, such as propantheline, 15 mg four times a day, and dicyclomine, 20 mg four times a day, also relieve intestinal cramping in some patients.

Dietary manipulation can benefit some patients with inflammatory bowel disease. Patients with significant obstructive symptoms can obtain relief by eating low-residue foods. Many patients with Crohn's disease are lactose intolerant; a trial of eliminating dairy products from the diet can decrease pain and diarrhea. Other dietary manipulations should aim at providing adequate amounts of protein and calories.

Resective surgery should be avoided whenever possible because the disease can recur in previously uninvolved segments of bowel. Nevertheless, significant intestinal obstruction and unhealed fistulas remain a common indication for surgery in this disease. Surgery is also indicated for the drainage of abscesses and for repair of intestinal perforation. Massive intestinal hemorrhage and toxic dilatation of the colon unresponsive to medical therapy are other rare indications for surgery in Crohn's disease.

Ulcerative Colitis

Etiology and Pathophysiology. Ulcerative colitis is another common type of idiopathic inflammatory bowel disease. Inflammation is limited to the mucosal surface of the colon, beginning at the anus and extending proximally for variable distances. Unlike Crohn's disease, the inflammatory process does not involve the more proximal gastrointestinal tract. Like Crohn's disease, the cause is unknown; the same pathogenic factors discussed in the previous section might also be involved in ulcerative colitis.

Symptoms and Signs. Most patients with ulcerative colitis have some combination of abdominal pain, diarrhea, and hematochezia during active flares of the disease. Bloody diarrhea is a more common complaint than pain. Pain is usually not as severe as that seen in some patients with Crohn's disease. Pain is usually located in the left lower quadrant of the abdomen, is cramping in character, and is generally accompanied by an urge to defecate, which often relieves the pain. A minority of patients have a fulminant onset of ulcerative colitis, known as *toxic megacolon*. In this situation, the colon distends to a large diameter and can produce severe diffuse abdominal pain and fever.

Perianal pain is not as common in ulcerative colitis as it is in Crohn's disease. Patients with ulcerative colitis can have anal fissures that cause pain during bowel movements, but perianal fistulas are not part of this disease.

Diarrhea is often a prominent symptom. Stools can be soft but formed, watery, full of mucus, or frankly bloody. Diarrhea can be present, with or without abdominal pain. Stools can be as frequent as every half hour and often awaken the patient at night.

Extraintestinal manifestations of ulcerative colitis are similar to those seen in Crohn's disease (79). Joint, skin, eye, and liver involvement can be indistinguishable from that seen in Crohn's disease.

Diagnosis. The diagnosis of ulcerative colitis is usually made when sigmoidoscopy is performed to investigate diarrhea and abdominal pain. The rectal mucosa is red, friable, and sometimes ulcerated in patients with active disease. Crohn's disease, infectious colitis, and ischemic colitis can give a similar clinical and sigmoidoscopic appearance and should be considered as other diagnostic possibilities. Stool cultures and serology for amebiasis should always be done in this setting to rule out an infectious cause. In chronically immunosuppressed patients, the diagnosis of cytomegalovirus infection should also be excluded. Rectal mucosal biopsies can sometimes help to distinguish among infectious colitis, Crohn's colitis, and ulcerative colitis.

Patients with ulcerative colitis have an increased risk for the development of colon carcinoma. Patients with disease that has involved the entire colon for longer than 10 years are at highest risk. Those with a change in the character of their diarrhea or abdominal pain should be investigated for this complication. Colonoscopy with multiple biopsies is the procedure of choice for detecting colon cancer or dysplasia in patients with ulcerative colitis.

Treatment. The same multidisciplinary approach used in the management of patients with Crohn's disease should be followed for patients with ulcerative colitis. Medical, surgical, psychological, and nutritional therapies all have roles in the management of patients with this disease. The specific treatment selected depends on the severity, extent, and duration of the disease.

Pain in patients with ulcerative colitis is best managed by controlling the colonic inflammation. Sulfasalazine (Azulfidine), in a dosage of 2 to 4 g per day orally, is usually effective in inducing remission and preventing relapse in patients with mild to moderate disease. Approximately 25% of patients taking this drug have nausea, epigastric pain, or headache; these side effects can be reduced by lowering the dose of Azulfidine or by switching to a newer aminosalicylate medication such as mesalamine, olsalazine, or balsalazide (see previous discussion). These newer aminosalicylate medications have also been shown to be effective in a dose-dependent manner for treating mild to moderately active ulcerative colitis as well as in maintaining remission (80). For patients with rectal or left-sided colonic involvement, aminosalicylate enemas can be effective in achieving clinical remission and preventing relapse.

Corticosteroids are effective in controlling colonic inflammation and the resultant abdominal pain and diarrhea. Patients with disease limited to the rectum and

descending colon often benefit from the daily administration of hydrocortisone enemas (Cortenema) or hydrocortisone suppositories. These preparations are especially helpful in patients with rectal urgency and tenesmus. More severe and diffuse colonic disease usually requires systemic corticosteroids. Prednisone, 40 to 60 mg per day, rapidly controls the symptoms of pain and diarrhea in most patients. Because disease relapse is not prevented by systemic corticosteroids, however, these drugs should be tapered rapidly and discontinued whenever possible.

Immunosuppressive medications, including 6-mercaptopurine and azathioprine, have been shown to be effective in refractory ulcerative colitis as well as in maintenance therapy. These medications are often useful for their steroid-sparing effect. Cyclosporine has been shown to be effective in avoidance of emergent colectomy in patients with severe ulcerative colitis refractory to corticosteroids (87), and tacrolimus (FK506) my also be useful in this circumstance (88). Long-term benefit is still under investigation.

Nicotine patches have been shown to be superior to placebo in treating patients with mild to moderately active ulcerative colitis (89); however, long-term studies are not available. This agent may be most useful in the patient whose colitis presents or flares with smoking cessation.

Antiperistaltic drugs are useful in decreasing the frequency of diarrhea in patients with ulcerative colitis. Diphenoxylate with atropine and loperamide are the most frequently used agents. A dosage of four to eight tablets per day is commonly used. These drugs can also decrease some of the lower abdominal cramping pain associated with bowel movements. Opiates should not be used in patients with severe disease because they have been associated with the development of toxic megacolon (90).

Colectomy is indicated in patients with ulcerative colitis for intractable disease and for specific complications. Colectomy is life saving in patients with toxic megacolon unresponsive to medical management. Others with continued abdominal pain and bloody diarrhea that is only controlled by high-dose corticosteroids should also be offered surgery. Total proctocolectomy cures ulcerative colitis and prevents the sequelae of long-term corticosteroid use in these patients. Colectomy is also indicated to prevent the development of carcinoma when mucosal biopsies show dysplasia in patients with long-standing disease.

Proctocolectomy with ileostomy and proctocolectomy with ileoanal anastomosis and ileal reservoir are the most commonly performed operations in patients with ulcerative colitis. The choice of operation depends on the medical condition, preference of the patient, and experience of the surgeon.

Intestinal Obstruction

Etiology and Pathophysiology. Mechanical or nonmechanical obstruction to the normal passage of intestinal contents from the stomach to the anus is another common cause of abdominal pain. Interruption of the luminal pathway can be a result of several different mechanisms, all of which produce the symptoms of abdominal pain, distension, vomiting, and failure to pass flatus. The causes and mechanisms of intestinal obstruction are listed in Table 66-2. In adults, adhesions most commonly cause mechanical small bowel obstruction, and cancer is the most frequent cause of large bowel obstruction. Nonmechanical obstruction of the intestine is caused by abnormal intestinal motor function, which can be either a primary intestinal abnormality, as in primary intestinal pseudoobstruction (91), or more commonly, secondary to other problems.

Mechanical obstruction	Nonmechanical obstruction
Luminal contents	Pseudoobstruction
Foreign bodies	Primary
Gallstones	Secondary: drugs, endocrinopathy, systemic illness
Bezoars	Paralytic ileus
Feces	Surgery
Intrinsic lesions	Trauma
Neoplasms	Infection
Strictures	Metabolic
Atresia	
Extrinsic compression	
Neoplasms	
Adhesions	
Abscess	
Intussusception	
Volvulus	
Herniation	

TABLE 66-2. Causes of intestinal obstruction

Symptoms and Signs. Abdominal pain resulting from intestinal obstruction is usually caused by intestinal distension proximal to the area of obstruction. Crampy periumbilical pain is characteristic of small bowel obstruction. The interval between cramps is approximately 5 minutes when the blockage is proximal and longer with more distal obstruction. Abdominal distension is usually present, except with the most proximal obstructions. Vomiting is bilious with upper intestinal obstruction and becomes darker and even feculent as the area of blockage is increasingly distal. Patients with colonic obstruction usually have more distension, pain, and vomiting occurring later. The pain caused by large bowel obstruction is often infraumbilical, in the midline, or on either side. Patients might continue to pass feces after the onset of obstruction because of preserved colonic motility, but they cease to pass flatus. Patients with nonmechanical obstruction generally have less severe pain than those with mechanical obstruction. Further diagnostic tests are required to distinguish between those in the two groups.

Diagnosis. Physical examination of the obstructed patient is important for diagnosis and for determining management. Measurement of the orthostatic blood pressure and assessment of mucous membranes help to guide fluid resuscitation. These patients are usually dehydrated. Bowel sounds are generally decreased, possibly with high-pitched rushes, but these findings are neither sensitive nor specific for obstruction. Although abdominal distension with mild diffuse or periumbilical tenderness is often present, marked localized or rebound tenderness and fever should raise the suspicion that intestinal infarction or perforation has complicated the obstruction.

Plain abdominal roentgenography is the single most useful test in the diagnosis of intestinal obstruction. Dilated bowel, filled with air and fluid, is seen except with early or extremely proximal intestinal obstruction. The location and appearance of dilatated bowel help both to localize the obstruction and to determine whether a mechanical or nonmechanical mechanism is involved. Elevated peripheral white blood cell counts increase the suspicion of perforation or strangulation. Whereas radiographic contrast examinations help to localize the point of obstruction, they are best used when the patient has been decompressed, especially with small bowel obstruction. Barium or water-soluble contrast enemas are useful in defining a colonic obstruction and can even be therapeutic if a volvulus or intussusception is present.

Treatment. The management of the patient with intestinal obstruction includes general supportive care, treatment of the underlying abnormalities, and avoidance of complications. Initially, dehydration should be corrected with intravenous fluids, and the bowel decompressed with nasogastric suction. When clinical findings and plain films suggest complete mechanical obstruction, early laparotomy both defines the cause of obstruction and allows intestinal diversion or definitive correction of the abnormality. Parenteral narcotics are indicated for relief of pain while the patient is awaiting surgery. The major complications of intestinal obstruction are perforation and strangulation or infarction. Both problems carry high morbidity and mortality, require immediate surgery, and could be masked by analgesic use. Therefore, analgesics should be withheld in this situation if the diagnosis is unclear and if surgical intervention is not yet planned. Significant pain relief is often obtained by bowel decompression alone.

Treatment of nonmechanical obstruction involves supportive care, correction of underlying electrolyte or hormonal abnormalities, minimizing the use of constipating medications, and nasogastric suction if required. Surgery is rarely indicated. Paralytic ileus secondary to the postoperative state, infections, and electrolyte imbalance usually resolve with time and treatment of the causative factors. However, in patients not responding to conservative management, use of the anticholinesterase agent neostigmine has shown promise in treating selected patients with acute colonic pseudoobstruction (91). Supportive care and fluid therapy are also helpful in patients with acute exacerbations of chronic pseudoobstruction, but definitive therapy for these patients is not generally available (92).

Intestinal Neoplasms

Etiology and Pathophysiology. Benign and malignant neoplasms of the colon, including polyps and cancers, are common. Adenocarcinoma of the colon is the second most common cause of cancer deaths in the United States and is the most common type of gastrointestinal cancer. Most carcinomas of the colon are thought to begin as small growths of neoplastic tissue, known as *adenomatous polyps*. These polyps have an increasing degree of malignant potential with increasing size. Other

types of polyps, with little or no malignant potential, are also commonly found in the colon, including hamartomatous and hyperplastic polyps. The cause of colonic adenomas and adenocarcinomas is unknown, but both genetic and dietary factors are probably involved. Certain patients have conditions that place them at high risk of developing colon cancer, such as ulcerative colitis, familial polyposis syndromes, nonpolyposis family cancer syndromes, and general family history of colon cancer. Neoplasms of the large intestine other than adenocarcinoma are rare; these include carcinoid tumors, lymphomas, and stromal tumors.

Tumors of the small intestine are uncommon. Adenocarcinoma, lymphoma, carcinoma, and malignant stromal tumors all occur in the small bowel but overall account for less than 5% of all intestinal neoplasms.

Symptoms and Signs. Most neoplasms of the intestine are painless until they produce luminal obstruction or extend to adjacent structures. When obstruction is present, the cancer is often incurable; the tumor must reach a large size before it causes obstruction. Occasionally, a small polyp presents with pain caused by intussusception. The characteristics of pain caused by intestinal obstruction and intussusception are similar to those described in the preceding section. Locally advanced carcinomas can cause abdominal pain by erosion into adjacent organs, such as the retroperitoneum and sacrum. Carcinomas can perforate and cause acute abdominal pain and signs of peritonitis. Other symptoms of neoplasms include bleeding, which is often occult, and changes in bowel habits, such as constipation. A reduction in stool caliber is often noted if the tumor is in the rectum or distal colon. Metastatic colon cancer frequently causes profound inanition, weight loss, and pain.

Diagnosis. Selection of diagnostic tests to detect intestinal cancer is based on the patient's clinical presentation. Patients with pain caused by complete intestinal obstruction usually require laparotomy, both for diagnosis and for treatment of the obstruction. Intermittent abdominal pain caused by partial bowel obstruction should be investigated by contrast radiography. Upper gastrointestinal roentgenography with a small bowel follow-through examination or abdominal CT scanning can detect small intestinal mass lesions, but laparotomy is sometimes required for diagnosis of these lesions. If symptoms or plain abdominal films suggest the presence of large bowel obstruction, rigid or flexible sigmoidoscopy followed by a barium enema should delineate the level of obstruction. Colonoscopy is necessary to biopsy mass lesions detected by roentgenography and can also reveal small polyps or cancers missed by radiography (93).

Patients with gross or occult blood in their stools, or a change in stool character and frequency, should have a colonoscopy to detect polyps and cancers. These lesions may be missed by barium enema. Blood tests (e.g., the level of carcinoembryonic antigen) can be useful in following patients with a history of resected colon cancer to monitor for recurrence.

Treatment. Treatment of intestinal neoplasms involves several types of therapies, including surgery, radiation therapy, and chemotherapy. Polyps can usually be removed by colonoscopy, but colectomy is needed if an invasive carcinoma is present. Surgical resection provides the best chance for cure of colon cancer; prognosis is directly related to the degree of invasion and spread. Radiation therapy decreases pain caused by spinal metastases and advanced pelvic tumors. In patients with stage III colon carcinoma, postsurgical adjuvant chemotherapy (5-fluorouracil with levamisole) has been shown to decrease tumor recurrence and prolong survival (94). The use of 5-fluorouracil with leucovorin may be as effective as 5-fluorouracil with levamisole. In patients with stage II colon adenocarcinoma, adjuvant treatment with 5-fluorouracil and levamisole may produce a decreased recurrence rate without a significant benefit in survival (94). In patients with limited liver metastasis, surgical resection may be possible. Hepatic arterial infusion of floxuridine can also decrease the size of liver metastases and thus decrease right upper quadrant pain caused by distension of the liver capsule, but survival might not be prolonged by this procedure (95). This therapy should be used in patients with symptomatic liver metastasis who are in otherwise good condition.

Treatment of pain in patients with advanced colorectal cancer is a challenging problem that often requires multiple medical disciplines. Many of these patients can be managed with narcotic analgesics, using the principles outlined in Chapter 36, Chapter 84, Chapter 102, Chapter 103, and Chapter 104. When narcotics are not well tolerated or are ineffective, other procedures should be attempted. Upper abdominal pain can be relieved by celiac plexus block with alcohol (55). Because pain is more commonly seen in the lower abdomen and pelvis in these patients, however, subarachnoid injection of alcohol to interrupt the affected segments can be used; epidural administration of morphine or some other narcotic can be alternatives to neurosurgical procedures in patients with intractable lower abdominal, pelvic, and sacral pain caused by colorectal cancer (96,97). Detailed discussions of these high-technology and surgical aspects of managing cancer pain can be found in Chapter 35 and Chapter 102, Chapter 103, Chapter 104, Chapter 105 and Chapter 106.

Irritable Bowel Syndrome

Etiology and Pathophysiology. Irritable bowel syndrome is a frequent cause of abdominal pain in the general population and is the most common diagnosis among patients referred to gastroenterologists (98). The cause of this disorder is unknown but most likely is multifactorial and may be related to altered visceral sensitivity or intestinal motility (99,100). Emotional stress is often associated with exacerbations of the irritable bowel syndrome. Patients with this disorder also perceive pain produced by small and large intestinal distension in more diverse abdominal and extraabdominal sites than do healthy people (11,56). Irritable bowel syndrome is twice as common in female than male subjects, can be associated with a history of prior physical or sexual abuse, most often begins in the third or fourth decade of life, and commonly recurs for the lifetime of the patient.

Symptoms and Signs. Most patients with irritable bowel syndrome have abdominal pain, a cramping or aching pain below the level of the umbilicus that is relieved by a bowel movement or by passing flatus (101). Pain lasts from a few minutes to hours and is usually recurrent. Some patients with irritable bowel syndrome have predominantly epigastric pain and are part of the nonulcer dyspepsia spectrum.

Alteration of bowel habits occurs in 90% of patients with irritable bowel syndrome. Constipation, diarrhea, or alternating episodes of constipation and diarrhea can occur. Individual patients often have a typical pattern of bowel evacuation that is constant over their lifetimes. Stools are often loose with an episode of pain, but the pain is usually relieved by the bowel movement (101). Abdominal distension, mucus in stools, nausea, vomiting, and excessive flatus are frequently associated symptoms. Symptoms are recurrent and are often associated with stressful life events.

Diagnosis. Diagnosis of irritable bowel syndrome requires recognition of the positive clinical features outlined previously, as well as exclusion of other known causes of the patient's symptoms (101). Lactose intolerance, giardiasis, inflammatory bowel disease, and intestinal obstruction should be considered in patients with recurrent abdominal pain and altered bowel habits. A trial lactose-free diet; examination of stool for blood, ova, and parasites; sigmoidoscopy; and barium enema examinations are usually needed to exclude these possibilities. Patients who have blood in their stool, fever, weight loss, progressive symptoms, nocturnal pain, or nocturnal diarrhea are more likely to have an illness other than irritable bowel syndrome; those in this group should have a more thorough investigation for other causes of their symptoms.

Treatment. No cure is available for irritable bowel syndrome, but patients can be helped in several ways. The concerned and supportive physician can do much to relieve patients' concerns about their symptoms. The importance of a supportive role is illustrated by the beneficial effects of placebos in reducing pain in these patients. Stress management techniques can also be useful in decreasing the frequency of symptoms. Tricyclic antidepressants have been shown to reduce abdominal pain and nausea significantly more than placebo in patients with irritable bowel syndrome (102).

Other medical therapies for irritable bowel syndrome can benefit individuals, but controlled trials have not proven their efficacy in large groups of patients. A high-fiber diet is usually helpful in reducing constipation, but abdominal pain might not be relieved. Loperamide or diphenoxylate with atropine, one or two tablets in the morning and evening, can be used to control diarrhea. Anticholinergic agents such as dicyclomine, 10 to 20 mg, hyoscyamine, 0.125 to 0.25 mg, and propantheline, 15 to 30 mg given before meals, can decrease abdominal pain that is induced by eating. Narcotic analgesics for pain in this syndrome have not, in our experience, been useful, nor are there published studies that indicate the utility of narcotics for this syndrome. Moreover, the risk of psychological and physical dependence from long-term opiates is real. Reassurance that symptoms usually resolve with time and that the patient's longevity is not decreased in irritable bowel syndrome is critical to successful long-term management.

DISEASES OF THE ANUS AND RECTUM

Basic Considerations

Anatomy

The rectum constitutes the distal 12 to 15 cm of the large intestine, beginning at approximately the level of the S-3 vertebra. Many diseases of the rectum are part of the spectrum of other colonic diseases and have been considered in the previous section (e.g., carcinoma, inflammatory bowel disease, and various obstructive

lesions). Other disease processes involving the rectum produce symptoms that are similar to those of anal disease and are included here to facilitate clinical recognition. The terminal 3 cm of the rectum pass through the anal canal, which is made up of an internal sphincter of smooth muscle and an external sphincter of striated muscle. The rectum is lined with columnar mucosa as far distally as the pectinate line, which is approximately 2 cm inside the anal verge.

Nerve Supply

Sensory innervation of the rectum is through visceral afferent nerves that course with parasympathetic nerves by way of the pelvic splanchnic nerves and the pelvic plexus to enter the spinal cord at the S-2 to S-4 levels (see Fig. 66-9). Rapid distension, inflammation, and infiltration of the rectum produce a sensation of aching in the region of the rectum or a poorly localized deep central pelvic pain. Patients with rectal diseases also often report a dull or aching pain in the region of the midsacrum (103).

The anal canal distal to the pectinate line is covered with stratified squamous epithelium and is innervated by somatic sensory nerves. These nerve fibers are carried by the inferior hemorrhoidal nerve and synapse in the dorsal root ganglion at the S-2 to S-4 levels. Unlike other parts of the rectum and intestine, the anal canal is sensitive to cold, heat, and touch. Pain from the anus is well localized and often severe. The pain is usually continuous and can be of a burning, throbbing, or aching nature (103).

Clinical Considerations

Anatomic Abnormalities

Anal stenosis and atresia with fistula formation to other perineal structures are common congenital defects caused by incomplete development of the hindgut. They are generally diagnosed by inspection in early infancy and thus are not considered further here.

Hirschsprung's disease, or congenital megacolon, is caused by the absence of the intramural neural plexuses of a segment of the colon and results in dilation of the bowel proximal to the abnormal segment (103). More than two-thirds of cases involve only the rectum and distal sigmoid colon. Most patients present in infancy with abdominal distension and vomiting, suggesting intestinal obstruction. If the problem remains undetected until later in childhood, constipation, failure to gain weight, and diffuse abdominal pain can result. The diagnosis is usually suspected when a dilatated colon is seen on plain abdominal radiographs or with barium enema. Diagnostic confirmation requires the demonstration of the absence of intramural nerve plexuses by rectal biopsy. Surgical resection of the rectosigmoid usually corrects the problem.

Foreign Bodies

Numerous types of foreign bodies have been known to be introduced into the rectum, causing local pain and irritation. Perforations and lacerations can also occur, resulting in severe pain and sometimes peritonitis. Blood or mucus might be seen in the stool. The presence of foreign bodies and the extent of mucosal damage can usually be assessed by sigmoidoscopy. Most foreign objects in the rectum can be removed through the sigmoidoscope, although anesthesia may be required for this procedure. Laparotomy is required for foreign bodies that cannot be removed endoscopically and for intestinal perforation.

Hemorrhoids

Etiology and Pathophysiology. Hemorrhoids are dilatated blood vessels of the anal canal. They are classified as internal if above the pectinate line and external if below the pectinate line. Several theories have been proposed to explain the formation of hemorrhoids (104). Increased venous pressure in the pelvis, high anal sphincter tone, low-residue diets with resulting hard stool, and prolonged straining with defecation can all contribute to hemorrhoid pathogenesis.

Symptoms and Signs. Internal hemorrhoids are usually painless and cause symptoms either by bleeding or by prolapsing into the anal canal (104). Most patients with internal hemorrhoids reveal a history of anal discomfort at some time, although this might only be a mild irritation. If prolapsed hemorrhoids become incarcerated and thrombose, however, intense pain can be produced. The pain is localized to the anal area and is made worse by bowel movements, sitting, and walking. Hemorrhoidal bleeding is usually bright red and painless and can be seen on the surface of the stool, on the toilet tissue, or in the toilet bowl.

External hemorrhoids are usually asymptomatic. They are frequently seen in young people as small perianal bluish masses covered with normal perianal skin. These hemorrhoids can be painful if they thrombose or rupture into the surrounding skin, causing traction on adjacent nerves. This usually follows an episode of constipation and straining with defecation. The patient presents with well-localized perianal pain that is continuous and exacerbated by sitting and defection. External hemorrhoids usually do not cause rectal bleeding.

Diagnosis. Hemorrhoids are usually diagnosed by inspection of the anus and by use of simple maneuvers. Internal hemorrhoids can be seen at anoscopy, but the best way to detect them is with a stress test. The patient is asked to sit on the toilet and strain as one would during defecation. After 30 seconds, and while the patient continues to strain, the examiner inspects the anal region by placing a handheld mirror under the patient's buttocks. Internal hemorrhoids are visualized as bluish structures that protrude from the anus. Incarcerated internal hemorrhoids can be seen directly without patient straining as erythematous masses in the anal canal, covered with pink rectal mucosa. These lesions are tender and might not easily reduce back into the rectum. Thrombosed external hemorrhoids are bluish masses outside the anus that are covered with normal perianal skin and are usually tender to palpation.

Patients with anorectal pain or bleeding should have nonhemorrhoidal causes of the symptoms ruled out. Infectious proctitis, inflammatory bowel disease, anorectal neoplasms, and anal fissures should be considered in these patients. Sigmoidoscopy usually excludes these problems in patients younger than the age of 35 years. If pain or bleeding persists after treatment, colonoscopy should be performed to exclude lesions in more proximal areas of the colon (104). Care must be taken so that bleeding caused by a colon cancer above the area of sigmoidoscopy is not incorrectly attributed to hemorrhoids.

Treatment. Most patients with mild bleeding and discomfort caused by hemorrhoids can be managed medically. An increase in dietary fiber is often sufficient to soften stools, resulting in decreased straining with defecation. Topical application of ointments containing local anesthetics, such as 2.5% lidocaine or 1% pramoxine, can be soothing to patients with thrombosed external hemorrhoids. Hydrocortisone ointment 1% is also sometimes helpful for this condition. Warm water baths can decrease painful spasms of the anal sphincter.

Surgical therapy of hemorrhoids should be used in patients with persistent pain, bleeding, and prolapse. Rubber band ligation is a simple outpatient procedure that is quite effective in patients with internal hemorrhoids that are reducible and not too large (105). This ligation is more efficacious and has fewer complications than cryosurgery or injection of sclerosing solutions. Infrared coagulation and laser therapy for hemorrhoids are also available (106). Surgical resection of hemorrhoids is the treatment of choice for large and unreducible prolapsing hemorrhoids. Incarcerated hemorrhoids can usually be reduced after 1% lidocaine is injected around the anus and under the protruding hemorrhoid. Pain usually subsides within several days. Early surgical hemorrhoidectomy should be performed if thrombosis or gangrene is present. Patients with persistent pain, despite medical treatment of thrombosed external hemorrhoids, should have the associated clot excised. A single elliptical incision after injection of a local anesthetic, such as 1% lidocaine, allows clot evacuation. The procedure is safe, effective, and well tolerated.

Proctitis

Etiology and Pathophysiology. Inflammation of the anus and rectum has both infectious and noninfectious causes. Infectious proctitis is seen most frequently in homosexual men in whom frequent and widespread anogenital and orogenital contact is common (107). Infectious causes of proctitis are listed in Table 66-3. Inflammatory bowel disease limited to the rectum, trauma from foreign bodies and anal intercourse, radiation therapy, and allergies to lubricants and enemas are noninfectious causes of proctitis.

Symptoms and signs	Causative organism
Pain and anal discharge	*Neisseria gonorrhoeae*
	Herpesvirus hominis
	Treponema pallidum
	Chlamydia trachomatis
Pain and diarrhea	*Entamoeba histolytica*
	Campylobacter jejuni
	Shigella species
	Chlamydia trachomatis

TABLE 66-3. Causes and symptoms and signs of infectious proctitis

Symptoms and Signs. Bleeding, mucous or purulent discharge, pain, burning, and rectal urgency are the chief symptoms produced by anorectal inflammation; these symptoms are similar for all causes of proctitis. Diarrhea can be present if inflammation extends to more proximal areas of the colon (see Table 66-3). Pain is often increased by bowel movements and by wearing tight clothing. The most severe pain occurs when inflammation is present distal to the pectinate line.

Diagnosis. Specific diagnosis of the cause of proctitis is important for directing therapy and determining prognosis. Sigmoidoscopy usually reveals erythematous and friable rectal mucosa, with or without ulcerations, and areas of adherent purulent material. Herpes simplex infections can show characteristic grouped vesicles. Cultures for bacterial, chlamydial, and herpes organisms should be obtained from swabs obtained at sigmoidoscopy. Rectal ulcers should be swabbed for darkfield microscopic examination, and a serum serologic test for syphilis should be obtained if the patient has a history of anal intercourse. Rectal biopsies should be obtained when symptoms are persistent and cultures are negative to rule out inflammatory bowel disease.

Treatment. Treatment of proctitis is directed at the specific cause as well as symptomatic relief. Antibiotic therapy should be based on the results of appropriate cultures. Treatment of inflammatory bowel disease has been discussed previously. Sitz baths, warm compresses applied to the perianal region, and local analgesic ointments, such as lidocaine, can provide some relief. If maceration is present, all lubricants and ointments should be avoided and the area kept as dry as possible. Oral narcotic analgesics are sometimes necessary in severe cases.

Anorectal Abscess

Etiology and Pathophysiology. Localized abscesses are common in the perianal and anorectal areas. These infections can arise in preexisting tears, fissures, or thrombosed hemorrhoids, or can be seen in systemic illnesses such as Crohn's disease, ulcerative colitis, and leukemia. An underlying cause, however, often cannot be found. Abscesses can be superficial and in the perianal region, or they can be deep, in any of several potential spaces around the rectum (108).

Symptoms and Signs. Perianal abscesses, the most common type of anorectal abscess, present as painful localized masses. Pain is usually throbbing and constant until the abscess bursts.

Symptoms of deep anorectal abscesses are often not as well defined as those of the more superficial lesions. An aching sensation in the rectum, or poorly defined lower abdominal and pelvic pain, can be present. Fever is common in these deep perirectal infections.

Diagnosis. Physical examination in patients with anorectal abscesses usually reveals the diagnosis. Superficial abscesses are easily recognized by the presence of a red, tender, localized swelling near the anus. Deeper abscesses are detected by an exquisitely tender area of rectum found on digital examination. If deeper abscesses have burst into the rectal lumen, a purulent discharge is present. Peripheral leukocytosis is common, especially with deeper abscesses. Anorectal abscesses are distinguished from pilonidal, Bartholin's, and periurethral abscesses by their anatomic relationships to other perineal structures.

Treatment. Treatment of all anorectal abscesses centers around surgical drainage (108). It is not necessary to wait for fluctuance before carrying out incision and drainage. Antibiotics are useful when cellulitis is present around the abscess. The patient should have a follow-up examination for the detection of complications, such as fistula formation.

Anal Fissures

Etiology and Pathophysiology. Fissures of the anus are one of the most frequently seen painful anal conditions. These superficial tears of the anal epithelium are localized to the posterior midline of the anus in more than 90% of cases (103). Most commonly found in young adults with a recent history of constipation, fissures are probably formed by a tearing force associated with the passage of a large firm stool (104). Most fissures heal spontaneously within a few weeks. Chronic fissures, which are less likely to heal, occur in patients with high internal anal sphincter pressures. Other chronic fissures are seen in patients with Crohn's disease, ulcerative colitis, carcinoma, syphilis, and tuberculosis.

Symptoms and Signs. Most patients can relate the acute onset of pain caused by a fissure to defecation. Pain is localized to the anal area. The pain is continuous but is exacerbated by sitting and further defecation. Secondary constipation often occurs because of the fear of provoking pain with further bowel movements. A small amount of rectal bleeding and discharge can be present.

Diagnosis. The diagnosis of an anal fissure can usually be made by physical examination. Inspection of the anus often reveals an edematous skin tag adjacent to the distal aspect of the fissure. Rectal examination, with the examiner's smallest finger lubricated with lidocaine jelly, confirms the localized indurated anal wall and excludes associated mass lesions. Anoscopy and sigmoidoscopy must usually be postponed until the fissure has healed, but should eventually be done to exclude other rectal lesions.

Treatment. Treatment of anal fissures involves local analgesics and stool softeners to avoid pain and recurrent tears (104). Orally administered mineral oil or bulk agents such as psyllium usually loosen the stool, which facilitates stool passage and results in decreased straining. After the fissure has healed, additional fiber in the diet in the form of bran is often all that is needed to prevent recurrence. Local application of a lubricant containing a local anesthetic is helpful before bowel movements. This is best applied into the anal canal with the patient's little finger. Surgical resection or lateral subcutaneous sphincterotomy is usually required to treat chronic idiopathic fissures (109). However, more recent trials suggest that topical nitrates or botulinum toxin injection are also effective (110,111).

Anorectal Neoplasms

Etiology and Pathophysiology. Neoplasms of the anal canal and perianal region account for less than 5% of lower gastrointestinal malignancies. Approximately 50% of the neoplasms that present as anal masses are adenocarcinomas of the rectum, with distal growth through the anal canal. Most of the remainder are squamous cell carcinomas of the anal canal. Melanomas, basal cell carcinomas, and cloacogenic carcinomas are other rare neoplasms of this region.

Anal squamous cell carcinomas are associated with the presence of benign anorectal disorders, although the exact role of these conditions in the pathogenesis of the carcinoma is unknown. More than 50% of patients with these cancers have a history of hemorrhoids, fistulas, fissures, leukoplakia, abscesses, or anal warts (112).

Symptoms and Signs. Neoplasms of the anus and distal rectum present with symptoms different from those of more proximal colorectal cancers. These tumors are first detected either as an anal mass, because of bleeding or mucous discharge, or because of painful defecation. Continuous localized pain unassociated with defecation can also occur. Narrowing of stool caliber is often noted. Symptoms of large bowel obstruction can be seen with advanced cases. Weight loss and inguinal adenopathy usually indicate the presence of metastases.

Diagnosis. The diagnosis of an anorectal neoplasm is usually obvious after visual inspection of the anus and a gentle rectal examination. Any firm or indurated lesion

of the anal canal should be suspected as being neoplastic. These mass lesions can be biopsied through the anoscope to obtain a histologic diagnosis. If the patient can tolerate the procedure, the proximal extent of the tumor should be assessed by sigmoidoscopy.

Treatment. Therapy of anorectal neoplasms can involve radiotherapy, surgery, or chemotherapy. Radiotherapy or combined chemoradiotherapy of squamous cell carcinoma of the anus provides excellent control in approximately 80% of patients. Abdominoperineal resection is the operative treatment of choice for large rectal and anal cancers. Wide local excision should be reserved for anorectal tumors smaller than 4 cm^2. Postoperative chemoradiation therapy in patients with stage II or stage III anorectal adenocarcinoma can lead to a significant improvement in local control and survival (113). Preoperative radiation alone or chemoradiation for advanced local rectal cancers may also be effective while also improving resectability, decreasing morbidity, and increasing the chance that a sphincter-sparing operation may be performed (114). Novel therapies using interferons, monoclonal antibodies, and autologous tumor vaccines are being pursued (114).

Palliative treatment of anorectal neoplasms involves multiple therapeutic procedures. Radiation therapy of unresectable rectal cancer relieves symptoms of pain, bleeding, and discharge in approximately 75% of patients (115). Narcotic analgesics should be used liberally during radiation and in patients with pain unresponsive to radiation. The use of intraarterial chemotherapy, chronic intrathecal morphine administration, and ablative neurosurgical procedures in patients with intractable pain caused by anorectal neoplasms is similar to the use of these treatments for intestinal neoplasms. Pain management in patients with advanced cancer remains a challenging problem (see Chapter 36 and Chapter 40).

CHAPTER 67

Painful Diseases of the Liver, Biliary System, and Pancreas

D. David Graham and John J. Bonica

Pain is a frequent concomitant of diseases of the liver, biliary system, and pancreas. Pain is important both as a diagnostic symptom to be interpreted and as a clinical management problem. Because of the high frequency of hepatobiliary and pancreatic disease in clinical practice, familiarity with hepatic, biliary, and pancreatic pain syndromes is essential.

In this chapter, pain syndromes associated with hepatic disorders, biliary disorders, and pancreatic disorders are presented. The causes and pathophysiology of primary disease processes involving each of these organ systems are discussed. Painful symptoms are examined from the viewpoint of underlying disease mechanisms. An outline of essential diagnostic tests is provided. Discussion of treatment options focuses on therapy of primary disease processes and on palliation of accompanying organic pain. Pathologic processes are examined to determine mechanisms of pain production as a guide to rational pain management.

LIVER

Basic Considerations

In humans, branches of both vagus nerves and branches of splanchnic nerves innervate the liver (1). Two separate but intercommunicating plexuses are formed by the sympathetic and parasympathetic nerve fibers (Fig. 67-1 and Fig. 67-2). An anterior plexus composed of parasympathetic fibers from the anterior vagus and of sympathetic fibers from the celiac ganglion surrounds the hepatic artery. The posterior plexus is located behind the bile duct and portal vein and is derived from the posterior vagus and right celiac ganglion. Hepatic nerves enter the liver in association with blood vessels and bile ducts and parallel these structures as they arborize within the liver parenchyma.

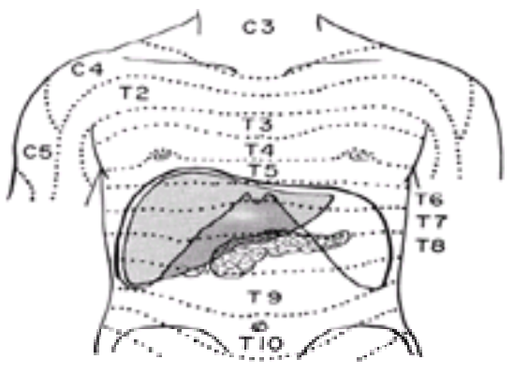

Figure 67-1. Schematic depiction of the position of the liver and pancreas in relation to body wall and dermatomes. The liver extends from T-5 to T-9, whereas the pancreas is located within T-7 to T-9.

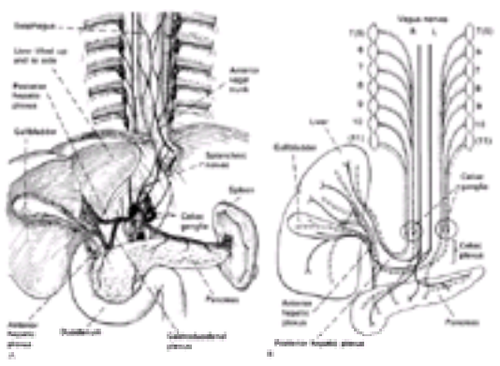

Figure 67-2. Anatomy of nerve supply to the liver, biliary system, and pancreas. **A:** Relationship of the vagus and sympathetic nerves contributing to the celiac plexus and the subsidiary plexuses, which follow vessels supplying the viscera. **B:** Schematic depiction of the course and distribution of two vagal nerves consisting primarily of preganglionic fibers, which synapse in the wall of the viscera with short postganglionic fibers (not shown). Preganglionic sympathetic fibers passing primarily from T-6 to T-9 (but also possibly from T-5, T-10, and T-11) pass through the superior and middle thoracic splanchnic nerves to the celiac ganglia, where they synapse with postganglionic fibers (*dashed lines*). Segments in parentheses in the sympathetic chain are variable. The afferent fibers are shown by the dotted lines. See text for details.

Hepatic pain is not transmitted by the vagi, although the liver receives a substantial vagal innervation and approximately 90% of vagal fibers are primary afferents. Vagotomy does not eliminate the perception of hepatic pain. Hepatic pain is believed to be transmitted to the central nervous system by afferent sympathetic fibers. In the cat, approximately 50% of visceral sympathetic fibers are afferent (2).

Clinical experience has attributed hepatic pain to stretch of Glisson's capsule by parenchymal swelling. The rate of hepatic enlargement can be the important variable in the production of pain; gradual hepatic enlargement is often painless. Morphologic evidence suggests that hepatic nerves might also be sensitive to changes in hepatic venous pressure (3). Nerve fibrils have been demonstrated in humans in association with intimal endothelial cells of hepatic veins that are structurally similar to known sensory nerves (4).

Hepatic inflammatory processes can produce well-localized somatic pain if the parietal peritoneum is involved. Sharp, intense, upper abdominal or lower thoracic discomfort is characteristic. Typically, inspiration intensifies such pain, and referred hepatic pain is usually noted in the right shoulder and scapular regions (Fig. 67-3).

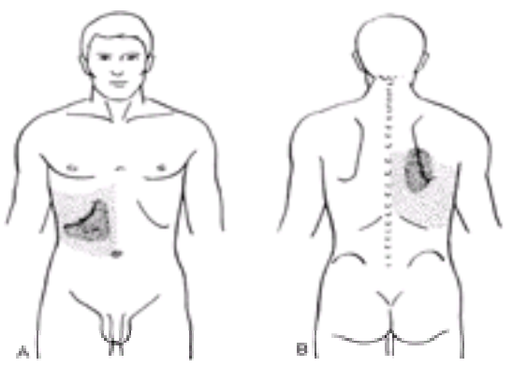

Figure 67-3. Areas of referred hepatic pain in the anterior **(A)** and posterior **(B)** regions of the body. The heavy stipple indicates the area of pain reference, whereas the light stipple indicates the extensive cutaneous hyperalgesia often associated with the pain.

Clinical Considerations

Viral Infection

Symptoms and Signs. Hepatic enlargement and pain resulting from capsular stretching frequently accompany acute viral hepatitis. During the early prodromal stage of the illness, pain is usually absent and physical findings are minimal. Fatigue, anorexia, arthralgias, and nonspecific constitutional complaints predominate. By the time jaundice appears, more than half of affected patients are symptomatic with hepatic pain. The discomfort is often described as a dull, heavy, unpleasant sensation, localized to the right upper abdomen. Hepatomegaly is common; the liver edge is usually smooth and tender to palpation just beneath the right costal margin.

Diagnosis. In the presence of appropriate symptoms, acute viral hepatitis can be diagnosed by determination of progressively elevated serum transaminase levels. The serum alkaline phosphatase levels can be normal or moderately elevated. Increases in the serum bilirubin level are variable. Assays to detect circulating viral antibodies and antigens should be performed to characterize the disease further.

Treatment. Treatment of uncomplicated acute viral hepatitis is largely supportive, consisting of nutritional care, pain relief, and avoidance of hepatotoxic drugs or agents. The accompanying hepatic discomfort is usually not a difficult management problem, but caution should be exercised in the administration of sedatives or analgesics. Agents with significant hepatic metabolic effects such as narcotics should be avoided, because the liver's ability to metabolize these substances may be compromised.

Bacterial Infection

Symptoms and Signs. Hepatic abscess should be suspected when hepatic pain is present in a patient with systemic sepsis. The most frequent localizing symptom is a constant dull pain in the right upper quadrant of the abdomen, present in 50% to 90% of such patients (5,6). Referred pain to the right shoulder and scapula is common. Most patients with hepatic abscess have a large, tender liver on physical examination. Jaundice is unusual, occurring in only 10% of patients (5). Ascites is rare. Systemic signs of sepsis predominate. Fevers, chills, rigor, and tachycardia are usually present. Malaise, anorexia, weight loss, nausea, and headache are frequent, nonspecific complaints.

Pathophysiology. Bacterial infection of the liver usually manifests as a parenchymal abscess. Hepatic abscesses can develop after bacterial contamination from several routes: (a) by direct extension from an adjacent suppurative process such as gangrenous cholecystitis; (b) by portal venous bacteremia from a distant septic focus such as appendicitis or diverticulitis; (c) through the biliary system via obstruction and cholangitis from either benign or malignant conditions; (d) from systemic infection such as endocarditis via the hepatic artery; or (e) due to secondary infection of blunt or penetrating hepatic trauma. The microbiology of hepatic abscesses reflects their common association with other gastrointestinal inflammatory diseases as well as biliary tract disease. Enteric organisms are recovered from cultures of the abscess in 80% of cases. *Escherichia coli, Streptococcus viridans*, and *Klebsiella* species are most prevalent and are discovered in greater than 50% of hepatic abscesses; anaerobic bacteria are frequent copathogens (7). Multimicrobial abscesses are common. More recently, fungal abscesses have become more common, likely due to the increased number of immunocompromised patients. Earlier this century, the majority of hepatic abscesses were the result of intraabdominal infections and subsequent extension to the liver, presumably via the mesenteric circulation and portal vein. However, with the advent of newer antibiotics, endoscopic biliary procedures, and percutaneous biliary tract manipulation, this etiology profile is changing. Currently, it is believed that biliary tract disease accounts for some 40% of liver abscesses. Interestingly, 20% to 40% of pyogenic liver abscesses have no identifiable cause (8). Hepatic abscesses are solitary in 60% of cases and multiple in the remainder. The right lobe is affected in 60% of cases, the left lobe is affected in 10% to 15% of cases, and 20% of cases are bilobar.

Diagnosis. Radiologic evaluation is essential to diagnose hepatic abscesses, to define the disease process anatomically, and to detect other foci of intraperitoneal sepsis. Ultrasonography is useful to rule out biliary tract disease. It is also a useful screening procedure for locating hepatic masses and to differentiate solid and cystic processes (6). Computed tomography (CT) scanning, however, currently provides the most detailed and accurate anatomic information for hepatic abscesses and has a higher overall diagnostic accuracy (95% to 100% sensitivity) than ultrasound. In most cases, CT scanning should be used in planning definitive therapy (9). ^{99}Technetium sulfur colloid scans have been used on a limited basis for some four decades. Such scans cannot detect lesions less than 2 cm in diameter, which limits their usefulness. Newer nuclear medicine technologies using gallium and indium have added little to the evaluation of these lesions. Magnetic resonance imaging (MRI) has not proven to be superior to CT scan in the diagnosis of hepatic abscess and does not allow for interventional techniques.

Treatment. The treatment of hepatic abscesses requires long-term (6-week) antibiotic therapy and percutaneous drainage of the abscess under CT or ultrasound guidance. Antibiotic therapy is usually started before detection of the abscess, because most patients have signs of systemic sepsis. The choice of antibiotic should reflect the polymicrobial enteric flora commonly associated with hepatic abscess; broad coverage of aerobic gram-negative organisms, *Streptococcus* species, and anaerobes should be achieved. Antibiotic therapy should include a 2-week intravenous course followed by oral antibiotics for an additional month. Once culture results return, antibiotics can be tailored for specific organisms. Percutaneous catheter drainage of hepatic abscesses is often successful if the infection is solitary and not associated with other intraperitoneal pathology, and it is most often the treatment of choice over operative therapy. In the case of multiple abscesses, percutaneous drainage is of little value. Operative therapy of accompanying foci of infection (e.g., suppurative cholangitis requiring cholecystectomy), however, is frequently required. Operative therapy may be required in the case of (a) patients in whom percutaneous drainage is not feasible, (b) a failed percutaneous drainage, and (c) patients with concomitant gastrointestinal disease requiring operation. Recently, laparoscopic drainage of hepatic abscesses has been introduced, which is also useful in addressing the primary disease process. Treatment of the pain associated with hepatic infection depends on successful treatment of the abscess. Chronic pain syndromes have not been associated with parenchymal hepatic infection.

Gonococcal Perihepatitis

Pathophysiology. Gonococcal perihepatitis, described in women as a cause of right upper quadrant pain, is known as the *Fitz- Hugh-Curtis syndrome*. The gonococcal organism is transmitted venereally and has an affinity for the urogenital epithelium. Ascending infection presumably enters the peritoneal cavity through the fallopian tubes and reaches the perihepatic space via the right paracolic gutter. Pelvic infection may not be clinically obvious. *Chlamydia* can also cause the syndrome in women in the presence or absence of gonococci.

Symptoms and Signs. Acute gonococcal perihepatitis begins as sudden right upper quadrant pain with radiation to the right shoulder. Inspiration intensifies the pain. Fever, tenderness, and rebound are common. Acute gonococcal perihepatitis can be suspected when these symptoms are present in sexually active women with clinical evidence of pelvic inflammatory disease or gonococcal organisms demonstrated on cervical culture.

Treatment. Treatment of acute gonococcal perihepatitis requires antibiotic therapy appropriate for treatment of the underlying pelvic inflammatory disease. Painful

symptoms should resolve promptly (10).

Chronic or incompletely treated perihepatitis has been reported to result in formation of adhesions from the liver to the surrounding parietal peritoneum. A chronic upper abdominal pain syndrome can result from traction of such adhesions on the parietal peritoneum. Laparoscopy can be used to identify this process. Lysis of offending adhesions usually eliminates the pain (11).

Neoplastic Disease

Involvement of the liver by primary and metastatic neoplasms remains a great challenge to those interested in the treatment of pain. The magnitude of this problem can be appreciated by considering that in total approximately 40% of patients dying with a solid tumor develop liver metastases (12). In addition, hepatocellular carcinoma is the most prevalent cancer in the world, killing more than 1 million annually. Furthermore, the incidence of hepatocellular cancer has doubled in the United States during the past 30 years. Without treatment, up to 70% of patients with hepatic metastases die within 1 year of diagnosis and nearly 100% die within 3 years. Results of a study by Jaffe and colleagues (13) suggested that metastatic replacement of the liver is the aspect of visceral cancers that most directly contributes to mortality. Because cure of primary or metastatic hepatic tumors is not common, palliation, including palliation of painful symptoms, is a major clinical goal.

Primary hepatic tumors cause approximately 1% of cancer deaths in the United States and are the twenty-second most common cancer in the United States (14). In parts of Africa and Asia, however, hepatocellular carcinomas cause up to 20% to 40% of cancer-related deaths. Hepatoma frequently develops in the setting of preexisting severe liver disease and often is related to hepatitis B and C infection. More than 50% of patients who develop hepatocellular carcinoma have histologic evidence of cirrhosis. Approximately 5% of patients with alcoholic cirrhosis in the United States develop hepatocellular carcinoma. The frequency is even greater in individuals with postnecrotic cirrhosis (10%), untreated hemochromatosis (20%), or cirrhosis caused by a ¡-antitrypsin deficiency. Because of the high absolute number of patients with alcoholism, the majority of patients in most reported series have Laënnec's cirrhosis, typical of alcohol abuse (15), although the number of cases related to chronic viral infection is increasing.

Symptoms and Signs. Most authors, although emphasizing that symptoms caused by hepatoma are vague and nonspecific, have reported that pain is a prominent symptom when patients first seek medical attention. Ihde and associates (16) noted that more than 70% of hepatoma patients have right upper quadrant or epigastric pain of a chronic nature, most commonly associated with a hepatic mass, weight loss, or ascites. The pain is frequently described as an epigastric pressure, fullness, or heaviness. Associated symptoms are nonspecific and include weakness, malaise, anorexia, and weight loss. The onset of symptoms is usually insidious. An abdominal mass is the main complaint in 10% to 20% of cases. Jaundice is present in some 25% of cases of primary hepatocellular carcinoma. A second relatively common presentation, noted in 8% of patients with hepatoma, consists of acute right upper quadrant pain, fever, and jaundice, mimicking that of acute cholecystitis.

Because hepatocellular carcinomas tend to develop in patients with hepatic functional impairment, systemic symptoms can be prominent and rapidly progressive. Cachexia and wasting, development of jaundice or worsening of preexisting jaundice, and intractable ascites are common. Hemorrhagic phenomena are frequent. Hemorrhage, including gastrointestinal bleeding from esophageal varices and rarely hemoperitoneum caused by intraperitoneal rupture of tumors, is a proximate cause of death in 50% of hepatocellular cancer patients. Hepatomas are among the tumors most frequently associated with paraneoplastic syndromes. Secondary paraneoplastic syndromes include polycythemia, thrombocytosis, hypoglycemia, hypercalcemia, and production of ectopic adrenocorticotropic hormone.

Treatment. Hepatocellular carcinoma is usually a relatively slow-growing tumor; resection, in the absence of cirrhosis, has often resulted in cure. Resection in the face of cirrhosis is much more likely to result in recurrence, although this may take several years to occur. In the United States, average survival after resection is 3 years, with 5-year survival rates in recent large series ranging from 11% to 46%. Resection is the only therapy that currently significantly prolongs survival. The response of hepatocellular carcinoma to intravenous single-agent and multiagent chemotherapy remains unimpressive. The most consistent response rates with respect to systemic chemotherapy have been reported with doxorubicin (Adriamycin). Response rates of 25% or less have been reported, without significant increase in survival time (17). The continuous infusion of chemotherapeutic agents into the hepatic artery has recently been described for the treatment of hepatomas, as well as other methods such as hepatic artery ligation, arterial embolization and chemoembolization, targeting irradiation, and direct tumor injection. Initial results suggest a modest improvement in palliation compared with those obtained with intravenous chemotherapy (12). Cryoablation is a new technique that has been shown to prolong survival slightly in otherwise unresectable patients (18). Pain during therapy is controlled with nonsteroidal antiinflammatory drugs and potent narcotics. In hospitals in which qualified personnel are available, severe pain can be temporarily relieved with segmental epidural analgesia (see Chapter 102) or intraspinal narcotics (see Chapter 103). See Chapter 35, Chapter 36 and Chapter 37 for a comprehensive summary of the management of cancer pain.

Hepatic Adenoma

In a woman of childbearing age who has been taking birth control pills and presents with chronic right upper quadrant pain, the diagnosis of hepatic adenoma should be seriously considered.

Diagnosis. Up to 80% of patients with adenoma will have symptoms related to the lesion (7). Biliary tract disease is first excluded by ultrasonography, which can also show the presence of a solid tumor in the liver. If the ultrasonography does not reveal biliary tract disease, the liver should be examined for masses. CT scanning or laparoscopic examination of the liver surface might be required. CT scan will show a solid, hypovascular mass that may contain hemorrhagic areas. Adenomas are composed of sheets of hepatocytes with thin-walled venous lakes lacking bile ducts or portal triads. Biopsy is generally considered safe but not often helpful.

Treatment. If the diagnosis of adenoma is suggested, the first step in treatment is to stop oral contraceptives. Smaller lesions may regress with 6 months of cessation of hormonal therapy. If the tumor is larger than 6 to 8 cm in diameter, and thus not likely to regress, or pain is not rapidly relieved, surgical excision is necessary. Pain rapidly resolves after excision. In patients for whom discontinuation of birth control medication and follow-up is decided on, gradual resolution of pain and tumor regression should occur. Otherwise, surgical excision should be considered. Because pregnancy increases the growth potential of adenomas, patients considering pregnancy are advised to undergo resection.

Hepatic adenomas can also present acutely, either with severe right upper quadrant pain or with spontaneous hemorrhage into the peritoneal cavity. Emergency surgery is indicated in these situations.

Metastatic Tumors

Metastatic tumors occur with 20 to 30 times the frequency of primary hepatic cancers. Hepatic metastatic disease is a particular problem for cancers drained by the portal venous system, being seven times more likely to occur than tumors arising outside the portal bed (19). In a series of 8,455 autopsies reported from the Roswell Park Cancer Center, 39% of adult patients with solid tumors had hepatic involvement (19).

Symptoms and Signs. Many patients with hepatic metastases are asymptomatic. Asymptomatic hepatic metastases are discovered in 15% to 20% of patients with colorectal carcinoma during staging of the cancers before operation or during laparotomy. Most patients with hepatic metastases are symptomatic, however, with pain as a prominent complaint. The pain associated with hepatic metastases is usually constant, dull, and localized to the epigastrium. Accompanying anorexia, weight loss, fatigue, fever, and epigastric fullness are common. Occasionally, acute episodes of right upper quadrant pain can herald hemorrhage into a hepatic metastasis or tumor necrosis. In contrast to primary hepatomas, jaundice and ascites are uncommon until the advanced stages of hepatic metastatic disease. When jaundice occurs as an initial finding, malignant biliary obstruction by enlarged nodes in the porta hepatis or by direct growth of biliary or pancreatic carcinomas is the usual finding. Death usually occurs as a result of liver failure from progressive replacement of the liver parenchyma.

Prognosis. The survival pattern in cases of hepatic metastasis depends on patients' functional status, the extent of hepatic replacement by the metastatic tumor, the presence or absence of an extrahepatic tumor, and the histology of the tumor type. Without treatment, 70% of patients with colorectal metastases to the liver die within 1 year and nearly 100% die within 3 years. Patients who undergo resection of a solitary metastatic lesion from a colorectal primary tumor may have a 40% 5-year survival rate. Metastatic gastric cancer is the second most common gastrointestinal tumor for which hepatic resection has been used for metastatic disease. Carcinoid tumor and islet cell or neuroendocrine tumors of the pancreas are somewhat favorable gastrointestinal tumor types for which hepatic resection is used. Other gastrointestinal cancers, especially pancreatic and esophageal cancers, are poor candidates because of unfavorable histology and rapid growth rates. Survival is markedly decreased in patients who are nutritionally debilitated when metastases are discovered or if extrahepatic tumor is also present.

Treatment. Selected patients with metastatic hepatic neoplasms (primarily colorectal cancers) can be candidates for curative surgery. They must meet rigorous

criteria: control of the primary cancer, absence of extrahepatic metastases, adequate functional hepatic reserve, and confinement of disease to one hepatic lobe. Less than 10% of all patients with hepatic metastases fulfill these criteria, and only 30% of potential candidates for surgical excision have resectable disease at the time of exploration. Sarcomas, neuroendocrine tumors, and endocrine tumors such as thyroid cancer and breast cancer are included among those nongastrointestinal tumor types for which hepatic resection is indicated. Some 20% to 40% of patients who undergo resection survive for 5 years postoperatively (7). Response to systemic chemotherapy depends on the site of the primary neoplasm, the extent of hepatic involvement, and the route of administration. Long-term palliation is occasionally possible (20).

Because cure of hepatic neoplasms is somewhat uncommon, symptomatic palliation is of cardinal importance. Measures to control the secondary manifestations of hepatic dysfunction are important therapeutic adjuncts. Relief of ascites by pharmacologic or mechanical means, treatment of the pruritus accompanying biliary obstruction, and attention to nutrition are examples of measures that make palliation of pain much more effective.

A commitment should be made to maintain patients with hepatic neoplasms on oral medications for as long as possible. It is generally possible and practical to maintain most patients with hepatic tumors on oral opioids and nonopioids plus adjuvants until the last few days of their lives (21). Sedation, the major adverse side effect, must be monitored but is generally not debilitating. Most patients remain ambulatory and can retain some independence. A discussion of specific agents, routes of administration, and dosage schedules is found in Chapter 36. If large doses of oral opioids are ineffective in relieving severe pain, intraspinal opioids should be given a trial. In patients with severe excruciating pain unaffected by the aforementioned procedures, a celiac plexus block with alcohol should be considered if a physician skilled in its administration is available.

BILIARY SYSTEM

Basic Considerations

In humans, the biliary system is supplied by sympathetic afferent fibers originating from the T-6 through T-10 dermatomes (see Fig. 67-2). Although sympathetic afferent innervation of the biliary system is bilateral, most fibers transmitting visceral pain traverse the right splanchnic nerves. The gallbladder and bile ducts receive extensive parasympathetic innervation, both through the hepatic branches of the left vagus and the celiac division of the posterior vagus. Visceral biliary pain, however, is not transmitted by afferent vagal fibers. Vagotomy does not alter the perception of biliary pain.

Visceral pain fibers in the biliary system are primarily sensitive to distension of the gallbladder or bile ducts and to forceful muscular contraction of the gallbladder in the presence of distal ductal obstruction (see Chapter 3 for details). Distension of the gallbladder or common bile duct most often causes pain when the distension occurs acutely; gradual enlargement usually does not cause painful symptoms. In humans, experimental dilatation of these structures causes an intense crampy pain in the epigastrium or right upper quadrant (22). The pain can be referred to the back at the level of the right scapula (Fig. 67-4). Active contraction of the gallbladder accompanying complete or nearly complete duct obstruction causes the pain of biliary colic. Colic is initiated when gallbladder contraction is stimulated by the hormone cholecystokinin. Cholecystokinin release, in turn, is stimulated by intraduodenal fats (23) or amino acids (24). Biliary visceral pain is usually not dramatic if the obstruction develops gradually within the common bile ducts, perhaps because of the capacity afforded by the extrahepatic and intrahepatic biliary systems.

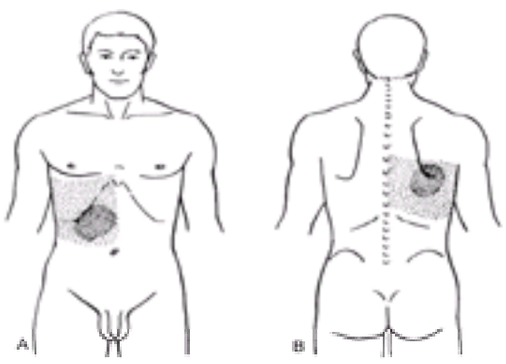

Figure 67-4. Areas of referred biliary pain in the anterior **(A)** and posterior **(B)** regions of the body. The heavy stipple indicates the area of pain reference, whereas the light stipple indicates the extensive cutaneous hyperalgesia often associated with the pain.

Inflammatory disease of the gallbladder can cause stimulation of the afferent nerve fibers of the parietal peritoneum, which is experienced as somatic pain. Nerve fibers that are activated by stimulation of the parietal peritoneum are distributed in the areolar connective tissue beneath the parietal mesothelium. These myelinated fibers are organized in dermatomes; biliary inflammation generally stimulates somatic afferents that reach the spinal cord through the sixth to ninth intercostal nerves, corresponding to dermatomes T-6 through T-9. Somatic pain associated with biliary disease is intense, easily described, and well localized to the right upper quadrant. When present, somatic pain tends to obscure accompanying visceral pain.

Clinical Considerations

Gallstones (XXI2)

Calculous biliary tract disease is a major problem in the United States. Approximately 12% of adults in this country are prone to the development of symptomatic gallstones. Approximately 1 million people annually in the United States develop symptoms attributable to their gallstones. More than 500,000 biliary tract operations are performed each year in the United States, and the numbers are increasing since the advent of laparoscopic cholecystectomy (25). Of those with symptoms from biliary calculi, 60% to 75% have colic as their initial symptom.

Symptoms and Signs. An episode of biliary colic usually begins with poorly localized pain in the midepigastrium. The pain can eventually move to the right upper quadrant. The discomfort is constant and may become severe. Often beginning 15 to 60 minutes after a meal, symptoms can persist for 4 to 8 hours before gradually abating. Accompanying anorexia, nausea, and vomiting, which may be bilious, magnify the unpleasant visceral sensations. Somatic pain is absent unless obstruction is complicated by inflammation. Referral of biliary visceral pain to the scapular area is frequently observed. Right upper quadrant tenderness and guarding are usually absent, as are systemic signs of inflammation.

The completeness of obstruction and the promptness of relief of obstruction probably determine whether gallbladder inflammation will occur to complicate biliary colic. In most people (90%) the obstruction relents and inflammatory changes are minimal and nonprogressive. If obstruction is not relieved, continued distension can result in the progressive inflammation of the gallbladder wall, which characterizes acute cholecystitis.

Pain associated with acute cholecystitis is usually well localized by history and physical examination to the right upper quadrant. Somatic pain can be present if the inflammatory process is in contact with the parietal peritoneum. Referred pain to the right shoulder due to diaphragmatic irritation can also be noted. Localized tenderness is noted in the right upper quadrant beneath the costal margin on physical examination and may be associated with muscle rigidity and rebound tenderness. Gentle, deep palpation heightens the discomfort, and Murphy's sign, inspiratory arrest during deep palpation in the right upper quadrant, may be elicited. In one-third of patients a palpable mass representing gallbladder and adherent omentum and bowel is noted. Low-grade fever (less than 101° F) is seen in 80% of patients with acute cholecystitis but does not reliably distinguish biliary colic and acute cholecystitis.

Diagnosis. Mild to moderate cases of acute cholecystitis are accompanied by modest leukocytosis, approximately 12,000 to 15,000 white blood cells per µL with a left shift. Serum bilirubin values are reported to be mildly elevated in 33% of patients with acute cholecystitis (usually lower than 4 mg per 100 mL). Serum alkaline phosphatase and serum amylase levels can also be modestly and nonspecifically elevated.

Radiopaque gallstones are visible on plain abdominal radiographs in 5% to 15% of patients. Ultrasonography has become the method of choice for demonstrating the presence of gallstones within the gallbladder. Using modern equipment and a real-time technique, several authors have reported that gallstones can be detected with

sensitivity and specificity of diagnosis that exceed 90% (26). The presence of acute cholecystic inflammation can be implied by the sonographic presence of a thickened gallbladder wall, pericholecystic edema or fluid, and tenderness during compression by the ultrasonic transducer (sonographic Murphy's sign). Occasionally, radionuclide scanning of the biliary system with hepatobiliary iminodiacetic acid scan can be useful in demonstrating cystic duct obstruction when the presentation is atypical. Hepatobiliary iminodiacetic acid scans are a highly sensitive (greater than 95%) but less specific (90%) measure of acute inflammation of the gallbladder (7). Alternative examinations, such as oral cholecystography, endoscopic retrograde cholangiopancreatography (ERCP), and percutaneous transhepatic cholangiography, have limited usefulness in uncomplicated cases.

Treatment. Initial therapy of acute cholecystitis includes administration of intravenous antibiotics, fluid resuscitation, restriction of oral intake, and parenteral analgesics. Elective laparoscopic cholecystectomy is the recommended treatment for patients with symptomatic cholelithiasis. In the presence of gallstones, the typical visceral pain associated with biliary tract disease is permanently relieved in 95% of patients (27). Nonspecific dyspeptic symptoms associated with definite gallbladder calculi are relieved in 75% of patients.

Postcholecystectomy Pain (XXI3)

In certain patients, cholecystectomy can be one of the most effective operations used for relief of pain. Nonetheless, up to 20% of patients continue to have abdominal pain that is severe enough to prompt medical evaluation after surgery (28)—the so-called postcholecystectomy syndrome. Often, the pain complex is similar to that for which surgery was recommended and may occur months to years after the initial surgery. These patients represent difficult diagnostic and therapeutic problems. They are frequently evaluated and cared for by physicians interested in chronic pain.

Pathophysiology. Several factors have been identified that place patients at increased risk of postcholecystectomy pain. For example, those patients who have noninflamed gallbladders or gallbladders without calculi have a high incidence of postcholecystectomy pain. In addition, the risk of developing postoperative symptoms increases the longer the symptoms were present preoperatively.

Possible causes of postcholecystectomy pain can be separated into four general categories: (a) incorrect preoperative diagnosis such as peptic ulcer disease; (b) unrecognized accompanying hepatobiliary disease, such as a stricture or a common duct stone; (c) incomplete cholecystectomy or retained gallbladder; and (d) papillary obstruction (Table 67-1).

General category	Histopathologic diagnosis	Method of investigation
Incorrect preoperative diagnosis	Peptic ulcer	Upper gastrointestinal endoscopy
	Pancreatitis	Serum amylase determination, ultrasonography
	Functional bowel disorders	Barium enema, colonoscopy
Unrecognized hepatobiliary disease	Retained common duct stone, biliary stricture, neoplasm	ERCP
Incomplete cholecystectomy	Gallbladder remnant, cystic duct remnant	ERCP
Papillary obstruction	Sphincter of Oddi dyskinesia, ampulla of Vater dysplasia	ERCP and biliary manometry

ERCP, endoscopic retrograde cholangiopancreatography

TABLE 67-1. Causes of postcholecystectomy pain syndromes

Incorrect Diagnosis. In patients with persistent abdominal pain after cholecystectomy, the possibility of an incorrect preoperative diagnosis must always be considered. Unrecognized peptic ulcer, pancreatitis, and irritable bowel syndrome are the disturbances most frequently misidentified as calculous biliary disease. The possibility of incorrect diagnosis is greatest for those patients who are found to have noninflamed or acalculous gallbladders at the time of operation. Patients with persistent symptoms after cholecystectomy should be evaluated for these as well as other possibilities using appropriate endoscopic, radiologic, and laboratory tests.

Unrecognized Diseases. The second general category of disorders that cause persistent pain after operation includes coexistent unrecognized hepatobiliary disorders originating in a portion of the biliary system separate from the gallbladder. The most frequent pathologic entities identified in this category are retained common bile duct stones, postoperative biliary strictures, and unrecognized biliary or pancreatic neoplasms.

Retained stones constitute the most common cause of recurrent biliary-type pain after cholecystectomy. Residual common bile duct stones have been reported in approximately 2% of patients after cholecystectomy (29), and calculi are found in 80% of patients who undergo secondary biliary operations after cholecystectomy (28). Retained bile duct stones should be suspected in patients with biliary pain and biochemical evidence of cholestasis or pancreatitis. A history of previously performed common bile duct exploration should heighten suspicion because this maneuver is associated with a five- to tenfold increase in the risk of retained or recurrent stones. ERCP is the preferred method for demonstrating suspected common duct stones. Endoscopy also provides the options of therapeutic papillotomy and endoscopically guided stone extraction (30). If endoscopic stone removal is not possible or successful, reoperation might be recommended, often with formation of a biliary-enteric anastomosis to prevent recurrence.

Postoperative biliary strictures are second in frequency to retained biliary stones as causes for postcholecystectomy pain caused by residual hepatobiliary disease. In more than 90% of patients, biliary stricture results from iatrogenic injury to the extrahepatic bile ducts during cholecystectomy (31). In most of the remaining patients, ductal obstruction occurs because of cicatrization of the intrapancreatic common bile duct as a result of pancreatitis. Clinical symptoms can appear months to years postoperatively. Typical biliary-type pain and laboratory evidence of cholestasis are common findings. Endoscopic cholangiography is essential for identifying the injury and for defining the extent of damage anatomically. Postoperative biliary strictures have been treated by operative repair, stenting, balloon dilation, and combinations of these techniques. Experience, familiarity with available options, and clinical judgment dictate the most appropriate approach for individual patients.

Malignancy. Because symptoms caused by biliary, periampullary, and pancreatic malignancies can sometimes mimic pain from calculous biliary disease, these cancers, if not recognized at operation, can cause persistent postoperative distress. The treatment of pain resulting from retained biliary stones or biliary strictures consists of treating the residual disease. Restoration of anatomic and functional normality results in relief of pain. Treatment of malignancy-associated pain is covered later in this chapter.

Remnant Structures. Two frequently cited causes of persistent symptoms after cholecystectomy are remnants of gallbladder or remnant cystic ducts (32). A cystic duct remnant is generally defined as a residual ductal structure longer than 2 cm. Such remnants have been hypothesized to cause symptoms by harboring residual calculi, by allowing new stones to form in an area of relative stagnation, and by continued chronic inflammation. The causal relationship of cystic duct remnants to symptoms has been difficult to prove. There is now general agreement that a long cystic duct remnant is in and of itself innocuous. This has been supported by the now widespread use of the laparoscopic method of gallbladder removal in which the cystic duct is purposefully left long. Several large studies have shown that most patients with long cystic duct remnants are asymptomatic and that symptomatic patients generally have other possible explanations for their pain, such as residual common duct stones (33). A stone trapped in a cystic duct remnant may be a source of crystal or stone formation in patients with a propensity to develop gallstone pancreatitis or stenosing papillitis.

The best treatment for the retained cystic duct syndrome, of course, is prevention. The routine use of operative cholangiography for detecting long cystic ducts permits removal at the first operation. Removal of a cystic duct remnant by a second operation may be recommended if residual calculi are demonstrated by postoperative cholangiography. The reported results do not support removal of cystic duct remnants in the absence of demonstrable calculi if pain relief is the therapeutic objective (34).

Functional Disorders. The last general category of causes of postcholecystectomy pain includes functional disorders of biliary emptying. Two different mechanisms have been suggested to account for biliary pain and apparent biliary obstruction. In one group, the continued presence of chronic inflammation of the ampulla of Vater has been postulated to result in fibrosis and fixed stenosis of the ampulla. Sphincter of Oddi dyskinesia has been suggested in the absence of inflammation, with

spasm of the sphincter raising intraductal pressure and impeding emptying.

These two mechanisms are the basis for the “postcholecystectomy syndrome,” a nonspecific and poorly defined term. *Biliary dyskinesia* is a preferable appellation, but this term is best reserved for clinical situations in which typical biliary-type pain, biochemical evidence of cholestasis, and cholangiographic and manometric evidence of papillary dysfunction exist in the absence of one of the previously described causes of postoperative symptoms.

Diagnosis. Biliary dyskinesia is a diagnosis of exclusion. Patients who may be considered for an attempt at surgical relief for their biliary dyskinesia or stenosing papillitis require an extensive evaluation for other sources of their pain. A CT scan of the abdomen with fine cuts at the level of the pancreas is required. In addition, ERCP is an important part of the workup of these patients. Biliary manometry, when available, is confirmatory. Diagnostic manometry uses single-lumen or multilumen perfused catheters positioned across the sphincter of Oddi and recording pressures in the common bile duct, the sphincter, and the duodenum. In humans, common bile duct pressure is approximately 10 mm Hg above duodenal pressure (35,36). In turn, the sphincter of Oddi basal pressure is 5 to 10 mm Hg greater than the common bile duct pressure. Phasic high-pressure contractions occur periodically within the sphincter at a rate of four to six per minute. These contractions appear to be peristaltic, moving in antegrade fashion from the common bile duct to the duodenum. Intravenous infusion of cholecystokinin decreases the basal sphincter of Oddi pressure as well as the frequency and amplitude of phasic contractions (37). The effects of morphine are opposite to those of cholecystokinin; morphine increases resting sphincter pressure and increases the frequency of phasic contractions (38).

It has been suggested that a subset of patients with pain after cholecystectomy have identifiable manometric abnormalities and demonstrable obstruction to ductal emptying. In affected patients, manometrically measured basal sphincter of Oddi pressure is elevated to approximately twice control values (39) and is in excess of 40 cm H_2O. In addition, in those patients with suspected biliary dyskinesia, propagation of phasic pressure waves is frequently retrograde, in an antiperistaltic direction. Furthermore, provocative testing with cholecystokinin infusion suggests that some patients with this disorder respond to the hormone not with the expected ampullary relaxation, but with a paradoxic increase in sphincter pressure (40). The functional significance of manometric abnormalities is confirmed by observing delayed emptying either of endoscopically injected radiographic contrast medium or hepatically excreted radionuclide (41).

Only those patients with manometric abnormalities and documented delayed biliary emptying, in whom other pathophysiologic processes have been excluded, should be considered to have biliary dyskinesia (Table 67-2). It is not currently possible to distinguish between fixed fibrotic stenosis and spasm; elements of each can be present in any one patient.

Feature	Findings characteristic of biliary dyskinesia
Associated hepatobiliary disease	Absence of retained or recurrent biliary stones, biliary stricture, neoplasms; transient elevation of alkaline phosphatase and parenchymal liver enzyme levels with symptomatic episodes
Cholangiographic results	Mild to moderate dilatation of extrahepatic bile ducts; delayed emptying of cholangiographic contrast medium
Biliary manometry	Increased basal sphincter pressure; retrograde propagation of phasic pressure waves; paradoxic response to cholecystokinin
Response to therapy	Symptomatic improvement after sphincterotomy in 85% of patients

TABLE 67-2. Distinguishing features of biliary dyskinesia

Treatment. Endoscopically performed sphincterotomy or surgical transduodenal sphincteroplasty is currently the recommended treatment for patients with suspected biliary dyskinesia who meet the above criteria. Symptomatic improvement has been reported in up to 85% of patients treated in this fashion (41). Less invasive forms of therapy might be possible for mildly symptomatic individuals. Nitrates relax the sphincter of Oddi and can prove helpful if sphincteric spasm is present (42) but are of limited utility in the case of stenosis or stricture. Narcotics, particularly morphine, should not be used in these patients because of their known contractile effects on the sphincter of Oddi. Patients with severe, persistent pain may be considered for surgical chemical splanchnicectomy after several prognostic blocks have indicated that interruption of these nociceptive pathways provides complete pain relief (see Chapter 102 and Chapter 105). Intrathecal opioids can also be useful for such patients (see Chapter 103).

PANCREAS

Basic Considerations

The pancreas is subject to a number of disease processes, both inflammatory and neoplastic, in which pain is a major clinical feature. Patients with pancreatic disorders constitute a large proportion of those seen by physicians interested in pain control. The location of the pancreas in the retroperitoneum of the upper abdomen, its anatomic relationships to surrounding organs, and its complex physiologic functions present difficulties in the diagnosis and management of pancreatic pain syndromes. An understanding of pancreatic pathophysiology is essential to all physicians caring for such patients.

The pancreas is a roughly triangular organ that lies transversely in the upper retroperitoneum between the duodenum on the right and the spleen on the left. The pancreas is related anteriorly to the pylorus, stomach, gastrocolic omentum, and liver. Inferiorly, the pancreas is in contact with the transverse portion of the duodenum, the jejunum, and the transverse mesocolon. The transverse colon can also form a portion of the inferior border.

The pancreas receives both sympathetic and parasympathetic innervation. Sympathetic innervation is derived from the upper thoracic splanchnic nerve, which is composed of preganglionic fibers from the T-5 through T-10 spinal segments (see Fig. 67-2). Additional pancreatic sympathetic fibers travel in the lesser splanchnic nerve and are derived from the T-9 through T-11 segments. Before reaching the pancreas, fibers from the upper and middle thoracic splanchnic nerves traverse the celiac plexus and ganglion. The cell bodies of efferent nerves to the pancreas are in the celiac ganglion. Cell bodies of afferent pancreatic sympathetic nerves are located in dorsal root ganglia. Sympathetic afferent connections with the central nervous system are bilateral; some afferent fibers cross the midline on traversing the celiac ganglion.

Parasympathetic innervation of the pancreas is derived from the celiac division of the posterior vagal trunk. The cell bodies of afferent vagal fibers are located in the nucleus ambiguus of the medulla of the brain. Efferent vagal fibers are dendrites of neurons with cell bodies in the dorsal motor nucleus. Both efferent and afferent parasympathetic fibers pass through the celiac ganglion. Neither type of parasympathetic nerve fiber synapses within this ganglion.

Pancreatic visceral pain is usually sensed as a severe constant discomfort localized to the upper midabdomen. Although intensely unpleasant and often intractable, pancreatic pain is often difficult to describe. “Stabbing,” “burning,” and “boring” are commonly used adjectives. Radiation of pancreatic pain to the back in the area of the lower thoracic spine is common (Fig. 67-5). Because the pancreas does not contact the somatically innervated parietal peritoneum, somatic pain is not associated with pancreatic disorders unless peripancreatic inflammatory complications extend beyond the lesser sac.

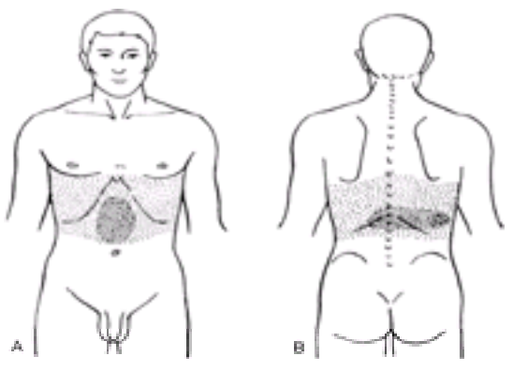

Figure 67-5. Areas of referred pancreatic pain in the anterior **(A)** and posterior **(B)** regions of the body. The heavy stipple indicates the pain reference, whereas the light stipple indicates the extensive cutaneous hyperalgesia often associated with the pain.

Vagal afferents do not appear to mediate pancreatic pain. Vagotomy alone is ineffective in the relief of pancreatic pain (43). Sympathetic afferents have been shown to transmit painful impulses from the pancreas. The use of sympathectomy in the treatment of pancreatic pain is discussed in Chapter 105.

Clinical Considerations

Acute Pancreatitis

Acute pancreatitis is one of the most common causes of acute abdominal pain requiring hospitalization. The disorder can vary in its clinical presentation, ranging from a transient mildly symptomatic illness in 90% of cases to a rapidly fatal abdominal catastrophe. Acute pancreatitis has proven difficult to diagnose reliably and to treat specifically. Palliation of the pain that accompanies acute pancreatic inflammation remains a major clinical challenge.

Etiology and Pathophysiology. Although the pathogenesis of acute pancreatitis in many cases is not definitely established, a number of factors are clearly associated with this disease (Table 67-3). In 80% to 90% of cases, the cause is related to excessive alcohol intake or biliary tract disease. Chronic alcohol abuse is the most common metabolic cause of acute pancreatitis in the United States, particularly in urban settings. Histologic evidence of antecedent pancreatitis has been reported in up to 45% of alcoholics in autopsy studies (44), but acute pancreatitis is recognized in less than 10% of such patients premortem. Individuals who develop acute alcoholic pancreatitis have abused alcohol for an average of 11 to 18 years before becoming symptomatic (45), with the mean ethanol consumption in these patients approximating 150 g per day. The triggering mechanism that initiates an episode of acute pancreatitis in the midst of chronic heavy alcohol intake is not known. The acute toxicity of ethanol for pancreatic acinar cells is believed to be the pathogenetic factor. Ethanol and its primary metabolite, acetaldehyde, have been shown to be toxic to pancreatic acinar cells. Cellular damage is postulated to occur by altering cellular membrane fluidity and composition (46), reducing mitochondrial protein synthesis (47) and enhancing abnormal amylase, trypsinogen, and chymotrypsinogen secretion (48). Several theories exist to explain alcohol- related acute pancreatitis. Currently, the most widely accepted theory suggests that pancreatic parenchyma is injured by pancreatic enzyme extravasation, which is facilitated by an increase in pancreatic ductal permeability and occurs in the presence of exocrine hypersecretion and partial ampullary obstruction (12).

Factor	Examples
Metabolic	Alcohol, hyperlipoproteinemia, hypercalcemia
Mechanical	Gallstones, posttraumatic, postoperative, after pancreatography
Vascular	Shock, cardiopulmonary bypass, polyarteritis nodosa
Drugs	Steroids, azathioprine, thiazide, estrogens, tetracycline, furosemide
Miscellaneous	Familial, viral infections, idiopathic

TABLE 67-3. Causative factors in acute pancreatitis

Acute pancreatitis has been reported in patients with both familial and acquired forms of hypertriglyceridemia. Individuals with Fredrickson type I hyperlipoproteinemia have a 30% risk of developing clinical pancreatitis. Pancreatitis occurs in 15% of those with type IV disease and in approximately 40% of those with type V hyperlipoproteinemia. A severe form of pancreatitis has been noted in association with the chylomicronemia syndrome (49).

Pancreatitis has been reported in association with hypercalcemia caused by hyperparathyroidism (50), multiple myeloma, and intravenous administration of calcium (51). Pancreatitis has been most clearly related to hyperparathyroidism that is long-standing and symptomatic. Acute pancreatic necrosis has been reported during hyperparathyroid crisis. The mechanism of hypercalcemia related to pancreatitis may involve calcium-induced trypsinogen activation with subsequent parenchymal autodestruction, calcium-associated stone formation in the pancreatic duct causing ductal obstruction, or calcium stimulated pancreatic exocrine hypersecretion.

Gallstones are recognized in more than 50% of nonalcoholic patients with acute pancreatitis. It is likely that passage of a gallstone through the ampulla of Vater is responsible for initiating pancreatitis in these patients. Gallstones can be retrieved from the stool of 85% to 95% of patients recovering from gallstone pancreatitis (52). In patients who underwent laparotomy within 48 hours of the onset of biliary pancreatitis, gallstones were reported to be present in the ampulla of Vater in 75% (53). In some patients, but not all, the anatomic structure of the ampulla of Vater can be a factor in the induction of gallstone pancreatitis by permitting transient obstruction of the pancreatic duct or obstruction of a common pancreatic-biliary channel. Cholangiographic studies have demonstrated a common channel between the common bile duct and the pancreatic duct in up to 90% of patients with a history of gallstone pancreatitis, compared with only a 20% to 30% incidence of a common channel in patients with calculous biliary disease and no history of pancreatitis. Mechanical disruption of primary or secondary pancreatic ducts by trauma, operative complications, or forceful ductal injection during pancreatography can also result in pancreatitis.

Numerous drugs have been reported to cause acute pancreatitis. The most compelling evidence supports estrogens and azathioprine (Imuran) in the direct causation of pancreatitis. Less common causes of pancreatic inflammatory disease include trauma, vasculitis, viral infections (Coxsackie and mumps viruses), pancreas divisum, ischemic pancreatitis, neoplasm, and familial pancreatitis.

Although a number of associations with acute pancreatitis have been clearly identified as causative factors, the mechanism of injury is not known in most cases. The pancreas responds to a spectrum of injuries in a stereotyped fashion. The essential pathogenetic feature of this response is the extravasation of activated pancreatic enzymes into pancreatic and peripancreatic tissues. Tissue necrosis, edema, and local and systemic inflammatory reactions result from this extravasation.

Symptoms and Signs. Abdominal pain is the hallmark symptom in patients with pancreatic inflammation. The abdominal pain begins acutely and usually increases gradually over several hours before reaching maximum intensity. The pain is most severe in the upper abdomen with penetration through to the back, often radiating to the chest and flanks. The pain of acute pancreatitis usually persists without relenting for hours to days. It is often aggravated by recumbency. If abdominal pain fluctuates markedly in intensity or ceases for periods of time, acute pancreatitis should be suspected. The rapid onset of symptoms and the severity of pain associated with acute pancreatitis can mimic those of other acute inflammatory processes such as gangrenous cholecystitis, perforated peptic ulcer, and intestinal ischemia. Nausea and vomiting are nearly constant accompanying symptoms in acute pancreatitis. Vomiting does not relieve the pain and is not progressive. Fever, tachycardia, and evidence of dehydration are present in most patients.

Acute pancreatitis usually results in intense nociceptive input that not only produces severe pain but also reflex responses that are usually inherent in serious tissue damage (see Chapter 9). Many patients develop severe reflex skeletal muscle spasm of the abdominal and lower chest walls, with a consequent marked decrease in chest wall compliance. Moreover, visceral reflexes also produce a decrease or inhibition of gastrointestinal tone with varying degrees of ileus, and also reflex bronchiolar constriction. The pain and reflex responses markedly impair ventilation, which frequently becomes rapid and shallow and produces hypercapnia and hypoxemia caused by increased physiologic shunting. As a result, the arterial oxygen tension falls steadily. In one series, 40% of patients with acute pancreatitis developed an arterial oxygen tension of less than 60 mm Hg while breathing room air some time during the first week of the ileus (54). Unless aggressively treated, this may contribute to a complex systemic response that may result finally in circulatory failure, respiratory failure, and death.

Diagnosis. Acute pancreatitis is a clinical diagnosis, suspected in susceptible individuals with acute abdominal pain and confirmed by appropriate laboratory and radiologic investigations. The diagnosis can be subtle. Pancreatic symptoms can be deceptive. In one report from a teaching institution, experienced clinicians correctly diagnosed severe pancreatitis in only 35% of patients at the time of admission (55). After 24 hours of hospitalization, 73% of patients had the disease correctly identified as pancreatitis. Even after 48 hours of hospitalization, however, only 83% of patients with severe acute pancreatitis had been diagnosed correctly.

Diagnostic confusion might be a result of the frequently nonspecific nature of pancreatic symptoms and of difficulties in physical examination. In addition, commonly used laboratory examinations, although sensitive, are relatively nonspecific. A serum amylase determination is the most useful indicator of pancreatic inflammation, with elevated serum amylase levels present in approximately 90% of cases of acute pancreatitis; however, increased amylase levels are fairly nonspecific, with both false-positives and false-negatives occurring. Unfortunately, hyperamylasemia often persists for only 24 to 48 hours after the initiation of pancreatitis, and the degree of hyperamylasemia does not correlate with the severity of pancreatic damage. Only 65% of patients with elevated serum amylase levels have pancreatitis. Normal serum amylase values are found in 10% to 15% of patients with acute pancreatitis. Urinary amylase measurements do not improve diagnostic capabilities, and the calculation of the urinary amylase to creatinine clearance ratio is generally not helpful.

Radiographic studies are often useful for evaluating the pancreas and supporting the clinical diagnosis of pancreatitis. In the setting of acute pancreatitis, CT scanning and ultrasonography have largely replaced other radiologic procedures in evaluation of the pancreas. These methods can provide useful anatomic information about the pancreatic gland, biliary system, and surrounding organs.

Newer CT scanners, with improved resolution and faster scanning times, have become the preferred study in most patients. The accuracy of CT scanning is improved with administration of both oral and intravenous contrast. CT scanning has been reported to demonstrate pancreatic abnormalities in 90% of patients with acute pancreatitis (56). The most common finding on CT examination is diffuse enlargement of the gland. The most frequent complication of acute pancreatitis detected by CT scanning is an extrapancreatic fluid collection. Pancreatic pseudocysts and pancreatic abscesses that occur frequently as sequelae of acute pancreatitis are readily identified by CT scanning.

Ultrasonography is only slightly less effective than CT scanning for demonstrating pancreatic edema, phlegmons, and pseudocysts. Because of the absence of ionizing radiation, ultrasound is a superior procedure to use for pregnant women. Ultrasound is also well suited to young children who might not be cooperative. Although CT scanning is superior to ultrasound in providing anatomic information about the pancreas, ultrasound is more sensitive for detecting biliary calculi as a cause for pancreatitis. Both MRI and spectroscopy are newer modalities that may hold promise as valuable tools for the evaluation of pancreatitis in the future. In addition, ERCP may be useful in the evaluation of the occasional patient with recurrent attacks of pancreatitis without an obvious etiology. ERCP may identify correctable etiologies in up to 50% of patients, such as pancreas divisum, stenosis of the ampulla of Vater, and focal pancreatic duct abnormalities.

Treatment. The clinical management of patients with acute pancreatitis combines measures to control the pancreatic inflammatory process with efforts to minimize pain and discomfort. The therapy of pancreatitis can be considered to have three phases: efforts to resuscitate and support the patient during the initial illness; attempts to limit pancreatic inflammation and abort development of complications; and measures to treat the complications that do occur. Physicians treating patients with acute pancreatitis must be aware that the process evolves, often unpredictably, often over a long period of time; therapeutic objectives must thus be reevaluated periodically. Relief of painful symptoms is a prime aspect of therapy throughout the course of the illness.

Patients with severe acute pancreatitis are at greatest risk of dying during the initial few days of the illness. Shock, respiratory failure, and hemorrhage are the main causes of mortality during this phase of the disease (57). Vigorous patient support has proven effective in preventing death during the early phase of acute pancreatitis. Maintenance of tissue perfusion by the appropriate restoration of intravascular volume is crucial. Respiratory support, prophylaxis against gastric stress ulceration, and appropriate transfusion have been shown to be effective measures in these patients. Intravenous nutritional supplementation is also essential and should be instituted early.

Numerous therapeutic measures and agents have been investigated in attempts to limit pancreatic inflammation and to prevent complications. Most proposed therapies have been empiric and based on an incomplete understanding of the pathophysiology of pancreatitis. Not surprisingly, most of the proposed therapies have not been found to be efficacious when subjected to controlled trials. The following are proposed measures for limiting pancreatic inflammation and preventing complications: (a) nasogastric suction, (b) hypothermia, (c) pancreatic irradiation, (d) steroids, (e) enzyme inhibitors (e.g., Trasylol), (f) early biliary operations, and (g) drugs (e.g., anticholinergics, cimetidine, antibiotics, octreotide, glucagon, calcitonin). Nasogastric suctioning prevents the accumulation of fluid and air in the gastrointestinal tract and treats the ileus that occurs with pancreatitis, but nasogastric suctioning has not been shown to result in a more rapid symptomatic or biochemical resolution of the pancreatic inflammatory process (58). Pancreatic inflammation is not positively influenced by steroid administration, trypsin inhibitors (59), or various other drugs, from anticholinergics to cimetidine (60). The administration of antibiotics prophylactically has been shown by a number of authors to decrease infection rates (61). Decrease in mortality has not been clearly demonstrated with the use of prophylactic antibiotics. Because food normally increases pancreatic secretion, fasting has been used to minimize pancreatic stimulation. Withholding food is logical and is usually effective in promoting pancreatic quiescence.

Because the passage of common bile duct stones is so frequently associated with the initiation of pancreatitis, it has been postulated that the length of the period of ampullary obstruction and the completeness of obstruction determine the severity of the resultant pancreatitis. Early biliary operation with disimpaction of the offending stone has been proposed as a means of limiting pancreatic inflammation. In a controlled trial of early operation reported by Stone and colleagues, no amelioration of pancreatic inflammation was noted (62). Because of the lack of positive effect on the pancreatic inflammatory process and because of the increased risk of infecting a sterile pancreatic phlegmon by operative manipulations, laparotomy during the early phase of acute pancreatitis is discouraged. An important exception to this recommendation exists for patients in whom serious coexistent pathology cannot be excluded. Positive evidence of acute pancreatitis does not exclude the presence of concomitant duodenal perforation, mesenteric infarction, or gangrenous cholecystitis. For similar reasons, including risk of exacerbation of acute pancreatitis, hemorrhage, perforation, and papillary stenosis, ERCP is generally to be avoided in the early stages of acute pancreatitis. An exception here is the use of ERCP for urgent decompression in the septic patient with an obstructed common bile duct.

Management of the pain associated with acute pancreatitis is an important aspect of patient care. Because of the severity of pancreatic symptoms, narcotic analgesia is the usual method of providing relief. Before narcotics are used, however, certainty of diagnosis is important. Relief of abdominal pain could remove an important diagnostic clue of some other nonpancreatic disease that might be mimicked by pancreatitis.

Morphine should be avoided in patients with pancreatitis because of its contractile actions on the sphincter of Oddi. Meperidine (Demerol) also produces spasm of the biliary tract, but its spasmogenic effect is less than that caused by morphine and thus is the preferred parenteral systemic analgesic for pancreatic pain. Epidural opioids produce better pain relief with less spasmogenic effects. Segmental epidural (T-5 to T-10) analgesia with a dilute solution of local anesthetic relieves pain, markedly improves ventilation, and decreases or eliminates the reflex muscle spasm and neuroendocrine response. Of course, hypovolemia should be treated before this procedure is initiated to minimize the hypotension caused by vasomotor blockade (see Chapter 9 and Chapter 102).

Chronic Pancreatitis

Chronic pancreatitis is an inflammatory disorder of the pancreas that includes recurrent or persistent abdominal pain and evidence of exocrine and endocrine pancreatic insufficiency. It is a distinct clinical entity frequently encountered by those caring for patients with chronic pain. Chronic pancreatitis differs markedly from acute pancreatitis in pathogenesis, sequelae, and response to treatment. Numerous experimental studies in animals and clinical observations in humans suggest that, for most patients, chronic pancreatitis does not evolve from recurrent episodes of acute pancreatitis with progressive, additive inflammatory changes. Most investigators agree that the mechanisms of injury for the two disease processes are fundamentally different. Support for this view has been provided by Sarles et al.

(63), who noted that the average age of onset for chronic pancreatitis is 38 years, whereas the average age of onset for acute pancreatitis is 51 years.

Etiology and Pathophysiology. Although numerous causative factors have been associated with chronic pancreatitis, pathogenic mechanisms are largely unknown. Therapy continues to be empiric and limited to management of symptoms, side effects, and complications of the disease. For most patients, chronic abdominal pain is the most prominent symptom and the most difficult complication of chronic pancreatitis to treat.

In the United States, the cause of chronic pancreatitis in 70% to 80% of patients is alcoholism. For most of the remaining patients the cause is not known, and the disease is labeled “idiopathic” chronic pancreatitis. Malnutrition is one of the major causes worldwide. Biliary calculi, so common as a cause of acute pancreatitis, are rarely a factor in the development of chronic pancreatitis. Other known causes include benign or malignant duct obstruction, cystic fibrosis, hereditary pancreatitis, hyperparathyroidism, hyperlipidemia, trauma, and pancreas divisum.

The histologic changes that characterize chronic pancreatitis usually develop in the setting of prolonged periods of excessive alcohol intake. Chronic alcohol ingestion, by mechanisms that are incompletely understood, causes sustained secretion of protein by pancreatic acinar cells. Increased secretion of protein, without a proportionate increase in secretion of pancreatic water and bicarbonate, has been postulated to cause precipitation of protein within the pancreatic ducts. Obstruction of primary and secondary pancreatic ducts by the precipitate can cause the damage to pancreatic acini, with the accompanying inflammation and fibrosis that typify chronic pancreatitis. Persistent ductal obstruction and lobular destruction result in the progressive loss of pancreatic exocrine tissue that characterizes chronic pancreatitis histologically. Although the islets of Langerhans are not initially involved in the inflammatory process, gradual loss of endocrine tissue occurs as well.

Symptoms and Signs. Pain is the central feature of chronic pancreatitis. Virtually 100% of patients suffer from chronic abdominal pain. Approximately 50% of patients with chronic pancreatitis experience a constant, gnawing epigastric pain. The pain can vary in intensity but never subsides completely. The discomfort frequently radiates to the back. Pain is frequently worsened by eating, and weight loss is a prominent accompaniment. Narcotic tolerance is frequent. Steady employment is rarely achieved. In a second group of patients, severe attacks of epigastric pain are episodic, with the affected individual pain free between attacks. Painful episodes might or might not be associated with signs of acute pancreatitis superimposed on chronic pancreatitis. The pain from episodic attacks can last for days to weeks. Constant pain is most frequently associated with alcoholic chronic pancreatitis, whereas intermittent pain is more common with nonalcoholic pancreatitis.

In addition to various pain syndromes, most patients with chronic pancreatitis have evidence of endocrine insufficiency. Of patients with chronic pancreatitis, 15% are insulin-dependent; most non–insulin-dependent patients have abnormally low basal insulin levels and abnormal glucose tolerance tests (64). Even when insulin dependence does occur, the patients have some circulating endogenous insulin and are not prone to diabetic ketosis. Nonetheless, the chronic complications of diabetes mellitus are significant causes of death in patients with chronic pancreatitis.

Exocrine insufficiency is detectable in approximately 50% of patients when they seek medical attention and occurs with increasing frequency over time. The repetitive cycles of tissue destruction result in a significant reduction in the ability of the pancreas to secrete amylase, lipase, and proteolytic enzymes. Steatorrhea and malabsorption result and contribute to chronic weight loss.

The natural history of chronic pancreatitis is not known with certainty. Most reported series have been retrospective and confounded by including patients undergoing pancreatic operations or patients with significant accompanying illnesses. A prospective report suggested that only 20% of patients with chronic pancreatitis die from causes directly related to pancreatitis or its complications (65). Malignancies, cardiovascular diseases, and severe infections were common nonpancreatic causes of death.

Diagnosis. Chronic pancreatitis should be suspected in all individuals with intractable abdominal pain. Chronic pancreatitis is a clinical diagnosis, based on appropriate signs and symptoms in susceptible individuals. Determination of serum enzyme values is usually of little value; serum amylase and serum lipase levels are infrequently elevated in patients with chronic abdominal pain and are nonspecific in their interpretation. Findings of endocrine or exocrine insufficiency strengthen the clinical impression.

When attempting to confirm the clinical suspicion of chronic pancreatitis, plain abdominal radiographs should be obtained because demonstration of pancreatic calcifications virtually assures the diagnosis. CT scanning, ultrasound, and endoscopic pancreatography have improved the diagnostic evaluation of chronic pancreatitis in recent years and help differentiate between chronic pancreatitis and malignancy. ERCP is most accurate, but it is invasive and is frequently reserved for patients in whom the diagnosis is unclear or in whom intervention is planned. Approximately 50% of patients with chronic pancreatitis have ductal abnormalities that can be demonstrated by these techniques. In these patients, pseudocysts or strictures, obstructions or stones in the pancreatic duct, or alternating areas of dilatation and narrowing are demonstrated. In the other half, normal biliary and pancreatic ducts are demonstrated. Ductal abnormalities constitute strong positive evidence for chronic pancreatitis.

Treatment. The treatment of chronic pancreatitis consists of three aspects: abstinence from alcohol, support for endocrine and exocrine insufficiency, and palliation of painful symptoms. Management of endocrine insufficiency usually requires administration of insulin, whereas support for exocrine insufficiency can be accomplished by oral administration of pancreatic enzyme preparations. When patient compliance is good, management of endocrine and exocrine disturbances is readily achieved; it is not discussed further here.

Medical Therapy. The mainstays of nonoperative management of pain associated with chronic pancreatitis include absolute abstinence from alcohol; dietary manipulations, including small-volume low-fat meals along with use of oral pancreatic enzymes to decrease pancreatic secretion thereby decreasing pain; and provision of analgesia. For most patients with chronic pancreatitis in whom pain is severe, medical therapy is not successful and surgical intervention becomes necessary. Simple nonoperative measures, such as manipulations of diet, have not been shown to ameliorate pancreatic pain in a controlled clinical trial. Pharmacologic attempts to suppress pancreatic secretion have also been largely unsuccessful. Anticholinergic drugs have been demonstrated experimentally to decrease pancreatic secretion, but administration of atropinelike drugs to patients has not reduced pancreatic pain. Cimetidine, a potent inhibitor of gastric acid secretin, has been used to decrease stimulation of the pancreas by secretin released by intraduodenal acid. Cimetidine, however, does not relieve pancreatic symptoms. Octreotide has recently been used for treatment of pain in chronic pancreatitis with limited success. In most instances, the medical management of chronic pancreatic pain relies on the use of narcotic analgesics. The long-term commitment to such analgesics required by patients with chronic pancreatitis often leads to physical dependence. Data reported by Ammann and coworkers (66) suggest that medically treated patients experience abdominal pain for a mean of greater than 5 years before pancreatic dysfunction becomes so severe that pain is relieved. The nihilistic approach of waiting until the disease “burns out” should not be encouraged.

Various procedures to ablate afferent nerves from the pancreas have been used in attempts to palliate pancreatic pain. Dramatic temporary relief of pain from acute pancreatitis can be obtained by injecting solutions of lidocaine or bupivacaine into the splanchnic nerves or the left celiac ganglion (67). Positive results in patients with acute pancreatitis have encouraged many investigators to extend these techniques to patients with chronic pancreatitis. Neural ablation may be achieved by several operative or nonoperative methods. One nonoperative approach involves the use of celiac plexus block with alcohol after prognostic blocks have produced effective pain relief (see Chapter 104). In patients who are undergoing operative pancreatic procedures, alcohol can be injected into the celiac ganglia directly at the time of laparotomy. Destruction of the celiac ganglia has also been accomplished by resection. The ganglia can be removed by a posterior incision through the twelfth rib below the diaphragm.

A prospective controlled study of splanchnicectomy for relief of chronic pancreatic pain has not been performed. Retrospective clinical series by proponents of the procedure claimed that permanent pain control is achieved in greater than 90% of patients (68). These initial encouraging results, however, have not been reproduced by most other surgical investigators. A definitive statement of the usefulness of neural ablative procedures in treatment of chronic pancreatitis probably cannot be made. Finally, spinal opioids may have use in chronic pancreatic pain (see Chapter 103).

Surgical Therapy. The use of endoscopic retrograde cannulation of the pancreas, ultrasonography, and CT scanning has improved the ability to assess the structural changes associated with chronic pancreatitis and its complications. Two major patterns have been recognized. Some patients, both alcoholic and nonalcoholic, have enlarged major pancreatic ducts alternating with segmental areas of narrowing. The ectatic ducts are often associated with intraductal stones and calcification. This form of structural abnormality has been termed *large duct* or *obstructive* disease. Many physicians have interpreted these changes as resulting from pancreatic ductal hypertension caused by blockage of the flow of pancreatic secretions. An alternative explanation is that the structural changes are a result of atrophy of pancreatic parenchyma and periductal scarring.

A second form of pancreatitis has been termed *small duct disease*. In these patients, pancreatography demonstrates chronic calcifying pancreatitis, in which major

pancreatic ducts are not enlarged. Proteinaceous plugs can be seen in terminal ductules and acini. Atrophy and dilatation of the fine arborizations of the pancreatic ductal system can be present.

The surgical treatment of chronic pancreatitis is based on two assumptions about the functional significance of these structural abnormalities. The first assumption is that pancreatic ductal obstruction is the cause of pain in large duct disease and that decompression of the pancreatic duct by operative manipulations relieves pain. The second assumption is that ductal hypertension is absent in small duct disease. Periductal or perineural inflammation is assumed to cause the chronic abdominal pain in patients with nondilated ducts. For these patients, pancreatic resection has been proposed to remove the source of chronic inflammatory stimuli. The type of operation selected depends, then, largely on pancreatic anatomy. Workup for surgery should include both CT scan and ERCP.

Operative therapy in chronic pancreatitis is effective in reducing pain but should not be undertaken for the purpose of improving endocrine or exocrine function. Glucose intolerance and fat malabsorption are not improved by operations for chronic pancreatitis (69).

Longitudinal pancreaticojejunostomy has become the standard surgical approach for patients in whom pancreatography demonstrates dilated pancreatic ducts or alternating areas of dilatation and stricture. As currently performed, the procedure decompresses the entire pancreatic duct by creating a side-to-side anastomosis between the opened pancreatic duct and a Roux-en-Y limb of jejunum (Fig. 67-6). The pancreatic duct should be at least 7 to 8 mm in diameter or larger for this procedure to be appropriate. A pancreatic duct greater than 1 cm in diameter, the presence of pancreatic calcifications, and an anastomosis between the pancreas and jejunum longer than 6 cm have been found to be determinants of success for the side-to-side pancreaticojejunostomy. The gland is left *in situ*. The main pancreatic duct is filleted along its entire length, nearly to the ampulla of Vater. Splenectomy is unnecessary.

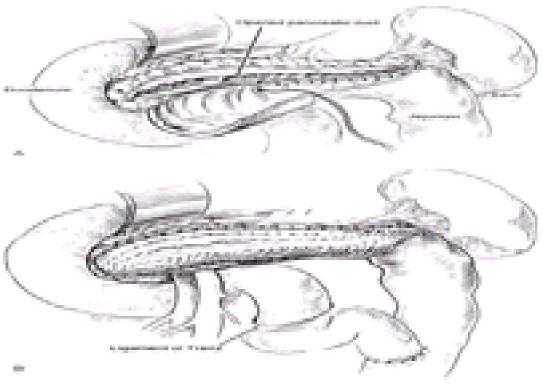

Figure 67-6. Operative performance of pancreaticojejunostomy. **A:** The anterior surface of the pancreas has been exposed by reflecting the stomach cephalad and the transverse colon caudad. The main pancreatic duct has been opened longitudinally, exposing a grossly dilated pancreatic ductal collecting system. A Roux-en-Y limb of jejunum has been constructed. The jejunal limb has been opened longitudinally for a distance equal to that of the longitudinal opening in the pancreatic duct. A side-to-side pancreaticojejunostomy is then performed by suturing the jejunal limb to the thickened fibrotic capsule of the pancreas. **B:** Completion of pancreaticojejunostomy, showing configuration of the Roux-en-Y jejunal limb. A double-layer pancreaticojejunostomy has been constructed. Pancreatic exocrine secretion can drain through the anastomosis through the Roux-en- Y limb of the jejunum.

Preservation of remaining pancreatic function is good because no pancreas is resected. However, even though neither islet cell nor acinar tissue is destroyed in performing pancreaticojejunostomy, the incidence of diabetes and clinically symptomatic exocrine insufficiency is increased in the years after the operation (Table 67-4). This observation suggests that the chronic destruction of pancreatic tissue associated with chronic pancreatitis is not halted by decompression of the duct.

Procedure	Operative mortality rate (%)	Late deaths (%)	Postoperative diabetes (%)	Postoperative steatorrhea (%)	Pain relief (%)
Pancreatic ductal drainage					
Pancreaticojejunostomy	4	[illegible]	[illegible]	[illegible]	[illegible]
Pancreatic resection					
Distal pancreatectomy	4	[illegible]	[illegible]	[illegible]	[illegible]
Pancreaticoduodenectomy	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

[illegible]

TABLE 67-4. Operative therapy for chronic pancreatitis

Many large series have reported the effectiveness of pancreaticojejunostomy in the treatment of pain. Complete relief or significant improvement can be expected in more than 80% of patients. Abstinence from alcohol improves the chance for pain-free survival. Unfortunately, there is an overall recurrence rate of 25% to 50% of patients within 5 years.

When pancreatography demonstrates normal pancreatic ducts or ducts of inadequate caliber for the performance of pancreaticojejunostomy, pancreatic resection has been performed for the treatment of pain of chronic pancreatitis. If the chronic inflammatory process is confined to the tail of the gland, distal pancreatectomy can be performed. Ideally, the extent of resection is determined by the limits of pancreatic disease. Removal of up to 95% of the gland has been reported (70). If the chronic inflammatory process is limited to the head of the pancreas, with relatively normal tissue distally, pancreaticoduodenectomy has been performed. The incidence of postoperative diabetes varies widely, from 30% to 80%, and is highly dependent on the extent of resection. Radical resection of 80% to 95% of pancreatic tissue guarantees the development of diabetes. Symptomatic fat malabsorption occurs in all patients after pancreaticoduodenectomy (71).

Reports of the success of pancreatic resection for relieving pain have varied (see Table 67-4). Pain relief is attained in up to 75% to 80% of patients undergoing 95% distal pancreatectomy, but the combination of the required splenectomy and a high incidence of insulin- dependent diabetes has resulted in infrequent performance of this procedure. Some 60% to 80% of patients treated with standard or pylorus-preserving pancreaticoduodenectomy are reported to have pain relief at 5 to 6 years (72).

The results of operative series must be viewed from the perspective of long-term studies, which suggest that chronic pancreatitis is associated with progressive pancreatic dysfunction and eventual relief of pain in most patients, even without operation. Ammann and coworkers (66) observed that deterioration in pancreatic exocrine function was closely related in timing to the relief of chronic pain. In 85% of alcoholic patients with chronic pancreatitis, spontaneous and long-lasting relief of pain was reported in surviving patients after 5 years. Cessation of pain was noted at the point at which pancreatic function began to decline markedly. These data imply that pain in chronic pancreatitis is related to secretory capacity, and with reduction in secretory capacity below some critical level, the mechanism that initiates the pain disappears. If this supposition is correct, pancreatic resection can be effective because it decreases exocrine function, and pancreaticojejunostomy can be useful because patients with dilated ducts have already lost a critical amount of secretory capacity. Operative therapy thus does not alter the natural history of chronic pancreatitis; rather, it may accelerate the symptomatic evolution of the disease.

Pancreatic Cancer (XXI7)

Pancreatic cancer is a highly lethal disease that currently ranks as the fifth most common cause of cancer-related deaths in the United States, exceeded only by lung, colorectal, breast, and prostate cancers. In the United States, there are approximately 28,000 new cases of cancer of the pancreas diagnosed each year. Since 1960,

the relative 5-year survival rate for all cases of pancreatic cancer has risen from 1% to 3%. Untreated, some 90% of patients die within the first year. Blacks, males, smokers, the aged, and those with diabetes mellitus appear to be at most risk. A history of chronic pancreatitis and ingestion of a diet high in fat may also be of importance. Finally, six specific disease entities carry an increased risk of pancreatic cancer: hereditary nonpolyposis colorectal cancer, familial breast cancer, the Peutz-Jeghers syndrome, ataxia-telangiectasia syndrome, familial atypical multiple mole-melanoma syndrome, and hereditary pancreatitis (73).

Symptoms and Signs. Pain is the hallmark symptom in patients with cancer of the pancreas (see Chapter 35). For nearly all patients with carcinoma of the pancreas, pain becomes a management problem at some time during their illness and is present in 70% of patients initially. Pain associated with cancer of the pancreas usually begins as a dull, nagging discomfort in the epigastrium but becomes rapidly and progressively more severe. The pain is gnawing, relentless, and visceral in character. Radiation to the back is noted in 25% of patients. Pain can be the only symptom associated with tumors of the body or tail of the gland; tumors in these locations can grow to a large size before causing secondary complications that prompt the correct diagnosis. Constant pain usually implies local invasion of surrounding structures and infiltration of the splanchnic nerves.

Anorexia and weight loss, seen in 75% of patients, are frequent but nonspecific accompanying symptoms. Nausea, vomiting, and weakness are each noted in approximately 50% of patients. A palpable abdominal mass is present in 20%. The most common physical finding is jaundice. Jaundice is present initially in 13% of patients with pancreatic cancer, although jaundice develops in 75% of these patients at some time during their illness. The presence of jaundice implies obstruction of the extrahepatic biliary system by direct neoplastic growth. Contrary to a widely held belief, the jaundice is usually not painless. In addition, a gallbladder is palpable in less than 30% of patients. At the initial examination, an enlargement of the liver is present in 33% of patients and ascites is noted in 20%.

The “hidden” retroperitoneal location of the pancreas largely accounts for the lack of specific symptoms, difficulty in physical examination, and problems in diagnosis. Most patients with cancer of the pancreas have locally or systemically disseminated disease at diagnosis. In addition, the anatomic relationship of the pancreas to other structures causes technical difficulties in the extirpation of pancreatic lesions.

Diagnosis. If pancreatic cancer is suspected, the diagnosis can be confirmed by a combination of techniques. CT scanning, endoscopic pancreatography and cholangiography, percutaneous biopsy, and operative exploration have important roles in the management of these patients. Selective celiac and mesenteric angiography along with portal venous evaluation are often used for staging and assessment of resectability. MRI cholangiogram is a newer technique that can be used for assessment of pancreatic and ductal anatomy.

The prognosis of cancer of the exocrine pancreas remains relatively poor and is largely dependent on the anatomic location. If the tumor has spread beyond the confines of the pancreas, surgical resection for cure is essentially not possible, and almost every patient with unresectable cancer of the pancreas dies of the disease. The majority of patients presenting with periampullary cancer are treated surgically. Currently, for all patients explored with a curative intent for a preoperative diagnosis of periampullary cancer, resectability rates of 35% to 40% are reported (12). The overall 5-year survival rate for all patients with resected periampullary cancer is 15% to 25%, depending on the exact site of origin of the tumor. Adenocarcinoma of the body and tail of the pancreas comprise some 30% of pancreatic cancers. The resectability rate of these cancers is less than 7% and the prognosis is dismal, with a mean survival of 5 to 6 months. Five-year survivors are rare.

Treatment. Currently, the only potentially curative therapy for cancer of the pancreas is surgical resection (74,75). Radiation therapy and chemotherapeutic approaches offer palliation to unresectable patients, but long-term survival is only modestly improved. Because of these considerations, symptomatic palliation is the primary goal for many patients with cancer of the pancreas.

Symptomatic palliation should be concerned with three general aspects of care: relief of anatomic complications, attention to nutritional depletion, and treatment of pain. Biliary obstruction and abnormal gastric emptying result from encroachment on the common bile duct and duodenum by tumor growth. Operative decompression of the biliary system is effective in relieving the intense pruritus associated with biliary obstruction. Gastric outlet obstruction usually requires the formation of some type of gastroenteric bypass. The malnutrition that so commonly accompanies pancreatic malignancy should be managed, when feasible, with oral or enteral feeding regimens. Pancreatic exocrine insufficiency, usually subclinical, may occasionally require oral pancreatic enzyme supplementation.

Most patients with carcinoma of the pancreas can be maintained on oral opioids and other analgesics as outpatients for most of the duration of their illness. Oral medications permit continued personal independence, with few intellectual or motor disturbances. For those patients in whom pain is not adequately controlled by oral or parenteral medication, celiac plexus block with alcohol or surgical splanchnicectomy is highly effective and should be considered if personnel skilled in these procedures are available. Newer approaches, including ambulatory epidural opioid analgesia, are discussed in Chapter 102 and Chapter 103.

CHAPTER 68

Painful Diseases of the Kidney and Ureter

Sandip P. Vasavada, Craig V. Comiter, and Shlomo Raz

Some of the most severe pain one can experience is the pain of acute urinary obstruction. There exist a wide variety of causes for upper urinary tract pain, from infection and obstruction to neoplasm and chronic renal diseases. In this chapter we emphasize those diseases of the kidney and ureter in which pain is the presenting symptom or potentially a major problem in the management of the patient. One must have a solid understanding of the anatomy of the kidney and ureter as well as a detailed knowledge of its innervation before approaching therapeutic decision making. The following discussion encompasses both basic anatomy of the nervous supply to the kidney and ureter as well as a presentation of various clinical upper urinary tract diseases that may present with pain.

BASIC CONSIDERATIONS

Anatomic Aspects

Figure 68-1 and Figure 68-2 depict the gross anatomy and nerve supply of the kidneys and ureters and indicate their relationship to other structures that are important in considering the pathophysiology of renal and ureteral pain. Both structures receive sympathetic, parasympathetic, and sensory (afferent) fibers (1,2,3,4,5 and 6).

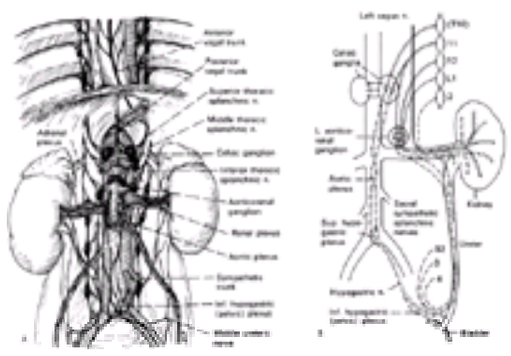

Figure 68-1. **A:** The gross anatomy and innervation of the kidneys. **B:** The autonomic and sensory nerve pathways supplying the kidney and ureters.

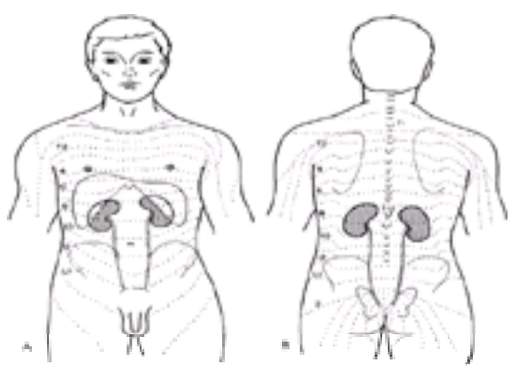

Figure 68-2. The relationship of the kidneys to the liver and the dermatomes (indicated by dotted lines and numbered for identification). **A:** Anterior view showing that the skin overlying the kidneys is supplied by dermatomes T-6 to T-9, with the left kidney higher than the right kidney. **B:** Posterior view showing that the dermatomes in the back overlying the kidneys are one segment lower than in the front because of the migration of the posterior division of the spinal nerves (see Chapter 8 for details).

Innervation of the Kidneys

Sympathetic Nervous System. The sympathetic fibers are derived mainly from the celiac and aorticorenal ganglia and also directly from the upper portion of the lumbar sympathetic trunk. These two collections of ganglia receive preganglionic fibers, which convey afferent (sympathetic) impulses to the kidneys from the T-8 to L-1 spinal cord segments via the corresponding white rami communicantes and paravertebral ganglia. They may also reach the kidney through the middle (lesser) and inferior (least) thoracic splanchnic nerves and the first (and perhaps the second) lumbar splanchnic nerves. The middle (lesser) thoracic splanchnic nerve derives from roots given off by the tenth and eleventh paravertebral ganglia and ends in the ipsilateral celiac or aorticorenal ganglion or both. The inferior (least) thoracic splanchnic nerve derives from the twelfth thoracic paravertebral ganglion and usually ends in the aorticorenal ganglion near the renal plexus. Within these ganglia, preganglionic neurons synapse with postganglionic neurons, which pass directly to form the renal plexus. Not infrequently, the least splanchnic nerve and the first (and perhaps the second) lumbar splanchnic nerve pass directly to the renal plexus to synapse in the posterior renal ganglion or in other smaller renal ganglia incorporated at nodal points in the renal plexus. The renal plexus occasionally also receives small communicating rami from the suprarenal plexus. Sympathetic fibers provide predominantly vasoconstrictor activity to the vessels of the kidney.

Parasympathetic Nervous System. The parasympathetic nerve supply comes from the vagus nerves, consisting of preganglionic neurons. Most of these fibers traverse the celiac plexus, but some fibers, particularly on the right side, pass directly to the renal plexus. Thus, together with the sympathetic innervation, the renal autonomic plexus is formed. Within the plexus the fibers proceed into the substance of the kidney in which parasympathetic fibers produce vasodilation. Interestingly, after renal transplantation, renal function is apparently unaffected despite separation of the kidney from its original autonomic nerve supply (7).

Afferent (Sensory) Fibers. The afferent (sensory) fibers are composed of spinal nerves whose cell bodies are located in dorsal spinal nerve root ganglia and whose central processes pass through the dorsal nerve roots of the tenth, eleventh, and twelfth thoracic spinal nerves to synapse with dorsal horn neurons. The distal branches of these fibers accompany sympathetic nerves and thus pass through the white rami communicantes, the paravertebral sympathetic ganglia (without

synapsing) and thence to the splanchnic nerves to reach the renal plexus.

Renal Plexus and Branches. The renal plexus consists of a fine network of sympathetic, parasympathetic, and sensory fibers surrounding the renal vessels, especially the renal artery. These fibers reach the pelvis and (except for the parasympathetic fibers) the calyces and substance of the kidney by following the branches of the renal artery, some of them traveling within the muscularis of the vessel.

Intrinsic Nerves. The nerves within the kidney form rich perivascular plexuses around the renal artery and its branches, continuing along even the smaller arterial branches, arterioles, and capillaries. The sympathetic postganglionic fibers are distributed to the vascular musculature and to the smooth muscles in the renal pelvis and calyces; from the slender rami associated with the interlobular arteries, strands of these fibers extend along the afferent arterioles to the juxtaglomerular apparatus. The parasympathetic postganglionic fibers supply the muscles of the pelvis and calyces and probably do not extend into the renal parenchyma. Afferent (sensory) nerve fibers terminate in the musculature of the renal pelvis, the adventitia and endothelium of the renal vessels, and the renal capsule.

The parenchyma is supplied mostly by thin unmyelinated fibers, although some small myelinated axons can be found. The renal pelvis and renal calyces also are richly supplied with unmyelinated nerve fibers, which terminate in relation to the musculature, but myelinated fibers are more abundant than in the parenchyma.

Innervation of the Ureters

The ureters receive sympathetic, parasympathetic, and sensory nerves derived from the renal, spermatic (or ovarian), and hypogastric plexuses. The upper half or two-thirds of each ureter receives the same nerve supply as the corresponding kidney. Preganglionic fibers with their cell bodies in T-10 to L-1 (and perhaps L-2) pass along the anterior roots, the white rami communicantes, the paravertebral sympathetic trunk, and thence through the splanchnic nerves, which end in the aforementioned ganglia, where they synapse with postganglionic fibers. The latter pass to and through the renal and spermatic (or ovarian) plexuses to reach and contribute to the upper portion of the ureteral plexus. Parasympathetic fibers to the upper portion of the ureter are derived from vagal fibers that pass through the celiac and renal plexus and then into the wall of the ureter, where they synapse with short, postganglionic fibers. The afferent (sensory) fibers to the upper portion of the ureter are derived from T-11 and T-12 and traverse the same structures as the sympathetic fibers without interruption to end in the muscles of the upper portion of the ureter.

The nerves to the lower portion of the ureter take a slightly different course. Preganglionic sympathetic fibers have their cell body in L-1 and possibly L-2 spinal segments and pass through the anterior roots, white rami communicantes, and paravertebral chain, within which they synapse with postganglionic fibers, some in the upper two ganglia and others in the sacral ganglia. Postganglionic fibers from the upper lumbar chain pass as lumbar splanchnic nerves to reach the aortic plexus and then pass to and through the superior hypogastric plexus and hypogastric nerves to reach the ureter. The postganglionic fibers that derive from the sacral trunk can be considered sacral splanchnic nerves and reach the inferior hypogastric plexus, where they pass to the ureter. The parasympathetic nerve fibers to the lower part of the ureter arise from S-2 to S-4 segments and pass sequentially through the pelvic splanchnic nerves (nervi erigentes) and the inferior hypogastric plexus (some go through the hypogastric nerves) to reach the lower portion of the ureter. The afferent (sensory) nerves to the lower portion of the ureter have their cell body in dorsal root ganglia of T-12 and L-1 (and perhaps L-2); the proximal branch enters the spinal cord and the distal branch passes in the company of the sympathetic fibers to the lower portion of the ureter. Although these various fibers are arranged in three corresponding groups—the superior, middle, and inferior ureteral plexus—they branch freely and intercommunicate with one another.

Despite the extensive network of nerve fibers, the majority of ureteral peristalsis does not require outside autonomic input. Instead, small intramural pacemakers within the intrinsic smooth muscle of the minor calyces help propagate the urine downstream.

Renal and Ureteral Pain

Location and Characteristics. Diseases of the kidneys, ureters, or both, like other visceral diseases, may cause localized (true) visceral pain and referred visceral pain. Moreover, if the disease involves the parietal peritoneum, it may cause either localized or referred parietal pain. Of these, referred visceral pain is the most frequent and most important.

Several investigators have studied the distribution of referred pain caused by diseases of the ureter and kidney. As early as 1900 (4 years after the first use of a practical cystoscope), Lennandier demonstrated that the distension of human kidney pelvis produced pain (8). Some four decades later, McLellan and Goodell carried out the most definitive study to date (9). Figure 68-3A illustrates the ascending location of the cutaneous sites of pain caused by ascending stimulation of the ureter by dilatation with a balloon at the ureterovesical junction and then at 5, 10, 15, 20, and 25 cm above the ureteral orifice. When stimulation of the ureter was at threshold intensity, pain was discretely localized and approximately 5 cm in diameter, the location being approximately on a line drawn along the lateral edge of the rectus muscle. Stimulation of the kidney pelvis at threshold intensity caused a similar type of pain in the back at the level of the costovertebral angle (Fig. 68-3B). Increasing the intensity of the stimulus produced an even larger area of pain. Stimulation in the upper part of the ureter and pelvis often caused splinting and “spasm” of the lateral abdominal and loin muscles, which did not relax when the stimulus was removed. Several hours later some of the subjects began to have “side ache,” which subsequently increased in intensity during the ensuing 12 hours, undoubtedly due to sustained contraction of the skeletal muscles.

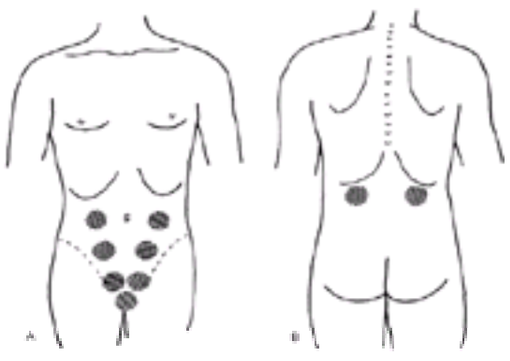

Figure 68-3. **A:** The anterior areas of pain reference to the skin from stimulation of the kidney pelves and of the ureters at the ureteral vesical junction and 5, 10, 15, 20, and 25 cm upward from there. **B:** Schematic representation of posterior area of pain reference produced by either faradic stimulation or local distension in the upper ureter or kidney pelvis, followed by contraction of skeletal muscles. Approximately an hour after the onset of muscle contraction, subject developed aching pain, which persisted from 6 hours to 2 days. (Modified from McLellan AN, Goodell H. Pain from the bladder, the ureter and kidney pelvis. *Pain*. Baltimore: Williams & Wilkins, 1943;23:252–259.)

Other authors also have studied the distribution of pain caused by distension of the pelvis and ureters by inflating distensible catheters in various parts of the upper urinary tract (Fig. 68-4). The following findings have been reported: (a) Distension of the renal pelvis consistently causes pain in the region of the costovertebral angle; (b) distension of the ureteropelvic segment of the ureter produces pain adjacent to the anterior superior iliac spine; and (c) distension of the midureter causes pain to be felt at the middle of Poupart's ligament, whereas distension of the ureterovesical portion of the ureter produces pain in the suprapubic region. Pain of renal pelvic origin is often referred to the ipsilateral testicle or ovary. Pain due to a stone in the terminal ureter may be referred to the scrotal or labial skin, or medial thigh. When the stone is located in the terminal ureter, irritation and edema in the adjacent trigone of the bladder may produce symptoms of frequency of urination as well. In addition to pain, the patient usually experiences hyperalgesia in the dermatomes T-10 to L-1 as well as in the testicle (Fig. 68-5).

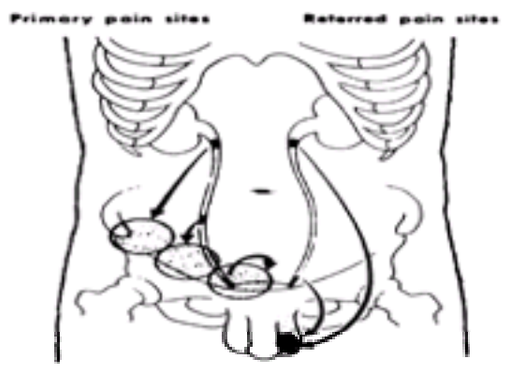

Figure 68-4. Sites of referred pain noted clinically from obstruction and distension of the ureter at the pelvic junction, the midureter, and the ureteropelvic junction. Note that pain of renal pelvic origin may be referred to the ipsilateral testicle (or ovary) and pain due to a stone in the terminal ureter is frequently referred to the scrotal or labial skin. (Modified from Wyker AW, Gillenwater JY. *Method of urology*. Baltimore: Williams & Wilkins, 1975:3.)

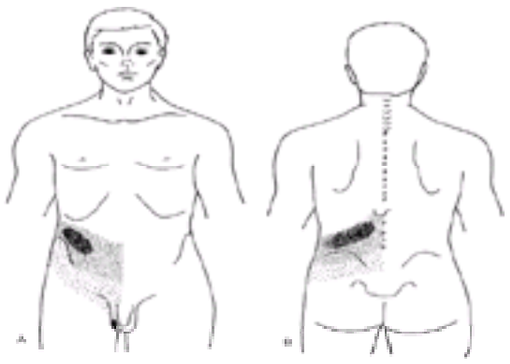

Figure 68-5. The anterior **(A)** and posterior **(B)** sites of pain (*black areas*) and hyperalgesia in the dermatomes (*stippled area*) caused by distension of the kidney, renal pelvis, or ureter.

Several colleagues who have experienced “colic” due to passage of calculi have provided a subtle subjective description of the pain that is worth repeating here. The pain starts as an expanded “bubble” located in the flank and rapidly becomes a feeling of unbearable, expanding pressure that cannot be ignored. The symptom is exacerbated by concern about what might possibly be causing this growing discomfort and the desire for relief. This sensation of something expanding uncontrollably internally may provoke restless attempts to find a comfortable position, but no position is better than any other. The agitated activity of the sufferer seeking relief from pain has even led to mistaken admission to the psychiatric service, from which the patient was transferred when red cells found on routine urinalysis helped in locating the source of the discomfort to the urinary tract.

Mechanisms Producing Pain

Pain related to a urinary organ may be produced by distension of the collecting system or renal capsule, extravasation of urine into the tissues, inflammation, ischemia, or traction and displacement on the pedicle of the organ itself or adjacent organs and structures. Pain related to distension is directly proportional to the rate of the distension (9). Sudden distension usually produces severe discomfort, whereas slow, progressive distension might produce little or no pain (Fig. 68-6).

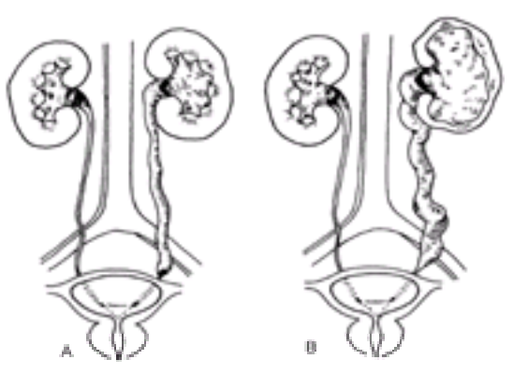

Figure 68-6. **A:** With acute distension of the left ureter and renal pelvis above an obstructing calculus, the patient experienced severe pain requiring narcotics for relief, although the ureter was only slightly dilated. **B:** When the ureter was slowly dilated over many months, the patient experienced no pain despite the fact that the ureter was greatly dilated. (From Wyker AW, Gillenwater JY. *Method of urology*. Baltimore: Williams & Wilkins, 1975.)

The use of contrast agents, which are secreted by the kidney in highly concentrated form, has shown that the acute obstruction associated with passage of urinary calculi is often accompanied by extravasation of significant amounts of the material into the renal parenchyma, surrounding fat, lymphatics, and veins. The severest colic is accompanied by extravasation. Therefore, pain that was formerly attributed solely to distension may also have a component due to extravasation of urine. Mild pain in the flank and costovertebral angle has long been associated with swollen kidneys affected by the inflammatory changes seen in glomerulonephritis and pyelonephritis. Whether such mild pain is due to inflammation of the parenchyma itself or to the distension of the renal capsule as a result of parenchymal swelling is not clear.

Another mechanism that produces pain related to distension of the renal capsule is subcapsular hematoma after accidental trauma. Once the bleeding has stabilized, the pain often remains steady and mild until the hematoma has resolved. Renal ischemia due to arterial embolization can produce severe steady disabling pain followed by abdominal distension. This phenomenon is clearest in individuals whose renal arteries are intentionally embolized to control neoplasia or hemorrhage, but it also occurs in patients with emboli from the left ventricle. Frequently, patients with renal pain will place a hand, with the fingers and thumb spread in opposite directions and palm down, on the affected flank as an aid in describing their pain (10).

The kidneys and ureters share both autonomic and sensory nerves with adjacent viscera; accordingly, diseases that can spread to or from adjacent anatomic structures may mimic pain patterns attributable to these structures and vice versa. Biliary and right renal colic are easily confused if there is no hepatic or bile duct involvement to highlight the difference. Right ureteral colic is occasionally misdiagnosed and treated as appendicitis if the urinalysis showing hematuria or pyuria is missed or ignored. Pain from pancreatitis, pancreatic calculi, or pancreatic pseudocyst can be attributed to the kidneys if these possibilities are not kept in mind and an amylase is not obtained. The duodenum, jejunum, vena cava, and hepatic or splenic colon can be partially obstructed by expanding renal masses.

A number of structures related to the kidneys can contribute to the pain. The anterior aspects of the kidneys are near the peritoneal surfaces, and infection and inflammation of kidneys and ureters can produce a mild peritoneal reaction with accompanying pain and other symptoms. Nausea and vomiting, however, usually *follow* the pain due to diseases of the urinary system, whereas nausea and vomiting usually *precede* the pain generated by disease in gastrointestinal organs.

The posterior superior aspect of each kidney is adjacent to the tendinous portions of each side of the diaphragm. Therefore, penetrating reaction to renal disease

occasionally produces characteristic findings referable to the diaphragm, pleura, and lower lungs, including symptoms of diaphragmatic irritation such as cough, hiccough, shoulder strap pain, pleuritis, pleural effusion, and pneumonitis. Stimulating the inside of the ureter with an electrode (9,11) has reproduced secondary ipsilateral skeletal muscular spasms and pain. The muscles on the affected side along the lateral border of the rectus muscles contracted painfully and ached for more than 24 hours thereafter. Similar spasms and aching occurred in the paraspinous muscles at the level of the costovertebral angle when the renal pelvis was so stimulated. The phenomenon is reproduced clinically by the frequent finding of spinal curvature concave to the affected side during acute obstruction.

Diagnostic Techniques

Sophisticated methods for diagnosing diseases of the upper urinary tract are available. In many cases, the pain history will direct attention to one side or the other, and physical examination may produce signs of mass or tenderness. Because the gonads and kidneys share pain pathways, the physician should carefully examine the ipsilateral testicle or ovary of an individual with occult pain thought to be of renal origin. Response of the kidney to fluid load can be assessed by isotope renography with furosemide-induced diuresis, intravenous pyelography with fluid loading, or urodynamic measurement of pressure during constant flow through a percutaneously inserted nephrostomy catheter (Whitaker test). If diagnostic studies made in the absence of fluid loading appear normal, the occurrence or reproduction of the characteristic pain in response to fluid load is a valuable way of establishing that the upper urinary tract is the source of the patient's pain problem. Diagnostic paravertebral somatic nerve blocks of T-10 to L-2 spinal nerves may also help to establish the nociceptive pathways that are involved. These are discussed briefly later in this chapter.

Computed tomography (CT), ultrasound, and magnetic resonance imaging produce complementary representations of the detailed anatomy and spectra of tissue densities, which are helpful in determining the cause of difficult pain problems affecting the kidneys, ureters, and adjacent structures (12,13,14,15,16 and 17). Moreover, spiral CT is rapidly becoming the procedure of choice for faster and more economical evaluation of acute flank pain (12). Angiography demonstrates arterial and venous anomalies that may obstruct the collecting system directly or secondarily as a result of bleeding. Endoscopic examination of the ureter and renal pelvis and collecting system is now an important addition to the armamentarium of the urologist with newly designed and smaller instruments for diagnostic uses.

In summary, the upper urinary tract can be displayed in intricate detail by current imaging techniques, it can be assessed hydrodynamically and functionally with the aid of pressure measurements and radioisotopes, and the urothelium can be examined almost in its entirety with instruments whose lenses magnify the surface several times. Radiographic imaging by means of ultrasound, plain film, radioisotopes, CT, and magnetic resonance imaging is available to examine the upper urinary tracts in minute detail. One can make arterial and venous angiograms of the vascular supply to these organs. Functional hydrodynamics can be assessed directly and indirectly. No lesion should be missed.

CLINICAL CONSIDERATIONS

Benign Renal Disorders—Inflammation/Infection

Pyelonephritis

Pyelonephritis represents an inflammation and infection of the kidney parenchyma and renal pelvis. The diagnosis is often made on basis of the clinical presentation, as it is quite characteristic. The signs include fever; chills; costovertebral angle tenderness; and occasionally irritative voiding symptoms of urinary urgency, frequency, and dysuria. It can result from hematogenous spread of bacteria or from an ascending infection of the lower urinary tract, yet a host of other causes may be possible (Table 68-1).

Vesicoureteral reflux
Urinary tract obstruction
Renal calculi
Neurogenic bladder
Diabetes mellitus
Immunosuppression
Congenital anomalies
Pregnancy
Catheter drainage

TABLE 68-1. Conditions that predispose to acute pyelonephritis

Laboratory Findings. Urinalysis usually demonstrates white blood cells, WBC casts, and red blood cells. Culture of the urine is usually positive but may be negative in up to 20% of patients with a colony count of less than 10^5 colony-forming units per mL of bacteria (18). Blood tests may reflect the infection, with a resultant elevated WBC count, C-reactive protein level, erythrocyte sedimentation rate, and creatinine level if renal failure is present. Blood cultures may be positive if the infection has entered the bloodstream.

The offending organism is most often *Escherichia coli*; it accounts for greater than 80% of cases. Less often, *Klebsiella, Proteus, Enterobacter, Pseudomonas, Serratia, Enterococcus*, and *Staphylococcus aureus* may be cultured (19).

Diagnosis. The clinical findings as outlined above are usually all that is necessary to diagnose acute pyelonephritis. One must evaluate for potential renal obstruction causing the pyelonephritis, and imaging studies should be performed to rule this out (20). Obstructive uropathy may be secondary to an obstructing calculus, stricture, or mass that precludes adequate drainage of the affected kidney. Also, a focal renal abscess would not respond well to antibiotic therapy alone and may require drainage.

Treatment. Pain-related issues from pyelonephritis tend to improve with appropriate treatment of the underlying infection with antibiotics. Analgesics can often help ease the flank pain while the antibiotics treat the infection; however, more intensive pain therapy is rarely necessary.

Perinephric Abscess

Perinephric abscess represents a focal collection of purulent material usually outside the renal capsule and contained by Gerota's fascia. The etiology may be secondary to hematogenous dissemination or ascending infections from the lower urinary tract. Often, there is a significant delay in making the diagnosis, and therefore there is an associated higher mortality rate (19,20). More recent advancements in diagnostic imaging and antimicrobial agents have improved the outlook dramatically.

Clinical Presentation. Most patients present with a urinary tract infection, which is then followed by severe flank pain, chills, night sweats, malaise, and fever. Of note is that up to one-third of patients may be afebrile (19). Other symptoms referable to the urinary tract infection may include dysuria, urgency, and frequency. In several reported series, there was a higher incidence of renal calculi and diabetes (21).

Laboratory and Radiographic Findings. Urine cultures may be positive in only one-third of cases (19). WBC count elevations and positive blood cultures may be suggestive of perinephric abscess, yet differentiation from acute pyelonephritis may require radiographic imaging. The most specific means for diagnosis of perinephric abscess is either renal ultrasonography or CT scanning (22).

Therapy. Antimicrobial agents are usually first-line therapy for small perinephric abscess; however, on only rare occasions does it result in eradication of larger purulent collections. The mainstay of therapy remains drainage, either percutaneously or by open surgical drainage. Symptoms of pain usually can be managed with

analgesics. Occasionally, reflex skeletal muscle spasms require analgesics and heat before drainage of the lesion (23).

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis (XGP) is a chronic infection of the renal parenchyma usually associated with renal calculi, urinary tract obstruction, or both. Thus, flank pain may be a presenting symptom of a patient afflicted with this condition and may be present in up to 65% of patients (24). Other common signs include urosepsis, hematuria, and hypertension.

Laboratory and Radiographic Evaluation. More than 50% of patients will have anemia and leukocytosis on hematologic evaluation (24). Abdominal plain films often demonstrate an enlarged renal outline and staghorn calculus in 60% (25). Intravenous pyelography will show an enlarged and nonfunctioning kidney with calculi and mass effect in most cases (25,26). Although renal ultrasonography or plain film modalities help in the diagnosis of XGP, CT scanning is the most useful and accurate means of diagnosis. This will demonstrate renal calculi without pelvic dilation and renal parenchyma replaced with water density masses representing calyces filled with pus. Other changes include thickening of Gerota's fascia and inflammatory changes of the perinephric space (27). The differential diagnosis includes renal tumors including renal cell carcinoma and transitional cell carcinoma (TCC) and other forms of renal cystic disease, tuberculosis, and chronic obstruction.

Therapy. In most instances, XGP is best treated by a complete nephrectomy. As is often the case, the exact diagnosis is not evident until after nephrectomy and pathologic analysis. In rare cases of localized XGP or XGP in a solitary kidney, partial nephrectomy may be performed. The pain associated with XGP usually responds once the chronic infection source (kidney) is removed.

Renal Tuberculosis

Tuberculosis of the kidney is usually secondary to hematogenous spread from another site. The original infection may have occurred years before and becomes reactivated in appropriate circumstances. Once the tubercles set in the renal parenchyma, an inflammatory reaction ensues and lymphocytic infiltration occurs. This tissue eventually becomes replaced by fibrous tissue but may coalesce to form areas of caseous necrosis. When these areas of fibrosis and necrosis occur in the pelvicalyceal system, strictures occur. These narrowings may then cause pain in the kidney due to obstruction and low-grade inflammation. In rare situations, the fibrosis creates squamous metaplasia, which may then degenerate to squamous cell carcinoma (28).

Clinical Presentation. The classic triad of weight loss, anorexia, and malaise is rarely seen in early stages. The diagnosis of renal TB is often very difficult and requires a high index of suspicion. Patients may have recurrent cystitis with its associated symptoms as many have superimposed *E. coli* infections. Of note is that patients may have very advanced genitourinary tuberculosis and have very few symptoms, thus reflecting the insidious nature of this disease process.

Laboratory and Radiographic Evaluation. Urinalysis will de-monstrate microscopic hematuria in approximately 50% of patients and sterile pyuria in almost all patients (28). Urine culture for acid-fast bacteria is paramount to the ultimate diagnosis of genitourinary tuberculosis. The usual cultured organism is *Mycobacterium tuberculosis*; however, it can be difficult to grow. Other laboratory tests, such as erythrocyte sedimentation rate and WBC count, may be elevated. Radiographic evaluation, including intravenous pyelography and retrograde studies, may demonstrate some of the strictured areas; however, CT scanning may help differentiate tuberculosis from other lesions that may be similar in appearance.

Therapy. Renal tuberculosis may have a variety of presentations. Therapy must be based upon the patient's symptoms and signs as well as laboratory data. In well over 90% of cases, renal tuberculosis responds to standard multiantibiotic therapy consisting of isoniazid and rifampin. Occasionally, streptomycin, pyrazinamide, or ethambutol also must be added. The usual course of therapy is 9 months (29). Most often, in cases of significant stricture disease, the offending lesion does not respond well to standard dilation maneuvers performed endourologically. The kidney or ureter often has more extensive disease than may be apparent and partial ureterectomy or nephrectomy may be required (30).

Retroperitoneal Fibrosis

Etiology. Retroperitoneal fibrosis is most commonly idiopathic, yet may be related to leaks from aortic aneurysms or associated with retroperitoneal malignancies or metastatic disease. Methysergide, an effective migraine medication, produced a rash of cases, but its use has now been restricted and carefully controlled. In more than half the cases of retroperitoneal fibrosis, the etiology is undetermined. A dense fibrotic process involves the retroperitoneal structures, surrounds the ureter, and compresses it. The earliest involvement usually occurs at the crossing of the iliac vessels, but later the process can extend to involve the kidneys, the great vessels, and the mediastinum (31).

Symptoms and Signs. The symptoms of retroperitoneal fibrosis are often nonspecific and can include moderate hypertension, vague back or abdominal pain, flank pain, scrotal swelling, and venous engorgement of the lower extremities and abdominal wall. Eventually, uremic symptoms appear after the slowly progressive bilateral renal obstruction interferes with renal function and the outflow of urine (32).

Diagnosis. The uremia secondary to retroperitoneal fibrosis often leads to the evaluation of the ureters and retroperitoneum. Typical findings on urography are hydronephrosis without an obvious point of obstruction and medial deviation of the lumbar course of the ureters. Retrograde passage of ureteral catheters is usually easy in spite of the antegrade obstruction (33). Magnetic resonance imaging and CT scanning demonstrate that the retroperitoneum is replaced by a fibrotic process and simultaneously shows the kidneys and encasement of the vasculature (34).

Treatment. Treatment of retroperitoneal fibrosis involves relief of obstruction. On a temporary or semipermanent basis, ureteral stents are effective. Longer-lasting correction requires surgical lysis of the ureters and replantation to an area less likely to be affected by the disease. An important fact is that retroperitoneal fibrosis or mass, or both, may be secondary to metastatic disease or a primary retroperitoneal tumor, and biopsy is mandatory. The ureters themselves can be replanted laterally or intraperitoneally to remove them from the fibrotic process. The disease process is often progressive, and prognosis is guarded in spite of good initial result (35).

Congenital Lesions Affecting the Kidney and Ureter

Polycystic Kidney Disease

Polycystic kidney disease, a congenital disease with a familial pattern, derives from failure of the junction between the uriniferous tubules and the collecting ducts. This nonunion results in blind secretory tubules connected to glomeruli, producing fluid that is unable to escape and slowly expands into huge cysts compressing the surrounding normal structures. The renal parenchyma is gradually destroyed, and the enlarging cysts swell the kidneys to huge masses, which may reach weights of 5 kg. Pain is produced by the weight of the organ pulling on the renal pedicle, hemorrhage into cysts, cyst rupture, or infection.

Background. Polycystic kidney disease is divided into autosomal recessive and dominant inheritance patterns. The presentation varies between the two inheritance types. In autosomal recessive polycystic kidney disease, infants and children are typically affected, and the cysts tend to be small (less than 2 mm), as compared with autosomal dominant polycystic kidney disease, which affects mostly adults and has larger cysts (36). Furthermore, the associated diseases, such as liver cysts, cerebral artery aneurysms, mitral valve prolapse, and diverticulosis, are more common in autosomal dominant polycystic kidney disease. In autosomal recessive polycystic kidney disease, biliary dysgenesis, hepatic fibrosis, biliary atresia, and portal hypertension predominate (37).

Symptoms and Signs. The presentation pattern in young people is commonly hematuria after athletic activity. Individuals with known family history may request evaluation to rule out the disease and eventually be discovered to have it. Patients who are diagnosed later in life often present with dull, intermittent flank pain. Of these patients, 60% will be hypertensive and 30% will already be uremic (37). In addition to hypertension, large, palpable bilateral lobular abdominal masses may be present. The affected area in patients with infected cysts or recent hemorrhage into a cyst will be tender to palpation.

Diagnosis and Treatment. Renal ultrasound images can differentiate polycystic kidney disease from other types of renal cystic disease, bilateral hydronephrosis, bilateral renal cell carcinoma, and Wilms' tumor. Treatment should include medications to control hypertension, diet modifications, low salt intake, and pain medication during passage of clots and infection. A supporting garment or corset may help with the chronic discomfort caused by the mass of these kidneys tugging on the renal pedicles. Occasionally, nephrectomy is performed on the hypertensive patient with polycystic disease who is about to undergo dialysis or transplantation for renal failure. Additionally, nephrectomy may be necessary before transplantation to allow the donor kidney to reside in the iliac fossa without compression from the

polycystic kidney. Infection of cysts tends to occur late in the disease and is therefore an ominous prognosticator.

Simple (Solitary) Renal Cyst

The cause of solitary renal cyst is unknown. These cysts, in contrast to those seen in polycystic kidneys, do not destroy significant amounts of parenchyma. They do not communicate with the collecting system and, accordingly, rarely cause obstruction of the collecting system by compression.

Symptoms and Signs. The typical patient is older than 40 years of age and complains of intermittent and dull unilateral flank pain that has been present for months or years. When such a cyst becomes infected, symptoms of sepsis will be described. The overwhelming majority of patients have no symptoms whatsoever from the cyst and it is unusual to become symptomatic. Other causes for flank pain must be evaluated before further investigation of renal cysts causing pain (38).

Diagnosis and Treatment. Renal ultrasound or a CT scan provides the best means of establishing the diagnosis of simple renal cyst. In cystic renal lesions of doubtful definition, it might be necessary to puncture the cyst with a fine-gauge needle under ultrasonic or scanning image control, aspirate the contents, and perform cytologic examination. The current radiographic techniques are very sensitive and specific at differentiating simple renal cysts from those more suspicious for neoplasm. Therefore, in most instances, this obviates the use of fine needle aspiration. The work by Bosniak has defined several subclasses of renal cysts based on CT criteria, from grade I to IV (I and II being more likely to be indolent, whereas III and IV are more suspicious for carcinoma) (39). The differential diagnosis includes renal neoplasm, renal carbuncle, hydronephrosis, and hydrocalycosis.

Percutaneous aspiration may temporarily relieve symptoms of simple renal cysts; however, the cystic collections may reaccumulate. It may ultimately be necessary to explore the kidney and unroof the cyst, either by open surgery or laparoscopically, if pain issues persist (40).

Calyceal Diverticulum

Etiology. Calyceal diverticula are outpocketings of the renal collecting system that may be congenital communications or secondary to rupture of a parenchymal abscess cavity into the collecting system. These diverticula become lined with urothelium and continue to communicate with calyces, infundibula, or renal pelves. The communications are often narrowed enough to cause blockage of the outflow of the diverticulum and therefore represent a nidus for infection or stone formation (41).

Symptoms and Signs. Individuals with these lesions are mostly asymptomatic but may complain of chronic, dull, intermittent flank pain. Stones trapped in the diverticula can harbor infection, with symptoms of pyelonephritis occurring from time to time. These lesions may require retrograde pyelography for full delineation and diagnosis. CT scanning may be a useful adjunct, as it can help determine the amount of surrounding parenchyma as well as the rotational direction of the diverticulum. This information assists in surgical planning and operative approach and procedure.

Treatment. Patients who are persistently symptomatic or whose infections cannot be controlled with antibiotics may require some form of definitive therapy for the diverticulum (42). Surgical techniques include percutaneous dilation of the diverticulum with ablation of the tract or percutaneous access with nephrolithotomy if stones are present. In cases in which there is a significant amount of renal parenchyma surrounding the diverticulum, one may choose to perform open diverticulectomy or partial nephrectomy as definitive therapy (43). Additionally, laparoscopic techniques have been applied to treat calyceal diverticula, with reasonable success and minimal morbidity (44).

Horseshoe Kidney

Pathophysiology. Because of its weight, position, and variable blood supply, congenital horseshoe kidney can produce traction on the renal vessels and other adjacent vascular structures, resulting in abdominal pain of a dull, intermittent, and vague nature. Additionally, these kidneys are more likely to have ureteropelvic junction obstruction, reflux, or other congenital urologic abnormalities. Any of the obstructive lesions found in the unfused kidney can occur in the horseshoe kidney and produce similar symptoms.

Treatment. Although successful treatment of obstructive conditions in the upper collecting systems of horseshoe kidneys depends on separation of the isthmus, this is not always feasible or desirable because of the vascular configuration (45,46). Symptoms due to lesions that cannot be corrected may respond to medications or regional analgesia achieved with paravertebral T-10 to L-1 blockade (45,46).

Medullary Sponge Kidney

Etiology. Medullary sponge kidney is a congenital autosomal recessive defect in which the distal collecting tubules are dilated and visible on intravenous pyelography. Associated findings are a high incidence of renal tubular acidosis, hypercalciuria, and hyperparathyroidism.

Symptoms and Signs. Most individuals with this defect are unaffected and asymptomatic (47). Pain is associated with infection and stone formation in the widened (at times cystic) collecting tubules. Because autoelimination of the stones requires erosion through a papilla into the collecting system, the pain is chronic and intermittent as well as difficult to treat.

Treatment. Nerve blocks to relieve the pain might be followed by renal denervation in selected cases. (Nerve blocks are discussed under Renal and Ureteral Calculi and Idiopathic Nephralgia.) Endourologic approaches to this disease may offer relief to the individual who suffers chronically because of pain from trapped intermittently obstructing calculi (48). The mainstay of therapy is modification of the diet and optimization of the patient's metabolic profile to prevent further stone formation. This regimen would include thiazide diuretics, increased fluid intake, and alkalinization of the urine and phosphates to bind the calcium.

Acquired Diseases Affecting the Kidney and Ureter

Renal Vein Thrombosis

Etiology. Dehydration, infection, and coagulopathy are thought to be involved in renal vein thrombosis. Whatever the cause, the obstruction of venous outflow by clot causes renal swelling, capsular distension, and pain.

Symptoms and Signs. Half of the patients present with acute flank pain, hematuria, and persistent proteinuria. The other half experience a gradual onset of chronic flank pain rather than acute pain. In some patients, the first symptom is that of pulmonary emboli.

Diagnosis and Treatment. Intravenous pyelogram will demonstrate a pronounced nephrogram and poor excretion of contrast dye from the affected kidney (49). CT scanning is better at delineating the exact nature of the thrombosis, as it provides some information about the contralateral renal vein and the inferior vena cava. More selective venacavography may be required to determine patency of the renal vein and allow for potential localized thrombolytic therapy.

Anticoagulation therapy often promotes return of full function within 4 to 6 weeks, but acute obstruction may be best treated with thrombolysis (49). Pain is relatively mild and controllable with aspirin and codeine, but the physician should be mindful of the effects of aspirin on the ongoing anticoagulation.

Renal Infarction

Renal infarction is secondary to underlying cardiac or vascular disease in the majority of cases. The most common causes are atrial fibrillation and bacterial endocarditis (50). Other less common etiologies include intimal tear, trauma, contraceptive use, syphilis, cocaine use, and idiopathic thrombocytopenia (51).

Clinical Presentation. Renal infarction can be quite difficult to diagnose, as one may present with a multitude of symptoms. Pain associated with renal infarction usually presents in the flank region; however, not uncommonly it presents as abdominal, chest, or lower back pain. Accordingly, acute abdomen, pyelonephritis, cholecystitis, and even myocardial infarction may mimic the pain of a renal infarct (51,52). Other common clinical features include hematuria, nausea, vomiting, fever, and decreased urine output.

Diagnosis. Several laboratory tests may be abnormal in the face of renal infarction, yet none is exclusively diagnostic. Elevated WBC count is present in up to 70% of patients, whereas elevated lactate dehydrogenase levels are present in almost all patients (53). Also, hematuria is present in varying degrees in up to 80% of patients, with the majority having microhematuria. Several imaging studies are routinely used to accurately diagnose renal infarction.

Intravenous Pyelogram. Imaging of suspected renal infarction usually begins with an intravenous pyelogram, as the diagnosis is often stone disease or obstructive phenomena of the upper urinary tract. The study will show an absent nephrogram, as no contrast penetrates into the kidney. This is in contradistinction to renal calculi, as the obstructive uropathy will often demonstrate a delayed or dense nephrogram. Segmental infarctions may show partial or no evidence of renal involvement (54).

Renal Ultrasound. Sonography again may be used to better define renal obstruction. As the infarcted segments pass through time, sonographic changes occur; however, the main usefulness of renal ultrasound is when it is combined with duplex to study the vasculature, and this aids in the diagnosis of renal infarction.

Nuclear Renal Scan. Nuclear scanning entails use of radioisotope to perfuse the kidney and identify flow through all or part of the kidney. When areas are underperfused, as in renal infarction, this leads to perfusion defects, or so-called cold spots. This study may provide valuable information about the relative function of the kidney as well as the contralateral side. Its usefulness may be limited in the setting of segmental branch occlusion, as renal scans are not as specific as compared with large vessel disease (54).

Computed Tomography. The CT scan is one of the best modalities at differentiating the various diseases that may mimic renal infarction. The finding may be complete absence of perfusion of part or the entire kidney depending on the nature of the infarct. Additionally, the “cortical rim sign” may be suggestive of an infarct. This is described as a high attenuation area on the periphery of the kidney, with the remainder unperfused. The peripheral contrast-enhanced margin is from the presence of preserved capsular and collateral vessels.

Arteriography. Selective renal arteriography is the diagnostic study of choice in the evaluation of infarction. Segmental infarcts appear as wedge-shaped perfusion defects and the arteriogram can demonstrate the exact location of the segmental branch occlusion. When the main renal artery is involved, arteriography shows the extent of collateralization and nature of the occlusion.

Therapy. The treatment of renal infarction is controversial; many options exist. In the setting of acute renal infarction, the options may include surgical revascularization, thrombolysis, or simply observation. The mortality rate has been traditionally high when surgery is performed, as the patients often have significant coexisting morbidities and surgical revascularization may be difficult (55).

Renal and Ureteral Calculi

Etiology. Nephrolithiasis has a multifactorial etiology, including hormonal, anatomic, environmental, genetic, and dietary factors that predispose one to developing stones. Calcium metabolism is intimately related to stone disease and modification of the diet may effect stone formation. Additionally, magnesium, citrate, sodium, uric acid and bicarbonate and others may influence stone formation. Investigation into abnormalities of any of these factors by 24-hour urine analysis is paramount for evaluation of the etiology of nephrolithiasis. The most common types of stones found in North America are calcium oxalate and calcium phosphate stones (70%), followed by infection stones (struvite, magnesium ammonium phosphate; 15%), uric acid stones (5% to 10%), and cystine stones (1% to 5%) (56,57 and 58).

Symptoms and Signs. Currently, metabolic diagnosis is not a cost-effective screening method for identifying stone formers, and the physician's first contact with such individuals usually is during the acute pain caused by the passing of a calculus. Pain of passage is characterized as an “expanding bubble” of severe discomfort unrelieved by position changes. The site of referred pain depends on the position of the stone in the collecting system. The severity of the pain is such that large doses of potent narcotics (e.g., 15 mg of morphine sulfate or 125 mg of meperidine) may not relieve the pain. Renal pelvis and calyceal stone pain is referred to the costovertebral angle, whereas stones obstructing the upper ureter refer pain to the flank and ipsilateral gonad. Midureteral stones cause referred pain in the anterior superior iliac crest and inguinal region, and lower ureteral stones refer pain to the pubic area and scrotal or labial skin. Stones in the terminal ureter may also cause significant urinary urgency and frequency due to irritation of the trigone of the bladder.

Hyperesthesia and tenderness of the kidney region and spasm of the abdominal and flank musculature may accompany the pain of kidney stones. Not infrequently, retraction of the testicle, nausea, vomiting, urgency, “cold sweat,” and, occasionally, signs of shock are present. Often there is a compelling urge to urinate or even defecate, and urination becomes very painful.

The mechanisms of pain are obstruction and distension of the collecting system and renal capsule, extravasation of urine into the tissues, and irritation of the mucosa. In addition to the reflex spasm of the skeletal muscles, reflex spasm of the smooth muscles of the ureteropelvic junction and ureters frequently occurs. This spasm becomes a new source of noxious stimuli that gives rise to pain and other reflex mechanisms, which in turn aggravate the spasm. In this fashion, a vicious circle is initiated, causing aggravation and persistence of the pain. Additionally, reflex vasoconstriction of the renal vascular complex can occur, with potential deterioration of renal function (3).

Diagnosis. Diagnosis of renal calculus disease is based on the history of the pain, which has a characteristic radiation and progression from flank to groin, along with physical findings of costovertebral angle tenderness. Gross or microscopic hematuria is typical, but in a significant percentage of individuals, the symptoms of stone passage vary from none to vague and poorly localized abdominal malaise. The patient may be cool and clammy during episodes of colic. In contrast to the patient with intestinal disease, whose problem is usually heralded by nausea, vomiting, or both, the patient with renal colic usually becomes nauseated after the onset of pain (i.e., the nausea is caused by intense pain). The patient with intraperitoneal lesions that irritate the peritoneum usually tries to lie still, whereas the patient suffering from urinary colic is often restless and seeks different positions in attempts to get relief from the pain.

Plain radiographs of the abdomen and pelvis may show calcific stones of fair size but will fail to demonstrate radiolucent stones or smaller calcific densities in the presence of much gas and fecal matter in the colon. Therefore, an intravenous pyelogram should be done in patients suspected to be passing a stone except for those known to be allergic to contrast agents. More recently, a move toward performing unenhanced helical CT scanning has shown that this modality can quickly and effectively diagnose most cases of stone disease with excellent accuracy. Viewig et al. reviewed 105 patients who presented to Duke University Medical Center with acute flank pain. Unenhanced helical CT yielded a sensitivity of 98%, specificity of 98%, and an overall accuracy of 96% for diagnosing ureteral stones (59). This technique is particularly useful for the patient suspected of being a narcotic abuser who visits emergency facilities feigning renal colic to obtain the analgesics but claims allergy to contrast agents as a means of avoiding discovery.

Treatment. Therapy depends on the size of the stone, its location, presence or absence of sepsis, the amount of pain the individual is experiencing, and occasionally social circumstances. Ureteral stones less than 5 mm in diameter will pass spontaneously in 80% of the cases; stones that are 5 to 10 mm in diameter will pass spontaneously in approximately 20% of patients; and stones larger than 10 mm in diameter are much less likely to pass on their own.

Opioids. In most patients, relief of the severe pain is one of the primary objectives of the treatment of ureteral colic. Morphine, like all other phenanthrene derivatives of opium, tends to cause contraction of all smooth muscles, with the notable exception of those of the blood vessels. Clinical studies have shown that morphine can increase intrabiliary pressure to 15 times the normal value (3). Although large doses of morphine (e.g., 15 mg intravenously, slowly) may relieve the pain through its central effects, it is likely to aggravate the smooth muscle spasm. Meperidine has a slightly less spasmogenic effect than other potent analgesics and can be used in combination with atropine given simultaneously. Dextroamphetamine given in conjunction with an opioid potentiates the latter's analgesic efficacy and thus reduces the narcotic dosage required to achieve pain relief, it also is an effective antiemetic drug (60).

Regional Analgesia. If none of these agents provides good pain relief, serious consideration should be given to use of nerve block techniques, which interrupt the innervation of the kidney and ureter. Of the several regional analgesic techniques available, paravertebral sympathetic block and segmental epidural block are the most practical and effective. Paravertebral block, first used by Mandl to successfully treat renal colic and subsequently used by many European clinicians with very good results, has the disadvantage of requiring insertion of several needles (61). For this reason, continuous segmental epidural analgesia, limited to T-10 to L-1 inclusive, is the more practical procedure; it not only provides complete and persistent relief of pain as long as the analgesia is continued, but also interrupts efferent sympathetic impulses and thus eliminates the reflex spasm and any associated renal vasospasm. This in turn increases the chance of spontaneous passage of stones that are less than 10 mm in diameter.

Bonica reported on the results of either paravertebral sympathetic block or continuous epidural block in 53 patients, including eight physicians, during the past four decades (62,63). In addition to providing complete pain relief, in some patients the treatment resulted in downward movement of stones that had not advanced for 18 to 36 hours before the block. In 23% of these patients, treatment was accompanied by passage of the stone into the bladder; in another 18% of patients with calculi that had not advanced for a number of hours, the stone moved to the ureterovesical junction, where it was extracted through a cystoscope (Fig. 68-7). An important advantage of regional analgesia is that it poses no risk of respiratory depression. In contrast, if the patient is given a narcotic and then suddenly passes the stone, the pain often promptly subsides along with the pain-induced respiratory stimulation; in this situation the patient may incur severe respiratory depression. In addition, epidural analgesia can be extended if it is necessary to treat the stone through percutaneous ultrasonic pyelolithotomy or open surgery.

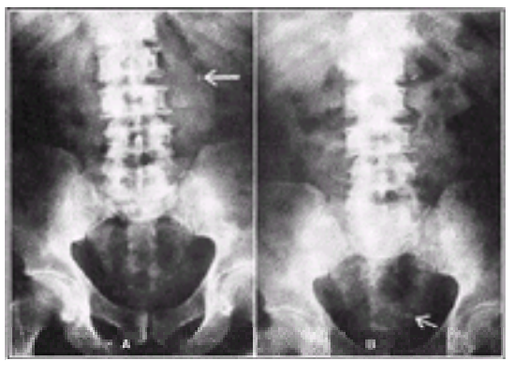

Figure 68-7. **A:** Radiograph of a patient with a stone in the left ureter at the level of the second lumbar interspace (*arrow*), which produced severe colicky pain in the left flank with radiation to the left groin, testicle, and inner aspect of the thigh. The stone did not advance for 48 hours, and the pain persisted despite repeated administration of narcotics. Paravertebral sympathetic block of T-10 to L-2 caused complete relief of pain and permitted the patient to be up and about. The nerve block was repeated in 12 hours. **B:** Radiograph taken after second nerve block showing that the calculus had descended to the ureterovesical junction (*arrow*). From this position, it was extracted with cystoscopic manipulation.

Urologic Therapy. Stones accompanied by sepsis are a truly life-threatening medical emergency. A history of chills and fever and findings of preshock or shock, fever, or elevated WBC count should alert the physician to the probability of concurrent sepsis. Intravenous lines must be established immediately for infusion of antibiotics and fluids, medications, and electrolytes to combat shock. Once the patient is in stable condition, this will be a convenient route for administration of potent opioid analgesics if someone experienced in epidural analgesia is not available.

Some means of drainage of the obstructed organ must be established. It can be drained percutaneously with the aid of local anesthesia or epidural block, or endoscopically via cystoscopic retrograde passage of a ureteral stent to bypass the stone and drain the infected collecting system. Topical anesthesia of the urethra may be achieved with 2% lidocaine (Xylocaine) jelly if the procedure is performed under local anesthesia. Instrumental manipulation within the bladder is made less uncomfortable by epidural block or by instillation through a small catheter of 20 mL lidocaine before cystoscopy. In instances in which sepsis and infection are not present, a wide variety of endourologic techniques are available to treat the stones, depending on their location. Most small upper urinary tract and some lower urinary tract stones are amenable to extracorporeal shock wave lithotripsy. Larger- or medium- sized stones in the kidney may necessitate percutaneous removal through a tract in the flank region to allow larger instruments to remove the stones. Ureteroscopy with a wide variety of baskets, probes, and lasers are also used, with good success rates for treatment of stones (64).

Urine and blood are cultured. Pending identification of the organism and its sensitivities, broad-spectrum antibiotics are administered. Because coliforms are the most likely offenders, although cocci may also be involved, a combination of antibiotics including an aminoglycoside is a good choice (e.g., ampicillin, 1 g every 6 hours, and gentamicin, 1 mg per kg every 8 hours). When the sepsis has been well controlled, removal of the stone by extracorporeal lithotripsy, percutaneous techniques, or endoscopic ureteral manipulation can be safely carried out as indicated.

An example of a socially motivated stone removal is the airline pilot discovered to have a renal calculus as a result of a workup for microhematuria found in an annual examination urinalysis. Such individuals are barred from flying commercial aircraft if they harbor stones. Therefore, otherwise asymptomatic stones in such individuals are often manipulated into a position that will allow them to pass or be broken up by extracorporeal shock wave lithotripsy (48).

Ureteropelvic Junction Obstruction

Etiology. In ureteropelvic junction obstruction, a minimally compensated congenital or acquired constriction of the ureteropelvic junction or adynamic segment decompensates as the result of sudden increase in local edema, angulation, or fluid load, producing acute renal colic. Aberrant vessels may also cause obstruction to the outflow of the kidney.

Diagnosis. When prompted, the patient might remember that past episodes of colic have followed increased intake of fluids, such as bouts of beer drinking, or high intake of salty foods such as smoked ham, pickles, or saltines, which induce a sodium-load diuresis. Diagnosis is made by obtaining an intravenous pyelogram during an episode of colic. Failing this, intravenous pyelography with a diuretic phase induced by furosemide may reproduce the colic and demonstrate the lesion. As a diagnostic maneuver, it may be possible to reproduce the pain during cystoscopy under local anesthesia and retrograde filling and overdistension of the renal pelvis through a ureteral catheter; however, this technique is seldom used today (65).

Treatment. Treatment of intermittent hydronephrosis involves surgical relief of the obstruction. In the period between diagnosis and definitive treatment, the patient is instructed to avoid fluid loading of the kidney; if an episode should occur, analgesics are dispensed as needed (65). Surgical therapy may be performed in a variety of ways, including open (dismembered pyeloplasty), antegrade, and retrograde techniques (66).

Clot Colic

Etiology. Renal bleeding unassociated with glomerulonephritis often produces clots. During passage, the clots can obstruct the ureter, producing colic indistinguishable from that due to passage of calculi as far as symptoms are concerned. Clot passage commonly occurs after blunt renal trauma, after renal surgery, with rupture of renal cysts, and from renal neoplasms.

Treatment. While diagnostic studies are under way, management of the pain is similar to management of pain due to acute obstruction of any kind. Analgesics are given, and if vomiting is a significant problem, intravenous fluids are administered. In the presence of severe bleeding, blood should be cross-matched in case transfusion becomes necessary, and vital signs and hematocrit should be closely monitored. Removal of the offending cause is the treatment of choice; however, angiographic embolization may yield temporary or permanent control (67).

Papillary Necrosis

Etiology. Patients at greatest risk of developing papillary necrosis—a rare, potentially life-threatening condition—are diabetics, chronic phenacetin abusers, alcoholics, persons with the sickle cell trait, and patients with chronic pyelonephritis. These disease processes cause the renal papilla to lose its vascular integrity and it sloughs into the collecting system, thereby obstructing the ureter and producing renal colic. Because infection is a common contributing factor, the danger of an infected, closed space threatens whenever a papilla sloughs and obstructs the collecting system. If this diagnosis is suspected, prompt action to relieve the obstruction is mandatory (68).

Diagnosis and Treatment. If pyelography is carried out in the patient with colic who is passing a papilla, a negative filling defect in the calyx outlining the bed of the slough can be seen. The appearance of this defect has been described as the “signet ring” sign. The location of radiolucent necrotic tissue in the ureter is also seen

as a filling defect.

If the ureter is obstructed, prompt relief by retrograde passage of a catheter or percutaneous nephrostomy is mandatory in the management of sepsis. The urine should be strained, and retrieved necrotic tissue should be sent to a pathologist to confirm the diagnosis (68).

Hydronephrosis of Pregnancy

Etiology. At the beginning of the fourth month of pregnancy, progressive dilation of renal calyces, pelves, and ureters above the pelvic brim starts and continues until the last 2 months, when it usually regresses. At least two factors are involved: mechanical compression by the enlarging uterus and endocrine effects on the smooth muscle of the ureter and renal pelvis. Because the left ureter is cushioned by the sigmoid colon, it is less affected by uterine compression than the right.

Symptoms and Signs. In the absence of infection or other complicating factors (see Ovarian Vein Syndrome), hydronephrosis of pregnancy does not typically cause pain or other symptoms. Complications combined with obstruction may produce persistent pain. One should evaluate for renal or ureteral stones causing the symptoms of flank pain, and microhematuria is often present (69).

Treatment. When persistent pain develops, care must be exercised in the use of narcotics because of the possible depressant effects on the fetus. Combining small doses of narcotics with nonsteroidal antiinflammatory drugs and perhaps even dextroamphetamines can minimize this risk. Because obstruction can be relieved with the aid of indwelling internal stents, which can usually be passed with the aid of topical anesthesia, the problem of long-term analgesics can be bypassed (69).

Ovarian Vein Syndrome

Etiology. Initially known as the *right ovarian vein syndrome*, this condition is most commonly seen in women of child-bearing age after pregnancy (see previous section). Presumably, a process is set in motion during pregnancy in which an aberrant ovarian vein traps the ureter after hormonal changes, and the obstruction caused by the uterine enlargement produces ureteral dilation. The resulting constriction persists postpartum, leaving permanent hydroureteronephrosis above the level of the surrounding vein. Because hydronephrosis of pregnancy is more common (80%) and more severe on the right side, that side is more frequently involved in the ovarian vein syndrome. Symptoms are pain in the involved flank due to obstruction and those of the accompanying infection.

Diagnosis and Treatment. Postpartum pain in the right flank or abdomen, or both, accompanied by chills, fever, malaise, nausea, and vomiting should alert the clinician to the possibility of ovarian vein syndrome. On examination there is flank tenderness. Ultrasound or pyelography helps establish the diagnosis.

Relief of pain with analgesics is required until obstruction is bypassed by ureteral stenting and antibiotic therapy is instituted to control infection. Permanent relief is provided by surgical excision of the obstructing vein (70).

Infundibular Stenosis (Fraley's Syndrome)

Etiology. In Fraley's syndrome, flank pain is caused by obstruction of the superior infundibulum and its calyces. The latter obstruction is produced by intrarenal vessels impinging on the infundibular channel as the secondary vessels wind around it in their course through the renal sinus.

Diagnosis and Treatment. All reported cases of Fraley's syndrome thus far have been adults (71). Patients complain of steady, dull pain in the costovertebral angle and flank, usually for months or years. The key to diagnosis is that lying down relieves the pain. Tenderness may or may not be present on examination. Upon careful review of the pyelogram, which includes oblique views, a linear filling defect caused by vascular compression is seen crossing the infundibulum to the superior calyx. A 30- or 60-minute drainage film shows contrast trapped in the superior calyx. Angiography may be helpful to further delineate the crossing vessel in relation to the collecting system.

Treatment of Fraley's syndrome requires severance and reanastomosis of the infundibulum or the occluding vessel, preferably the former (71).

Conditions Causing Pseudorenal Pain

Etiology. Ilioinguinal neuropathy and genitofemoral nerve entrapment, which cause pseudorenal pain, almost always follow inguinal surgery, most frequently herniorrhaphy. Genitofemoral entrapment is rare, but both conditions can be mistaken for renal pain by the unwary (72,73).

Symptoms and Signs. These conditions are characterized by radicular (segmental) pain in the distribution of dermatomes T-10 to T- 12 that can mimic renal pain. Unlike renal colic, however, pseudorenal pain is usually brought on by a physical strain such as heavy lifting, sleeping in an awkward posture, or occasionally by a blow to the spine. It is relieved by a change of position, which is not the case with most renal pain [for an exception to this see Infundibular Stenosis (Fraley's Syndrome)].

Diagnosis. Conditions causing pseudorenal pain are rare; they are mentioned in this chapter for the sake of completeness in considering the differential diagnosis of renal pain (72,73).

Idiopathic Nephralgia/Loin Pain-Hematuria Syndrome

Etiology. Idiopathic nephralgia and loin pain-hematuria syndrome are extremely rare conditions characterized by intractable flank pain and hematuria and less frequently symptoms of frequency, nocturia, and dysuria, in the absence of demonstrable pathology. In former years, the condition was diagnosed more frequently and was attributed to irregular and incomplete contraction of the calyces and renal pelvis resulting from uncoordinated overactivity of the sympathetic nerve supply so that impulses for peristalsis either did not reach or did not pass beyond the ureteropelvic junction (74).

As knowledge of renal pathophysiology increased and advanced diagnostic methods became available; the number of patients diagnosed with this syndrome steadily declined and now is minuscule. Nonetheless, if after comprehensive urologic, neurologic, orthopedic, psychiatric, and radiologic evaluation, no demonstrable pathology is found for persistent and disabling renal-type pain and other related symptoms, one is faced with the need for treatment. In the rare instances in which this occurs, patients should be submitted to comprehensive psychosocial evaluation, including psychometric testing, to eliminate pain due to psychological problems.

Therapy. If all of the diagnostic procedures discussed so far prove negative and the patient has persistent, disabling pain, diagnostic-prognostic paravertebral nerve block of T-10 to L-2 inclusive with a local anesthetic is carried out. At least three such procedures should be carried out using local anesthetics with different durations of action and the patient's response carefully monitored and compared with the predicted duration of the analgesia. If the patient derives complete pain relief for the duration of the blockade, a series of such blocks might alter the behavioral response to the underlying stimulus, whatever it may be, and provide adequate relief of the pain syndrome. When such procedures provide complete but only temporary relief, renal denervation may be considered.

Denervation. In the early part of the twentieth century, denervation of the kidneys was achieved by periarterial stripping of the nerves. This procedure does not effect complete denervation, however, because some of the nerves run in the wall of the vessel. Moreover, because the fibers removed are postganglionic and only small sections are removed, regeneration occurs within weeks and months. These factors, together with the fact that the operation is tedious and carries an inherent risk of laceration of vessels, caused a number of clinicians to abandon this procedure and replace it with aorticorenal ganglionectomy. Fontaine et al., among others, obtained good results by combining aorticorenal ganglionectomy and splanchnicectomy (75).

The most impressive report on the efficacy of denervation for idiopathic nephralgia is that published by Bauer (7). He noted that in a large series of cases, all but one patient was freed of persistent “idiopathic” renal pain by denervation of the kidney. More recently, White and Sweet (76) reported that four patients, in whom paravertebral block of T-10 to L-1 (or L-2) produced complete temporary relief, derived relief for 1 to 8 years after sympathetic denervation. For reasons previously mentioned, the preganglionic operation of dividing small and lesser splanchnic nerves and removing the three lower thoracic and first and second lumbar sympathetic ganglia, as well as the intervening trunks, is the procedure of choice. We have performed this procedure in one patient with a successful outcome. As has been amply demonstrated after autotransplantation and heterotransplantation of kidneys in many patients, total denervation has little effect on renal function. Accordingly, renal autotransplantation is used often in these cases, as renal denervation shows some promise in terms of therapy for these exceptionally difficult-to-manage patients

(77). Nonetheless, despite surgical denervation with autotransplantation, recurrent graft pain has been demonstrated and overall success rates are less than 70% (78). Although some have proposed a psychological or even factitious etiology of the loin pain-hematuria syndrome, there is some evidence to support the neuropathic basis of this condition. It has been reported that capsaicin irrigation of the renal pelvis will provide long-term relief (79).

Malignant Disorders Affecting the Kidney and Ureter

Renal and Ureteral Tumors

A variety of tumors of the kidney and ureter can cause pain in the flank and various other symptoms and signs. The most important tumors are renal cell carcinoma, TCC of the renal pelvis and ureter, sarcomas, renal oncocytoma, and Wilms' tumor of the kidney (see Chapter 35).

Renal Cell Carcinoma. Renal cell carcinoma represents an adenocarcinoma of the renal parenchyma. Because of the variety and diversity of the presenting symptoms and signs related to secondary effects of this tumor (paraneoplastic syndrome), it has been dubbed *the internist's tumor* (80). The tumor occurs in all age groups, but it is most prevalent in the sixth and seventh decades of life and has a male predominance, with a ratio of 3 to 2 (81). This tumor afflicts all races, but its highest incidence is in Scandinavia. This tumor accounts for 3% of adult malignancies and in 1995 accounted for 28,000 new cases and an associated 11,000 new deaths (82).

Etiology. Although the exact cause of renal cell carcinoma has not been defined, there is evidence for carcinogenic and genetic factors. Smoking increases the risk of renal cancer by approximately 40%. Cadmium exposure also has been associated with an increased risk; the presence of both factors increases the risk of renal cancer even further (81). A genetic propensity for renal carcinoma also has been demonstrated by mutations in chromosome 3p25–26, particularly in patients with Von Hippel- Lindau disease (83). Cohen et al. described an abnormal karyotype caused by reciprocal translocation of chromosomes 3 and 8 in families in which a kidney tumor was prevalent (84). He reported that eight of 10 of the family members with tumors had the chromosomal abnormality, whereas the 22 without cancer did not. These data support a multifactorial basis for renal cell carcinoma, including environmental, genetic, and hormonal factors.

Grawitz (85) originally postulated that these tumors arose from adrenal rests because of their microscopic resemblance to adrenal tissues, which prompted him to name the tumor *hypernephroma*; subsequent studies established that the tumors are of renal tubular origin. Three main cell types can be identified in these malignancies: (a) clear cell carcinoma, (b) granular cell carcinoma, and (c) sarcomatoid cells. Renal cell carcinomas are given a pathologic grade of I, II, or III, based on degree of cellular anaplasia, with grade I being least anaplastic and grade III showing the greatest degree of anaplasia (Furhman grading system). Metastatic spread occurs both by direct extension and through lymphatic and hematogenous routes. The most common sites of metastasis are lungs (55%), lymph nodes (34%), liver (33%), bone (32%), adrenal (19%), contralateral kidney (11%), brain (6%), heart (5%), spleen (5%), bowel (4%), and skin (3%) (86).

Symptoms and Signs. Renal cell carcinoma may present with a wide variety of clinical symptoms and signs, including the classic triad of flank pain, hematuria, and a palpable flank mass. Additionally, nonspecific systemic symptoms and numerous paraneoplastic syndromes may be evident and may imply higher-stage disease (87). In several series, the classic triad occurred in only 4% to 6% of the patients studies (81). The individual features of the triad occurred more frequently than the entire triad. Hematuria, noted in 35% to 59% of the patients reviewed, was most common. Pain directly related to the primary tumor, provoked by stretching of the renal capsule or sudden expansion due to bleeding into it, was found in approximately one-third of the cases (range of 10% to 38%), although in one study of 309 patients, pain was present in 41% of the patients (55). A palpable mass was found in approximately 22% (range of 2% to 35%) (86), although in the study of 309 patients, it was noted in 45% of the patients. In the series of studies cited by Bagley, 30% of the patients had none of the classic triad of symptoms (81). Thus, the disease may remain clinically silent during the early stages, and in more than 50% of patients, metastatic disease is present at the time of diagnosis (86).

Hypertension and weight loss are relatively uncommon presenting signs of renal cell carcinoma except in cases of advanced disease. Tumor obstructing the spermatic vein can cause a varicocele, which fails to disappear when the patient lies down. Furthermore, a right-sided varicocele with similar characteristics may be indicative of vena caval obstruction. Abnormal liver function tests are found in approximately 15% of patients, including some without metastasis, the cause of which is unknown. A similar fraction have hypercalcemia.

The paraneoplastic syndromes associated with renal cell carcinoma may rarely lead to the diagnosis of the tumor. Other secondary symptoms include intermittent fever, weakness, anemia, or erythrocythemia due to overproduction of erythropoietin. Fever is the presenting symptom in one out of eight of the cases. Cardiac failure associated with hypertension may occur because of the arteriovenous shunting within the neovasculature of the tumor.

Diagnosis. The diagnosis of renal cell carcinoma requires thorough history and physical examination as well as radiography and other more sophisticated diagnostic procedures mentioned earlier in this chapter. The presence of a spiking fever in conjunction with regional mass makes differential diagnosis between renal tumor and renal abscess quite difficult, and radiologic findings may not distinguish between these two lesions; final diagnosis must await surgical exploration or fine needle aspiration. Currently, the tumor is likely to be discovered incidentally by ultrasound imaging or CT scanning for other abnormalities. If the cancer is identified within the kidney at the time of screening for other diseases, approximately 85% of the patients survive 5 years (88). However, if one or more of the symptoms of renal cell carcinoma is present, 5-year survival rates diminish (89). Once ultrasound imaging suggests diagnosis of renal carcinoma, further studies of the mass by CT scan and angiography usually confirm the diagnosis and lead to exploration and excision. Tumors picked up incidentally in early stages by these means are much less likely to have developed a neovasculature, which lights up the angiogram in large neoplasms.

Treatment. Surgical removal remains the only effective treatment for renal cell carcinoma. Localized stage I (tumor confined to the kidney) and stage II (tumor locally invasive but confined to Gerota's fascia) and locally advanced renal cell carcinomas are amenable to radical nephrectomy (87). This procedure includes early control of the renovascular pedicles and removal of the kidney and the associated tumor, the adrenal gland and the surrounding perinephric fat, and Gerota's fascia along with the regional lymph nodes. More recently, data suggest that tumors confined to the mid- and lower poles or smaller upper pole tumors do not necessitate ipsilateral adrenalectomy (90). In cases of small (less than 4 cm) tumors, solitary kidney, and presence of conditions that may predispose one to lose renal function in the future (e.g., diabetes, stone disease, renal artery disease), partial nephrectomy is an accepted surgical option (91,92).

Metastatic Renal Cell Carcinoma. Stage III renal carcinoma, which by definition includes regional invasion of the renal vein or vena cava, or both, or metastasis to regional lymph nodes, or a combination of these, is also treated by radical nephrectomy. This procedure results in 42% to 50% 5-year survival (87). Local extension of the tumor into the renal vein appears to have less effect on the prognosis than nodal involvement. Accordingly, tumor thrombus in the renal vein and inferior vena cava still has a 5-year survival rate of greater than 50% when lymph nodes are negative (93).

No uniformly satisfactory treatment exists for stage IV renal cell carcinoma, which by definition includes invasion of surrounding organs and widespread metastatic disease. Because up to 50% of patients have evidence of metastatic disease at the time of diagnosis, therapy remains a major problem. In selected patients who have a proven solitary metastasis, surgical excision of the primary tumor and the metastasis, may provide long-term cure, whereas in patients with widespread metastasis, the prognosis is poor even when radiation, chemotherapy, or hormonal manipulation is added to the surgery. Currently, immunotherapy with a wide variety of agents is used to control metastatic disease (94). These agents may include interferon, various interleukins, and other cytokines.

In patients with metastatic lesions from renal cell carcinoma, pain control is a very critical issue. Pain due to metastatic lytic lesions of the bone or periosteal elevation can often be successfully treated by irradiation of the involved area. Occasionally, long bone lesions may benefit from internal fixation. Pain caused by infiltration of nerves or nerve plexuses or spread to other organs can be severe, intractable, and not relieved by oncologic therapy. Treatment should include the use of nonopioid and narcotic analgesics and various adjuvant agents, such as amitriptyline and other antidepressants, which have proven useful in relieving the lancinating deafferentation pain. Attempts should be made to use a multimodal approach, combining pharmacologic therapy, psychological techniques, neurostimulation techniques, nerve blocks, intraspinal opioids, and neuroablative procedures.

Sarcomas. Sarcomas account for only 3% of the malignancies of the kidney or renal pelvis. The majority of these lesions are leiomyosarcomas, but other histologic varieties have been reported (81). The mean age of patients who develop this type of tumor is approximately 50 years, with a range of 10 to 86 years.

The symptoms and signs depend on the size of the lesion. These tumors have a tendency to be locally infiltrative and may involve local area nerves. Large tumors cause pain by stretching of the renal capsule and perhaps by compression or irritation, or both, of intercostal nerves. No radiologic findings have been considered diagnostic despite use of modern imaging techniques. Treatment generally has consisted of excision by nephrectomy and mass excision. The poor results noted, with frequent local recurrence and metastases, have prompted interest in combining surgery with radiotherapy and chemotherapy, which has been promising with

sarcomas in other sites (81).

Renal Oncocytomas. Oncocytomas are solid tumors of the renal parenchyma that have a benign course. This type of tumor accounts for 3% to 5% of all renal tumors (87). The age of patients with these tumors has ranged from the third to the ninth decade and there is a slightly higher incidence among males than females. However, renal oncocytomas can have coexistent renal cell carcinomas in up to 30% of cases. The management scheme should therefore follow the same course as that for any suspicious renal mass (95).

The signs and symptoms are somewhat similar to those of renal cell carcinoma and include flank pain, hematuria, and a palpable mass. The prognosis of patients with oncocytoma appears to be excellent.

Transitional Cell Carcinoma (TCC) of the Upper Urinary Tract. Upper tract TCC constitutes 5% of all renal tumors (96). These tumors first appear in the fifth and sixth decades of life, with a progressive increase in incidence with advancing age. Carcinoma of the ureter is most common in older age groups, being rare before 30 years of age. The incidence of carcinoma of the pelvis and ureter is greater in males than females by a ratio of 2 to 1. The incidence of bilaterality is 2% to 4% and approximately 30% to 50% of patients with renal pelvic TCC will develop TCC of the bladder.

Etiology and Pathology. Transitional epithelial cells lining the calyces and renal pelvis, as well as the ureter, are subject to environmental carcinogens. A strong relationship between carcinoma of the renal pelvis and a long-standing history of phenacetin ingestion has been established, as has an association between carcinoma of the renal pelvis and Danubian endemic familial nephropathy. Tobacco abuse is also associated with a higher incidence of transitional cell cancers (97).

Malignant lesions of the renal pelvis can be classified into TCCs, squamous cell carcinomas, adenocarcinomas, and connective tissue tumors. Approximately 90% of all tumors of the renal pelvis are transitional cell tumors. In the ureter, more than 70% of TCCs are primary transitional cell malignancies, and only 8% are squamous cell tumors (96). TCC is spread by direct extension and through blood and lymphatic channels. Approximately 85% of TCCs of the renal pelvis are papillary and less often demonstrate muscle invasion at the time of resection. The other 15% are sessile; of these, approximately 80% show muscle invasion at the time of resection.

Symptoms and Signs. Gross or microscopic hematuria appears in 80% to 90% of patients with upper tract TCC (96). Pain is usually precipitated by ureteral or ureteropelvic junction obstruction secondary to the tumor mass. These patients are likely to suffer pain in the psoas, quadratus lumborum, and erector spinae muscles; if there has been extension to the vertebral column, back pain is present. Palpable flank mass in a patient with TCC signifies massive extrarenal extension or hydronephrotic renal destruction secondary to obstruction.

Diagnosis. Diagnosis is helped by the appearance of a defect in the collecting system or renal pelvis on excretory pyelography. In patients with ureteral tumors, approximately 50% will present with urinary frequency or dysuria. Radiographically these patients will have ureteral dilatation, which develops as a result of accommodation of a slowly expanding tumor mass and reflects the absence of ureteral spasm produced by the presence of a calculus. Urine cytology will be atypical in most patients with higher-grade lesions (96).

Treatment. Nephroureterectomy traditionally has been the treatment of choice for TCC of the pelvis, ureter, or both. A stage I tumor of the ureter can be managed by excision of the tumor along with an ureteroureterostomy. In patients with tumor of the renal pelvis, radical nephroureterectomy is advocated; this includes *en bloc* removal of the kidney, ureter with the cuff of the bladder, and the surrounding lymphatic structures. The addition of lymphadenectomy at the time of surgical resection may not provide any improved disease control but does provide information with regard to the stage of the disease, which can be used to select patients for adjunctive chemotherapy when appropriate agents have been identified. The 5-year survival rate is greater than 80% in grade I tumors, approximately 70% in grade II, but less than 30% to 50% in grades III and IV. The prognosis in patients with transitional cell cancer of the ureter is less favorable, with patients rarely living more than 2 years after diagnosis. Other options now include endourologic management of the upper tract TCC in both antegrade and retrograde fashions. Additionally, adjunctive use of Calmette-Guérin bacillus placed in the kidney or ureter may decrease local recurrence rates (98).

Wilms' Tumor. Wilms' tumor, which develops in approximately 500 children each year in the United States, accounts for approximately 95% of primary renal malignancies in childhood (99). Moreover, it is the third most common solid tumor in childhood, following tumors of the central nervous system and neuroblastoma in incidence. During the past three decades, methods of treating this tumor have improved significantly, providing striking increases in survival rates.

Etiology and Pathology. The cause of Wilms' tumor is unknown, but the predilection of patients with certain genetic factors to develop this type of neoplasm suggests a partial genetic basis. Recent chromosomal studies have localized the Wilms' tumor gene (*WT-1*) locus to the 11p13 (99). Children with aniridia, hemihypertrophy, Von Recklinghausen's disease, or genitourinary congenital anomalies have an increased risk of developing Wilms' tumor as well (99).

Grossly, most Wilms' tumors are large, fleshy, soft tumors that grow in extensive fashion within an apparent “capsule.” In advanced stage III of the disease, metastasis to the regional lymph nodes is present, whereas in stage IV of the disease, there is a hematogenous metastasis to the lung, liver, brain, or bone.

Symptoms and Signs. Most children present because of an abdominal mass first noted by a parent (often when bathing the child). Other frequent presenting symptoms and signs include pain, anorexia, fever, or hematuria. The latter symptom is a sign of renal-collecting system involvement and is seen with much less frequency than in renal cell carcinoma. Mild hypertension is noted in many children, and plasma renin levels may be increased. Primary Wilms' tumor often undergoes extremely rapid growth in apparent size.

Diagnosis. In addition to a thorough history and physical examination, roentgenograms of the chest and ultrasonography should be performed in all children (99,100). The evaluation of the inferior vena cava, best also performed by ultrasonography, should be done routinely to provide information about tumor size, site, and extent. CT may assist in delineating any lung lesions as well as determining the exact extent of the kidney tumor and adjacent organ or contralateral kidney involvement. Other diagnostic procedures mentioned in the earlier part of this chapter should also be considered.

Treatment. Treatment of Wilms' tumor consists of surgical removal of the kidney and the entire tumor, a segment of the ureter, and regional lymph nodes (99). Depending on the tumor stage and histopathologic findings, the addition of chemotherapy or radiation therapy, or both, is used adjunctively to prevent relapse. Additionally, in select instances, preoperative chemotherapy is warranted (100). Most recent studies suggest that nearly 80% of all patients with Wilms' tumor are cured with optimal current therapy. Survival is inversely proportional to the stage of the disease. The 5-year survival rate is 97% for those with stage I (favorable histology) and 92% for those with stage II (favorable histology). Stage III disease 5-year survival is 84% with favorable histology and drops to 68% with unfavorable histology, whereas it is only approximately 55% for those who have pulmonary metastasis and even lower for the very few patients who have metastasis to the liver, bone, and brain (stage IV unfavorable histology) (100,101). Metastasis to the lungs accounts for approximately two-thirds of the relapses, but with aggressive treatment, control of metastasis is possible in at least half of the cases.

Effective pain control before and after the surgical operation is an important part of management. Recent studies have provided impressive evidence that the prevalent misconception that children do not experience as much pain as adults is incorrect. Parenteral, oral, or intraspinal narcotics may be useful in the management of this type of pain.

CHAPTER 69

Abdominal Pain Caused by Other Diseases

Kaj H. Johansen, E. Patchen Dellinger, and John D. Loeser

This chapter discusses disorders that cause abdominal pain not discussed in the preceding four chapters of this section and includes Intraabdominal Vascular Diseases; Diseases of the Peritoneum, Mesentery, and Diaphragm; Other Intraabdominal Diseases, including abscesses, neurogenic ileus, gas entrapment syndrome, and abdominal migraine; Systemic Disorders, including hematologic, biochemical, and biological disorders; and Extraabdominal Diseases, including thoracic visceral disease, gynecologic disease, pain of neuropathic origin, and pain of musculoskeletal and tegumentary origin (Table 69-1). Many disorders discussed in this chapter have been considered in more detail by Sleisenger and Fordtran (1) and Nyhus and colleagues (2).

TABLE 69-1. Abdominal pain caused by other disorders

INTRAABDOMINAL VASCULAR DISEASES

Abdominal pain can arise from multiple different vascular causes but is of special importance because it may presage several different and highly lethal conditions: expansion or rupture of an arterial aneurysm, abdominal implications of aortic dissection, or acute intestinal ischemia leading to infarction, perforation, and peritonitis. Recognition of the underlying cause is thus a crucial aspect of the successful management of such abdominal pain. In this section the pertinent pathophysiologic states are discussed; the symptoms associated with each condition are elucidated; appropriate means of diagnosis and management, both of the pain and the underlying conditions, are presented; and the natural history of these conditions, both in the untreated state and following appropriate management, are discussed. We first consider aortic aneurysm, then aortic dissection, then acute and chronic intestinal ischemia. Finally, intestinal consequences of systemic vasculitis are briefly considered. A more comprehensive discussion of these conditions can be found in several excellent textbooks on vascular surgery (3,4 and 5).

Abdominal Aortic or Iliac Aneurysm

Etiology

The vast majority of intraabdominal aneurysms are found in the infrarenal aorta, starting 1 or 2 cm distal to the renal artery orifices and ending at or just before the aortic bifurcation (Fig. 69-1). Historically, aneurysms were once a common consequence of trauma, bacterial infection, or syphilis, but the overwhelming majority now arises as a consequence of an apparent systemic lathyrism (a collagen-elastin defect) manifested by a weakening and fragmentation of the arterial media. Causes for this collagen-elastin defect are probably multiple, including inheritance of a biochemical defect (6), inadequate nutrition because of sparse arterial vasa vasorum (7), hydraulic stresses (8), and increased lytic enzymes, either primary or secondary to such exogenous stresses as cigarette smoking (9). While aneurysm shares numerous risk factors with atherosclerosis (advanced age, male gender, smoking, hypertension) the two entities are morphologically, anatomically, and histopathologically distinct (10). Because aneurysmal dilatation is a systemic disorder, it is not surprising that other intraabdominal vessels can occasionally (although much less commonly) develop aneurysms as well (11). These are most commonly seen in the renal, hepatic, superior mesenteric, celiac, and pancreaticoduodenal arteries. Aneurysmal dilatation can also occur in a special circumstance in the splenic artery; this is a rare but serious disorder in pregnant women, unfortunately too commonly presenting with hypovolemic shock following rupture (12).

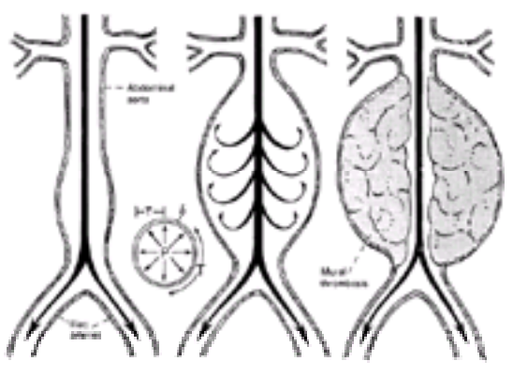

Figure 69-1. Development and progression of an abdominal aortic aneurysm. **A:** Initial phase. The insert shows that tension (*T*) on the wall varies directly with the

product of the intraluminal pressure (*P*) and the radius (g) of the lumen and inversely with the thickness (d) of the wall. T is proportional to Pg/d. Any slight dilatation shown in A increases the radius and decreases the thickness, thereby increasing the tension and progressively enlarging the aneurysm. **B:** As the artery dilates, blood near the wall flows more slowly, creating turbulence. Turbulent flow causes the wall of the vessel to vibrate, further weakening it. **C:** Both turbulence and irregularity on the lining of the damaged wall promote the formation of a mural thrombus, which significantly reduces the diameter of the lumen. (Modified from Johansen K. Aneurysms. *Sci Am* 1982;247:110–111.)

Aneurysms occasionally arise as a consequence of infection, most commonly in the aorta or in one of its branches. Formerly, this was usually related to embolization from subacute bacterial endocarditis, but a more recent report suggests that mycotic aneurysms arise more commonly from vascular trauma, various immunosuppressed states, and concurrent sepsis (13). An aneurysm of special importance, both because it is iatrogenic and because it heralds such potentially lethal conditions as graft infection or aortoenteric fistula, is the anastomotic aneurysm arising at a suture line of a previously placed arterial prosthetic graft, resulting in aorto- or graft-enteric fistula (14).

Pathophysiology

Pain arising from aneurysms within the abdomen results primarily from the stretching of sensory nerves of the retroperitoneum due to aneurysm expansion; such nerves may be stimulated even more significantly with aneurysmal rupture. Because aortic aneurysmal rupture most commonly occurs to the patient's left side into the retroperitoneum beneath the sigmoid colon (Fig. 69-2), stimulation of nerves of the lumbosacral plexus on the left side is usual. Indeed, individuals with slowly leaking aneurysms are sometimes first evaluated by a urologist, neurosurgeon, or orthopedist because of the initial mistaken impression of ureteral colic or lumbar disk disease. Erosion of an expanding aortic aneurysm into the lumbar vertebrae can cause severe back pain, probably a consequence both of irritation of lumbar nerve roots and of the overlying periosteum. On unusual occasions patients with aneurysmal rupture can present with pain in the right upper quadrant so that the initial impression is that of biliary colic, as noted during the terminal illness of Albert Einstein (15).

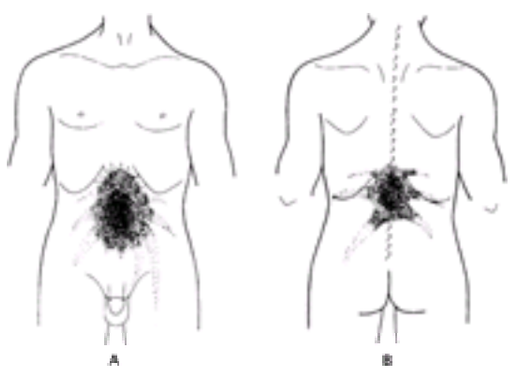

Figure 69-2. **A,B:** Distribution of the pain caused by rupture of the abdominal aorta consequent to aneurysm.

Symptoms and Signs

Most infrarenal abdominal aortic aneurysms are asymptomatic until rupture. Patients occasionally complain of a dull, diffuse, poorly localized midabdominal pain, commonly not significant enough to prompt medical consultation. Rarely, aneurysms can obstruct the gastrointestinal tract or the ureter by extrinsic compression, resulting in intermittent or constant symptoms appropriate to those organs. Erosion of an aneurysm into the lumbar spine can cause symptoms either locally, presenting as chronic back pain, or as a consequence of encroachment on nerve roots, wherein projected pain might be noted in the distribution of these lumbosacral nerve roots (i.e., into the pelvis, groin or scrotum, or lower extremity).

Much more commonly, pain is a cardinal feature of acute aneurysmal expansion or rupture. The patient frequently notes sudden tearing aching pain in the midabdomen and mid-back, most commonly radiating into the left flank or groin for reasons noted previously. Such pain is commonly associated with the symptoms and signs of hypovolemic shock, because what might be a substantial portion of the patient's blood volume exits into the retroperitoneum. Similar tearing aching pain followed by hypovolemic shock results from the rupture of aneurysms of various intraabdominal visceral arteries and their branches as well. The *double rupture* sign has been reported with splenic artery aneurysm rupture, seen primarily in pregnant women (see previous discussion). Severe sharp left upper quadrant pain occurs and then subsides as the initial aneurysm rupture is tamponaded in the lesser sac; further pain and shock supervene when the rupture breaks into the free peritoneal cavity (12).

Diagnosis

Aneurysms are found most commonly in elderly men; the average age for a standard population of patients with abdominal aortic aneurysm is 70 years, and the male to female ratio is 4:1 to 8:1 in most series. A history of aneurysm elsewhere strongly predicts abdominal aortic aneurysm, and hypertension and cigarette smoking are associated with greater frequency in patients with aneurysms. A tendency to aneurysmal deterioration of arteries may be traced in families, suggesting that the elderly relatives of aneurysm patients might be at increased risk of developing aneurysms themselves (16). Risk factors for the development of mycotic or anastomotic aneurysms have been mentioned previously. As noted, the vast majority of intraabdominal aneurysms are asymptomatic and most commonly are discovered by serendipity during physical examination or on roentgenographic or other imaging evaluation performed for other purposes. For example, calcium outlining the wall of an intraabdominal aneurysm can be discovered on plain roentgenograms or computed tomographic (CT) scans of the lumbosacral spine performed for low back pain or on excretory urograms performed for putative ureteral colic. Abdominal ultrasonograms obtained for evaluation of possible biliary colic can demonstrate an occult abdominal aortic aneurysm.

Because the aorta bifurcates at the level of the umbilicus, the physical examination should emphasize careful palpation of the epigastrium. Aneurysm is diagnosed on physical examination by evidence for a pulsatile mass substantially broader than the 2-cm upper limits for the diameter of the normal adult infrarenal aorta. Tortuosity of the abdominal aorta can sometimes mimic aneurysm formation, especially in the elderly, and overlying inflammatory or neoplastic masses can transmit the aortic pulse and cause the mistaken impression of aneurysm (17). Aneurysms of visceral arteries are rarely symptomatic until rupture. A large iliac aneurysm might occasionally be palpable on rectal examination, frequently presenting initially with urologic or gynecologic symptoms; these are sinister lesions with a dismal prognosis following rupture (18).

Current diagnostic procedures most important for demonstrating the presence and size of intraabdominal aneurysms include B-mode ultrasonography (19) and CT scanning (20). With a high sensitivity, specificity, and overall accuracy, these can be used to define the presence of aneurysms as well as to discern their sizes, with a resolution rate of less than 1 mm. Arteriography generally has little to add in the diagnosis of aneurysms and on occasions it can be frankly misleading because aneurysms in general (and infrarenal abdominal aortic aneurysms in particular) fill circumferentially with thrombus so that the angiographic dye column can appear little different from the normal aortic lumen. Arteriography may be useful in the preoperative evaluation of certain aneurysm patients (e.g., those with hypertension or peripheral arterial occlusive symptoms).

Patients whose aneurysms rupture present with signs and symptoms of sudden abdominal, flank, and back pain and circulatory collapse. Thus, the clinician usually can differentiate this condition from several others that might resemble it superficially, including perforating peptic ulcer, visceral artery embolism, and myocardial infarction accompanied by cardiogenic shock. Although the pain patterns and collapse seen with each of these conditions can be similar to those of aneurysm rupture, initially all are usually characterized by relative *normovolemia* (in the case of perforated ulcer or mesenteric embolism) or *hypervolemia* (in the case of myocardial infarction), in contrast to the signs of profound *hypovolemia* that accompany ruptured aneurysm. Subacute rupture of an aneurysm can, as noted previously, lead to confusion with ureteral or biliary colic or with the orthopedic or neurosurgical implications of lumbar spine disease.

Treatment

No effective nonoperative therapy for intraabdominal aneurysms exists. Whereas hypertension and cigarette smoking can play a role in the early genesis of the arterial wall degeneration leading to aneurysm formation, once developed the arterial dilatation proceeds inexorably toward rupture in consonance with Laplace's law (21). Aneurysms of the abdominal aorta exceeding 5 cm in greatest diameter warrant repair in otherwise good-risk patients.

In brief, the operative management of aneurysm involves proximal and distal control of the artery and, in cases of aortic or iliac aneurysms, opening of the artery and intraluminal insertion of an appropriately sized prosthesis (Fig. 69-3). Visceral artery aneurysms can often be treated by simple ligation, although those involving the hepatic or superior mesenteric artery frequently require bypass grafting, usually with autogenous vein. Advances in endovascular techniques and materials make it possible that certain aneurysms (e.g., in patients who are poor operative candidates) may be managed by relatively minimally invasive transcatheter procedures.

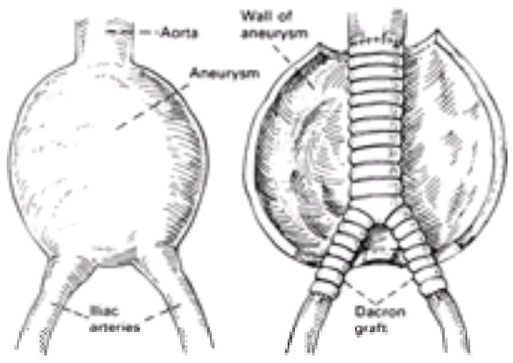

Figure 69-3. **A:** Large aneurysm of the abdominal aorta, extending cephalad from just above the bifurcation of the aorta. The aorta above the aneurysm and the two iliac vessels are clamped, the dilated sack is opened, and a graft is sutured in place from within. **B:** Dacron prosthetic graft in place, resulting in reestablishment of blood flow. (Modified from Johansen K. Aneurysms. *Sci Am* 1982;247:110–111.)

When an aortic or visceral arterial aneurysm ruptures, repair must be performed under emergent circumstances in a patient who frequently is in hypovolemic shock and who requires simultaneous volume resuscitation. Initial control of the proximal aorta, usually at the aortic hiatus of the diaphragm, is crucial; the retroperitoneal hematoma accompanying aneurysm rupture can make dissection around the aneurysm neck difficult. Control of the distal thoracic aorta by left thoracotomy or by direct opening of the aneurysm and passage of a proximal balloon-tipped catheter might be necessary. In addition to their severe hypovolemia, these elderly patients are at markedly increased risk for myocardial infarction, stroke, acute renal failure, and colon ischemia (22).

Outcome. Surgery for intraabdominal aneurysms is highly successful when performed on an elective basis. Despite the advanced age of patients with intraabdominal aneurysms, and the not infrequent concurrence of atherosclerotic involvement of the coronary and cerebrovascular vessels, the operative mortality in several large series is as low as 1% to 3%. Several studies have confirmed that an operative mortality of 5% can be achieved for elective aneurysmorrhaphy, even in octogenarians (23). Equivalent results have been found for the management of other intraabdominal aneurysms approached electively.

The outcome is different for patients who suffer aneurysmal rupture prior to appropriate management. Those who can undergo urgent repair operation before development of hypotension and shock might have an outcome little different from that of patients undergoing elective operations. In those in whom hypotension develops, operative mortality is at least 50%, up to 70% in some series; including those patients who succumb from aneurysmal rupture prior to reaching the hospital, overall mortality may exceed 90% (24). The outcome can be equally dismal for rupture of other intraabdominal aneurysms, frequently because they might be hidden deep in the pelvis, as in the case of iliac aneurysms, or might mimic other intraabdominal problems and therefore delay diagnosis, as in the case of various visceral artery aneurysms. Because the mortality of rupture associated with splenic artery aneurysms in young women exceeds 65%, the presence of such lesions in these patients warrants an aggressive resectional approach (12).

Landmark studies by both DeBakey and colleagues (25) and Szilagyi and associates (26) have demonstrated that successful aneurysm operation restores the patient to a life expectancy not different from that of an age-matched control population. This, and the well-documented low operative mortality for elective surgery, clearly supports adoption of an aggressive posture toward resection of almost all intraabdominal aneurysms. On follow-up these patients must be examined serially for the development of aneurysms elsewhere, as well as for anastomotic or infectious complications of their prosthetic grafts, which occur in 1% to 2% of all patients (14).

Abdominal Pain Associated with Aortic Dissection

Aortic dissection almost always occurs in the ascending or descending thoracic aorta and presents initially with severe tearing upper or mid-back or chest pain; the entity is fully discussed in Chapter 61. On rare occasions, aortic dissection may develop in the abdominal aorta (particularly after blunt trauma) and result in abdominal, flank, or low back pain: More commonly, such symptoms develop as complications resulting from distal extension of a thoracic aortic dissection. Two mechanisms leading to abdominal pain are relevant in this regard. First, the false lumen associated with thoracic aortic dissection may involve and thus occlude somatic branches of the abdominal aorta, leading to ischemia or even infarction of, for example, the gut, spleen, kidney, or spinal cord. Even for type B dissections starting in the descending thoracic aorta, which are otherwise conventionally treated medically (b-blocker drug administration), evidence for visceral or other abdominal aortic tributary involvement is an indication for operative repair of the thoracic aortic dissection, usually by thoracotomy and graft replacement of the damaged aorta. Innovative transcatheter approaches with stenting of branch arteries or fenestration of the dissection flap may be useful alternatives to thoracotomy.

Second, approximately one-third of aortic dissections extending into the abdominal aorta or iliac artery become aneurysmal. The natural history of these lesions is ominous and operative repair is indicated when symptoms occur or (as for standard aortic aneurysms) when the diameter grows to exceed 5.0 cm. Symptoms are similar to those for standard abdominal aortic aneurysms: Operative repair is complicated by the thin friable wall of the dissected, aneurysmal aorta. Operative management involves graft replacement of the aneurysmal dissection, sometimes requiring complex thoracoabdominal aortic reconstruction.

Intestinal Ischemia

Intestinal ischemia can either be acute or chronic, arising from embolic phenomena to the visceral arteries (usually the superior mesenteric artery) or secondary to thrombotic occlusion of atherosclerotic stenosis of one or more of these vessels. A further poorly understood syndrome of bowel ischemia is characterized by peripheral mesenteric vasoconstriction in the absence of proximal arterial disease, the *nonocclusive mesenteric ischemia syndrome* (27). Uncommon causes of pain secondary to visceral ischemia may result from rare vascular disorders involving the splanchnic vessels. These include the *celiac band syndrome*, various forms of vasculitis, fibromuscular dysplasia, and the effects of irradiation. In this subsection we first briefly mention the anatomy and regulation of mesenteric blood flow, then consider the causes, pathophysiology, and symptoms and signs of acute ischemia and chronic ischemia, and finally discuss the diagnosis and therapy for both types of intestinal ischemias. This is followed by a brief discussion of vasculitis.

Basic Considerations

A sound clinical approach to intestinal ischemia is necessarily based on an understanding of the anatomy and physiology of the splanchnic circulation. The gastrointestinal tract is supplied by the celiac axis and its branches and the superior and inferior mesenteric arteries. The blood supply to the intraabdominal portion of the gastrointestinal tract is richly endowed with several anastomotic interconnections that help to protect it against the consequences of occlusive vascular disease (28). In the presence of chronic progressive arterial occlusive disease these anastomotic interconnections, including the pancreaticoduodenal arcades, the arch of Riolan, and the marginal artery of Drummond, usually are robust enough to maintain intestinal viability. On the other hand, in certain sites the collateral supply might be only marginally adequate.

The blood flow to the abdominal viscera, like that in other parts of the body, is regulated by various intrinsic mechanisms, including local response to alterations in

pressure or to an increase in tissue metabolites. In addition, the function of the extrinsic autonomic nervous system is relevant. Intrinsic or local modulation of blood flow occurs in response to changes in arteriolar transmural pressure or to alteration in tissue oxygenation, appearing to involve changes in both arteriolar resistance and precapillary sphincter activity. The extrinsic neurogenic regulation of mesenteric and intestinal flow is mediated by the sympathetic postganglionic fibers supplied by the splanchnic nerves: Increased activity causes vasoconstriction while decrease or inhibition of the sympathetics results in vasodilation. In addition to the intrinsic and neurogenic regulation of mesenteric blood flow, gastrointestinal hormones, as well as various endogenous or exogenous circulating vasoactive substances, can exert an important circulatory effect. Vasodilators include cholinergic stimuli, cholecystokinin, gastrin, prostaglandin E, and other gastrointestinal hormones (see Chapter 66), as well as circulating b-adrenergic stimulants. Operative vasoconstrictors include a-adrenergic stimulants, vasopressin, angiotensin II, and digitalis glycosides (29,30,31 and 32).

Acute Intestinal Ischemic Syndromes

Most patients with acute intestinal ischemic syndromes present with a sudden episode of severe abdominal pain and prostration. The most important syndromes are acute mesenteric arterial occlusion, mesenteric arterial embolization, the nonocclusive mesenteric ischemia syndrome, and mesenteric venous thrombosis. The causes, pathophysiology, and symptoms and signs of these acute ischemic syndromes are discussed, after which the diagnosis and treatment of both types are considered.

Etiology. Arterial embolization occurs most commonly in the superior mesenteric artery because of the caliber of the vessel and the obliquity of its takeoff from the abdominal aorta. Emboli to the celiac axis and the inferior mesenteric artery are less common. Most mesenteric emboli occur in patients who have atrial fibrillation, valvular or atherosclerotic heart disease, or mural thrombi in the heart following myocardial infarction.

Acute mesenteric arterial occlusion and the consequent ischemic necrosis of the gut are most commonly caused by thrombosis of advanced arteriosclerotic disease affecting at least two of the major visceral branches of the aorta, with the lesion usually affecting the most proximal segment of both the celiac and superior mesenteric arteries near their origins from the aorta.

Nonocclusive mesenteric ischemia syndrome is characterized by severe mesenteric malperfusion without apparent organic occlusion in the major splanchnic arterial branches (27). It is most commonly seen in elderly patients with congestive heart failure who frequently are being treated with digitalis. Other precipitating factors are shock, hypoxia, hemoconcentration, or a recent myocardial infarction. Occasionally, however, a precipitating event is not identifiable (33,34). Approximately 50% of patients have angiographic findings considered to be specific for the syndrome; these include a narrowed and irregular superior mesenteric artery, spasm of the mesenteric branch arcades, and impaired filling of intramural vessels (34,35).

Acute mesenteric venous thrombosis occurs much less frequently than arterial occlusion, accounting for much less than 10% of patients with intestinal ischemia (36). The thrombotic process involves the superior mesenteric vein in 95% of patients with this condition. It is caused by (or is associated with) various disorders predisposing to stasis in the mesenteric venous bed, including congestive heart failure, portal hypertension, abdominal neoplasm, intraabdominal inflammation, abdominal surgery or trauma, and hypercoagulable states such as polycythemia vera or deficiencies in protein C, S, or antithrombin III (36).

Pathophysiology. The extent, severity, and possible reversibility of intestinal ischemic processes depend on the rapidity with which the occlusion occurs and, to a lesser extent, on the anatomic characteristics of particular vessels. If occlusion of a large vessel occurs gradually, adequate collateral circulation may develop, so ischemia might be minimized or prevented if the large vessel becomes completely blocked. Thus, chronic arterial occlusive diseases ordinarily do not cause symptoms or signs of ischemia unless two or more major vessels are affected because of the large number of collateral channels that interconnect the major arterial trunks. In contrast, occlusion of a vessel that occurs abruptly or over a period of time too brief to allow the development of adequate collateral circulation is likely to result in ischemic necrosis. A classic example of this is embolization to the superior mesenteric artery in an individual with atrial fibrillation but normal mesenteric arteries (28).

With acute visceral ischemia, ultrastructural changes are evident in the absorptive cells within 5 minutes after occlusion of the mesenteric artery, after which the epithelium becomes detached from the basement membrane, especially at the villus tips, and subepithelial blebs form (28,37). Within 30 to 60 minutes the upper portion of the villi is denuded of epithelium and the mucosa undergoes necrosis and alteration with the appearance of a variable inflammatory infiltrate, probably in response to both tissue necrosis and secondary bacterial invasion (28). Among the phenomena that characterize acute ischemic intestinal necrosis is an increase in capillary permeability followed by loss of capillary integrity, as reflected by submucosal gut edema and hemorrhage (38). Later, the exudation of protein-rich fluid and frank blood into the lumen of the bowel reflects extensive loss of vascular epithelial integrity. Eventually even the relatively resistant muscular layers become necrotic and bowel perforation occurs, usually with consequent development of peritonitis. In those ischemic episodes that do not perforate or require immediate resection, the resolution of the acute inflammatory reaction is followed by development of granulation tissue, fibrosis, and finally the scar and stricture formation that frequently characterizes this process.

Symptoms and Signs. Acute mesenteric occlusion with consequent infarction of the small intestine produces severe, poorly localized abdominal pain that initially can be colicky in nature and periumbilical in location. Early in the clinical presentation the patient's pain often appears to be out of proportion to physical findings or laboratory studies. Generally, this is accompanied by gastrointestinal hyperperistalsis characterized by vomiting and by the passage of loose nonbloody stools.

Development of peritonitis and specific localized pain and tenderness occurs only after transmural gut infarction and perforation has occurred. On the other hand, patients who suffer acute mesenteric artery thrombosis on the basis of prior atherosclerotic stenosis present with steady, aching midabdominal pain with early superimposed spasm or colic, the bowel's initial response to ischemia. Again, peritonitis is a late sign, following infarction, perforation, and peritoneal soiling, at which time the patient commonly manifests symptoms and signs of sepsis including tachycardia, hypotension, fever, acidosis, and marked leukocytosis, often in excess of 30,000 per µL. Other physical signs include severe generalized tenderness to direct palpation, rebound tenderness, and abdominal muscle spasm with rigidity and other signs of peritonitis (see Diseases of the Peritoneum, Mesentery, and Diaphragm, later in this chapter). At this point, severe and unrelenting abdominal pain persists, even if massive doses of narcotic analgesic agents are administered.

Chronic Intestinal Ischemic Syndromes

In contrast to the frequently occurring acute intestinal ischemic syndromes, chronic or, more precisely, recurrent acute ischemia is uncommon and is represented by intestinal angina and celiac compression syndrome.

Etiology and Pathophysiology. Intestinal angina is the symptom complex associated with gradual and progressive mesenteric arterial occlusive disease, usually atherosclerotic, that affects at least two of the three major splanchnic vessels. While nutrients are undergoing digestion and absorption in the small intestine, sufficient vascular perfusion is required to permit increased intestinal blood flow and oxygen consumption; a partially or completely occluded mesenteric arterial system cannot provide ample blood flow and a relative ischemia results. Consequently, the patient experiences postprandial periods of pain that can be considered analogous to those of angina pectoris in the heart.

The *celiac band compression syndrome* is characterized by recurrent abdominal pain associated with a narrowing of the celiac axis alone (39). This disorder is an apparent exception to the general rule that at least two major visceral arteries must be narrowed before symptoms occur. Among patients who have been surgically explored, the celiac artery has been found to be compressed by the median arcuate ligament of the diaphragm or by neurofibrous tissue surrounding the celiac plexus (28).

Symptoms and Signs. Intestinal angina is characterized by stereotypic bouts of intermittent dull or cramping midabdominal pain that characteristically occurs from 15 to 30 minutes after a meal. The relationship to meals, presumably the time when bowel blood supply cannot meet metabolic demands, leads to the descriptive term *intestinal angina*. Rarely, it is colicky in nature. Duration of the pain is usually less than 1 hour in the early part of the natural history of this syndrome, but as the underlying superior mesenteric artery stenosis increases, the pain becomes more severe and longer in duration until it becomes continuous. Other symptoms include weight loss (which may be substantial) and occasionally diarrhea and signs of malabsorption.

Celiac band compression syndrome, found most frequently among women younger than those expected to have significant atherosclerotic disease, is characterized by epigastric pain of variable frequency and duration. The pain might or might not be related to meals and is infrequently associated with nausea and vomiting (28). The only physical finding noted with regularity is an epigastric bruit that does not radiate to the lower abdomen.

In chronic visceral ischemic syndromes, the patient is often initially unaware of the relationship of pain to eating, as well as the fact that weight loss and diminished oral intake have been subconsciously accepted to avoid recurrent abdominal pain.

Management of Intestinal Ischemic Syndromes

Diagnosis. The major predictive factors for developing acute mesenteric ischemia relate to a prior history of rheumatic heart disease or myocardial infarction, intracardiac thrombus, which ultimately leads to mesenteric embolus, or a picture of widespread premature atherosclerosis, as with acute mesenteric artery thrombosis. The clinical picture of patients with nonorganic mesenteric ischemia has been noted previously. Patients with mesenteric embolization sometimes relate a history of prior embolization and might have been on anticoagulant therapy in the past. Prior cardiac disease is noted in 90% to 95% of patients with emboli, most commonly in regard to a past history of myocardial infarction with akinetic or dyskinetic left ventricular segments (40).

The crucial diagnostic procedures in all circumstances, building on a heightened sense of clinical suspicion, are the performance of contrast aortography and selective mesenteric arteriography; these can provide the bases for both diagnosis and possible treatment. Duplex sonography has been a highly accurate screening maneuver, especially to examine the origins of the mesenteric vessels in a noninvasive fashion (41). Other studies, including plain roentgenography, radioisotope or malabsorption studies, and other imaging techniques have yet to prove their value in the diagnosis of the mesenteric ischemic syndromes. It is widely believed that polymorphonuclear leukocytosis, metabolic acidosis, hyperkalemia, and hyperamylasemia can frequently be demonstrated in those with mesenteric ischemic syndromes; they are actually the consequences of bowel infarction and are thus the late manifestations of a clinical situation that, by the time they appear, often represent a clinically unsalvageable situation.

Flush aortography with selective arteriographic injections into the orifices of the celiac axis and the origins of the superior and inferior mesenteric arteries is frequently diagnostic for the various conditions that lead to acute and chronic mesenteric ischemia. Superior mesenteric artery embolization often shows a characteristic *meniscus sign* on arteriography (i.e., dye outlines the crescentic *tail* of the embolus), usually 3 to 10 cm from the origin of the superior mesenteric artery. Because acute superior mesenteric artery thrombosis generally occurs at the site of an ostial atherosclerotic stenosis, in such cases only a stub of artery can be seen. This is best (and sometimes only) seen on lateral aortography.

Aortography can also demonstrate spasm of the large splanchnic arteries, a sign seen most notably with nonocclusive organic mesenteric ischemia. Contrast studies are also useful for demonstrating the celiac band syndrome, in which the crura of the diaphragm are felt to impinge on the celiac axis or superior mesenteric artery (39). Pressure studies to define gradients across the stenosis, before and after the administration of rapid-acting vasodilating agents such as papaverine, can be of further diagnostic use.

Certain features of acute mesenteric ischemia can be confused with those of perforated peptic ulcer, appendicitis, ruptured aneurysm, or occasionally, myocardial infarction. When the condition is chronic it can mimic such conditions as pancreatic or gastric cancer or chronic relapsing pancreatitis; occasionally, the profound weight loss from dietary changes that occurs with chronic mesenteric ischemia can be confused with that of depression or neurosis, and unavailing treatment with pain medications, antidepressants, and tranquilizers may be continued for a substantial period of time.

Treatment. Management of acute and chronic mesenteric ischemic conditions can sometimes be initiated at the time of diagnostic arteriography. The advent of techniques for the administration of low-dose fibrinolytic agents (e.g., streptokinase, urokinase, and specific tissue plasminogen activators) suggests that, in selected cases of intestinal ischemia not accompanied by impending tissue infarction, the embolic or thrombotic occlusion might be relieved nonsurgically. In the case of mesenteric arterial thrombosis, as has been demonstrated in the peripheral arteries, lysis of an acute thrombosis can often reveal a high-grade atherosclerotic stenosis that may then be treatable by percutaneous transluminal angioplasty or stenting (42). The angiographic catheter is probably most effective in treating the syndrome of nonorganic mesenteric ischemia; once relatively normal proximal mesenteric arteries with peripheral splanchnic vasoconstriction have been demonstrated, the administration of intraarterial vasodilators such as papaverine has been shown (27,35) to be a useful therapeutic maneuver in this otherwise lethal condition.

Unfortunately, in many cases of both acute and chronic mesenteric ischemia, the onset of severe abdominal symptoms heralds gut infarction, perforation, and peritonitis; therefore, the diagnosis of significant mesenteric ischemia generally requires laparotomy. Superior mesenteric artery embolus frequently can be treated by a relatively straightforward embolectomy. Generally, the patient should already have been heparinized by the time of operation, and anticoagulation should be continued with heparin and then with warfarin indefinitely. Resection of clearly nonviable bowel is necessary; the presence of marginally viable intestine left *in situ* mandates a formal second-look exploration in 12 to 24 hours (43). Techniques for assessing tissue viability, such as intraoperative Doppler, fluorescein clearance, and tissue oximetry, have been used, but a consensus has not been reached concerning their accuracy. Some have advocated the use of postresection vasodilators administered through a percutaneous catheter in an attempt to salvage such marginal tissue (44).

In the case of atherosclerotic superior mesenteric artery stenosis or thrombosis, or both, general management usually involves bypass grafting from the aorta to the superior mesenteric artery just distal to the site of occlusion (45). Thromboendarterectomy has been used, but can require a more extensive dissection to expose the most proximal part of the superior mesenteric artery (46). As with mesenteric artery embolus, bowel resection might be required, and a second-look operation is prudent.

The celiac band syndrome, when identified by careful lateral aortography and pressure gradient measurements, is approached successfully by a combined complete exposure of the celiac axis, including lysis of the diaphragmatic crura at this level, or bypass grafting using a saphenous vein or prosthetic graft as previously described. Some have argued that the extensive dissection in this area effectively performs a splanchnic neurectomy, thereby resulting in the pain relief noted in most patients so treated.

Outcome. Untreated, acute mesenteric infarction leads to death in almost all circumstances. For acute mesenteric ischemia the mortality is still excessive, primarily because the diagnosis is often delayed and the aggressive therapy required for intestinal salvage frequently cannot be effectively carried out in these desperately ill patients. Nevertheless, some patients can be treated successfully, and their follow-up requires consideration of the basic underlying pathophysiology. Patients who have suffered a mesenteric artery embolus must be indefinitely anticoagulated against the possibility of future emboli; myocardial revascularization and resection of left ventricular aneurysm might be useful to diminish the incidence of recurrent cardiogenic emboli.

In patients who have suffered mesenteric artery thrombosis superimposed on an atherosclerotic stenosis, the systemic nature of this disease, and these patients' markedly elevated risk for coronary and cerebrovascular ischemic events, must be emphasized. Patients who undergo transcatheter stenting or elective surgical reconstruction for atherosclerotic mesenteric vessel stenosis, or who have operative repair of the celiac band syndrome often enjoy a gratifying relief of their chronic pain and weight loss following resumption of normal food intake and body weight.

Mesenteric Vasculitis

A number of systemic collagen diseases associated with vasculitis can cause abdominal pain. These disorders have several common denominators that are of interest to physicians and surgeons. They can involve multiple intraabdominal organs, often producing pain; they can begin suddenly, occasionally evoking a crisis with severe abdominal pain that can mimic that of a surgical lesion; and they may be accompanied by a serositis that can affect the peritoneum (47). These conditions include polyarteritis nodosa, lupus erythematosus, Henoch-Schönlein purpura, dermatomyositis, polyarteritis, and rheumatoid vasculitis.

Symptoms and Signs

Polyarteritis Nodosa. Abdominal pain and other gastrointestinal symptoms have been reported in up to 65% of patients with polyarteritis nodosa (48). This condition occurs most commonly in young men and is characterized by a necrotizing vasculitis of the muscular arteries that can affect not only the gastrointestinal tract but most other organs as well. This condition is particularly confusing because some patients experience such severe abdominal pain, but no lesion can be found at surgery to explain the pain. Clinically apparent ischemic disease of the bowel is more frequent and can range from massive infarction to segmental ischemia with ulceration, hemorrhage, or perforation (28). Although clinically significant liver disease is uncommon in this condition, hepatic artery thrombosis caused by polyarteritis is the leading cause of otherwise unexplained cases of infarction of the liver.

Systemic Lupus Erythematosus. Systemic lupus erythematosus (SLE) involves the gastrointestinal tract in as many as 60% of patients (28). Nonspecific

gastrointestinal symptoms such as anorexia, nausea, mild pain, and diarrhea occur in approximately 30% of patients. Vasculitis of the intestine is the most dangerous manifestation of SLE because it causes acute or subacute cramping pain, vomiting, and diarrhea and results in intestinal perforation and death in almost 50% of affected patients (49). Another gastrointestinal manifestation of SLE is a pseudoobstruction picture in which patients present with acute cramping abdominal pain, and radiographs show dilated loops of small bowel, which might be edematous. Surgery should be avoided unless true obstruction is present. Acute pancreatitis occurs with SLE and can be severe; it can result from glucocorticoid therapy or from active SLE itself (28). Abdominal pain can also be caused by serositis.

Henoch-Schönlein Disease. Henoch-Schönlein disease, also referred to as *anaphylactoid purpura*, is a disorder of unknown cause associated with small vessel vasculitis. Typically it is associated with a clinical triad of palpable purpura, arthritis, and abdominal pain (28). Although the disease is usually seen in children and young adults, individuals of any age can be affected. Gastrointestinal involvement, which is seen in approximately 70% of pediatric patients, is characterized by colicky abdominal pain generally associated with nausea, vomiting, diarrhea, or constipation; these are frequently accompanied by passage of blood and mucus rectally. The symptoms and signs reflect localized or segmental ischemia and ulceration. Intussusception, gross infarction, and perforation rarely occur. Most patients recover completely and some do not require therapy.

Dermatomyositis. Dermatomyositis is important because of an increased incidence of associated gastrointestinal malignancy with this disorder (28). The malignancy can antedate or postdate the onset of myositis by up to 2 years; this is usually classified as group III dermatomyositis. Group IV dermatomyositis is associated with vasculitis in the skin, muscles, gastrointestinal tract, and other organs and can cause ischemic infarction of the gastrointestinal tract.

Diagnosis. The diagnosis of mesenteric vasculitis is greatly aided by systemic features of each of these conditions and less so by abdominal findings, which are nonspecific. One finding that differentiates vasculitis from chronic atherosclerotic mesenteric insufficiency is that these patients can have steatorrhea in the absence of pain (28). Radiographs demonstrate a mucosal ulceration or edema (*thumbprinting*) that can be indistinguishable from Crohn's disease either in appearance or location. Abdominal angiography is useful, especially in demonstrating aneurysms at the bifurcation of the medium-sized arteries, thereby suggesting the diagnosis of polyarteritis nodosa.

Treatment. The prognosis of untreated polyarteritis nodosa is extremely poor, with death often resulting from gastrointestinal or renal complication or other causes. Aggressive therapy using corticosteroids significantly increases the 5-year survival rate (49). A combination of prednisone, 1 mg per kg per day, and cyclophosphamide, 2 mg per day, during the first month of therapy, given thereafter every other day and eventually tapered after approximately 6 months, has been reported to result in a long-term remission rates of up to 90%, even following the discontinuation of therapy (48). Similar results have been obtained with this treatment in patients with Wegener's granulomatosis and other types of vasculitis that involve the upper and lower respiratory tracts.

No cure for SLE is known; complete remissions occur but are rare, so the patient and physician should plan to control acute severe flares and to develop maintenance therapies in which symptoms are suppressed to an acceptable level (49). The patient who is disabled because of pain and fatigue should be managed with nonsteroidal antiinflammatory drugs, including salicylates. Life- threatening and severe disabling manifestations of SLE should be treated with high doses of glucocorticoids (1 to 2 mg per kg per day).

Most patients with Henoch-Schönlein purpura recover completely, and some do not even require therapy. When corticosteroid therapy is required, it is usually administered as 1 mg per kg per day of prednisone and tapered according to the clinical response.

If corticosteroids are not sufficiently effective in providing good pain relief for all these conditions, they should be supplemented with appropriate doses of nonsteroidal antiinflammatory drugs alone or in combination with codeine or other mild narcotics to tide the patient over.

Many vasculitis patients pose a dilemma to surgeons who must make the decision of whether to carry out a surgical exploration for possible infarction or perforation. If clinical signs of an acute abdomen are present, laparotomy should be carried out: Laparoscopic exploration is less invasive but may be less complete. The clinical assessment is made more difficult because many patients with systemic vasculitis are already receiving corticosteroids, and these agents can mask important signs of a serious intraabdominal process.

DISEASES OF THE PERITONEUM, MESENTERY, AND DIAPHRAGM

Anatomically, the surface of the peritoneal membrane is 1.7 m^2 and is similar to the total body surface area, although the functional work surface of this membrane is substantially less (60%) because of changes in vascularity, membrane potential, and diffusion gradient. Both parietal and visceral peritoneum normally secrete small quantities of serous fluid. When exposed to insult, however, their porosity increases, with a rapid outpouring of fluid from both vascular and interstitial spaces (third space) that allows the sequestration of large amounts of fluid. This impaired diffusion also allows the reverse to occur (i.e., the rapid absorption of bacteria and microscopic debris that can lead to bacteremia). This exposes the perfused organs to two specific effects: (a) microscopic bacterial seeding of the offending organism, and (b) the functional organ response to the shower of bacteria and endotoxins. As the process progresses, the damaged membrane leaches fluid from the vascular compartment and provides a pathway for bacteria to reach the vascular tree.

Several intraperitoneal factors mitigate against the sequence of events being constant. Gravity helps to localize all peritoneal collections in dependent locations, consisting of the pelvis and flanks. Moreover, the greater omentum acts as an initial sealer of perforations, and the lymphatic system is important in removing bacteria and other particulate matter. Following peritoneal insult, fibrin deposition also tends to seal visceral leaks and wall off the contaminated region. This inflammatory response, which includes the exudation of lymphocytes, neutrophils, macrophages, and opsins, occurs rapidly so that intraperitoneal bacterial phagocytosis and destruction occur immediately following the initial insult. After this protective action, the fibrin can be removed from the peritoneal cavity through fibrinolysis by regeneration of mesothelial cells that demonstrate increased fibrinolytic activity, but this process is depressed in injured cells. This temporary suppression of fibrinolysis can provide time for fibroblasts to convert fibrins to fibrous adhesions. Normally, however, peritoneal injuries or defects heal without formation of fibrous adhesions unless other factors such as infection, ischemia, or foreign bodies are associated or superimposed.

Diseases of the Peritoneum

Table 69-1 lists the diseases of the peritoneum. The cardinal symptoms of peritoneal disease are abdominal pain and ascites, with fever, distension, nausea, vomiting, and altered bowel habits varying in their occurrence. Direct tenderness, percussion tenderness, and involuntary spasm of the abdominal musculature are the major signs of irritation of the parietal peritoneum. These signs and symptoms can be minimal or absent in the elderly or debilitated patients and vary depending on the location, cause, and acuteness of the underlying process. In addition to a complete history and physical examination, diagnosis of diseases of the peritoneum is helped by plain radiography, barium contrast studies, peritoneography, ultrasonography, CT scanning, and gallium 67 scanning. In addition, all patients with prior ascites and any suspicion of peritoneal disease should undergo paracentesis to permit analysis of the ascitic fluid. Percutaneous peritoneal biopsy can also yield a tissue diagnosis of the cause of the peritoneal disease, but its use is limited to patients with ascites. Peritoneoscopy (laparoscopy) is an excellent diagnostic tool for visualization and direct biopsy of observed lesions of the peritoneum.

Acute Bacterial or Chemical Peritonitis

Bacterial peritonitis most commonly results from perforation of an abdominal viscus, such as perforated ulcer or diverticulum, ruptured appendix, and during abdominal trauma (50,51). Chemical peritonitis is caused by perforation of an ulcer with liberation of sterile acid, enzymatically active pancreatic juice, or other chemicals.

Symptoms and Signs. Regardless of cause, abdominal pain, nausea, vomiting, tachycardia, and fever are the cardinal signs of bacterial peritonitis. The severity of these symptoms and signs is related to the extent of the peritoneal contamination. If the infection is localized, symptoms and signs can be mild, whereas with generalized peritonitis, symptoms and signs are severe; as a significant third-space deficit develops, the blood pressure eventually falls and the pulse becomes weak, rapid, and thready. The fluid volume contained in the abdomen in a case of severe, generalized peritonitis approximates the fluid losses seen with 50% body surface red burns (52). Because motion is painful, patients usually lie still, preferably on their side with their hips slightly flexed, to relax their abdominal muscles.

Early in the course of the disease the abdomen is scaphoid and contracted, particularly across the epigastrium, an appearance produced by spasm of the rectus abdominis muscle in response to motion of the diaphragm. Abdominal distension develops later. Diffuse tenderness is present, with percussion tenderness referred to the point of pressure, and abdominal muscle spasm is felt, the degree of which depends on the site of the peritonitis. In patients in whom the anterior parietal peritoneum is inflamed, the abdominal musculature is often completely unyielding, whereas rigidity is not a prominent sign if the posterior peritoneum is primarily

involved, as seen with retroperitoneal or pelvic abscess. Ileus usually develops rapidly.

Diagnosis. Laboratory findings are not specific. Leukocytosis is present and can be marked. Hemoconcentration results from loss of fluid into the peritoneal cavity, electrolyte concentrations vary, and metabolic acidosis and respiratory alkalosis are often seen. Plain abdominal films show distension of the small and large intestines and demonstrate air–fluid levels. On upright films air may be seen beneath the diaphragm if a viscus is perforated. If the patient cannot stand for upright films, free air can be seen over the liver on a left lateral decubitus film.

Complications of peritonitis can be local, consisting of wound infection, intraperitoneal abscess, and fistula formation, or systemic, consisting of septicemia, shock, and organ dysfunction.

Treatment. Patients with mild cases of diverticulitis in whom the process is well localized should be managed nonoperatively (50,51,53). Treatment should include nasogastric suction, antibiotics, pain control with analgesics or other appropriate methods, administration of fluids, and monitoring of blood volume, acid–base, and electrolyte status, as well as of cardiopulmonary and renal function. Percutaneous drainage of a localized abscess should be given serious consideration.

In patients with generalized, severe peritonitis in whom surgery is indicated, ample preoperative preparation is necessary to restore fluid balance and to stabilize circulatory and pulmonary function. In addition to nasogastric suction, which reduces distension and thus helps pulmonary function, adequate volumes of electrolyte solutions are administered to correct the hypovolemia. Complete blood and other laboratory studies should be carried out.

Because these patients have severe abdominal pain they may be managed with epidural opioid analgesia during the preparation for surgery. As soon as the blood volume has been restored, opioids can be supplemented with low concentrations of local anesthetic to provide more effective relief and also to eliminate the intense vasoconstriction of the splanchnic region that is frequently found in such patients. Moreover, epidural analgesia may decrease the ileus and degree of muscle spasm that invariably decrease chest wall compliance and thus produce hypoxemia. In most patients, the ideal anesthesia is a combined segmental epidural block with tracheal intubation carried out under topical anesthesia, followed by light inhalation or intravenous analgesics and sedatives.

Antibiotic therapy is essential and should be initiated early with an antimicrobial drug or combination possessing activity against a polymicrobial flora consisting of aerobic, facultative, and anaerobic species (50,51). Twenty percent to 30% of patients have bacteremia, usually caused by *Escherichia coli*, *Bacteroides fragilis*, or both.

Other Types of Infectious Peritonitis

Although peritonitis is an unusual form of tuberculosis, it constitutes an important disease of the peritoneum. Its insidious nature and the clinical circumstances in which it occurs often cause it to be mistaken for neoplastic disease or ascites caused by cirrhosis (53,54).

The most common complaints are fever, anorexia, weakness, malaise, and weight loss. Abdominal pain is reported in only 50% of patients, and this is usually described as a vague, dull, diffuse discomfort. Abdominal tenderness is usually diffuse and present in 65% of patients.

With the advent of antituberculosis agents, the mortality of tuberculous peritonitis has been reduced from 60% to almost 0. Symptoms should begin to improve within 1 to 2 weeks of the onset of therapy, and fever should resolve within 4 weeks. The pain is managed with nonopioid systemic analgesics.

Peritoneal inflammation caused by fungi and parasites is uncommon, and pain is not a major symptom; therefore, it is not considered further here.

Familial Paroxysmal Polyserositis (XXII-1)

Etiology and Pathophysiology. Familial paroxysmal polyserositis (FPP), also called familial Mediterranean fever, is a disease characterized by recurring episodes of acute self-limited serositis, especially peritonitis. It is an inherited disease transmitted as an autosomal recessive trait that occurs predominantly in Mediterranean peoples, with Sephardic Jews accounting for 50% of cases, Armenians 22%, Arabs 11%, Turks 7%, and other ethnic groups the remaining 10% (55). The onset of the disease is usually within the first two decades of life, but 20% of patients have their first episode after the age of 20 and 4% after the age of 30. About 60% of patients are boys or men.

Symptoms and Signs. Disease usually appears suddenly with attacks of serositis that include peritonitis in 55% of patients, arthritis in about 25%, and pleuritis in 5%. During the course of FPP 95% of patients eventually develop peritonitis; this is the sole manifestation in 30% (55). The attack consists of a sudden onset of fever, usually 101° to 103°F (38.3° to 39.4°C), with localized or diffuse abdominal pain, exquisite direct abdominal tenderness with marked rebound tenderness, and leukocytosis in almost 90% of patients. The plain film of the abdomen shows air–fluid levels. After 6 to 12 hours these signs and symptoms recede and the patient is usually well within 24 to 48 hours. The attacks occur at irregular and unpredictable intervals and the patient is entirely well between them. Except for the rapid resolution and recurrent nature of the disease, FPP presents all the characteristics of an acute surgical abdomen.

Treatment and Prognosis. The therapy that has proven to be highly effective consists of the administration of colchicine in doses of 0.6 mg twice or three times a day (55,56). Studies have shown that this decreases both the severity and frequency of attacks, and long-term studies report continuous suppression of attacks with little evidence of adverse effects (56).

Prognosis of FPP is excellent, and many patients have been followed for years with persistent good general health despite hundreds of attacks (55). Attacks can increase in frequency with age, perhaps with occasional remissions or periods in which the disease is quite intractable.

Neoplasm of the Peritoneum

Primary Mesothelioma

Primary mesotheliomas are tumors arising from the epithelial and mesenchymal elements of the mesothelium. Approximately 25% of these tumors involve the peritoneum, 65% involve the pleura, and 10% are pericardial (57).

Etiology and Pathology. Asbestos is the only substance that has been shown to have an epidemiologic relationship to mesothelioma, and the apparent increased incidence since the 1950s can be related to expansion of the asbestos industry (57). In addition to historic evidence of asbestos exposure, 50% of patients with mesothelioma have pathologic evidence of pulmonary asbestosis, including pulmonary fibrosis, pleural hyaline plaques, and asbestos bodies in the lungs. Because at least 30% of patients with mesothelioma have no history of asbestos exposure, however, other factors also play a role.

Mesotheliomas, especially peritoneal ones, are more common in male subjects, possibly reflecting occupational factors. The highest incidence is in the sixth decade, but the condition has been reported in young children (57).

Symptoms and Signs. Patients presenting with peritoneal primary tumors usually complain first of abdominal pain and abdominal mass or increased abdominal girth, along with anorexia, nausea, vomiting, constipation, and weight loss (57). Signs of asbestosis are evident in chest radiographs in 50% of patients, and early pleural mesothelioma can be apparent, with chest pain, dyspnea, or cough.

Diagnosis and Treatment. Other than an elevated sedimentation rate, the blood count and blood chemistries are normal. Radiography is not useful. Ultrasonography, CT, and magnetic resonance scanning can demonstrate sheetlike masses and ascites. Paracentesis reveals an exudate that can be hemorrhagic. Peritoneal cytologic studies and biopsy and peritoneoscopy can suggest a diagnosis, but laparoscopy is usually necessary to provide adequate biopsy samples for definitive diagnosis and to rule out a primary neoplasm. The prognosis of mesothelioma is poor, and most patients survive only 1 year after diagnosis (57). Surgical resection and radiation therapy are not curative.

Secondary Carcinomatosis

Peritoneal involvement by spread from a primary neoplasm is one of the most common causes of peritoneal disease. Pathologic studies of selected open peritoneal biopsy specimens in a large general hospital showed that approximately 65% were neoplastic and, of these, 75% were metastatic adenocarcinomas (58). Sarcomas, carcinoids, teratomas, and nervous tissue tumors are rare. Malignancies of lymphoid or myeloid tissue can also infiltrate the peritoneum. The most common lesions involved are malignant lymphoma, Hodgkin's lymphoma, Hodgkin's disease, and myeloid metaplasia (59).

Symptoms and Signs. Patients with peritoneal carcinomatosis present with ascites, diffuse abdominal pain, weight loss, and, less frequently, nausea and vomiting. The pain can be produced by various interactions between the tumor and intraabdominal organs. Barium contrast studies can show nodular indentation of the intestine or angulated fixed or displaced intestinal loops, especially if attention is paid to major areas of intraperitoneal seeding. These areas include the pouch of Douglas at the rectosigmoid, the right lower quadrant at the lower end of the small bowel, the left lower quadrant along the superior border of the sigmoid mesocolon and colon, and the right paracolic gutter lateral to the cecum and ascending colon (58).

Diagnosis. In addition to barium contrast studies, other diagnostic procedures include paracentesis, ultrasonography, and CT scanning. The diagnosis is made most directly by cytology, peritoneal biopsy, laparoscopy, or abdominal exploration.

Treatment. Once the neoplasm has spread to the peritoneum, the prognosis is poor. Paracentesis is useful for removal of a large volume of fluid and is tolerated without hemodynamic problems. Cytotoxic agents, radioisotopes, and sclerosing agents have been used with varying success. Peritoneovenous shunting has become more widely used as a method of palliation for malignant ascites. Surgery is not indicated except in patients with intestinal obstruction that is not responsive to conservative measures.

Diseases of the Mesentery and Omentum

Patients with mesenteric disease usually present with nonspecific symptoms such as abdominal pain, abdominal distension, or intestinal obstruction. The most frequent physical finding is a mass that might be mobile. Associated lymphatic obstruction can cause steatorrhea, chylous ascites, or protein-losing enteropathy, with hypoalbuminemia and edema. Of the various pathologic processes, only mesenteric inflammatory disease and mesenteric and omental tumors produce abdominal pain (59).

Mesenteric inflammatory disease is characterized by recurrent episodes of cramping abdominal pain, either localized or generalized, and weight loss, nausea, vomiting, and low-grade fever. Corticosteroids have been claimed as useful therapy.

Mesenteric tumors are rare and can arise from any of the cellular elements of the mesentery. Metastatic tumors of the mesentery are more common than primary mesenteric tumors and are usually the result of an enlarged lymphomatous or carcinomatous lymph node. In contrast to mesenteric tumors, omental tumors are derived from muscle in 60% of patients and include leiomyomas, leiomyosarcomas, and hemangiopericytomas (58). These are characterized by abdominal pain, abdominal mass, and weight loss.

Torsion of the omentum is an acute condition that mimics appendicitis or cholecystitis and is characterized by abdominal pain in the right lower (80% of patients) or the right upper quadrant (10%). Tenderness, guarding, and ileus are usually present, and nausea, vomiting, abdominal mass, and leukocytosis are present in 50% of patients. Surgical excision of the gangrenous omentum is necessary.

Diseases of the Diaphragm (XVII-8)

Diseases of the diaphragm that can cause pain are diaphragmatic hernias, rupture, and tumors.

Herniation (XIX-2)

Diaphragmatic hernias are caused by congenital abnormalities in the formation of the diaphragm (60). Most commonly the left pleural and peritoneal membrane fails to fuse with the septum transversum, causing a left posterolateral defect without a hernia sac. The fusion may be complete, but a failure of muscularization posterolaterally is present. A hernia with a sac is formed, called the *Bochdalek's hernia*. Approximately 25% of patients with Bochdalek's hernia are asymptomatic, but 50% have vague intermittent abdominal pain and 25% have chest pain, cardiovascular symptoms, and dyspnea (61). Incarceration of the intestine leads to acute sharp retrosternal pain that radiates to the left upper quadrant or back, along with the typical symptoms of intestinal obstruction.

The diagnosis can usually be made on the lateral chest film, which reveals a blunted cardiophrenic angle, a small effusion, and a gas-filled intestinal loop. Surgery is always indicated in patients with incarceration or obstruction because of the danger of strangulation (60).

Rupture

Blunt injury to the abdomen can cause diaphragmatic rupture that is said to occur in about 5% of all patients undergoing surgery for trauma (62). Because the early clinical course can be dominated by signs of other injuries, signs of visceral herniation are often delayed. Patients can present many years later with postprandial fullness, chest pain, nausea, vomiting, cramps, dyspnea, or obvious bowel obstruction and strangulation, with severe epigastric and chest pain (62).

Diaphragmatic rupture should be suspected in any patient who has vague abdominal symptoms and a history of blunt abdominal trauma. Because of the high frequency of later visceral herniation, diaphragmatic laceration should be repaired surgically.

Tumors and Cysts

Diaphragmatic neoplasms usually cause pleuritic chest pain simulating that of intraabdominal disease, with the pain referred primarily to the epigastrium. Chest radiographs reveal irregularity of the diaphragm or a large mass that abuts the diaphragm.

Diaphragmatic cysts can also cause upper abdominal pain, located primarily in the epigastrium. When located on the right side, however, they suggest possible hepatic or subphrenic abnormalities. The cysts are usually bronchogenic, mesothelial, or fibrous. They can be acquired or congenital. If pain is severe and persistent, surgical removal is necessary.

OTHER INTRAABDOMINAL DISEASES

Intraabdominal Abscesses

The three types of intraabdominal abscesses are intraperitoneal, retroperitoneal, and visceral and occur with about equal frequency. Intraperitoneal abscesses (subdiaphragmatic, midabdominal, or pelvic) (50,51) are localized collections of pus that can occur consequent to either generalized peritonitis or a more localized intraabdominal disease process or injury. In the former case the normal barriers that limit the inflammatory process are inadequate and the abscess can occur at some distance from the original source of contamination. In the latter instance the spread of peritonitis is limited by contiguous viscera, omentum, and peritoneum, and the abscess develops closer to the source of contamination. Intraabdominal abscess can be a postoperative complication of the surgical treatment of peritonitis. Retroperitoneal abscesses can be located in the anterior or posterior part of the space. Visceral abscesses can involve the liver, pancreas, spleen, kidney, and gallbladder. Because many of these are discussed elsewhere in this section, the discussion here is limited to subdiaphragmatic, midabdominal, anterior retroperitoneal, and splenic abscesses.

Most intraabdominal abscesses develop from infecting organisms that are a complex mixture of anaerobic, facultative, and aerobic bacteria, which are part of the normal bowel flora. The most important isolates from these abscesses are facultative gram-negative rods, such as *E. coli* and *Klebsiella* spp., and anaerobes, especially *Bacteroides fragilis* (50,51). Antimicrobial therapy requires agents effective against these organisms.

Subdiaphragmatic Abscess (XIX-1)

The subdiaphragmatic space, arbitrarily defined as lying below the diaphragm and above the transverse colon, consists of four subdivisions. On the right side are the suprahepatic and subhepatic spaces, while on the left side the subhepatic and suprahepatic spaces freely communicate and constitute a single combined subphrenic space. The other left-sided space behind the stomach and anterior to the pancreas is the lesser sac. A subhepatic abscess is found on either side of the falciform ligament, between the liver and the transverse colon. Some clues to localization are afforded by a knowledge of the primary disease process. A right-sided abscess is more frequent after appendicitis, whereas perforated duodenal ulcer causes right anterior subhepatic abscess and pancreatic disease is more likely to result in a lesser sac abscess.

Symptoms and Signs. The clinical manifestations of subphrenic abscess usually begin within 1 to 6 weeks following surgery, but occasionally do not appear for several months (50,51). Fever is nearly always present and can be the only evidence of abscess. Nonspecific constitutional symptoms such as anorexia and weight loss are less common. The most frequent findings relate to the thorax and abdomen and include nonproductive cough, chest pain, dyspnea, and shoulder pain caused by the irritation of the diaphragmatic pleura. Rales, rhonchi, or a friction rub can be audible. Dullness to percussion and decreased breath sounds might be present when basilar atelectasis, pneumonia, or pleural effusion occurs. Pain, the most common abdominal complaint, may be poorly localized. Abdominal distension and hypoactive bowel sounds may occur. Physical findings are subtle or absent due to the difficulty of examining the abdominal cavity above the costal margin. A mass, wound drainage, or sinus tract of a previous abdominal incision site is sometimes present. Subhepatic abscess usually presents with symptoms referable to the abdomen and is less likely to cause any pleural or diaphragmatic abnormality. Abdominal pain and tenderness are usually present, and a mass is occasionally found.

Diagnosis. Leukocytosis occurs in most patients with subphrenic abscess, and blood cultures are occasionally positive. Chest radiographs usually demonstrate ipsilateral pleural effusion, an elevated or immobile hemidiaphragm, pneumonitis, and atelectasis. Plain abdominal films can reveal extraintestinal gas in the abscess, displacement of adjacent organs, or a soft tissue density representing the abscess. Ultrasonography is especially useful in right-sided subphrenic abscess. A left-sided subphrenic area is more difficult to examine, however, because of the gas-filled stomach, splenic flexure, and aerated lung and ribs, and also because the spleen varies in size and shape and can produce a few echoes that resemble those of an abscess. CT scanning generally provides the most accurate information about the presence and extent of abscess into these areas.

Treatment. Treatment of these abscesses involves surgical drainage, either by open operation or by percutaneous catheter drainage. The drain remains in place until the abscess cavity is obliterated, usually 2 to 3 weeks or longer. Antibiotics effective against both aerobic, facultative, and anaerobic organisms are a good adjunct but are no substitute for drainage. Adequate nutrition is critical during the often-prolonged hospital course.

Midabdominal Abscess

A midabdominal abscess can form in the peritoneal cavity anywhere between the transverse colon and pelvis. It is frequent in the paracolic gutters but can be located between the loops of the small bowel and mesentery. They are referred to as right lower quadrant, left lower quadrant, or interloop abscesses according to their location.

Etiology, Symptoms, and Signs

Right Lower Quadrant Abscess. Abscess in the right lower quadrant develops most commonly as a complication of acute appendicitis and less frequently from colonic diverticulitis, regional enteritis, or perforated duodenal ulcers, with drainage down the right paracolic gutter. The clinical manifestations include right lower quadrant pain and tenderness and a mass that develops following symptoms suggesting those of acute appendicitis. The mass may be associated with partial or complete small bowel obstruction.

Left Lower Quadrant Abscess. Left lower quadrant abscess usually develops from perforation of a diverticulum in the descending or sigmoid colon and less commonly from a perforated colonic carcinoma. The symptoms are those of acute diverticulitis and include left lower quadrant pain, tenderness, anorexia, and nausea followed by fever, leukocytosis, and development of a palpable mass.

Interloop Abscess. Interloop abscess comprises loculations of pus between the folded surfaces of the small and large intestines and their mesenteries. It is usually a complication of bowel perforation, anastomotic disruption, or Crohn's disease. Clinical manifestations are usually subtle and consist of fever, leukocytosis, and abdominal pain and tenderness. Signs of paralytic ileus that may be difficult to distinguish from obstruction or palpable mass can develop. Plain abdominal films occasionally suggest the diagnosis by the presence of bowel wall edema, separation of bowel loops, localized ileus, and air–fluid levels on upright films.

Treatment. The therapy of midabdominal abscess includes surgical drainage and antibiotics. CT scan often shows the abscess, but if ileus prevents opacification of all bowel loops with contrast, it may be difficult to distinguish an abscess from a fluid-filled bowel loop. Occasionally, in a gravely ill patient with no localizing findings, abdominal exploration might be necessary to find and drain the abscess. At operation the abdomen must be explored thoroughly, because these abscesses are frequently multiple. If the clinical picture does not improve promptly, reexploration might be necessary to find missed or new abscesses.

Anterior Retroperitoneal Abscess

Etiology, Symptoms, and Signs. Abscess in the anterior retroperitoneal space is a complication of acute appendicitis, colonic perforation from diverticulitis or tumor, gastric or duodenal perforation, regional enteritis, or pancreatitis. The major symptoms are abdominal or flank pain, fever, nausea and vomiting, and pain in the hip, thigh, or knee from psoas muscle involvement. Physical examination may reveal a palpable mass in addition to the abdominal or flank tenderness. Extension of the hip may aggravate the pain.

Diagnosis and Treatment. Diagnosis is based on the symptoms and signs, the presence of leukocytosis, and findings on plain radiographs, which show extraintestinal gas in the abscess, displacement of adjacent organs, and loss of the psoas muscle shadow. Barium studies of the intestinal tract can show displacement of adjacent viscera. CT scanning often defines retroperitoneal abscess when other studies are negative or equivocal.

Treatment usually involves surgery or percutaneous catheter drainage and antibiotics effective against enteric aerobic, facultative, and anaerobic organisms. Occasionally, a small diverticular or appendiceal abscess resolves with antimicrobial therapy alone.

Splenic Abscess

Etiology. Most splenic abscesses develop as a result of uncontrolled infection elsewhere. In 75% of patients they are small, multiple, and clinically silent and are found incidentally at autopsy (63). In the remaining 25% of patients the splenic abscess is solitary, and diagnosis is especially important because splenectomy is usually curative. A solitary abscess can arise from the following: systemic bacteremia that originated in another site and is now causing infection in a previously normal spleen; infection, presumably of hematogenous origin; a spleen damaged by blunt or penetrating trauma; bland infarction such as occurs in sickle cell trait or disease or other diseases such as malaria; or extension from contiguous infection, such as subphrenic abscess. The most common infecting organisms are staphylococci, streptococci, anaerobes, and facultative gram-negative rods, including *Salmonella* (63).

Symptoms and Signs. The clinical manifestations include subacute onset of fever and left-sided pain that is often in the flank, upper abdomen, or lower chest and that can radiate to the left shoulder (63). The left upper quadrant is commonly tender to palpation and splenomegaly may be present. Occasionally, a splenic friction rub is audible. Leukocytosis is usual and blood cultures sometimes grow the infecting organisms.

Diagnosis. The signs and symptoms and radiographic findings should lead to a diagnosis. Radiographs show a left upper quadrant mass; extraintestinal gas in the abscess from gas-forming organisms; displacement of other organs, including the kidney, colon, and stomach; elevated left hemidiaphragm; and left pleural effusion. Liver and spleen radionuclide scanning, CT scanning, and ultrasonography should demonstrate intrasplenic defects with abscesses larger than 1 to 2 cm.

Treatment. Untreated abscesses are followed by such complications as hemorrhage into the abscess cavity or rupture into the peritoneum, bowel, bronchus, or

pleural space. Treatment consists of systemic antibiotics and splenectomy, which are curative (see previous discussion).

Other Gastrointestinal Disorders

Two conditions that can cause abdominal pain, distension, and other symptoms and signs of an acute abdomen are briefly discussed here. They are neurogenic intestinal obstruction (adynamic ileus) and abdominal migraine. Although pain is usually not severe and the conditions are self-limited, they are considered here to emphasize simple methods of treatment usually not considered by surgeons or internists.

Neurogenic Intestinal Obstruction

In Chapter 66 it was noted that intestinal obstruction is a common cause of abdominal pain. In most cases the obstruction is caused by mechanical factors that require surgical intervention. A number of cases have been noted, however, in which the obstruction is caused by neurogenic factors that produce adynamic ileus, which often can be corrected by interrupting certain sympathetic pathways. Adynamic ileus is said to be the most common cause of intestinal obstruction. Dynamic ileus, in contrast, which is characterized by prolonged contraction or spasm of a segment of the large bowel, is uncommon.

Etiology. Adynamic ileus occurs to some degree after any intraabdominal operation. Its severity and duration vary directly with the amount of intestinal handling and length of the operation. It usually lasts 2 to 3 days after most operative procedures, but in some cases, it can last for a longer period. The pathophysiology of this condition is discussed in detail in Chapter 41. It is the result of viscerovisceral, cutaneovisceral, and somaticovisceral reflexes that are consequent to tissue injury, marked nociceptive input, and reflex sympathetic hyperactivity. The severity and duration of ileus tend to be less following laparoscopic procedures when compared with similar procedures performed via celiotomy.

Acute adynamic ileus also occurs after any peritoneal insult, and its severity and duration are dependent to some degree on the type of peritoneal injury. Thus, hydrochloric acid, colonic contents, and pancreatic enzymes are the most irritating, whereas blood and urine are less irritating. Patients with severe acute hemorrhagic pancreatitis frequently develop severe ileus that lasts for days and sometimes a week or longer.

Another common cause of severe prolonged adynamic ileus is fracture of one of the lower thoracic vertebrae. This causes severe compression of one or more nerves with consequent radiculalgia and reflex responses, including sympathetic hyperactivity in those segments adjacent to the fracture. Other retroperitoneal conditions that cause adynamic ileus include ureteral calculus, severe pyelonephritis, retroperitoneal infection, and hematoma. Thoracic disorders, including lower lobe pneumonia, fractured ribs, myocardial infarction, and pulmonary embolism, frequently produce adynamic ileus, as do electrolyte disturbances, particularly potassium depletion. Intestinal ischemia, whether it results from vascular occlusion or intestinal distension itself, can perpetuate an adynamic ileus. Dynamic ileus occurs in patients with heavy metal poisoning, porphyria, and extensive intestinal ulceration.

Pathophysiology. The pathophysiologic mechanism is predominantly an autonomic functional imbalance with an increase in sympathetic activity and perhaps a concomitant decrease in the activity of the parasympathetic nerves supplying the gastrointestinal tract. It was formerly thought that in this condition the intestinal musculature is paralyzed. This is not the case, however, because it has been repeatedly demonstrated experimentally and clinically that interruption of sympathetic supply to the gut causes a progressive decrease in the ileus and increases the ability of intestinal musculature to return to normal function. Thus, the term *paralytic ileus* should be discarded and replaced by the term *reflex inhibition ileus* (64). Obviously, adynamic ileus caused by peritonitis, with marked electrolyte imbalance (particularly hypokalemia), is exacerbated by interference with normal ionic movements during smooth muscle contractions. Certain drugs, such as phenothiazines and narcotics, inhibit bowel motility.

Symptoms and Signs. Clinically, acute adynamic ileus is characterized by cramping abdominal pain, distension, vomiting, absence of peristaltic sounds, and other signs and symptoms of intestinal obstruction. An important deleterious effect of severe ileus is a marked increase in intraabdominal pressure with consequent cephalad displacement of the diaphragm, encroachment of the lower lobes of the lungs, and a decrease of lung capacities and pulmonary compliance. If the ileus is a result of postoperative pain or some other painful disorder, reflex responses decrease chest wall compliance; combined with the effects on the lungs, atelectasis is produced, with consequent alveolar-arterial mismatch and hypoxemia that can progress to pneumonitis. As a consequence, the patient develops tachypnea associated with dyspnea that results in inadequate pulmonary ventilation.

Treatment. The standard treatment for adynamic ileus is use of nasogastric suction and intravenous fluid administration to correct electrolyte imbalance, particularly hypokalemia.

Although these procedures are usually effective and certainly reasonable in patients with mild ileus, the most effective therapy for severe ileus is interruption of the sympathetic supply to the bowel using a segmental epidural block with local anesthetics. The use of sympathetic blockade to increase the tone and motility of the gastrointestinal tract and enhance its function was first suggested by Wagner in 1919, who published a more extensive report containing favorable results 3 years later (64). This prompted a number of others to use spinal anesthesia and splanchnic block. In 1928 Ochsner and colleagues (65) reported that physiologic, chemical, and paralytic ileus in dogs could be relieved by injection of the splanchnic nerves, and they suggested that this method be used in the treatment of clinical ileus. Two years later, they reported their extensive experience in humans. In the first edition of this book (64), a large number of favorable reports were cited of the use of this method by many highly respected surgeons, including Ochsner and colleagues, Smithwick, Morton and Scott, J. C. White and associates, and a number of distinguished European clinicians. Continuous segmental epidural blockade is an effective method of decreasing the incidence of postoperative ileus and as an effective treatment for patients who developed it after surgery, following fractures of the thoracic vertebrae, and as a result of other conditions that provoke segmental reflex inhibition of the gastrointestinal tract (see Chapter 102 and Chapter 103). Continuous segmental block using appropriate doses of local anesthetics to block thinly myelinated and unmyelinated sympathetic and nociceptive fibers relieves the ileus and any consequent discomfort.

Sarnoff and associates (66) reported the successful use of differential spinal block to treat patients with dynamic ileus. Under the influence of sympathetic visceromotor block, peristaltic action became coordinated, large amounts of flatus and feces were expelled, and the colicky pain and distension were relieved.

Abdominal Migraine (XXII-2)

Etiology, Symptoms, and Signs. Abdominal migraine is a migraine equivalent that occurs mostly in children, but adult cases have also been recorded (67). Many synonyms exist, including periodic syndrome of children, cyclic vomiting, recurrent abdominal pain and headache, and navel colic. This symptom complex consists of recurrent and identical attacks of periumbilical pain, nausea, vomiting, headache, pallor, perspiration, slowing of the pulse, fever, occasional diarrhea, and limb pains. Attacks usually last less than 6 hours, with most occurring in children between the ages of 3 and 10, particularly in those whose parents have migraine (68,69). No abdominal symptoms are noted between attacks. Gastrointestinal abnormalities have been reported in patients with migraine; their relation to symptoms is unclear (70).

The close relationship between recurrent abdominal crisis and migraine was substantiated by Farquhar (71), who found that one- third of those in a series of 112 children between the ages of 3 and 15 years with this syndrome suffered from associated migraine while one or more relatives of two-thirds of these children had migraine. The combination of migraine and abdominal pain was seen in 20% of 73 children aged 9 to 15 years who had migraine and in 12% of 100 migraineurs aged 50 to 66 years (72). It has also been noted that a significant percentage of children who have recurrent abdominal pain (crises) develop migraine during adult life.

Diagnosis and Treatment. Bruyn (68) emphasized that if the physician takes the trouble to explore the patient's biography in detail, and a history emerges of common or classic migraine attacks, the diagnosis is made whether the abdominal attacks replace migraine attacks or are associated with them. The diagnosis is also more probable when a family member has migraine. If ergotamine is prescribed and the attacks then diminish or even cease altogether, this can be interpreted as confirmation of the diagnosis.

Because the symptoms and signs simulate those of appendicitis, biliary colic, pancreatitis, lead intoxication, and gallbladder disease, these should be excluded. Bruyn (68) cited reports of adult patients with abdominal migraine who had been mistakenly subjected to as many as five futile laparotomies and of one patient who underwent cholecystectomy and thoracic sympathectomy and subsequently became a morphine addict. Obviously, therefore, a thorough physical and laboratory examination is essential to exclude the possibility of an intraabdominal disease.

Bruyn (68) further emphasized that the diagnosis should not be difficult if the following points are borne in mind: (a) migraine in the history of the patient or relatives; (b) repetition of identical abdominal crises; (c) attack-free intervals; (d) absence of systemic signs such as an increase in erythrocyte sedimentation rate, leukocytosis,

and abnormal urinalysis results during and between attacks; (e) unremarkable physical examination during and between attacks; (f) normal electrocardiographic results during and between attacks; (g) positive response to ergotamine; and (h) the occasional presence of other migrainous symptoms, such as nausea, vomiting, perspiration, and body temperature changes. Prevention and treatment are similar to migraine as discussed in Chapter 48.

Abdominal Adhesions

All patients who have undergone prior abdominal operations have at least some intraabdominal adhesions. The adhesions are likely to be more extensive if there were multiple prior operations, if any of the prior intraabdominal events involved significant inflammation such as occurs with peritonitis, or both. Many physicians and patients have the belief that these adhesions can cause abdominal pain. Adhesions can cause bowel obstruction, and bowel obstruction is often painful. However, bowel obstruction is readily diagnosed by its clinical presentation and characteristic radiologic studies. In the absence of bowel obstruction, intraabdominal adhesions do not cause pain, and it is a waste of time to refer such patients to a surgeon for lysis of adhesions. It is also not helpful to put the idea of painful adhesions in the mind of a patient.

SYSTEMIC DISORDERS

A number of systemic disorders cause abdominal pain that simulates that of intraabdominal disease but do not require surgical intervention. Laparotomy is not only unnecessary for such patients but can set the stage for postoperative problems associated with the underlying disease as well as for complications of the operation itself. Among the most important of these systemic problems are hematologic disorders and metabolic or biochemical disorders. Because they are complex, they produce widespread symptoms and signs, but here only those aspects relevant to abdominal pain are considered.

Hematologic Disorders

Various hematologic conditions can produce abdominal pain as part of their symptom complex. Most have pain as a prominent feature only during a *crisis*. In some, however, such as paroxysmal nocturnal hemoglobinuria, pain is a prominent constant feature.

Sickle Cell Anemia

Sickle cell anemia is a chronic hemolytic anemia occurring almost exclusively in blacks. It is characterized by the sickle- shaped red blood cells produced by homozygous inheritance of hemoglobin S (HbS). This condition is a significant cause of morbidity and mortality among blacks. Approximately 0.15% of black children in the United States have the disease (73). The prevalence is lower among adults because patients with sickle cell anemia have a decreased life expectancy.

The protean clinical manifestations of this disorder can all be attributed to a specific molecular lesion, the substitution of valine for glutamic acid in the sixth acid of the beta chain. On exposure to low levels of oxygen, a red blood cell containing HbS changes from a biconcave disk to an elongated crescent-shaped or sickle-shaped cell. In addition, sickling is precipitated by a lowering of pH and by an increase in body temperature (73,74). As a red blood cell sickles, it becomes rigid. The distorted but inflexible red blood cells plug small arterioles and capillaries, leading to occlusion and infarction. Because sickled red blood cells are too fragile to withstand the mechanical trauma of circulation, hemolysis occurs when they are released into the circulation. Almost all the systemic effects of this disease are related to the sickling phenomenon and to the increased fragility of the red cell. Severe disease is incompatible with long life, and 50% of patients with severe sickle cell anemia are dead before the age of 10 years (47). Those in the surviving pool of patients often develop a crisis. Improvements in treatment have increased survival (74).

Symptoms and Signs. With heterozygous inheritance, patients have sickling trait but are healthy and do not experience hemolysis, painful crises, or thrombotic complications. In contrast, the clinical manifestations in homozygotes are caused by anemia and by tissue ischemia and infarction. Anemia is usually severe but varies greatly among patients, with most patients having mild jaundice. Anemia can be exacerbated in children by acute sequestration of sickle cells in the spleen, producing splenomegaly. If the splenomegaly is severe, it can cause abdominal pain because of its capsule stretching and compressing surrounding viscera or impinging on the diaphragm.

Throughout their lives the homozygotes are plagued by recurrent painful crises (74,75). These episodes can appear with explosive suddenness and attack various parts of the body, particularly the abdomen, chest, and joints. Approximately one-third of the painful crises are preceded by a viral or bacterial infection. The frequency of painful crises is highly variable. A given patient might have months or even years without a crisis and then have a cluster of frequent and severe attacks. In some individuals crises occur more frequently in cold weather, perhaps precipitated by reflex vasospasm, while in others crises occur more often in warm weather when patients are likely to become dehydrated.

The episodic abdominal pain is usually severe and associated with vomiting and is a frequent feature of the painful vasoocclusive crisis. The organs most often involved include the liver, gallbladder, and spleen. The severity of the pain and other symptoms simulates that of acute severe intraabdominal disorders, and thus it is often difficult to distinguish between painful sickle crisis and such acute processes as biliary colic, appendicitis, and perforated viscus. Many patients have undergone surgical exploration because they were thought to have an acute surgical problem. The clue that the patient is undergoing a sickle cell crisis rather than an acute abdomen is the presence of increased sickling on the peripheral blood smear and evidence of some degree of hemolysis. Moreover, whereas abdominal tenderness is common, the guarding is of a voluntary nature because the muscles can relax and bowel sounds are usually normal, with no rebound tenderness.

Those who are SS homozygotes frequently develop attacks of acute pleuritic chest pain with fever. Although the initial chest radiograph is usually unremarkable, an infiltrate can evolve. The important differential is between pneumonitis and pulmonary infarction. Culture and Gram's staining of the sputum help in establishing the presence of pneumonia.

Diagnosis. The diagnosis is made through the history, physical examination, and comprehensive laboratory studies of the blood. The homozygous state is determined by electrophoresis, which shows only HbS and a variable amount of HbF. The heterozygote is recognized by the presence of both HbA and HbS, with more HbA than HbS.

Treatment. Therapy is usually symptomatic. Splenectomy and hematinics have proven valueless (73). Transfusions should be given only for an anemia that is more severe than usual. The severe abdominal pain should be managed with vigorous oral intravenous hydration and with nonopioid and opioid analgesics. In those hospitals in which such services are available, patient-controlled analgesia is an excellent method of providing effective pain relief. Prophylactic antibiotics, pneumococcal vaccine, early identification and treatment of serious bacterial infection, and general prophylaxis have reduced the mortality, particularly during childhood (73,74 and 75).

Acute Hemolytic Crisis

In some instances autoimmune hemolytic anemia, thrombotic thrombocytopenia, purpura, or other hemolytic disorders can begin abruptly and cause moderate to severe pain in the abdomen, back, or limbs. The abdominal pain can be severe, and the accompanying muscular spasm and rigidity might simulate the signs of an acute surgical emergency (47). Profound prostration and shock can develop, followed by oliguria or anuria. Pallor, jaundice, tachycardia, and other symptoms of severe anemia can be prominent.

Such patients require careful evaluation and supportive therapy consisting of effective pain control, infusion of appropriate fluids, and other measures to prevent or treat shock.

Chronic Hemolytic Anemia

Other congenital hemolytic anemias can also cause abdominal pain as part of their complex clinical manifestations. The major features relate to anemia, jaundice, the occurrence of crises, splenomegaly, and the development of gallstones. The jaundice of hemolytic disease is acholuric, with the bilirubin being unconjugated and thus not excreted in the urine. The spleen is commonly enlarged in this group of patients, but usually the degree of enlargement is mild to moderate. If the spleen assumes gigantic proportion, as in a few patients, it can produce abdominal pain described as a vague sensation of oppression or weight in the left side of the abdomen or, less commonly, is the site of an attack of acute abdominal pain (47). Crises can result from the transient failure of red cell production, so-called aplastic crises. It is the hemolytic crisis, however, that produces a manifestation of an acute abdominal catastrophe (see Acute Hemolytic Crisis, previously in this chapter). In these patients

the abdominal pain can be severe and accompanied by muscular spasm and rigidity, possibly simulating the signs of an acute surgical emergency.

In some patients symptoms of gallbladder disease might be the initial manifestation of a hemolytic crisis because of one of these congenital hemolytic anemias and can be what brings the patient to the physician (47). The stones are of the pigmented type and are presumed to be the consequence of continuous excessive bilirubin load presented to the liver. Such patients have a progressive increase in the incidence of gallstones with age. In some disorders, particularly in hereditary spherocytosis, as many as 85% of adult patients develop stones.

The therapy of patients with congenital hemolytic anemias is usually supportive. Effective pain control with nonopioid and opioid analgesics in appropriate doses is part of the initial treatment. Fluid replacement and transfusions might be required. In cases of major thalassemia (Cooley's anemia), the obvious benefits of transfusion therapy are partially offset by the risk of iron overload hepatitis and alloimmunization. Despite these problems, children with Cooley's anemia fare better if their hemoglobin is maintained at a level greater than 9 g per dL (47). In view of the increased demand of the hyperplastic marrow, it is reasonable to maintain these patients on a daily supplement of folic acid. Because splenic sequestration contributes to shortened red blood cell survival, many patients derive some benefit from splenectomy because the need for transfusions is decreased. Splenectomy is also indicated if the size of the tumor is so great that it produces severe respiratory problems or is a source of great discomfort because of its encroachment on the diaphragm and other organs.

Biochemical and Biological Disorders

Acute Intermittent Porphyria (XXII-3)

Acute intermittent porphyria is a dominantly transmitted inherited disorder that can exist in latent form indefinitely or be manifested as acute attacks of neurologic dysfunction precipitated by various environmental and endogenous factors (76,77).

Etiology and Pathophysiology. The basic enzyme defect in this disease is a 50% decrease of uroporphyrinogen synthetase. Consequently, d-aminolevulinic acid, porphobilinogen, and uroporphyrinogen are produced in excess by the liver and excreted in the urine. This metabolic abnormality is accompanied by acute attacks of mental or abdominal neurologic symptoms. It is inherited as an autosomal dominant trait with an overall prevalence of 5 to 10 per 100,000 population in the United States. The prevalence, however, is much higher in some countries (76); for example, in Sweden, it is 1 in 13,000 population (47). The frequency and severity of attacks and prevalence are greater in women (60% to 75%) than in men.

The disease exists in latent form until an attack of acute neurologic dysfunction is precipitated by one of four groups of factors: drugs, starvation, sex hormones, and infection. Drugs implicated in precipitating attacks of acute porphyria include barbiturates, sulfonamides, phenytoin, methsuximide, griseofulvin, meprobamate, amidopyrine, antipyrine, dipyrone, imipramine, ergot preparations, methyldopa, pentazocine, danazol, chloramphenicol, and chlorpropamide (76). Starvation and crash dieting precipitate attacks of porphyria. The deleterious effects of diet relate to the ability of glucose and certain other carbohydrates to block the induction of hepatic d-aminolevulinic acid synthetase. Female sex hormones are also implicated in precipitating attacks of porphyria; a small percentage (less than 5%) of women with this disorder have an attack during pregnancy. Acute attacks of porphyria can also follow bacterial and viral infections, but the mechanism is unknown.

Symptoms and Signs. Symptoms of the acute attack result from nervous system damage. Any part of the system can be involved, and the specific clinical findings depend on the areas that are affected. The outcome of the acute attack can vary through a spectrum from death to complete recovery, although some patients who recover can retain varying types of neurologic deficits. Symptoms rarely occur before puberty.

Abdominal pain is frequently the initial and most prominent symptom of the porphyric attack, occurring in approximately 95% of the patients. The pain can be moderate but more frequently is severe in degree and cramping or colicky in nature. It can be localized in one of the lower quadrants or in the periumbilical region, but in some cases it is felt throughout the abdomen. The pain can radiate to the back or loins and is accompanied by vomiting, constipation, and mild abdominal tenderness (76,77). It has been suggested that the pain results from autonomic neuropathy that causes disturbed gastrointestinal motility or alternating areas of spasm and dilation. Low- grade fever and mild leukocytosis along with the pain can suggest other diagnoses. Other autonomic manifestations include labile hypertension, sinus tachycardia, postural hypotension, and sweating. Because these symptoms can be attributed to various conditions requiring emergency surgery, many patients have already been subjected to unnecessary laparotomy when seen with another acute attack.

Patients can also manifest peripheral neuropathy that is predominantly motor, but sensory components can also be present. Deep tendon reflexes are diminished or absent. Neuralgia in the extremities associated with areas of hypesthesia and paresthesia and foot- or wristdrop are typical. Central nervous system involvement can produce an organic brain syndrome, seizures, cerebellar and basal ganglia manifestations, hypothalamic dysfunction, and bulbar paralysis.

Acute attacks can last from days to months and vary in frequency and severity. The characteristic finding of this disease is increased porphyrin precursor excretion in the urine.

Diagnosis. Diagnosis is made by establishing the presence of excessive urinary porphobilinogen. These precursors can be quantitated accurately by chromatographic techniques. Clinically they can be detected by qualitative analysis using the Watson-Schwartz or Hoesch's test (76). If these tests are not available, a useful technique involves collecting a sample of urine and exposing it to light and air. Because porphobilinogen is colorless the initial sample appears normal, but on exposure to light or air the urine darkens. This phenomenon is largely accounted for by the formation of porphobilin, a dark brown nonporphyrin oxidation product of porphobilinogen.

Treatment. Treatment involves prevention of attacks, treatment of symptoms, and attempts to reverse the fundamental disease process. Prevention of attacks entails instructing patients to avoid the known precipitating factors listed previously. Many patients scheduled for surgery should inform both the anesthesiologist and surgeon of their conditions, because physicians know to avoid the use of thiopental or other barbiturates for sedation or induction of anesthesia.

Pain control is the first step in symptom management. Some believe that phenothiazines can be useful for the control of abdominal pain, presumably by their effects on decreasing autonomic outflow. Usually, these patients require large doses of intravenous opioids, either in incremental doses or by continuous infusion. An excellent alternative is patient-controlled analgesia. If these methods do not provide effective relief, serious consideration should be given to the induction of continuous segmental epidural analgesia with a local anesthetic (see Chapter 102). This technique has the advantage of providing complete pain relief because it blocks all nociceptive input from the abdomen and interrupts sympathetic efferent impulses, thus helping to decrease the effects of the pathophysiologic process.

Other Porphyrias

Other rare types of porphyrias cause intermittent acute attacks of abdominal pain, including hereditary coproporphyria (IASP XXII-4) and variegata porphyria (IASP XXII-5). Both can be associated with neurologic and mental disturbances. Variegata porphyria also causes photosensitivity and is accompanied by cutaneous lesions. Photosensitivity occurs with hereditary coproporphyria, but not as frequently as with variegata porphyria.

Other Metabolic and Biochemical Disorders

Other metabolic and biochemical disorders that cause abdominal pain include diabetes, uremia, lead and other heavy metal poisoning, food poisoning, and spider bites. In all these conditions, abdominal pain is only one of many symptoms and signs. In each case the pain is controlled symptomatically with nonopioid or opioid analgesia or with a combination of these, depending on the severity of the pain.

Lead Poisoning. Abdominal pain is an especially frequent symptom of lead poisoning in children. Obviously, analgesics must be given in reduced but appropriate dosages to provide good pain relief. If the pain is expected to persist for several days or weeks, continuous epidural opioid analgesia is highly effective and has advantages over other methods of administration of these drugs (see Chapter 103).

Spider Bite. Spider bite first produces a momentary sharp pain at the site of bite, followed by a cramping pain that begins locally within 15 to 60 minutes and gradually spreads (78). The abdomen becomes boardlike and the waves of pain become excruciating, causing the patient to turn, toss, and cry out (78). Respirations are often labored and grunting. The pain is associated with nausea, vomiting, headache, sweating, salivation, hyperactive reflexes, twitching, tremor, paresthesia of the hands and feet, and occasionally, systolic hypertension. A mild leukocytosis is usual, but many patients have high fever. After several hours the pain subsides, although a mild recurrence for 2 to 3 days is common. It can be a week before well-being is restored. Death caused by cardiac or respiratory failure has ensued mostly in children

and the aged.

Treatment consists of pain relief measures and administration of antivenom. Initial treatment should begin with pain control with opioids, first administered intravenously and subsequently intramuscularly at regular intervals. If the patient is hospitalized, a better alternative would be epidural opioid analgesia or segmental epidural analgesia with local anesthetics. A 10-mL vial of 10% calcium gluconate injected intravenously slowly over 10 to 20 minutes usually produces dramatic but transient cessation of cramps (78,79). A solution of 10% methocarbamol administered intravenously can also be effective in treating the muscle spasm. When the symptoms are severe, or when the patient is a small child or is at special risk because of other associated medical problems, treatment with *Latrodectus* antivenom is indicated. An intravenous injection of one vial (2.5 mL) diluted in 50 mL of saline and administered over a 15-minute period is usually effective; this can be repeated within a few hours if symptoms recur (78).

EXTRAABDOMINAL DISORDERS

Abdominal pain can and often does occur as a referred phenomenon that is part of the symptoms and signs of thoracic or pelvic visceral disease, or as a projected pain from disease of the spine or other musculoskeletal, and, rarely, neuropathic disorders. Most of these are discussed in detail in Chapter 60, Chapter 61, Chapter 62, Chapter 63 and Chapter 64 in Section C) and Chapter 72 (Gynecologic Pain), and only brief comments are made here in regard to the abdominal pain.

Thoracic and Pelvic Visceral Disease

Diseases arising within the thoracic cavity can produce diaphragmatic irritation or referred pain that is often indistinguishable from pain arising from the pancreas, stomach, or biliary tract. Fortunately, certain general guidelines can be used that help to differentiate a thoracic from an abdominal origin (47). Thoracic pain is almost never associated with abdominal tenderness. Bowel sounds are usually present and, with careful questioning, the time sequence reveals that symptoms and signs of a cardiopulmonary or esophageal disorder preceded the development of the abdominal pain.

Acute Myocardial Infarction

Generally, acute myocardial infarction produces characteristic symptoms of retrosternal and anterior chest pain with radiation to one or both arms, neck, and, occasionally, the jaw. A significant percentage of patients, however, also have radiation of pain in the epigastrium. Indeed, in some patients, the epigastric pain is the predominant symptom. It is probably caused by an inferior wall infarction that produces diaphragmatic pleuritis with pain referred to the lower chest and abdomen, associated with belching and occasionally back pain. One or more of these symptoms can mimic the initial symptoms of a penetrating ulcer, cholecystitis, or pancreatitis and can present a difficult differential diagnosis.

In either case it is essential for the patient to be admitted to the hospital, often with a stay in the coronary care unit, while serial electrocardiograms, cardiac monitoring, and cardiac enzyme levels are obtained. The pain of myocardial infarction usually begins to decrease within 12 to 24 hours, whereas if the condition is an acute intraabdominal problem pain continues and is associated with severe abdominal tenderness, reflex muscle spasm that produces rigid abdomen, and the absence of peristalsis.

Acute Pericarditis

Acute pericarditis of the diaphragmatic portion of the pericardium can cause irritation of the diaphragm that involves not only the central portion, supplied by the phrenic nerve, but also the peripheral part, supplied by the lower sixth and seventh thoracic spinal nerves, with consequent pain and muscle spasm in the lower chest and epigastrium. The pericardial source of the pain can be ascertained by the fact that this pain is markedly aggravated by deep breathing, is associated with dyspnea and triphasic pericardial friction rub, and radiates to the neck and trapezius ridge. On the other hand, all symptoms and signs except the pericardial friction rub can be present with a subdiaphragmatic irritation caused by subphrenic abscess, acute cholecystitis, or pancreatitis.

Pulmonary Embolism

Confusion between the pain of pulmonary embolism and that of intraabdominal disease arises primarily with medium-sized emboli that produce a pleuritis with consequent pleuritic pain. If the pleuritis involves the diaphragmatic portion of the pleura, the patient might experience pain in the epigastrium and lower part of the thorax laterally and posteriorly. Again, the pain is markedly aggravated by deep breathing and is associated with friction rub and radiographic evidence that the lesion is in the chest.

With a large central embolus the patient experiences sudden, severe, crushing central pain that can radiate to the upper epigastrium. The preeminence of pain in the retrosternal region, however, associated with a feeling of impending death (*angor animi*) that lasts from a few minutes to several hours, should suggest pulmonary embolism. If massive central pulmonary emboli produce certain cardiovascular collapse and death, symptoms are usually not confused with those of an acute abdomen. Other symptoms and signs that differentiate acute pulmonary embolism from an acute intraabdominal disorder include dyspnea, which is found in most patients with pulmonary embolism, hemoptysis, a history of venous disease, changes in blood viscosity, obesity, and a period of prolonged bed rest or inactivity.

Pneumonia

The clinical symptoms and signs of pneumonia include fever, cough, purulent sputum, mild dyspnea, and usually pain, which can be retrosternal or, most frequently, pleuritic, and is felt in the side and back of the chest. On the other hand, if the pneumonia involves the diaphragmatic pleura, the patient experiences pain in the lower chest and upper abdomen. A differential diagnosis is aided by the fact that the pain is exaggerated by deep breathing and coughing and by the presence of rales and other signs of pneumonic consolidation.

Upper Respiratory Infection

The symptoms and signs of upper respiratory infection in adults are located in the chest and should never cause confusion with those of abdominal disorders. On the other hand, as Kirkpatrick indicated (47), children with an upper respiratory infection can experience nonspecific abdominal pain localized in the right lower quadrant that might be mistaken for that of acute appendicitis. In such cases the lower quadrant pain is caused by a mesenteric adenitis, a relatively uncommon complication that occurs consequent to a respiratory infection and afflicts children 5 to 15 years of age, more commonly in boys than in girls. Characteristically, the child has an acute pharyngitis or otitis media and develops cramping periumbilical pain during the recuperative phase. Leukocytosis ranging from 12,000 to 18,000 per µL and a mild fever of 99°F to 100°F (37.2°C to 37.8°C) suggest either appendicitis or mesenteric adenitis. Kirkpatrick (47) suggested that, if signs of upper respiratory infection are still present, reevaluation as an outpatient in 12 hours should help to avoid an unnecessary operation and minimize the risk of missing appendicitis. If the upper respiratory infection has resolved but the pain persists, however, then hospital admission, repeat blood work, and close observation are necessary to avoid missing an attack of acute appendicitis.

Esophageal Disease

Acute and chronic esophagitis produced by chemical or infectious disorders often cause pain in the sternum that extends down into the epigastrium. The pain is usually constant with periodic increases in intensity produced by esophageal spasm and is markedly aggravated by swallowing (odynophagia). It is rare for the pain to be located only in the epigastrium and therefore the differential diagnosis should not be difficult, especially with a history of ingestion of a chemical or other signs of esophagitis.

Esophageal motor disorders can also cause retrosternal pain with radiation to the epigastrium and back and also to the neck, jaw, teeth, or both arms, thus simulating the pain of acute myocardial infarction (see Chapter 63). The pain, which lasts seconds to many hours, is aggravated by cold liquids, solids, and emotional stress and is partially relieved by nitroglycerin. The differential diagnosis is aided by manometry, scintigraphy, and provocative tests using pharmacologic agents.

Esophageal lacerations and rupture can also cause pain in the lower sternum and epigastrium; if located in the lower part of the esophagus the epigastric pain can be the most prominent. Spontaneous rupture, called *Boerhaave's syndrome*, also causes excruciating, crushing, or tearing pain in the lower retrosternal region and epigastrium. Because the rupture occurs during intense vomiting following a large meal, together with other symptoms and signs, it is easily differentiated from

intraabdominal disorders.

Similarly, carcinoma of the esophagus produces moderate to severe retrosternal pain with radiation to the epigastrium when the lesions are in the lower part of the esophagus. The pain radiates to the back and interscapular region, is continuous, and is aggravated by food ingestion. The differential diagnosis is aided by the history and by radiography, CT scanning, and esophagoscopy.

Retroesophageal reflux caused by incompetent gastroesophageal sphincter also produces a symptom complex characterized by retrosternal epigastric burning pain, dysphagia, and occasional bleeding. When these signs and symptoms are present the diagnosis should be suspected from the history and confirmed by esophagoscopy, acid perfusion test, and pH monitoring.

Gynecologic Disorders

Some gynecologic conditions can mimic those of acute abdomen by producing pain in the right or left lower quadrant or in the suprapubic region, with radiation to the back. These include acute salpingitis, twisted ovarian cyst, ruptured ovarian follicle, and various other disorders (see Chapter 72). To avoid a misdiagnosis, it is mandatory for pelvic and rectal examinations to be carried out; if necessary, a pregnancy test is done. Pelvic examination reveals exquisite cervical tenderness (other differential diagnostic procedures are discussed in Chapter 72 and summarized in Table 70-3).

Pain of Neuropathic Origin

In Chapter 60 it was noted that most pathologic processes of the thoracic portion of the spinal cord and of the thoracic spinal nerve roots or peripheral nerves produce similar pain syndromes in the chest and the abdomen. They have been discussed in detail in Chapter 60. To avoid repetition, only a few comments pertinent to abdominal pain are made here.

Brain Lesions

It is uncommon in the brain or brainstem to cause pain only in the abdomen without causing pain or other sensory disturbances in the extremities. The one exception is a very rare form of epilepsy that can cause pain in the abdomen as an aura or as part of the seizure itself (80). Abdominal epilepsy is more common during childhood and can abate spontaneously in adolescence. The patient usually complains of unpleasant sensations that can vary from paresthesiae to pain. Nausea and vomiting can occur (81). Some of these patients were described as having intussusception in association with their epileptiform disorder. Motor phenomena and a sensory deficit are usually not present (82), but autonomic phenomena are common. Most patients with this type of seizure disorder also report environmental distortions and emotional changes.

Central pain caused by vascular lesions or by tumors of the brain and brainstem usually leads to pain in the contralateral extremities and side of the trunk and other signs and symptoms of brainstem lesions. Although some of the pain can be felt in the abdominal wall on the same side, it is rarely, if ever, localized only to the abdomen.

Lesions of the Spinal Cord, Meninges, and Epidural Space

Intramedullary lesions or diseases of the lower thoracic portion of the spinal cord, including tumors, syringomyelia, trauma, multiple sclerosis, abscess, hemorrhage, and other conditions, can produce pain in the trunk that includes the abdominal wall. The pain can be a spontaneous, burning, diffuse, poorly localized pain that is continuous or explosive in nature or, in some cases, the pain can have a radicular (segmental) distribution involving several segments, depending on the extent of the lesion; this is often associated with hyperalgesia, hyperpathia, and paresthesia.

Extramedullary intrathecal lesions such as primary or metastatic lesions, abscesses, and hemorrhages initially produce low back pain localized around the segments of the lesions. Subsequently, however, the pain becomes radicular and is aggravated by straining and coughing and is associated with paravertebral tenderness and paresthesia. These are followed by sensory loss, muscle weakness, and lower motor neuron signs at the level of the lesion.

Epidural spinal cord compression caused by primary or metastatic tumor, hemorrhage, posterior disk protrusion, abscess, or hemorrhage produces localized low back pain at the level of the site of lesion in 95% of patients and bilateral radicular pain involving the abdominal wall in 55% (83). The pain is aggravated by neck flexion, straight leg raising, coughing, sneezing, and Valsalva's maneuver. Deep palpation and fist pounding produce back tenderness. Early in the course of the disease no other signs are seen but muscle weakness develops later, varying from mild weakness to paraplegia. Numbness and paresthesia are noted in 50% of patients and bladder and bowel dysfunction are frequent (57%) (see Chapter 60 for details).

Arachnoiditis, characterized by inflammation and fibrosis of the arachnoid membrane, is a well-recognized cause of chronic pain. Although the cauda equina is the most common site, arachnoiditis can occur at any spinal level. It can be focal and involve only one root, thereby leading to a segmental pain syndrome with variable loss of sensory and motor function. Arachnoiditis can also affect multiple segments and lead to a more diffuse pain syndrome in the lower trunk and abdomen. The pain of arachnoiditis is constant but is worsened by physical activity. Often a dysesthetic component is present, and paresthesiae are common. Patients often report both a deep aching and a superficial sharp jabbing pain. This type of pain is not often ameliorated by narcotics.

Lesions of Roots and Trunks of the Thoracic Nerves (XX-3)

Lesions of the nerve roots produce radiculopathy and consequent radiculalgia or segmental pain. The pathology can be a result of an acute or chronic infectious process or of mechanical compression.

Herpes Zoster. Herpes zoster is an infection by the varicella-zoster virus that involves the ganglion cells, rootlets, and posterior horn. It produces a continuous aching, itching, or burning pain with superimposed bouts of severe lancinating pain. Hyperalgesia and hyperesthesia are present in the affected segments. These patients usually develop a rash in the involved segments that spreads along the entire nerve or part of the affected nerve, frequently in the upper or lower anterior abdomen. Some patients develop postherpetic neuralgia, which is a chronic condition that produces severe, intractable, continuous, unrelenting, burning pain and itching accompanied by severe spasm with stabbing lancinating pain that persists long after the acute phase. The skin of the posterior and lateral lower thoracic cavity and abdominal wall has dried white or brownish black scars that represent the healing of the vesicles. Patients may experience hyperalgesia, hyperesthesia, and hyperpathia and frequently hypesthesia, depression, sleep disturbance, anorexia, lassitude, and constipation (see Chapter 22 and Chapter 60).

Tabes Dorsalis. Tabes dorsalis is one of the many forms of tertiary syphilis. Formerly a common affliction, the development of serologic testing and effective antibiotic therapy has made this an exceedingly rare disease in most developed nations. The immunosuppression that is part of acquired immunodeficiency syndrome has led to a recrudescence of syphilis. Pains are often the earliest signs of tabes; the vast majority of patients has typical lightning pains during the course of the disease. The electric shock– like stabbing pain might last only a brief moment or be continuous for days. Girdlelike pains about the thorax or abdomen are common, although most patients have pains in the limbs. Paresthesiae and objective sensory changes in the region of the pain occur in about 25% of patients. Most patients with tabes dorsalis have altered position sense, absent deep tendon reflexes, hypotonia, ataxia, and Argyll Robertson pupils (miotic pupils that fail to react to light but contract with accommodation).

Even worse than the intermittent lancinating pains is the pain syndrome known as *gastric crisis*. This has been reported in about 10% of tabetics. The patient has a sudden onset of agonizing epigastric pain associated with nausea and vomiting. Such an attack can last for days, but spontaneous remission always occurs. This pain syndrome is exceedingly difficult to differentiate from renal or biliary colic or penetrating ulcer on the basis of the clinical presentation alone. A similar pain syndrome can affect the lower abdomen and pelvic areas.

Nerve Root Compression. Many factors can cause compression radiculopathy, including tumors, disk protrusions, vertebral fractures, osteophytes, and adhesive arachnoiditis. All of these produce a segmental sharp burning pain, hyperesthesia, hyperalgesia, hypesthesia, and dysesthesia in the segments involved.

Protrusion of the intervertebral disk deserves special note here because, contrary to former teachings, herniation of a thoracic intervertebral disk is now being recognized with increasing frequency. In most cases it involves one of the lower thoracic disks, producing radiculalgia with segmental pain in the lower abdomen.

Initially, the pain is vague and poorly localized and can be referred laterally or bilaterally in the abdomen. Typically, the pain is aggravated by neck flexion and by an increase in intraspinal pressure resulting from coughing, sneezing, or straining. The pain is usually relieved by recumbency. Subjective numbness and paresthesia, such as coldness and a burning sensation, are early and outstanding symptoms. If the disk is posterior, it produces compression of the spinal cord with weakness and heaviness of the leg. Physical signs of upper neuron damage can also be present, including hyperactive deep reflexes, spasticity, and the Babinski's response. Early recognition and removal prevent irretrievable damage to the spinal cord (see Chapter 60).

Other causes of the segmental abdominal pain of neuralgia are vertebral compression resulting from arthritis, metastatic or traumatic fractures, tumors of the vertebrae, osteomyelitis of normal curvature, and paravertebral compression resulting from adenopathy. All these usually produce unilateral segmental neuralgia characterized by continuous burning or sharp pain that affects part or the entire segment of the nerve and is associated with paroxysms of stabbing pain. Patients frequently have paravertebral tenderness and segmental hyperalgesia, hyperesthesia, and hypesthesia, and usually show radiographic evidence of the disease.

Intercostal Neuropathy

One or more of the lower six or seven intercostal nerves can be irritated, infected, or damaged by lesions of the ribs, which can include trauma, fractures, and primary or metastatic tumors. These conditions are characterized by superficial continuous burning pain in the lower part of the posterior and lateral chest and the abdominal wall. Pain is usually unilateral.

Abdominal Cutaneous Nerve Entrapment Syndrome (XX-5)

The cutaneous entrapment syndrome is a special type of intercostal neuropathy that deserves mention because it causes pain in the anterior abdominal wall or can cause segmental neuralgia.

Etiology. The most common type is a result of entrapment of one or more of the anterior cutaneous branches of the thoracoabdominal intercostal nerve(s) in the rectus sheath. Applegate (84) described a small fibromuscular ring near the lateral margin of the rectus abdominis muscle through which the intercostal nerve turns sharply in an anterior direction on its terminal course through the skin in which it is firmly anchored. The nerve enters the ring accompanied by the epigastric artery and vein from which it is separated by a well-defined fatty mass. All these structures continue in a channel between the fibers of the rectus muscle and its anterior sheath, passing subcutaneously and ending at the skin (Fig. 69-4A).

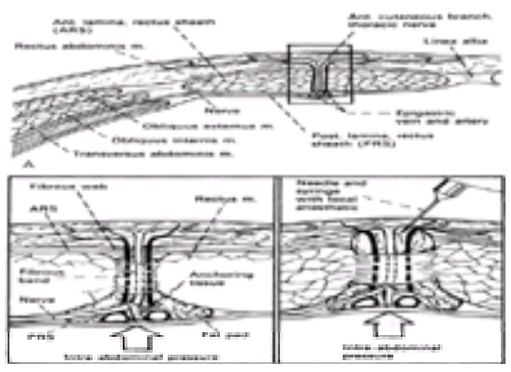

Figure 69-4. Mechanism of abdominal cutaneous nerve entrapment syndromes. **A:** Normal anatomy of the neurovascular bundle as it passes through the fibrous muscular foramen in the rectus muscle, together with increased intraabdominal pressure, cause the nerve, which is anchored by fibrous tissue, to be stretched. **B:** Herniation of the neurovascular bundle and the fat pad surrounding it through the fibromuscular foramen in the rectus muscle and the aponeurotic opening at the rectus margin. **C:** Technique of injecting a local anesthetic to confirm the diagnosis and as part of the treatment. (Modified from Applegate WV. Abdominal cutaneous nerve entrapment syndrome. *Surgery* 1972;71:118–124.)

In some patients the walls of the muscular channels are split or spread apart. This allows the fat and neurovascular bundle to herniate into the subcutaneous tissue, where they are intermittently compressed or become incarcerated as a tender mass that is palpable from the surface (Fig. 69-4B). The weakness of the channel is induced by sustained and increased intraabdominal pressure or by stretching of the abdomen during pregnancy, or is consequent to severe ascites or a large intraabdominal tumor. The weakness can also be caused by a chronic, persistent strong cough.

Contraction of the abdominal muscles causes local compression of the trapped nerve in the muscular channel, which provokes bouts of sharp burning pain. Pain is also produced by sudden twisting or lateral flexion of the spine away from the affected side, causing the nerve to be stretched and pressed tightly against unyielding fibrous tissue in the ring.

Entrapment of the lateral cutaneous branch of the thoracoabdominal intercostal nerves can also occur as each traverses the internal and external intercostal and serratus anterior muscles to reach the subcutaneous tissue, where it divides into anterior and posterior subdivisions (see Chapter 60). Indeed, the cutaneous branch of the posterior primary division can also become trapped as it traverses the paraspinal muscles and their fascia.

Symptoms and Signs. Initially, most patients experience bouts of intermittent dull aching pain that can be associated with sharp piercing pain in the distribution of the dermatome and paresthesia, hyperesthesia, and local tenderness, the characteristics of neuropathy. The distribution of the pain symptoms depends on the site of entrapment and on the number of nerves involved. In most cases one anterior cutaneous nerve is entrapped, causing pain in the medial part of the anterior abdominal wall over the rectus muscle. The pain is reproduced by localized pressure with a fingertip. Entrapment of the lateral cutaneous branch produces pain and sensory disturbance in its distribution and is also reproduced by fingertip pressure at the midaxillary line.

Diagnosis. Pain from cutaneous nerve entrapment can be confused with acute pain caused by intraabdominal visceral disease; the latter must be ruled out to avoid unnecessary surgery. The diagnosis is made by keeping entrapment syndromes in mind, by the characteristics (quality, location, intensity, and duration of pain), and by reproducing the pain with fingertip pressure. The anterior cutaneous syndrome is also reproduced by increasing the tension of the rectus abdominis muscles by having the patient raise the head and shoulders from the examining table. Often the symptoms are also reproduced by strong coughing efforts in the standing position. The diagnosis is confirmed by prompt and complete relief of the pain following injection of the localized tender area with 1 to 2 mL of a local anesthetic solution (Fig. 69-4C).

Treatment. Conservative measures such as heat, cold, massage, and transcutaneous electric nerve stimulation can provide moderate but temporary relief of the pain. Repeated injection with a local anesthetic usually produces only temporary relief, although some patients experience progressively longer intervals of pain relief with a series of injections. In patients who obtained complete but only transient relief of the pain following a series of blocks, Mehta and associates (85,86) recommended injection of a 5% aqueous phenol solution. They reported relief at 2 to 3 weeks postinjection in 60% of 103 patients treated and long-term relief in 70% of 82 patients who could be contacted several months after injection. An alternative method is surgical exploration and relief of the entrapment.

Pain Primarily of Musculoskeletal Origin

Disorders of the lower thoracic spine are likely to produce localized pain in the lower part of the back, with occasional spread to the lateral part of the thorax; rarely do they produce pain in the abdomen unless the lesion causes a radiculopathy or neuropathy. Occasionally, fractures of the anterior part of the lower ribs or fracture or dislocation of the lower costal cartilages can result in upper abdominal pain. The epigastric pain can also be caused by damage, infection, or irritation of the xiphoid process. Finally, myofascial syndromes involving one or more of the abdominal muscles can cause moderate to severe continuous pain. These three conditions are discussed briefly here.

Slipping Rib Syndrome

The slipping rib syndrome, also known as a *rib tip syndrome* or *slipped rib cartilage syndrome*, is characterized by sharp stabbing pain localized to the upper quadrant or to the epigastrium. The pain is present at rest and is aggravated by movement, especially twisting, hyperextension, or raising the arm. Occasionally, the pain is dull aching or burning, located below the costal margin and radiating to the back. The condition is discussed in detail in Chapter 60.

Xiphoidalgia

Xiphoidalgia, or painful tender xiphoid process, is characterized by spontaneous deep aching or sharp pain that varies in intensity from a slight to agonizing discomfort simulating that of myocardial infarction. The pain is felt in the region of the xiphoid process, with radiation to the epigastrium and occasionally to the lower chest. The pain is aggravated by movements that act on xiphoid processes such as bending, stooping, or turning or by an increase in intragastric pressure caused by a large meal. The pain can be constant or recur several times a day and last for minutes to several hours. Pressure on the xiphoid process produces spontaneous pain that is felt most severely in the region of the xiphoid process, with radiation to the epigastrium, retrosternally, and occasionally to the precordium. The condition can persist for weeks or months but usually disappears spontaneously (see Chapter 60). Nonsteroidal antiinflammatory drugs are often helpful for this condition.

Epidemic Myalgia

Epidemic myalgia, also known as *Bornholm's disease*, epidemic pleurodynia, and devil's grip, has already been discussed in Chapter 62 (see Disorders of the Pleura). It is mentioned here because it affects not only the intercostal but also the abdominal muscles in many patients and causes abdominal pain. After a nondescript course of from 1 to 10 days adult patients experience bouts of severe sharp pain in the lateral chest wall, while in children the pain involves the upper abdominal muscles. The involved muscles are usually tender. Bouts of pain are separated by symptom-free intervals. Fever, headache, and pharyngitis are present. The illness usually lasts 3 to 7 days, but relapses can occur. Specific diagnosis is made by isolation of the virus from the throat or feces early in the course of the disease or by demonstration of a rising titer of type-specific neutralizing antibodies.

Treatment is usually conservative, consisting of pain control using systemic analgesics; these also relieve headache and reduce fever.

Myofascial Pain Syndromes

Myofascial pain syndromes are common causes of pain in various parts of the body. Their etiology, pathophysiology, characteristics of the pain, other symptoms, diagnostic procedures, and therapy are discussed in detail in Chapter 29. Here, we briefly mention the characteristics of the syndromes with trigger points (TPs) that can be located in the externus obliquus, transversus abdominis, and rectus abdominis muscles. Painful TPs are frequently found in the muscle of the anterior wall and all major quadrants; in particular, the rectus abdominis muscles usually contain multiple TPs.

These syndromes are important because TPs in these abdominal muscles can initiate somatovisceral reflex phenomena that might induce visceral dysfunction, possibly resulting in as much distress as that induced from the referred pain (87). Symptoms referred from these myofascial TPs commonly confuse the diagnosis by mimicking those of visceral disease. Sola (88) has successfully treated several patients with confirmed cardiospasm by injection of these TPs with dilute solutions of local anesthetics. In these patients the TPs were located in the left upper rectus abdominis muscles. Edegawa and Friedman (89) described a similar treatment for cardiospasm as well as for functional gastrointestinal disturbances, such as bloating, diarrhea, and constipation involving injection of all four major abdominal quadrants.

Pain patterns of TPs in the abdominal muscles, especially the obliques, are less consistent from patient to patient than are the patterns for most other muscles. Abdominal pain referred from TPs on one side frequently causes bilateral pain. In addition to the localized and referred pain, patients can complain of burning, fullness, bloating, and swelling of gas, although objective evidence is frequently missing.

Figure 69-5 and Figure 69-6 depict the location of TPs and the areas of referred pain that they produce. The solid area of referred pain in the figures indicates the essential zone, the site of pain that is experienced by most patients. The area that is stippled indicates the spillover zone, the site of pain that is experienced by some patients. Referred pain from myofascial TPs in the abdominal musculature is likely to appear in the same quadrant and occasionally in any other quadrant of the abdomen, as well as in the back (87,88). These TPs can initiate somatovisceral responses, including projectile vomiting, anorexia, nausea, intestinal colic, diarrhea, urinary bladder and sphincter spasm, and dysmenorrhea (87). When such visceral symptoms occur with abdominal pain and tenderness, the combination can strongly mimic the manifestations of acute visceral disease, especially appendicitis and cholecystitis.

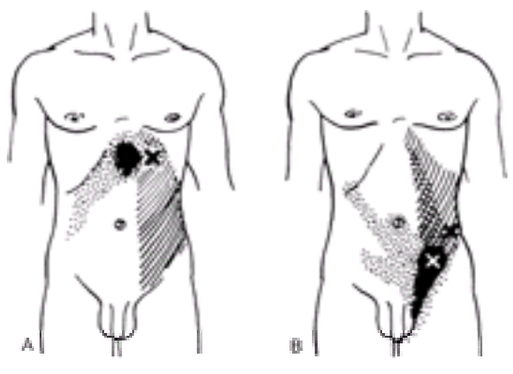

Figure 69-5. Pain patterns produced and sustained by trigger points (*X*) in the abdominal muscles. **A:** Trigger point in the external oblique muscle overlying the lower part of the anterior chest wall. **B:** Pain in the groin and testicle, with radiation to the upper lateral abdominal caused by a trigger point in the lower lateral abdominal wall musculature. The solid black depicts the essential zone and the stippled pattern depicts the spillover zone. See text for details.

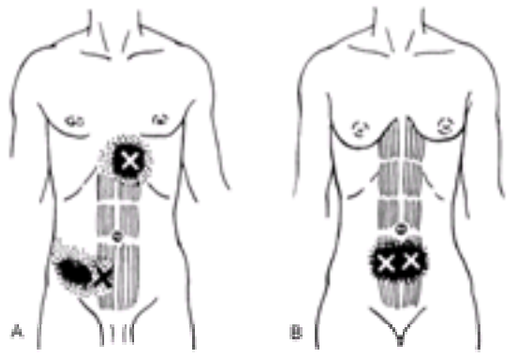

Figure 69-6. Pain patterns produced and sustained by trigger points (*X*) in the rectus abdominis muscle. **A:** Right lower quadrant pain and tenderness in the region of McBurney's point caused by a trigger point in the lateral border of the ipsilateral rectus abdominis muscles and by a trigger point at the upper attachment of the rectus muscle that occasionally causes lower esophageal spasm (*cardiospasm*). **B:** Pain pattern in the hypogastric region produced by trigger points in the lower part of both rectus abdominis muscles. Through somatovisceral reflexes, the trigger point can intensify the pain of dysmenorrhea or can cause other types of visceral dysfunction. The solid black depicts the essential zone and the stippled pattern depicts the spillover zone.

Activation of TPs in the abdominal musculature can be a result of trauma or stress of the muscle or can represent viscerosomatic responses to visceral disease,

including peptic ulcer, intestinal parasites, ulcerative colitis, diverticulosis, and cholecystitis (87). Once activated, TPs can then be perpetuated by emotional stress, occupational strain, faulty posture, and overenthusiasm for fitness exercises.

TPs are located by systemic point pressure of the area in which the TPs are suspected to exist. When the pressure is applied to the TP, patients experience aggravation of pain similar to the spontaneous pain that they have had. Local muscle twitch and other signs can also be felt.

Treatment. Treatment of myofascial syndromes is discussed in detail in Chapter 29. It consists of therapy directed at decreasing the activity of the TP, supportive measures, and corrective actions (Fig. 69-7) as described in detail in Chapter 29. Stretch and spray of the involved abdominal muscles involves hyperextension of the spine, protrusion of the abdomen, and a downward spray pattern. Corrective actions include self-administration of ischemic compression, learning how to breathe with the abdomen (diaphragm), and carrying out various progressive exercises (87).

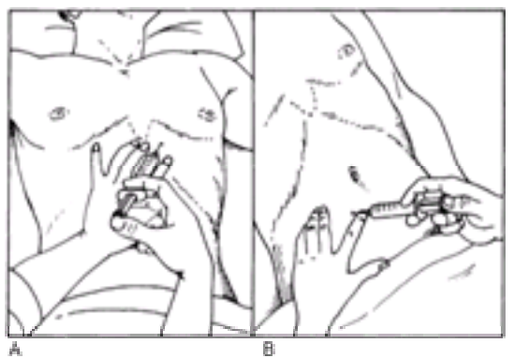

Figure 69-7. Technique of injection in patients with myofascial syndromes caused by trigger points in the abdominal muscles. **A:** Injection of the trigger point in the upper part of the external oblique muscle responsible for the pain pattern shown in Figure 69-5A. **B:** Injection of the lower part of the right rectus muscle to eliminate the pain shown in Figure 69-6A.

Abdominal Pain of Tegumentary Origin

Painful Scars

Pain in the abdominal or flank region can be caused by posttraumatic or postoperative scars that usually contain small neuromata. These painful abdominal disorders are similar to those of postthoracotomy and postmastectomy pain (see Chapter 64). The scars can occur in any part of the abdomen but develop most frequently following a subcostal curved incision for cholecystectomy, a flank incision for operation on the kidney, and incision for appendectomy. They are especially likely to develop into painful scars if the scar drains persistently or is infected.

Patients usually complain of a continuous aching, burning pain in the region of the scar and, around it, occasional bouts of lancinating pain that can develop spontaneously with movement of the trunk, can be provoked by pressure on the neuroma, or result from both. In most patients the pain is mild to moderate and can be managed with nonopioid analgesics and adjuvants. In patients with severe lancinating pain, diagnostic and prognostic blocks consisting of infiltration of small amounts of dilute solutions of a local anesthetic into the scar can be performed. If properly done, these produce complete pain relief that lasts for several hours, usually beyond the duration of the pharmacologic effect of the local anesthetic. Repeated injections provide longer and longer periods of pain relief and can be curative. Injection of alcohol into a neuroma can produce prolonged relief (see Chapter 102, section Local Infiltration). If injection therapy does not produce prolonged pain relief, however, excision of the scar by plastic surgery should be considered.

Acute and Chronic Dermatologic Diseases

Various acute and chronic dermatologic diseases can involve the abdominal wall and flank region and cause pain (see Chapter 32).

Chronic postburn pain can also involve the abdomen and cause persistent aching, burning pain in the site of the postburn scar. These disorders are often difficult to treat, but if the pain is sufficiently severe, intercostal block with a long-lasting local anesthetic should be given a trial. This chronic pain syndrome might also respond to intravenous infusion of local anesthetics (see Chapter 102).

Postoperative Pain

Acute postoperative pain is most severe following upper abdominal and thoracic operations and following renal surgery. The incidence and severity of pain following lower abdominal surgery are lower, but moderate to severe pain occurs in a significant percentage of patients. Postsurgical pain is discussed in detail in Chapter 41.

CHAPTER 70

General Considerations

John S. McDonald and Andrea J. Rapkin

Pain that arises from the pelvic cavity and the perineum is a common cause of pain that afflicts women. The prevalence of chronic pelvic pain is really undefined, yet studies quote percentages from 12% to 20%, with a lifetime occurrence rate as high as 33% (1). Up to 10% of gynecologic referrals are for chronic pelvic pain and many of these are handled by initial surgical intervention, with statistics revealing 44% undergo laparoscopies (2). In pain clinic referrals, 30% of the women have already had a hysterectomy (2,3). Curiously, though, only 12% of all hysterectomies are performed for the treatment of pelvic pain.

This chapter provides an introduction of general considerations and a basic review of the underlying essentials of pain of pelvic origin. It also addresses how to approach the patient with pain in the pelvic and perineal areas. In doing so, we first address basic considerations including anatomy, neurology, physiology, etiology, and epidemiology. We then address clinical considerations that include physical examination, differential diagnosis, the actual diagnosis, and finally, suggestions on treatment. Much of the anatomic and neurologic data are derived from the last edition of this book.

BASIC CONSIDERATIONS

Anatomy of the Pelvis

The pelvis is the lowest segment of the abdominal cavity and is roughly shaped like a basin, with the top being in a line from the top of the pubis extended to the top of S-1 and the bottom being in a line from the bottom of the pubis extended to the tip of the coccyx. The boundaries anteriorly are the pubic arch, posteriorly the sacrum and coccyx, and laterally the iliac bones (4). The skeletal pelvis is composed of its ligaments and muscles and contains the respective male and female pelvic viscera. The muscles of the pelvis include the obturator internus muscles, piriformis and coccygeus muscles, and the levatores ani muscles, which form the pelvic diaphragm. Additionally, the muscles include the deep transverse perineal muscle and sphincter urethrae, which together constitute the urogenital diaphragm. The pelvis also contains the urinary bladder, terminal part of the ureters, sigmoid colon, rectum and a few coils of small intestine, and internal genitalia, together with blood vessels, lymph vessels, lymph nodes, and nerves.

Skeletal Pelvis

The anatomies of the female and male pelvises are shown in Figure 70-1. The pelvis is massively constructed in line with the primary function of withstanding stresses caused by the entire upper body weight and the powerful body musculature (4,5). The pelvis is composed of two parts, the greater segment and the lesser segment, sometimes called the *false* and *true* pelvis.

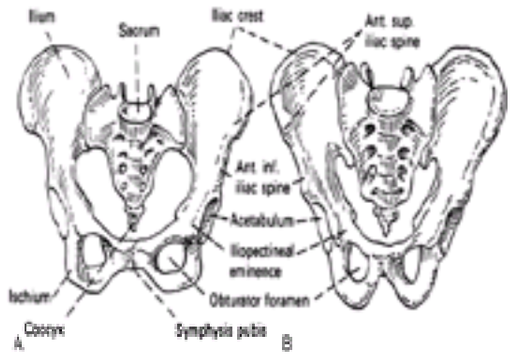

Figure 70-1. Anterior view of the female pelvis **(A)** and male pelvis **(B)**. (Modified from Clemente CD, ed. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:273.)

Greater Pelvis

The greater (false) pelvis consists of the phalangeal parts of the iliac bones above the linea terminalis on each side and the base of the sacrum posteriorly. The bone structure along this junctional zone is particularly massive and forms the main pathway on each side from the acetabular fossae to the vertebral column around the visceral cavity. The cavity of the greater pelvis is part of the abdomen and, because of the inclination of the pelvis as a whole, the cavity has little skeletal wall anteriorly.

Lesser Pelvis

The lesser (true) pelvis encloses a true basin when the soft tissues of the pelvic floor are in place (4,5). From the skeletal point of view it is a narrowed continuation of the greater pelvis with irregular but more complete walls bounding the pelvic cavity or canal. This cavity, which is of special obstetric importance, has an axis that is curved in the median plane. It is limited above by a superior opening, occupied in life by viscera traversing it, and limited below by the inferior opening that is largely closed by the pelvic floor and its sphincter mechanisms. Figure 70-2 depicts the boundaries and diameters of the superior pelvic aperture (see Fig. 70-2A) and of the inferior pelvic aperture. Figure 70-2B and Figure 70-2C show a sagittal section through the female pelvis depicting the planes of the inlet and outlet and their relation

to each other (see Fig. 70-2D). From a standing position, the pelvic canal curves obliquely backward relative to the trunk and abdominal cavity. The whole pelvis is tilted forward so that the plane of the pelvic brim makes an angle of 50 to 60 degrees with the horizontal.

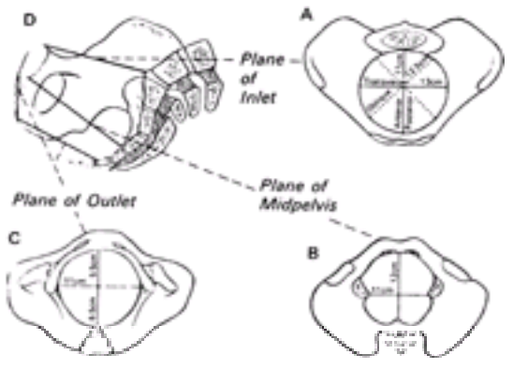

Figure 70-2. Planes and diameters of the pelvis. **A:** Superior plane or obstetric inlet, bounded posteriorly by the promontory of the sacrum, laterally by the iliopectineal line, and anteriorly by the rami of pubic bones and the upper margin of the symphysis pubis. **B:** Midpelvic plane, bounded posteriorly by the sacrum near the junction of the S-3 and S-4 vertebrae, laterally by the ischial spine, and anteriorly by the inferior aspect of the symphysis. **C:** Inferior plane or obstetric outlet, composed of two triangular components. The posterior component is bounded behind by the sacrococcygeal joint, laterally by the sacrotuberous ligament, and anteriorly by the biischial diameter; the anterior component is bounded by the biischial diameter behind, laterally by the inner margin of the pubic arch, and anteriorly by the inferior margin of the symphysis. The floor or the pelvic outlet is composed of the soft tissues of the perineum and the structures making up the urogenital diaphragm. **D:** Sagittal view of the pelvis showing important anteroposterior diameters (*solid lines*). (From Bonica JJ, McDonald JS. *Principles and practice of obstetric analgesia and anesthesia*, 2nd ed. Baltimore: Williams & Wilkins, 1995:763.)

Joints and Ligaments of the Pelvis

The pelvis has a massive complex of joints and ligaments that tie together the ilium with the sacrum and with the fifth lumbar vertebra. The two pubic bones meet in the midline plane, where they form the cartilaginous joints of the pubis symphysis.

Sacroiliac Joint

The sacroiliac articulation is synovial between the articular surfaces of the sacrum and ilium. The articular surfaces exhibit irregular elevations and depressions that are more pronounced in the male and fit into one another. These surfaces restrict movement but contribute to the strength of the joint that transmits weight from the vertebral column to the lower limb. The articular surface is covered by hyaline cartilage and the ilium by fibrocartilage (Fig. 70-3). The articular capsule is attached close to the margin of the articular surfaces of the sacrum and ilium (4,5). The joint is held together by anterior, interosseous, and posterior sacroiliac ligaments (Fig. 70-4; see Fig. 70-3), which are all supplied by the posterior primary divisions of the upper three sacral nerves.

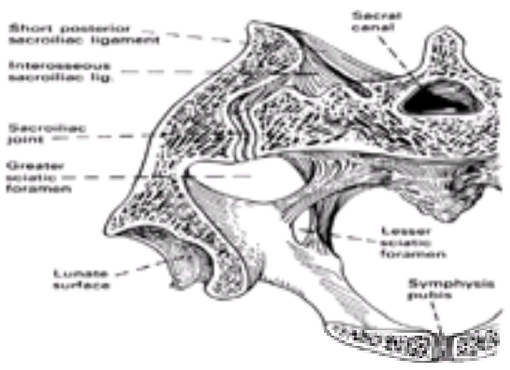

Figure 70-3. Coronal section through the pelvis showing the sacroiliac joint through the anterior sacral segment. The anterior part of the joint is covered by hyaline cartilage on the sacral surface, and fibrocartilage overlies the surface of the ilium. The interosseous sacroiliac ligament fills the cleft above and behind the joint cavity. The joints of the surfaces are irregularly shaped and the interconnecting bones fit snugly, thus restricting movement but buttressing the weight-bearing function of the joint. (Modified from Clemente CD, ed. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:360.)

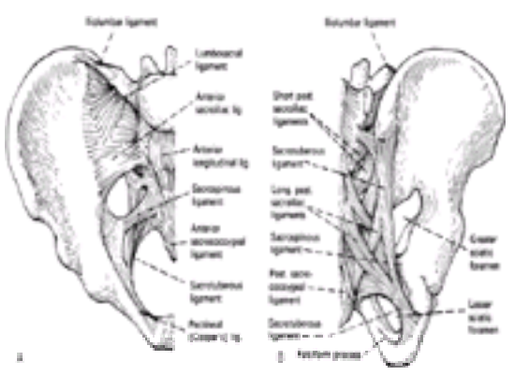

Figure 70-4. Joints and ligaments of the right half of the pelvis. **A:** Anterior view. **B:** Posterior view. See text for details. (Modified from Clemente CD, ed. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:361–362.)

Anterior Sacroiliac Ligament. The anterior sacroiliac ligament is a thickening of the anterior inferior parts of the fibrous capsule. It is well developed at the level of the arcuate line and inferiorly at the level of the posterior inferior iliac spine, where it connects the base and lower part of the sacrum to the auricular surface of the ilium and preauricular sulcus.

Interosseous Sacroiliac Ligament. The interosseous sacroiliac ligament is massive and strong and forms the chief bond between the two bones. It fills the irregular space immediately above and behind the joint and is covered by the posterior sacroiliac ligament. It consists of deeper and more superficial parts, with the deeper parts having cranial and caudal bands that pass from the depression behind the auricular surface of the sacrum to the depression in the iliac tuberosity. These bands are covered by and blend with the more superficial part, which forms a fibrous sheet connecting the cranial and posterior margins of the rough area behind the auricular surface on the sacrum with the corresponding margin of the iliac tuberosity.

Posterior Sacroiliac Ligament. The posterior sacroiliac ligament overlies the interosseous ligament, from which it is separated by the dorsal rami of the sacral spinal nerves and vessels. It consists of several fasciculi that course in various directions. The deeper upper part is called the *short posterior sacroiliac ligament* and passes from the lateral sacral crest with varying degrees of obliquity to the posterior superior iliac spine and inner lip of the posterior part of the iliac crest. The lower fibers, which make up the long posterior sacroiliac ligament, pass from the second, third, and fourth sacral crests to the posterior superior iliac spine. This ligament descends

obliquely and becomes continuous with the sacrotuberous ligament and medially with the posterior layer of the thoracolumbar fascia.

Movement. The sacroiliac joint allows a small amount of anteroposterior rotatory movement around a transverse axis that is usually 5 to 10 cm below the promontory of the sacrum vertically. These movements occur during flexion and extension of the trunk. The range is the same in male and nonpregnant female subjects but is increased considerably during pregnancy. The greatest change in position of the sacrum in relation to the iliac bones occurs when the individual arises from a recumbent to a standing position: The sacral promontory moves forward as much as 5 to 6 mm as the body weight is taken on the sacrum. The backward movement of the lower end of the sacrum is considerably less. In middle age and beyond, fibrous adhesions and a gradual obliteration of the synovial cavity occur in both genders, earlier in men and after menopause in women (4,5). In old age the joints can become completely fibrosed and even ossified.

Vertebropelvic Ligament. The ilium is connected with the L-5 vertebra by the iliolumbar ligament, and the sacrum is connected to the ischium by the sacrotuberous and sacrospinous ligaments (see Fig. 70-4).

Iliolumbar Ligament. The iliolumbar ligament is attached to the tip and to the lower and front part of the transverse process of the L-5 vertebra. Sometimes it has an additional weak attachment to the transverse process of the L-4 vertebra. It radiates as it passes laterally and is attached by two main bands to the pelvis. The inferior band, the lumbosacral ligament, runs from the inferior aspect of the L-5 transverse process to the upper medial aspect of the ilium, blending with the anterior sacroiliac ligament. The superior band passes from the transverse process of the L-5 vertebra to the posterior surface of the medial part of the iliac crest. This band gives partial origin to the quadratus lumborum muscle, which is also attached to the crest of the ilium immediately in front of the sacroiliac joint.

Sacrotuberous Ligament. The sacrotuberous ligament is attached by a broad, flat base to the posterior superior and inferior iliac spines (where it partially blends with the posterior sacroiliac ligament), to the fourth and fifth transverse tubercles of the sacrum, and to the lateral margin of the lower part of the sacrum and upper part of the coccyx (see Fig. 70-4). These fibers run obliquely downward and laterally and converge to form a thick, narrow band that is fixed to the medial margin of the ischial tuberosity and then continues along the ramus of the ischium as the falciform process. The free concave edge of the falciform process blends with the fascial sheath of the internal pudendal vessels and pudendal nerve. The lowest fibers of the gluteus maximus are attached to the posterior surface of the sacrotuberous ligament. The ligament is pierced by the coccygeal branch of the gluteal artery, by the perforating cutaneous nerve, and by minute filaments of the coccygeal plexus.

Sacrospinous Ligament. The sacrospinous ligament is a thin, triangular-shaped structure that attaches to the spine of the ischium. It attaches medially by its broad base to the lateral margin of the sacrum and coccyx in front of the sacrotuberous ligament. The pudendal nerve passes posteriorly to the point at which the ligament attaches to the spine. It is an important landmark in carrying out pudendal nerve block for vaginal delivery or during surgical procedures on the perineum.

Function. The sacrotuberous ligament and, to a lesser extent, the sacrospinous ligament, oppose upward tilting of the lower part of the sacrum under the downward thrust that is imparted to the upper end of the bone by the weight of the trunk. These two ligaments convert the sciatic notches into two foramina. The greater sciatic foramen is bounded in front and above by the greater sciatic notch, behind by the sacrotuberous ligament, and below by the sacrospinous ligament in the spine of the ischium. It is partially filled by the piriformis muscles that emerge from the pelvis through it. Above this muscle the superior gluteal vessels and nerves pass out of the pelvis while below it pass the inferior gluteal vessels and nerves, internal pudendal vessels and pudendal nerves, sciatic nerve, posterior femoral cutaneous nerve, and nerves to the obturator internus and quadratus femoris muscles. The lesser sciatic foramen is bounded in front by the body of the ischium, above by the spine of the ischium and sacrospinous ligament, and behind by the sacrotuberous ligament. It transmits the tendon of the obturator internus muscle, the nerve to this muscle, and the internal pudendal vessels and pudendal nerves.

Pubic Symphysis. The pubic symphysis is the point at which the two pubic bones meet each other in the medial plane to form a cartilaginous ligament and are connected by the superior pubic and arcuate pubic ligaments and by an interpubic disk of fibrocartilage. The superior pubic ligament connects the pubic bone superiorly and extends as far as the pubic tubercles. The arcuate ligament is a thick arch of fibers that connects the lower borders of the symphysis surface of the two pubic bones and forms the upper boundary of the pubic arch. Above, it blends with the interpubic disk and is attached laterally to the inferior rami of the pubic bone. The interpubic disk connects the adjacent surfaces of the pubic bones; each surface is covered with a thin layer of hyaline cartilage and is firmly attached to the bone, an arrangement that resists shearing forces. The opposed surfaces of the hyaline cartilage are connected by a lamina of fibrocartilage that varies in thickness. Some separation between the pubic bones occurs late in pregnancy and during childbirth.

Mechanism of the Pelvis

Although the skeletal pelvis supports and protects the contained pelvic viscera, it is primarily part of the lower limb and affords surfaces for the attachment of the muscles of the trunk and lower limbs (4,5). Its most important mechanical function is transmission of the weight of the head, trunk, and upper limbs to the lower extremities. Movements of the sacrum are regulated by its form and ligamentous attachment. When viewed as a whole, it presents the shape of a wedge, with its base upward and forward. The first component force is therefore acting against the resistance of the wedge, and its tendency to separate the iliac bones is resisted by the sacroiliac and lumbar ligaments posteriorly and by the ligaments of the symphysis pubis anteriorly. During pregnancy hormonal changes cause the pelvic ligaments and joints to become relaxed and capable of more extensive movements. This renders the locking mechanism of the sacroiliac joint less restrictive and permits greater rotation, a change that allows alteration in the diameter of the pelvis during childbirth. The less effective the locking mechanism, the more the strain of weight bearing pulls the ligaments, frequently resulting in sacroiliac strain during and after pregnancy. After childbirth the ligaments tighten up again and the locking mechanism becomes more effective. In some cases, however, the locking occurs in the position of rotation of the hip bones that occurred during pregnancy. This so-called subluxation of the sacroiliac joint causes pain by the unusual tension that is imposed on the ligaments. Reduction by forcible manipulation after the joint is completely anesthetized can be attempted.

Pelvic Muscles and Fascia

The muscles within the pelvis are divided into two groups: (a) the piriformis and obturator internus muscles; and (b) the levator ani and coccygeus muscles that, with the corresponding muscles of the opposite side, form the pelvic diaphragm. All the fascia investing the muscles form a continuum of connective tissue that joins the fascial covering of the pelvic viscera above with the fascia of the perineum below.

Pelvic Fascia

The pelvic fascia consists of the parietal pelvic fascia, which constitutes the fascial sheaths of the pelvic muscles, and the visceral pelvic fascia, the fascial sheaths of the pelvic viscera and of their blood vessels and nerves (see Anatomy of the Perineum and Neurology of the Perineum, later in this chapter). The parietal pelvic fascia covering the pelvic surface of the obturator internus muscle is well differentiated as the obturator fascia. The fascia of the piriformis muscle is thin and fuses with the periosteum of the anterior surface of the sacrum around the margin of the anterior sacral foramina. Its sacral attachment ensheathes the nerves emerging from these foramina. The fascia of the pelvic diaphragm extends over both surfaces of the levator ani muscles. The portion above is called the *superior fascia* of the pelvic diaphragm, and the part below it is called the *inferior fascia* of the pelvic diaphragm, also known as the *anal fascia*. Laterally the superior fascia follows the line of attachment of the muscle and therefore varies somewhat. Anteriorly it is attached to the back of the symphysis pubis about 2 cm above its lower border. It can be traced laterally across the back of the superior ramus of the pubis for a short distance to the obturator fascia, with which it blends along a somewhat irregular line to the spine of the ischium. The inferior fascia of the pelvic diaphragm covers the medial wall of the ischiorectal fossa. Above it is continuous with the fascia of the pudendal canal and with the obturator fascia along the line of attachment of the levator ani muscle. It is continuous below with the fascia on the sphincter urethra and sphincter ani externus muscle.

Levator Ani Muscle

Figure 70-5 depicts a sagittal section of the pelvis with the viscera removed to show the pelvic aspect of the left levator ani and coccygeal muscles. The levator ani muscle is a broad, thin structure attached to the inner surface of the side of the true pelvis. It unites with the opposite muscle to form the greater part of the floor of the pelvic cavity. It is attached anteriorly to the pelvic surface of the body of the pubis, lateral to the symphysis, behind to the medial surface of the spine of the ischium, and between these two points to the obturator fascia. Morphologically the levator ani can be divided into the pubococcygeus and iliococcygeus muscles.

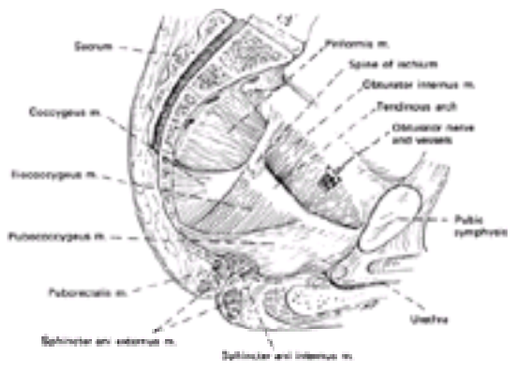

Figure 70-5. Sagittal section of the pelvis showing the muscles of the left lateral wall of the pelvis. The obturator nerve and vessels pass through the obturator muscle, which is normally covered by fascia (not shown). (Modified from Clemente CD, ed. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:499.)

Pubococcygeus Muscle

The pubococcygeus muscle arises from the posterior surface of the pubis and from the anterior part of the obturator fascia. Its fibers are directed backward almost horizontally along the line of the anal canal and become attached to the front of the coccyx by a tendinous plate that is continuous with the anterior sacrococcygeal ligament. The medial coccygeus muscle arises from the ischial spine and from the posterior part of the tendinous arch of the levator ani muscle. Its fibers attach to the sides of the coccyx and to the opposite muscle in the median raphe on the undersurface of the tendinous plates of the pubococcygeus that contribute to the anococcygeal ligament. The superior or pelvic surface of the levator ani is separated by its covering fascia from the bladder, prostate, rectum, and peritoneum, while its inferior or perineal surface forms the medial boundary of the ischiorectal fossa and is covered by the inferior fascia of the pelvic diaphragm. Its posterior border is free and is separated from the coccygeus muscle by areolar tissue, while the medial borders of the two muscles are separated by the visceral outlet, an interval through which the urethra, vagina, and anorectum pass from the pelvis. The nerve supply of the levator ani muscle includes a branch from the S-4 nerve, a branch that arises either from the inferior rectal nerve or from the perineal branch of the pudendal nerve. The function of the levator ani muscle is constriction of the lower end of the rectum and vagina, and probably fixation of the perineal body. The levator ani, together with the coccygei, form a muscular diaphragm that supports the pelvic viscera and opposes itself to the downward thrust produced by any increase in intraabdominal pressure.

Coccygeus Muscle

The coccygeus muscle is posterosuperior in the same tissue plane as the levator ani muscle. It consists of a triangular sheath of muscular and tendinous fibers, arising by its apex from the pelvic surface of the spine of the ischium and sacrospinous ligament. It is attached at its base to the margin of the coccyx and side of the S-5 segment. The muscle receives its nerve supply through branches from the S-4 and S-5 spinal nerves. The coccygeus functions in pulling forward and supporting the coccyx after it has been pressed backward during defecation or parturition. The coccygeus, together with the levator ani and piriformis muscles, closes the posterior part of the pelvic outlet.

Pelvic Viscera and Their Peritoneal Covering

The pelvic viscera consist of the urinary bladder, terminal parts of the ureters, sigmoid colon, rectum and a few coils of small intestine, blood vessels, lymph vessels, nodes, nerves, and internal genitalia. In men the internal genitalia consist of the prostate, seminal vesicles, ejaculatory ducts, and vas deferens; in women the internal genitalia consist of the ovaries, uterine tubes, uterus, and vagina. A description of the anatomy of each of these structures is beyond the scope of this book and is limited to the illustration of these organs (Fig. 70-6 and Fig. 70-7). Painful disorders of female internal genital organs are discussed in Chapter 72, while those that affect the male genital organs and the bladder are described in Chapter 73. Because pain from diseases of these organs usually involves inflammation of the pelvic peritoneum that overlies these structures, it is briefly described here. Following the suggestion by Williams and Warwick (4) to trace the peritoneum from one viscus to another and from the viscus to the parietes, it is helpful to follow its continuity in the vertical and horizontal directions. Here the discussion is limited to its vertical disposition.

See text for details. (**A** modified from Clemente CD, ed. *Gray's anatomy of the human body*, 30th ed. Philadelphia: Lea & Febiger, 1985:502; **B** modified from Bonica JJ. *Principles and practices of obstetric analgesia and anesthesia*. Vol 1. Philadelphia: Davis, 1967:502–503.)

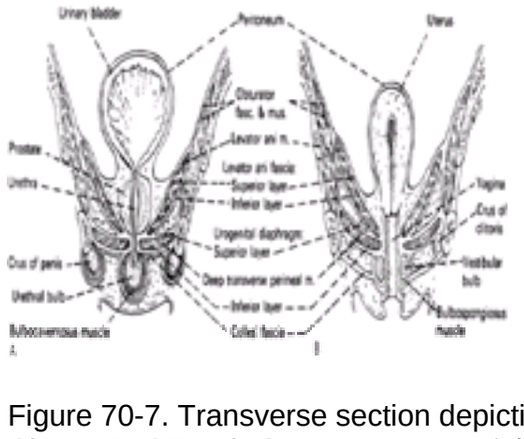

Figure 70-7. Transverse section depicting the fascia and muscles of the male **(A)** and female **(B)** pelvic and anal regions. See text for details. (Modified from Clemente CD, ed. *Gray's anatomy of the human body*, 27th ed. Philadelphia: Lea & Febiger, 1959:476.)

Vertical Disposition of the Pelvic Peritoneum

The peritoneum descends from the abdomen proper over structures in the pelvic cavity. It is reflected from the posterior pelvic wall as the anterior layer of the sigmoid mesocolon, which invests the sigmoid colon and returns to the pelvic wall as the posterior layer of the sigmoid mesocolon. It then descends, covering the front and

sides of the upper third of the rectum and the front of the middle third of the rectum.

In the Male. In the male, the peritoneum leads to the front of the rectum (at the junction of the middle and lower thirds) and passes forward onto the upper end of the seminal vesicles and the upper surface of the urinary bladder. Between the rectum and bladder it dips slightly downward to form a recess, the rectovesical pouch, the bottom of which is a little below the level of the upper ends of the seminal vesicles and approximately 7.5 cm from its anal orifice (4). From the apex of the bladder it is carried along the medial umbilical ligaments to the anterior abdominal wall, up to the level of the umbilicus. When the bladder is distended the peritoneum is stripped away from the lower part of the anterior abdominal wall so that a considerable part of the anterior surface of the bladder lies directly against the abdominal wall, without the intervention of the peritoneum. This permits an instrument to be passed through the abdominal wall into the distended bladder without passing through the peritoneal cavity.

In the Female. In the female, the peritoneum passes from the front of the rectum onto the posterior fornix of the vagina and from there to the back of the cervix and body of the uterus to form the rectouterine fold. This dips downward to form the rectouterine pouch of Douglas, the bottom of which is approximately 5.5 cm above the anal orifice. The peritoneum continues over the fundus of the uterus and descends on its anterior (vesical) surface as far as the body of the uterus and cervix. From here it is reflected anteriorly onto the upper surface of the bladder to form a shallow recess, the vesicouterine pouch. The layers of the peritoneum on the anterior and posterior surfaces of the uterus are reflected laterally from the lateral margins of the uterus to the side walls of the pelvis to form an expanded fold on each side, the broad ligament of the uterus (Fig. 70-8).

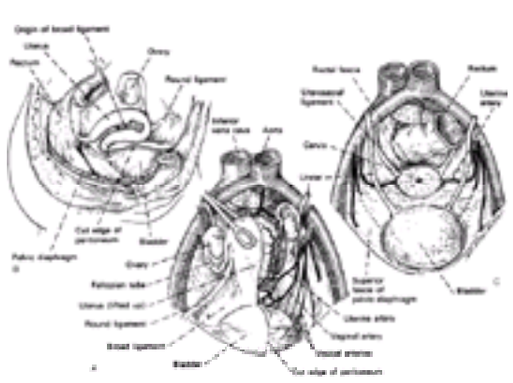

Figure 70-8. Ligaments of the uterus. **A:** Anterior view. **B:** Parasagittal view. **C:** Superior view. (Modified from Netter FH. *The CIBA collection of medical illustrations.* Vol 2, Reproductive system. Summit, NJ: CIBA Pharmaceuticals, 1979:89, 95, and 97.)

Uterine Ligaments

The uterus is connected to the bladder, rectum, and walls of the lesser pelvis by a number of ligaments. Some of these are merely peritoneal folds and have little supporting effect, while others consist of nonstriated muscles and fibrous tissue and function as real ties to provide some measure of dynamic control. These ligaments consist of the anterior, uterosacral (posterior), broad, round, and transverse ligaments (see Fig. 70-8).

Anterior and Posterior Ligaments. The anterior ligament consists of the uterovesical fold of the peritoneum, which is reflected onto the surface of the bladder from the front of the uterus at the junction of the cervix and body of the uterus. The posterior ligament consists of the rectovaginal fold of peritoneum, which is reflected from the back of the posterior fornix of the vagina onto the front of the rectum. It forms the bottom of the deep rectouterine pouch that is bounded anteriorly by the posterior wall of the body of the uterus, supravaginal portion of the cervix, and posterior fornix of the vagina, posteriorly by the rectum, and laterally by two folds of the peritoneum that pass backward from the cervix, one on each side of the rectum, to the posterior wall of the lesser pelvis. These are the rectouterine folds, which contain a considerable amount of fibrous tissue and nonstriated muscular fibers, are attached to the front of the sacrum, and constitute the uterosacral ligament. On rectal examination, the uterosacral ligaments can be palpated as they pass backward on the side of the rectum (4).

Broad Ligaments. Each of two broad ligaments passes from the side of the uterus to the lateral wall of the pelvis (see Fig. 70-8). With the uterus, both form a septum across the cavity of the lesser pelvis, dividing it into an anterior part containing the bladder and a posterior part containing the rectum, terminal coils of the ileum, and part of the sigmoid colon. When the bladder is empty or only slightly distended, the surface of the broad ligaments is directed superiorly and inferiorly, and they have a free anterior (unattached) border. As the bladder fills, the plane of the ligaments alters and their free border becomes superior in position; in this condition the broad ligaments consist of anterior and posterior layers that are continuous with each other at their upper free border and diverge from each other below, where they approach the superior surface of the levator ani muscle. The uterine tube is contained in the free border. The lateral part of the ligament between the tubes and ligament of the ovary and mesovarium is known as the *mesosalpinx*. The infundibulum of the uterine tube projects from the free border near its lateral extremity. The ovary is attached to the posterior layer by the mesovarium. The part of the broad ligament that extends from the infundibulum of the tube and the upper pole of the ovary to the lateral wall of the pelvis contains the ovarian vessels, nerves, and lymph vessels and is known as the *suspensory ligament* of the ovary. The term *mesometrium* is applied to that part of the broad ligament extending from the pelvic floor to the ovary, ligament of the ovary, and body of the uterus. The uterine artery, vein, and nerves pass between the layers of the broad ligaments at their inferior border approximately 1.5 cm lateral to the cervix and then ascend in the medial part of the broad ligament, turning laterally below the uterine tube to anastomose with the ovarian artery.

Round Ligaments. The round ligaments of the uterus are two narrow, flat bands from 10 to 12 cm long that are situated between the layers of the broad ligament in front of and below the uterine tubes. Each ligament begins at the lateral edge of the uterus and is directed anteriorly and laterally across the vesical vessels, obturator vessels and nerves, and obliterated umbilical artery, and over the externus iliac vessels. It then passes through the deep inguinal ring to hook around the beginning of the inferior epigastric artery, traversing the inguinal canal. It finally breaks up into strands that merge with the areolar tissue in the labium majus.

Transverse Cervical Ligaments. Each transverse cervical ligament of Mackenrodt, also called the *cardinal ligament*, is attached to the side of the cervix uteri and to the vault and lateral fornix of the vagina. Both are continuous with the fibrous tissue that surrounds the pelvic blood vessels and help to maintain the position of the uterus.

Function. All these ligaments act as mechanical supports for the uterus, helping to maintain it in its normal position. The levator ani and coccygei muscles, the muscles of the uterogenital diaphragm, and the perineal body appear to be of particular importance in this respect.

Anatomy of the Perineum

The perineum overlies the inferior pelvic aperture, or pelvic outlet. Its deep boundaries are the pubic arch and arcuate pubic ligament anteriorly, the tip of the coccyx posteriorly, and the inferior ramus of the pubis and ramus of the ischium, ischial tuberosity, and sacrotuberous ligament laterally (4,5). The space within these boundaries is somewhat trapezoidal in shape. The surface of the body of the perineum in the man is limited by the scrotum in front, the buttocks behind, and the medial sides of the thighs laterally, whereas in the woman the external genitalia (labia majora and minora) limit the perineum anteriorly. Most anatomists divide the perineum into two parts by drawing a line transversely in front of the ischial tuberosity. The region posterior to this line contains the termination of the anal canal and is thus known as the *anal region* or *anal triangle*, while the anterior part contains the external urogenital organs and is known as the *urogenital region* or *urogenital triangle*. The muscles and fascia of the perineum are also divided into these two groups, anal and urogenital, although these two groups meet in the perineal body and actually constitute a single morphologic unit (4,5).

Muscles and Fascia of the Anal Region

Figure 70-9 depicts the musculature of both the male and female perineum. Each muscle is briefly described.

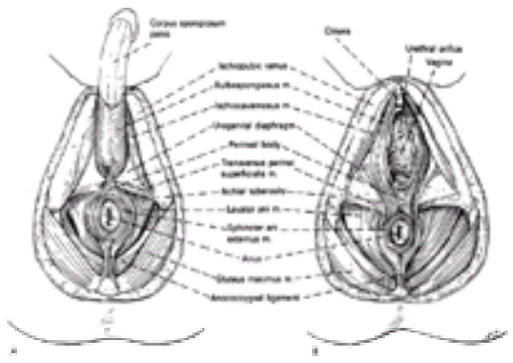

Figure 70-9. Muscles of the perineum. The inferior fascia of the urogenital diaphragm has been removed to depict the muscles. **A:** Muscles of the male perineum. **B:** Muscles of the female perineum.

Sphincter Ani Externus Muscle. The sphincter ani externus muscle surrounds the lower part of the anal canal and is intimately adherent to the skin below, whereas above it overlaps the sphincter ani internus. The muscle is composed of three parts: subcutaneous, superficial, and deep. The subcutaneous lamina is a band of fibers that lies beneath the skin and surrounds the anal orifice. Some fibers are attached anteriorly to the perineal body and posteriorly to the anococcygeal ligament. The superficial lamina lies deep to the subcutaneous lamina and constitutes the main portion of the muscle (5). It also arises from the narrow tendinous anococcygeal ligament that stretches from the tip of the coccyx to the posterior margin of the anus. The muscle fibers then encircle the anus and meet anterior to the anus to be inserted into the perineal body. Here the muscle joins with fibers from the transversus perinei superficialis, levator ani, and bulbospongiosus muscles. The deep lamina forms a complete sphincter to the anal canal with its fibers surrounding the canal closely applied to the internal anal sphincter, while its deep fibers are interlaced with fibers of the puborectalis muscle. In front the deep part of the external anal sphincter blends with other muscles at the perineal body. This muscle is supplied by the perineal branch of the S-4 spinal nerve and by twigs from the inferior rectal branch of the pudendal nerve (S-2 and S-3 spinal nerves).

The sphincter ani internus muscle is a muscular ring that surrounds approximately 2.5 cm of the anal canal. Its inferior border is in contact with, but quite separate from, the external sphincter. It is approximately 5 mm thick and is formed by an aggregation of the involuntary circular fibers of the large intestine. The distal border is approximately 6 mm from the orifice of the anus. This muscle is supplied by fibers from the middle rectal plexus (see previous discussion).

Corrugator Cutis Ani Muscle. The corrugator cutis ani muscle is a thin layer of involuntary muscle and yellow elastic fibers that radiates from the orifice. It is believed that the fibers fade into the submucous tissue, while blending with the true skin laterally. By its contraction this muscle puckers the skin, raising it into ridges around the anal orifice.

Fascia. The superficial fascia of the region is thick and areolar in texture and contains many fat cells in its meshes. On each side a pad of fatty tissue extends deeply into the lateral space between the levator ani and obturator internus muscles called the *ischiorectal fossa*. The deep fascia lines the ischiorectal fossa and makes up the inferior fascia of the pelvic diaphragm and the part of the obturator fascia below the attachment of the levator ani muscles (see Fig. 70-9).

Ischiorectal Fossa. The ischiorectal fossa is somewhat wedge shaped, with its space directed to the surface of the peritoneum and its thin edge at the line of meeting of the obturator internus and levator ani muscles covered by the obturator fascia and by the inferior fascia of the pelvic diaphragm. The internal pudendal vessels and their accompanying nerves are in the lateral wall of the ischiorectal fossa and are enclosed in a special sheath of fascia to form the pudendal canal. This sheath is fused with the lower part of the obturator fascia, extending upward to blend with the inferior fascia of the pelvic diaphragm and downward to become continuous with the falciform process of the sacrotuberous ligament.

Muscles and Fascia of the Male Urogenital Region

Muscles. In both men and women the muscles of the urogenital region consist of the bulbospongiosus, ischiocavernosus, transversus perinei superficialis and profundus, and sphincter urethrae. The muscles are grouped into superficial and deep layers. The superficial urogenital muscles include the midline bulbospongiosus, right and left ischiocavernosus, and right and left transversus perinei superficialis, all of which occupy the superficial perineal space. The deep perineal space is occupied by the sphincter urethra and right and left deep transversus perinei profundus, collectively known as the urogenital diaphragm (see Fig. 70-7). The following review of these muscles is intended to supplement this illustration.

Transversus Perinei Superficialis Muscle. The transversus perinei superficialis muscles consist of a pair, each of which is composed of a narrow strip of muscle fibers that passes more or less transversely across the superficial space in front of the anus. Each arises by tendinous fibers from the medial and anterior parts of the tuberosity of the ischium. Running medially they end in the perineal body, where they join the muscle of the opposite side. At the perineal body they are also joined by the superficial part of the sphincter ani externus muscle posteriorly and by the bulbospongiosus muscle anteriorly.

Bulbospongiosus (Bulbocavernosus) Muscle. The bulbospongiosus (bulbocavernosus) muscle is located in the medial line of the perineum in front of the anus. It consists of two symmetric parts united by a median tendinous raphe. The muscle arises from this median raphe and from the perineal body, and its fibers diverge into two halves (4,5) (see Fig. 70-7A and Fig. 70-9A). The most posterior fibers form a thin layer that is lost on the inferior fascia of the urogenital diaphragm. The middle fibers encircle the bulk and adjacent part of the corpus spongiosum penis and join with fibers of the opposite side on the upper part of the corpus cavernosum penis in a strong aponeurosis. The anterior fibers spread out over the side of the corpus cavernosum penis and are inserted partly in that body, anterior to the ischiocavernosus, and partly in the tendinous expansion that covers the dorsal vessels of the penis (5). This muscle aids in emptying the urethra after the bladder has expelled its contents. Its middle fibers assist in the erection of the corpus spongiosus penis by compressing the erectile tissue of the bulb. The anterior fibers also contribute to the erection of the penis by compressing the deep dorsal vein of the penis because their tendinous expansion is inserted into and is continuous with the deep fascia covering the deep dorsal vessels of the penis.

Ischiocavernous Muscle. The ischiocavernous muscle, also called the *erector penis muscle*, consists of a pair, with each covering the crura of the penis (see Fig. 70-7A and Fig. 70-9A). Each is an elongated muscle, broader in the middle than at either end and situated at the lateral boundary of the perineum. It is erected by tendinous and fleshy fibers from the inner surface of the ischial tuberosity behind the crus penis and from the rami of the pubis and ischium, on both sides of the crus. From these points, fleshy fibers course anteriorly along the crus and end in an aponeurosis that is inserted into the sides and undersurface of the crura as they become the body of the penis. This muscle compresses the crus penis and thus helps to maintain erection of the penis.

Transversus Perinei Profundus Muscle. The transversus perinei profundus muscle arises from the inner surface of the ramus of the ischium and passes to the median line, where it interlaces in a tendinous raphe with its fellow of the opposite side. Lying in the same plane as the sphincter urethra, these two muscles are interposed between the superior and inferior fascial layers of the urogenital diaphragm and form much of the bulk of the structure (see Fig. 70-7). These two muscles were formerly described together as the constrictor urethrae. They are believed to help in steadying the perineal body and therefore are likely to contribute to the general supportive function of the region (4).

Sphincter Urethrae Muscle. The sphincter urethrae muscles, in the man, surround the whole length of the membranous portion of the urethra and are enclosed in the fascia of the urogenital diaphragm. The superficial or external fibers arise in front of the transverse perineal ligament and from the neighboring fascia, and pass backward on each side of the urethra to converge on the perineal body. Their deep fibers arise from the inner surface of the ramus of the pubis and pass medially to form a continuous circular investment of the membranous urethra. The muscles of both sides act together as a sphincter to compress the membranous region of the urethra, particularly if the bladder contains fluid. Like the bulbospongiosus muscle during micturition, they are relaxed and only come into action at the end of the process to eject the last drops of urine. These muscles are also concerned with ejaculation. All the muscles of the urogenital region are supplied by the perineal branch of the pudendal nerve.

Fascia. The fascia of the male urogenital diaphragm consists of a superficial (external, inferior) fascia and deep (internal, superior) fascia. The inferior fascia is a flat, triangular, membranous sheet that bridges the angular interval between the ischiopubic rami. It is attached laterally to the medial border of the rami from the arcuate pubic ligament to the ischial tuberosity. The middle portion of the fascia is pierced by the urethra. The superior fascia of the urogenital diaphragm is also a flat

triangular membrane that stretches across the same interval as the superficial fascia. It lies between the transversus perinei profundus and pubococcygeus portions of the levator ani, representing the fused fascial membranes of both these muscles. It is securely attached to the symphysis pubis anteriorly and joins other perineal layers at the central tendinous point posteriorly. Laterally it is attached to the medial borders of the ischiopubic rami, where it is continuous with the obturator fascia.

Muscles and Fascia of the Female Urogenital Region

Muscles. This group of muscles in the woman is composed of the same five paired muscles as in the man, with some difference in size and disposition because of the presence of the vagina and female external genitalia. They are similarly grouped into superficial and deep layers, with the latter constituting the urogenital diaphragm (see Fig. 70-7B and Fig. 70-9B).

Transversus Perinei Superficialis Muscle. The transversus perinei superficialis muscle in the woman is a narrow muscular slip that differs little from the corresponding muscle in the man.

Bulbospongiosus Muscle. The bulbospongiosus muscle surrounds the orifice of the vagina and has been called the *sphincter vaginae*. Each muscle covers the lateral parts of the vestibular bulbs and is continuous posteriorly with the perineal body, where it blends with the external and sphincter muscles. Its fibers pass forward on each side of the vagina to become attached to the corpora cavernosa clitoridis. A fasciculus crosses over the body of the clitoris and compresses the deep dorsal vein. The anterior fibers contribute to the erection of the clitoris by compression of the deep dorsal vein.

Ischiocavernosus Muscle. The ischiocavernosus muscle in the woman is smaller than in the man. It covers the unattached surface of the crus clitoridis. It is erected by tendinous and fleshy fibers from the inner surface of the tuberosity of the ischium from the surface of the crus clitoridis and from the adjacent surface of the ramus of the ischium. The muscular fibers end in an aponeurosis that is attached to the sides and undersurface of the crus clitoridis. This muscle compresses the crus clitoridis and thus retards the return of blood through the veins that help to erect the clitoris.

Transversus Perinei Profundus Muscle. The transversus perinei profundus muscle in the woman courses from the inferior ramus of the ischium to the side of the vagina, meeting fibers of the muscles from the opposite side. It helps to fix the perineal body.

Sphincter Urethra Muscle. The sphincter urethra muscle, as in the man, consists of superficial and deep fibers. The superficial fibers arise on each side from the margin of the inferior ramus of the pubis and transverse perineal ligament. These fibers are directly across the pubic arch in front of the urethra and pass around it to blend with the muscular fibers of the opposite side between the urethra and vagina. The internal fibers encircle the lower end of the urethra. The actions of these muscles are similar to those of the man. All the muscles of the woman in the genital region are supplied by the perineal branch of the pudendal nerve.

Fascia. The urogenital diaphragm in the woman, as in the man, is formed by two layers of fascia between which are interposed a deep transverse perineal muscle and sphincter urethra (see Fig. 70-7B). The fascial layers are not as strong in the woman as in the man. The fascial layers are attached anteriorly to the pubic arch by connecting to the arcuate pubic ligament and posteriorly the two continuous deep layers of the superficial fascia surround the superficial transverse perineal muscle. In the midline the fascial layers are divided by the aperture of the vagina and blend with its external coat. The urogenital diaphragm is perforated by the urethra anterior to the midline. Between the two fascial layers are the dorsal vein of the clitoris, a portion of the urethra, the deep transverse perineal muscle and sphincter urethrae muscle, the greater vestibular glands and their ducts, the internal pudendal vessels, the dorsal nerves of the clitoris, the arteries and nerves of the vestibular bulbs, and a plexus of veins.

Neurology of the Pelvis

Like other abdominal viscera, the viscera of the pelvis are supplied by sympathetic and parasympathetic nerves that contain both efferent and afferent fibers. Chapter 65 contains a description of the distribution of the celiac plexus and its subsidiary plexuses, which supply viscera in the abdomen proper. It is mentioned in Chapter 65 that the aortic plexus contributes fibers to the formation of the superior and inferior hypogastric plexuses, which totally innervate the pelvic viscera. The inferior mesenteric plexus also supplies the pelvic portion of the large bowel. These and other subsidiary plexuses supplying the pelvic viscera are briefly described here.

Superior Hypogastric Plexus

The plexus is formed above by the union of branches from the aortic plexus, with contributions by the L-3 and L-4 splanchnic nerves (4,5,6,7,8 and 9). The plexus is situated in front of the bifurcation of the abdominal aorta, left common iliac vein, median sacral vessel, body of the last lumbar vertebra, and promontory of the sacrum, and between the two common iliac arteries (Fig. 70-10). Although surgeons in the 1920s and 1930s who resected this nerve for the treatment of severe dysmenorrhea referred to it as the presacral nerve, it is rarely sufficiently condensed to resemble a sacral nerve but rather is a complex structure of intertwining fibers. Moreover, the plexus is prelumbar rather than presacral in position. It lies in the extraperitoneal connective tissue, and the parietal peritoneum can easily be stripped off its anterior surface. The plexus varies in breadth and in degree of condensation of its constituent nerves and often lies a little to one side of the median plane, more often to the left than to the right. The root of the sigmoid mesocolon containing the superior rectal vessels lies to the left side of the lower part of the plexus. Scattered nerve cells are found in the plexus.
